Most environmental tests for a functional hardware can be divided into two categories: *durability* tests and *reliability* [2] (often referred as *capability* [1] *or robustness*) tests. The durability tests are intended to simulate a full mission life and may trigger some fatigue failure mechanisms. For example, the most common automotive durability tests are vibration, high temperature endurance, low temperature endurance, PTC (power temperature cycling), and others. These types of tests require costly test equipment and are often lengthy and expensive to perform. For example, an automotive electronics PTC tests may take several weeks and are often sequenced with other environmental tests. The capability /reliability / robustness tests do not simulate the mission life, but instead are used to verify that the product is capable of functioning under certain environmental conditions. Failures in capability tests can result in a permanent damage or a temporary loss of function that can be "reset" after the environmental stressing condition is withdrawn. The examples of these tests can include dust exposure, over-voltage, transportation packaging, altitude, moisture susceptibility, and some others.

With increasing demands for development cost reduction and shortening of the product development cycle time, there is often a pressure to reduce the test sample size, test duration, or both. Even with the accelerated test levels there are certain limits on achieving that objective, therefore the modern validation program should accommodate all the available knowledge about the product, its features, functionality, environments, expected failure modes, *etc*. The durability testing is where the potential cost savings can be substantial due to the longer tests intended to represent the total mission life as opposed to capability tests that are targeted at discovering more easily detectable design flaws. Considering that a product is normally designed to survive a predetermined mission life (*e.g*., 10 years

and/or 150,000 miles for automotive products) reliability demonstration concepts most often applied to demonstrate that the particular reliability would reveal the adequacy of the design to the engineering specifications as well the consistency of the product parameters across the production lot.

Most engineering product specifications have reliability demonstration requirements, which are usually expressed in terms of B_X life, MTBF, MTTF, failure rates, and reliability-confidence terms. B_X life is the time at which X% of the units in a population will have failed and can be expressed by the equation below.

$$R(B_X) = (100 - X)\% . \qquad (34.1)$$

For example the B_{10} life of 10 years would be equivalent to 90% reliability for 10 year mission life. MTBF (mean time between failures), MTTF (mean time to failure), and failure rates are all reliability terms derived under assumption of exponential distribution (34.2), where MTBF applies to repairable systems and MTTF to non-repairable,

$$R(t) = e^{-\lambda t} , \qquad (34.2)$$

where:
$R(t)$ = reliability as a function of time,
λ = failure rate, and
t = time.

Under exponential distribution assumption of (34.2) MTTF is a time period where 62.3% of the population fail, and failure rate can be calculated as λ = 1/MTTF for non-repairable systems and λ = 1/MTTF for repairable.

One form of reliability requirement can usually be converted to the other and used interchangeably. For example, the B_{10} life of 10 years can be converted into MTTF by merging (34.1) and (34.2) in the following way:

$$R(10yr) = 0.9 = e^{-\frac{10yrs}{MTTF}} . \qquad (34.3)$$

Therefore by solving (34.3) we would find that MTTF = 94.9 years is required to meet the B_{10} life requirement of 10 years. The application of technical specifications containing system reliability and confidence level will be discussed in detail in the next section.

In addition to reliability demonstration, product technical specifications may also contain requirements on reliability prediction, which is simply the analysis of parts and components in an effort to predict and calculate the rate at which the system will fail. A reliability prediction is usually based on an established model. Common models are MIL-HDBK-217, RDF2000, Telcordia for electronic components and NSWC-98/LE1 for mechanical components. Reliability predictions usually reflect the inherent reliability of the product and due to their analytical nature are often higher than those required for the reliability demonstration. This alone can be a cause of confusion and misunderstanding between design engineers, system engineers, and reliability specialists. More detailed information on reliability prediction methods can be found in [3].

34.3 Reliability Demonstration Techniques

34.3.1 Success Run Testing

One of the most common techniques utilized in the industry, where survival of the product at the end of the test is expected, is called *success run testing*. Industry dependent, it is also referred to as an attribute test, a zero failure substantiation test, a mission life test, or a non-parametric binomial. Under those conditions a product is subject to a test, which is often accelerated, representing an equivalent to one mission life (*test to a bogey*), which is expected to be completed without failure by all the units in the test sample.

Success run testing is most often based on the binomial distribution, requiring a particular test sample size in order to demonstrate the desired reliability number with the required confidence level [4]. For example, a common requirement in automotive industry is to demonstrate a reliability of 97% with a 50% confidence level.

Mathematically it can be presented as follows: let us consider p as a probability of a product to fail. According to binomial distribution the probability of obtaining k bad items and $(n-k)$ good items $f(k)$ is:

$$f(k) = \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k}. \quad (34.4)$$

If applied to reliability, where $R=1-p$, and based on (34.4)

$$C = 1 - \sum_{i=0}^{k} \frac{N!}{i!(N-i)!} R^{N-i} (1-R)^i, \quad (34.5)$$

where R = unknown reliability,
C = confidence level required, and
N = total number of test samples.

If k = 0 (no units failed), (34.2) turns into the equation for success run testing:

$$C = 1 - R^N. \quad (34.6)$$

Equation (34.6) can be solved for the test sample size N as:

$$N = \frac{\ln(1-C)}{\ln R}. \quad (34.7)$$

From (34.7) it is easy to notice that if the demonstrated reliability R is approaching 1.0 the required sample size N is approaching infinity. Table 34.1 illustrates (34.7) for the confidence levels of 50% and 90%.

Table 34.1. Examples of reliability sample sizes at confidence levels of 50% and 90%

Reliability, R	Sample size N at $C=50\%$	Sample size N at $C=90\%$
90%	7	22
95%	14	45
97%	23	76
99%	69	230
99.9%	693	2,301
99.99	6,932	23,025

Cost considerations are always an important part of the test planning process. The test sample size carries the cost of producing each test sample (which can be quite high in some industries), equipping each sample with monitoring equipment, and adequate test capacity equipment to accommodate all the required samples (for the cost details see the section on cost reduction). The last contribution to the test sample size can present a significant cost problem, since a large sample may require additional capacities of expensive test equipment, such as temperature/humidity chambers or vibration shakers costing tens or hundreds of thousands of dollars. More details on product validation costs will be presented later in this chapter

Example 1

To simplify the calculations, let us consider 500 cycles of PTC (Figure 34.1) as a test equivalent of one mission life of 10 years in the fields. In order to meet the automotive electronics requirement of R = 97%, C = 50% [1] it would be required according to (34.7) to run $N = \ln(0.5)/\ln(0.97) = 23$ samples without failure for the duration of 500 cycles. It is important to note that by testing the product to pass we would in practice demonstrate the lower boundaries of the obtained values. In this example, a 97% demonstrated reliability establishes the lower boundary value ($R \geq 97\%$), and would not automatically doom the remaining 3% of the population to failure.

Among the advantages of success run testing is its shorter time and the ease of monitoring. Indeed, the test duration would be limited to only one equivalent of the mission life and it would be necessary to check the hardware functionality only after the test is complete. On the downside, a success run does not provide enough information about the design margins, since the entire test results are only relevant to the completed tests. For example, after successful completion of the 8-hour bogey vibration testing we would not be able to tell if the product would have failed soon after the 8-hour mark or would have enough design margin to survive another mission life.

34.3.2 Test to Failure

Due to increasing computing power and a desire to better understand the product design margins test to failure is often requested by the customer as a part of reliability demonstration program. The Weibull distribution is one of the most widely used lifetime distributions in reliability engineering. It is a versatile distribution that can take on the

characteristics of other types of distributions, based on the value of its shape parameter.

Under two-parameter Weibull distribution the product reliability function *R(t)* can be presented in form of:

$$R(t) = e^{-\left(\frac{t}{\eta}\right)^{\beta}}, \qquad (34.8)$$

where:
β = Weibull shape parameter,
η = Weibull scale parameter, and
t = time.

For analysis purposes (34.8) can be rewritten as:

$$\frac{1}{1-F(t)} = e^{\left(\frac{t}{\eta}\right)^{\beta}}, \qquad (34.9)$$

where $F(t) = 1 - R(t)$ is a cumulative failure function often calculated using median ranks for the 50% confidence level [5].

If we take two natural logarithms of (34.9) it will take the form of:

$$\ln\ln\frac{1}{1-F(t)} = \beta(\ln t) - (\beta \ln \eta). \qquad (34.10)$$

This equation has a linear form $Y = \beta X + C$,
where :
$Y = \ln(\ln[1/(1-F(t))])$,
$X = \ln t$, and
$C = -\beta \ln \eta$.

Equation (34.10) represents a straight line with a slope β and intercept C on the Cartesian X, Y coordinates. Hence the plot of $\ln(\ln[1/(1-F(t))])$ against $\ln t$ will be a straight line with the slope of β. According to (34.8) parameter η can be determined as an X-coordinate corresponding to the unreliability of 63.2% on the Y-axis. The obtained Weibull parameters β and η can be substituted into (34.8) in order to define the reliability as a function of time $R(t)$. With the use of the available on the market software packages the Weibull function can be easily calculated within any confidence bounds required by the product's technical specifications. For more details on test to failure and Weibull distribution see [5] or [6].

Example 2

Let us consider reliability requirements [1], where test-to-failure can be an alternative to success run testing with the expected test duration not exceeding two mission lives. 23 samples were placed on test for 1000 temperature cycles (2× mission life). During that time 5 units have failed at 550, 600, 700, 750, and 1000 cycles. The remaining 18 functional units were considered suspended at the end of the test. The Weibull plot in Figure 34.2 demonstrates 97% reliability at 500 cycles with 50% confidence. Please note that the suspended units are not shown in the Weibull plot, but accounted for in the process of calculating median ranks and therefore $F(t)$.

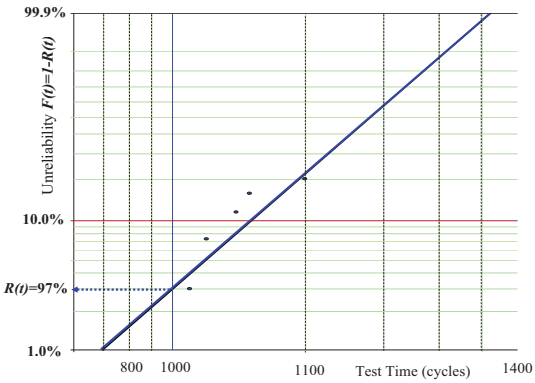

Figure 34.2. Weibull plot of the life data in the example (generated with ReliaSoft®, Weibull++)

The test to failure approach and consequently Weibull analysis has many advantages, since it provides more comprehensive information about the product reliability. It includes the analytical description of the reliability as a function of time $R(t)$, a better understanding of the product's design margins, and a better determination of the product's life phase on the bathtub curve (infant mortality, useful life, or wear-out mode) [4]. That is partly the reason why an increasing number of customers wants to see Weibull analysis as a part of their validation programs. On the downside, it is typically a longer test, which also requires some form of monitoring equipment to record failure times with a reasonable degree of accuracy. The PTC test in Example 2 took 1000 cycles, which is

twice as long as was required for the success run testing. Therefore, due to the ever-increasing pressure for the development of cycle reduction, project managers, when given the choice, often opt for success run testing.

It is also important to remember that two-parameter Weibull distribution does not hold the monopoly on reliability data analysis. Other statistical distributions such as three-parameter Weibull, lognormal, gamma, exponential, and others are also commonly utilized in the life data analysis.

34.3.3 Chi-Squared Test Design – An Alternative Solution for Success Run Tests with Failures

A method for designing tests for products that have an assumed constant failure rate, or exponential life distribution (34.2), draws on the chi-squared distribution. This method only returns the necessary accumulated test time for a demonstrated reliability or MTTF. The accumulated test time is equal to the total amount of time experienced by all of the units on test combined. The chi-squared method can be useful in the case of failures during a bogey test. This method is often utilized when the failures are unanticipated and/or their exact times are not known. Assuming that the failures follow an exponential distribution pattern (34.2), a one-sided estimate for MTTF based on the total test time T [7] will be:

$$MTTF \geq \frac{2T}{\chi^2_{\alpha,2(k+1)}}, \qquad (34.11)$$

where:
$\chi^2_{\alpha,\,2(k+1)}$ = chi-square distribution,
$\alpha = 1 - C$ = risk factor,
N = number of test units, and
k = number of failures,

Since the failure rate λ = 1/MTTF such that:

$$\lambda \leq \frac{\chi^2_{\alpha,2(k+1)}}{2T}. \qquad (34.12)$$

Therefore, based on (34.12)

$$R \geq \exp\left(-\frac{\chi^2_{\alpha,2(k+1)}}{2N}\right). \qquad (34.13)$$

Example 3

Let us consider the case where one of the 23 test samples required by [1] failed during the expected mission life test. In this case k = 1 with 50% confidence and, therefore $\chi^2_{0.5,\,2(1+1)} = 3.357$. Thus according to (34.13) the demonstrated reliability will be reduced from the 97% obtained earlier to a lower value of

$$R = \exp\left(-\frac{3.357}{2\times 23}\right) = 92.7\%. \qquad (34.14)$$

When failures occur during a success run test, several different outcomes are possible. If a root cause analysis determines that the problem can be attributed to a non-design related problem, such as a test sample quality, test equipment problem, workmanship, or some other assignable cause, the customer may accept the results of the test and continue with the development program. When the failure is attributed to a product design flaw, the customer may request some form of a hardware redesign, material change, or other corrective actions.

34.4 Reducing the Cost of Reliability Demonstration

34.4.1 Validation Cost Model

Naturally one of the goals of test planning is to lower the overall cost of the testing, and one of the ways to achieve that is to reduce a test sample. The expenses linked to the test sample size may be qualified as variable costs. Needless to say, the larger the test sample size the greater the cost of validation. Despite this, the cost effect of the number of samples required to be tested is rarely given enough attention. Meanwhile, each test sample carries the following costs associated with the sample population:

1. The cost of producing a test sample.
2. The cost of equipping each test sample. Applied to electronics it would include harnesses, cables, test fixtures, connectors, *etc*.
3. The cost of monitoring each sample during the test. In the electronics industry this would include the labor costs of:
    - designing and building the load boards simulating the inputs to the electronic units,
    - connecting and running the load boards,
    - recording the data, and
    - visual and other types of inspection.

Considering that some tests may run for weeks or even months, these expenses can be quite substantial. Calculation of product validation cost includes both the cost of ownership of test equipment and the expenses associated with each test sample size [8]. The key cost contributors are: capital and depreciation cost D, which includes acquisition, installation, and cost of scraping, spread over the useful life of the equipment; maintenance cost M, which includes both scheduled and unscheduled maintenance plus indirect maintenance cost; indirect maintenance including technician training, lost revenue due to the equipment idle time, *etc*.;and miscellaneous costs Y including energy cost, floor space, upgrades, insurance, *etc*. Therefore, assuming the 24-hour operation of the test facilities, the total cost of product validation per test can be represented by

$$VAL_Cost = t_T\left(\varphi_T + \frac{(M+D+Y)}{365\times 24}\right)\left\lceil \frac{N}{K} \right\rceil + N(\alpha_p + \alpha_e + \alpha_m) \tag{34.15}$$

where:

φ_T = hourly labor rate of performing the test,
t_T = test duration,
N = test sample size,
K = equipment capacity, and
$\lceil\ \rceil$ = ceiling function, indicating rounding up to the next highest integer,
α_p = cost of producing one test sample,
α_e = cost of equipping one test sample, and
α_m = cost of monitoring one test sample.

It is also important to note that the increase in sample size may cause the growth of the equipment-related cost as a step-function due to a discrete nature of the equipment capacity. For example, if a temperature chamber can accommodate 25 units of a particular geometric size, then a test sample of 26 units would require two chambers instead of the one needed for 25 samples, *i.e.*, $\left\lceil \frac{N}{K} \right\rceil = \left\lceil \frac{26}{25} \right\rceil = 2$.

As can be seen from (34.15) the test sample size N is a critical factor in defining the cost of validation program. Depending on the geometry along with the complexity of the product test samples and what is involved in validating them, test sample sizes above certain level become impractical due to the rapidly growing "variable" cost of validation. With ever-increasing reliability requirements, the sample population to be tested would require more and more of human resources and capital equipment.

34.4.2 Extended Life Testing

Test duration can be used as a factor to affect the cost of product validation. There is a relationship between the test sample size and the test duration referred to as the *parametric binomial*, which allows the substitution of test samples for an extended test time and *vice versa*. This relationship is based on Lipson equality [9] tying one test combination (N_1, t_1) with another (N_2, t_2) needed to demonstrate the same reliability and confidence level,

$$\frac{N_2}{N_1} = \left(\frac{t_1}{t_2}\right)^{\beta}, \tag{34.16}$$

where:

β = the Weibull slope for primary failure mode (known or assumed),
N_1, N_2 = test sample sizes, and
t_1, t_2 = test durations.

Therefore it is possible to extend the test duration in order to reduce the test sample size. The new test duration $t_2 = Lt_1$, where t_1 is a product mission life or its test equivalent and L is

the life test ratio. Thus combining (34.15) and (34.16) will produce

$$N_1 = L^{\beta} N_2 . \quad (34.17)$$

With the use of (34.17) the classical success run formula (34.6) will transform into:

$$C = 1 - R^{NL^{\beta}} \ or \ R = (1-C)^{\frac{1}{NL^{\beta}}} . \quad (34.18)$$

Besides the understandable cost saving objective, (34.18) is often used to match the test equipment capacity in the cases, where N is slightly higher than K, see (34.15). The required number of test samples can be reduced L^{β} times in the cases of extended life testing ($L > 1$). Therefore, this approach allows an additional flexibility in minimizing the cost of testing by adjusting the test sample size up or down according to the equipment capacity. The detailed derivation of (34.18) and its applications can be found in [9] and is also reproduced in [10]

Example 4

The relationship (34.18) is widely utilized in the automotive electronics industry and beyond and it has been included in various engineering specifications. In Example 3 let us assume that the temperature chamber along with the test monitoring rack has a capacity of only 12 units. Applying (34.18) as recommended by [1], we propose the alternative test sample size of 12 units instead of the previously discussed 23. The value of Weibull slope β, suggested by [1] is 2.0. Thus substituting $R = 97\%$, $C = 90\%$, $n = 12$, and $\beta = 2.0$ into (34.18) produces:

$$L = \left(\frac{\ln(1-C)}{N \ln R} \right)^{\frac{1}{\beta}} = \left(\frac{\ln(1-0.9)}{12 \ln 0.97} \right)^{\frac{1}{2}} = 1.38 . \quad (34.19)$$

Therefore the original test duration of 500 cycles (see Example 1) would be transformed into Lt = 1.38×500=690 cycles without failures in order to demonstrate our initial reliability goals with only 12 samples instead of 23.

It is important to note that (34.18) is derived under the assumption of success run testing, *i.e.*, no failures are experienced during the test. However as L increases, the probability of a failure occurrence also increases. Therefore, the value of L should be limited to provide a reasonable duration within the framework of success run testing. The β-value in (34.18) is corresponding to the end-of life conditions and, therefore, the higher β the sooner the product would be expected to fail, and the higher the probability that the *zero-failure* assumption will be violated.

34.4.3 Other Validation Cost Reduction Techniques

As demonstrated before, the test sample size grows exponentially with the increasing reliability targets. For example, Table 34.1 shows that the demonstration of $R = 99.9\%$ with 90% confidence would require the impractical number of 2,301 samples. However in some cases customer requirements do contain very high reliability targets, which cannot be supported by conventional reliability demonstration testing. In those instances, alternative methods and techniques should be considered. The approaches to reduce the test sample size to a manageable level include knowledge-based techniques, such as Bayesian analysis. Most of the designed products are created through a development cycle of evolutional rather than revolutionary changes. Thus a certain amount of existing product information can be incorporated into a validation program by utilizing the Bayesian approach of analyzing priors and obtaining posteriors. In the cases where priors are favorable, *i.e.*, high reliability of the existing product or its prototypes, a significant reduction in sample size can be achieved. More detailed information about these methods can be found in [11, 12, 13].

Another cost reduction alternative is HALT (highly accelerated life test) where the specially designed test equipment creates environmental conditions well exceeding those in the field and even exceeding the conditions applied during conventional accelerated tests. More details about HALT can be found in [14]. Even though HALT is often utilized in reliability testing due to significant cost savings, its appropriateness as a reliability demonstration tool has often been debated due to the inconsistency of HALT-induced failure modes with those observed in the field. The HALT test is

considered as an excellent qualitative learning method that quickly identifies product weaknesses or operating limits from vibration and temperature, rather than as a conventional reliability demonstration tool.

Analytical methods such as finite element analysis, stress-strength calculations, stochastic simulation, design for six sigma, and field return analysis can also be applied in estimating expected product reliability. However they are not generally considered as reliability demonstration methods and are not covered in this chapter.

34.5 Assumptions and Complexities of Reliability Demonstration

In the industrial setting involving suppliers and customers, validation programs often require approvals of OEMs or a lower-tier supplier, which sometimes becomes a source of contention. As mentioned before, in some instances customers set the reliability targets to a level not easily achievable by the conventional methods listed in this chapter, which might require the interference of the deep-skilled reliability professionals on both sides.

It is important to remember that the upward potential of the demonstrated reliability is severely limited by the test sample size no matter which method you choose and therefore by the amount of money a company can afford to spend on validation activities. Moreover, the issue of reliability demonstration becomes even more confusing when the customer directly links it with the expected product performance in the field [15]. More than once we have heard the argument that reliability of 99.9% would be equivalent to 5,000 babies going home from the hospital with the wrong parents, 2000 wrong prescriptions per year, 1000 lost articles of mail per week, or some other scary statistics. Naturally, nobody wants all those bad things to happen, but that is the point where the issue of reliability demonstration by test gets confused. In order to clarify some of these issues, the following are the arguments against equating the number of units subject to test with the outcome of product's quality and reliability.

Firstly, the reliability of R=99.9% implies 0.1% accuracy, which cannot possibly be obtained with the methodologies applied. Most of the tests performed by reliability engineers (the automotive industry is no exception) are accelerated tests with all the uncertainties associated with testing under conditions different from those in the field, the greatest contributor to which would be the field to test correlation. In other words, based on a test lasting from several hours to several weeks, we are trying to draw conclusions about the behavior of the product in the field for the next 10–15 years. There are humidity failure modes, thermal cycling failure modes, vibration failure modes, high temperature dwell failure modes, *etc*. With so many unknown factors the overall uncertainty well exceeds 0.1% accuracy.

Secondly, system interaction problems contribute heavily to warranty claims. The analysis of automotive warranties shows that reliability related failures comprise only a fraction of the field returns. Thus even if such a high reliability is demonstrated, it would not nearly guarantee that kind of performance in the field, since many other failure factors would be present. Quality defects (items not produced to design specifications) also contribute heavily to the amount of warranty returns. The purpose of reliability testing is to validate the product design and the process design; it is not a tool to capture or control quality defects, design variations, process variations, system non-conformances, customer abuse, *etc*.

As mentioned before, reliability analysis has a considerable element of uncertainty. The business of predicting the life of a product has also much in common with biological and medical sciences. At present no amount of tests can accurately predict the life expectancy of a particular individual. It can be done on a statistical level and only on a large population, while the accuracy of that prediction will be low for a small group of individuals. The same is true of hardware life. There are many models that can provide data on product life under given conditions, but there is no model that can exactly predict a product life for all failure modes. It often takes some paradigm adjustment to accept a certain level of fuzziness in reliability science, and therefore reliability engineers should not

become fixated on one model or method and should instead try to find the right tool(s) for the job. Stepped overstress testing, finite element analysis, stress-strength calculations, stochastic simulation, design for six sigma, HALT programs, and field return analysis are often more appropriate than hopelessly trying to meet quadruple or quintuple reliability *nines* by stuffing chambers with ever-increasing numbers of test units. The practicality of testing should be a strong consideration of what reliability and confidence level to select, taking into account the feasibility and cost aspects of a particular testing. Reliability demonstration testing is just one tool among many in the large toolbox available to reliability engineers and test development professionals.

34.6 Conclusions

Now, with all that said, let us summarize what indeed the practical value of reliability demonstration testing is. It offers a consistent approach to testing and to addressing the issue of product and process design performance. It provides a consistent approach to sample size selection based on the testing goals. Indeed, it always helps to plan a test when there are mathematical criteria as to why 20 samples are better than 10 and how much better. In addition, it provides a clear trigger for when corrective actions need to be taken by meeting or not meeting the initial reliability requirements linked to the test sample size. It can also be a good figure of merit for comparing product design A versus design B in terms of expected reliability. Based on that, reliability testing and demonstration will most likely remain a valuable engineering tool for many years to come.

Abstract: Quantitative accelerated testing can reduce the test time requirements for products. This chapter explains the fundamentals of quantitative accelerated life testing data analysis aimed at quantifying the life characteristics of the product at normal use conditions and the currently available models and procedures for analyzing data obtained from accelerated tests involving time-independent single stress factor, time-independent multiple stress factors and time varying stress factors.

35.1 Introduction

Accelerated tests are becoming increasingly popular in today's industry due to the need for obtaining life data quickly. Life testing of products under higher stress levels, without introducing additional failure modes, can provide significant savings of both time and money. Correct analysis of data gathered *via* such accelerated life testing will yield parameters and other information for the product's life under use stress conditions.

Traditional "life data analysis" involves analyzing times-to-failure data (of a product, system or component) obtained under "normal" operating conditions in order to quantify the life characteristics of the product, system or component. In many situations, and for many reasons, such life data (or times-to-failure data) is very difficult, if not impossible, to obtain. The reasons for this difficulty can include the long life times of today's products, the small time period between design and release, and the challenge of testing products that are used continuously under normal conditions. Given this difficulty, and the need to observe failures of products to better understand their failure modes and their life characteristics, reliability practitioners have attempted to devise methods to force these products to fail more quickly than they would under normal use conditions. In other words, they have attempted to accelerate their failures. Over the years, the term *accelerated life testing* has been used to describe all such practices.

35.2 Types of Accelerated Tests

Different types of tests, that have been called accelerated tests, provide different information about the product and its failure mechanisms. Generally, accelerated tests can be divided into three types:

35.2.1 Qualitative Tests

In general, qualitative tests *are not designed to yield life data that can be used in subsequent analysis or for "accelerated life Test analysis.* Qualitative tests do not quantify the life (or reliability) characteristics of the product under normal use conditions. They are designed to reveal probable failure modes. However, if not designed properly, they may cause the product to fail due to modes that would not be encountered in real life.

Qualitative tests have been referred to by many names including elephant tests, torture tests, HALT (highly accelerated life testing) and shake and bake tests. HALT and HASS (highly accelerated stress screening) are covered in more detail in [5] and [6].

35.2.2 ESS and Burn-in

ESS (environmental stress screening) is a process involving the application of environmental stimuli to products (usually electronic or electromechanical products) on an accelerated basis. The goal of ESS is to expose, identify and eliminate latent defects that cannot be detected by visual inspection or electrical testing but which will cause failures in the field.

Burn-in can be regarded as a special case of ESS. According to MIL-STD-883C, burn-in is a test performed for the purpose of screening or eliminating marginal devices before customers receive them. Marginal devices are those devices with inherent defects or defects resulting from manufacturing aberrations that cause time-dependent and stress-dependent failures.

ESS and burn-in are performed on the entire population and do not involve sampling. Readers interested in the subject of ESS and burn-in are encouraged to refer to Kececioglu and Sun [1] for ESS and for burn-in to [2] by the same authors.

35.2.3 Quantitative Accelerated Life Tests

Quantitative accelerated life testing, unlike the qualitative testing methods, consists of quantitative tests designed to quantify the life characteristics of the product, component or system under normal use conditions, and thereby provide "reliability information." Reliability information can include the determination of the probability of failure of the product under use conditions, mean life under use conditions, and projected returns and warranty costs. It can also be used to assist in the performance of risk assessments, design comparisons, *etc*.

Accelerated life testing can take the form of "usage rate acceleration" or "overstress acceleration". Both accelerated life test methods are described next. Because usage rate acceleration test data can be analyzed with typical life data analysis methods, the overstress acceleration method is the testing method relevant to this chapter.

For all life tests, some time-to-failure information for the product is required, since the failure of the product is the event we want to understand. In other words, if we wish to understand, measure, and predict any event, we must observe the event!

35.2.3.1 Usage Rate Acceleration

For products that do not operate continuously under normal conditions, if the test units are operated continuously, failures are encountered earlier than if the units were tested at normal usage. For example, if we assume an average washer use of 6 hours a week, the testing time could conceivably be reduced 28-fold by testing these washers continuously. Data obtained through usage acceleration can be analyzed with the same methods used to analyze regular times-to-failure data.

35.2.3.2 Overstress Acceleration

For products with very high or continuous usage, the accelerated life-testing practitioner must stimulate the product to fail in a life test. This is accomplished by applying stress level(s) that exceed the level(s) that a product will encounter under normal use conditions. The times-to-failure data obtained under these conditions are then used to extrapolate to use conditions. Accelerated life tests can be performed at high or low temperatures, humidity, voltage, pressure, vibration, *etc.*, and/or

combinations of stresses to accelerate or stimulate the failure mechanisms.

Accelerated life test stresses and stress levels should be chosen so that they accelerate the failure modes under consideration but do not introduce failure modes that would never occur under use conditions. Normally, these stress levels should fall outside the product specification limits but inside the design limits (Figure 35.1)

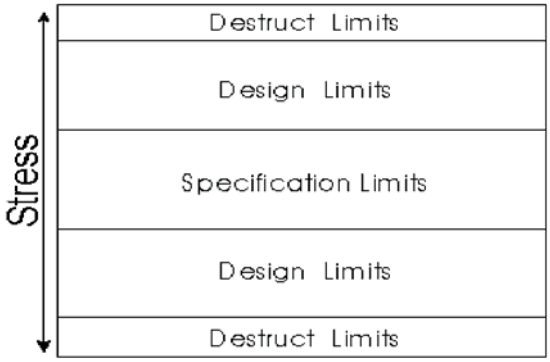

Figure 35.1. Typical stress range for a component, product or system

This choice of stresses as well as stress levels and the process of setting up the experiment are of the utmost importance. Consult your design engineer(s) and material scientist(s) to determine what stimuli (stress) is appropriate as well as to identify the appropriate limits (or stress levels). If these stresses or limits are unknown, multiple tests with small sample sizes can be performed in order to ascertain the appropriate stress(es) and stress levels. Information from the qualitative testing phase of a normal product development process can also be utilized in ascertaining the appropriate stress(es). Proper use of design of experiments (DOE) methodology is also crucial at this step. In addition to proper stress selection, the application of the stresses must be accomplished in some logical, controlled and quantifiable fashion. Accurate data on the stresses applied as well as the observed behavior of the test specimens must be maintained.

It is clear that as the stress used in an accelerated test becomes higher, the required test duration decreases. However, as the stress level moves away from the use conditions, the uncertainty in the extrapolation increases. This is what we jokingly refer to as the "there is no free lunch" principle. Confidence intervals provide a measure of this uncertainty in extrapolation.

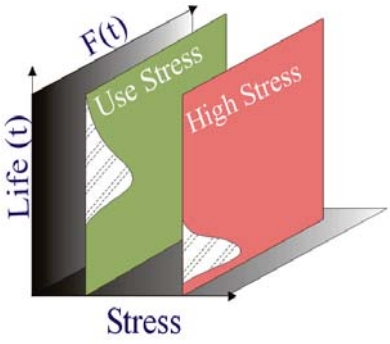
35.3 Understanding Accelerated Life Test Analysis

In accelerated life testing analysis, we face the challenge of determining the use level pdf from accelerated life test data rather than from times-to-failure data obtained under use conditions. To accomplish this, we must develop a method that allows us to extrapolate from data collected at accelerated conditions to arrive at an estimation of use level characteristics. To understand this process, let us look closely at a simple accelerated life test. For simplicity we will assume that the product was tested under a single stress and at a single constant stress level. The pdf of the stressed times-to-failure can be easily obtained using traditional life data analysis methods and an underlying life distribution. The objective in an accelerated life test, however, is not to obtain predictions and estimates at the particular elevated stress level at which the units were tested, but to obtain these measures at another stress level, the use stress level. To accomplish this objective, we must devise a method to traverse the path from the overstress pdf to extrapolate a use level pdf.

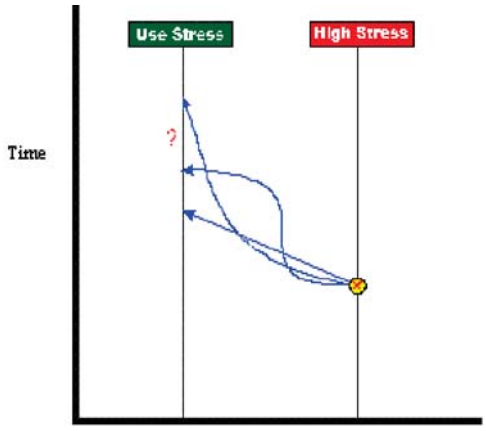
Figure 35.2(a) illustrates a typical behavior of the pdf at the high stress (or overstress level) and the pdf at the use stress level. Figure 35.2(b) illustrates the need to determine a way to project (or map) a certain failure time, obtained at the high stress, to the use stress.

Obviously there are infinite ways to map a particular point from the high stress level to the use stress level. We will assume that there is some road map (model or a function) that maps our point from the high stress level to the use stress level. This model or function can be described mathematically and can be as simple as the equation for a line. Figure 35.3 demonstrates some simple models or relationships. Even when a model is assumed (*i.e.*, linear, exponential, *etc*.),

the mapping possibilities are still infinite since they depend on the parameters of the chosen model or relationship. For example, we can fit infinite number of lines through a point.



(a)



(b)

Figure 35.2. Traversing from a high stress to the use stress

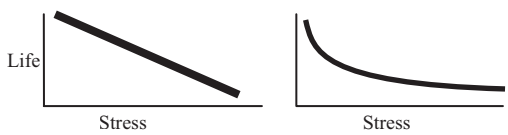


Figure 35.3. A simple linear and a simple exponential relationship

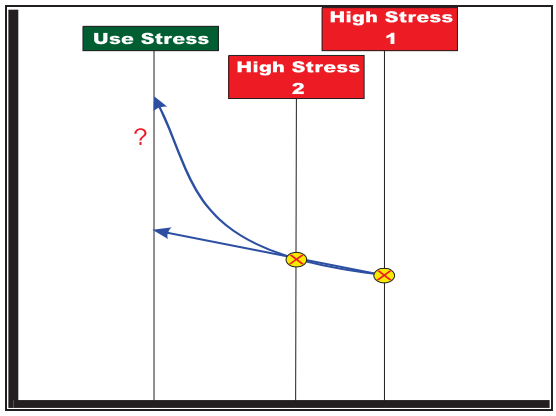

Figure 35.4. Testing at two (or more) higher stress levels allows us to better fit the model

However, if we tested specimens of our product at two different stress levels, we could begin to fit the model to the data. Obviously, the more points we have, the better off we are in correctly mapping a particular point, or fitting the model to our data. Figure 35.4 illustrates the need for a minimum of two stress levels to properly map the function to a use stress level.

35.4 Life Distribution and Life-stress Models

Analysis of accelerated life test data, then, consists of an underlying life distribution that describes the product at different stress levels and a life-stress relationship (or model) that quantifies the manner in which the life distribution (or the life distribution characteristic under consideration) changes across different stress levels. These elements of analysis are shown graphically in Figure 35.5.

The combination of both an underlying life distribution and a life-stress model can be best seen in Figure 35.6 where a pdf is plotted against both time and stress.

The assumed underlying life distribution can be any life distribution. The most commonly used life distributions include, Weibull, the exponential and the lognormal distributions.

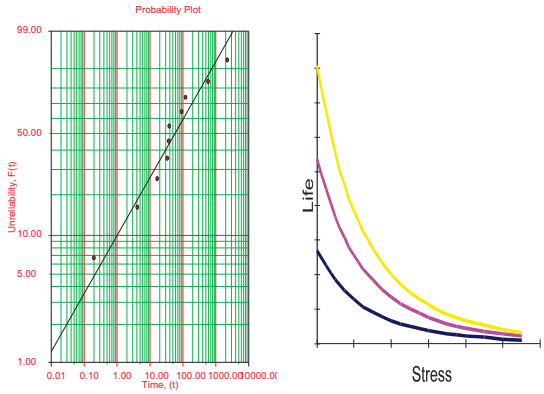

Figure 35.5. A life distribution and a life-stress relationship

The practitioner should be cautioned against using the exponential distribution, unless the underlying assumption of a constant failure rate can be justified. Along with the life distribution, a life-stress relationship is also used. A life-stress relationship can be one of the empirically derived relationships or a new one formulated for the particular stress and application. The data obtained from the experiment is then fitted to both the underlying life distribution and life-stress relationship.

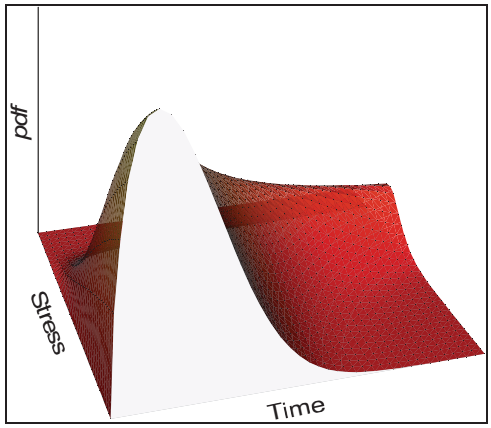

Figure 35.6. A three-dimensional representation of the pdf *vs.* time and stress created using ReliaSoft's ALTA 6.0 software [7]

35.4.1 Overview of the Analysis Steps

35.4.1.1 Life Distribution

The first step in performing an accelerated life test analysis is to choose an appropriate life distribution for your data. The commonly used distributions are the Weibull, lognormal, exponential (usually not appropriate because it assumes a constant failure rate) distributions.

35.4.1.2 Life-Stress Relationship

The second step is to select (or create) a model that describes a characteristic point or a life characteristic of the distribution from one stress level to another (*i.e.,* the life characteristic is expressed as a function of stress). The life characteristic can be any life measure such as the mean, median, *etc*. Depending on the assumed underlying life distribution, different life characteristic are considered. Typical life characteristics for some distributions are shown in Table 35.1

For example, when considering the Weibull distribution, the scale parameter, η, is chosen to be the "life characteristic" that is stress-dependent, while β is assumed to remain constant across different stress levels. A life-stress relationship is then assigned to η. The assumption that β remains constant across different stress levels implies that the same failure mechanism is observed at different stresses. The objective of accelerated testing is to make the studied failure mode occur faster so as not to introduce new failure modes that do not normally occur in normal condition. For thisreason, β is assumed to remain constant across different stress levels. The same reasoning is applied on the assumption that σ is constant when the lognormal distribution is used.

Table 35.1. Typical life characteristics

Distribution	Parameters	Life characteristic
Weibull	β*, η	H
Exponential	Λ	Mean life = 1/ λ
Lognormal	$\overline{T}$, σ*	Median: $\breve{T}$

**Usually assumed independent of the stress level*

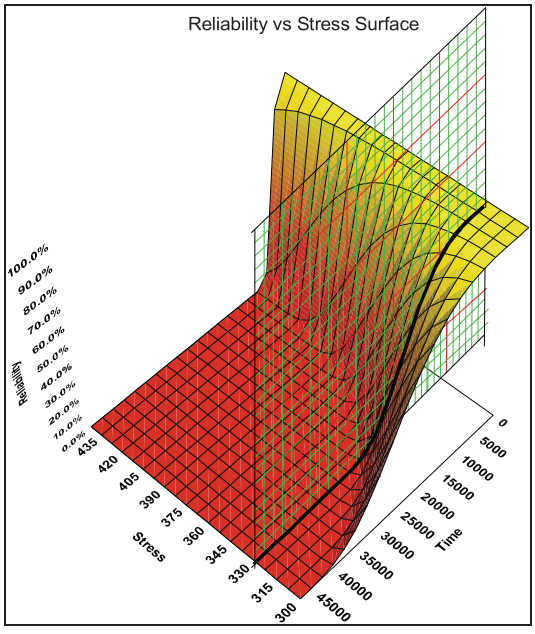

Figure 35.7. A graphical representation of a Weibull reliability function plotted as both a function of time and stress

There are many life-stress models, including:

- The Arrhenius relationship.
- The Eyring relationship.
- The inverse power law relationship.
- The temperature–humidity relationship.
- The temperature–non-thermal relationship.

These models will be discussed in more detail later in this chapter.

The data obtained from the experiment is then fitted to both the underlying life distribution and the life-stress relationship. The combination of both an underlying life distribution and a life-stress model can be best seen in Figure 35.6 where a pdf is plotted against both time and stress. Reliability is also dependent on time and stress as shown in Figure 35.7.

35.5 Parameter Estimation

The next step is to estimate the parameters of the combined model based on the selected life distribution and life-stress relationship that best fit the accelerated test data. The task of parameter estimation can vary from trivial (with ample data, a single constant stress, a simple distribution, and a simple model) to impossible. Available methods for estimating the parameters of a model include the graphical method, the least squares method, and the maximum likelihood estimation (MLE) method. MLE is typically the more appropriate method because its properties are desired in accelerated life test analysis. Computer software can be used to accomplish this task [1, 5, 7].

35.6 Stress Loading

Different types of loads can be considered when an accelerated test is performed. Accelerated life tests can be classified as constant stress, step stress, cycling stress, or random stress. These types of loads are classified according to the dependency of the stress with respect to time.

There are two possible stress loading schemes: loadings in which the stress is time-independent and loadings in which the stress is time-dependent. The mathematical treatment varies depending on the relationship of stress to time.

35.6.1 Time-independent (Constant) Stress

When the stress is time-independent, the stress applied to a sample of units does not vary. In other words, if temperature is the thermal stress, each unit is tested under the same accelerated temperature, *e.g.*, 100°C, and data are recorded (Figure 35.8).

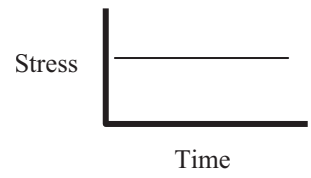

Figure 35.8. Time-independent stress loading

Constant stress loading has many advantages over time-dependent stress loadings. Specifically:

- Most products are assumed to operate at a constant stress under normal use.
- It is far easier to run a constant stress test (*e.g.*, one in which the chamber is maintained at a single temperature).
- It is far easier to quantify a constant stress test.
- Models for data analysis exist, are widely publicized, and are empirically verified.
- Extrapolation from a well executed constant stress test is more accurate than extrapolation from a time-dependent stress test.
- Smaller test sample sizes are required (compared to time-dependent tests).

35.6.2 Time-dependent Stress

When the stress is time-dependent, the product is subjected to a stress level that varies with time (Figures 35.9, 35.10 and 35.11). Products subjected to time-dependent stress loadings will yield failures more quickly and models that fit them are thought by many to be the "holy grail" of accelerated life testing. For more details about analysis of time-dependent accelerated testing, the reader is referred to [6]. Analyses of time-dependent stress models are more complex models and require advanced software packages [1].

Figure 35.11. Continuously time-dependent stress models

35.7 An Introduction to the Arrhenius Relationship

One of the most commonly used life-stress relationships is the Arrhenius model. It is an

exponential relationship and was formulated by assuming that life η is proportional to the inverse reaction rate of the process. Thus the Arrhenius life-stress relationship is given by (35.1).

$$L(V) = C \cdot e^{\frac{B}{V}}, \qquad (35.1)$$

where:

- L represents a quantifiable life measure, such as mean life, characteristic life, median life, or BX life, *etc*.
- V represents the stress level (formulated for temperature and temperature values in absolute units *i.e.*, degrees Kelvin or degrees Rankine. This is a requirement because the model is exponential, thus negative stress values are not possible).
- C and B are model parameters to be determined ($C > 0$).

Since the Arrhenius relationship is a physics-based model derived for temperature dependence, it is strongly recommended that the model be used for temperature-accelerated tests. For the same reason, temperature values must be in absolute units (Kelvin or Rankine), even though (35.1) is unitless.

The Arrhenius relationship can be linearized and plotted on a life *vs.* stress plot by taking the natural logarithm of both sides in (35.1), which leads to (35.2),

$$\ln\left(L(V)\right) = \ln(C) + \frac{B}{V}. \qquad (35.2)$$

Note that the inverse of the stress, and not the stress, is the variable. In Figure 35.12, life is plotted versus stress and not versus the inverse stress. The shaded areas shown in Figure 35.12 are the imposed pdf's at each test stress level. From such imposed pdf's one can see the range of the life at each test stress level, as well as the scatter in life.

The points shown in these plots represent the life characteristics at the test stress levels (the data were fitted to a Weibull distribution, thus the points represent the scale parameter, η).

Depending on the application (and when the stress is exclusively thermal), the parameter B can be replaced by (35.3),

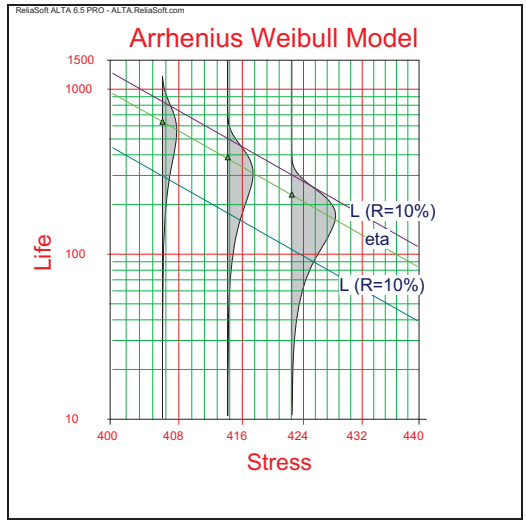

Figure 35.12. The Arrhenius relationship linearized on log-reciprocal paper

$$B = \frac{E_A}{K} = \frac{\text{activation energy}}{\text{Boltzman's constant}} = \frac{\text{activation energy}}{8.623\times10^{-5}\,\text{eV}\cdot\text{K}^{-1}} \qquad (35.3)$$

Note that in this formulation, the activation energy must be known *a priori*. If the activation energy is known then there is only one model parameter remaining, C. Because in most real life situations this is rarely the case, all subsequent formulations will assume that this activation energy is unknown

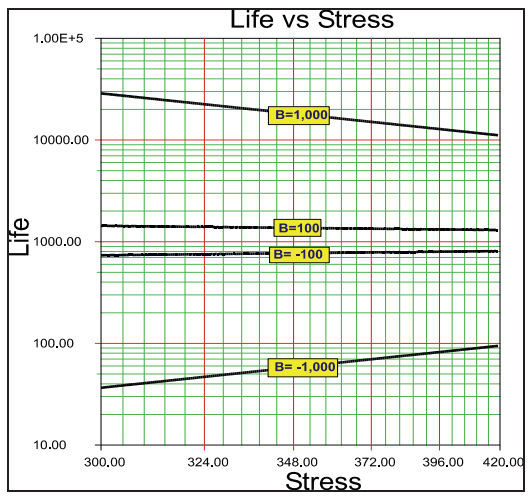

Figure 35.13. Behavior of the parameter B

and treat B as one of the model parameters. B is a measure of the effect that the stress has on the life. The larger the value of B, the higher the dependency of the life on the specific stress. B may also take negative values (*i.e.*, life is increasing with increasing stress), see Figure 35.12. An example of this would be plasma filled bulbs that last longer at higher temperatures.

35.7.1 Acceleration Factor

Most practitioners use the term acceleration factor to refer to the ratio of the life (or acceleration characteristic) between the use level and a higher test stress level or as shown in (35.4).

$$A_F = \frac{L_{Use}}{L_{Accelerated}}. \qquad (35.4)$$

For the Arrhenius model this factor is shown in (35.5),

$$A_F = \frac{L_{USE}}{L_{Accelerated}} = \frac{C \cdot e^{\frac{B}{V_u}}}{C \cdot e^{\frac{B}{V_A}}} = \frac{e^{\frac{B}{V_u}}}{e^{\frac{B}{V_A}}} = e^{\left(\frac{B}{V_u} - \frac{B}{V_A}\right)}. \qquad (35.5)$$

If B is assumed to be known *a priori* (using an activation energy), the assumed activation energy alone dictates this acceleration factor!

35.7.2 Arrhenius Relationship Combined with a Life Distribution

All relationships presented must be combined with an underlying life distribution for analysis.

We illustrate the procedure for combining the Arrhenius relationship with an underlying life distribution, using the Weibull distribution. The two-parameter Weibull distribution equation is shown in (35.6),

$$f(t) = \frac{\beta}{\eta} \cdot \left(\frac{t}{\eta}\right)^{\beta - 1} e^{-\left(\frac{t}{\eta}\right)^{\beta}} \qquad (35.6)$$

The Arrhenius–Weibull model pdf can be obtained by setting $\eta = L(V)$ in (35.7) to (35.8),

$$\eta = L(V) = C \cdot e^{\frac{B}{V}}. \qquad (35.7)$$

Substituting for η in (35.7), we get the Arrhenius–Weibull model in (35.8),

$$f(t,V) = \frac{\beta}{C \cdot e^{\frac{B}{V}}} \cdot \left(\frac{t}{C \cdot e^{\frac{B}{V}}}\right)^{\beta - 1} e^{-\left\{\frac{t}{C \cdot e^{\frac{B}{V}}}\right\}^{\beta}} \qquad (35.8)$$

An illustration of the pdf for different stresses is shown in Figure 35.14. Figure 35.15 illustrates the behavior of the reliability function at different stress levels.

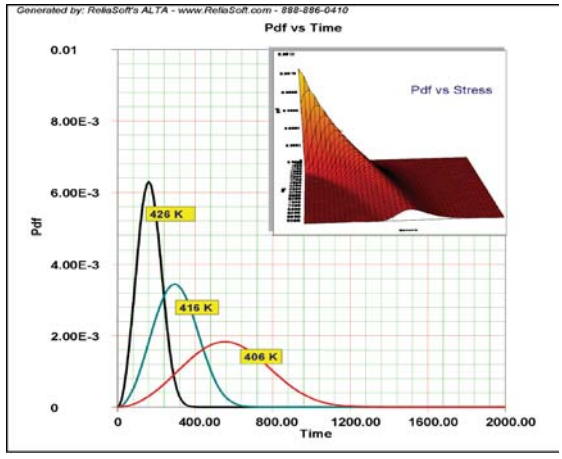

Figure 35.14. Probability density function at different stresses and with the parameters held constant

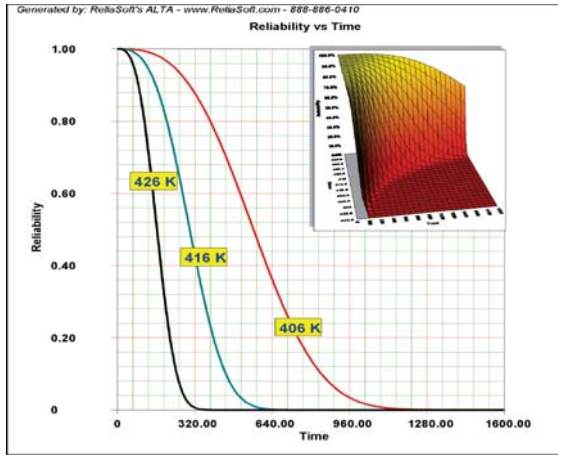

Figure 35.15. Reliability function at different stresses and with the parameters held constant

The following equations ((35.9)–(35.11)) are a summary of the Arrhenius model combined with some common distributions.

Arrhenius–Weibull

$$f(t,V) = \frac{\beta}{C \cdot e^{\frac{B}{V}}} \cdot \left(\frac{t}{C \cdot e^{\frac{B}{V}}} \right)^{\beta-1} e^{-\left(\frac{t}{C \cdot e^{\frac{B}{V}}} \right)^{\beta}} \tag{35.9}$$

Arrhenius–lognormal

$$f(t,V) = \frac{1}{T' \cdot \sigma_{T'} \sqrt{2\pi}} \cdot e^{-\frac{1}{2}\left(\frac{T' - \bar{T}'}{\sigma_{T'}} \right)^2} \tag{35.10}$$

Arrhenius–exponential

$$f(t,V) = \frac{1}{C \cdot e^{\frac{B}{V}}} \cdot e^{-\frac{1}{C \cdot e^{\frac{B}{V}}} \cdot t} \tag{35.11}$$

Once the pdf has been obtained, all other metrics of interest *(i.e.*, reliability, MTTF, *etc.*) can be easily formulated. For more information, see [1 , 5].

35.7.2.1 Example

Consider the following times-to-failure data at three different stress levels.

Table 35.2. Times-to-failure data at three different stress levels

Stress	393 K	408 K	423 K
Time Failed (hrs)	3850	3300	2750
	4340	3720	3100
	4760	4080	3400
	5320	4560	3800
	5740	4920	4100
	6160	5280	4400
	6580	5640	4700
	7140	6120	5100
	7980	6840	5700
	8960	7680	6400

The data were analyzed jointly and with a complete MLE solution over the entire data set, using [7]. The analysis yields.

$$\hat{\beta} = 4.291,\ \hat{B} = 1861.618,\ \hat{C} = 58.984 \cdot$$

Once the parameters of the model are estimated, extrapolation and other life measures can be directly obtained using the appropriate equations. Using the MLE method, confidence bounds for all estimates can be obtained.

35.7.3 Other Single Constant Stress Models

Similarly to the approach described in Section 35.6.2, combining the distribution and the life-stress relation in one model is done by substituting the appropriate life characteristic (as indicated in Table 35.1) of the distribution with the life-stress relationship. Equations (35.12)–(35.17) summarize some of the most common life-stress/life distribution models.

Eyring–Weibull

$$f(t,V) = \beta V^{n} \cdot e^{\left(A - \frac{B}{V}\right)} \cdot \left(t V^{n} \cdot e^{\left(A - \frac{B}{V}\right)} \right)^{\beta-1} e^{-\left(t V^{n} \cdot e^{\left(A - \frac{B}{V}\right)} \right)^{\beta}} \tag{35.12}$$

Eyring–lognormal

$$f(t,V) = \frac{1}{T' \cdot \sigma_{T'} \sqrt{2\pi}} \cdot e^{-\frac{1}{2}\left(\frac{T' + \ln(V^{n}) + A - \frac{B}{V}}{\sigma_{T'}} \right)^2} \tag{35.13}$$

Eyring–exponential

$$f(t,V) = V^{n} \cdot e^{\left(A - \frac{B}{V}\right)} \cdot e^{-V^{n} \cdot e^{\left(A - \frac{B}{V}\right)} \cdot t} \tag{35.14}$$

IPL–Weibull

$$f(t,V) = \beta K V^{n} \left(K V^{n} t \right)^{\beta-1} \cdot e^{-\left(K V^{n} t \right)^{\beta}} \tag{35.15}$$

IPL–lognormal

$$f(t,V) = \frac{1}{T \cdot \sigma_{T'} \sqrt{2\pi}} \cdot e^{-\frac{1}{2}\left(\frac{T' + \ln(K) + n\ln(V)}{\sigma_{T'}}\right)^2} \tag{35.16}$$

IPL–exponential

$$f(t,V) = K V^n e^{-K V^n t} \tag{35.17}$$

One must be cautious in selecting a model. The physical characteristics of the failure mode under consideration must be understood and the selected model must be appropriate. As an example, in cases where the failure mode is fatigue, the use of an exponential relationship would be inappropriate since the physical mechanism are based on a power relation (*i.e.*, the inverse power law model is more appropriate).

35.8 An Introduction to Two-stress Models

35.8.1 Temperature–Humidity Relationship-Introduction

The temperature–humidity (T–H) relationship has been proposed for predicting the life at use conditions when temperature and humidity are the accelerated stresses in a test. This combination model is given by (35.18),

$$L(U,V) = A \cdot e^{\left\{\frac{\phi}{V} + \frac{b}{U}\right\}}, \tag{35.18}$$

where,

- Φ, b and A are three parameters to be determined. b is also known as the activation energy for humidity;
- U is the relative humidity (decimal or percentage); and
- V is temperature (in absolute units)

Since life is now a function of two stresses, a life vs. stress plot can only be obtained by keeping one of the two stresses constant and varying the other one.

When using the T–H relationship, the effect of both temperature and humidity on life is sought. Therefore, the test must be performed in a combination manner between the different stress levels of the two stress types. For example, assume that an accelerated test is to be performed at two temperature and two humidity levels, then the test should be performed at three out of the four possible combinations in order to be able to determine the effect of each stress type.

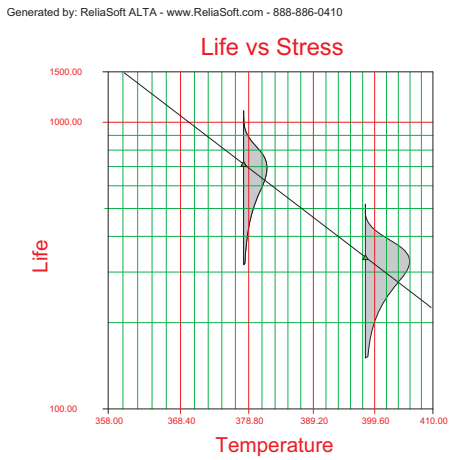

Figure 35.16(a). Life *vs*. stress plots for the temperature-humidity model, holding humidity constant

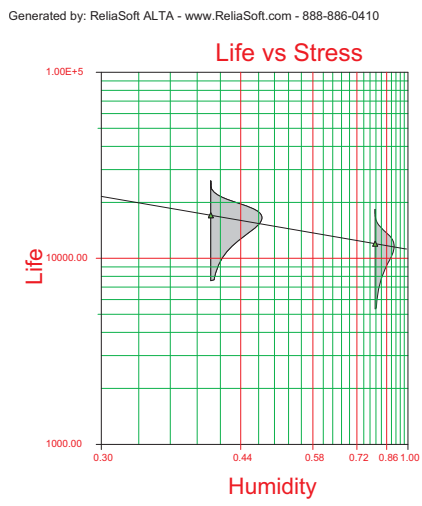

Figure 35.16(b). Life *vs.* stress plots for the temperature-humidity model, holding temperature constant

35.8.1.1 An Example Using the T–H Model

The data in Table 35.3 were collected after testing twelve electronic devices at different temperature and humidity conditions.

Table 35.3. T–H data

Time, hr	Temperature, K	Humidity
310	378	0.4
316	378	0.4
329	378	0.4
411	378	0.4
190	378	0.8
208	378	0.8
230	378	0.8
298	378	0.8
108	398	0.4
123	398	0.4
166	398	0.4
200	398	0.4

Using [7], the following results were obtained assuming a Weibull distribution and using the T–H life stress model:

$$\hat{\beta}=5.874,\ \hat{A}=0.0000597,\ \hat{b}=0.281,\ \hat{\phi}=5630.330.$$

Figure 35.16 shows the effect of temperature and humidity on the life of the electronic devices.

35.8.2 Temperature–Non-thermal Relationship Introduction

When temperature and a second non-thermal stress (*e.g.*, voltage) are the accelerated stresses of a test, then the Arrhenius and the inverse power law models can be combined to yield the temperature–non-thermal (T–NT) model. This model is given by (35.19),

$$L(U,V)=\frac{C}{U^{n}e^{-\frac{B}{V}}}, \qquad (35.19)$$

Where:

- U is the non-thermal stress (*i.e.*, voltage, vibration, *etc.*);
- V is the temperature (in absolute units); and
- B, C and n are parameters to be determined.

In Figure 35.17, data obtained from a temperature and voltage test were analyzed and plotted on a log-reciprocal scale.

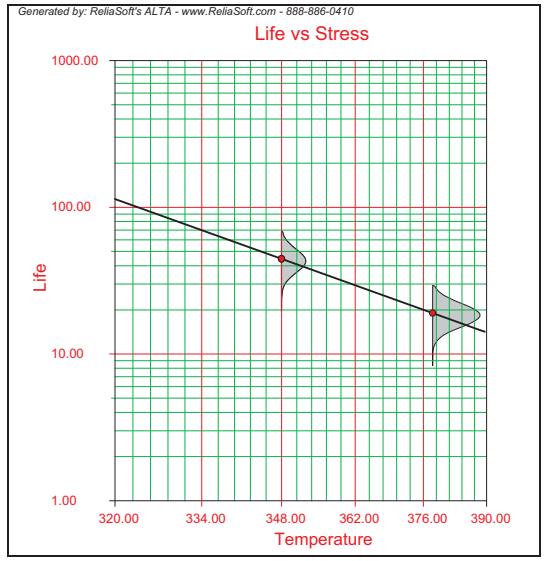

Figure 35.17(a). Life *vs.* stress plots for the temperature–non-thermal model, holding voltage constant

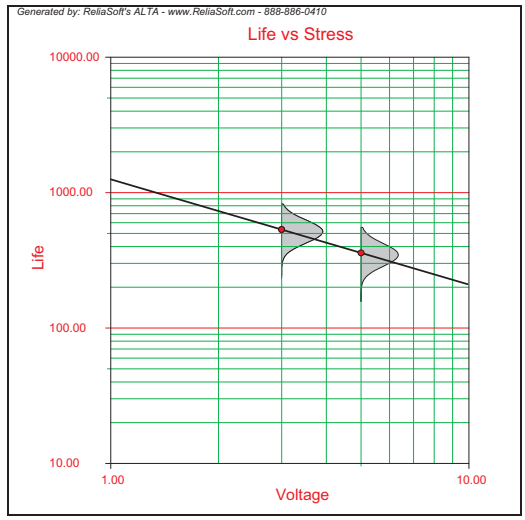

Figure 35.17(b). Life *vs.* stress plots for the temperature–non-thermal model, holding temperature constant

35.9 Advanced Concepts

35.9.1 Confidence Bounds

The confidence bounds on the parameters and a number of other quantities such as the reliability and the percentile can be obtained based on the asymptotic theory for maximum likelihood estimates, for complete and censored data. This type of confidence bounds is most commonly referred to as the Fisher matrix bounds. For more details about analysis in time-dependent accelerated testing analysis, the reader is referred to [6].

35.9.2 Multivariable Relationships and the General Log-linear Model

So far in this chapter the life-stress relationships presented have been either single stress relationships or two stress relationships. In most practical applications however, life is a function of more than one or two variables (stress types).

In addition, there are many applications where the life of a product as a function of stress and of some engineering variable other than stress is sought. A multivariable relationship called the general log-linear relationship, which describes a life characteristic as a function of a vector of n stresses is used. Mathematically the general log-linear (GLL) model is given by (35.20),

$$L\left(\underline{X}\right) = e^{\left(a_0 + \sum_{i=1}^{n} a_i X_i\right)}, \qquad (35.20)$$

Where:

- a_0 and a_j are model parameters,
- $\underline{X}$ is a vector of n stresses, And
- X_n are the levels of the n stresses.

This relationship can be further modified through the use of transformations. As an example, a reciprocal transformation on X, or $X=1/V$ will result in an exponential life stress relationship (for example, thermal factors), while a logarithmic transformation, $X=\ln(V)$, results in a power life stress relationship (for example, non-thermal factors.) Note that the Arrhenius, the inverse power law, the temperature–humidity and temperature–non-thermal relationships are all special cases of the GLL model.

Like the previous models, the general log-linear model can be combined with any of the available life distributions by expressing a life characteristic from that distribution with the GLL relationship.

35.9.2.1 Example

Consider the data summarized in Table 35.4 and Table 35.5.

Table 35.4. Stress profile summary

Profile	Temp (K)	Voltage (V)	Operation Type
A	358	12	On/Off
B	358	12	Continuous
C	378	12	On/Off
D	378	12	Continuous
E	378	16	On/Off
F	378	16	Continuous
G	398	12	On/Off
H	398	12	Continuous

Table 35.5. Failure data

Profile	Failure Time / Suspensions
A	498, 750
B	445, 586, 691 20 units suspended at 750
C	176, 252, 309, 398
D	211, 266, 298, 343, 364, 387 14 units suspended at 445
E	118, 163, 210, 249
F	145, 192, 208, 231, 254, 293 10 units suspended at 300
G	87, 112, 134, 163
H	116, 149, 155, 173, 193, 214 7 units suspended at 228

The data of Table 35.5 is analyzed assuming a Weibull distribution, an Arrhenius life-stress relationship for temperature, and an inverse power life-stress relationship for voltage. No transformation is performed on the operation type. The operation type variable is treated as an indicator variable, using the discrete values of 0 and 1, for on/off and continuous operation, respectively.

The best fit values for the parameters are:

$\hat{\beta} = 3.7483,\ \hat{\alpha}_0 = -6.0220;\ \hat{\alpha}_1 = 5776.9341;$

$\hat{\alpha}_2 = -1.4340;\ \hat{\alpha}_3 = 0.6242$

In this case, since the life is a function of three stresses, three different plots can be created. Such plots are created by holding two of the stresses constant at the desired use level, and varying the remaining one. The use stress levels for this example are 328 K for temperature and 10 V for voltage. For the operation type, a decision has to be made by the engineers as to whether they implement on/off or continuous operation. From Figure 35.18, it can be concluded that the continuous operation has a better effect on the life of the product than the on/off cycling.

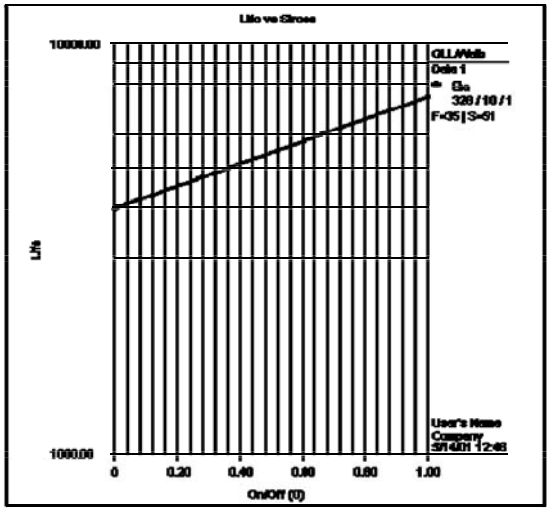

Figure 35.18. Effect of operation type on life

35.9.3 Time-varying Stress Models

When dealing with data from accelerated tests with time-varying stresses, the life-stress model must take into account the cumulative effect of the applied stresses. Such a model is commonly referred to as a "cumulative damage" or "cumulative exposure" model. Nelson [3] defines and presents the derivation and assumptions of such a model.

Time-varying stress models apply for any of the following situations:

- The test stress is time-dependent and the use stress is time-independent.
- The test stress is time-independent and the use stress is time-dependent.
- Both the test stress and the use stress are time-dependent.

We illustrate the derivation of the cumulative damage mode using the Weibull distribution as the life distribution model and the inverse power relationship as the life-stress model. Given a time-varying stress $x(t)$, the reliability function of the unit under a single stress is given by (35.21),

$$R\left(t, x\left(t\right)\right) = e^{-\left[\int_0^t \frac{1}{\eta(u)} du\right]^{\beta}}. \quad (35.21)$$

The inverse power law relationship is expressed by (35.22):

$$\eta(t) = \left(\frac{a}{x\left(t\right)}\right)^{n}. \quad (35.22)$$

Therefore, the pdf is as given in (35.23),

$$f\left(t, x\left(t\right)\right) = \beta\left(\frac{x\left(t\right)}{a}\right)^{n} \cdot \left(\int_0^t \left(\frac{x\left(t\right)}{a}\right)^{n} du\right)^{\beta-1} \cdot e^{-\left[\int_0^t \left(\frac{x\left(t\right)}{a}\right)^{n} du\right]^{\beta}} \quad (35.23)$$

The above procedure can be used with other distribution types or life-stress relationships and can be extended to analysis involving multiple stress types using the general-log linear model concept. Parameter estimation can be accomplished via maximum likelihood estimation methods and confidence intervals can be approximated using the Fisher matrix approach.

35.9.3.1 Example

12 units were tested using the time-dependent voltage profile shown in Figure 35.19.

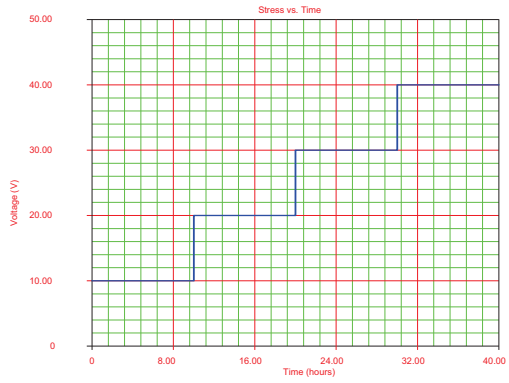

Figure 35.19. Stress profile

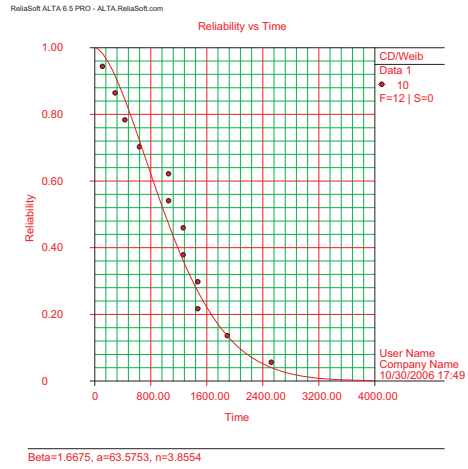

Figure 35.20. Reliability plot at use condition

The failure times (in hours) were, 17, 22, 24, 27, 31, 31, 32, 32, 33, 33, 35 and 38.

Assuming the Weibull distribution and using the power life-stress model and MLE as the analysis method, we use [7] to obtain the reliability plot in Figure 35.20 at the normal use condition of 10 V.

HALT and HASS Overview: The New Quality and Reliability Paradigm

Gregg K. Hobbs

Hobbs Engineering, 4300 W 100th Ave., Westminster, CO 80031, USA

The following quote reminds me of my struggles to introduce the new paradigms in the mid-1960s through enthusiastic acceptance in the late 1990s.

"Every truth passes through three stages before it is recognized.
In the first, it is ridiculed,
In the second, it is opposed,
In the third, it is recognized as self-evident." - 19th century German philosopher, Aurther Schopenhauer.

Abstract: Highly accelerated life tests (HALT) and highly accelerated stress screens (HASS) are introduced and discussed in this chapter. A few successes from each technique are described. These techniques have been successfully used by the author, and some of the author's consulting clients and seminar attendees for more than 38 years. Most of the accomplished users do not publish their results because of the pronounced financial and technical advantages of the techniques over the classical methods, which are not even in the same league in terms of speed and cost. It is important to note that the methods are still evolving as is the equipment required in order to implement the techniques. This chapter is an overview of the methods and also gives a partial chronology of their development. Full details are available in [1] and [2].

36.1 Introduction

The HALT and HASS methods are designed to improve the reliability of products, not to determine what the reliability is. The approach is therefore proactive as compared to a rel-demo (reliability demonstration) or MTBF tests that do not improve the product at all but simply (attempt to) measure what the reliability of the current design and fabrication is. This is a major difference between the classical and the HALT approaches. HALT is discovery testing whereas MIL-SPEC testing is compliance testing. These are two totally different paradigms and the differences should be completely clear to anyone attempting to perform either one. In HALT, every attempt is made to find the weak links and then fix them so that the problems will never occur again. In compliance testing, one simply attempts to satisfy all design testing requirements in order to obtain customer acceptance of the design, usually resulting in a very marginal if not completely inadequate design.

In compliance testing, overstress testing is definitely not used as it would expose weak links, which are not desired to be exposed; that is, the goal is to pass regardless of any design flaws, fabrication flaws or any other things that would prevent successful operation in the field. If failures occur, every attempt is made to discount the failure by whatever means that seem plausible so that customer acceptance will be obtained. The author started his technical life in the MIL-SPEC arena and so knows it all too well, although I must admit to having some guilty thoughts about the methods at that time. But, in the compliance arena, one must comply with the contract or payment is not forthcoming. Doing too much may actually reduce the payments, as faults could be discovered and delay certification and or payment.

HALT is performed during the design stages to eliminate design weaknesses and HASS is performed during the production stages to eliminate process problems. Therefore, HALT is basically a design tool and HASS is basically a process control tool. No matter where we find problems, it is always beneficial to take corrective action.

36.2 The Two Forms of HALT Currently in Use

It is appropriate to briefly discuss the two forms of HALT currently in use. Classical HALT uses one stress at a time with the product fully monitored with high coverage and also with good resolution. The stresses to be used are all of the field stresses plus any that could contribute to relevant flaw discovery by the Cross Over Effect™. The usual way to proceed is to expose the product to sequentially increased stresses such as:

36.2.1 Classical HALT™ Stress Application Sequence

- Apply monitoring with high coverage.
- Low temperature.
- High temperature.
- Voltage and frequency margining.
- All axis vibration (three linear axes and three angular axes, all broadband random and of appropriate spectra).
- Other stresses as appropriate for the product.
- Combine stresses a few at a time, then all at once.
- Modulated Excitaiton™ for detection of anything missed so far.
- Improve any weaknesses found if they will reduce field reliability or increase the cost of HASS.
- Do it all over again until an appropriately robust level is reached.

The above sequence is not the only one which could work, it is just the first one that I used and it works well, so why change it?

36.2.2 Rapid HALT™ Stress Application Scheme

- Apply monitoring with high coverage.
- Apply all stresses simultaneously in step-wise fashion.
- Modulated Excitation™ for detection of anything missed so far.
- Improve any weaknesses found if they will reduce field reliability or increase the cost of HASS.
- Do it all over again until an appropriately robust level is reached.

Both schemes require high coverage and resolution in order to be the least bit effective. That is, both high coverage and resolution are necessary in order to detect and then fix any problems that may have surfaced.

I have successfully used Rapid HALT™ since 1969 in my consulting roles, but only started to teach it in 2000 because the paradigm jump required to even perform Classical HALT was barely possible with most seminar attendees up until about 2000. I thought that it would be better to wait until the Classical HALT was widely accepted before attempting to teach the next quantum jump to Rapid HALT. By the way, Rapid HALT is not suggested for beginners, as it is likely

that many design flaws will be precipitated nearly simultaneously and trouble shooting will be extremely difficult to perform. Later, when the designers have learned the many lessons to be learned from a good HALT program, Rapid HALT will probably not precipitate several failures simultaneously because there will probably not be many design flaws present. Rapid HALT saves substantial time in precipitation of defects, but the "fix it time" which is the time required to determine the root cause of the problem and then to implement a fix, remains the same.

A major mistake that is observed today is that some of those attempting HALT will step stress until something is observed and then to just stop there and say "I did HALT!" Others step stress until the operational limits and/or destruct limits in temperature and vibration (only) are found and then just stop. These approaches are not HALT at all and are completely useless, maybe less than useless as they give the impression of accomplishing something when indeed they have not. The improvements are what HALT is all about. If there are no improvements, then there will be no gain.

HALT is an acronym for highly accelerated life test, which was coined by the author in 1988 after having used the term "design ruggedization" for several years. In HALT, every stimulus of potential value is used at accelerated test conditions during the design phase of a product in order to find the weak links in the design and fabrication processes very rapidly. Each weak link found provides an opportunity to improve the design or the processes which will lead to reduced design time, increased reliability and decreased costs. HALT compresses the design time and therefore allows earlier (mature) product introduction. Studies have shown that a six-month advantage in product introduction can result in a lifetime profit increase of 50% [3]. HALT may well accomplish such an earlier release to production.

The stresses applied in HALT and HASS are not meant to simulate the field environments at all, but are meant to expose the weak links in the design and processes using only a few units and in a very short period of time. The stresses are stepped up to well beyond the expected field environments until the "fundamental limit of the technology" [1, 2] is reached in robustness. Reaching the fundamental limit generally requires improving everything relevant found even if found at above the "qualification" levels! This means that one ruggedizes the product as much as possible without unduly spending money (which is sometimes called "gold plating"). Only those failures that are likely to occur in normal environments or ones that would increase the costs of HASS are addressed. One could easily overdo the situation and make the product much more rugged than necessary and spend unnecessary money and time in the process. Intelligence, technical skills and experience must all be used and a specification approach is totally incorrect in this technique. I believe that anyone who purports to have a "HALT specification" simply does not comprehend what the methods are all about. Most of the weaknesses found in HALT are simple in nature and inexpensive to fix; such as:

1. A capacitor which flew off of the board during vibration can be bonded to the board or moved to a node of the mode causing the problem, or
2. a particular component which is found to have a less than optimum value can be changed in value, or
3. an identified weak link component can be replaced with a more robust one, or
4. a screw which backs out during vibration and thermal cycling can be held in place with a thread locker of some kind.

There are many more examples in [1, 2]. The above were just illustrative.

HALT, or its predecessor, ruggedized design, has, on many occasions provided substantial (50 to 1000 times, and in a few cases, even higher) reductions in field failures, time to market, warranty expenses, design and sustaining engineering time and cost and also total development costs. One of the main benefits of HALT is that it minimizes the sample size necessary for HALT—a few will do. After a correct HALT program, the design will usually sail through DVT or Qual without any problems. The basic philosophy of HALT has been in use for many years and has been used by the author and others on many products from various fields. Some of these fields are listed in Table 36.1.

Many others exist, but cannot be mentioned due to non-disclosure agreements. Most of these companies have not published at all about their HALT successes.

Some attendees at the author's seminars have, in addition, used the techniques on thousands of products, so the *basic* methods are not new, but have not been publicized much until recently because of the tremendous advantages in reliability and cost gained by their use. The techniques continue to be improved and, in 1991, the author introduced precipitation and detection screens, decreasing screen cost by at least an order of magnitude and simultaneously increasing the effectiveness by several orders of magnitude. A precipitation screen uses screens well above the in-use levels in order to gain time compression and a detection screen attempts to find the patent or detectable defects in order to .determine the conditions under which an intermittent will be exposed. It is noted in passing that many soft failures are only detectable under a limited set of conditions. The industry average seems to be that over 50% of the defects cannot be detected on the test bench. Hence, the vast number of "cannot duplicate", "cannot verify", "no defect found" situations in the industries. Detection screens would expose most of these, saving lots of time and money for the customer and the manufacturer.

In 1996, the author introduced the concept of a search pattern which makes the detection of precipitated defects better by *at least* one order of magnitude, if not many orders of magnitude. This concept is called Modulated Excitation™. Briefly explained, it is a search pattern in the two space of temperature and vibration (or any other set of stresses such as voltage and frequency) for the combination wherein an intermittent will be observable and can then be fixed. Many flaws are only detectable within a narrow band of a combination of stresses and so trouble shooting must be accomplished in the chamber at temperature and at vibration. This is one fact that makes farming out HALT less than completely satisfactory.

Software HALT™ was introduced in 1998. In this software development technique, one exposes lack of coverage in the test hardware/software system by inserting faults intentionally, finding lack of coverage situations and then improving the test coverage. The results of Software HALT are currently being held as company private by the users and the author has seen only one publication on it through non-disclosure agreements with consulting clients. Paybacks measured in a few days are common in Software HALT, that is, the total cost of purchasing the test equipment and running the tests is recovered in a few days. The test equipment is then available for another series of tests and can again achieve a similar payback. This payback, assuming a two week payback, could be accomplished 26 times in one year on this one piece of equipment. Without compounding the rate of return, the simple rate of return is 2,600% per year! Reasons such as this are why the few leaders will not publish their results and give their competition the information necessary for them to start using the same techniques! Equipment to accomplish the methods is available [4].

HASS is an acronym for highly accelerated stress screens, which was also coined by the author in 1988 after using the term "enhanced ESS" for some years. These screens use the highest possible stresses (frequently well beyond the "QUAL" level) in order to attain time compression in the screens. Note that many stimuli exhibit an exponential relationship between stress level and "damage" done resulting in a much shorter duration of stress (if the correct stress is used). It has been proven that HASS generates extremely large savings in screening costs as much less equipment such as shakers, chambers, consumables (power and liquid nitrogen), monitoring systems and floor space are required due to time compression in the screens. The time compression is gained in a precipitation screen which utilizes stresses far above the field operational stresses. Enhanced detection is obtained in detection screens which are usually above the field stress levels if possible to enhance detection. Additionally, Modulated Excitation™ is used to improve detection. The screens must be, and are proven to be, of acceptable fatigue damage accumulation or lifetime degradation using Safety of HASS™ techniques. Safety of HASS demonstrates that repeated screening does not degrade the field performance of the unit under test and is a crucial part of HASS development. Safety of HASS, sometimes called SOS or safety of screen, is used as the term of choice as the author likes the connotation of a lifeboat.

HASS is generally not possible unless a comprehensive HALT has been performed as the margins would be too small to allow the overstress conditions required for time compression. Without HALT, fundamental design limitations would restrict the acceptable stress levels in production screens to a very large degree and will prevent the large accelerations of flaw precipitation, or time compression, which are possible with a very robust product. A less than robust product probably cannot be effectively screened by the "classical" screens without a substantial reduction in its field life.

It is only necessary that the products retain sufficient life in them to perform adequately in the real world after repeated screens. We care how much life is left, not how much life we took out during the screens. Focusing on the life removed is counterproductive and has been mentioned at many conferences as if it were the main concern. Focusing on the life removed is a typical mistake of mammoth proportions in a HALT and HASS program.

36.3 Why Perform HALT and HASS?

The general reason to perform accelerated stress conditions in the design phases is to find and improve upon design and process weaknesses in the least amount of time and correct the source of the weaknesses before production begins. The purposes of HASS are to discover and eliminate process related problems so as to take corrective action to eliminate the source of problems as soon as possible and to reduce the number of units which have to be reworked or recalled or even replaced in the field.

Table 36.1. Saving factors

Cost of Fixing a Design Defect	Savings Factor
\$35 during design	19,712:1
\$177 before procurement	3,898:1
\$368 before production	1,875:1
\$417,000 before shipment	41:1
\$690,000 on customer sites	1:1

In 1991, Horoshi Hamada, President of Ricoh, presented a paper at the EuroPACE Quality Forum. He gave costs of fixing problems at different stages during the design or during field service. Savings factors compared to the costs of failures in the field were calculated by me and are stated as "savings factor" shown in Table 36.1.

It is readily seen that fixing a problem during design is far more cost effective than fixing it later. This is what HALT is all about.

It is generally true that robust products will exhibit much higher reliability than non-robust ones and so the ruggedization process of HALT, in which large margins are obtained, will generate products of high potential reliability. In order to achieve the potential, however, defect free hardware must be manufactured or, at least, the defects must be found and fixed before shipment. In HASS, accelerated stresses are applied in production in order to shorten the time to failure of the defective units and therefore shorten the corrective action time and the number of units built with the same flaw. Each weakness found in HALT or in HASS represents an opportunity for improvement. The author has found that the application of accelerated stressing techniques to force rapid design maturity (HALT) results in paybacks that far exceed that from production stressing (HASS). Nonetheless, production HASS is cost effective in its own right until reliability is such that a sample HASS or highly accelerated stress audit (HASA) can be put into place. The use of HASA demands excellent process control as most units will be shipped without the benefit of HASS being performed on them, and only those units in the selected sample will be screened for defects. Corrective action is tantamount here.

The stresses used in HALT and HASS include but are not restricted to all axis simultaneous vibration, high rate broad-range temperature cycling, power cycling, voltage and frequency variation, humidity, and any other stress that may expose design or process problems. No attempt is made to simulate the field environment, one only seeks to find design and process flaws by any means possible. The stresses used generally far exceed the field environments in order to gain time compression, that is, shorten the time required to find any

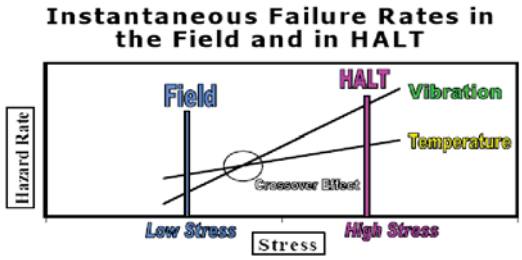

Figure 36.1. Instantaneous failure rates in the field and in HALT

problem areas. When a weakness is discovered, only the failure mode and mechanism are of importance, the relation of the stress used to the field environment is of no consequence at all. Figure 36.1 illustrates this point. In this figure, the hazard rate, λ, is the instantaneous failure rate for a given failure mode. The two curves illustrating a thermally induced failure rate and a vibration induced failure rate are located so that the field stresses at which failure occurs and the HALT stresses at which failures occur are lined up vertically for each stress. It is then seen that a failure mode that would most often be exposed by temperature in the field is likely to be exposed by vibration in the HALT environment. If one thinks of overlapping Venn diagrams in temperature and vibration, then one can see that the situation pictorially represented could occur as vibration usually occurs at hundreds of cycles per second and thermal cycles only occur at several cycles per hour in HALT. Therefore, fatigue damage occurs much more rapidly in vibration than in thermal cycling. This effect is called the Crossover Effect™ by the author. Knowledge of the crossover effect can save tremendous time and money. Many recently published papers totally miss the concept, however.

The Crossover Effect occurs frequently in HALT and HASS and should be expected. Many users who are not aware of this possibility miss this effect and, therefore, do not fix some design flaws uncovered by HALT and usually say "The product will never see that stress in the field so we do not have to fix it!" This erroneous thinking is at the root of many field failures even though the design defect was discovered in HALT, but not fixed.

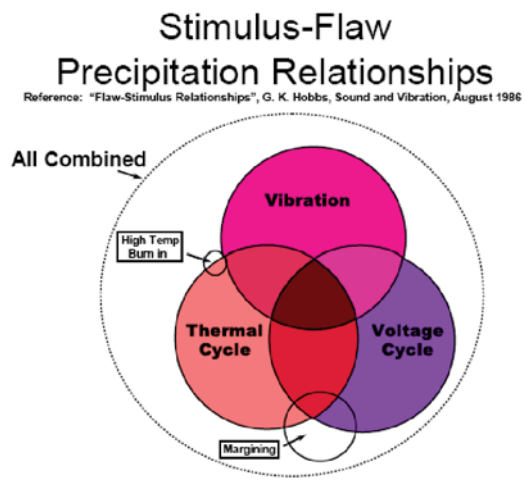

Figure 36.2. Stimulus–flaw precipitation relationship

There is another way to express the Crossover Effect and that is in Venn diagrams as shown in Figure 36.2.

Whenever the Venn diagrams overlap, then the Crossover Effect is present. It is very common to expose weaknesses in HALT with a different stress than the one that would make the weakness show up in the field. It is for this reason that one should focus on the failure mode and mechanism instead of the margin for the particular stress in use when deciding whether to fix a weakness or not.

"Mechanism" here means the conditions that caused the failure such as melting, exceeding the stable load or exceeding the ultimate strength. The corresponding failure mode could be separation of a conductor, elastic buckling and tensile failure, respectively. Considering the margin instead of the failure mode is a major mistake which is made by most engineers used to conventional test techniques, which I call "compliance" or "success" testing. In HALT and HASS, one uses extreme stresses for a very brief period of time in order to obtain time compression in the failures. In doing so, one may obtain the same failures as would occur in the field environments, but with a different stress. For example, a water sprinkler manufacturer had a weakness which was exposed by the diurnal thermal cycle in the field. HALT exposed the same weakness with all axis vibration after extensive thermal cycling failed to expose the

weakness. After the weakness was addressed, the field failures were eliminated, which proves that the weakness exposed by all axis vibration was a valid discovery. For another example, consider a reduction in cross sectional area of a conductor during forming of a bend. This reduction would create a mechanical stress concentration and an electrical current density concentration. This flaw might be exposed by temperature cycling or vibration in HALT or HASS and might also be exposed by electromigration during power cycling in HALT or HASS. Either way, flaw introduces a weakness that can be eliminated by changing the operation that introduced the reduction in area.

In addition to stresses, other parameters are used to look for weaknesses. In the author's experience, these have included the diameter of a gear, the pH of a fluid running through the product, contaminants in the fluid running through a blood analyzer, the thickness of a tape media, the viscosity of a lubricant, the size of a tube or pipe, the lateral load on a bearing, and an almost endless additional number of factors. What is sought is any information that could lead to an opportunity for improvement by decreasing the sensitivity of the product to any conditions that could lead to improper performance or to catastrophic failure. Anything that could provide information for an improvement in margin is appropriate in HALT. Accepting this philosophy is one of the most difficult shifts in thinking for many engineers not trained in the HALT/HASS approach. *Any* method for finding design and process weak links is OK.

Depending on the product and its end use environment, many "unusual" stresses could and should be used in HALT and HASS. For example, suppose that a product is to be used in a high magnetic field environment. Then strong magnetic fields should be used in HALT and maybe HASS as well. As another example, suppose that we are working on a military product that is supposed to function after a nuclear event or on a product that will reside near a CAT scanner which emits some radiation. It would be proper to expose the product to stepped up levels of radiation in order to determine if the product could successfully survive such events and then function normally. This same stress, namely radiation, would probably be nonsensical for a car radio. So, the stresses to use are tightly coupled to the real world environments considering the Crossover™ Effect.

Generally stated, one should use all field environments as well as any others that would help due to crossover effects in both HALT and HASS. This definitely is a paradigm shift from compliance testing. In addition, we use stresses far above the real world in order to attain time compression.

In the HALT phase of product development, which should be in the early design phase, the product should be improved in every way practicable bearing in mind that most of what is discovered in HALT as weaknesses will almost surely become field failures if not improved. This has been demonstrated thousands of times by users of HALT. Of course, one must always use reason in determining whether or not to improve the product when an opportunity is found and this is done by examining the failure mode and mechanism. Just because a weakness was found "out of spec" is no reason to reject the finding as an opportunity for improvement. There are numerous cases where weaknesses found "out of spec" were not addressed until field failures of the exact same type occurred. If you find it in HALT, it is probably relevant. In various papers from Hewlett-Packard over the years, it has been found that most of the weaknesses found in HALT and not addressed resulted in costs to the company in the neighborhood of $10,000,000 (in the 1990s) per failure mode to address later, when failure costs were included. It cannot be emphasized too much that it is imperative to focus on the failure mode and mechanism and not on the conditions used to make the weakness apparent. Focusing on the margin will usually lead one to allow a detected weakness to remain, resulting in many field failures of that type before a fix can be implemented. Learn from other's mistakes and do not focus on the stress type or level used, but on the failure mode and mechanism. This point is crucial to success and is frequently missed by those without sufficient knowledge of the HALT and HASS techniques.

36.3.1 An Example of the Crossover Effect

Suppose that our product contains a typical resistor, not surface mounted, but with leads on it.

Also suppose that someone has bent one lead into a very nice arc, the correct way to form the lead. However, the other end is very sharply kinked with an almost square corner on it. If we expose this defective resistor, mounted on a circuit board, to thermal cycling, it will fail at the sharp corner. One could perform extensive calculations of the fatigue damage done at the corner by the thermal cycles and differential thermal expansion in order to come to a conclusion as to whether or not to fix the shape in production, but this is hardly necessary once one sees the square corner as it is known to be a forming problem and should just be fixed with no further analysis work. Similarly, one could use vibration to precipitate a break at the square corner and then perform extensive vibration calculations to determine if the lead will break in the real service life, but, again, it is obvious that a forming problem exists and should be cured. As a last example, one could use increased current in the lead and would then obtain an electromigration induced failure at the square corner. If this lead were to be taken to the failure analysis lab, they would declare "excess current". One could then perform extensive current calculations in order to figure out how to reduce the current, including surges, so that the failure would not occur. This is all not necessary once the square corner is found as the whole problem is just a simple one of forming, nothing more difficult than that. Many failures and fixes in HALT and HASS are just as simple as discovering a poorly formed lead and taking corrective action in the forming process. It is important not make this whole thing really difficult when most of it is very simple. Some aspects, however, become complicated in terms of engineering and financial analyses. In this case, some real intellectual power is required.

36.4 A Historical Review of Screening

Many mistakes have been and currently are being made in screening and so a review of some historical events is educational in the sense that we want to go forward and learn from collective past errors. As Philosopher George Santayana said, "Those who cannot learn from history are doomed to repeat it."

In the 1970s, the U.S. Navy, which was not alone in this regard, experienced very poor field service reliability. In response to this, an investigation was performed and it was found that many of the failures were due to defects in production that could be screened out using thermal cycling and random vibration. The Navy issued a stress screening guideline, NAVMAT P-9492, which laid out guidelines for production screening on Navy programs. This document was included in most Navy contracts and so production screening became a requirement on most Navy programs. Although the document was frequently treated as a MIL-SPEC, which was not the intent, tremendous gains in reliability resulted from the techniques required by the Navy on some programs. I believe that reliability was severely compromised on many others due to precipitation without detection. Among other things, random vibration and thermal cycling were required, but were not required to be applied simultaneously. Data acquired later by many investigators would show that combined vibration and thermal cycling is more than ten times as effective as singular application of the stresses and is less expensive due to the reduction of test hardware and time. The author has found in many workshops with actual production hardware as well as on consulting assignments that no defects at all were found unless Modulated Excitation™ was used. This is fundamental to good detection.

In the late 1970s, the Institute of Environmental Sciences (IES), now the Institute of Environmental Sciences and Technology (IEST) began to have annual meetings which addressed the subject of environmental stress screening (ESS). The IES issued guidelines on the production screening of assemblies in 1981 and 1984 and on the screening of parts in 1985. There were three major problems with the survey and the published results [5, 6].

1. The companies surveyed were mostly under contract to the U.S. military and screens had been imposed by contract in many cases and had not been carefully tuned to be successful. Some had even been tuned *not* to be successful by those striving to "pass the specs". Most of the contracts issued even made it more

profitable for the contractors to produce hardware which did not have high field reliability but would pass the screens. In these cases, the contractor could sell almost everything produced; and, since the field reliability was poor, many spares were needed as was a rework facility to fix those units which failed in the field. It is readily apparent that the screens used in these types of contracts would not be the most effective screens that the technology of the day could produce. The thought process that led to the situation then still prevails today and will continue to exist until the military contractors are trained correctly in the HALT and HASS techniques and then are forced to use them, perhaps by contractual requirements regarding field failures or some other significant tests.

2. The IES polled the contractors doing screening and asked which screens were the most effective and also restricted voting to those stresses used. Since most specs required thermal cycling and many fewer required vibration, there were many more users of thermal cycling than of vibration. Therefore, when the IES then published the results as "effectiveness" of various screens instead of a more accurate term of "popularity" or "what was required to be done", it created much mis-understanding of the survey. See [7] for some details. Among the misconceptions in the guidelines was the concept that thermal cycling was the most effective screen. This misconception is present to a large extent today, however, many HALT results have shown that all axis vibration far surpasses the effectiveness of thermal cycling for the broad spectrum of faults found in many types of equipment including electronics. The last statement is only true if a six-axis shaker is used. The two stresses combined are much better than any one alone, so one should not beat the drum for vibration alone either.
3. The Guidelines emphasized 100% screening instead of emphasizing corrective action which would eventually allow the screening to be reduced to a sample. An interesting observation is that the definition of screening as a process on 100% of the production maximized the equipment, manpower and other costs! This led to a bonanza for some equipment manufacturers and for contractors working on a "cost plus fee" basis. This paradigm of incorrect and very expensive screening is firmly entrenched in the USA military manufacturers even today. This is a truly sad situation.

These three problems in the IES Guidelines led many novices to try the techniques which were relatively ineffective and inordinately expensive. With only the IES Guidelines as a source of information, many financially and technically unsuccessful screening programs were tried. Many companies simply gave up and went back to their old ways or simply complied with contractual requirements.

There was a further complication due to NAVMAT P-9492 which was issued by the Naval Material Command in June of 1979 [8]. This guideline, unfortunately, gave a vibration spectrum that was a qualification spectrum from Grumman used to qualify avionics which were hard mounted to the panel of a navy fighter aircraft. Also, unfortunately, MIL-STD 2164 gave the same spectrum as a requirement for qualification. Since this spectrum was in the MIL-STD and was in the guideline as well, it became an accepted profile by many companies all over the world. The author had warned the Navy about such an event but was ignored. Even today, the totally inappropriate vibration profile is required in many company specifications and still in some military specifications. This profile is inappropriate for several reasons:

a). It is a qualification level for a specific application and, therefore, is not an appropriate screen for other applications.
b). There is no mention of anything like Safety of Screen.

c). The vibration is only one linear axis whereas the real world is six axes, three linear and three angular.

The NAVMAT document did correctly point out that stimulation was intended, not simulation. This point seemed to be totally missed by readers, however, based on actions taken by them. Obviously, many companies had a "compliance" attitude then and some still do today.

The result of the MIL-SPEC mentality when the NAVMAT profile was applied was very ineffective and sometimes damaging at the same time using unproven screening profiles without detection. The author observed many programs wherein the NAVMAT approach was taken resulting in seriously degraded reliability as well as increased costs. Many became disgusted and simply quit trying; others generated massive field failures, sometimes upon first real use in the field. One result of the confusion was that some military (and civilian) contractors were required to build many spares for which they were paid and they were also required to repair all of those that failed in the field, for which they were also paid. This turned out to be a gold mine for many companies as the poorer their products, the better the profits. Some of these same companies today staunchly refuse to adopt the new techniques either because of ignorance or because the old method is so lucrative to them. The military created this situation themselves while all the time being advised by the author of what would happen if they proceeded on the then current path. We taxpayers are footing the bill and risk for such actions.

In the meantime, some very successful screening techniques were developed, tried, improved and retried. These techniques are so successful compared to the Guideline's methods that the most successful of the companies using the new techniques will not publish their results. Some companies are starting to publish to a limited extent but are omitting critical factors such as eliminated design flaws, warranty return rates, and returns on investments (ROIs). However, from knowledge gained in consulting under non-disclosure agreements, most of the truly outstanding successes are still not being published. Many disasters from the misapplication of HALT and HASS, almost always from incorrect training, are also not being published. The author has been called in as a consultant in many cases, many times by the customer, not the manufacturer, wherein HALT did not succeed in producing acceptable hardware. In every case, the techniques of HALT and/or HASS had not been properly applied and immediately obvious design defects were present as well. In one of those cases, the manufacturer had used HALT on one program and proceeded to produce the worst product ever made by that company! After an in-house seminar and one day of consulting, the company was on the right track and is now making some of the best-of-the-best for that industry. Unfortunately for that company, the very poor product produced early-on severely hurt the reputation of the company, and it may take decades to overcome the stigma of producing such a low reliability product. Properly applied, however, HALT and HASS always work!

Along with the technique improvements, equipment for performing the new techniques was developed. When the newer equipment was available, further technique improvements were possible. This confluence of technique and equipment improvements has been in effect for several cycles. The author sees no end to the development in sight and is currently in the development, patent, and production stages on equipment that far surpasses anything yet available for the techniques [9].

36.5 The Phenomenon Involved and Why Things Fail

HALT and HASS are not restricted to electronic boxes, but apply to many other technologies as well. Some of the technologies are listed at the end of the chapter and include such diverse products as shock absorbers, lipstick, bricks, airframes, auto bodies, exhaust systems, surgical equipment, and power steering hoses, to name just a few. Before getting into the techniques in general, it is beneficial to know the history of early attempts at stress screening that paralleled the development of HALT and HASS. Note that HALT addresses design and process weaknesses whereas classical ESS only addresses production weaknesses and then very inefficiently and perhaps even makes

things worse instead of better. HASS may expose design weaknesses if any remain or are introduced after production start.

HALT and HASS are tests aimed at discovering things incorrectly done whereas the MIL-SPEC type tests are usually performed with a view to passing; *i.e.*, compliance testing. The goals of HALT and HASS are therefore "discovery" and the MIL-SPEC tests are "compliance".

Several phenomena may be involved when screening occurs. Among these are mechanical fatigue damage, wear, electro-migration, chemical reactions as well as many others. Each of these has a different mathematical description and responds to a different stimulus or stimuli. Chemical reactions and some migration effects proceed to completion according to the Arrhenius model or some derivative of it. It is noted that many misguided screening attempts have assumed that the Arrhenius equation *always* applies; that is, that higher temperatures lead to higher failure rates, but this is not an accurate assumption. For many excellent discussions of the use and misuse of the Arrhenius concepts, one can refer to [10]. MIL-HDBK 217, a predictive methodology for electronic reliability without any scientific basis whatsoever, was based on these concepts. It is quite invalid for predicting the field reliability of the products which are built today. MIL-HDBK 217 is even less valid and completely misleading when used as a reverse engineering tool to improve reliability, as it will lead one to reduce temperatures even when a reduction will not reduce the failure rate and may even increase it due to changes made to decrease the temperature such as the addition of cooling fans. That is, new failure modes may be introduced and the basic reason for some existing failures may not be changed at all. Hakim [11] gives an excellent discussion of temperature sensitivities of many microelectronics parts which are stated to be insensitive to temperature below 150 degrees Centigrade.

If HALT and HASS are properly done, then the prediction approach has some validity as only component flaws will remain. In that case, one could use the prediction approach(es) to calculate a field reliability and then wait until field reliability numbers are available and then calculate a "fudge factor" that corrects for field usage stress intensity and mix of stresses. Then, if another product with the same mix of components were to be designed for the same field usage, the fudge factor would be correct and we could accurately estimate the field MTBF. However, by the time we have been able to calculate the fudge factor, the component mix may change, the product design may change and even the field usage environments may change. We would therefore be chasing an ever-changing fudge factor! Even this approach will, therefore, not work in the end.

Many failures in electronic equipment are mechanical in nature: the fatigue of a solder joint, the fatigue of a component lead, the fracture of a pressure bond or similar modes of failure. The mechanical fatigue damage done by mechanical stresses due to temperature, rate of change of temperature, vibration, or some combination of them can be modeled in many ways, the least complex of which is Miner's criterion. This criterion states that fatigue damage is cumulative, is non-reversible, and accumulates on a simple linear basis which in words are "The damage accumulated under each stress condition taken as a percentage of the total life expended can be summed over all stress conditions. When the sum reaches unity, the end of fatigue life has arrived and failure occurs." The data for percentage of life expended is obtained from S–N (number of cycles to fail *versus* stress level) diagrams for the material in question. A general relationship [12] based on Miner's criterion is as follows:

$$D \approx n s^{\beta},$$

where:
D is the fatigue damage accumulated, normalized to unity,
n is the number of cycles of stress,
s is the mechanical stress (in pounds per square inch, for example), and
ß is an exponent derived from the S–N diagram for the material and ranges from 8 to 12 for most materials.

Physically, it represents the negative inverse slope of the S–N diagram. David Steinberg uses ß = 3.4 for solder joints in some cases based on experience.

The flaws (design or process) that will cause field failures usually, if not almost always, will cause

a stress concentration to exist at the flaw location (and this is what causes the early failure). Just for illustrative purposes, let us assume that there is a stress which is twice as high at a particular location which is flawed due to an inclusion or void in a solder joint. According to the equation above with Beta assumed to be about 10, the fatigue damage would accumulate about 1,000 times as fast at the position with the flaw as it would at a non-flawed position having the same nominal stress level; that is, having the same applied load without the stress concentration. This means that the flawed area can fatigue and break and still leave 99.9% of the life in the non-flawed areas.

Our goal in environmental stress screening is to do fatigue damage to the point of failure at the flawed areas of the unit under test as fast as possible and for the minimum cost. With the proper application of HALT, the design will have several, if not many, of the required lifetimes built into it and so an inconsequential portion of the life would be removed in a HASS. This would, of course, be verified in Safety of HASS. Note that the relevant question is "How much life is left after HASS?" not "How much did we remove in HASS?" Also note that all screens remove life from the product and that even normal usage will contribute some life removal or fatigue damage. This is a fundamental fact that is frequently not understood by those unfamiliar with the correct underlying concepts of screening. A properly done HALT and HASS program will leave more than enough life remaining and will do so at a much reduced total program cost.

Flaws of other types have different equations describing the relationship between stress and the damage accumulation, but all seem to have a very large time compression factor resulting from a slight increase of the stress. This is precisely why the HALT and HASS techniques generate such large time compression.

36.6 Equipment Required

The application of the techniques mentioned in this chapter generally is very much enhanced by, if not impossible without, the use of environmental equipment of the latest design such as all axis exciters and combined very high rate thermal chambers (80°C/min. or more product rate). All axis means three translations and three rotations, all simultaneous, all broadband random. See Figure 36.3 of a HALT chamber.

Figure 36.3. HALT chamber. Courtesy of HALT&HASS Systems Corp, TC-2 Cougar Time Compression System

A single axis, single frequency shaker will only excite some modes in the particular direction of the vibration and only those nearby in frequency. For example, the second mode of a circuit board will not be excited as the modal participation factor is zero for pure linear motion in any one direction. It takes rotational motion to excite this mode. A swept sine will sequentially excite some modes in the one direction being excited. Single axis random will simultaneously excite some modes in one direction. A six-axis system will simultaneously excite all modes within the bandwidth of the shaker in all directions. If all modes in all directions are not excited simultaneously, then many defects can be missed. Obviously, the all axis shakers are superior for HALT and HASS activities as one is interested in finding as much as possible as fast as possible as we are doing discovery testing, not compliance testing.

In the very early days of design ruggedization (the precursor to HALT), a device had been severely ruggedized using a single axis random shaker system. This effort was reported in [13]. Then, in production, a very early all axis system

was used and three design weaknesses which had not been found on the single axis system were exposed almost immediately. Increasing the shaker vibration to the full bandwidth (which had been restricted on purpose) exposed even another design flaw. That experience showed the author the differences in the effectiveness of the various systems. Since then, the systems of choice have been an all axis broadband shakers of ever improving characteristics.

Other types of stresses or other parameters may be used in HALT. In these cases, other types of stressing equipment may be required. If one wanted to investigate the capability of a gearbox, one could use contaminated oil, out of specification gear sizes and a means for loading the gearbox in torsion either statically or dynamically. If one wanted to investigate various end-piece crimping designs on power steering hoses, one could use temperature, vibration and oil pressure simultaneously. This has been done and worked extremely well, exposing poor designs in just a few minutes. In order to investigate an airframe for robustness in pressurization, the hull could be filled with water and rapid pressure cycling done. This is how it is done at several aircraft manufacturers. Water is used as the pressurized medium as it is nearly incompressible and so when a fracture occurs, pressure drops quickly preventing an explosive type of failure as would occur if air were to be used. A life test simulating thousands of cycles can be run in just a few days using this approach.

In HALT and HASS, one tries to do fatigue damage as fast as possible; and the more rapidly it is done, the sooner it can stop and the less equipment is needed to do the job. It is not unusual to reduce equipment costs by *orders* of magnitude by using the correct stresses and accelerated techniques. This comment applies to all environmental stimulation and not just to vibration. An example discussed in [1] shows a decrease in cost from $22 million to $50 thousand on thermal chambers alone (not counting power requirements, associated vibration equipment, monitoring equipment and personnel) by simply increasing the rate of change of temperature from 5°C/min to 40°C/min. The basic data for this comparison is given in [14]. Another example shows that increasing the RMS vibration level by a factor of 1.4 times would decrease the vibration system cost from $100 million to only $100 thousand for the same throughput of product. With these examples, it becomes clear that HALT and HASS techniques, when combined with modern screening equipment designed specifically to do HALT and HASS provide quantum leaps in cost effectiveness. This reason is precisely why the real leaders in this field simply keep their results to themselves.

36.7 The Bathtub Curve

The pattern of failures that occur in the field can be approximated in three ways. When there are defects in the product, so called “infant mortalities”, or failures of weak items will occur. Another type of failure is due to externally induced failures where the loads exceed the strength. Finally, wear out will occur even if an item is not defective. When one superimposes all three types of failures, a figure called the bathtub curve results. One such curve is shown in Figure 36.4.

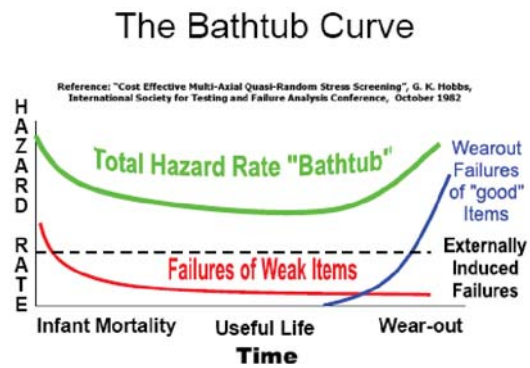

Figure 36.4. The bathtub curve

The bathtub curve is grossly affected by the HALT and HASS technique:

1. HALT and HASS will reduce the early segment of the curve by eliminating early life failures due to design weaknesses and manufacturing flaws and will also eliminate those failures due to gross weaknesses.

2. Ruggedization (HALT) of the product will lower the mid-portion of the curve which is due to externally induced failures.
3. HALT will extend the wear out segment far to the right.

Some typical results of HALT and HASS applied to product design and manufacturing are described in the following paragraphs. Some of these are from early successes and have been published in some form, usually technical presentations at a company. Later examples using the later technology in terms of technique and equipment have largely not been published. The later results are, of course, much better, but the early results will make the point well enough, since they represent a lower bound on the expected successes today when far better techniques and equipment are available than were present then.

36.8 Examples of Successes from HALT

a. In 1984, an electro-mechanical impact printer's MTBF was increased 838 times when HALT was applied. A total of 340 design and process opportunities for improvement were identified in the several HALTs which were run. All of these were implemented into the product before production began, resulting in an initial production system MTBF, *as measured in the field,* of 55 years! This product is about 10" x 18" x 27" and weighs about 75 lb. It is interesting that the MTBF never got better than it was at initial product release, but it did get worse when something went out of control. The out-of-control conditions were spotted by the 5% sample HASS called HASA for highly accelerated stress audit. The reason there was no reliability growth after product introduction is that the system was born fully mature due to HALT. This is one of the major goals of HALT and it is the case *if and only if* advantage is taken of all of the discovered opportunities for improvement. This product was produced by robots for ten years, after it was technically obsolete, at a rate of about $10,000,000 of product per hour!

b. A power supply which had been in production for four years in 1983 with conventional (IES Guidelines) low rate, narrow range thermal screening had a "plug and play" reliability of only 94% (That is, 6% failed essentially out of the box.) After HALT and HASS were applied using a six-axis shaker and 20°C/minute air ramp rates, the plug and play jumped to 99.6% (*i.e.*, 0.4% failed out of the box) within four months, a 15x improvement. A subsequent power supply, which had the benefit of HALT and HASS before production began, had a plug and play of 99.7% within two months of the start of production! This company has been able to simultaneously increase sales and to reduce the QA staff from 60 to 4 mostly as a result of HALT and HASS and the impact that it had on field reliability. The company also reports that the cost of running reliability demonstration tests (rel-demo) had been reduced by a *factor* of about 70 because all relevant attributable failures were found in HALT. After the application of HALT, seven products (as of 1986) had gone through rel-demo with *zero* attributable failures. Plug and play has been 100% since 1986!

c. In 1988, an electro-mechanical device was run through a series of four HALTs over a four month period. In these tests, 39 weaknesses were found using only all axis vibration, thermal cycling, power cycling and voltage variation. Revisions were made to the product after each HALT and then new hardware with revisions was built and then run through HALT. The designers refused to change anything unless it was verified in a life test. Extended life tests were run on 16 units for 12 weeks for 24 hours per day with three technicians present at all times to interact with the hardware. The tests revealed 40 problems,

39 of them the same as had been found in the HALTs. The HALTs had missed a lubricant degradation mode that only showed up after very extensive operation. A review of the HALT data revealed that the clues to this failure mode were in the data, but no actual failure had occurred because a technician had "helped out" and re-greased a lead screw every night (without the author's knowledge) so that the failure that he knew about would not occur, a success in the mind of the technician at that time, before he learned what HALT was all about. His well intended action caused an important failure mode to be missed. The author now locks up HALT units when not actually running the tests in order to prevent well meaning employees from "helping". Vibration to 20 GRMS all axis random, temperatures between -100°C and +127°C, and electrical overstress of +/- 50% were used along with functional testing in the HALT on the units in question. "Specs" were vibration of 1 GRMS and temperatures between 0–40°C. Standard commercial components were used.

d. In an informal conversation in February of 1991 between Charles Leonard of Boeing Commercial Aircraft and the author, the former said that a quote had been received for an electronics box to be built under two different assumptions. The first was per the usual Mil-Spec approach and the second was using "best practices" or the HALT and HASS approach. The second approach showed a price reduction from $1,100 to $80, a weight reduction of 30%, a size reduction of 30% and a reliability improvement of "much better". The choice as to which product to choose was obvious.

e. In 1992, the author gave a three-hour demonstration of Rapid HALT™ after a seminar. In this demonstration, three different products seen for the first time by the author were exposed to HALT. The three products had been under standard engineering investigation using normal stresses for five, four, and three years respectively. The products had been in field use for years with many field failures reported. Each product had one failure precipitated and detected in only one hour each. All of the failures reported were exposed in the three-hour demonstration HALT. *This means that in only one hour per product all major field failure modes had been determined.* The manufacturer had not been able to duplicate the field failures using classical simulation techniques and therefore could not understand the failure modes and determine the appropriate fixes before the abbreviated HALTs were performed. Two of the three failure modes were found just beyond the edge of the temperature spec, one hot and one cold, and the last one was found in ten minutes at four times the "spec" GRMS using an all axis shaker!

f. Boeing Aircraft Company reported [15] that the HALT "revealed a high degree of correspondence between failures induced in the lab and documented field failures". "Vibration appears to have been the most effective failure inducement medium, particularly in combination with thermal stress". "The 777 was the first commercial airplane to receive certification for extended twin-engine operations (ETOPS) at the outset of service. To a significant extent, this achievement was attributable to the extremely low initial failure trends of the avionics equipment resulting from the elevated stress testing and the corrective actions taken during development". In a conversation in December 1995, Charles Leonard of Boeing related that the "777 dispatch reliability after only two months of service was better than the next best commercial airliner after six years."

g. Nortel reported [16] a 19x improvement in field returns when a HASSed population of PCBAs was compared to a similar population run through burn-in.

h. In 1997, a car tail light assembly was subjected to HALT costing "x". The

improved assembly was run through an MTBF test costing 10 "x". The measured MTBF was 55 car lifetimes. Note that the HALT did much more good for the company than did the MTBF test and at a much lower cost. This result is fairly typical of the results of a properly run HALT which must include corrective action. A discussion of this is covered in [17].

i. In 1998, Otis Elevator reported on their web site that: "A test that would normally take up to three months to conduct can now be carried out in less than three weeks. HALT used for qualifying elevator components has saved Otis approximately US $7.5 million during the first 15 months of operation." In a presentation at a seminar by the author, an Otis employee related that a particular problem was found in a circuit board and, on one product, corrective action was taken while on another product it was not. On the non-improved product, failure occurred after six months of use in Miami with exactly the same failure mode found in HALT. From this the author jokingly says that two days in HALT is equivalent to six months in Miami! None of the improved products failed in service.

j. During a short course at an air conditioning manufacturer, a quick HALT was run on a rooftop compressor system which was experiencing over $2,000,000 per month in field failures (about 50% of them failed). A quick investigation with a strobe light and using a large hydraulic shaker for vertical excitation, determined that a coil was resonating at a very low frequency and that it was the cause of the field failures. A support strut was fabricated of a tube of aluminum from the trash can in the machine shop, squashed flat at the ends and bent at 45 degrees so that it could be screwed to the housing and to the coil so as to stop the troublesome mode of vibration. Tests showed the mode gone (of course!). The improvement was on hardware shipped that day and the corresponding failure mode dropped to zero. This experience is quite typical of the situation when the product has a substantial defect and the correct techniques are applied in order to expose the defect.

Some product lines to which HALT and HASS have been successfully applied are listed in Table 36.2.

36.9 Some General Comments on HALT and HASS

The successful use of HALT or HASS requires several actions to be completed. In sequence these are: precipitation, detection, failure analysis, corrective action, verification of corrective action, and then entry into a database. All of the first five must be done in order for the method to function at all, adding the sixth results in long-term improvement of future products.

1. Precipitation means to change a defect which is latent or undetectable to one that is patent or detectable. A poor solder joint is such an example. When latent, it is probably not detectable electrically unless it is extremely poor. The process of precipitation will transpose the flaw to one that is detectable, that is, cracked. This cracked joint may be detectable under certain conditions such as modulated excitation. The stresses used for the transformation may be vibration combined with thermal cycling and perhaps electrical overstress. Precipitation is usually accomplished in HALT or in a precipitation screen.
2. Detection means to determine that a fault exists. After precipitation by whatever means, it may become patent, that is, detectable. Just because it is patent does not mean that it will actually be detected, as it must first be put into a detectable state, perhaps using Modulated Excitation™, and then it must actually be detected. Assuming that we actually put the fault into a detectable state and that

Table 36.2. Some products successfully subjected to HALT and HASS

Abs systems	Distance measuring equipment	Portable communications
Accelerometers	Down hole electronics	Portable welding systems
Air conditioners	Electronic controls	Power tools
Air conditioner control systems	Electronic carburetors	Power supplies
Air bag control modules	Electronics	Power control modules
Aircraft avionics	Fax machines	Printers
Aircraft flap controllers	Fire sensor systems	Prostate treatment system
Aircraft hydraulic controls	Flight control systems	Proximity fuses
Aircraft instruments	Flow sensing instruments	Racks of electronics
Aircraft pneumatic controls	Fm tuners	Radar systems
Aircraft engine controls	Garage door openers	Refrigerators
Aircraft antenna systems	Global positioning systems	Respiratory gas monitors
Anesthesiology delivery devices	Guidance and control systems	Safety and arming devices
Anti skid braking systems	Heart monitoring systems	Shaker tables
Area navigation systems	Impact printers	Solid state memory systems
Arrays of disk drives	Ink jet printers	Spectrum analyzers
Asics	Instant cameras	Speed brake controls
Audio systems	Invasive monitoring devices	Stationary welding systems
Automation systems	Iv drip monitors	Stereo receivers
Automotive dashboards	Jet engine controllers	Switching power supplies
Automotive engine controls	Laptop computers	Tape drive systems
Automotive exhaust systems	Laser printers	Tape players
Automotive interior electronics	Lipstick	Target tracking systems
Automotive speed controls	Ln2 thermal cycling chambers	Telecommunications equipment
Automotive traction controls	Locomotive engine controls	Telephone systems
Blood analysis equipment	Locomotive electronics	Televisions
Calculators	Loran systems	Thermal control systems
Cameras	Magnetic resonance instruments	Thermal imaging gun sight
Card cages	Manual transmissions	Thermostats
Casagranian telescope structure	Mainframe computers	Torpedo electronics
Cash registers	Medical electronics	Traction control systems
Cassette players	Meters	Tractor engine control modules
Cat scanner	Microwave communication systems	Tractor instrumentation
Cb radios	Microwave ranges	Transmission controls
Centrifuges	Missiles	Trash compactors
Check canceling machines	Modems	Turbine engine monitoring equip
Circuit boards	Monitors	Turbine engine control modules
Climate control systems	Mri equipment	Typewriters

Clothes dryers	Notebook computers	Urine analysis machines
Clothes washers	Oscilloscopes	Vibration control systems
Computers	Ovens	Vibration monitoring systems
Computer keyboards	Oximeters	Vibrators
Communication radios	Pacemakers	Video recorders
Copiers	Personal computers	Vital signs monitors
Dialysis systems	Plotters	Water sprinkler systems
Dish washers	Pneumatic vibration systems	Work stations
Disk drives	Point of sale data systems	X-ray systems

the built in test or external test setup can detect the fault, we can then proceed to the most difficult step, which is failure analysis. If coverage does not exist for such a fault, then it will not be detected and nothing will be done about it.

3. Failure analysis means to determine why the failure occurred. In the case of the solder joint, we need to determine why the joint failed. If doing HALT, the failed joint could be due to a design flaw; such as, an extreme stress at the joint due to

vibration or maybe due to a poor match of thermal expansion coefficients. When doing HASS, the design is assumed to be satisfactory (which may not be true if changes have occurred) and in that case, the solder joint was probably defective. In what manner it was defective and why it was defective need to be determined in sufficient detail to perform the next step which is corrective action.

4. Corrective action means to change the design or processes as appropriate so that the failure will not occur again in the future. This step is absolutely essential if success is to be accomplished. In fact, corrective action is the main purpose of performing HALT or HASS. A general comment is appropriate here. One of the major mistakes that the author sees happening in industry is that they "do HALT" and discover weaknesses and then dismiss them as due to overstress conditions. This is a major blunder! It is true that the failures occurred sooner than they would in the field due to the overstress conditions, but they would have occurred sooner or later in the field at lower stress levels.
5. Verification of corrective action needs to be accomplished by testing to determine that the product is really fixed and that the flaw which caused the problem is no longer present. The fix could be ineffective or there could be other problems causing the anomaly which are not yet fixed. Additionally, another fault could be induced by operations on the product and this necessitates a repeat of the conditions that prompted the fault to be evident. Note that a test under zero stress conditions will usually not expose the fault. One method of testing a fix during the HALT stage is to perform HALT again and determine that the product is at least as robust as it was before and it should be somewhat better. If one is in the HASS stage, then performing HASS again on the product is in order. If the flaw is correctly fixed, then the same failure should not occur again.
6. The last step of the six is to put the lesson learned into a database from which one can extract valuable knowledge whenever a similar event occurs again. Companies which practice correct HALT and utilize a well kept data base soon become very adept at designing and building very robust products with the commensurate high reliability and much lower costs. These companies usually are also very accomplished at HASS and so can progress to HASA, the audit version of HASS.

It is essential to have at least the first five steps (1–5) completed in order to be successful in improving the reliability of a product. If any one of the first five steps is not completed correctly, then no improvement will occur and the general trend in reliability will be toward a continuously lower level. The second law of thermodynamics verifies this when stated as "A system will always go to a lower organizational state unless something is done to improve that state."

A comparison of the HALT and HASS approach and the classical approach is presented in Table 36.3. Note that HALT and HASS are proactive; that is, seek to improve the product's reliability, and much of the classical approaches are intended to measure the product's reliability, not to improve it.

36.10 Conclusions

Today, HALT and HASS are required on an ever increasing number of commercial and military programs. Many of the leading commercial companies are successfully using HALT and HASS techniques with all axis broadband vibration and moderate to very high rate thermal systems as well as other stresses appropriate to the product and to its in-use environment. However, most are restricting publication of results because of the phenomenal improvements in quality and reliability and vast cost savings attained by using the methods. HALT and HASS is very difficult to

Table 36.3. Comparision of HALT (discovery) and classical (compliance) approaches

STAGE	DESIGN		PRE-PRODUCTION			PRODUCTION		
TEST TYPE	**QUALIFI-CATION**	**HALT**	**LIFE TEST**	**HASS DEV-ELOPMENT**	**SAFETY of HASS**	**REL-DEMO**	**HASS**	**HASS OPTI-MIZATION**
Purpose	Satisfy customer requirements	Maximize margins, minimize sample	Demo life	Select screens and equipment	Prove OK to ship	Measure reliability	Improve reliability	Minimize cost, maximize effectiveness
Desired outcome	Customer acceptance	Improve margins	MTBF & spares required	Minimize cost, maximize reliability	Life left after test	Pass	Root cause corrective action	Minimize cost, maximize effectiveness
Method	Simulate field environment sequentially	Step stress to failure	Simulate field	Maximize time compression	Multiple repeats without wearout	Simulate field	Accelerated stimulation	Repeat HASS, modify profiles
Duration	Weeks	Days	Months	Days	Days	Months	Minutes	Weeks
Stress level	Field	Exceeds field	Field	Exceeds field	Exceeds field	Field	Exceeds field	Exceeds field

specify or to interpret in contractual language. This is one of the reasons why the aerospace and military have been slower to accept these advanced techniques. Training of vendors is crucial as most vendors have the compliance testing mindset, not the discovery testing mindset. Without proper training in the HALT and HASS techniques, the vendors usually just say "Tell me exactly what to do and then pay me for it". After reading [1], it should be obvious that it is impossible to tell anyone exactly how to perform HALT on their product, so it is imperative to train them on the discovery techniques and on how the techniques will benefit their company.

The best-known method to determine the actual reliability of a product is to test numerous samples of the product in field environments for extended periods of time. This would, of course, either delay the introduction of the product, or provide reliability answers far too late in order to take timely corrective action. Significant time compression can be obtained by eliminating low stress events which create little fatigue damage and simulating only the high stress events. This approach [18] may reduce the test time from years to months. The HALT and HASS approach accelerates this even further by increasing the stresses far beyond the actual field levels and decreases the time to failure to a few days or even hours, sometimes only a few seconds. The use of accelerated testing and Weibull analysis combined can help to estimate lifetimes in the field environments before wear out [15].

One has to want to obtain top quality in order to adopt the cultural change necessary for the adoption of HALT and HASS. The basic philosophy is, simply stated, "find the weaknesses however one can and use their discoveries as opportunities for improvement". This constitutes a new paradigm compared to the old "pass the test" approach! HALT and HASS focus on improving reliability, not on measuring or predicting it. Many companies have saved millions of dollars using these techniques. It is now time for you to try them.

Modeling Count Data in Risk Analysis and Reliability Engineering

Seth D. Guikema and Jeremy P. Coffelt

Texas A&M University, USA

Abstract: This chapter presents classical (non-Bayesian) regression models for count data. This includes traditional multivariate linear regression, generalized regression models, and more recent semi-parametric and non-parametric regression models used in data mining. Then, the Bayesian approach for handling count data is also presented. The focus here is on formulating priors. Finally, the chapter concludes with a discussion of computational issues involved in using these models.

37.1 Introduction

One of the main goals of risk analysis and reliability engineering is to estimate the probabilities and consequences of possible adverse outcomes in a given situation in order to support the allocation of limited resources to best reinforce technical systems and manage the situation. For example, risk analysis can be used to help allocate resources in managing the development of inter-planetary space missions [1, 2]. There are two basic sources of information to support risk analysis and reliability engineering – expert knowledge and data.

In some cases, expert knowledge is the best information available. For example, the system being designed may be much different from any previous system, making existing data about the performance of the previous systems problematic as a basis for risk and reliability analysis. If the new system is also difficult to test under the conditions it will face in use, one is left with a situation in which expert knowledge and engineering models represent the best available information. An example of this is the main mirror on the Hubble Space Telescope (HST). At the time it was on ground, the HST main mirror was unique in both its size and the tightness of the tolerances to which it was to be manufactured. No particularly good way existed to test the mirror in zero-gravity, so no test was conducted. Instead, the engineers relied on their best judgment and concluded that the mirror would perform as expected in space. However, the mirror subsequently distorted in zero-gravity, necessitating a very costly and difficult in-orbit repair. Expert opinion can be used in risk analysis through the methods of probabilistic risk analysis (PRA). Modarres [3] provides a recent overview of these methods. However, if relevant data are available, these data can significantly strengthen the results of the risk analysis or reliability assessment.

When the system is not a unique, one of a kind system, there is often data available about the performance of it or similar systems under similar loadings. This information might come from records from past use of the same system, records

from similar systems, or testing of the system being analyzed. In all cases, the goal of using the data in risk analysis or reliability engineering is to use the past data to probabilistically predict the likely performance of the system in the future. One particular type of data that arises frequently in risk analysis and reliability engineering is count data.

Count data arises whenever one is concerned with the number of occurrences of some discrete event, and an analyst wishes to use relevant past data to estimate the likelihood of different numbers of events in the future. Examples include using records of past breaks in a water distribution system to estimate which pipes are most likely to break in the next planning period [4, 5] and using past data about power outages during hurricanes to estimate the number and location of outages in an approaching hurricane [6, 7]. Further examples are the use of launch records for space launch vehicles to estimate the probability that a given vehicle will fail on its next launch [8, 9], and the use of past data about mercury releases and autism counts in schools to estimate the impact of mercury releases on autism rates [10].

Count data is common in risk analysis and reliability engineering, and recent research advances have created a number of promising, state of the art modeling frameworks for analyzing count data. However, these methods have not been widely used in risk analysis and reliability, especially the more recent advanced methods. The purpose of this chapter is to give an overview of these methods, concentrating especially on those that involve modeling a relationship between the counts of interest, y, and a set of variables, x, that might help to explain the variability in y and predict the likelihood of different values of y in the future. This is a type of regression problem in which $y = f(x)$ where $f(x)$ is an unknown function of the explanatory variables in x.

37.2 Classical Regression Models for Count Data

The purpose of regression modeling is to find a relationship between predicting or explanatory variables $x = (x_1,x_2,\ldots,x_n)$ to a variable y referred to as the response variable. More specifically, the goal is to find the best approximation of the function f satisfying $y= f(x)$. Bayesian methods involve utilizing information relevant to the model and then updating this information based on available data. This allows for additional information such as expert opinion and historic data sets not included in the data set being analyzed. In contrast, classical approaches rely entirely on data to determine models. Another difference resulting from the theoretical foundations of these two approaches is in how the models are fit. Classical models are generally fit by analytically or numerically maximizing the likelihood of the observed data in selecting parameter values. This is quite different from the Bayesian methods described in the following section, which generally rely on much more involved computation. These differences and tradeoffs are discussed further in the following section.

The classical models considered in this section vary over a wide range of interpretability and flexibility. The simplest to formulate, least flexible, and most well known is ordinary least squares regression (OLS). On the other end of the spectrum is multivariate adaptive regression splines (MARS), which offer the most flexibility, but may also substantially sacrifice interpretability. Compromises between these two extremes include generalized linear models (GLMs), generalized linear mixed models (GLMMs), and generalized additive models (GAMs).

37.2.1 Ordinary Least Squares Regression (OLS)

The most common regression model, OLS, is also the simplest to state. OLS requires only that the response variable is somehow distributed around a linear combination of the predicting covariates. That is, this model has the form

$$y = \beta_0 + \sum_i \beta_i x_i + \varepsilon \,, \tag{37.1}$$

where ε is a residual error term. The least squares nomenclature follows from the traditional assumption that the residuals are normally distributed, which results in maximum likelihood

estimators (MLEs) for the parameters $\beta = (\beta_1,\beta_2,,\ldots,\beta_n)$ that minimize the sum of the squares of the residuals. To be consist with the notation to follow, note that (37.1) can be rewritten as

$$y \sim Normal\left(\mu, \sigma^2\right), \tag{37.2}$$

with

$$\mu = \beta_0 + \sum_i \beta_i x_i . \cdot \tag{37.3}$$

The flexibility of the OLS model can be substantially increased by transforming and combining the data into more suitable covariates. For example, when modeling count data it is assumed that y is nonnegative. Therefore, one might consider in place of (37.1), a relationship more along the lines of

$$\ln(y+1) = \beta_0 + \sum_i \beta_i x_i + \varepsilon \tag{37.4}$$

ensuring the predicted y is at least a nonnegative real number. Notice that this transformation and others like it can only address the non–negativity, not the discreteness of count data. Other common transformations of predicting covariates include taking logarithms, reciprocation, and various other simple algebraic manipulations.

There are several limitations of the OLS framework that are overcome by the models to follow. The first is that the distribution of y conditional on the observed data x is required to be normal. This assumption is often invalid as is certainly the case when considering the integral nature of count data. Also, even though count data typically demonstrate heteroskedasticity, the magnitude of the errors in the OLS model is implicitly assumed to be independent of the magnitude of y. Perhaps most importantly, though, is that the predicting covariates are assumed independent of each other and can therefore only result in linear impacts on the response variable.

Despite such shortcomings, the OLS model has found numerous applications in risk analysis and reliability engineering. Two particular examples given in the introduction and found in the literature involve the reliability of utility distribution systems. In Radmer *et al*. [11], OLS was used to predict outages in electric power distribution systems. Pipe breaks in water distribution systems have also been modeled using OLS models (see in particular [12–15]).

37.2.2 Generalized Linear Models (GLMs)

GLMs, which consist of three components, are a natural extension of the OLS model. The first component, referred to as the random component, specifies the behavior of the response variable for fixed predicting variables. More formally, it allows the normal distribution in (37.2) to be replaced with any distribution from the exponential family. Almost all familiar distributions, including the normal, binomial, exponential, Poisson, and negative binomial distributions are members of the exponential family. Therefore, the random component of GLMs allows for the type of response variable to be taken into account when formulating the model. For example, count data can be modeled as such by using the Poisson or negative binomial distributions in place of the continuous normal distribution required in the OLS model. Also of interest to those in reliability engineering and risk analysis is that the probability of a binomial response, such as success/failure outcome, can be modeled using the Bernoulli distribution. Another component in a GLM specifies the predicting variables and the relationships between them. This systematic component is typically of the same form as in (37.3), *i.e.,*

$$\eta = \beta_0 + \sum_i \beta_i x_i . \tag{37.5}$$

The final component links the systematic and random components. This link component generally is of the form

$$g(\eta) = \alpha , \tag{37.6}$$

where α is some parameter of the underlying distribution specified in the random component and g is referred to as the link function. Two important examples include the Poisson and logistic regression models. The Poisson model is specified by:

$$y \sim Poisson\left(\lambda\right) \tag{37.7}$$

with the log link given by (37.8).

$$\log \lambda = \beta_0 + \sum_i \beta_i x_i. \tag{37.8}$$

The logistic model is specified by

$$y \sim Binomial(p, n) \tag{37.9}$$

and the logit link

$$\begin{aligned} \text{logit}\, p &= \log \frac{p}{1-p} \\ &= \beta_0 + \sum_i \beta_i x_i, \end{aligned} \tag{37.10}$$

where p is the probability of a success. Two good references for these models introduced by Nelder and Wedderburn [16] are the books by Cameron and Trivedi [17] and Agresti [18].

The Poisson GLM defined above is by far the most common regression model used for count data. However, this model has several shortcomings. Most significantly is the assumption of equidispersion inherent to the Poisson distribution. This assumption that the mean and variance are equal is commonly contradicted by the observed data. In fact, the situation in which the variance of the counts is greater than the mean, called overdispersion, is common enough that numerous studies have been devoted to generalizing the Poisson GLM to properly deal with it. The simplest and most common of these is the negative binomial GLM, which is appropriate when overdispersion is present. The formulation of the negative binomial GLM is the same as that for the Poisson GLM except that (37.7) is replaced with

$$y \sim Negative\ Binomial(\lambda, \alpha). \tag{37.11}$$

where α is a parameter related to the variance of the distribution.

As in the case of OLS, GLMs have been widely applied in reliability engineering and risk analysis. For example, Liu *et al.* [6] used a negative binomial GLM to estimate power outages during hurricanes, Guikema *et al*. [19] used a negative binomial GLM to relate power outage frequencies to system maintenance practices, and Andreou *et al*. [4, 5] used a Poisson GLM to estimate pipe break frequency in water distribution systems.

37.2.3 Generalized Linear Mixed Models (GLMMs)

GLMMs extend GLMs through the addition of error terms to the systematic component of a GLM. One purpose of this extra structure is to specifically account for temporal or spatial correlation in the counts [18, 20]. More generally, though, this additional random term helps explain variances in the counts caused by any unknown or unobserved variables. The mixing of distributions in the random and systemic components allows for greater flexibility in describing hierarchical effects and the randomness associated with modeling complex systems.

The most familiar GLMM to those modeling count data is the Poisson GLMM with a single–level random structure given by

$$y_j \sim Poisson(\lambda_j), \tag{37.12}$$

$$\log \lambda_j = \beta_0 + \sum_i \beta_i x_{j,i} + \varepsilon_j, \tag{37.13}$$

where ε_j is a random term for the *j*th measurement. Generally, the error terms are assumed to be Normally distributed, though other distributions such as the Student's *t*–distribution can offer greater flexibility [21].

GLMMs have found much more limited applications in the risk and reliability analysis literature. Examples relevant to engineers and risk analysts include modeling the impacts of traffic on human health [22] and modeling failures of electric power distribution systems [19, 21].

37.2.4 Zero–inflated Models

Often the number of observed zero counts is much larger than would be predicted by any common statistical distribution. Examples can be found in many of the applications already discussed, but others include pathogen counts in water treatment plants and deaths from exposure to a specific carcinogen. Inflations in zero accounts frequently occur as a result of limits in the operational range of measurement devices, but are also common in situations where some activation point must be reached in order to trigger an event. In such situations, zero-inflated models may often be more

appropriate than those discussed above. There are several zero-inflated models available and most require only simple modifications to the models already introduced. Perhaps the simplest is to ignore the zero counts and model $y-1$ according to the methods discussed above. However, a more desirable approach might be to treat zeros as if occurring because of two separate processes. For example, suppose with probability δ a count y occurs according to a Poisson distribution p(y) and otherwise only a zero count can occur. Then the probability of observing a zero count is

$$(1-\delta)+\delta \cdot p(0), \tag{37.14}$$

while for any other y the probability is simply

$$\delta \cdot p(y). \tag{37.15}$$

37.2.5 Generalized Additive Models (GAMs)

One assumption of each of the models introduced so far is that the explanatory variables have only linear effects on the response variable. GAMs extend GLMs by subdividing the domain of the predicting covariates and specifying the local behavior of the response surface on each subregion. Though still requiring independence of the explanatory variables, GAMs can permit arbitrary and nonparametric dependencies on the explanatory variables. For example, a Poisson GAM can be written as

$$y \sim Poisson(\lambda), \tag{37.16}$$

$$\log \lambda = \beta_0 + \sum_i f_i(x_i), \tag{37.17}$$

where f_i is generally approximated by a continuous parametric spline. GAMs can not only involve any other distribution function such as the negative binomial distribution, but can also allow for interaction between explanatory variables through the proper choice of spline [23]. In fact, numerous splines exist and almost as many methods exist for fitting them. A common choice for the functions in (37.17) is penalized regression splines, which penalize excessive "wiggliness" to avoid over fitting the data.

GAMs often significantly improve the fit over more traditional models such as GLMs by capturing interactions not permitted in the less flexible models. However, this increase in flexibility typically results in a significant loss of interpretability. Both of these measures depend highly on the types of splines chosen in (37.17) and the bounds placed on the parameters specifying them. The most substantial benefit of GAMs is that interactions between predicting variables and their effects on the response variable can be captured when otherwise missed by using less flexible methods such as GLMs.

37.2.6 Multivariate Adaptive Regression Splines (MARS)

MARS models, introduced by Friedman in 1991 [24], further extend GAMs by allowing much more complex interactions between the responses and predicting covariates. More importantly, though, is that the data determines the interactions necessary, be it linear, additive, or a more complicated nature [25–27]. Therefore, MARS models can allow both non-linear and interdependent explanatory effects. In Holmes and Mallick [26] it was shown, based on random hold-out sample testing, that GLMs and GAMs can have significantly less predictive accuracy than the MARS approach. However, as is the case of GAMs, this increase in flexibility over simpler models comes at a price in interpretability.

MARS models have a similar structure to GAMs. For example, a MARS model used for count data could be of the same form as the Poisson GAM given in (37.16) and (37.17). The difference between MARS models and GAMs is that the functions f are not approximated by splines, but would instead be of the form

$$f(x_i) = \sum_{j=1}^{k} \beta_j B(x_i, \theta_j), \tag{37.18}$$

where the β are regression coefficients and the $B(x_j,\theta_j)$ are non-linear basis functions. Choices for basis functions include cubic and thin-plate splines, neural nets, and wavelets. In the literature, the parameter θ_j is often referred to as the knot point or knot location of the jth basis and determines the points in the domain of x that determine the changes in behavior of B.

37.2.7 Model Fit Criteria

Numerous statistics exist for determining the "best" model for the given data. Most involve the likelihood that the given parameters of the model are correct for the observed data. One of the most common is the deviance

$$D = -2(L - L^*), \tag{37.19}$$

where L is the log–likelihood of the given parameters and L^* is the log–likelihood of the saturated model with one parameter per observation. Another common fit statistic is the Akaike information criterion defined as

$$AIC = -2L + 2\nu, \tag{37.20}$$

where ν is the number of independent parameters in the model. Both of these statistics assess how well the specified model fits the given data. Both also require an underlying probability distribution and can therefore be inappropriate for models such as GAMs and MARS. An alternative goodness-of-fit statistic appropriate for all of the models is the generalized cross-validation

$$GCV = \frac{1}{(1-\nu/n)^2}\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2, \tag{37.21}$$

where n is the number of observations, ν is the number of independent parameters in the model, and y_i is the predicted approximation to y_i

Other statistics such as the root mean square error

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{37.22}$$

and the mean absolute relative error

$$MARE = \frac{1}{n}\sum_{i=1}^{n}\frac{|y_i - \hat{y}_i|}{\hat{y}_i} \tag{37.23}$$

quantify instead how well the predicted values of the model fit the observed values in the given data.

37.2.8 Example: Classical Regression for Power System Reliability

A data set involving power system reliability will be used to compare the different classical parametric regression methods discussed above. A similar analysis to that in this example can be found in Guikema *et al*. [19] and Guikema and Davidson [21] where the counts of electrical outages are related to various system, maintenance, and population factors. The data set consists of information collected over several years from a large U.S. electric company and includes lengths of overhead and underground wire, frequency of tree trimming, and population information for approximately 650 circuits serviced by the company.

Using traditional systematic and link components of the form

$$\log(\mu) = \beta_0 + \sum_i \beta_i x_i. \tag{37.24}$$

Table 37.1 and Figures 37.1 and 37.2 were obtained. As can be seen from the residual plots, the OLS model and Poisson GLM offer the poorest fit of the models considered, while the negative binomial GLM and Poisson GLMM fit reasonably well. In every model examined, all predicting variables were standardized without any other transformation being applied.

Table 37.1. Fit statistics for classical parametric regression models fit to power outage data set

Fit Criteria	Deviance	AIC	GCV	RMSE	MARE
OLS model	173848	5479	274	16.4	0.49
Poisson GLM	6032	9073	316	17.6	0.50
Negative binomial GLM	684	5052	463	21.3	0.50
Poisson GLMM	6844	1188	429	20.4	0.58

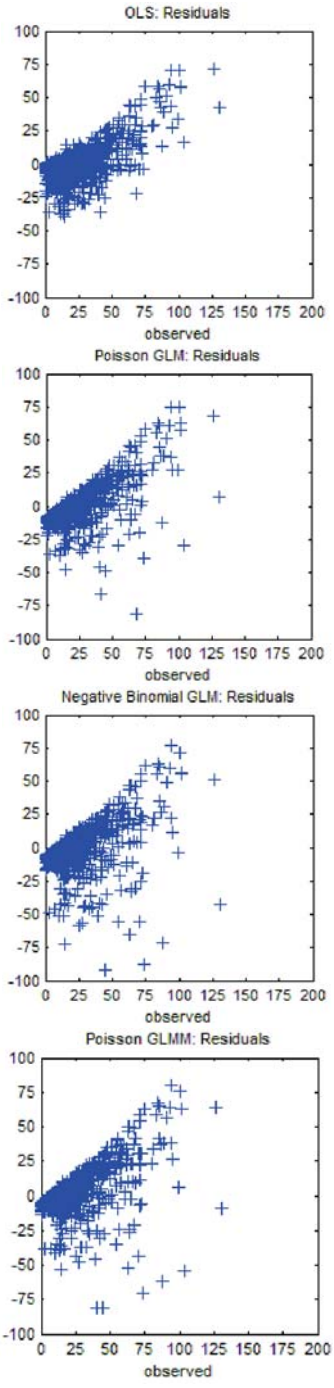

Figure 37.1. Residual plots for classical regression models fit to power outage data set

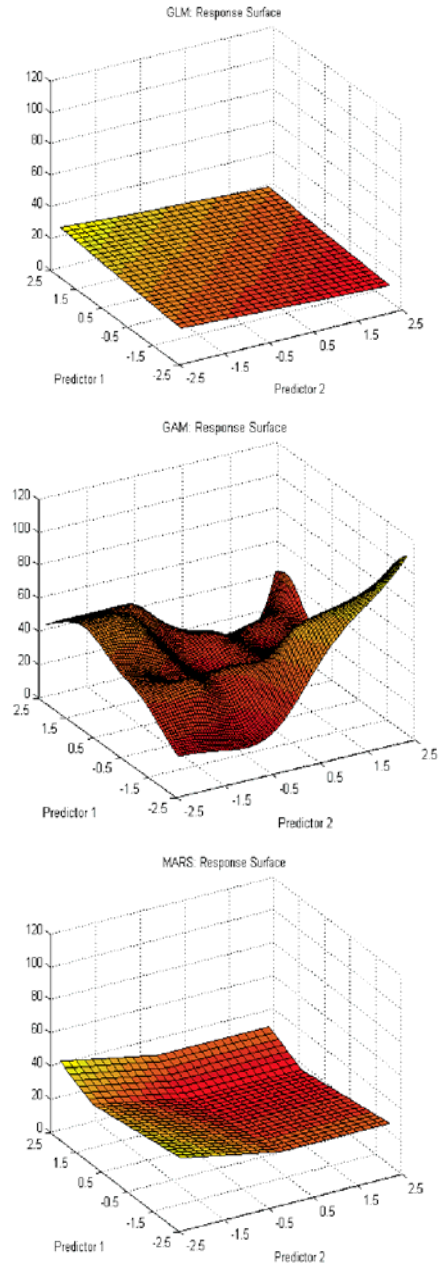

Figure 37.2. Predicted counts estimated from GLM, GAM, and MARS models for the example tree trimming data set

The link function for λ predicted by the Poisson GLMM is given by

$$\log \lambda = 25.8225 + 0.9112 \cdot ftrim - 1.2785 \cdot ltrim + 11.4139 \cdot oh + 1.3275 \cdot ug + 6.4864 \cdot cust + 4.4905 \cdot popdens \quad (37.25)$$

where ltrim is the standardized number of years since the most recent tree trimming, ftrim is the standardized number of years since the next most recent tree trimming, oh is the standardized length of overhead wire, ug is the standardized length of underground wire, cust is the standardized number of customers served by the given circuit, and popdens is the standardized density of the zip code in which the given circuit is located.

Though the magnitudes varied, all but one of the regression coefficients in (37.25) was positive. The exception is the covariate associated to the number of years since the most recent trimming of trees near power lines. The coefficient associated with this covariate is, in contrast, negative in all of the models. Therefore, as would be expected, increases in customers served, lengths of overhead and underground wire, time since most recent tree trimmings all result in an increase in the expected number of power outages. On the other hand, the models suggest that decreasing the time since the most recent tree trimming decreases the average number of power outages on a given circuit.

It is also instructive to examine the inferences that can be drawn from the estimated model response surfaces. As shown in the results from the example data set shown in Figure 37.2, GLMs produce a simple plane as their response surface while GAMs and MARS models can capture non-linearities in their response surfaces. The increased flexibility of the GAM and MARS approaches makes them more appealing for complex, non-linear systems. However, as previously discussed, this increased flexibility comes at the cost of decreased interpretability and increased computational burden in the fitting process.

37.3 Bayesian Models for Count Data

Bayesian methods represent a fundamentally different approach to modeling uncertainty than the classical methods discussed in the previous section. Bayesian methods start with a probability density function, the prior, which represents the analyst's *a priori* knowledge about the situation [27–29]. This prior is then updated with a probability density function that represents the likelihood of obtaining the observed data given the initial beliefs. Mathematically, Bayesian updating is done through Bayes' theorem, given in (37.26) where the data is represented by D, a is the parameter of interest in the problem, and A is the random variable from which a is drawn.

$$f_{A|D(t)}\left(a \mid D(t)\right) = \frac{\left(likelihood\right) \times \left(prior\right)}{\left(total\ probability\ of\ the\ data\right)} = \frac{f_{D|A}\left(D \mid a\right) f_A\left(a\right)}{\int_x f_{D|A}\left(D \mid x\right) f_A\left(x\right) dx} \quad (37.26)$$

Bayesian methods offer two main advantages over classical (frequentist) methods. The first advantage of Bayesian methods over classical methods is that they allow expert knowledge and other forms of imprecise information to be included in a model. Expert knowledge and imprecise data can be directly incorporated into a Bayesian analysis through the use of informative prior distributions for model parameters. The second advantage of Bayesian methods is that they provide a more complete characterization of the uncertainty present in a modeling problem. Unlike classical methods, which typically yield estimates of parameters or moments of an assumed distribution, Bayesian methods yield a full posterior density function for the measures of interest. This posterior may be a complex density function that is not approximated well by standard distributions. Modeling the posterior density directly removes the need to appeal to asymptotic arguments to make inferences about measures of interest.

The advantages of Bayesian methods do come at a cost though. For complex models, simulation-based approaches such as Markov chain Monte Carlo Methods (MCMC) are needed to estimate the posterior distributions of interest [29]. This imposes a computational burden on the analyst that is not present with classical methods.

37.3.1 Formulation of Priors

Because the prior probability density functions are the way in which expert knowledge and imprecise data are incorporated into a Bayesian analysis, these priors play a critical role in Bayesian modeling. There are two main classes of priors – informative priors and non-informative priors. Informative priors contain some degree of information about the measure(s) of interest that is not contained in the data used in the likelihood function.

Non–informative priors, onthe other hand, contain the minimum amount of information possible. Informative priors are used when the analyst has additional information not included in the data being analyzed. For example, Paté-Cornell *et al.* [2] needed to assess the likelihood that a rover spacecraft would be able to land successfully on Mars as part of a risk analysis. Little data is available about past landings of this type of spacecraft on Mars because only a handful of spacecraft have attempted Mars landings of this sort. However, a considerable amount of information is available from engineering models of system behavior, testing of the system done on earth, and the expert knowledge of senior engineers on the design team. This type of information can be incorporated through an informative prior.

Non-informative priors are used when either (i) the analyst does not have any additional information or knowledge about the measure(s) of interest beyond the information contained in the data used in the likelihood, or (ii) the analyst wishes to assume no additional information to let the data drive the analysis. Often the second of these, letting the data drive the analysis, is done to facilitate comparisons with classical models. Non-informative priors generally spread the probability density evenly over the possible sample space. For example, a non–informative prior for a parameter that must lie between 0 and 1 (*e.g.*, the unknown probability of a discrete event) can be a uniform (0,1) variable. Similarly, an approximately non-informative prior for a parameter that can take on any real value is a normal distribution with a mean of 0 and a large variance. However, Jeffreys [30] argued that in the case of continuous positive parameter α, the prior probability should be proportional to $(1/\alpha)$ (see [31] p. 423 for a discussion). Regardless of which form of non-informative or minimally informative prior is used, the goal is the same: to use the Bayesian framework without including any additional information in the prior distribution.

If, instead of using a non-informative prior, an analyst wishes to formulate and use an informative prior, different approaches exist. Each of these has strengths and weaknesses. However, a fundamental distinction is between those priors that are based solely on expert knowledge and those priors that are based on data from related situations.

Priors based solely on expert knowledge can be formulated. A number of approaches exist for formulating priors, and these approaches generally rely onassessing the parameters, moments, quartiles, or other summary statistics of a distribution directly with the expert(s). Spetzler and von Holstein [32] give an overview of the early development of these methods.

The basic approach is to present the expert with a series of trade-offs. For example, if the probability p, of some event, is to be assessed, the expert is asked to choose between two lotteries. In one lottery, he or she would win a prize X with a specified probability q but win nothing with probabiltiy $1-q$. In the other lottery, he or she would win X if some well known event occurs (*e.g.*, a 2 is drawn from a shuffled deck containing 52 cards) and win nothing if that event did not occur. The probability of the known event is changed and the choice iteratively offered until the expert is indifferent between the two lotteries. When the decision-maker is indifferent between the lotteries, q equals p.

When data is to be used in formulating a prior distribution, the question becomes one of how to best use the available information to formulate priors without adding any information to the data in the process of formulating priors. The greater the amount of data that is available, the stronger (*i.e.*, less variable) the prior distribution can be.

There are a number of methods available for formulating an informative prior on the basis of past data. These include using traditional distribution fitting methods such as maximum

likelihood estimation and the method of moments, as well as approaches such as maximum entropy methods and confidence interval matching. In all cases, the goal is to match some subset of the parameters, moments, or quantiles of a density function to the data as a basis for using that density function as a prior in the analysis. Guikema [33] reviewed these approaches. The general conclusions from Guikema [33] were:

1. If strong prior information is available, it should be used to formulate a prior with a relatively small variance. Doing so will increase the strength of the inferences, provided that the prior information is an accurate reflection of the underlying situation.
2. If there is uncertainty about whether or not the prior data is representative or if there is considerable uncertainty in the prior data, a method that assumes as little information as possible while maintaining consistency with the prior data is preferable. Such an approach will maximize the flexibility of the prior, allowing the data to more easily 'guide' the results of the analysis.

A brief overview of four methods will be given here. These are maximum likelihood estimation, the method of moments, maximum entropy estimation, and the preprior approach from Guikema and Paté-Cornell [2].

37.3.1.1 Maximum Likelihood

A maximum likelihood estimate (MLE) maximizes the likelihood of the observed data. That is, the parameters of an assumed distribution are chosen such that the likelihood of the data is maximized. A common prior formulation problem in risk analysis is the formulation of a prior for the probability of a binary failure/success event such as the success or failure of a system component. An appropriate likelihood to use to update the prior is the Binomial distribution. A conjugate prior, the prior that leads to a posterior from the same distribution family as the prior, is the Beta distribution. If an analyst has data about the mean rate of occurrence of the failure event in the past, bootstrapping can be used and a MLE prior for the probability of failure can be formulated according to (37.27) where α and β are the two parameters of the Beta distribution [33]. As discussed by Sorenson [34], an MLE is consistent and it is asymptotically efficient. However, little can be concluded about the efficiency of MLEs for situations with little data. In some situations the ML approach can be computationally intensive to implement.

$$\begin{aligned}(\alpha,\beta) &= \arg\max_{\alpha',\beta'}\left[\prod_i Beta\left(\mu_i^{(b)} \mid \alpha',\beta'\right)\right] \\ &= \arg\max_{\alpha',\beta'}\left[\prod_i\left[\frac{\Gamma(\alpha'+\beta')}{\Gamma(\alpha')\Gamma(\beta')}\left(\mu_i^{(b)}\right)^{\alpha'-1}\left(1-\mu_i^{(b)}\right)^{\beta'-1}\right]\right]\end{aligned} \tag{37.27}$$

37.3.1.2 Method of Moments

The method of moments (MM) approach was developed early as an approach for fitting a distribution to data [35]. The basic idea of MM is to match the moments of the data to the moments of the distribution being fit to that data. For example if $\mu_{d'}$ and $\sigma_{d'}^{(b)}$ are the estimated mean and standard deviation of the failure rate based on the data and bootstrap resample of the data, and a two-parameter distribution (*e.g.*, a Beta distribution) is to be used, the parameters are adjusted to yield a density function with a mean and variance equal to the sample mean and variance of the failure rate. Continuing with the Beta-binomial Bayesian example started in the MLE discussion, the mean and variance of a Beta distribution can be fit to a data sample by setting α and β equal to [33]:

$$\alpha = \frac{\hat{\mu}^2 - \hat{\mu}^3}{\left(\hat{\sigma}^{(b)}\right)^2} - \hat{\mu}^2, \tag{37.28}$$

$$\beta = \frac{\alpha\left(1-\hat{\mu}\right)}{\hat{\mu}}. \tag{37.29}$$

The MM approach is intuitively appealing, generally easy to implement, and provides estimators that asymptotically converge in probability to the true parameter as the amount of data increases. However, the MM estimators do

not, in general, have the smallest error covariance of all unbiased estimators.

37.3.1.3 Maximum Entropy

Entropy, defined in (37.30) for a given density function *f*, can be used as a measure of the amount of uncertainty contained in a probability distribution [36–38].

$$S = -\int_{-\infty}^{\infty} f(x) \log f(x)\, dx \qquad (37.30)$$

In assessing a probability density function based on a set of information, maximizing the entropy yields the density function that minimizes unwarranted assumptions of accuracy based on the data. The resulting distribution is consistent with the available data while maximizing the variability in the data. This approach has been applied in a number of areas such as image fusion [39] and composing priors for reliability analysis [33].

37.3.1.4 Pre-prior Updating

Guikema and Paté-Cornell [8] developed a method for composing a prior based on past data by using a two stage Bayesian updating approach. The analyst starts with a suitable non-informative prior. In the case of a Beta prior, this could be either a Beta (0.5, 0.5) prior, the Jeffreys prior, or a Beta (1,1), a uniform prior. This non-informative prior is then updated with the initial data sample, the data to be used in formulating the prior. This informative prior is then updated with the new data through the likelihood function to yield the posterior distribution for the problem. This approach has the advantage of being truly Bayesian in that the change in information state from no information (the pre-prior) to some information (the prior) to the final state of information (the posterior) is explicitly modeled. However, this approach does not involve both likelihood or entropy arguments; and it thus does not share the same theoretical basis as either of these other approaches.

Guikema [33] compared the results from using these prior formulation methods. The general conclusion is that the stronger the prior (*e.g.*, the smaller the variance) the greater the amount of data required to modify the prior through the likelihood if the prior information does not match that in the likelihood. However, if the prior information does match the likelihood information, a stronger prior leads to stronger posterior inferences than a prior with a higher variance. This means that the higher variance priors tend to be the most flexible, while the lower variance priors are better suited for situations with strong prior information. The most flexible informative priors tend to be those formulated on the basis of maximum entropy using minimal information from the prior data (*e.g.*, using only the mean rather than the mean and the variance). On the other hand, MLE priors tend to be more precise. There is a trade-off between precision and flexibility in formulating priors for Bayesian analysis, and an analyst must carefully weigh this trade-off on the basis of his or her degree of confidence in the prior data.

37.3.1.5 Example: Bayesian Analysis of Launch Vehicle Reliability

A Bayesian analysis of space launch vehicle success rates will be used as an example of the prior formulation process. This example is from Guikema and Paté-Cornell [8], where the probability of failure of 33 of the major families of launch vehicles in the world was analyzed. Data was collected about their past launch records, and the goal was to use this data to estimate the probability of failure of any given launch vehicle in its next flight. Launch vehicles were assumed to be binary failure/success systems, where a success occurs only if the payload is released into the intended orbit or interplanetary trajectory. This led to a model with a binomial likelihood distribution for the k successes in n trials, each with an unknown probability of occurrence of p. A prior was placed on the parameter p. Three different approaches were used for formulating the prior.

The first approach involved using a non-informative Beta prior for the p for each launch vehicle. This corresponds to the assumption that we know nothing about launch vehicle reliability before observing actual launches, or at least we will assume we know nothing. Both a uniform, or Beta (1,1), prior and a Jeffreys, or Beta (0.5,0.5),

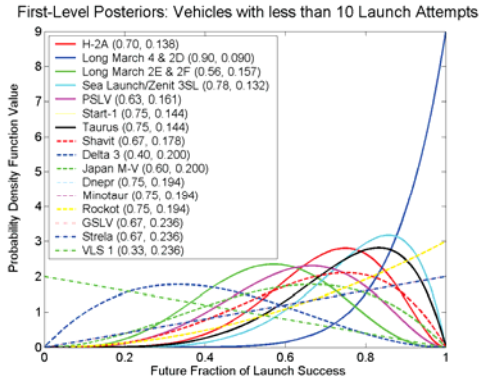

Figure 37.3. First–level posterior probability density functions for vehicles with less than 10 launch attempts. Mean, standard deviation for each distribution described in the legend. Taken from Guikema and Paté-Cornell [8]

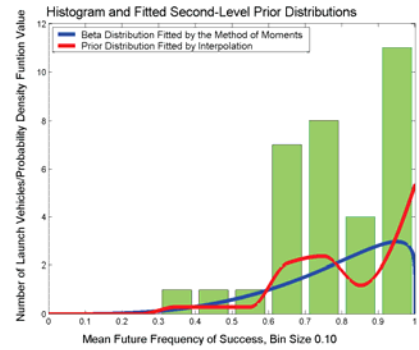

Figure 37.4. Histogram of first–level posterior means and fitted second–level prior distributions. Taken from Guikema and Paté-Cornell [8]

prior were used. Figure 37.3 shows the results of the analysis for launch vehicles with less than 10 launch attempts. The posterior density functions are quite broad for these vehicles, reflecting the lack of a large data set that would impart significant information for these vehicles.

The second approach involved plotting a histogram of the posterior means from the first approach, fitting a Beta density function to this histogram, and using this density function as the prior. This approach makes use of a basic summary statistic from the past data from all of the launch vehicles in order to develop a prior for analyzing a given launch vehicle. The implicit assumption is that the reliability of a given launch vehicle is, in some sense, believed to be similar to the average reliability of the other vehicles until data from the given launch vehicle proves otherwise. However, this approach does double-count the data from the vehicle being analyzed in the sense that the data enters into both the prior formulation (the posterior mean from that vehicle in the first level approach is included in the prior formulation) and the likelihood. Figure 37.4 shows the two priors used in this second approach. One was fit based on the method of moments, while the other used an interpolation of the means, rescaled to be a valid density function.

Figure 37.5 shows the results of the second-level analysis for vehicles with at least 96 launch attempts. The graphs show that when significant amounts of data are available, the form of the prior does not have a large impact on the results. The data "swamps" the prior information.

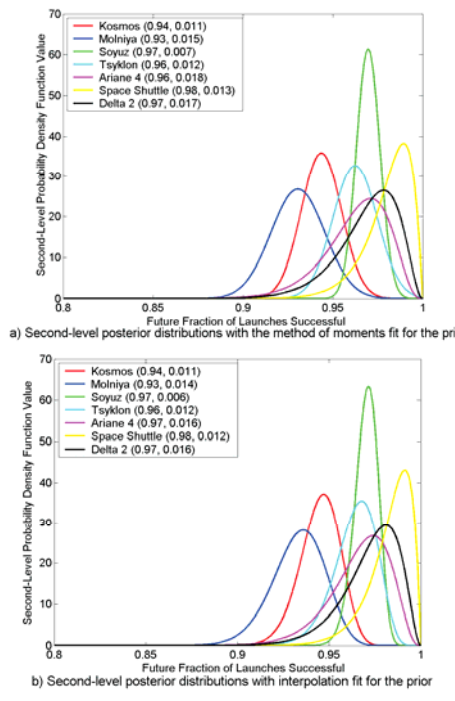

Figure 37.5. Second–level posterior probability density functions for vehicles with at least 96 launch attempts. Mean, standard deviation for each distribution described in the legend

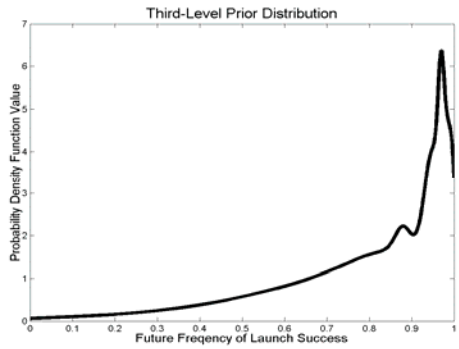

Figure 37.6. Third-level prior probability density function for a new vehicle. Taken from Guikema and Paté-Cornell [8]

Figure 37.6 shows the third approach prior for a new vehicle, and Figure 37.7 shows the third approach posterior distributions for each of the launch vehicles with less than ten launches. We see that the distributions have been shifted to the right relative to the first approach. This occurs because the prior distribution is both substantially more informative and suggests *a priori* a higher success rate in this case. This again highlights the usefulness of prior distributions for improving inferences in Bayesian analysis, especially when strong prior information is available.

37.3.2 Bayesian Generalized Models

Bayesian methods can also be used with the types of generalized regression models for count data discussed earlier in this chapter. There are a number of excellent textbooks written on this subject [40], and we do not duplicate these by giving an in–depth discussion of Bayesian count regression models here. Rather, we introduce the subject through a relatively simple example – a Bayesian Poisson GLMM. The model was originally presented in Guikema and Davidson [21],. Guikema and Davidson [21] used a Poisson GLMM to analyze the data set about electric power distribution reliability discussed earlier in this chapter.

The link function used in Guikema and Davidson [21] was

$$\lambda_i = \sum_j \beta_j x_{ij} + u_j \qquad (37.31)$$

where $u \sim t(0,df)$ with df considered an unknown parameter to be estimated based on the data. Non–informative normal $(0,1x10^6)$ priors were used for the regression parameters (the βs), and a non-informative Gamma distribution was used for the parameter df. These non-informative parameters were used to facilitate comparisons with classical models. Note that the major differences between this model and the classical Poisson GLMM are (i) the model was estimated within the Bayesian paradigm, and (ii) the random term in the link function used the more flexible Student's t–distribution rather than the standard normal distribution.

Figure 37.8 gives the comparison of the distributions of the random terms from the classical model with a Normally distributed random term and the posterior Bayesian density with an error term having a Student's t–distribution.

The results, especially the heavier tails in the Student's t-distribution, suggest that the Student's t–based random term captures additional variability that the normally distributed random terms do not. However, in this case, the β parameter estimates were similar in the two models.

Informative priors may also be used for the regression parameters of a GLM or GLMM or the knot points in a GAM or MARS approach. Holmes

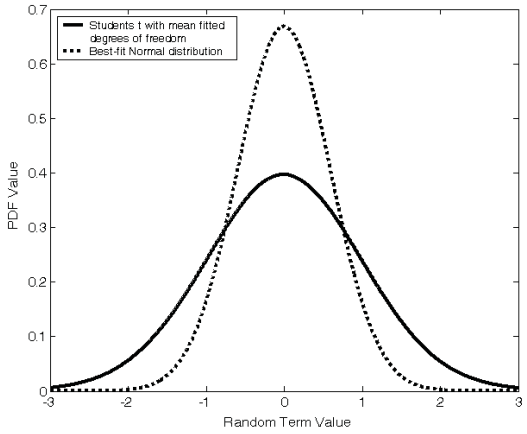

Figure 37.8. Comparison of posterior Student's *t* PDF with the estimated standard normal distribution. Taken from Guikema and Davidson [21]

and Mallick [26] discuss Bayesian approaches for the MARS approach, and similar methods may be useful for GAM approach. However, Bayesian approaches for GLMs, GLMMs, GAMs, and MARS models have generally used non–informative priors. If one wished to use informative priors, the process used to formulate these priors could potentially have large impacts on the results of the analysis, particularly if there was not a great deal of data available. One approach would be to use a pre-prior approach with a segmented data set. Another approach would be to directly assess density functions for the parameters with an expert in the subject matter being analyzed. Additional research is needed explore these different options and their impacts on modeling and model conclusions.

37.4 Conclusions

Properly accounting for and modeling count data in risk analysis and reliability engineering has the potential to significantly improve inferences and risk management decision-making. This chapter has given an introduction to these models and provided direction to more detailed discussions in the research literature and statistics textbooks. However, no discussion of modeling count data would be complete without at least a brief mention of computational issues.

Models for count data can be computationally expensive, especially Bayesian models. The basic classical models such as OLS, Poisson GLMs, and binomial GLMs can be easily fit in Matlab for small and moderate size data sets. However classical GLMMs, GAMs, and MARS models require the use of specialized statistical packages. SAS, S-plus, and R all have the capabilities needed to fit these models. R is particularly attractive to practicing engineers because it provides an open-source statistical platform that is available at no cost from http://www.r-project.org/. With the exception of the computationally simplest models (*e.g.,* models with conjugate priors), Bayesian modeling requires either numerical integration or a simulation–based approach. In the launch vehicle example, numerical integration was used to estimate the posterior distributions. In more complex regression–type problems, simulation–based Markov chain Monte Carlo (MCMC) approaches will likely be needed. This was the approach used in the Bayesian GLMM example. WinBUGS is an open–source Bayesian analysis package available at http://www.mrc–bsu.cam.ac.uk/bugs/, and it enables MCMC methods for a wide variety of models without programming the simulation. Among others, Gelman *et al.* [29] provides an overview of MCMC techniques.

Despite the computational challenges inherent in some count modeling techniques, properly accounting for and modeling count data can improve risk analysis and reliability engineering models. Stronger inferences can be drawn, and more informed risk management decisions can be made. A variety of models and techniques have been introduced in this chapter, and it is hoped that these tools will form the basis for continuing use and exploration of count modeling techniques in risk analysis and reliability engineering.

Fault Tree Analysis

Liudong Xing[1] and Suprasad V. Amari[2]

[1] Department of Electrical and Computer Engineering, University of Massachusetts-Dartmouth, USA
[2] Relex Software Corporation, Greensburg, USA

Abstract: In this chapter, a state-of-the-art review of fault tree analysis is presented. Different forms of fault trees, including static, dynamic, and non-coherent fault trees, their applications and analyses will be discussed. Some advanced topics such as importance analysis, dependent failures, disjoint events, and multistate systems will also be presented.

38.1 Introduction

The fault tree analysis (FTA) technique was first developed in 1962 at Bell Telephone Laboratories to facilitate analysis of the launch control system of the intercontinental Minuteman missile [1]. It was later adopted, improved, and extensively applied by the Boeing Company. Today FTA has become one of the most widely used techniques for system reliability and safety studies. In particular, FTA has been used in analyzing safety systems in nuclear power plants, aerospace, and defense.

FTA is an analytical technique, whereby an undesired event (usually system or subsystem failure) is defined, and then the system is analyzed in the context of its environment and operation to find all combinations of basic events that will lead to the occurrence of the predefined undesired event [2]. The basic events represent basic causes for the undesired event; they can be events associated with component hardware failures, human errors, environmental conditions, or any other pertinent events that can lead to the undesired event. A fault tree thus provides a graphical representation of logical relationships between the undesired event and the basic fault events. From a system design perspective, FTA provides a logical framework for understanding the ways in which a system can fail, which is often as important as understanding how a system can operate successfully.

In this chapter, we first compare the FTA method with other existing analysis methods, in particular, reliability block diagrams, and then describe how to construct a fault tree model. Different forms of fault trees, including static, dynamic, and non-coherent fault trees and their applications will also be discussed. We then discuss different types of FTA as well as both classical and modern techniques used for FTA. We also discuss some advanced topics such as importance analysis, common-cause failures, generalized dependent failures, disjoint events, as well as application of fault trees in analyzing multistate systems and phased-mission systems. Some FTA software tools will be introduced at the end of this chapter.

38.2 A Comparison with Other Methods

System analysis methods can be classified into two generic categories: inductive methods and deductive methods. Induction constitutes reasoning from specific cases to a general conclusion. In an inductive system analysis, we postulate a particular fault or initiating event and attempt to find out the effect of this fault on the entire system failure. Examples of inductive system analysis include failure mode and effect analysis (FMEA) [2–4], failure mode effect and criticality analysis (FMECA) [2, 4, 5], preliminary hazards analysis (PHA) [2], fault hazard analysis (FHA) [2], and event tree analysis [4, 6]. In a deductive system analysis, we postulate a system failure and attempt to find out what modes of system or component behavior contribute to the system failure. In other words, the inductive methods are applied to determine what system states (usually failed states) are possible; the deductive methods are applied to determine how a particular system state can occur. FTA is an example of deductive method and is the principle subject of this chapter. Similar to FTA, we can also use reliability block diagrams (RBD) [7] to specify various combinations of component successes that lead to a specific state or performance level of a system. Therefore, RBD can also be viewed as a deductive method. In the following subsection, we give a brief comparison between fault trees and RBD.

38.2.1 Fault Trees *Versus* RBD

The most fundamental difference between fault trees and RBD is that an RBD is a success-oriented model, while a fault tree is failure-oriented. Specifically, in an RBD, one works in the "success space" and thus looks at system success combinations, whereas in a fault tree one works in the "failure space" and thus looks at system failure combinations. For practical applications in which the system failure depends only on combinations of its component failures, we may choose either a fault tree or an RBD to model the system structure. Both methods will produce the same results. But in most applications, particularly for safety critical systems, it is recommended to start by constructing a fault tree instead of an RBD because thinking in terms of failures will often reveal more potential failure causes than thinking from the function point of view [4].

In most cases, we may convert a fault tree to an RBD or *vice versa*. Particularly, the conversion is possible for all static coherent structures. In the conversion from a fault tree to an RBD, we start from the TOP event of the fault tree and replace the gates successively. A logic AND-gate is replaced by a parallel structure of the inputs of the gate, and an OR gate is replaced by a series structure of the inputs of the gate. In the conversion from an RBD to a fault tree, a parallel structure is represented as a fault tree where all the input events are connected through an AND-gate, and a series structure is represented as a fault tree where all the input events are connected through an OR-gate. Figure 38.1 shows the relationship between a fault tree and an RBD. Note that the events in the fault tree are failure events. Blocks in the RBD means the components represented by the blocks are functioning.

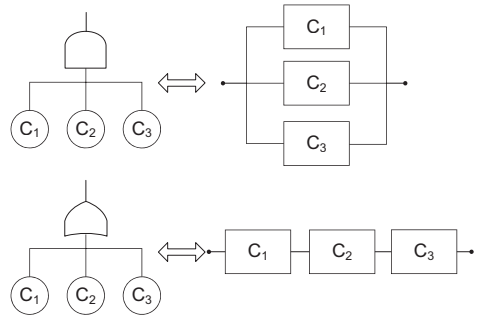

Figure 38.1. Conversion between RBDs and fault trees

Both FTA and RBD are evolutionary in nature, meaning that their modeling capabilities are enhanced as needed to support a wide range of scenarios. For example, introducing new gates, the FTA is enhanced to support sequence dependent failures. However, RBDs are not enhanced to support these modeling features. Similarly, there are some other enhancements to RBDs that are not available in FTA. Hence, it is not possible or practical to covert all fault trees into equivalent RBDs and *vice-versa*.

38.3 Fault Tree Construction

FTA is a deductive technique where we start with the failure scenario being considered, and decompose the failure symptom into its possible causes. Each possible cause is then investigated and further refined until the basic causes of the failure are understood. For more details, one can refer to [21, Chapter 8] or [32, Chapter 7]. The failure scenario to be analyzed is normally called the TOP event of the fault tree. The basic causes are the basic events of the fault tree. The fault tree should be completed in levels, and they should be built from top to bottom. However, various branches of a fault tree can be built to achieve different levels of granularity.

38.3.1 Important Definitions

The following concepts are critical for the proper selection and definition of fault tree events, and thus for the construction of fault trees:

- An *undesired event* constitutes the TOP event of a fault tree model constructed for a system. Careful selection of the undesired event is important to the success of FTA. The definition of the TOP event should be neither too general nor too specific. Here are several examples of undesired events that can be suitable for beginning FTA: overflow of a washing machine [8], no signal from the start relay of a fire detector system when a fire condition is present [4], car does not start when ignition key is turned [2], and loss of spacecraft in the space exploration [2].
- A *primary (or basic) failure* is a failure caused by natural aging of the component. For example, fatigue failure of a relay spring within its rated lifetime, and leakage of a valve seal within its pressure rating.
- A *secondary failure* is a failure induced by the exposure of the failed component to environmental and/or service stresses exceeding its intended ratings. The stresses may be shocks from mechanical, electrical, chemical, thermal, or radioactive energy sources. The stresses may be caused by neighboring components within the system, external environment, or system operators. For example, the component has been improperly designed, or selected, or installed for the application, and a failed component is overstressed or under-qualified for its burden.

38.3.2 Elements of Fault Trees

The main elements of a fault tree include:

- A TOP event: represents the undesired event, usually the system failure or accident.
- Basic events: represent basic causes for the undesired event, usually the failures of components that constitute the system, human errors, or environmental stresses. No further development of failure causes is required for basic events.
- Undeveloped events: represent fault events that are not examined further because information is unavailable or because its consequence is insignificant;
- Gates: are outcomes of one or a combination of basic events or other gates. The gate events are also referred to as intermediate events.

Readers may refer to [2, 8, 9, 21, and 32] for more details of these elements as well as their graphical representation in the fault tree model.

38.3.3 Construction Guidelines

To achieve a consistent analysis, the following steps are suggested for constructing a successful fault tree model:

1) Define the undesired event to be analyzed. The description of it should provide answers to the following questions:
   a. What: describe what type of undesired event is occurring (*e.g.*, fire, crash, or overflow).
   b. Where: describe where the undesired event occurs (*e.g.*, in a motor of an automobile).
   c. When: describe when the undesired event occurs (*e.g.*, when the power is applied, when a fire condition is present).

2) Define boundary conditions for the analysis, including
   a. Physical boundaries: define what constitutes the system, *i.e.* which parts of the system will be included in the FTA.
   b. Boundary conditions concerning environmental stresses: define what type of external stresses (*e.g.*, earthquake and bomb) should be included in the fault tree.
   c. Level of resolution: determine how far down in detail we should go to identify the potential reasons for a failed state.
3) Identify and evaluate fault events, *i.e.,* contributors to the undesired TOP event: if a fault event represents a primary failure, it is classified as a basic event; if the fault event represents a secondary failure, it is classified as an intermediate event that requires a further investigation to identify the prime causes.
4) Complete the gates: all inputs of a particular gate should be completely defined before further analysis of any one of them is undertaken (complete-the-gate rule) [2]. The fault tree should be developed in levels, and each level should be completed before any consideration is given to the next level.

38.3.4 Common Errors in Construction

Errors observed frequently in constructing fault trees are listed. The mistakes listed here are not intentional. Instead, they happen due to simple oversights, misconceptions, and/or lack of knowledge about the fault trees.

- *Ambiguous TOP event*: the definition of the undesired TOP event should be clear and unambiguous. If it is too general, the FTA can become unmanageable; if it is too specific, the FTA cannot provide a sufficiently broad view of the system.
- *Ignoring significant environment conditions*: another common mistake is to consider only failures of components that constitute the system and ignore external stresses, which sometimes can contribute significantly to the system failure.
- *Inconsistent fault tree event names*: the same name should be used for the same fault event or condition throughout the analysis.
- *Inappropriate level of detail/resolution*: the level of detail has a significant impact on the problem formulation. Avoid the formulations that are either too narrow or too broad. When determining the preferred level of resolution, we should remember that the detail in the fault tree should be comparable to the detail of the available information.

38.4 Different Forms

Fault trees can be broadly classified into coherent and noncoherent categories. Coherent fault trees do not use inverse gates, that is to say, the inclusion of inversion may lead to a noncoherent fault tree. Coherent trees can be further classified as static or dynamic trees depending on the sequence relationship between the input events. We describe these three types of fault trees in this section and their evaluation methods in Sections 38.6, 38.7, and 38.8, respectively.

38.4.1 Static Fault Trees

In a static fault tree, logical gates are restricted to static coherent gates, including AND, OR, and *K*-out-of-*N* gates. Static fault trees express the failure criteria of the system in terms of combinations of fault events. Moreover, the system failure is insensitive to the order of occurrence of component fault events [8].

38.4.2 Dynamic Fault Trees

In practice, the failure criteria of a system may depend on both the combinations of fault events and sequence of occurrence of input events. For example, consider a fault-tolerant system with one primary component and one standby spare connected with a switch controller (Figure 38.2) [10]. If the switch controller fails after the primary component fails and thus the standby is switched into active operation, then the system can continue to operate. However, if the switch controller fails

before the primary component fails, then the standby component cannot be activated, and the system fails when the primary component fails even though the spare is still operational. Systems with sequence dependence are modeled with dynamic fault trees (DFT). Dugan and Doyle [8] described several different types of sequence dependencies and corresponding dynamic fault tree gates. A brief description of them is given as follows.

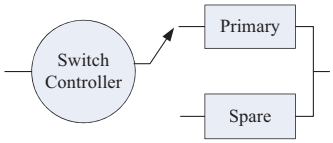

Figure 38.2. A standby sparing system

38.4.2.1 Functional Dependency (FDEP) Gate

A FDEP gate (Figure 38.3) has a single trigger input event and one or more dependent basic events. The trigger event can be either a basic event or the output of another gate in the fault tree. The occurrence of the trigger event forces the dependent basic events to occur. The separate occurrence of any of the dependent basic events has no effect on the trigger event. The FDEP gate has no logical output, thus it is connected to the fault tree through a dashed line.

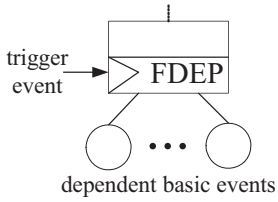

Figure 38.3. Functional dependency gate

For example, the FDEP gate can be used when communication is achieved through a network interface card (NIC), where the failure of the NIC (trigger event) makes the connected components inaccessible.

38.4.2.2 Cold Spare (CSP) Gate

A CSP gate (Figure 38.4) consists of one primary input event and one or more alternate input events. All the input events are basic events. The primary input represents the component that is initially powered on. The alternate inputs represent components that are initially un-powered and serve as replacements for the primary component. The output occurs after all the input events occur, *i.e.,* the primary component and all the spares have failed or become unavailable. As an example, the CSP gate can be used when a spare processor is shared between two active processors. The basic event representing the cold spare processor is the input event to two CSP gates. However, the spare is only available to one of the CSP gates, depending on which of the primary processors fails first.

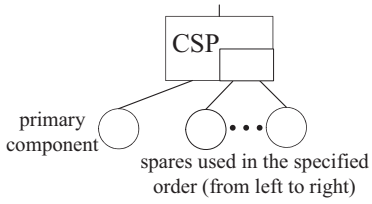

Figure 38.4. Cold spare gate

There are two variations of the CSP gate: hot spare (HSP) gate and warm spare (WSP) gate. The graphical layouts of these two gates are similar to Figure 38.4, only changing CSP to HSP and WSP respectively. In HSP, the spare components have the same failure rate before and after being switched into active use. In WSP, the spare components have reduced failure rate before being switched into active use. Note that the cold, warm, and hot spare gates not only model sparing behavior, but also affect the failure rates of basic events attached to them. As a result, basic events cannot be connected to spare gates of different types, because attenuation of the failure rate would not be defined.

Coppit *et al.* [11] suggest using a generic spare instead of a temperature (cold, warm, or hot) notion for the spare gate. The attenuation of failure rate of an unused, unfailed replica of a basic event

is dictated solely by a dormancy factor of the basic event. This change can provide more orthogonality between spare gates and basic events, and can remove the restriction on sharing of spares among spare gates. This design is implemented in Relex fault tree analysis software [12].

38.4.2.3 Priority-AND Gate

The priority-AND gate (Figure 38.5) is logically equivalent to a normal AND gate, with the extra condition that the input events must occur in a defined order. Specifically, the output occurs if both input events occur and the left input occurs before the right input. In other words, if any of the events has not occurred or if the right input occurs before the left input, the output does not occur.

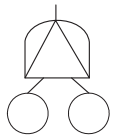

Figure 38.5. Priority-AND gate

As an example, the priority-AND gate can be used to describe one of the failure scenarios for the standby sparing system in Figure 38.2: if the switch controller fails before the primary component, the system fails when the primary component fails. Assume the cold spare is used in this example, and then the fault tree model for the entire system is shown in Figure 38.6.

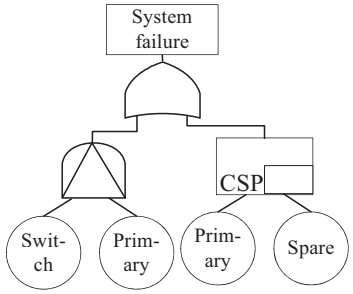

Figure 38.6. DFT of the standby sparing system

38.4.2.4 Sequence Enforcing (SEQ) Gate

The SEQ gate (Figure 38.7) forces all the input events to occur in a defined order: left-to-right order in which they appear under the gate. It is different from the priority-AND gate in that the SEQ gate only allows the events to occur in a specified order whereas the priority-AND gate detects whether the input events occur in a specified order, the events can occur in any order in practice, though.

Figure 38.7. Sequence enforcing gate

38.4.3 Noncoherent Fault Trees

A noncoherent fault tree is characterized by inverse gates besides logic gates used in coherent fault trees. In particular, it may have Exclusive-OR and NOT gates (Figure 38.8). A non-coherent fault tree is used to describe failure behavior of a noncoherent system, which can transit from a failed state to a good state by the failure of a component, or transit from a good state to a failed state by the repair of a component. The structure function of a noncoherent system does not increase monotonically with additional number of functioning components.

(a) NOT gate (b) Exclusive-OR gate

Figure 38.8. Noncoherent fault tree gates

Noncoherent systems are typically prevalent in systems with limited resources, multi-tasking and safety control applications. As an example, consider a *k*-to-*l*-out-of-*n* multiprocessor system where resources such as memory, I/O, and bus are shared among a number of processors [13]. If less than a certain number of processors *k* is being

used, the system will not work to its maximum capacity; on the other hand, if the number of processors being used exceeds *l*, the system efficiency also suffers due to the traffic congestion on a limited bandwidth bus. In FTA, we can consider the system has failed for these two extreme cases. Other examples of noncoherent systems include electrical circuits, traffic light systems, load balancing systems, protective control systems, liquid level control systems, pumping systems, and automatic power control systems [13–18].

In addition, noncoherent systems are often used to accurately analyze disjoint events [19], dependent events [20], and event trees [6]. The wide range of applications of noncoherent systems has gained the attention of reliability engineers working in safety-critical applications. As a result, several commercial reliability software vendors have extended the support of NOT logic from fault trees to reliability block diagrams [12].

38.5 Types of Fault Trees Analysis

Depending on the objectives of the analysis, FTA can be qualitative or quantitative. In the following subsections, possible results and analysis methods for qualitative and quantitative FTA will be discussed in detail.

38.5.1 Qualitative Analysis

Qualitative analysis usually consists of studying minimal cutsets. A cutset in a fault tree is a set of basic events whose occurrence leads to the occurrence of the TOP event. A minimal cutset is a cutset without redundancy. In other words, if any basic event is removed from a minimal cutset, it ceases to be a cutset.

To find the minimal cutsets of a fault tree, a top-down approach is applied. The algorithm starts at the top gate representing the TOP event of the fault tree and constructs the set of cutsets by considering the gates at each lower level. If the gate being considered is an AND gate, then all the inputs must occur to activate the gate. Thus, the AND gate will be replaced at the lower level by a list of all its inputs. If the gate being considered is an OR gate, then the occurrence of any input can activate the gate. Thus, the cutset being built is split into several cutsets, one containing each input to the OR gate.

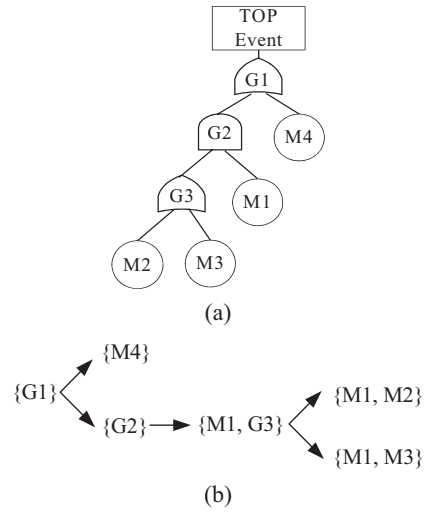

Figure 38.9. An example fault tree and its cutsets. **(a)** Fault tree, **(b)** minimal cutset generation

Consider a fault tree in Figure 38.9(a). Figure 38.9(b) shows its cutset generation. The top-down algorithm starts with the top gate G1. Since G1 is an OR gate, it is split into two sets, one containing each input to G1, that is, {G2} and {M4}. G2 is an AND gate, so it is replaced in the expansion by its two inputs {M1, G3}. Finally, the expansion of G3 splits the cutset {M1, G3} into two, yielding {M1, M2} and {M1, M3}. Therefore, there are three minimal cutsets for this example fault tree: C_1={M1, M2}, C_2={M1, M3}, and C_3={M4}.

Possible results from the qualitative analysis based on minimal cutsets include:

- All the unique combinations of component failures that may result in a critical event (system failure or some unsafe condition) in the system. Each combination is represented by a minimal cutset. For the fault tree in Figure 38.9(a), if both M1 and M2 fail, or both M1 and M3 fail, or M4 fails, the system fails.

- All single-point of failures for the system. A single-point of failure is any component whose failure by itself leads to the system failure. It is identified by a minimal cutset with only a single component. For the fault tree in Figure 38.9(a), M4 is a single-point of failure.
- Vulnerabilities resulting from particular component failures. The vulnerabilities can be identified by considering minimal cutsets that contain the component of interest. For the example system in Figure 38.9(a), once M1 fails, the system is vulnerable to the failure of either M2 or M3.

Those qualitative results can help to identify system hazards that might lead to failure or unsafe states so that proper preventive measures can be taken or reactive measures can be planned.

38.5.2 Quantitative Analysis

Quantitative analysis is used to determine the occurrence probability of the TOP event, given the occurrence probability (estimated or measured) of each basic event. Approaches for quantitative FTA can be broadly classified into three categories: state space oriented methods (see, *e.g.*, [22–26]), combinatorial methods (see, *e.g.*, [27–29]), and a modular solution that combines the previous two methods as appropriate (see, *e.g.*, [30, 31]).

The state space oriented approaches, which are based on Markov chains and/or Petri nets, are flexible and powerful in modeling complex dependencies among system components. However, they suffer from state explosion when modeling large-scale systems. Combinatorial methods can solve large fault trees efficiently. However, a widely held view among researchers is that combinatorial models are not able to model dependencies and thus cannot provide solutions to any dynamic fault tree.

The modular approach combines both combinatorial methods and state space oriented methods. Specifically, in the modular approach, independent subtrees are identified and the decision to use a state space oriented solution or a combinatorial solution is made for a subtree instead of for the fault tree as a whole. These independent subtrees are treated separately and their solutions are integrated to obtain the solution for the entire fault tree. The advantage of the modular approach is that it allows the use of state space oriented approach for those parts of a system that require them and the use of combinatorial methods for the more "well-behaved" parts (static parts) of the system, so that the efficiency of combinatorial solution can be retained where possible. In Section 38.7.2, an example of the modular approach that combines the use of the Markov chain solution for dynamic subtrees and binary decision diagrams based solution for static subtrees will be discussed in detail. The following three sections are devoted to the quantitative analysis techniques for static, dynamic, and noncoherent fault trees, respectively.

38.6 Static FTA Techniques

Quantitative analysis techniques for static fault trees using cutsets or binary decision diagrams will be discussed in this section.

38.6.1 Cutset Based Solutions

In Section 38.5.1, the top-down approach to generate the minimal cutsets from a static fault tree has been described. Each cutset represents a way in which the system can fail. So the system unreliability (denoted by U_{sys}) is simply the probability that all of the basic events in one or more minimal cutsets will occur. Let C_i represent a minimal cutset and there are n minimal cutsets for a system, thus we have:

$$U_{sys} = \Pr(\bigcup_{i=1}^{n} C_i) \cdot \tag{38.1}$$

Because the minimal cutsets are not generally disjoint, the probability of the union in (38.1) is not equal to the sum of the probabilities of the individual cutsets. Actually, for coherent systems, the sum of the individual cutsets gives an upper bound of the system unreliability since the intersection of the events from two minimal cutsets may be counted more than once. Several methods exist for the evaluation of (38.1) [10, 21, 33]. We describe two commonly used ones: inclusion-exclusion and sum of disjoint products.

38.6.1.1 Inclusion–Exclusion (I–E)

The I–E method is a generalization of the rule for computing the probability of the union of two events: $\Pr(A \cup B) = \Pr(A) + \Pr(B) - \Pr(A \cap B)$. It is given by the sum of probabilities of cutsets taken one at a time, minus the sum of probabilities of the intersection of cutsets taken two at a time, plus the sum of probabilities of the intersection of cutsets taken three at a time, and so on, until reaching an term which contains the probability of the intersection of all the cutsets [8]. The equation for representing the above procedure is:

$$U_{sys} = \Pr\{\bigcup_{i=1}^{n} C_i\} = \sum_{i=1}^{n} \Pr(C_i) - \sum_{i<j} \Pr(C_i \cap C_j) + \sum_{i<j<k} \Pr(C_i \cap C_j \cap C_k) \mp \ldots \pm \Pr(\bigcap_{j=1}^{n} C_j) \tag{38.2}$$

Consider the example system in Figure 38.9, there are three minimal cutsets: C_1={M1, M2}, C_2={M1, M3}, and C_3={M4}. The system unreliability can be calculated as:

$$U_{sys} = \Pr\{C_1 \cup C_2 \cup C_3) = \sum_{i=1}^{3} \Pr(C_i) - \Pr(C_1 \cap C_2) - \Pr(C_1 \cap C_3) - \Pr(C_2 \cap C_3) + \Pr(C_1 \cap C_2 \cap C_3)$$

The evaluation of (38.2) gives the exact system unreliability. As each successive summation term is calculated and included into the sum, the result alternatively overestimates (if the term is added) or underestimates (if the term is subtracted) the desired system unreliability. Hence, lower and upper bounds on the system unreliability can be determined by using only a portion of the terms in (38.2).

38.6.1.2 Sum of Disjoint Products (SDP)

The basic idea of the SDP method is to take each minimal cutset and make it disjoint with each preceding cutset using Boolean algebra, as shown in (38.3):

$$\bigcup_{i=1}^{n} C_i = C_1 \cup (\overline{C_1} C_2) \cup (\overline{C_1}\,\overline{C_2} C_3) \cup \ldots \cup (\overline{C_1}\,\overline{C_2}\,\overline{C_3} \ldots \overline{C_{n-1}} C_n) \tag{38.3}$$

$\overline{C_i}$ represents the negation of the set C_i. Because the terms in the right-hand side of (38.3) are disjoint, the sum of probabilities of these individual terms gives the exact system unreliability, that is,

$$U_{sys} = \Pr(\bigcup_{i=1}^{n} C_i) = \Pr(C_1) + \Pr(\overline{C_1} C_2) + \ldots + \Pr(\overline{C_1}\,\overline{C_2} \ldots \overline{C_{n-1}} C_n) \tag{38.4}$$

Consider the example system in Figure 38.9, the system unreliability using the SDP method will be calculated as: $U_{sys} = \Pr(C_1) + \Pr(\overline{C_1} C_2) + \Pr(\overline{C_1}\,\overline{C_2} C_3)$. Similar to the I–E method, lower and upper bounds on the system unreliability can be obtained by using a portion of the terms in (38.4) [8].

38.6.2 Binary Decision Diagrams

Binary decision diagrams (BDD) were, at first, used in the circuit design and verification as an efficient method to manipulate Boolean expressions [34, 35]. It has recently been adapted to solve a static fault tree model for the system reliability analysis. It has been shown by many studies [36–42] that in most cases, the BDD based method requires less memory and computational time than other methods. Thus, it provides an efficient way to analyze large fault trees.

A BDD is a directed acyclic graph (DAG) based on Shannon decomposition. Let f be a Boolean expression on a set of Boolean variables X and x be a variable of X, then the Shannon decomposition and its if-then-else (*ite*) format is:

$$f = x \cdot f_{x=1} + \overline{x} \cdot f_{x=0} = x \cdot F_1 + \overline{x} \cdot F_2 = ite(x, F_1, F_2)$$

The BDD has two sink nodes, each labeled by a distinct logic value 0, 1, representing the system being operational or failed, respectively. Each non-sink node is associated with a Boolean variable x and has two outgoing edges called *then*-edge (or 1-edge) and *else*-edge (or 0-edge), respectively. The two edges represent the two corresponding expressions in the Shannon decomposition as shown in Figure 38.10. In other words, each non-sink node in the BDD encodes a Boolean expression, or an *ite* format. One of the key

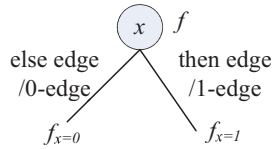

Figure 38.10. A non-sink node in BDD

characteristics of the BDD is the disjointness of $x \cdot f_{x=1}$ and $\bar{x} \cdot f_{x=0}$.

An ordered BDD (OBDD) is defined as a BDD with the constraint that variables are ordered and every source to sink path in the OBDD visits the variables in an ascending order. Further, a reduced OBDD (ROBDD) is an OBDD where each node represents a distinct Boolean expression. Two reduction rules will be introduced in Section 38.6.2.2 to obtain an ROBDD from an OBDD.

To perform a quantitative analysis of a static fault tree using the BDD method, we convert the fault tree to the BDD first, and then evaluate the resulted BDD to yield the system unreliability. In the following, we discuss the conversion and evaluation processes in detail.

38.6.2.1 Converting Fault Trees to BDDs

To construct an OBDD from a fault tree, the ordering of variables/components has to be selected first. The ordering strategy is very important for the OBDD generation, because the size of the OBDD will heavily depend on the order of input variables. A poor ordering can significantly affect the size of BDD, thus the reliability analysis solution time for large systems. Currently there is no exact procedure for determining the best way of ordering variables for a given fault tree structure. Fortunately, heuristics can usually be used to find a reasonable variable ordering [43].

After each variable is assigned a different order or index, a depth-first traversal of the fault tree is performed and the OBDD model is constructed in a bottom-up manner [44]. Specifically, the OBDDs are created for basic events first. Then these basic event OBDDs will be combined based on the logic operation of the current gate traversed. The resulted sub-OBDDs are further combined based on the logic operation of the traversed gate. The mathematical representation of the logic operation on two sub-OBDDs is described as follows.

Let $\Diamond$ represent any logic operation (AND/OR). Let the *ite* format for Boolean expressions G and H, representing two sub-OBDDs, be: $G = ite(x, G_{x=1}, G_{x=0}) = ite(x, G_1, G_2)$ and $H = ite(y, H_{x=1}, H_{x=0}) = ite(y, H_1, H_2)$.

Then:

$$G \Diamond H = ite(x, G_1, G_2) \Diamond ite(y, H_1, H_2) = \begin{cases} ite(x, G_1 \Diamond H_1, G_2 \Diamond H_2) & index(x) = index(y) \\ ite(x, G_1 \Diamond H, G_2 \Diamond H) & index(x) < index(y) \\ ite(y, G \Diamond H_1, G \Diamond H_2) & index(x) > index(y) \end{cases} \quad (38.5)$$

The same rules can be used for logic operation between sub-expressions until one of them becomes a constant expression '0' or '1'. Note that Boolean algebra ($1+x=1$, $0+x=x$, $1 \cdot x=x$, $0 \cdot x=0$) is applied to simplify the representation when one of the sub-OBDDs is a constant expression '0' or '1'.

To illustrate the fault tree to BDD conversion process, we present the construction of the OBDD from the fault tree in Figure 38.9 (a). Assume the variable ordering is M1<M2<M3<M4. Consider the subtree rooted at the OR gate G3; the first path traversed leads to the basic event M2. This means that the OR gate G3 will be applied once OBDDs are built for all the inputs of G3, that is, M2 and M3. Figure 38.11 shows the initial OBDDs for the two basic events M2 and M3 as well as the OBDD resulting from the application of the logic OR gate G3. M2 is the root of the resulted OBDD since it has a lower index than M3.

Figure 38.12 shows the OBDD resulting from the application of the logic AND gate G2 on the OBDD of Figure 38.11 and the OBDD for the basic event M1. M1 is the root of the resulted OBDD since it has a lower index than M2.

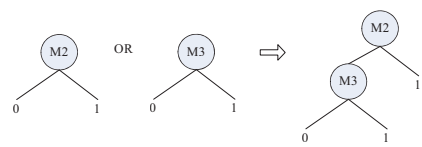

Figure 38.11. OBDD construction up to G3

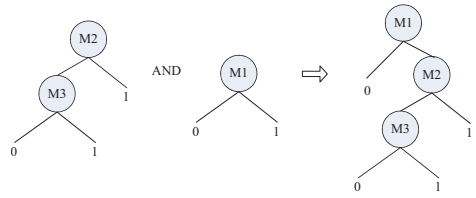

Figure 38.12. OBDD construction up to G2

Figure 38.13 shows the OBDD resulting from the application of OR gate G1 on the OBDDs which represent the inputs of G1, *i.e.,* the OBDD generated in Figure 38.12 and the OBDD for the basic event M4. Since G1 is the top gate of the fault tree, the OBDD in Figure 38.13 gives the full OBDD representing the entire fault tree of Figure 38.9 (a). This graph demonstrates that if both M1 and M2 fail; or if M1 fails, M2 does not fail, and M3 fails; or if M1 fails, M2 and M3 do not fail, and M4 fails; or if M1 does not fail and M4 fails, the entire system fails.

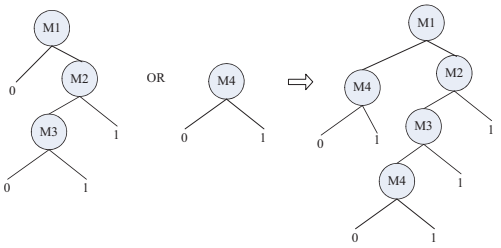

Figure 38.13. OBDD construction up to G1

38.6.2.2 Generating a Reduced OBDD (ROBDD)

As the OBDD is built, the following two reduction rules can be applied to ensure that the OBDD that results is minimal for the chosen ordering:

- Rule#1: isomorphic subtrees are merged since two isomorphic subtrees encode the same Boolean expression. Thus at least one is superfluous and the isomorphic sub-OBDDs can be merged as one sub-OBDD (Figure 38.14). For example, the two sub-BDDs rooted at node M4 in Figure 38.13 are isomorphic and can be merged. Figure 38.15 shows the ROBDD for the fault tree of Figure 38.9 (a) after applying this reduction rule to the OBDD in Figure 38.13.

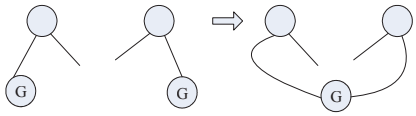

Figure 38.14. Rule#1: merging isomorphic sub-OBDDs

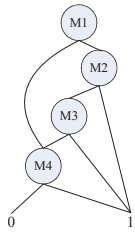

Figure 38.15. An example ROBDD

- Rule#2: deletion of useless nodes. A node encoding a function of form $(x \wedge G) \vee (\bar{x} \wedge G)$ is superfluous and thus can be deleted from the model because the function is simply equivalent to *G* (Figure 38.16).

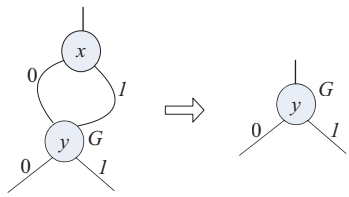

Figure 38.16. Rule#2: deleting useless nodes

38.6.2.3 Calculating System Unreliability

The final BDD model must be evaluated to obtain the system unreliability. Observing the BDD (Figure 38.15) generated for the fault tree in Figure 38.9(a), it is easy to find that each non-sink node in the BDD represents a component that can fail, and each path from the root to a leaf/sink node represents a disjoint combination of component failures and non-failures. If a path leads from a node to its then-edge (or right branch), then the failure of the component should be considered for that path. If a path leads from a node to its else-edge (or left branch), then the non-failure of the component should be considered for that path. If the sink node for a path is labeled with a "1", then the path leads to system failure; if the sink is labeled with a "0" then the path represents the

system being functioning. The probabilities associated with the then-edges on each path are the failure probabilities of corresponding components; the probabilities associated with the else-edges on each path are the operational probabilities of the corresponding components. Because all the paths are disjoint, the system unreliability is given by the sum of the probabilities for all the paths from the root to a sink node labeled "1", or the system reliability is given by the sum of the probabilities for all the paths from the root to a sink node labeled "0".

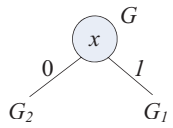

Figure 38.17. An ROBDD branch

The recursive algorithm for evaluating the ROBDD is described as follows. Consider a ROBDD branch G rooted at node x in Figure 38.17. The 1-edge of node x is associated with the failure probability of the component $q(x)$. The 0-edge is associated with the operational probability of the component $1\text{-}q(x)$. The unreliability concerning the sub-BDD G is calculated as: $U(G) = q(x)U(G_1)+[1\text{-}q(x)]U(G_2)$. When x is the rood node of the entire system BDD, $U(G)$ gives the entire system unreliability. The exit condition of this recursive algorithm is: if $G = 0$, then $U(G) = 0$; if $G = 1$, then $U(G) = 1$.

38.6.2.4 Variations of BDDs

Recently the BDD model has been combined with the multistate concept to analyze the reliability of systems subject to imperfect coverage behaviour [45–47], where an uncovered component fault can lead to extensive damage to the entire system despite the presence of fault-tolerant mechanisms [8]. There are three states for a system with imperfect coverage and its components: operation, covered failure and uncovered failure [8]. Readers may refer to Chapter 22 for detailed discussion on imperfect fault coverage. In the multistate BDD based method, each state of the component is represented using a Boolean variable indicating whether the component is in that particular state and the system BDD is generated using these Boolean variables. Because statistical-dependence exists among variables representing different states of the same component, special treatments are needed to address the dependence when applying the traditional Boolean algebra for BDD evaluation [46, 47]. In [42, 48] a similar similar idea was applied to the analysis of general multistate systems in which both the system and its components may exhibit three or more than three performance levels (or states) varying from perfect operation to complete failure. However, the disadvantage of the BDD-based method is that many Boolean variables must be dealt with and dependence among variables representing different states of the same component must be addressed.

To decrease the number of variables involved in the generation and evaluation of the system model, Xing and Dugan first adapted multiple-valued decision diagrams (MDD) [49] for the reliability analysis of fault tolerant systems with imperfect coverage [50, 51]. In their work, a MDD is a directed acyclic graph with three sink nodes each labeled by a distinct logic value 0, 1, 2, representing the system being in the operation, covered failure, and uncovered failure state, respectively. Each non-sink node representing a three-state component is labelled by a ternary-valued variable and has three outgoing edges; one corresponding to each logic value or component state. According to the special characteristic of an uncovered failure, *i.e.*, it leads to the entire system failure [8], a set of special *ternary-valued algebra* rules was developed for performing the logic AND/OR operation on the two basic events. Xing and Dugan showed that the MDD-based method provides smaller models and a much neater and simpler evaluation algorithm for analyzing systems subject to imperfect coverage than the BDD-based method. However, the MDD and rules developed in [50, 51] apply only to systems subject to imperfect coverage, in which both the system and its components have the same set of three states (operation, covered failure, and uncovered failure), and once a component is in the uncovered failure state, the entire system is in that state too. They cannot apply to the general multistate systems in

which the component states may not be consistent with the system states, and characteristics of each state can be nondeterministic.

Recently, a new modelling approach called multistate multivalued decision diagrams (MMDD) has been proposed, which provides an efficient and effective means for analyzing general large-scale multistate systems [52]. Different from the MDD model used in [50, 51], which can have more than two sink nodes representing the system being in each of the multiple states, a MMDD model can have two and only two sink nodes representing the system being or not being in a specific state. Results of case studies in [52] show that the MMDD based method provides smaller models in terms of the number of nodes and much neater and simpler generation and evaluation processes than the BDD-based approach proposed in [42]. Moreover, similar to the BDD-based method, the MMDD model can implicitly represent the sum of disjoint products, each of which indicates a disjoint combination of component states that cause the system to be in a specific state.

38.7 Dynamic FTA Techniques

38.7.1 Markov Chains

Dynamic fault trees (DFT) extend traditional FTA to include dynamic system behavior such as sequence dependence and shared pool of resources. The DFT model includes special purpose gates (dynamic gates described in Section 38.4.2) to incorporate the dynamic behavior into Markov chains, which are used for the solution to the system unreliability analysis.

The two main concepts in the Markov model are system states and state transitions. The state of a system represents a specific combination of system parameters that describe the system at any given instant of time. For representing the system reliability, each state of the Markov model generally represents a distinct combination of faulty and fault free components. The state transitions govern the changes of a state that occur within a system. As time passes and failures occur, the system goes from one state to another until one of the absorbing states (usually the system failure states) is reached. The state transitions are characterized by parameters such as failure rates, fault coverage factors, and repair rates [53].

Solving a Markov model consists of solving a set of differential equations: $\boldsymbol{AP}(t) = \boldsymbol{P}'(t)$. The specific form is:

$$\begin{bmatrix} -\alpha_{11} & \alpha_{21} & \alpha_{31} & \dots & \alpha_{n1} \\ \alpha_{12} & -\alpha_{22} & \alpha_{32} & \dots & \alpha_{n2} \\ \alpha_{13} & \alpha_{23} & -\alpha_{33} & \dots & \alpha_{n3} \\ \dots & \dots & \dots & \dots & \dots \\ \alpha_{1n} & \alpha_{2n} & \alpha_{3n} & \dots & -\alpha_{nn} \end{bmatrix} \bullet \begin{bmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \\ \dots \\ P_n(t) \end{bmatrix} = \begin{bmatrix} P_1'(t) \\ P_2'(t) \\ P_3'(t) \\ \dots \\ P_n'(t) \end{bmatrix}$$

where $\alpha_{jk}, j \neq k$ is the transition rate from state j to state k. The diagonal element α_{jj} in the matrix $\boldsymbol{A}$ is the sum of departure rates from state j, that is, $\alpha_{jj} = \sum_{k=1,k\neq j}^{n} \alpha_{jk}$. Thus, the sum of each column of $\boldsymbol{A}$ is 0. $P_i(t)$ is the probability of system being in state i at time t, and n represents the number of states presented in the Markov model.

To solve the differential equations, Laplace transform is typically applied [4]. The solution includes the probability of the system being in each state. The system unreliability can be calculated by adding the probability of being each failure state: $\sum_{\forall F} P_{F_i}(t)$, where $P_{F_i}(t)$ is the probability of system being in the failure state F_i at time t.

Markov model has more power as a solution method than the combinatorial methods in that it can solve system with dynamic and dependent behaviors. However, Markov model has the significant disadvantage that its size grows exponentially as the size of the system increases. This rapid growth of the number of states may lead to intractable models. Therefore, many researchers made efforts to the approximate bounding methods where only a portion of the state space of Markov chain is generated [54, 55]. In addition, Markov model assumes *exponential* time-to-failure distribution, whereas, combinatorial methods can be applied to any arbitrary failure distribution. Since Markov and combinatorial approaches both have their *pros* and *cons*, a dynamic fault tree modular approach has been proposed to combine both solutions in the system reliability analysis (refer to the following section for details).

38.7.2 The Modular Approach

Gulati and Dugan [30] presented an exciting hybrid approach, called the modular approach, for the efficient analysis of both static and dynamic fault trees. It provides a combination of BDD solution for static subtrees and Markov chain solution for dynamic subtrees coupled with the detection of independent subtrees. The modular approach allows the use of Markov models for dynamic parts of a system that require them, and use of combinatorial methods for static parts of the system to retain the efficiency of combinatorial solutions where possible.

Specifically, in the modular approach, the fault tree is divided into independent subtrees (subtrees that share no input events) using a fast and efficient algorithm [56]. These independent subtrees are further identified as static or dynamic depending on the relationships between the input events. Static subtree gates express the failure criteria in terms of combinations of events. Dynamic subtree gates express the failure criteria in terms of both combinations of events and order of occurrence of input events.

As an example, the modular approach is applied to the fault tree in Figure 38.18 [57]. The fault tree is divided into four independent subtrees: two static subtrees and two dynamic subtrees, as indicated in Figure 38.18. The static subtrees can be solved using the combinatorial BDD-based method. The dynamic subtrees can be solved using the Markov chain based method.

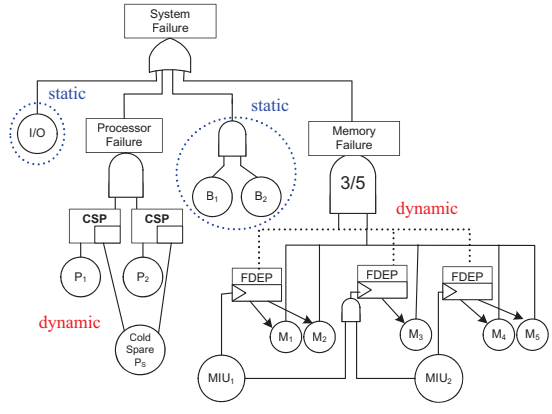

Figure 38.18. The modular approach [57]

Note that modularization is a recursive process as subtrees might themselves contain independent subtrees [30]. Solutions of various independent subtrees are integrated using a relatively straightforward and recursive algorithm to obtain the solution to the entire system.

38.8 Noncoherent FTA Techniques

38.8.1 Prime Implicants

The traditional approach to analyzing a non-coherent system is using prime implicants in the place of minimal cutsets [58]. A prime implicant in a fault tree is a minimal set of basic events whose occurrence or non-occurrence leads to the occurrence of the TOP event (system being unavailable). Similar to the FTA using cutsets, either I–E or SDP method can be applied to obtain the system unavailability based on prime implicants. We use two examples to illustrate the prime implicant based method for the analysis of noncoherent fault trees.

In the first example, we consider a noncoherent fault tree containing an Exclusive OR gate with two inputs: x and y. There are two prime implicants: $I_1 = \{x, \bar{y}\}$ and $I_2 = \{\bar{x}, y\}$. Applying the I-E method, we obtain the expression of system unavailability as:

$$\begin{aligned} \Pr(I_1 \cup I_2) &= \Pr(I_1) + \Pr(I_2) - \Pr(I_1 I_2) \\ &= \Pr(x\bar{y}) + \Pr(\bar{x}y) - \Pr(x\bar{y}\bar{x}y) \\ &= \Pr(x)\Pr(\bar{y}) + \Pr(\bar{x})\Pr(y) - 0 \\ &= \Pr(x)(1-\Pr(\bar{y})) + (1-\Pr(\bar{x}))\Pr(y) \end{aligned} \tag{38.6}$$

Note that $\Pr(I_1 I_2)$ is zero since $I_1 I_2$ contains disjoint events: x and $\bar{x}$; y and $\bar{y}$.

In the second example, we consider the traffic light system used at the crossing of two mono-directional roads (Figure 38.19) [14, 59]. Assume the light functions properly and is RED for road 1 and GREEN for road 2. We define three basic events: event a –car A fails to stop; event b – car B fails to stop; and event c – car C fails to continue. The system has three prime implicants:

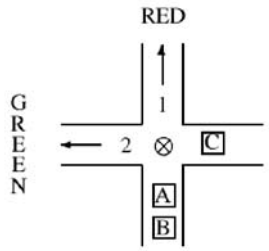

Figure 38.19. Traffic light system

- $I_1 = \{a, \bar{c}\}$: the accident occurs when car *A* fails to stop (*a*) and car *C* moving towards road 2 is crossing ($\bar{c}$);
- $I_2 = \{\bar{a}, b\}$: the accident occurs when car *A* acts properly and stops ($\bar{a}$) and car *B* fails to stop (*b*);
- $I_3 = \{b, \bar{c}\}$: the accident occurs when car *B* fails to stop (*b*) and car *C* continues through the light ($\bar{c}$), no matter what car *A* does.

Define the probability of an event *a* occurring as q_a, and not occurring as p_a. Applying the I–E method, the expression for computing the occurrence probability of an accident is:

$$\begin{aligned}
&\Pr(I_1 \cup I_2 \cup I_3) \\
&= \Pr(I_1) + \Pr(I_2) + \Pr(I_3) - \Pr(I_1 I_2) - \Pr(I_1 I_3) \\
&\quad - \Pr(I_2 I_3) + \Pr(I_1 I_2 I_3) \\
&= \Pr(a\bar{c}) + \Pr(\bar{a}b) + \Pr(b\bar{c}) - 0 - \Pr(a\bar{c}b\bar{c}) \\
&\quad - \Pr(\bar{a}bb\bar{c}) + 0 \\
&= q_a p_c + p_a q_b + q_b p_c - q_a q_b p_c - p_a q_b p_c
\end{aligned} \tag{38.7}$$

38.8.2 Importance Measures

Considerable research efforts have been expended in the component importance analysis for coherent systems and many different importance measures have been proposed for coherent system analysis [4, 60, 61]. However, these measures cannot be directly applied to the analysis of noncoherent systems. In [62, 63] it was proposed to extend four commonly used importance measures for noncoherent systems: 1) Birnbaum's measure [64], 2) component criticality measure [4], 3) Fussell–Vesely measure [65], and 4) initiator and enabler measure [66]. Because Birnbaum's measure is central to the other three importance measures, we discuss it in detail in this section. Readers may refer to [63] for details on the definitions and applications of the other three measures.

Birnbaum's measure of component importance is defined as the probability that a component is critical to system failure, or the probability that the system is residing in a critical state for a component such that its failure causes the system failure [64]. Define:

- $B_i(\underline{q}) \equiv$ Birnbaum's measure of component *i*.
- $q_i(t) \equiv$ the probability that a component *i* is not working at time *t*, it can be either unreliability for a non-repairable system or unavailability for a repairable system.
- $p_i(t) \equiv$ the probability that a component *i* is working at time *t*, *i.e.*, $1 - q_i(t)$.
- $\underline{q} \equiv$ a vector of component unavailability or unreliability for all other components except *i*.
- $Q_{sys}(1_i, \underline{q}) \equiv$ the probability that the system fails with component *i* failed.
- $Q_{sys}(0_i, \underline{q}) \equiv$ the probability that the system fails with component *i* functioning.
- $Q_{sys}(t) \equiv$ the probability that the system fails at time *t*.

The Birnbaum's measure can be expressed as:

$$B_i(\underline{q}) = Q_{sys}(1_i, \underline{q}(t)) - Q_{sys}(0_i, \underline{q}(t)) = \frac{\partial Q_{sys}(t)}{\partial q_i(t)} \tag{38.8}$$

When dealing with a coherent system, the system failure can only be caused by component failures. Therefore, a component in a coherent system can only be *failure-critical*. However, when dealing with a noncoherent system, the system failure can be caused, not only by the failure of a component (referred to as an event *i*), but also by the repair of the component (referred to as event $\bar{i}$). Thus, a component in a noncoherent system can be *failure-critical* or *repair-critical*. These two criticalities must be considered separately because a component can exist in only one state at any time.

Birnbaum's measure for a noncoherent system is given by:

$$B_i(\underline{q}) = B_i^F(\underline{q}) + B_i^R(\underline{q}) \tag{38.9}$$

where $B_i^F(\underline{q})$ represents the component *failure-criticality*, specifically, the probability that the system is in a working state such that the failure of component *i* would cause the system failure; $B_i^R(\underline{q})$ represents the component *repair-criticality*, specifically, the probability that the system is in a working state such that the repair of component *i* would cause the system failure. It has been shown that the failure and repair criticalities can be calculated separately by differentiating $Q_{sys}(t)$ with respect to q_i and p_i, respectively [62]:

$$B_i^F(\underline{q}) = \frac{\partial Q_{sys}(t)}{\partial q_i(t)}, \quad B_i^R(\underline{q}) = \frac{\partial Q_{sys}(t)}{\partial p_i(t)} \tag{38.10}$$

For example, consider the traffic light system in Section 38.8.1. The system unavailability is given in (38.7): $Q_{sys}(t) = q_a p_c + p_a q_b + q_b p_c - q_a q_b p_c - p_a q_b p_c$. According to (38.10), the failure criticality and repair criticality for event *a* are:

$$B_a^F(\underline{q}) = \frac{\partial Q_{sys}(t)}{\partial q_a(t)} = p_c - q_b p_c = p_c(1-q_b) = p_c p_b$$

$$B_a^R(\underline{q}) = \frac{\partial Q_{sys}(t)}{\partial p_a(t)} = q_b - q_b p_c = q_b(1-p_c) = q_b q_c$$

According to (38.9), the Birnbaum's measure of event *a* is: $B_a(\underline{q}) = B_a^F(\underline{q}) + B_a^R(\underline{q}) = p_b p_c + q_b q_c$.

38.8.3 Failure Frequency

Perhaps, the first paper on frequency calculations of noncoherent systems is by Inagaki and Henley [58]. Their method is similar to the method proposed by Vesely for coherent system analysis [67]. For noncoherent systems, prime implicants will be used in the place of minimal cut sets for the failure frequency calculation. According to the method proposed in [58], the expected number of failures within $[t, t + \Delta t]$ is:

$$N(t,t+\Delta t) = \Pr\left\{\bigcup_{i=1}^{p}\theta_i\right\} - \Pr\left\{B\bigcup_{i=1}^{p}\theta_i\right\} \tag{38.11}$$

$$\text{where } B \equiv \bigcup_{i=1}^{p} d_i \text{ and } B\bigcup_{i=1}^{p}\theta_i \equiv B\bigcap\left(\bigcup_{i=1}^{p}\theta_i\right)$$

If Δt is small and is equivalent to the time unit, $N(t,t+\Delta t)$ is equivalent to the failure frequency denoted by $\omega(t)$. It should be noted that $\omega \equiv \omega(t) = \lim_{\Delta t \to 0} \frac{N(t,t+\Delta t)}{\Delta t}$.

Although the method proposed in [58] produces correct results for noncoherent systems, it is unnecessarily complex. The evaluation of (38.11) involves an *NP* problem within each step of another *NP* problem. Therefore, even for the simple example problem considered in [58], a complex procedure is required to solve it. In this section, we describe a simple rule-based method proposed in [59]. The method converts the expression for system unavailability *U* obtained using the calculation procedure of [58] into an expression for ω. The general form of the expression for *U* is the sum of products form: $U = \sum_{i=1}^{m} c_i T_i$, where *m* is the number of product terms, T_i is the product of component availabilities and unavailabilities, and c_i is an integer coefficient that can be negative or positive. For example, in (38.7), the terms are:

i	1	2	3	4	5
c_i	1	1	1	-1	-1
T_i	$q_a p_c$	$p_a q_b$	$q_b p_c$	$q_a q_b p_c$	$p_a q_b p_c$

Each term T_i is in the form of $q_j q_k \ldots p_m p_n$. The general form of T_i is: $T_i = \prod_{j \in F_i} q_j \prod_{k \in S_i} p_k$, where F_i and S_i are the set of component indices corresponding to the unavailability and availability terms in T_i, respectively.

The rule for converting *U* into ω is to multiply every term $c_i T_i$ with the effective rate term $R_i = \sum_{j \in F_i} \alpha_j + \sum_{k \in S_i} \beta_k$, where $\alpha_i = \frac{\omega_i}{q_i} = \frac{p_i \lambda_i}{q_i}$ and $\beta_i = \frac{\nu_i}{p_i} = \frac{q_i \mu_i}{p_i}$. If the system is in the steady-state, then $\alpha_i = \mu_i$ and $\beta_i = \lambda_i$. Refer to [59] for the proof. In simple terms, if T_i is in the form of $q_j q_k \ldots p_m p_n$, then multiply that term with $(\alpha_j + \alpha_k + \ldots + \beta_m + \beta_n)$. Hence, we have: $\omega = c_i T_i R_i$. For example, the R_i terms for (38.7) are:

i	c_i	T_i	R_i
1	1	$q_a p_c$	$\alpha_a + \beta_c$
2	1	$p_a q_b$	$\beta_a + \alpha_b$
3	1	$q_b p_c$	$\alpha_b + \beta_c$
4	-1	$q_a q_b p_c$	$\alpha_a + \alpha_b + \beta_c$
5	-1	$p_a q_b p_c$	$\beta_a + \alpha_b + \beta_c$

Therefore, the failure frequency of the traffic light system (Figure 38.19) is:

$$\omega = q_a p_c(\alpha_a + \beta_c) + p_a q_b(\beta_a + \alpha_b) + q_b p_c(\alpha_b + \beta_c) - q_a q_b p_c(\alpha_a + \alpha_b + \beta_c) - p_a q_b p_c(\beta_a + \alpha_b + \beta_c)$$

38.9 Advanced Topics

38.9.1 Component Importance Analysis

Results from fault tree reliability analysis have been key contributors to system design and tuning activities. However, reliability analysis tells only part of the story; in particular, reliability analysis gives very little information about each individual component's contribution to the entire system failure. Follow-up questions such as "How does a change in one component's reliability affect the entire system reliability?", "How can the entire system reliability be best improved given limited resources?" have to be answered. These and similar questions can be best answered using results of component importance analysis (also called sensitivity analysis) [68].

The importance analysis helps the designer to identify which components contribute most to the system reliability and thus these components would be good candidates for efforts leading to improving the entire system reliability. From the maintenance point of view, the analysis would, by means of a list, tell the repairperson in which order to check the components that may have caused the system failure. Ideally speaking, the maintenance-oriented importance analysis [61] will rank the component whose repair will hasten the system recovery the most, the highest. Section 38.8.2 presents the component importance analysis for noncoherent systems. Xing [72] considers the importance analysis of components in a generalized phased-mission system subject to modular imperfect coverage. Here, we discuss the component importance analysis in the general term.

Two classes of component importance measures have been proposed for the case where the support model is a fault tree: structural-importance (SI) measures and reliability-importance (RI) measures. The SI measures assess the importance of a component to the system operation or reliability by virtue of its position in the fault tree structure, without considering the reliability of the component [70]. Thus, they can be used even if the component reliability is unknown or subject to changes. However, the SI measures cannot distinguish between components that occupy similar structural positions but have drastically different component reliabilities. On the other hand, the RI measures consider both the position of the component in the system and the reliability of the component in question. Thus, the RI measures can generally provide more useful information for generating the ranked list than the SI measures.

Xing [61] studied seven different RI measures, including conditional probability (CP) [71], risk achievement worth (RAW) [60], risk reduction worth (RRW) [60, 70], diagnostic importance factor (DIF), Birnbaum's measure (BM) [4], the criticality importance factor (CIF) [4], and the improvement potential (IP). Refer to [61] for their mathematical definitions as well as physical interpretations. The study in [61] compared the performance of these measures in assisting the system design and maintenance activities. Results of the study show that CP, RAW, and BM may induce misleading conclusions in terms of guiding the system maintenance, though some of these measures serve a good indicator for selecting components that are the best candidates for efforts leading to improving the entire system reliability. RRW, CIF, and IP generally induce reasonable conclusions. However, they give the same importance result for all components in a parallel structure irrespective of the (drastic) difference among the component reliabilities. In addition, the CIF and IP measures become impractical for large dynamic systems because they must be solved using Markov approaches which suffer from the

well-known state explosion problem. Furthermore, the computation of both CIF and IP measures involves the assessment of BM measure that involves simultaneously solving a set of differential equations (the number of equations is the same as the number of states present in the Markov model) for the state occupation probabilities and a much larger set of partial differential equations for the component importance analysis [73]. The solutions to those equations are computationally intensive.

Based on the experimental results obtained in [61], the DIF measure is the most informative and appropriate measure for the maintenance-oriented importance analysis among the nine measures. The DIF measure generally produces the ranking that is consistent with those produced by using the RRW, CIF, and IP measures; it accounts for the effects of exceptionally unreliable component; it can always distinguish components that occupy similar structural positions (for both series and parallel structures) but have different reliabilities.

38.9.2 Common Cause Failures

Common cause failures (CCF) are multiple dependent component failures within a system that are a direct result of a shared root cause or common cause (CC), such as sabotage, flood, earthquake, lightening, power outage, sudden changes in environment, design weaknesses, or human errors. According to [74], CCF are defined as "A subset of dependent events in which two or more component fault states exist at the same time, or in a short time interval, and are direct results of a shared cause." CCF typically occur in systems designed with redundancy techniques, which are characterized by the use of *s*-identical components [75]. It is critical to consider CCF in the system reliability analysis because failure to consider CCF can lead to overestimated system reliability [76, 77].

Considerable research efforts have been expended in the study of CCF for the system reliability modeling and analysis. However, most of these CCF models suffer from various limitations, such as being concerned with a specific system structure [78, 79]; applicable only to systems with exponential time-to-failure distributions [80–82]; being subject to combinatorial explosion as the redundancy level of the system increases [83, 84]; limiting analysis to components being affected by at most a single common-cause [75, 77]; having a single CC that affects all components of a system [79, 85]; or defining CC as being *s*-independent or mutually exclusive [86]. Xing [39] proposed a generic CCF model that addressed these restrictions of the existing CCF models in the reliability analysis of computer network systems by allowing for multiple CC that can affect different subsets of system components, and which can occur *s*-dependently.

Xing [87] utilized the generalized CCF model of [39] and incorporated this CCF model into dynamic fault trees using a new dynamic gate, called CCF gate, for the reliability analysis of hierarchical systems subject to CCF. Moreover, an efficient decomposition and aggregation (EDA) approach was proposed for incorporating CCF into the reliability analysis of hierarchical systems. The basic idea of the EDA approach is to decompose an original reliability problem into a number of reduced reliability problems according to the total probability theorem. The effects of CCF are factored out through the reduction. The reduced problems are represented in a dynamic fault tree model by the CCF gate, which is modeled after the FDEP gate [8]. These reduced problems can be solved using any reliability evaluation approaches that ignore CCF; for example, an efficient one is the BDD based method (Section 38.6.2). The final reliability measure is obtained by aggregating the results of each reduced problem.

Specifically, the EDA approach can be applied in the following three steps:

Step 1: Building common-cause event (CCE) space. Assume the system is subject to *m* common-causes (CC). The *m* CC partition the event space into the 2^m disjoint subsets, each called a CCE:

$$CCE_1 = \overline{CC_1} \cap \overline{CC_2} \cap \ldots \cap \overline{CC_m},$$
$$CCE_2 = CC_1 \cap \overline{CC_2} \cap \ldots \cap \overline{CC_m},$$
$$\ldots\ldots,$$
$$CCE_{2^m} = CC_1 \cap CC_2 \cap \ldots \cap CC_m.$$

A space called "CCE space" (denoted by Ω_{CCE}) is built over this set of collectively exhaustive and mutually exclusive CCE that can occur in the system, *i.e.*, $\Omega_{CCE} = \{CCE_1, CCE_2, ..., CCE_{2^m}\}$. If $\Pr(CCE_j)$ denotes the occurrence probability of CCE_j, then we have $\sum_{j=1}^{2^m} \Pr(CCE_j) = 1$ and $CCE_i \cap CCE_j = \phi$ for any $i \neq j$. Define a common-cause group (CCG) as a set of components that are cause to fail due to the same elementary CC. Let S_{CCE_i} denote the set of components affected by CCE_i, then S_{CCE_i} is simply the union of CCG whose corresponding CC occur. For example, define $CCE_i = \overline{CC}_1 \cap \overline{CC}_2 \cap CC_3$ as a CCE in a system with three elementary CC; S_{CCE_i} is then equal to CCG_3 because CC_3 is the only active elementary CC. For another example, consider $CCE_j = \overline{CC}_1 \cap CC_2 \cap CC_3$, S_{CCE_i} is then equal to $CCG_2 \cup CCG_3$ because both CC_2 and CC_3 are active elementary CC.

Step 2: Generating and solving reduced problems. Based on the CCE space built in step 1 and the total probability theorem, the system unreliability can be calculated as:

$$U_{sys} = \sum_{i=1}^{2^m} [\Pr(\text{system fails} \mid CCE_i) \bullet \Pr(CCE_i)] = \sum_{i=1}^{2^m} [U_i \bullet \Pr(CCE_i)] \quad (38.12)$$

As defined in (38.12), U_i is a conditional probability that the system fails conditioned on the occurrence of CCE_i. The evaluation of U_i is actually a reduced reliability evaluation problem in which the set of components affected by CCE_i do not appear. Specifically, in the system DFT model, each basic event (the failure of a component) that appears in S_{CCE_i} will be replaced by a constant logic value "1" (*true*). After the replacement, a Boolean reduction can be applied to the system DFT to generate a simpler DFT in which all the components of S_{CCE_i} do not appear. Most importantly, the evaluation of the reduced DFT can proceed without further consideration of CCF. The studies in [87] showed that most of DFT after reduction become trivial to solve. In addition, given the fact that systems are usually subject to a small number (m) of root common causes, and considering the parallel processing capability of modern computing systems, even though there are 2^m reduced problems involved in the EDA approach, the overall solution complexity is still low.

Step 3: Integrating for the final result. After obtaining the results for all the reduced problems in (38.12), we integrate them with the occurrence probabilities of CCE, *i.e.*, $\Pr(CCE_i)$ to obtain the final unreliability of the system subject to CCF.

Advantages offered by the EDA approach include: 1) it enables the analysis of multiple CC that can affect different subsets of components within the system, and which may occur *s*-dependently; 2) it allows reliability engineers to use their favorite software package that ignores CCF for computing reliability, and adjust the input and output of the program slightly to produce the system reliability considering CCF. Due to the separation of CCF from the solution combinatorics, the EDA approach has higher computational efficiency and is easier to implement than other potential methods such as Markov methods, which can accommodate CCF by expanding the state space and number of transitions, worsening the state explosion problem [30].

38.9.3 Dependent Failures

In FTA, a common assumption made is that all system components fail independently. However, this is not necessarily true in practical systems. CCF and failure dependence described in the FDEP gate are two examples of dependent failures.

In general, there are two types of dependencies: *positive dependence* and *negative dependence* [4]. *Positive dependence* occurs if the failure of one component leads to an increased tendency for another component to fail. For example, when several components share a common load, the failure of one component may lead to an increased load on the remaining components and thus may

lead to an increased likelihood of failure. N*egative dependence* occurs if the failure of a component leads to a reduced tendency for another component to fail. For example, if an electrical fuse fails open such that downstream circuit is disconnected, the load on the electrical devices in this circuit is removed and thus their likelihood of failure is reduced.

In probability theory, we say that two events E1 and E2 are independent if $Pr(E1 \cap E2) = Pr(E1) \cdot Pr(E2)$ or $Pr(E1|E2) = Pr(E1)$ and $Pr(E2|E1) = Pr(E2)$, meaning that the occurrence of one event has no influence on the occurrence of the other event. A component has a positive dependence when $Pr(E1|E2) > Pr(E1)$ and $Pr(E2|E1) > Pr(E2)$, such that $Pr(E1 \cap E2) > Pr(E1) \cdot Pr(E2)$. A component has a negative dependence when $Pr(E1|E2) < Pr(E1)$ and $Pr(E2|E1) < Pr(E2)$, such that $Pr(E1 \cap E2) < Pr(E1) \cdot Pr(E2)$.

Besides CCF discussed in Section 38.9.2 and functional dependence discussed in Section 38.4.2.1, another type of dependent failure we would like to briefly mention here is cascading failures, also called propagating failures. According to [4], cascading failures are "multiple failures initiated by the failure of one component in the system that results in a chain reaction or domino effect." Cascading failures are common in power grids when one of the elements fails (completely or partially) and shifts its load to nearby elements in the system. Those nearby elements are then pushed beyond their capacity so they become compromised and shift their load onto other elements [88]. Cascading failures may be modeled and analyzed by event trees and fault trees.

38.9.4 Disjoint Events

Disjoint events, also referred to as mutually exclusive events, are events that cannot occur at the same time. For example, two failure modes of a relay: "stuck-open" and "stuck-closed" cannot occur simultaneously. This event dependence can be easily modeled using Markov chains. However, due to the well-known state explosion problem, the Markov chain solution is only practical for small systems. Another alternative is to approximate the mutually exclusive events in a fault tree by stochastically independent events. Thus cutsets containing more than one of mutually exclusive events can occur, leading to incorrect quantitative reliability evaluation, although the errors are usually insignificant. Twigg *et al*. [19] proposed an accurate method to model the mutually exclusive events by converting each of the mutually exclusive events to a subtree that is constructed from ordinary and stochastically independent events as well as logic AND, OR, and NOT gates. Next, we review the basics of the approach through an example fault tree with two disjoint events from [19].

Consider the fault tree in Figure 38.20. Events D1 and D2 are two disjoint events representing two disjoint failure modes of a component D. B and C represent two independent component failure events. Figure 38.20 actually models the two disjoint failure events as independent events, which means that the two failure events D1 and D2 may occur at the same time, leading to errors in reliability calculation. This can also be seen from the cutsets generation.

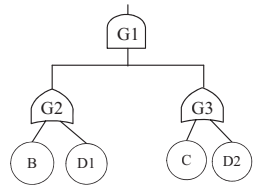

Figure 38.20. Fault tree without modeling disjoint

Apply the top-down approach described in Section 38.5.1, we obtain the minimal cutsets for this fault tree as: {D1, C}, {D2, B}, {B,C}, and {D1, D2}. The minimal cutset {D1, D2} representing the simultaneous occurrence of the two disjoint failure events appears because the dependence between those two events has not been modeled in the fault tree analysis. In the solution of [19], each disjoint event in the original fault tree will be replaced with a disjoint subtree as shown in Figure 38.21.

Specifically, the basic event D1 is replaced with a subtree encoding the Boolean expression of $D1=A \cap A1$, and D2 is replaced with a subtree encoding the Boolean expression of $D2=A \cap \overline{A1}$, where A and A1 are independent arbitrary events

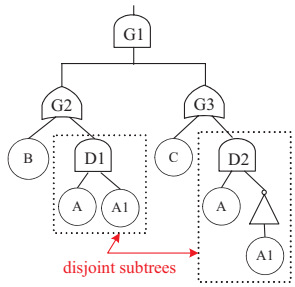

Figure 38.21. Fault tree with modeling of disjoint dependence using disjoint subtrees

and $A = D1 \cup D2$. The minimal cutsets, more accurately, the prime implicants, generated from the new fault tree (Figure 38.21): {B, C}, {A, A1, C}, {A, $\overline{A1}$, B} will be used in the system reliability calculation. Note that the set {A, A1, $\overline{A1}$} was also generated from the top-down approach, but since both A1 and $\overline{A1}$ occur in this set, this set can be automatically removed in the cutset generation.

In general, give a set of *n* mutually exclusive events {D_1, D_2, …, D_n}, each event D_i with probability of π_i. To construct *n* disjoint subtrees with the equivalent occurrence probability π_i, we introduce *n* stochastically independent events: {A, A_1, …, A_{n-1}}, where $A = \bigcup_{i=1}^{n} D_i$, and {$A_1$, …, A_{n-1}} are arbitrary events. The disjoint sets {D_1, D_2, …, D_n} are constructed by subdividing A using A_1, …, A_{n-1} consecutively:

$$
\begin{aligned}
&D_1 = A \cap A_1,\\
&D_2 = A \cap \overline{A_1} \cap A_2,\\
&\ldots\ldots,\\
&D_{n-1} = A \cap \overline{A_1} \cap \ldots \cap \overline{A_{n-2}} \cap A_{n-1},\\
&D_n = A \cap \overline{A_1} \cap \ldots \cap \overline{A_{n-2}} \cap \overline{A_{n-1}}.
\end{aligned}
$$

In particular, the value of *n* is 2 for the example fault tree in Figure 38.20. In general, each disjoint event D_k is converted to a subtree encoding the Boolean function of $D_k = A \cap \overline{A_1} \cap \ldots \cap \overline{A_{k-1}} \cap A_k$. Apparently, the subtree requires one AND gate and (*k*-1) NOT gates. To decrease the number of gates, Morgan's law is applied to D_k:

$$
\begin{aligned}
D_k &= A \cap (\overline{A_1} \cap \ldots \cap \overline{A_{k-1}}) \cap A_k\\
&= A \cap \overline{(A_1 \cup A_2 \cup \ldots \cup A_{k-1})} \cap A_k
\end{aligned}
$$

which requires only three gates: one AND gate, one OR gate, and one NOT gate.

To ensure the subtrees have the same occurrence probabilities as the corresponding disjoint events, Twigg *et al.* [19] derived the probabilities of each independent event in the set {A, A_1, …, A_{n-1}} as:

$$\alpha = \Pr(A) = \Pr(\bigcup_{i=1}^{n} D_i) = \sum_{i=1}^{n} \Pr(D_i) = \sum_{i=1}^{n} \pi_i,$$

$$p_1 = \Pr(A_1) = \frac{\pi_1}{\alpha},$$

$$p_2 = \Pr(A_2) = \frac{\pi_2}{\alpha(1-p_1)} = \frac{\pi_2}{1-\pi_1},$$

……

$$p_k = \Pr(A_k) = \frac{\pi_k}{\pi_{k-1}}\left\{\frac{p_{k-1}}{1-p_{k-1}}\right\} = \frac{\pi_k}{\alpha - \sum_{j=1}^{k-1}\pi_j}.$$

These probabilities are used in the quantitative evaluation of the system unreliability using prime implicants method (Section 38.8.1).

38.9.5 Multistate Systems

A multistate system is a system in which both the system and its components may exhibit multiple performance levels (or states) varying from perfect operation to complete failure [89]. Examples abound in real applications such as communication networks, computer systems, circuits, power systems, and fluid transmission systems [36, 42, 90, 91]. Analyzing the probability of the system being in each state, and thus the reliability of a multistate system is essential to the design and tuning of dependable multistate systems. The difficulty and challenge in analysis arise from the non-binary state property of the system and its components.

Due to the wide use of fault tree in the analysis of systems in other applications, the traditional fault trees have been adapted to model and analyze multistate systems. And the adapted fault trees are called multistate fault trees (MFT) [42]. Similar to the traditional fault tree, a MFT provides a mathematical and graphical representation of the

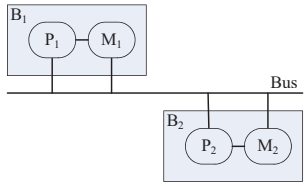

Figure 38.22. An example multistate system

combination of events that can cause the system to occupy a specific state. The quantitative analysis of MFT will be used to determine the probability of system being in that specific state, given the occurrence probabilities of basic events. Each basic event in the MFT represents a component being in a specific state. Also, each MFT consists of a top event representing the system being in a state S_j. The top event is resolved into a combination of events that can cause the occurrence of S_j by means of AND, OR, and *K*-out-of-*N* logic gates.

As an example, consider a multistate computer system that consists of two boards B_1 and B_2 (Figure 38.22) [42]. Each board has a processor and a memory. The two memories (M_1 and M_2) can be shared by both processors (P_1 and P_2) through a common bus. Each board can be considered as a single component with four mutually exclusive and complete states: $B_{i,4}$ (both P and M are functional), $B_{i,3}$ (M is functional, but P is down), $B_{i,2}$ (P is functional but M is down), and $B_{i,1}$ (both P and M are down). Note that $B_{i,j}$ represent the board B_i being in state j, where $i = 1, 2$ and $j = 1, 2, 3, 4$. The entire computer system has three states, which are defined as: S_3 (at least one processor and both memories are functional), S_2 (at least one processor and exactly one memory are functional), and S_1 (no processor or no memory is functional). For illustration purpose, Figure 38.23 shows the MFT for the computer system being in state S_3. Clearly, the system is in state S_3 if the board B_1 is in state 4 and the board B_2 is in state 3 or state 4; or if the board B_1 is in state 3 and the board B_2 is in state 4.

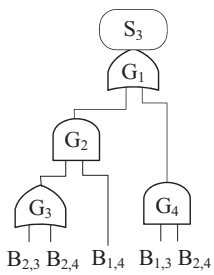

Figure 38.23. MFT of the example system in S_3

Various approaches have been proposed for the analysis of multistate systems; examples include universal moment generating function based methods [91], BDD based methods [38, 42, 92], and MDD based methods [50–52]. Note that among the work, the methods proposed in [38, 50, 51, 92] can only apply to the analysis of multistate systems with multiple failure modes along with a single operational mode, for example, systems subject to imperfect coverage. They cannot directly apply to the general multistate systems, which may contain the states of perfect operation and complete failure, as well as multiple degraded performance levels between those two states. The details of all those approaches for multistate system analysis are outside the scope of this chapter. Readers may refer to the references indicated above for more details.

38.9.6 Phased-mission Systems

A phased-mission system (PMS) is a system used in the mission characterized by multiple, consecutive, and non-overlapping operational phases [38]. During each mission phase, the system has to accomplish a specified task. Since the tasks may differ from phase to phase, the system may be subject to different stresses as well as different reliability requirements. Thus, system configuration, success/failure criteria, and component failure parameters may also change from phase to phase. In the fault tree analysis, the representation of structure functions of a PMS usually requires multiple different fault trees, one for each phase. Further complicating analysis are the statistical dependencies that exist across the phases for a given component

Extensive research has been conducted in the reliability analysis of PMS [38, 41, 46, 51, 72, 92]. Similar to the fault tree analysis methods for non-PMS (Section 38.5.2), the PMS analysis approaches can be classified into three groups: state space oriented approaches based on Markov

chains and/or Petri nets, combinatorial methods, and a modular approach. Readers may refer to Chapter 23 for a state-of-the-art review of these various phased-mission analysis techniques.

38.10 FTA Software Tools

Various software tools have been developed based on the fault trees models. NUREG-0492 [2] summarized available computer software for fault tree analysis and categorized them into five groups. Most of the software codes described in NUREG-0492 were developed in 1970s. In this section, we introduce two software tools that are commonly used by industries and academic research: Galileo dynamic fault tree analysis tool [93] and Relex fault tree analysis software [12]. For details on other available software packages, refer to [94].

Galileo is a dynamic fault tree modeling and analysis tool developed at the University of Virginia [93, 95]. Galileo combines the innovative dynamic fault tree analysis methodology, *i.e.,* the modular approach (Section 38.7.2) with a rich user interface built using package-oriented programming. The important modeling and analysis features of Galileo include: 1) automatic modularization of fault trees and independent solution of modules: efficient BDD based method for static subtrees and Markov chains for dynamic subtrees; 2) multiple time-to-failure distributions (fixed probability, exponential, lognormal, Weibull); 3) imperfect fault coverage modeling in both static and dynamic subtrees; 4) phased mission modeling and analysis; and 5) component importance analysis, *i.e.* sensitivity analysis.

Relex fault tree analysis software [12] supports both quantitative and qualitative analyses, providing computation flexibility based on users' requirements. Relex fault tree analysis tool can compute system unreliability, unavailability, failure frequency, and the number of failures. In addition, it incorporates a minimal cutset (MCS) engine that can quickly determine the minimal cutsets and support interactive, on-screen cutset highlighting. It is the only commercial software package that supports the exact analysis of dynamic fault trees. Relex fault tree analysis tool also supports Lambda-Tau calculations, various importance measures, and noncoherent fault trees.

Common Cause Failure Modeling: Status and Trends

Per Hokstad[1] and Marvin Rausand[2]

[1] SINTEF, Technology and Society, NO 7465 Trondheim, Norway
[2] Department of Production and Quality Engineering, Norwegian University of Science and Technology, NO 7491 Trondheim, Norway

Abstract: This chapter presents a status of common cause failure (CCF) modeling. The well known beta-factor model is still the most commonly used CCF model. The strengths and limitations of this model are therefore outlined together with approaches to establish plant specific beta-factors. Several more advanced CCF models are also described with a special focus on the new multiple beta-factor model. Problems relating to data availability and estimation of the unknown parameters of the various models are discussed, and ideas for further research are suggested.

39.1 Introduction

Reliability modeling of common cause failures (CCF) was introduced in the nuclear power industry more than 30 years ago [1]. This industry has had a continuous focus on CCF, and has been in the forefront regarding development of CCF models, and on collection and analysis of data related to CCF. The aviation industry has also given these failures close attention. The Norwegian offshore industry has for some 20 years focused on CCF related to reliability assessment of safety instrumented systems (SIS) [2].

More recently, the IEC 61508 [3] standard points at the need to control CCF in order to maintain the safety integrity level (SIL) of safety functions. The standard suggests a method to calculate the probability of failure on demand (PFD) where the contribution of CCF is modeled by the well known beta-factor model.

The objective of this chapter is to present the current status concerning modeling and analysis of CCFs in risk and reliability analyses.

The chapter is structured as follows. In Section 39.1 we give an introduction to CCF and define CCF and related concepts. In Section 39.2 we present and discuss various ways of classifying CCFs and introduce the concepts of root causes and coupling factors. Section 39.3 presents the status related to modeling of CCF with a main focus of the beta-factor model together with challenges and extensions of this model. Various approaches to determine a plant specific beta-factor are outlined. A new extension of the beta-factor model, the multiple beta-factor model, is introduced and discussed. In Section 39.4 we present data sources and methods for estimating the parameters of the models presented in Section 39.3. Concluding remarks and suggestions for further research are presented in Section 39.5.

39.1.1 Common Cause Failures

When components of a system fail, the failures cannot always be considered as independent events. We may distinguish between two main types of dependence: *positive* and *negative*. If a failure of one component leads to an increased tendency for another component to fail, the dependence is said to be positive. If, on the other hand, the failure of one component leads to a reduced tendency for another component to fail, the dependence is called negative.

In reliability applications, positive dependence is usually the most relevant type of dependence. Negative dependence may, however, occur in practice. Consider, for example, two components that influence each other by producing vibrations or heat. When one component is "down" for repair, the other component will have an improved operating environment, and its likelihood of failure is reduced.

Consider a system of two components, 1 and 2. Let A_i denote the event that component i is in a failed state $(i = 1, 2)$. One way of formulating dependence stems from the idea that the components are susceptible to some common stress that causes simultaneous failures. When this common stress occurs, the event "A_1 and A_2" is referred to as a CCF event. The CCF event may be due to several types of dependencies, for example:

- Physical dependencies
- Functional dependencies
- Location/environmental dependencies
- Plant configuration related dependencies
- Human dependencies

There is no generally accepted definition of CCF. This implies that people in different industry sectors may have different opinions of what a CCF event is. Smith and Watson [4] review nine different definitions of CCF and suggest that a definition of CCF must encompass the following six attributes:

1. The components affected are unable to perform as required.
2. Multiple failures exist within (but not limited to) redundant configurations.
3. The failures are "first in line" type of failures and not the result of cascading failures.
4. The failures occur within a defined critical time period (*e.g.*, the time a plane is in the air during a flight).
5. The failures are due to a single underlying defect or a physical phenomenon (the common cause of failures).
6. The effect of failures must lead to some major disabling of the system's ability to perform as required.

In the nuclear power industry a CCF event is defined as "a dependent failure in which two or more component fault states exist simultaneously, or within a short time interval, and are a direct result of a shared cause" [5].

In the space industry a CCF event is defined as "the failure (or unavailable state) of more than one component due to a shared cause during the system mission" [6].

39.1.2 Explanation

The term CCF implies the existence of a cause-effect relationship that links the CCF event to some cause. Such a relationship is not, however, reflected in most of the CCF models that are presented later in this chapter [7].

A crucial question when using the definitions of CCF is how to interpret the term *simultaneous*. It is obvious that there can be a strong dependence even if the failures do not occur at the same time. In the NASA definition [6], a multiple failure is classified as a CCF event if the failures occur during the same mission. Such a mission may last a long period of time. In the aviation industry the term CCF is used for multiple failures during the same flight. For safety instrumented systems [3] the main functional failures are often *hidden* and can only be detected during periodic function tests. In this case, it seems natural to classify a multiple failure as a CCF if failures of redundant components occur within the same test interval. The test interval may be several months and even years. When multiple failures are detected during a test, it is not straightforward to decide whether the

failures have occurred due to the same cause, or whether they have occurred at the same time. Consider, for example, a number of fire detectors that are installed in the same room. The detectors are sensitive to humidity and will tend to fail if the humidity in the room increases above a certain level. If the humidity becomes too high, the detectors will deteriorate and fail, but *not* necessarily at the same time. The failures may be spread out over a rather long period of time. When the detectors are checked in the periodic test, the problem will likely be detected and both the failed and the deteriorated detectors will be replaced.

Whether or not the multiple failures that are detected in the test represent a true CCF event must be decided on the basis of a thorough investigation of the causes of the component failures.

Due to lack of information it may be difficult to decide whether or not the failures had the same cause. In practice, the term CCF is therefore often used synonymously with *multiple* failure.

However, a single failure can actually be seen as a CCF. The common cause may, for example, be erroneous maintenance or environmental stresses (*e.g.,* vibration, high temperature or high humidity). These causes may lead to failures of different multiplicities. Following this argument, a common cause may lead to just one component failing, thus a CCF of multiplicity one is also possible.

Often, it is most simple to use the term CCF synonymously with multiple failures that occur close in time. We should, avoid classifying a multiple failure due to joint occurrence of independent failures as a CCF. The classification should be based on the cause of the failures.

39.2 Causes of CCF

Many authors find it useful to split CCF causes into *root causes* and *coupling factors* [8, 9]. A root cause is a basic cause of a component failure (*e.g.*, a corrosive environment), while a coupling factor explains why several components are affected by the same root cause (*e.g.*, inadequate material selection for several valves).

39.2.1 Root Causes

A *root cause* of a failure is the most basic cause that, if corrected, would prevent recurrence of this and similar failures. There is often a series of causes that can be identified, one leading to another. This series of causes should be pursued until the fundamental, *correctable* cause has been identified [10]. The concept of root cause is tied to that of *defense*, because there are, in many cases, several possible corrective actions *(i.e.*, defenses) that can be taken to prevent recurrence. Knowledge about root causes allows system designers to incorporate countermeasures for reducing the susceptibility to both single failures and CCFs.

A number of studies have investigated the root causes of CCF events, and several classification schemes have been proposed and used to categorize these events. Tables 39.1–39.3 (adapted from [9]) show root causes of CCF events arranged in a hierarchy. Thus, the hierarchy starts with those causes that are introduced during the design phase and proceeds through the manufacturing, construction, installation, and commissioning phases. Root causes introduced during plant operation, maintenance or due to the environment are given in Tables 39.1 and 39.2. Several other taxonomies of root causes have also been proposed, (*e.g.*, see [5, 10, 11]). Several studies of CCFs in complex systems have shown that the majority of the root causes are related to human actions and procedural deficiencies. A study of centrifugal pumps in nuclear power plants indicates that the root causes of about 70% of all CCFs are of this category [12].

In practice, root causes of component failures can seldom be determined from failure cause descriptions. CCF root causes have to be identified through root cause analyses, supported by check-lists of generic root causes [10]. The description of a CCF in terms of a single root cause is in many cases too simplistic [8]. Cooper *et al.* [13] advocate using the concept of common failure mechanism instead of root cause to cater for multiple root causes.

Table 39.1. Root causes of CCF events (design, manufacturing, construction, installation and commissioning)

Cause type	Examples of specific cause
Design requirements and specifications inadequacy	Designer failure to predict an accident
	Designer failure to recognize what protective action is needed
Design error or inadequacy in design realization	Inadequate facilities for operation, maintenance, testing or calibration
	Inadequate components
	Inadequate quality assurance
Design limitations	Financial
	Spatial
Manufacturing error or inadequacy	Failure to follow instructions
	Inadequate manufacturing control
	Inadeqaute inspection
	Inadequate testing
Construction/installation/commissioning	Failure to follow instructions
	Inadequate construction control
	Inadequate inspection
	Inadequate testing

39.2.2 Coupling Factors

A *coupling factor* is a property that makes multiple components susceptible to failure from a single shared cause. Such properties include:

- Same design
- Same hardware
- Same software
- Same installation staff
- Same maintenance or operation staff
- Same procedures
- Same environment
- Same location

Table 39.2. Root causes of CCF events (operation)

Cause type	Examples of specific cause
Lack of procedures	Lack of repair procedures
	Lack of test or calibration procedures
Defective procedures	Defective repair procedures
	Defective test or calibration procedures
Failure to follow procedures	Failure to follow repair procedures
	Failure to follow test or calibration procedures
Supervision inadequacy	Inadequate supervisory procedures
	Inadequate action or supervisory communication
Communication problems	Communication among maintenance staff
Training inadequacy	Operator training in handling emergency situations

Table 39.3. Root causes of CCF events (environmental)

Cause type	Examples of specific cause
Stresses	Chemical reactions (corrosion)
	Electrical failure
	Electromagnetic interference
	Materials interaction (erosion)
	Moisture
	Pressure
	Radiation
	Temperature
	Vibration
Energetic	Earthquake
	Fire
	Flood
	Impact loads

A more detailed taxonomy of coupling factors is given in [5, 14, 15]. Studies of CCFs in nuclear power plants indicate that the majority of coupling factors contributing to CCFs are related to operational aspects [12].

To save money and ease operation and maintenance, the technical solutions in many industries become more and more standardized. This applies both to hardware and software and increases the presence of coupling factors. Sintef, a Norwegian research organization, has recently carried out several studies of the impacts of this type of standardization on Norwegian offshore oil and gas installations, where new operational concepts and reduced manning levels are feeding this trend [16].

Two different approaches can be applied to the modeling of CCFs, an *explicit* method and an *implicit* method. Assume that a specific cause of CCF can be identified and defined. By the explicit method, this cause of dependency is included into the system logic models, for example as a basic event in the fault tree model, or as a functional block in a reliability block diagram [17, 18]. Explicit causes may also be included in event trees. Examples of causes that may be modeled explicitly are:

- Human errors
- Utility failures (*e.g.,* electricity, cooling, heating)
- Environmental events (*e.g.,* earthquakes, lightning)

Some causes of dependencies are difficult or even impossible to identify and model explicitly. These are called *residual* causes and are catered for in a so-called implicit model. The residual causes cover many different root causes and coupling factors, such as common manufacturer, common environment, and maintenance errors. There are so many causes that an explicit representation of all of them in a fault tree or an event tree would be unmanageable.

When establishing the implicit model, it is important to remember which causes were covered in the explicit model, so that they are not counted twice. For small system modules it may be possible to use Markov techniques to model both explicit and implicit causes. This is not pursued further in this chapter. See, for example, chapter 8 of [18] for a further treatment of this topic.

Modeling and analysis of CCF as part of a risk or reliability study should, in general, comprise at least the following steps (see also [11, 19]):

1. *Development of system logic models*: This activity comprises system familiarization, system functional failure analysis, and establishment of system logic models (*e.g.*, fault trees, reliability block diagrams, and event trees).
2. *Identification of common cause component groups*: The groups of components for which the independence assumption is suspected not to be correct are identified.
3. *Identification of root causes and coupling factors:* The root causes and coupling factors are identified and described for each common cause component group. Suitable tools are checklists and root cause analysis.
4. *Assessment of component defenses:* The common cause component groups are evaluated with respect to their defenses against the root causes that were identified in the previous step.
5. *Explicit modeling*: Explicit CCF causes are identified for each common cause component group and included into the system logic model.
6. *Implicit modeling*: Residual CCF causes that were not covered in the previous step are included in an implicit model as discussed later in this section. The parameters of this model have to be estimated based on checklists (*e.g.*, IEC 61508 [3] part 6) or from available data.
7. *Quantification and interpretation of results*: The results from the previous steps are merged into an overall assessment of the system. The step will also cover importance, uncertainty, and sensitivity analyses – and reporting of results.

In most cases, we will not be able to find high quality input data for the explicitly modeled CCF causes. However, even with low-quality input data, or guesstimates, the result will usually be more accurate than by including the explicit causes into a general (implicit) CCF model.

The CCF models that are discussed in the rest of this section are limited to cover implicit causes of CCF.

39.2.3 The Beta-factor Model and its Generalizations

The *beta-factor model* was introduced by Fleming [20] in 1975 and is still the most popular CCF model. The beta-factor model may be explained by the following simple example: Consider a system of n identical components each with a constant total failure rate λ. In the following these identical components are referred to as *channels*. Given that a specific channel has failed, this failure will, with probability β, cause all the n channels to fail, and with probability $1-\beta$, just involve the given channel. The system will then have a CCF rate $\lambda_C = \beta\lambda$, where all n channels fail. In addition, each channel has a rate of independent failures, $\lambda_I = (1-\beta)\lambda$. The total failure rate of a channel may be written as $\lambda = \lambda_I + \lambda_C$.

The beta-factor model may also be regarded as a *shock model* where shocks occur randomly according to a homogeneous Poisson process with rate λ_C. Each time a shock occurs, all the channels of the system fail, irrespective of the status of the channels. Each channel may hence fail due to two independent causes; shocks and channel specific (individual) causes. The rate λ_I is sometimes called the rate of *individual* failures.

The parameter β can be interpreted as the mean fraction of all failures of a channel that also affect all the other channels of the system.

When a failure occurs, the *multiplicity* of the failure event is either one or n. Intermediate values of the multiplicity are not possible when assuming the beta-factor model. This is illustrated in Figure 39.1 for a system of three identical channels, where A_i denotes failure of channel i,

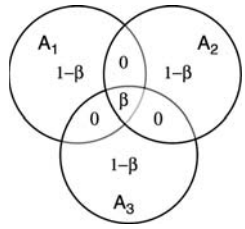

Figure 39.1. Fractions of different multiplicities of failures for a system with three identical channels when using the beta-factor model

for $i = 1, 2, 3$. Due to its simplicity, the beta-factor model is often preferred in practical applications of CCF modeling. IEC 61508 [3] recommends using the beta-factor model to quantify the probability of failure on demand (PFD) of safety instrumented systems. A single "plant specific" β can be determined for each of the channel groups of the safety instrumented system by using the checklist in IEC 61508 [3], part 6.

This approach is briefly introduced later in this section. It does, however, determine a β that is more or less independent of the system configuration.[1] For system configurations with voting 1oo2 (1-out-of-2), 1oo3 (1-out-of-3), 2oo3 (2-out-of-3), and so on, the system unavailability will be dominated by the CCF event, and we will get approximately the same unavailability for all configurations. This makes a comparison between different configurations and voting logics rather meaningless. The main advantage of the beta-factor model is its simplicity, requiring only one extra parameter, β.

The original beta-factor was defined for identical channels with the same constant failure rate λ. Many systems are, however, diversified with channels that are not identical. In this case it is more difficult to define and interpret the beta-factor. An approach that is sometimes used is to define β as a percentage of the geometric average of the failure rates of the various channels of the system.

1) A system has a *k*-out-of-*n* configuration (or reliability structure) when it is functioning if and only if at least *k* of the *n* (redundant) components, or channels, are functioning. In analyzes of safety systems this is often referred to as a *koon* voting

The parameter β is easy to interpret and also rather easy to estimate when data are available. Note that several data sources, like OREDA [21], present estimates for the total failure rate, λ. In many analyses this failure rate is accepted and taken as being constant. This approach implies that the rate λ_I of individual (single) failures will be *reduced* when we increase the value of β. Other data sources, like MIL-HDBK 217F [22], present only the individual failure rate, λ_I, and the rate of CCFs must therefore be added to give the total failure rate.

C-factor model:

The C-factor model was introduced by Evans *et al*. [23], and is essentially the same model as the beta-factor model, but defines the fraction of CCFs in another way. In the C-factor model, the CCF rate is defined as $\lambda_C = C \cdot \lambda_I$, that is, as a fraction of the *individual* failure rate λ_I. The total failure rate may then be written as $\lambda = \lambda_I + C \cdot \lambda_I$. In this model, the individual failure rate λ_I is kept constant and the CCF rate is added to this rate to give the total failure rate.

39.2.4 Plant Specific Beta-factors

The defenses against CCF events that are implemented in a plant will affect the fraction β of CCF events. Estimates of β based on generic data are therefore of limited value.

There are several suggestions on how to choose a more "correct" β, based the actual system's vulnerability to possible causes of CCF events. Some of the methods that are designed to determine "plant specific" (application specific) β's are briefly reviewed in this section.

Humphreys' method

One of the first methods to determine a plant specific β was suggested by Humphreys [24]. He identifies eight factors that are considered to be important for the actual value of β (grouped in *design*, *operation* and *environment*). The various factors are weighted based on expert judgment and discussions amongst reliability engineers as shown in Table 39.4. Some other potential factors are not included because they were found to be too difficult to quantify.

Each of the chosen eight factors is described in the Appendix of [24] and classified into five categories from a (= worst) to e (= best). For a specific application, the eight sub-factors are classified into categories a-e, and given weights (score) according to Table 39.4. A simple procedure is next used to produce an application specific β estimate:

Table 39.4. Factors and weights in Humphreys' (1987) method

Factor	***Sub-factor***	***Weights***				
		a	**b**	**c**	**d**	**e**
Design	Separation	2400	580	140	35	8
	Similarity	1750	425	100	25	6
	Complexity	1750	425	100	25	6
	Analysis	1750	425	100	25	6
Operation	Procedures	3000	720	175	40	10
	Training	1500	360	90	20	5
Environment	Control	1750	425	100	25	6
	Tests	1200	290	70	15	4

Table 39.5. The partial beta-factor method [19]

Defenses	Reference values
Design control	0.6
Design review	0.8
Functional diversity	0.2
Equipment diversity	0.25
Fail-safe design	1.0
Operational interfaces	0.8
Protection and segregation	0.8
Redundancy and voting	0.9
Proven design and standardization	0.9
Derating and simplicity	0.9
Construction control	0.8
Testing and commissioning	0.7
Inspection	0.9
Construction standards	0.9
Operational control	0.6
Reliability monitoring	0.8
Maintenance	0.7
Proof test	0.7
Operations	0.8
	$\prod_{i=1}^{19}\beta_i = 0.001$

1. The sum of column "a" representing the worst possible case should correspond to $\beta = 0.3$, a value that is considered to be a realistic worst case scenario [24].
2. The sum of column "e" representing the best possible case should correspond to $\beta = 0.001$ (*i.e.,* it is not realistic to attain any lower value of β).
3. To allow the convenience of whole numbers a divisor of 50000 was chosen, in which case the sum of column "a" should be 15000, and the sum of column "e" should be 50.

The application specific β is determined by adding the weights for the chosen categories and dividing by 50000. Consider, for example, a system of identical channels. This system will be a worst case (*i.e.*, category "a") with respect to the sub-factor "similarity", and get the weight 1750 for this factor. If all the other factors are of the best category "e", the total weight will be 1795, and the estimated value of β is hence 0.036. This means that the lowest possible β-value for a system of identical channels is 3.6% when we are using the method of Humphreys [24].

Partial Beta-factor Method

Johnston [19] suggested the partial beta-factor method. Also this method requires a qualitative analysis in order to assess a plant specific β. In the partial beta-factor method, the plant specific β is determined as a product of a number of partial betas that are derived from judgments of the system defenses. 19 different defenses are defined and reference values are allocated to each defense, as shown in Table 39.5.

When all 19 factors are assigned their reference value, we multiply them and end up with the estimate of β. However, the qualitative analysis may result in alternative (higher) values being used. Johnston [19] also discusses a generalization where this approach is applied separately for different CCF causes.

IEC Model for Determining the Beta-factor

IEC 61508 [3], part 6, Annex D suggests an approach that is based on an idea similar to the one suggested by Humphreys [24]. The IEC approach is adapted to safety instrumented systems (SIS). A SIS generally consists of one or more input elements (*e.g.,* sensors, transmitters), one or more logic solvers (*e.g.,* programmable logic controllers [PLC], relay logic systems), and one or more final elements (*e.g.,* safety valves, circuit breakers). Application specific β-values must be calculated for input elements, logic solvers, and final elements separately. To estimate β, about 40 specific questions have to be evaluated/answered

concerning the following factors for each type of elements of the safety system [3, 25]:

- Degree of physical *separation/ segregation*
- *Diversity/redundancy*, (*e.g.,* different technology, design; different maintenance personnel)
- *Complexity/maturity of design/experience*
- Use of *assessments/analyzes and feedback data*
- *Procedures/human interface* (*e.g.,* maintenance/testing)
- *Competence/training/safety culture*
- *Environmental control* (*e.g.,* temperature, humidity; personnel access)
- *Environmental testing*

The system elements are then assigned X_i and Y_i scores related to question no. i, where X_i is selected if diagnostic testing will lead to improvement and Y_i is selected if not. The ratio X_i / Y_i presents the benefit of diagnostic testing as a defense against CCF related to question no. i. Total scores are next calculated using simple formulas, and compared with predefined values in Table D.4 in part 6 of IEC 61508 [3], to give the estimate of β. The result of this procedure is one out of five possible β-values; 0.5% (applies to logic only); 1%, 2%, 5%, and 10% (input and final elements only). The highest possible β-value for input and final elements is therefore 10%, which is a low value compared to Humphreys' method [24]. The main reason for this is that most SIS channels are subject to frequent diagnostic testing and that failures thereby can be removed and CCFs can be avoided.

There are two scores X and Y, since the IEC standard gives different β's for detected failures and undetected failures, and hence also incorporates the diagnostic coverage (DC) into the calculation of β.

Unified Partial Model

The unified partial method (UPM) was developed for the British nuclear power industry [26] and is based on the beta-factor model. In the UPM framework, the defenses against CCFs are broken down to eight factors:

1. Environmental control
2. Environmental tests
3. Analysis
4. Safety culture
5. Separation
6. Redundancy and diversity
7. Understanding
8. Operator interaction

The actual system is assigned one out of five possible levels $x_{i,j}$ for $i = 1, 2, \ldots, 5$, across each defense, $j = 1, 2, \ldots, 8$, and scores $s_j(x_{i,j})$ are given accordingly from generic tables that have been deduced from past research. The overall beta-factor is obtained as a scaled sum of these scores. The UPM model has been discussed in [27, 28] where a novel approach based on influence diagrams is suggested for assessment of the plant specific beta-factor.

39.2.5 Multiplicity of Failures

Let Z denote the number of failed channels when a CCF occurs in a system with n channels. When using the beta-factor model, Z can only take the values 0 and n. Various generalizations are suggested. Either we could assume some parametric distribution of Z, say a binomial distribution, or we could allow Z to have a completely general distribution, but could introduce various ways to parameterize the distribution.

Considering a system with n channels, we note that the following symmetry assumptions apply for most parametric CCF models:

- There is a complete symmetry in the n channels, and the components of each channel have the same constant failure rate (*i.e.,* independent of time). Further, all specific combinations where k channels are failing and $n-k$ channels are not failing have the same probability to occur.
- Removing j of the n channels will have no effect on the probabilities of failure of the remaining $n-j$ channels.

These assumptions imply that we do not have to specify completely new parameters for each n. The parameters defined to handle CCF for $n = 2$ are retained for $n = 3$, and so on.

Remark: Beckman [29] claims that the susceptibility to CCF is architecture sensitive and postulates that triple redundant architectures are three times more sensitive to CCF than dual architectures. He does not, however, give any formal justification for his assertions.

In the remaining part of this section we first consider the main example of Z having a parametric model. Next we look at the general cases, in particular the so-called multiple Greek letter model. Finally we present the multiple beta-factor (MBF) model and a special case of this model.

39.2.6 The Binomial Failure Rate Model and Its Extensions

The binomial failure rate (BFR) model was introduced by Vesely [30] and is a special case of the Marshall-Olkin's multivariate exponential model [31]. The situation under study is the following: A system is composed of n identical channels. Each channel can fail at a random time, independent of each other, and they are all supposed to have the same individual (independent) failure rate λ_I.

The BFR is based on the premise that CCFs result from shocks to the system [23]. The shocks occur randomly according a homogeneous Poisson process with rate ν. Whenever a shock occurs, each of the individual channels is assumed to fail with probability p, independent of the states of the other channels. The number Z of channels failing as a consequence of the shock is thus binomially distributed (n, p). The probability that the multiplicity, Z, of failures due to a shock is equal to z is

$$\Pr(Z = z) = \binom{n}{z} p^z (1-p)^{n-z},$$

for $z = 0, 1, \ldots, n$.

The mean number of channels that fail in one shock is $E(Z) = n \cdot p$. The following two conditions are assumed:

- Shocks and independent failures occur independently of each other.
- All failures are immediately discovered and repaired, with the repair time being negligible.

As a consequence, the time between independent failures of a channel, in the absence of shocks, is exponentially distributed with failure rate λ_I, and the time between shocks is exponentially distributed with rate ν. The number of independent failures in any time period of length t_0 is therefore Poisson distributed $\lambda_i \cdot t_0$, and the number of shocks in any time period of length t_0 is Poisson distributed $\nu \cdot t_0$.

The channel failure rate caused by shocks thus equals $p \cdot \nu$, and the total failure rate of one channel equals

$$\lambda = \lambda_I + p \cdot \nu$$

By using this model, we have to estimate the independent failure rate λ_I and the two parameters ν and p. The parameter ν relates to the degree of "stress" on the system, while p is a function of the built-in channel protection against external shocks. Note that the BFR model is identical to the beta-factor model when the system has only two channels.

This is Vesely's original BFR model. The statistical analysis of such models is discussed by Atwood [32]. Several aspects of the situation must be clarified to make the analysis possible. It may, for example, happen that ν cannot be estimated in a direct way from failure data, because shocks may occur unnoticed when no channel fails.

Several extensions of Vesely's BFR model have been studied. It may, for example, happen that p varies from one shock to another. One way of modeling this is to assume p to be beta distributed, that is, it has a beta distribution with parameters r and s. Such an approach is discussed, for example, by Hokstad [33]. He introduces a re-parameterization of the beta

distribution. Instead of r and s, the model can be expressed by the shock rate and a measure of dependence between the failure of two channels. The model reduces to the beta-factor model and the BFR model, respectively, for specific choices of model parameters.

The assumption that the channels will fail independently of each other, given that a shock has occurred, represents a rather serious limitation, and this assumption is often not satisfied in practice. The problem can, to some extent, be remedied by defining one fraction of the shocks as being "lethal" shocks, that is, shocks that automatically cause all the channels to fail $p = 1$. If all the shocks are "lethal," one is back to the beta-factor model. Observe that this case $p = 1$ corresponds to the situation that there is no built-in protection against these shocks.

Situations where independent failures may occur together with non-lethal as well as lethal shocks are often realistic. Such models are, however, rather complicated, even if the non-lethal and the lethal shocks occur independently of each other.

39.2.7 The Multiple Greek Letter Model

A large number of further extensions of the beta-factor model have been suggested, for example, by Apostolakis and Moieni [34]. Some models allow a completely general multiplicity distribution. However, different parameterizations give rise to different models. Three of the most well known models are

- The basic parameter (BP) model [35]
- The alpha factor model [36, 37]
- The multiple Greek letter (MGL) model [38]

The MGL model was introduced by Fleming *et al*. [38] and is briefly discussed below. A more recent model, the multiple beta-factor (MBF) model is presented in the next section.

In the MGL model various conditional probabilities are introduced, and for a system with $n = 3$ channels (say, A_1, A_2, and A_3) we define:

$\beta =$ the conditional probability that the cause of a failure of a specific channel will be shared by at least one additional channel.

$\gamma =$ the conditional probability that a channel failure known to be shared by at least one additional channel will be shared by at least two additional channels. Additional Greek letters are introduced for systems of higher order n. Here, β is the probability that, given one channel (A_1) has failed, at least one of the other $n-1$ will also fail (either A_2 or A_3 or both for a system of three channels). We note that the beta-factor model is a special case of the MGL model when $n = 2$, and also when all the parameters of the MGL model, except for β, are equal to 1.

In a system of three channels, this model implies that the channel failure probability, Q, can be split as follows:

Pr(channel has a single failure) $= 1 - \beta \cdot Q$.
Pr(channel has a double failure) $= \beta(1-\gamma) \cdot Q$.
Pr(channel has a triple failure) $= \beta\gamma \cdot Q$.

Here, $\beta(1-\gamma)$ is the probability that, given one channel (A_1) has failed, also exactly one additional channel (either A_2 or A_3) has failed. Similarly, $\beta\gamma$ is the probability that given one channel (A_1) has failed, then both A_2 and A_3 have also failed. In this way we can for any n give the probability of failure of any multiplicity expressed by conditional probabilities (Greek letters).

39.2.8 The Multiple Beta-factor Model

The multiple beta-factor (MBF) model [39] is, like the MGL, completely general, since any multiplicity distribution can be adapted. However, in the MBF model the rate of CCF causing system failure for a *koon* configuration is given as $\lambda_{koon} = C_{koon} \cdot \beta\lambda$. Here λ is the channel failure rate, β is the beta-factor (of two channels), and C_{koon} is a *configuration factor* taking into account the reliability structure of the *koon* system. The same β is used for all configurations. Further, the MBF model uses $C_{1oo2} = 1$, and the β used in MBF will for $n = 2$ channels have the same interpretation as in the beta-factor model.

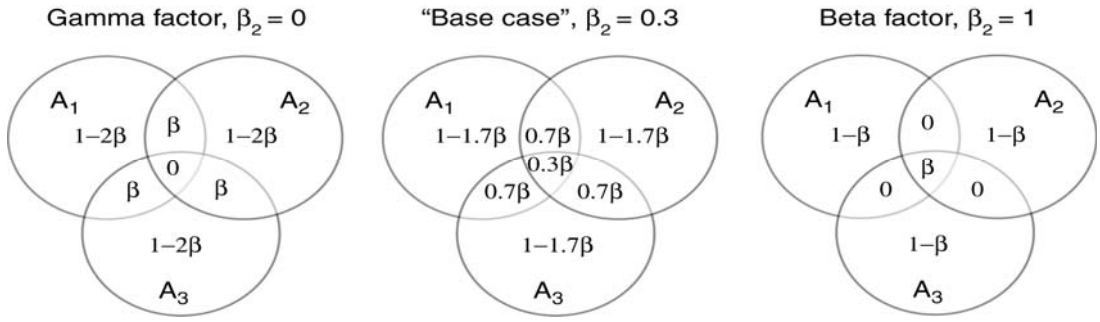

Figure 39.2. Illustration of the multiple beta-factor (MBF) model for a triplicated system $(n=3)$. Three different choices of the parameter β_2

Analogously, if Q is the probability of a channel being in the failed state, the probability of a *koon* configuration being in the failed state due to a CCF equals $Q_{koon} = C_{koon} \cdot \beta \cdot Q$. This factorization of the system failure probability Q_{koon} into the single channel failure probability (Q), the double channel failure probability (β), and the multiple channel failure probability (C_{koon}) is the key feature of the modeling. For Q and β there should be data available for estimation, and a "plant specific" β could be estimated, for example, using the approach in IEC 61508 [3].

As there is often rather limited information available to carry out a formal estimation of the C_{koon} factors, we may as a starting point apply a set of *generic* values that can be applied in quick and simple analyses when limited information on the multiplicity of CCF is available. This will then represents a modeling of intermediate complexity, in between the very simple beta-factor model and the rather detailed modeling (as multiple Greek letter model) used by some analysts for instance in the nuclear industry. If some consensus can be reached on generic C_{koon} values, then more realistic input, and better decision support is obtained than by just applying $C_{koon} = 1$ for all configurations, as suggested by the beta-factor model.

In order to give explicit formulas for C_{koon}, we introduce the probability, β_j that channel $j+1$ fails, given that channels $1, 2, \ldots, j$ have just failed in a CCF.

Note that $\beta_1 = \beta$. In order to analyze a system with three channels, we also need to specify β_2, and so on. Figure 39.2 illustrates the case for $n=3$.

The probability $f_{k,n}$ that exactly k of the n channels are failed can now be expressed by these β values [39] and the probability of system failure due to a CCF is given as

$$Q_{koon} = \Pr(\text{at least } n-k+1 \text{ channels fail in CCF}) = \sum_{j=n-k+1}^{n} f_{j,n}$$

We can write $Q_{koon} = C_{koon} \cdot \beta \cdot Q$, where C_{koon} is independent of β and Q. The configuration factors C_{koon} are given explicitly as a function of β_k, for $k = 2, 3, \ldots, n-1$.

Example (Special Case $n=3$)

This parameterization easily gives the multiplicity results for a system of $n=3$ channels (see Figure 39.2).

By direct probabilistic arguments, it follows that the probability of the system having k $(=1,2,3)$ channels failed equals

$$f_{1,3} = 3[1-(2-\beta_2)\beta]Q$$
$$f_{2,3} = 3(1-\beta_2)\beta Q$$
$$f_{3,3} = \beta_2\beta Q$$

For a 1oo3 configuration, system failure occurs if all three channels fail, and thus the probability of system failure due to CCFs is $Q_{1oo3} = f_{3,3} = \beta_2\beta Q$. This directly gives $C_{1oo3} = \beta_2$. For a 2oo3 configuration, the system fails if at least two channels fail, and the probability of system failure equals $Q_{2oo3} = f_{2,3} + f_{3,3} = (3-2\beta_2)\beta Q$, directly giving $C_{2oo3} = 3-2\beta_2$.

The parameter β_2 can take any value in the interval [0, 1]. Choosing the value $\beta_2 = 1$, we get the ordinary beta-factor model. The other extreme, $\beta_2 = 0$, is here referred to as the *gamma factor model* (see Figure 39.2). Note that the value $\beta_2 = 0.3$ is introduced as a *base case*. This gives $C_{1oo3} = 0.3$, $C_{2oo3} = 2.4$, being factors that are easily recognized in Figure 39.2 (as $C_{2oo3} = 0.7 + 0.7 + 0.7 + 0.3$).

Since the explicit expressions for the configuration factors, C_{koon}, are rather complex for large n, and since there is often few data available to perform separate estimation of all $\beta-$ s, some simplification of the model is appropriate. One special case is that $\beta_j = \beta_p$, for all $j \geq p$. Here we select $p = 3$.

Special Case: $\beta_j = \beta_3$ for $j \geq 3$.

It follows that [39]

$$C_{koon} = \beta_2 \sum_{j=n-k+1}^{n} \binom{n}{j} \beta_3^{j-3}(1-\beta_3)^{n-j}$$

for $k = 1, 2, \ldots, n-2$.

$$C_{(n-1)oon} = \binom{n}{2}(1-\beta_2/\beta_3) + \beta_2 \sum_{j=2}^{n} \binom{n}{2} \beta_3^{j-3}(1-\beta_3)^{n-j}$$

The choice of β_2 has indeed a dominant effect on the configuration factors. The two extremes, $\beta_2 = 0$ and $\beta_2 = 1.0$, usually give quite unrealistic models. However, the knowledge about the "true" β_2 is in many cases very limited. So it is useful to define a generic value as a *base case*, applicable when little information is available. If we strictly remove common channels as cause of the CCF, and if we are rather restrictive with the meaning of *simultaneous* failure, it is believed that the typical β_2 value is usually closer to 0 than 1, and somewhat arbitrarily the value $\beta_2 = 0.3$ is suggested (based on some previous expert judgment for failure multiplicity distributions of safety systems). Also $\beta_2 = 0.5$ could be a reasonable choice when little information is available. For $k \geq 3$ the value $\beta_k = 0.5$ is suggested unless more information is available. Table 39.6 presents some numerical results (sensitivities) for C_{koon}. The following examples are given

- *Sensitivity 1*: $\beta_k = 0.3$ for all $k \geq 2$;
- *Base case*: $\beta_2 = 0.3$; $\beta_k = 0.5$ for all $k \geq 3$;
- *Sensitivity 2*: $\beta_k = 0.5$ for all $k \geq 2$.

Note that there are two real extreme (most often unrealistic) cases:

Table 39.6. Numerical values of configuration factors (Note: $C_{1oo2} = 1$)

Parameter choice	Configuration factor C_{koon}				
	1oo3	**2oo3**	**1oo4**	**2oo4**	**3oo4**
$\beta_j = 0.3$ $(j \geq 2)$	0.3	2.4	0.09	0.93	3.9
Base case	0.3	2.4	0.15	0.75	4.0
$\beta_j = 0.5$ $(j \geq 2)$ β_k	0.5	2.0	0.25	1.25	2.8

- The "gamma factor model" ($\beta_k = 0$ for all $k \geq 2$) gives $C_{(n-1)oon} = \binom{n}{2}$ and $C_{koon} = 0$ for $k < n-1$
- The beta-factor model ($\beta_j = 1$ for all $j \geq 2$) gives $C_{koon} = 1$ for all $k < n$.

Such a table can also be used for sensitivity considerations, for example, regarding the ranking of configurations. As expected 1oo4 is ranked the best of these configurations, and 3oo4 is the worst with respect to CCF. However, it may be hard to distinguish 2oo4 from 1oo2, unless more explicit data are available.

39.3 Data Collection and Analysis

This section reviews recent data sources for CCF and discusses some questions related to parameter estimation and to the collection and analysis of data that are used as input to CCF model estimation.

Today, CCF must be considered rare events, and the individual plants present limited experience. Thus, global industry experience is needed to make statistical inferences. Then there can be need for "data mapping." This is used when we have data from systems with different degree of multiplicity/redundancy. However, if data from different plants are used, it must be kept in mind that there could be a significant variability amongst the plants.

39.3.1 Some Data Sources

Rather few data sources on CCF are available. To a large extend they are from the nuclear industry.

Some data are rather old, and a few sources are listed in Hokstad [40]. Here we restrict to discuss the ICDE data base and SKI data.

The ICDE data base:

The best recent source of CCF data is probably the International Common Cause Failure Data Exchange (ICDE) project [41].

The ICDE project was initiated in 1994 and collects and analyzes CCF event data from the nuclear industry in nine OECD countries. Since April 1998, the project has been operated by the Nuclear Energy Agency (NEA). The objectives of the ICDE project are to:

1) Collect and analyze CCF events over the long term so as to better understand such events, their causes, and their prevention.
2) Generate qualitative insights into the root causes of CCF events which can then be used to derive approaches or mechanisms for their prevention or for mitigating their consequences.
3) Establish a mechanism for the efficient feedback of experience gained in connection with CCF phenomena, including the development of defences against their occurrence, such as indicators for risk based inspections.
4) Generate quantitative insights and record event attributes to facilitate quantification of CCF frequencies in member countries.
5) Use the ICDE data to estimate CCF parameters.

Various summary reports are available on the internet also for non-members. Examples of available ICDE project reports are (see http://www.-eskonsult.se/icde/):

- Collection and analysis of common-cause failure of safety and relief valves.
- Collection and analysis of common-cause failure of check valves.
- Proceedings of the ICDE workshop on qualitative and quantitative use of ICDE data.

ICDE also gives general recommendations regarding classification of CCF data, for example regarding

- Coupling factors
- Root causes

- Corrective actions
- Detection methods

The project has published papers on "lessons learned" and general insight and results from the CCF data collection [42–44]; all papers appearing at the PSAM/ESREL conference in 2004.

SKI data reports:

SKI (Statens Kärnkraft Inspektion/Swedish Nuclear Power Inspectorate) has through several reports investigated CCFs in boiling water reactors (BWR). In particular, [45] gives actual data on safety/relief valves (SRV), and the number of SRVs usually varies from 12 to 16 in these systems. The analysis is based on data from different BWR generators, located in Forsmark, Oskarshamn, Barsebäck, and Ringhals. The database contains about 200 events, and failures are classified according to severity, failure mode, detection method, and which part of the channel that failed. Failure cause is given, and the multiple events are classified as "actual CCFs", "potential CCFs" or "recurring faults". A couple of other relevant reports from SKI are [46, 47], where [47] covers events that potentially lead to CCF. Such events, named "common cause initiators," are not just causing a disturbance in plant operation, but can also degrade or even disable the function of a safety system that is needed to cope with the disturbances.

The SKI project undertakes the following tasks:

- SRV data analysis: data being collected from Finnish and Swedish BWR plants.
- Specification of reference application: Detailed study on one plant in order to test analysis methods.
- Application and comparison of CCF models: A number of different CCF models are employed, and their applicability in high redundancy systems is discussed.
- Conclusions and recommendations: Give qualitative insights from the CCF mechanisms and possible defenses.

39.3.2 Parameter Estimation

The standard estimators for the parameters of main CCF models are given in Mosleh [35], and are referred, for example, in [40]. Here we restrict ourselves to discuss the estimation of beta-factors, referring to the MBF model and the standard beta-factor model. We let

$X_{k,n} =$ the number of observed failure events resulting in exactly k channels failing of a system with n channels (*i.e.*, the number of failures of multiplicity k).

$\hat{\beta}_{k,n} =$ estimator for β_k (see the MBF model), based on data from a system with n channels.

It is of some interest to compare the estimator of β_1 in the MBF model with the estimator of β in the standard beta-factor model. Considering now a system with n channels, Hokstad *et al*. [48] give the following estimator for $\beta = \beta_1$

$$\hat{\beta}_{1,n} = \frac{\sum_{j=2}^{n} j \cdot \frac{j-1}{N-1} X_{j,n}}{\sum_{j=1}^{n} j \cdot X_{j,n}} .$$

The beta-factor model is a special case of the MBF model, by letting $\beta_j = 1$ for all $j \geq 2$. However, the definition of $\beta_1 = \beta$ is not identical in the two models. The "ordinary" β is the probability that *all* other channels are affected, given the failure of a specific channel, and the β_1 of the MBF model is the probability that a specific other channel is affected. So the interpretation of the two β's coincide only for $n = 2$.

For a n-channels system a commonly suggested estimator for β is (*e.g.,* see [35, 48]):

$$\beta^* = \frac{\sum_{j=2}^{n} j \cdot X_{j,n}}{\sum_{j=1}^{n} j \cdot X_{j,n}}$$

and, as expected, for $n = 2$, the two estimators coincide. However, for $n > 2$, the beta-factor model has a problem with the estimation. The model does not allow for CCFs of multiplicities less than n. However, the estimator of β includes failures of all multiplicities. Since these failures of multiplicity $< n$ actually do occur, (and thus should be accounted for), there will necessarily

become some sort of discrepancy between the theoretical model and the estimator. Irrespective of how these $X_{j,n}$ for $j < n$, are taken into account, it will imply an interpretation of β^* that differs from that of the actual β in the beta-factor model.

The above estimator β^* seems related to the definition of β in the multiple Greek letter (MGL) model. Here the beta-factor is defined as the conditional probability that the cause of a failure of a specific channel will be shared by *at least one* additional channel; (*i.e.*, given one channel has failed, at least one of the other $n-1$ will also fail).

To highlight this interpretation, we compare $\hat{\beta}_{1,3}$ and β^* for the case $n = 3$. Then

$$\beta^* = \frac{2X_2/3 + X_3}{X_1/3 + 2X_2/3 + X_3}$$

$$\hat{\beta}_{1,3} = \frac{X_2/3 + X_3}{X_1/3 + 2X_2/3 + X_3}$$

Here the numerator of $\hat{\beta}_{1,3}$ is the number of failure events involving two specific channels, (say A_1 and A_2), and the numerator of β^* is the number of failures involving one channel (say A_1) and *at least* one additional channel (*i.e.*, either A_2 or A_3). Obviously, $\hat{\beta}_{1,3} \le \beta^*$. Actually, from the formula for β^* and $\hat{\beta}_{1,n}$ it is seen that $\hat{\beta}_{1,n}$ is always smaller than β^* when $n > 2$ (as also follows from the definition of β^* and β_1).

It is concluded that the estimator of β in the standard beta-factor model is somewhat inconsistent, (and actually *has to* be inconsistent, due to the definition of β). This is another argument for applying more general CCF models.

39.3.3 Impact Vector and Mapping of Data

For each failure event of a system with n channels exposed to CCF we may define an impact vector [37]. This vector has $n+1$ elements, one for each value for number of failures. The vector can be written $(I_0, I_1, \ldots, I_n)$, where $I_k = 1$ if the outcome is that exactly k of the n channels fail, and 0 otherwise.

The following two main problems are encountered in the use of CCF data:

- The CCF events are often not well defined, giving rise to various hypotheses regarding how many (which) channels have failed; (*i.e.*, the I_k are random variables rather than indicator variables).
- Scarcity of data will imply that it is needed to apply data from various plants to assess CCF probabilities/rates; (or we have the situation that the data comes from a *source* plant with operational experience, but are going to be applied on a *target* plant). Then it is required to investigate differences between the plants with respect to environment, operations, *etc*. If, in addition, the various plants have different n values, it is also required to *map* the data before they can be used on the target plant.

The use of a stochastic impact vector is discussed by Knochenhauer *et al.* [49] who give an example for diesel generators, and includes uncertainty estimation of CCF parameters (Bayesian approach). Another estimation approach is given by Xie [50]. He uses a "knowledge-based multi-dimension discrete" (KBMD) CCF to assess probabilities of the various failure multiplicities. Here various environment load-channel strength relationships are embodied implicitly. The approach can be used to estimate high redundancy system CCF based on low multiplicity failure event data of the system. The results of the KMBD model regarding multiplicity distribution are also compared with other models.

We have the general problem that failure events observed at one or few plants are often not sufficient to estimate the parameters of the CCF model. So, assimilating experience from other plants may be essential. However, the plants may have different lay-out, design and channel separation principles. So there is a need to assess similarity/applicability, to assess applicability/-modification factors.

When source and target plant have different numbers of channels (n-values, different degree of

redundancy), we need to use data mapping [37, 51]. In particular, the impact vector of the source plant is mapped up/down to the impact vector of the target plant, and thus derives the expected failure probabilities of various failure multiplicities in a "corresponding" failure event with the n-value of the target plant. Also Hokstad *et al.* [48] use data mapping in the estimation of the parameters of MBF model, assuming data coming from plants with different n-values.

Vaurio [52] has recently given a comprehensive discussion on the topic of mapping, related to estimation in CCF models. He refers to two kinds of generic mapping-down rules, based on two different CCF mechanisms and assumptions:

- The first set of mapping down rules can be obtained assuming *externally caused* CCFs, and assuming that the plants with $n-1$ channels are similar to the plants with n channels with one channel removed. "Similarity" here means that all cause events occur with the same frequency and have equal consequences, *i.e.*, the cause events fail existing channels equally likely at both families of plants.
- The second set of mapping down rules has been developed for cascading failures or *channel-caused* CCFs, meaning that a single channel failure causes other channels to fail with certain probabilities. Furthermore, it is assumed that plants with $n-1$ channels have the same single failure rates and the same failure propagation probabilities as the plant with n channels.

Both kinds of events can occur in reality, and both sets of rules assume identical design, separation, operations and maintenance principles in plants with different sizes n. Such mapping rules are purely mathematical, based on combinatorial arguments. Further references are found in [52], who also presents mapping-*up* rules suggested in the literature.

It can be shown that the mapping down equations for the weights of the impact vectors are based on the ideal case of *externally caused* CCF as defined above [53].

39.4 Concluding Remarks and Ideas for Further Research

The beta-factor model is by far the most commonly used CCF model, and its use is also supported by standards like IEC 61508 [3]. A main challenge related to using the beta-factor model is to estimate/choose an appropriate, plant specific value of β. A range of "tools" [3, 19, 24, 26] have been proposed for this purpose. Several of these "tools" have been developed based on experience without any structured basis. Zitrou *et al.* [28] propose to use a more structured approach based on influence diagrams. This is a promising approach that should be subject to further research.

CCFs are especially important for safety instrumented systems (SIS). A SIS has two main failure modes [18]: Fail to function on demand (FTF) and spurious operation (SO). The method in IEC 61508 [3] part 6 is applicable for FTF failures. In most practical analyses, however, analysts tend to use the same estimate for β both for FTF and SO failures. This is an erroneous approach since the mechanisms leading to the two failure modes are totally different. More research should be devoted to estimating β for common cause SO failures. SO failures can in some cases be safety critical, and even more critical than FTF failures. Consider, for example, the airbag system in a car. If the airbag does not function as intended in a crash, we have an FTF failure. If the airbag blows up spuriously, we have a SO failure. The consequences of the SO failure will depend on the situation in which it occurs. It is easy to imagine a situation where an SO failure of the airbag will give fatal consequences.

The approach described in IEC 61508 [3] part 6 for estimating a plant specific β results in one out of a few distinct values for β. This implies that we have to make rather significant improvements to the system, environment or operational procedures to see any effect on the value of β. In situations where a contractor is obliged to follow the IEC 61508 procedure, he may be de-motivated in his efforts to make improvements, because it does not show any effects on the calculated PFD. The procedure in IEC 61508 should therefore be

replaced by a new procedure that is more sensitive to improvements.

Another issue is related to the understanding of how various types of diagnostic testing may influence the occurrence of CCFs, and how to take account of the diagnostic testing when estimating β. More research is also needed to fully understand how the practical inspection and testing procedures – and human errors, influence on the occurrence of CCFs.

When we establish models for systems exposed to CCFs, it is important to start by identifying the significant causes for CCFs and to include these causes explicitly into the model. More research should be devoted to developing checklists and other tools that can support the explicit modeling of CCFs. Such tools need to be based on a thorough understanding of the physical mechanisms that may lead to CCF.

It is further observed that all current implicit models are based on the exponential failure model. The occurrence of CCF in models with deterioration (*e.g.,* Weibull models) should be further investigated.

Above we observed that the mapping down equations for the weights of the impact vectors are based on the ideal case of *externally caused* CCF, as defined above. This generally seems to be the case in the current literature, and could be a topic for development to further investigate alternative, or more general models to this CCF mechanism.

A final topic for further research related to CCFs is to apply fuzzy logic in the collection and utilization of input data to determine the specific CCF parameters. See, for example, Maisseu and Xingquan [54] for a recent reference.

A Methodology for Promoting Reliable Human–System Interaction

Joseph Sharit

Department of Industrial Engineering,
University of Miami, Coral Gables, Florida, 33124-0623, USA

Abstract: A qualitative methodology is proposed that can help both designers and managers anticipate problems, which are often manifest as human errors, that people will have in interacting with various products and systems. The methodology adapts a number of well-known hazard evaluation techniques so that they can be applied to human performance, and combines them in a way that increases the analytical team's ability to predict the possibility for human performance failures and their consequences. A basis is also provided for examining explanations for these failures, and for providing categorical severity and likelihood assessments of these consequences. The importance of assessing the impact of barriers on adverse consequences is also discussed.

40.1 Introduction

Despite enormous technological advances in products, services, and industrial work processes, the human remains and will likely remain an integral system component. In some cases, particular operations or system functions either cannot be automated or cannot be done so with sufficient reliability, thus requiring the human's presence. In other cases, human-system interaction is necessary if only for enabling the human to acquire an adequate account of ongoing system information, which provides the opportunity for adapting the system to changing events and for implementing interventions that can lead to system improvement. Designers, managers, and supervisors of these systems are faced with a challenging goal: how does one ensure that the human's presence does not lead to adverse outcomes such as injuries, poor system performance, and economic losses, while at the same time allow the human the flexibility to engage in the kinds of activities that can promote a better understanding of system operations, and ultimately improved system performance?

This broad objective is often stated in terms of the seemingly simpler goal of minimizing human "errors" and violations that could undermine joint human-system performance. Human reliability, which in its most literal sense represents the analogue of mechanical component reliability, has been defined as the probability of successful completion of an activity or task within some prescribed or implied time period. If we identify an activity or cluster of activities dedicated to meeting some task objective, and consider the criteria that denote successful performance of that activity or task, then strictly speaking failure to meet these

criteria represents human failure. In human reliability analysis (HRA), human failures are represented by human errors in task performance. Quantitative perspectives to HRA focus on obtaining quantitative estimates of these errors, and there exist a variety of methods intended for meeting this goal [1, 2, 3]. The importance of quantitative HRA derives from the need, either mandated or governed by management policy, to supply analysts with quantitative estimates of human reliability in order to more accurately account for the risks associated with systems that encompass human, equipment, and environmental aspects.

With technology evolving at very rapid rates, forcing continual modifications to existing systems and possibly even to the organizational structures that are responsible for managing them, many designers and managers face more fundamental issues. Specifically, they would like to know: (1) how the designs or operations that they are responsible for might lead to human error or violations; (2) what the potential consequences of these human behaviors are; and (3) what barriers or safeguards can prevent or mitigate the potentially negative consequences of these behaviors while, at the same time, not introduce new opportunities for human errors and violations. This set of challenges represents a qualitative perspective to HRA. Quantitative perspectives often require sufficient resolution of qualitative considerations in order to address the goal of quantitative human error estimation. Obviously, if potentially erroneous actions are not identified, then their quantification cannot be considered and the risks to the system are underestimated.

The most common tools for incorporating estimates of human error into quantitative system risk assessments are fault tree (FT) analysis and event tree (ET) analysis [2]. FTs use Boolean AND and OR operations to determine deductively the combinations of events that are capable of causing some unwanted top event. ETs use an initiating event as a starting point and, through inductive reasoning, infer different accident scenarios that can be propagated depending on whether various barriers or mitigating actions are successfully applied. In either case human actions may need to be considered. FTs and ETs are often used in combination, where FTs serve to determine the possibilities of success for each mitigative or barrier function represented along the path of accident propagation within the ET. Both FTs and ETs can be used qualitatively by deriving cut sets. A cut set is a set of one or more events which, if all occur, can result in the occurrence of the top event in a FT or in the designated accident scenario in an ET. It is when human actions need to be considered and quantitative risk analysis studies are required that risk analysts will be compelled to obtain quantitative estimates of human errors.

The earlier approaches to HRA, whether relatively resource efficient such as TESEO (*tecnica empirica stima errori operati*) [4], or very resource intensive such as THERP (technique for human error rate prediction) [5], generally suffered from an inability to adequately account for human involvement that is of a more cognitive nature and for the complexity of the various contexts in which the human performs. The "second-generation" approach to HRA, referred to as CREAM (cognitive reliability and error analysis method) [3], in its qualitative form, does overcome some of these limitations, especially in its ability to create elaborate linkages between various work conditions in order to predict events. However, once the method shifts the objective to human quantitative performance prediction it, like all such approaches, must resort to some type of decomposition-aggregation scheme whereby factors characterizing the work context are decomposed and, according to some rule or scheme, aggregated to provide a quantitative estimate.

Although the decomposition-aggregation cycles inherent to these approaches can be very revealing of issues and factors that can undermine system reliability, the conceptual understanding that is needed for promoting organizational learning will often be masked by the emphasis given to generating quantitative estimates of human error. Thus the goal of quantitative approaches to human reliability assessment can be disruptive. A more reasonable approach would be to identify the ways in which human activities or required behaviors could be erroneous in the sense of potentially

creating hazards or putting some aspect of the system at risk. A risk category—that is, a level of likelihood and severity—could then be associated with the possible consequences of these actions or behaviors; this risk category would be based in part on the explanations that can be considered for failed behaviors. This approach is consistent with the view [6] that encourages "a move away from the search for objective probabilities via standard probabilistic risk assessment tools…toward an exploratory or descriptive approach" (p. 82).

Motivating this approach is the assumption that what designers and managers require, especially when implementing new technologies or managing systems with complex interactions, are the *possibilities* of exposure to risk. Strict quantification of human error generally imposes constraints on analysis due to the need for employing some type of formalization to ensure that a quantitative figure can be arrived at. Although loosening the constraints compelled by strict quantification will necessarily expand the space of possibilities of human behaviors that can cause adverse consequences, it could provide insights that would otherwise be ignored or handled awkwardly if they were to be funneled into a quantitative estimate. The option always exists, however, for extending qualitative perspectives of HRA to quantitative end products [3, 7] if these data are required, for instance, when fault-tree analysts seek human reliability estimates.

To illustrate the need to consider human reliability within a more expanded space of possibilities, consider a designer who is assigned the task of building a computerized physician order system for hospitals. The potential impact of such a system in reducing prescribed medication errors by physicians is enormous. However, there is evidence that such systems can introduce new unforeseen adverse consequences arising from the actions of physicians by virtue of the interplay between the user's information-processing limitations, interface design features, and characteristics of the hospital's organizational structure and policies [8]. Thus a presumed barrier to human error may in fact produce new anticipated "errors" [9], and it has been suggested that it may take many years of organizational learning for these problems to become remedied [10]. Are attempts to provide quantitative estimates of these errors necessary or should we instead attempt to expose them?

As another example, when performing certain work procedures there may be a tendency for workers to invoke short cuts in order to minimize the outlay of effort the procedure calls for or because they feel that the procedure exposes them to unnecessary risks. Do we want to identify work-related factors (such as the existence of opportunities for invoking short-cuts to minimize effort) and organizational factors (such as the inability for designers to be more specific concerning procedural steps and thereby place the burden on the worker to adapt the procedure) that could predict such possibilities, or do we want to quantify these occurrences? Many other examples could be given that present the same dilemma, and that point to the need for a resolution that favors exposing the possibilities for undermining system performance.

The methodology presented below combines a number of very fundamental hazard evaluation (HE) methods within the context of creative brainstorming to predict possible human failures and the possible consequences of these failures. It also provides a template for deriving explanations for these failures in order to provide a logical basis for imposing barriers or safeguards. The HE methods, in particular failure modes and effects analysis (FMEA), and hazard and operability analysis (HAZOP), will be adapted to consider exclusively "human failures." The purpose of this approach is to enable managers and designers to identify *possibilities* for exposure of the system to risk. The "human failure" HAZOP and subsequent What-IF analysis are overlaid iteratively on the human FMEA to open up the analytic process to further brainstorming, for example, to consider how the consequences of one human failure might impact other actions or other aspects of the system. This type of analysis is especially important in systems that are interactively complex [11].

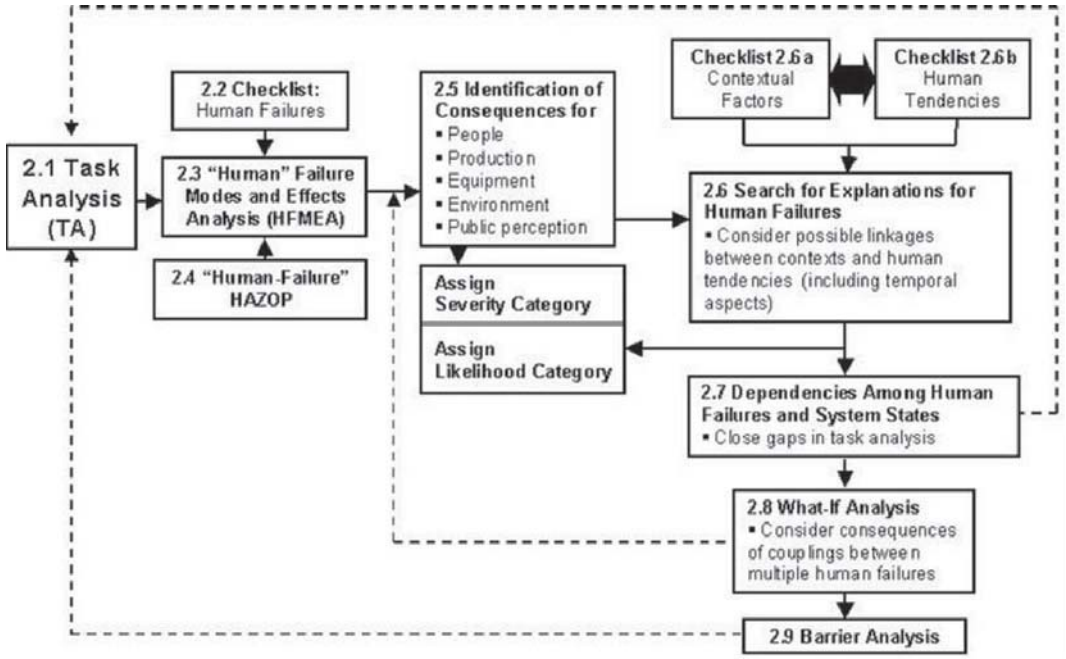

Figure 40.1. Overview of the methodology for exposing human failures and their consequences and causes (the block numbers correspond to the sections in the text where those topics are discussed)

40.2 Methodology

The overall approach to prediction of human failures and their consequences is illustrated in Figure 40.1. In this figure, the various methods or stages comprising the overall methodology are numbered and presented as a flow process with iterative loops. The discussion below corresponds to this numbering scheme.

40.2.1 Task Analysis

The starting point of this methodology, task analysis (TA), is fundamental to the entire endeavor. Many different TA methods exist [12, 13]. TA describes the human's involvement with a system in terms of the goals to be accomplished and all the human's activities, both physical and cognitive, that are necessary to meet these goals. If the operations underlying a goal cannot be usefully described or examined, then the goal can be reexamined in terms of its subordinate goals and their accompanying plans—a process referred to as "redescription" [14] that defines a task analysis methodology referred to as hierarchical task analysis (HTA). The level of detail in the TA will depend on whether it is being applied during the preliminary or later stages of design, or during the operational stages of the product or system.

When examining each of the various human-system interactions that generally encompass TA, the analyst will typically focus on a goal or sub-goal that is capable of being adequately characterized. Analysis of these interactions could be performed using a variety of perspectives and methods. The analyst may resort to simple models of human information processing to determine if the human is receiving sufficiently salient, clear, complete, and interpretable input; has adequate time to respond to the input with respect to being able to mentally code, classify, and resolve the information or in terms of the time the system

allows for executing an action; and whether feedback is available to enable the human to determine whether the action is or was executed correctly and is appropriate for dealing with the goal in question. More complex information processing schemes can also be used. For example, one could determine if working memory—the human's short-term memory store to which a good deal of our conscious effort or attention is dedicated, as when we plan, evaluate, conceptualize, and make decisions—may be overloaded [15], which can result in many different forms of erroneous activities depending on the particular context. The analyst may also question whether the human has available in long-term memory adequate facts, schemas, or mental models that he or she may need to translate inputs into appropriate actions.

If the task element concerns making a decision, various limitations associated with human decision making can be explored, such as tendencies to overweight or underweight critical sources of information, or resort to heuristics that lead to various biases in judgment.

In some situations, the analyst may find it useful to exploit similarities that may exist between operations from different domains by identifying characteristics of a current operation and relating these to other operations the analyst may have encountered or has insights into. Similar task elements (such as the need to recall previous steps in a procedure, working in restricted spaces, the need to scan monitors for information, the need to discriminate between various alarms) arise in different contexts. The analyst may also employ checklists that cover a broad range of ergonomic considerations to determine if the human is being subjected to factors (such as illumination, noise, posture) that can contribute to erroneous actions. These types of checklists can be expanded to include what are often referred to as performance shaping factors that consider task, workplace, interface, and organizational design factors.

Finally, analysts can resort to other types of methods of data collection if they feel there are still important performance issues that need to be resolved. For example, one can use concurrent verbal protocols (where people think aloud as they perform the task), retrospective verbal protocols (where people view their performance on a video or the results of their performance on a computer screen), or prospective verbal protocols (where people verbalize how they plan to perform a task or accomplish some goal or subgoal). Other approaches are also discussed in [14]. With HTA, if exploration of the human-task interaction proves to be too difficult or is not sufficiently revealing of potential points of weakness, the analyst should consider "redescribing" the goal in terms of a set of subordinate goals (*i.e.*, subgoals) and an organizing component called a "plan" that specifies the conditions under which these sub-goals have to be carried out to meet the system goal in question.

40.2.2 Checklist for Identifying Relevant Human Failure Modes

The primary "table" or organizing device driving this methodology is the one typically used with the failure modes and effects analysis (FMEA) hazard evaluation technique. This technique requires specifying the failure modes for each component as well as the consequences and causes of these failure modes. In this case, however, the failures under consideration are human; thus the mapping from the steps of the task analysis to the possible failure modes within the FMEA results in a human FMEA (HFMEA). This procedure typically will require some form of classification system that can provide a wide range of human behaviors that could occur in human-system interaction. The classification system should be sufficiently flexible so that the specific behaviors could be easily adapted to the particular work domain or task under consideration.

One such classification system considers four broad categories of behavior: perceptual processes (searching for and receiving information, and identifying objects, actions, and events); mediational processes (information processing and problem solving/decision making); communication processes; and motor processes. This classification system can be traced to the various stages that can occur in human information processing, specifically, perceptual encoding, central processing, and responding [15]. Table 40.1 represents an

example of such a classification system in the form of a checklist. The categories are not meant to be exhaustive; many more items could conceivably be proposed. Nor are they truly mutually exclusive given that perceptual, communication, and response execution activities are inextricably linked to thought (*i.e.*, mediational) activities.

Thus the distinctions in Table 40.1 are motivated primarily by a leaning towards one or another category based on how dominant that category appears to be for the task analysis step being analyzed.

The proposed methodology for predicting possible adverse consequences resulting, at least in part, from human failures thus begins by an exhaustive consideration of possible failure modes for a particular human activity within some operational context. In this respect, the approach is consistent with traditional FMEA, which also attempts to consider every possible failure mode, although it does so for mechanical components. Because a single analyst can, in principle, perform a TA and, using the checklist, derive possible failure modes for the task step, this approach is relatively efficient. There are, however, other approaches one can adopt. For example, starting with TA, one could use a detailed analysis of the contexts in which the human performs the task, along with knowledge concerning human tendencies and limitations, to predict how human failures may come about. This approach would be more resource intensive, requiring from the outset more group brainstorming. It also shifts the focus almost immediately to work contexts. By initially laying out all possible (*i.e.*, relevant) failure modes, as is done in a traditional FMEA, the process of seeking out the conditions that comprise the contexts in which human performance occurs becomes more simplified.

Note that in traditional FMEA the failure modes of a device or component are explicit, and it is not debatable as to whether these failure modes constitute an external mode of failure or an explanation for the failure. The adaptation of FMEA to human performance, as driven by TA, is not intended to maintain this same distinction. If the true purpose of the method is to establish possible consequences of human failures and ultimately to design barriers to mitigate or prevent these consequences, then a strict application of the concept of external manifestation of human error will necessarily lead to a reduced set of possible consequences. Thus the human failure "uses the wrong rule" clearly is an inferable "error" that, in the strict sense advocated in [3], does not meet the criteria of an externally manifest error. However, within the context surrounding a particular step in a task analysis, it may have severe consequences and thus may be a valid human "error" to consider. Otherwise we become restricted to a sparse set of external error modes of which "action omitted" and "wrong action performed" characterize almost all observable human failures. This lack of specificity would not adequately address the requisite variety of possible consequences, which is what the designer and manager are interested in, and would like to be able to consider without tracing these general error modes through complex sequences or networks of contexts within which the human performs. Although analysis of accidents that have already occurred may require more objectivity in terms of what actually happened, such restrictions should not impede the exploration of what "could happen," which is what this methodology intends to pursue.

While some degree of inference may be required when selecting a number of the items in this checklist, the inclusion criterion used for many of the items was that they should be capable of passing the "fly on the wall" test. In this test, a hidden observer very familiar with the task and the contexts under which it may be performed should be able to be reasonably assured that an item from this checklist applies if that observer can "see" both the human and the context within which the human is performing. In addition, the types of failures comprising these categories should, for the most part, be separable from the explanations that potentially underlie these failure modes.

Table 40.1. Checklist of human failures

Perceptual activities	Communication activities	Mediational activities	Response execution activities
▪ Misses signal/cue or insufficient signals considered ▪ Ignores signal ▪ Confuses signals ▪ Fails to detect changes (*e.g.*, trends) in situations ▪ Fails to detect changes in situations related to deterioration within the system ▪ Fails to verify or correlate unusual information ▪ Only partial information gathered ▪ Gathered information from unreliable sources	▪ Absence of communication ▪ Communication ambiguous (key details omitted) ▪ Communication using a medium that is not likely to be checked on time ▪ Communication is overloading (too much raw data given too quickly) ▪ Communication to wrong individual or team member ▪ Communication lacks necessary context (and thus details can be misleading) ▪ Communication is unintelligible (*e.g.*, due to language barriers or distortion in communication channel) ▪ Communication too aggressive in tone (and thus may not produce adequate questioning) ▪ Communication not understandable (*e.g.*, due to use of inappropriate terms or lack of knowledge by the receiver) ▪ Understanding of communication by receiver not verified	▪ Computation is incorrect (*e.g.*, computing a dosage requirement) ▪ Estimation/anticipation is incorrect (*e.g.*, how many orders will get delayed, how long it will take for temperature to stabilize) ▪ Misinterpretation of information being attended to (*e.g.*, thinks data is in cm and not mm) ▪ Judgment is incorrect (*e.g.*, safety implications of a lab result or display reading) ▪ Assigns too much importance to a source or item of information ▪ Fails to define task goals ▪ Fails to select a plan to meet task goals ▪ Ignores pre-conditions in selecting a plan ▪ Ignores feedback during problem solving or system operations ▪ Misinterprets feedback ▪ Uses the wrong rule ▪ Confuses one rule for another ▪ Fails to invoke a rule that should have been invoked ▪ Performs a routine violation of a procedure ▪ Performs an exceptional violation of a procedure ▪ Failed to consider side effects of actions ▪ Allowed oneself to become distracted during an interdependent sequence of actions ▪ Insufficient consideration of information during problem solving ▪ Incorrect sources of information used during problem solving or for making a decision	▪ Action is too early or too late (*e.g.*, in initiating an order) ▪ Action is insufficient or excessive (*e.g.*, force or movement) ▪ Actions are performed in the wrong sequence(*e.g.*, steps are reversed) ▪ Actions are omitted (*e.g.*, in an assembly operation) ▪ Actions are repeated (*e.g.*, administering a drug twice) ▪ An extraneous action is substituted ▪ A correct action is applied to the wrong object or process ▪ An incorrect action is applied to the right object ▪ A check on an action is omitted ▪ Action is performed too fast or too slow ▪ Actions are in the wrong direction (*e.g.*, when setting a thermostat) ▪ Actions are of the wrong movement type

Thus, although "uses the wrong rule" may be construed as an *explanation* or *cause* for a "wrong action performed," it is also conceivable that an error such as "uses the wrong rule" can be represented within a TA and thus be considered in terms of its consequences, as would be the case for any failure mode—whether human or mechanical component. Furthermore, as causes of failure modes will generally be attributed to an interplay between human tendencies and the contexts in which these tendencies or limitations are embedded, "uses the wrong rule" should, in turn, require an explanation that, as we shall see, will be based on linkages between human tendencies (that essentially define human fallibility) and the contexts within which the human performs. Finally, as will be discussed further on, these failure modes represent a first pass. There will an opportunity to refine or generate new failure modes that are based on a more detailed understanding of the operational context by employing yet another variation of a well known hazard evaluation technique—in this case, a human failure hazard and operability analysis (HAZOP).

40.2.3 Human Failure Modes and Effects Analysis (HFMEA)

As indicated above, the hazard evaluation technique referred to as failure modes and effects analysis (FMEA) is more accurately referred to as a human FMEA (HFMEA) when its focus is on the ways or "modes" in which the human can "fail." An advantage of the FMEA technique is that it lends itself to thoroughness, and is thus often acknowledged for its ability to optimize designs and incorporate protective features into the system design. However, it has disadvantages as well. One problem with it is that there is no method for assessing the degree of thoroughness of the analysis. In adapting FMEA for human failures [1], this drawback is minimized by preceding this analysis with a TA, which provides the template for identifying failure modes—that is, the requirements specified in the TA dictate the possible failure modes that are considered by the HFMEA. What this in effect does is shift the burden to ensuring a thorough TA.

A disadvantage of FMEA that remains as well in the HFMEA relates to the emphasis in the conventional FMEA on single-point failures (*e.g.*, a valve failing open), which increases the likelihood of failing to account for adverse system outcomes deriving from multiple co-existing hazards or failures. As we shall see, FMEA adapted for human failure modes ultimately will need to be combined with other hazard analysis techniques that can serve to incite creative brainstorming about higher-order threats to the system. This exercise should logically follow the HFMEA, and will need to be tailored to the specific system in question.

40.2.4 Human-failure HAZOP

To further refine the failure modes, the analytical team can also consider applying the HAZOP analysis method [16]. This well known hazard evaluation technique uses a very systematic and thorough approach to analyze points of a process or operation, referred to as "study nodes" or "process sections" [17]. In its most fundamental form, this analysis is conducted by applying, at each point of the process being analyzed, "guide words" (such as "no," "more," "high," "reverse," "as well as," and "other than") to parameters (such as "flow," "pressure," "temperature," and "operation") in order to generate deviations (such as "no flow" or "high temperature") that represent departures from the design intention. Analogous to FMEA, HAZOP analysis also includes determining reasons for the deviations, consequences of the deviations, and recommendations in the form of design changes, procedural changes, or areas for further study. The guide words are the key to stimulating the brainstorming process that underlies hazard identification. In fact, HAZOP is distinct from many other hazard analysis techniques in that it depends highly on nature of the team assembled and the team's brainstorming dynamics in terms of the stimulation of creative analyses and the generation of new ideas.

Although HAZOP was initially intended for process industries, as with FMEA there is no reason it cannot be adapted to human failures. However, in the proposed methodology, the

emphasis is on the creative aspect of HAZOP—the application of guide words to parameters. Thus HFMEA remains the core template for organizing the human failure analysis, while other methods feed into it (like TA) or embellish it (like HAZOP). The key is to derive "guide words" and "parameters" that are applicable to the TA. As in traditional HAZOP, where teams often supplement lists of deviations with ad hoc items, the analysts can consider any descriptor relevant to the task or context that can qualify or quantify the human failure. As noted in [1], this "*human-error HAZOP*…can range from a simple biasing of the HAZOP procedure towards the identification of human errors to an actual alteration of the format of the HAZOP procedure itself" (p. 95). For example, this human HAZOP used knowledge of drilling operations and a number of taxonomies of human error to create an additional set of HAZOP guidewords as an aid for identifying human errors in an offshore drilling exercise [18].

40.2.5 Identifying Consequences and Assessing Their Criticality and Likelihood

Conventional FMEAs usually incorporate a cause for each failure mode identified as well as the consequences of these failures. These consequences are sometimes referred to as failure events as it may be necessary in some instances to surmise the consequences from the events (for instance, the implications of a failure event described in terms of a clutch pedal that does not move or a lack of response to the activation of a switch).

It is also possible for each failure event to have adverse consequences for one or more "system targets" such as personnel, production (including quality), equipment, the environment, and the public (including public perception). Depending on the risk assessment approach adopted, a criticality value could also be assigned to each failure-target combination. Qualitative risk assessment perspectives would assign a subjectively designated level of severity and likelihood to the consequences of the failures. Four levels of severity that are often used are negligible, marginal, critical, and catastrophic. Levels of likelihood could include impossible, improbable, remote, occasional, probable, and frequent. Taken together, these levels would determine whether actions are recommended for mitigating the risk [17]. Quantitative approaches would attempt to compute a component criticality number, defined as the number of system failures in a particular class of severity per hour or trial caused by the component across all its failure modes [2].

Unlike the generation of possible failure modes for a given TA step, the complex events that may intercede between human failures and adverse consequences argue for making consequence analysis a dynamic team enterprise. As with traditional FMEA, the analysis of consequences should not be biased by knowledge derived from the analysis of causes of the human failures, implying that the initial emphasis should be on *identification* of consequences and their severity. For example, a causal explanation for the consequences of a human failure that requires many concurrent conditions to be in place and several human limitations acting in concert, while possible, may appear very remote and thus predispose analysts to exclude the consequences from consideration. This works against maintaining independence between likelihood and severity assessments of consequences, which is fundamental to risk assessment [2]. Thus, in addition to the identification of consequences, it should also be possible to assign a level of severity to the failure effect. However, the consideration of the likelihood of the consequences is a different matter; likelihoods of a consequence depend, in part, on the likelihood of the human failures that instigated the consequences. Gauging an appropriate likelihood category for consequences thus requires a consideration of the possible causes or explanations for the human failures, as indicated in Figure 40.1.

One approach to likelihood assessment is to assign "confidence weights" to the different sets of causes or explanations that are being considered for the human failure (as discussed below, a set of causes comprises some combination of contextual factors and their interaction with human tendencies and limitations). The ability to generate several high weights would then imply a possibly high likelihood category for the consequences being considered.

40.2.6 Explanations of Human Failures

Causal analysis from a systems perspective requires an understanding of the context in which the human performs and how human tendencies and limitations can interact with these contexts. Although this analysis can suggest how likely the possibility is for certain human errors, its real benefit lies in its ability to bring about a deeper qualitative understanding of the interactive human-system process. This knowledge is essential for suggesting safeguards or barriers, or other courses of action (*e.g.*, replacing or eliminating parts or entire systems) for the purpose of reducing risks associated with human errors. The generation and use of this knowledge also provides an organization with the ability to learn (*e.g.*, in regards to weaknesses in the system or how common work-related conditions and events can combine to produce adverse consequences).

To aid analysts in identifying important interactions between relevant performance conditions and human tendencies and limitations, two checklists can be used (steps 2.6a and 2.6b in). Table 40.2 presents a number of categories of contextual factors that can impact upon human performance, and Table 40.3 lists a number of human tendencies. Many of the human tendencies reflect human cognitive or physiological limitations and thus represent aspects of human fallibility. The information contained in these checklists derives from a wide variety of sources that include [3, 7, 15], as well as other sources and personal research studies. These checklists can easily be extended or modified to be more applicable to a particular work domain or a specific set of operations of interest to an organization. To the extent that they do not represent a compilation of simple sparse statements, as are typically found in applications of HRA, but provide some logic and inherent guidance as to their potential applicability, then these checklists become aids. In this regard, both tables were constructed with the intent of demonstrating their pedagogical nature, although the extent to which this is done is more illustrative rather than exhaustive.

Using an aid such as Table 40.2, the task is to *assemble* various scenarios than can possibly characterize performance conditions, by identifying relevant contextual factors or categories and then their corresponding attributes (*i.e.*, items). These contextual factors can be depicted in a small graphical network to highlight the ways in which these factors can interact and thus induce a demanding performance environment [9]. These depictions are not intended to constrain the effects of the contextual factors by examining how one factor sequentially impacts upon another, but rather attempt to capture the totality of the context. Temporal attributes in the interactions between these factors can also be considered. For example, feedback that is delayed or in a form that is difficult to access may be missed, and this may impact upon how information becomes documented for use by other people

Following the construction of relevant networks of contexts, the analytical team would need to determine which human tendencies or limitations are relevant to the contexts under examination, and how these tendencies could result in "errors." Note that many of the human tendencies that are listed are not mutually exclusive—some imply the existence of others. Also, many of these tendencies can be thought of as subsumed under a superordinate tendency such as load shedding or minimizing cognitive load [19], which ultimately may be manifest in behaviors that are referred to in [20] as the efficiency-thoroughness tradeoff. As suggested earlier, when possible linkages between human fallibility and contexts are discovered, confidence ratings can be used to assess how likely the analyst feels that the interplay identified represents a credible explanation for the possible human failure.

There will be times when the linkages between context and human tendencies are relatively straightforward. In fact, such linkages are probably good starting points in the analysis. For example, a working environment characterized by spontaneous interruptions and that requires activities involving face-to-face communication can form a context that on its own can be conducive to omissions in communication. By building on this context, for example, by recognizing that cues needed to trigger recall of the required communication are generally absent, the confidence in the generation of this

human error through the interplay of context and human tendencies is increased.

This analytical process discourages the view of the expert [6] or lone analyst in favor of brainstorming. Thus, as with the application of more conventional hazard evaluation techniques, careful attention needs to be given to the makeup of the analytical team [17]. Brainstorming also can expand the scope of the analysis. For example, it can enable better conceptualization of how actions at earlier steps or how different system states can interact with an error, and how different system states that emerge can result in new problems for the human performing the task. It can also encourage suggestions for barriers and discussion concerning the possible implications on the system of these barriers.

40.2.7 Addressing Dependencies

A fundamental disadvantage of the FMEA technique is that it does not address adverse consequences induced by co-existing multiple-element failures within the system. In the case of a HFMEA, the effects of prior human failures on impending human actions or behaviors may be important. In fact, human failures may transform the system in ways that may require rethinking the TA in terms of alternative actions the human may take, both imminently and more distally. For example, consider a person performing maintenance operations involving a series of steps under time constraints, and in a restricted space with poor lighting that makes it difficult to access or consistently refer to written work procedures. An error in this operation (which could take on a number of different forms depending on the nature of the task and other individual factors) could result, at a later time, in an unexpected system state that further disposes the human to error.

This raises a related issue, which concerns whether TA as a technique can capture the fluctuations that may occur in human response to system demands, including those demands that are now imposed due to previous human performance shortcomings. In general, a good TA should account for alternative human actions in the form of contingencies if goals and plans are not accomplished. When a HTA is displayed in a tabular format, it is not uncommon to devote a separate column to considerations such as whether problems associated with a particular step in the TA can impact other steps, or whether the person has opportunities to detect or recover an error that was performed. However, even if the TA is limited in this respect, the consideration of prior human failures on impending human actions at this stage of the overall analysis provides the opportunity to close such gaps in the TA, as illustrated by the feedback loop from step 2.7 to step 2.1 (Figure 40.1). In this sense, the prediction of human failures and their consequences is, like any design procedure, an iterative process that seeks to revisit assumptions and revise the analysis.

40.2.8 What-If Analysis

In addition to consideration of whether human failures can impact upon other (impending) human behaviors, the effects on the system of multiple human failures that may or may not be coupled need to be addressed. This clearly necessitates a brainstorming process, and use of techniques such as What-If analysis [17] is appropriate. In traditional hazard analysis, this technique can, in principle, be used to examine virtually any aspect of a system's design or operation.

40.2.9 Design Interventions and Barriers

Once explanations for the possible human failures have been proposed, barriers that can prevent or mitigate the adverse consequences can be considered. A useful classification system for barriers [20] considers four categories: physical barrier systems (that physically prevent an action from taking place); functional barrier systems (that impede the actions from taking place); symbolic barrier systems (that require interpretation); and incorporeal barrier systems (that depend on the knowledge of the user).

With regard to each of these barrier systems, the barrier can perform its function in various ways. For example, some of the functions of physical barrier systems include containing or preventing (walls, restricted access, containers), restraining or preventing movement (harnesses, cages), maintaining

resilience (rigid consoles, shatterproof glass), and separating and protecting (scrubbers and filters). Functions of functional barrier systems include preventing movement or action (interlocks, passwords, pre-conditions), hindering actions (controls out of reach), attenuating (noise reduction), and dissipating energy (air bags, sprinklers). As noted, symbolic barrier systems require interpretation and include functions such as countering or preventing actions (labels and warnings), regulatory actions (instructions, procedures), indicating system status (traffic signs, warnings, alarms), and communication (air-traffic controller giving clearance, approval by a supervisor to begin work). Finally, incorporeal barrier systems depend upon functions such as complying (social or group pressure, ethical norms) and prescribing (rules, laws).

In addition, systems that are designed to provide feedback that can promote self-detection of errors, and the use of redundant independent checks (*e.g.*, by co-workers or supervisors) can also serve as barriers. The important factor in the consideration of barriers is that these systems can also impact upon the context within which the human performs [9]. Thus the consequences on the system of these barriers also needs to be evaluated (Figure 40.1), consistent with the iterative nature of any design process.

40.3 Summary

This chapter has presented a methodology proposed for the purpose of exposing possible human errors and violations and for analyzing the potential consequences and possible causes of these behaviors. The argument was made that such a qualitative approach to proactively accounting for human failures in human-system interaction can be conducive to organizational learning. The approach is highly dependent on producing a thorough task analysis as its starting point, but then hinges on the application of a combination of hazard evaluation techniques that have been adapted for analysis of human failures. The possible need for iterative analysis and the importance of using a dynamic group process for brainstorming was emphasized.

Table 40.2. Factors governing the contexts under which the human performs

Time available to perform any of the task Activities
• Is there enough time to: perceive the inputs or information; understand what is being perceived; integrate what is being perceived; or interpret what is being perceived? • Is there enough time to respond (*e.g.*, manually) to what is being perceived or cued? • Is there enough time to put together an adequate plan? • Does time allow for effective strategies in time-sharing, for example, in performing some task and intermittently communicating with other people?
Adequacy of Human–Machine Interface or Task Design
• Is the location of displays or other important items consistent with the geographical layout of the environment that needs to be monitored or controlled? • Are displays or controls that serve similar functions grouped together? • Are displays or controls that are frequently used or serve important functions placed in prominent positions? • Are displays and controls appropriately positioned so that there is minimal confusion concerning which controls are associated with which displays? Are displays and controls properly and conspicuously labeled so that there is minimal confusion concerning what one is looking at or listening to or what control is being activated? Are displays and especially controls too crowded so that there is the possibility for confusing displays or controls?

Table 40.2. (continued)

- Is there a hierarchical organization of information available to the human concerning the overall system, from its individual components to representations that capture the general functions and objectives of that system, so that a range of different types of activities, from normal control to diagnosis and decision making can be supported?
- Do actions such as button presses provide adequate feedback (that is salient and that provide redundant cues)?
- Does the human have to invest reasonable effort to acquire information from the device or system, for example, by having to be very precise in physical input actions, by having to negotiate many menu systems on a single display in order to find the needed information, or by excessive scrolling or following activated links?
- Are the displays that the human must monitor or controls that the human must activate organized so that the human must expend reasonable effort to move between displays or controls? If so, the tendency to minimize effort may result in minimizing walking around, possibly leading to omissions or reading errors.
- Is the content of the information complete and unambiguous so that the human can reliably identify and classify needed information, and is the information being provided relevant to the task?
- Are task-related events or information input occurring at a frequency that is possibly beyond the ability for a human to adequately process?
- If the human needs to see historical trends in data or information, can the system interface provide this information, and do so in a form that the human can easily process?
- Can information easily be transitioned between its raw forms (for example, the values of individual variables) and the integration and suitable presentation of this information according to various rules that the human may need to apply?
- If the human needs to assess what-if scenarios can the interface provide such assessments, for example, through predictive displays?
- If the human is interacting with a hand-held device, is it easy to locate the device, get to the desired function, and negotiate its display of information?
- If alarms are present, do they provide sufficient feedback concerning the nature of the problem and possibly even some indication of appropriate actions to take?
- Have alarms been designed to strike a balance between "nondetection" and "overstimulation" (which can result in shutting off alarms)? Can alarms disrupt the processing of other alarms or important speech communication?
- How extensive is the use of synthesized speech? Because listening to synthetic speech may demand more mental resources than listening to natural speech, it may interfere with other ongoing tasks.
- When people need to handle objects, controls, or tools, has redundancy been considered (*e.g.*, by providing "haptic" information regarding the shape of manipulated objects)? This may be critical where protective clothing such as gloves may diminish the ability to correctly identify the object.
- Are controls "isometric" in the sense that they do not move when pressure is applied to them? This lack of feedback could undermine human control activities.
- Are lockouts appropriately designed and labeled so that their operation and status is clear?

Table 40.2. (continued)

• When the person's hands/eyes are busy when multitasking, are voice commands available to perform the additional task or tasks?
Automation and New Technology
• Is the human required to passively monitor displays or automated systems for considerable amounts of time? • If something were to go wrong with the automated system or subsystem, are the deviations presented quickly enough to the human and in a way that would allow the human to be reasonably successful at diagnosing the problem? • Is the reliability of the system sufficiently high to ensure that the human has adequate trust in its performance? If not, is there an understanding of the types of strategies the human may resort to in the face of such unreliable performance? • Is the human given sufficient hands-on experience with the system in order to ensure that control of the automated system can be maintained in the event of automation failures? • As a result of limits in automation, are there tasks the human needs to perform that are fragmented in the sense that they are simply pieces of larger tasks that disrupts or distracts from the larger continuity of the task? • Does the human have an adequate model of the automation so that if distracted the human can quickly assess what the automated system is doing? • Is the system designed in such a way that the human can easily identify the mode in which the automated system is operating in? • Is the system designed in such a way so that the implications of human actions to the automated system are made apparent to the human? • If new technology is introduced, can there be problems confusing previous information or activities with ones that are now required?

Work Procedures
• Are written procedures or procedures in some other form available to guide performance of the task, or is the human expected to know how to perform task activities without resorting to any procedures? • Are procedures integrated with training, so that during training people had the opportunity to reference and test the procedures, or are training and work procedures unlinked? • Were the procedures directed or guided by a task analysis? • Have the procedures been performed by their designers to determine the feasibility or adequacy of the procedures? • Are the procedures written in a clear, unambiguous language, with relatively short sentences (so that the meaning of a sentence is not apparent until a later portion of the sentence is read), and minimal use of negation? • Are the procedures organized and formatted well, so that the persons following them can easily anticipate where other information is and have a good model of the relationships among different sections of the procedure? • Do procedures have good implicit placeholders so that workers can easily find their place following an interruption? • Are the instructions in the procedure congruent in the sense that the order of the words or commands corresponds to the order in which they are to be carried out? • If the procedure is similar to one or more other procedures the worker may perform, for instance, in terms of common sequences of operations or the need to identify similar conditions but which require different responses, are there mechanisms present to ensure that the worker continues to use the correct procedure?

Table 40.2. (continued)

• Are sufficient information, examples, and context provided to allow people to develop sound mental models from the procedures, so that the procedures generate a set of expectancies about how the device or system will behave? • Are the procedures consistent with the expertise of the workers? • Do the procedures expose the people who must perform them to undo risk or hazards? • Are the procedures cumbersome, so that they require a good deal of mental or physical effort, or do they appear unduly time consuming? If so, are short-cuts or easier ways of doing the procedure identifiable by workers? • Do workers have a convenient work area for consulting the procedural documentation? • Are people expected to improvise procedures when there are procedural aspects that lack specificity? If so, are they given any guidelines about how to go about doing this (for example, strategies to use in certain situations or boundary conditions governing when they should or should not attempt certain activities)? • If people improvise on procedures, is this information documented in some way so that the organization can better understand the implications of such improvisation? • Do procedures identify contingencies, backout criteria, indications that an error or abnormal system response has occurred, and potential recovery points to eliminate or reduce the adverse consequences of errors? • Do the conditions under which the task needs to be performed prevent easy reference or access to the procedures?
• Have procedures been revised to take into account changes that have been made to the operations, such as the use of different equipment, communication protocol, and objectives? • Are the people who are to perform the procedures involved in their design? If not, procedural violations are more likely due to incompatibilities between workers and designers or managers in perception of the adequacy of the procedure. • Have procedures taken into account lessons learned by the organization? If not, they may lose their credibility and thus become susceptible to violation. • Do procedures indicate ways in which the person performing the procedure can recover from potential errors or circumstances that can result in losses?
Training
• People will tend to perform tasks that are procedural (*i.e.*, based on the kinds of knowledge that allows us to do tasks, but that is difficult to verbalize) more effectively if training is conducted using actual task performance rather than the presentation of facts, *etc.* • It may be more effective to offer instructions that use pictures and voice since these can be processed in parallel and tend to place less load on the person during training. • In cases where work procedures will be used, does training adequately address the concerns and challenges implied in the procedure? • If certain aspects of a procedure may not apply in particular situations, have rules or boundary conditions been explicitly communicated so that workers can clearly map a procedure's directives to the given situation?

Table 40.2. (continued)

- For situations in which it is essential that a vast array of perceptual cues be accurately identified and integrated with a variety of control responses, has simulation been used as a vehicle for training?
- Is training dominated by the presentation of vast amounts of declarative (facts, rules) information prior to gaining experience with the work activities? If so, much of this information may become "inert" and become useless. Consider more active involvement with task activities, where knowledge is gradually accumulated as experience is gained.
- Are workers trained in developing accurate and useful mental models of aspects of the process or operations in addition to more fundamental information on task operations? If not, the person may be less likely to deal with abnormal or novel situations and more likely to perform actions with adverse consequences.
- Has appropriate performance support (*e.g.*, job aids, troubleshooting support) been considered?
- Does training impart sufficient knowledge for the person to adequately perform the task?
- Is there adequate and sufficiently frequent training for emergency procedures or operations?
- When new technology or automation is introduced, does training address the relevant concerns? For example, if new technology results in different team communication patterns, are these changes anticipated and adequately addressed in training? If automation requires understanding the underlying dynamics of the technology and incorporation of new control strategies, are these issues anticipated and adequately addressed in training?
- Has training considered informing people about the miss/false alarm tradeoff?
- Has training considered the possibility that people may not use a device or system for an extended period of time and may require becoming reacquainted?
- Has training considered how people can detect their mistakes and the mistakes of others?

Task Feedback

- Does the human receive feedback concerning his of her actions?
- How quickly is feedback given? Delayed feedback could be problematic.
- What is the form of the feedback? Is it in a form where it could be easily missed if distracted or not paying attention? Is it in a form that is legible and understandable? Is it in a form that makes it difficult to access?
- Does the human have control over the feedback; that is, can the human request feedback, and manage the form in which that feedback is received?
- Does the control device or system only provide artificial visual feedback (*e.g.*, a red light turning on) to indicate a state change? Such feedback can easily be missed or misinterpreted.

Information Sources and Documentation (Related to Procedures)

- Are there multiple sources from which the person can obtain information from? Does the human have to make a choice concerning which source to consult?
- Is the information in the source legible, unambiguous, accurate, and complete?
- Is it relatively easy to obtain information from the source or does it require reasonable effort?
- Is it relatively easy to embellish or edit the information in the source, for example, adding comments or information, or changing values?

Table 40.2. (continued)

• Does the human have the ability to manage the information in the source by having the information organized and displayed in different formats (for example, requesting that trend information be displayed)? If so, how easily can this be done?
Multiple Objectives
• Are there multiple objectives to satisfy? How many? • Is it clear what these objectives are? • Are these objectives relatively stable or are they changing over time? • Do the objectives have different priorities? Do these priorities shift over time?
Ergonomic Considerations
• Are there high levels of noise? Is there noise in frequency ranges that can mask important communications or alarms? • If communication between people is essential and the individuals are not always in physical proximity, is there a protocol to ensure that all possibly needed communication channels are available in working order? • Do people need to perform activities in restricted spaces? If so, can these workers attend to all relevant stimuli? Can they assume their postures for the time needed to perform the activities without becoming fatigued? Can they maneuver and control tools, protective clothing, and equipment adequately? Can they communicate effectively with other people when necessary? • Are certain jobs difficult to carry out when wearing personal protective equipment such as earplugs, helmets, goggles, gloves, breathing apparatus, full body suits, safety belts, and safety footwear? If so, the risk of injury is increased.
• Are lighting conditions adequate for the work operations? Is their sufficient illumination, appropriate visual contrasts in the person's field of view, a lack of glare or flicker, and an absence of large external viewing areas (*e.g.*, windows) that can be distractive? • Can all visual stimuli, such as labels and icons, be sufficiently discriminated from one another? • Are there conditions of heat, humidity, or cold? If so, workers are likely to become fatigued or accelerate or bypass activities. • Are tools designed appropriately for the tasks they are used to perform? If not, can they induce too much or too little force, excessive variability in movement, or insufficient control? • Are there concerns for poor air quality due to pollutants or other factors? If so, the person's mental functioning may become compromised. • Do controls require excessive force or static forces? If so, these actions may be subject to suboptimal control.
Workload
• Is most of the activity concentrated in relatively small blocks of time? If so, there are concerns that the person is sufficiently alert and ready to confront the demands. • Is the workload excessive, in terms of the rate at which events occur and need to be handled, or in terms of the degree of multitasking required? If so, load shedding through simplification or other approaches may lead to neglecting procedures. • Is the person required to work long shifts so that fatigue is an issue? In the event of shift changes, this may erode the effectiveness of communication to the incoming shift. • Are there sufficient rest pauses for highly mental or physical work activities?

Table 40.2. (continued)

• Are there long or uneventful vigilant periods? If so, the human may be vulnerable to missed information or incorrect processing of events. • Are there demands to perform calculations? These activities often take time and if unsupported (*e.g.*, by computer aids) are error prone and can take time away from other activities.
Organizational and Psychosocial Factors
• If there are highly interrelated tasks that require considerable communication and cooperation among a number of people, is some systematic method of team training on these tasks incorporated by the organization? • For tasks or operations involving teamwork, has the distribution of workload among team members been given adequate consideration? Overloading can result in the inability to address certain ongoing activities for which one is responsible, and underloading can result in a lack of alertness. • Does role ambiguity exist, whereby a person is uncertain about his or her role at work? Has the organization made the work objectives, what coworkers and supervisors are to expect, and the scope of the responsibility clear to the worker? • Is it likely that a worker may skip an activity by assuming that it will be done by someone else at some later time? This usually occurs under time pressure and when clear roles and responsibilities are not defined. • Does role conflict exist? That is, is the person simultaneously subjected to two or more sets of pressures such that complying with one set undermines compliance with another? • If a person is uncertain about how to perform an operation, would it be clear that assistance should be solicited and where such assistance should come from? If not, the person is likely to ignore that operation. • Have clear protocols for communication been established for different task situations? For example, do workers know when and what information needs to be specified to prevent ambiguity and thus the possibility for false assumptions? • Have clear protocols for communication been established so that people know which channels of communication are appropriate for the different situations? For example, during shift changes, face-to-face communication may be needed whereas phone contact may be appropriate for other situations. • Have clear protocols for communication been established to mitigate the potentially detrimental effects of a lack of questioning by passive types who are receiving the communication and intimidation by aggressive types providing information? • Does the organization subcontract workers? If so, is the organization assured that these workers understand the communication protocols and other work-related policies that are in place among the full-time workers, and that would need to be known if these subcontracted workers were to communicate with full-time employees, especially across shifts? • Is there a clear leadership within teams or groups of workers? • Do individual work group cultures exist within the organization? Do these cultures impose pressure on individuals within the group to follow certain practices?

Table 40.2. (continued)

- Has the organization addressed staffing issues so that workers understand that understaffing is not the organization's policy?
- Does the organization embody a culture that emphasizes repeated and independent checks?
- Does the organization provide adequate time and resources for personnel involved in design activities? For example, are designers working under undo time pressure? Are they deprived of the opportunity for adequate testing of their design concepts and iterating their designs?
- Does the organization have a "blame culture" whereby management exonerates itself when incidents or accidents occur and shifts the blame to those who violated procedures or who otherwise were responsible for the final actions that gave rise to the adverse event? Such cultures create distrust between workers and supervisors, a lack of learning and improvement within the organization, and violations of procedures.
- Does the organization possess a good safety culture? Such organizations provide the opportunity for organizational learning from incidents, accidents, and operations in general. They typically have open feedback channels between their workers and management that enables ongoing revisions to procedures, strategies, and designs to be incorporated and evaluated. Such organizations have more "open" climates that view their employees as stakeholders; the employees, in turn, are usually more willing to offer important information on operations and incidents.
- Is there a tendency for the organization to only report deviations from normal operations? If so, workers are likely to interpret the absence of reporting as indications that their performance is appropriate when in fact it may not be.

Perceptual/Memory Tendencies

- People can only attend (*i.e.*, focus on) a limited number of cues (due to memory limitations).
- When information is received over time, the earlier aspects of this information tend be given the greatest weight. Information that occurs later or that changes over time has a greater likelihood of being ignored.
- People are more apt to attend to perceptually salient information, and this information is likely to be given more weight.
- People tend to simplify the processing of information by treating many of the features or aspects of the "message" as if they were about equal in significance and thus tend to overweight unreliable cues.
- People tend to look for information that confirms the selected diagnosis, decision, or idea, and avoid seeking information that could support an alternative theory.
- People tend to "sample" the world where they expect to find information, and attend to channels based on how valuable it is to look or costly to miss.
- People are limited in how many absolute judgments they can make, for instance, in being able to absolutely identify a particular alarm or pressure level. Thus if there are too many alarms that each need to be identified, confusion becomes an issue.

Table 40.3. (continued)

- Accuracy and speed of recognition of features or aspects of information will be greatest when the displayed features are compatible with how those features are represented in long-term memory (LTM).(LTM contains our storehouse of potentially retrievable information; it provides the basis for storing information and retrieving it at a later time.)
- People tend to rely on good articulation of the edges of objects for their recognition.
- As stimulus quality degrades, people tend to rely on increased contextual information as well as redundancy to successfully negotiate the information.
- People tend to perceive negation in sentences poorly because our perceptual system treats the positive meaning of a sentence as the default state of the message.
- The need to select information from a larger array of information sources will tend to be inhibited or reduced in its emphasis if this activity is effortful.

Tendencies Due to Memory Limitations or Resorting to Heuristics

- Working memory (or short-term memory) is a kind of "workbench" of consciousness in which we visualize, plan, compare, evaluate, transform cognitive representations, develop an understanding of information, make decisions, and solve problems. People can only keep a limited number of items in their working memory (short-term memory) and, unless this information is rehearsed, can only do so for a limited time—otherwise this information decays rapidly.
- People tend to have greater difficulty accurately recalling items in WM if the items sound or look similar to other items being entertained.
- People tend to have difficulty comprehending text that requires retention of words whose meaning is not apparent until a later portion of the sentence is read.
- People tend to process instructions better if the order of the words or commands in the instructions corresponds to the order in which they are to be carried out.
- People tend to be better at recalling or reactivating information of a particular type that has been frequently activated in the past (which allows that information to have a stronger trace in LTM).
- People tend to be better at recalling or reactivating information of a particular type that has been recently activated.
- When people receive new information about events or situations, they do not make appropriate adjustments in the likelihoods of those events; typically, their "new" likelihood assessments are too low or too high.
- Different pieces of information that are activated together in WM tend to become associated in our memory and these associations can form the basis for later reactivation from LTM. When processing information that is or can be represented in the form of If-Then rules, as may occur in troubleshooting, the activation (for instance, by virtue of what one perceives or mentally considers) of parts of the If portion of the rule or other representation will tend to increase the likelihood of other associated information becoming activated as well.

Table 40.3. (continued)

- People tend to fail to retrieve information that is stored in their LTM because that information is weak in strength due to there having been a low frequency or lack of recency in its activation, weak or few associations with other information contained in LTM, or interfering associations as might occur when too many associations needed to be acquired in a short period of time.
- The knowledge that people have about many things, topics, or concepts tends to be organized (*i.e.*, associated) in LTM. People often rely on mental models, which is organized knowledge concerning concepts, equipment, or systems that allow people to generate a set of "expectancies" about how the system or equipment will behave.
- Unless people are very well trained and have rehearsed needed information thoroughly, information that is "out of sight" will often be "out of mind" (*i.e.*, not considered), especially in the face of distractions or interruptions, or when there are many activities taking place.
- People tend to have knowledge about their own knowledge and abilities, including the anticipated effort required to gain additional information, and this will factor into their strategies.
- People are often overconfident in the accuracy of their own knowledge (knowledge in the head), and thus may disregard the need to expend effort to gather information (knowledge in the world)
- Powerful interface features or computer aids that require high degrees of cognitive effort to learn may be disregarded unless the costs incurred by their disuse are made sufficiently high. When time-sharing (*i.e.*, performing multiple activities almost concurrently), people will have greater success if one or more of the tasks has become almost automatic to the point of requiring almost no cognitive effort (*i.e.*, attention). For a task to become automatic there must be consistent mapping between its elements—for example between what the person sees and what the response to that stimulus should be.
- People tend to be better at time-sharing when the inputs from the tasks are spread across different modalities (for example, vision and hearing) as opposed to forcing the human to use the visual channel or the auditory channel for processing both tasks.
- There is a better chance of successful time sharing if people know the details regarding the relative importance of the tasks.
- Guesses that people make about what events or situations are occurring or have occurred are usually based on expectations, which, in turn, are based on past experiences that are stored in one's LTM. Expectations for these events or situations will be high if they have been frequently encountered in the past, or if they have associations with other events, cues, or scenarios that have been experienced within the same context.
- People are only able to entertain a limited number of hypotheses or alternative explanations at a time.
- People will retrieve hypotheses most easily that have been considered recently or frequently.

Table 40.3. (continued)

- People tend to judge an event as likely (*e.g.*, that a person should be classified as "suspicious" or that there is a malfunction in a connection between two subsystems) if the event
- "represents" the typical features of the category in question. Thus if a set of symptoms resembles the features for a particular hypothesis, this set will generate that hypothesis as a likely candidate.
- People tend to be overconfident concerning the hypotheses they have decided to consider and are thus less likely to seek out evidence for alternative hypotheses.
- Although people may have in their LTM a number of possible action plans associated with some hypothesis (for example different alternative actions if in fact the problem is insufficient power or is a particular disease or condition), people are limited in the number of such alternatives that they can consider at any one time.
- People tend to consider the most available alternative from their memory (*e.g.*, based on how recently or how frequently those alternatives have been used).
- The likelihoods that people assign to the outcomes of possible alternative or action plans will be distorted to the extent that instances of outcomes are available in one's LTM.
- In situations involving making decisions or judgments, people are susceptible to how the situation is framed; thus, depending on how a situation is cast, an investment in a safety system may seem appropriate or inappropriate.
- Tasks characterized by a relatively large and variable amount of information that is presented simultaneously but briefly, where there are many relationships among the different inputs of information, and where there is a relatively short time period for making decisions, tend to induce an intuitive decision-making process. Hallmarks of this process include low levels of cognitive effort, low conscious awareness, rapid processing, and high confidence in one's answer.

Slips and Lapses

- Are there tasks that are similar in sequence or have operations that are similar? For example, two assembly tasks may have similar sequences so that the operations governing one assembly task is embedded in a sequence of operations normally associated with the other assembly task. A distraction on the less frequently performed assembly task may result in the person resuming the task by performing the operations associated with (*i.e.*, "slipping into") the more frequently performed task.
- Does each step of a task adequately cue the next step? If not, distractions or interruptions may cause the person to believe the task was completed (*i.e.*, lapsing) when in fact it wasn't or result in the person repeating an operation.

Table 40.3. (continued)

Use of Rules
• When people perform activities by resorting to rules such as "If conditions A B C exist then the problem must be X" or "If the problem is X then actions Y and Z are required," they are vulnerable to first exceptions. This may occur, for example, when conditions A B C exist but in a different context, which may now invalidate the rule or require its modification. For example, a wrong diagnosis is made based on discovering 3 features symptomatic of a condition; the critical absence of another feature, which would negate the diagnosis, was not taken into account. • Inadequate knowledge can lead a person to believe that a particular rule is appropriate when it is not. This often occurs if the person's knowledge represents a partial match of the antecedent conditions of the rule; however, because the other antecedent elements have not been verified, that rule may be invalid for that situation.
• A rule that has been used with frequent success will tend to be made to fit a situation; thus, information may be perceived incorrectly, in part because it is similar to antecedent information of a frequently used rule. • When people need to make up time or feel compelled to minimize effort, bad rules are often adopted. These often form the basis for violations of procedures ("If I do it that way, then all the orders should still be processed in time").
Psychomotor Control
• Due the inherent noise within the human's neuromuscular system, the human is limited in the accuracy associated with any given motor movement. • When the input bandwidth is high relative to the system lag, people usually correct too quickly and do not wait until the system output stabilizes before applying another corrective input (*i.e.*, they don't filter out the high-frequency inputs). • In general, bandwidth, gain, and lag can all produce instability in human control actions.
Personality and Risk Taking
• Some personality types tend to heed the advice of group authority figures within work groups or organizations, even if that advice (*e.g.*, what to do if a machine jams or minimizing safety implications in prioritizing objectives) may lead to very adverse outcomes. • People will tend to be more motivated to perform if human-machine interfaces are well designed, ergonomic factors have been given attention, people are given good training and job performance support, people are actively involved in the design of procedures and incident reporting systems, and both vertical and horizontal feedback channels are available to them. • People tend to give more weight to the severity of adverse outcomes as compared to the likelihood of adverse outcomes in their perceptions of risk. • Decreasing danger by increasing barriers or other safety improvements (*e.g.*, in sensors or warnings) may increase a person's risk-taking tendencies. • People are more likely to be at risk of injury or inducing system losses when they step out from under supervision and become more independent and active in their work activities, most likely due to still working with an incomplete mental model.

Table 40.3. (continued)

	Tendencies when Under Stress
• A person's risk taking behavior will, to some extent, be determined by whether they have adequate knowledge concerning whether a hazard exists, what actions are available to cope with the hazard, and what the consequences are of safe behavior versus alternative behaviors (by considering alternative actions based on the risks and values of their outcomes). • Familiarity with a device or hazard tends to decrease the perception of risk. Recent negative experiences with a device or hazard tend to increase a person's perception of that risk. • People with a "locus of control" that is primarily internal, so that they perceive themselves as having control over external events rather than the other way around, are more likely to be successful in coping with external events such as emergencies because they feel their actions can affect what happens to them. People with a "locus of control" that is primarily external may seek the help of colleagues because they assume that the situation is out of their control. However, the external personality may be more cautious during normal task activities in risk taking. • People described as having a type B personality (relaxed, relatively satisfied, not always fighting situations) may be more effective in performing under stress than people having a type A personality (feeling more pressured and preoccupied with success). However, the type A personality may be more motivated to accumulate knowledge and acquire high skill levels. • Risk-taking tends to be increased when people operate in a group, possibly due to the fact that responsibility becomes diffused across team members and the problem appears less unique when it is debated within a group discussion.	• If conditions are dangerous, people may rely on others to make a decision. • People tend to focus on explaining past facts, which may no longer be important for the problem on hand (but provides a sense of control). • People do not delegate responsibility well. • The information overload that typically accompanies stress can lead to short-term paralysis in processing available information, possibly due to the sudden transition from a relatively low information-processing state to an overloaded state. • Confirmation bias is more likely, where people seek information to confirm an initial hypothesis rather than information that may disconfirm it. • People seek a single cause and do not tend to think in terms of multiple causes, and also fail to recognize many of the alternatives that are available and adopt an approach that is familiar or that seems to offer "a way out" of the problem. • Focused attention (*i.e.*, mental effort) at will becomes more difficult, most likel y due to the scope and degree of distraction of attention processes. • People resort to encysting (excessive attention directed to possibly insignificant details while important aspects are disregarded) and thematic vagabonding (for example, when diagnosing a fault jumping from issue to issue, but never pursuing any theme to its natural conclusion, often picking up previously abandoned attempts, forgetting that they were already pursued).

Table 40.3. (continued)

Other Human Limitations
• Emotional states (as may be induced by personal difficulties, including problems a person may be having with coworkers) and the state of fear (as may be induced when performing under perceived dangerous circumstances) can induce various forms of physiological and psychological stress that, in turn, can produce many of the tendencies people display under stress. Overall, one may expect to see a loss in orientation (failing to remember where one is in the task or what one is supposed to do) and a lack of attention. • When people become fatigued, their ability to focus their attention and mentally process information becomes reduced, and their physical responses (especially in response to cues) become slower and more variable (*i.e.*, less controlled). • Disturbances to circadian rhythms due to sleep loss, shift changes, or other factors can lead to physiological and psychological stress responses.

Risk Analysis and Management: An Introduction

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: Risk is the possibility of a hazardous event occurring that will have an impact on the achievement of objectives. Risk is measured in terms of consequence (or impact) and likelihood of the event. Qualitatively, risk is considered proportional to the expected losses which can be caused by an event and to the probability of this event. Quantatively, it is the product of probability of hazardous event and the consequences. General views about risk perception and risk communication are discussed that help decision making. Risk management and risk governance along with probabilistic risk assessment and alternative approaches to risk analysis are also discussed.

41.1 Introduction

From the time of emergence of *Homo sapiens* on this planet, man with his intellect, inventive nature, ingenuity, and skills has always been trying to improve his living conditions and create favorable conditions for his survival. In this process, man created man-made systems for his own benefit and comfort. The history of industrial development indicates that as man has tried to use technology to improve his standard of living, in doing so several new problems not anticipated earlier have cropped up. Technology became a means to provide objects and conditions for sustenance and contentment, and technology can be viewed as the changing environment of humanity. Ingenuity and innovation were required to overcome several practical problems associated with new inventions and technological improvisations. In fact, right from the dawn of the industrial revolution, safety and dependability have been very much on the mind of man, and through innovative designs man has been resolving these safety and reliability problems very ably.

41.1.1 Preliminary Definitions

All technological advancements have *hazards* associated with them. A *hazard* is an implied threat or danger of possible harm. It is a potential condition to become a loss. A *stimulus* is required to cause the hazard to transfer from the potential state to a loss (or accident). This stimulus could be a component failure, a condition of the system, an operator failure, a maintenance failure, or a combination of other events and conditions. Thus a *stimulus* can be defined as a set of events or conditions that transforms a hazard from its potential state to one that causes harm to the system, property, or personnel. An *accident* is usually considered as the loss of a system or part of a system, injury to or fatality of operators or

personnel in proximity, and damage of property such as equipment or hardware. Technically speaking, an accident can be defined as a dynamic mechanism that begins with the activation of a hazard and flows through the system as series of events in a logical sequence to produce a loss. Simply put, an accident is an undesired and unplanned event. Now coming to the definition of *risk* in simple terms, it can be called the expected value of loss. Risk is associated with likelihood or possibility of harm. It would not be out of place to mention safety here and to underline its difference from risk, which some people often misunderstand. Safety, in simple terms, is the condition of being free from undergoing or causing harm, injury or loss. Safety can be thought of as characteristics of a system, like quality, reliability, or maintainability. Safety can be defined as an attribute of a system that allows it to function under predetermined conditions with an acceptable minimum accidental loss or risk. *System safety* is a planned, disciplined, systematically organized, and before-the-fact process characterized by an *identify-analyze-control* strategy. In fact, the emphasis is placed on an acceptable level of safety designed into the system before it is produced or put to operation. *Hazard analysis* is at the core of the system safety approach. Anticipating and controlling hazards at the design stage of an activity is the cornerstone of system safety analysis. Incidentally, system safety is not *failure analysis* since *hazard* has wider connotation than a *failure*. Hazard involves risk of loss or harm. A failure on the other hand is an unintended state of operation; a failure can occur without a loss. On the other hand, severe accidents have occurred while a unit was operating as intended, *i.e.,* without a failure.

41.1.2 Technological Progress and Risk

All technological developments in the history of mankind have had risks associated with them. Therefore one has to look into the benefits accruing from these developments and the risks that go with the use of such technological innovations. In fact, man has to learn to live with them and accept risks as part of life. But before we come to the subject of acceptability of risk, let us take a glance at technological developments chronologically.

Steam Age Accidents: In 1866, during the steam age, there were 74 steam boiler explosions in England, resulting in 77 deaths. This was reduced to 17 explosions with 8 deaths in 1900 as a result of inspections performed by Manchester Steam Users Association. Better designs, such as tube-fired boilers, and boiler inspections reduced it further to about once every 100,000 vessel-years.

Rail Accidents: The history of railroad travel is also very old and it is full of accidents, the causes of which can be traced either to natural calamities, to technical faults in the locomotives or the signaling system, or to human error. Derailing has been a major cause of accidents. The worst accident was in Sri Lanka in 2004 due to a tsunami, where some 1700 persons died, followed by one in Bihar, India in 1981, where over 800 persons died due to derailment and plunging of coaches into a river. Head-on collisions have also been reported. A Japanese train crash in 2005 is said to have occurred, killing 106 and injuring over 555 passengers due to driver's over-speeding to keep train schedule. This was Japan's most serious accident after a 1963 Yokohama train accident, when two passenger trains collided with a derailed freight train killing 162 passengers. The Intercity Express high speed train in Germany near Hanover met an accident on June 3, 1998 due to the breakage of the rim of an axle followed by a chain of events leading to a crash in which more than 101 were dead and several others injured. The train was travelling at a speed of 200 km per hour.

Marine Accidents: Ships, being the oldest mode of transport and trade, have their own risks associated with them. Later on, submarines were also added. Collision and grounding happen to be major causes of accidents throughout the long maritime history. The luxury liner Titanic was considered unsinkable until it sank on its maiden journey. Besides these, there have been many cases of engine failures, other technical faults, and fires onboard. The main difficulty is facility of repairs while on the high seas. Oil tankers have had oil spills, leading to ecological hazards and threat to marine life.

Road Accidents: With the development of personal vehicles or cars for transport towards the end of nineteenth century, these vehicles also became sources of risk. The first human fatality associated with a motor vehicle was a pedestrian killed in 1899. In 1990, about 5 million people died worldwide as a result of injury. It is estimated that by the year 2020, 8.4 million people will die every year from injury, and injuries from road traffic accidents will be the third most common cause of disability worldwide and the second most common cause in the developing world. Also, it is worth noting that the statistics show a ten to one ratio of in-vehicle accident deaths between the least safe and most safe models of car.

Aviation Accidents: Man entered the aviation age around the beginning of the twentieth century. In the beginning, the safety criteria of aircrafts was in terms of mean permissible failure rate but by 1940s the safety criteria began to be expressed in terms of the accident rate, and a figure of one accident per 10^5 hours of flying was acceptable. During the 1960s it was reduced to one in 10^6 landings of the aircraft, and finally with automatic landing systems it was reduced to one in 10^7, and travelling by air became safer and popular.

With the air traffic increasing enormously and airplane security having been advanced considerably, the accident data analyzed between 1970 and 2004 shows that accidents have decreased from over 300 in the 1970s to approximately 250 in the 1980s and 1990s. The maximum number of accidents was found in the year 1970, with a total of 38 planes. Since the late 1990s, the number of plane crashes has stabilized to approximately 22 per year.

The Tenerife Disaster remains the worst accident in aviation history. In this disaster, which took place on March 27, 1977, 583 people died when a KLM Boeing 747 attempted take-off without clearance and collided with a taxiing Pan Am 747 at Los Rodeos Airport. Pilot error, communications problems, fog, and airfield congestion (due to a bomb threat at another airport) all contributed to this catastrophe. Also, the crash of Japan Airlines Flight 123 in 1985 is the worst single-aircraft disaster. In this crash 520 died on board a Boeing 747. The aircraft suffered an explosive decompression, which destroyed its vertical stabilizer and severed hydraulic lines, making the 747 virtually uncontrollable.

Nuclear Age Accidents: Then came the nuclear age around middle of 1950s, and man has attempted, rather successfully, to anticipate the hazards before they would occur and learn to avoid them through design, control and regulation. But even after taking all these steps, accidents have taken place in nuclear plants, and the two most serious nuclear accidents, TMI-2 and Chernobyl-IV, had energy planners reconsider the desirability of nuclear option in the energy sector. On October 7, 1957, at Windscale Pile No. 1, north of Liverpool, England, a fire in a graphite-cooled reactor spewed radiation over the countryside, contaminating a 200-square-mile area. On March 28, 1979, at Three Mile Island near Harrisburg**,** Pa, USA, one of two reactors lost its coolant, which caused overheating and partial meltdown of its uranium core. Some radioactive water and gases were released. This was the worst accident in U.S. nuclear-reactor history.

The Chernobyl accident was the worst in the history of nuclear power plants, and as a result of this accident some 203 people were hospitalized with severe thermal burns and severe radiation exposure, while 31 people died (which is rather a very small number). Some 3,36,000 people in Ukraine, Belarus and Russia were relocated. About one-fifth of the population of Byelorussia was subjected to radioactive exposure of various intensities, and the republic lost over 1.6 million hectares (or 20%) of its farm land and one million hectares of its forests were affected by the nuclear radiation.

An uncontrolled chain reaction in a uranium-processing nuclear fuel plant in Japan on September 30, 1999 spewed high levels of radioactive gas into the air, killing two workers and seriously injuring one other. More recently, on July 17, 2007, radiation leaks, burst pipes, and fires at a major nuclear power plant at Kashiwazaki, Japan occurred following a 6.8 magnitude earthquake near Niigata. Japanese officials, frustrated at the plant operators' delay in reporting the damage, closed the plant a week later until its safety could be confirmed. Investigations revealed that the plant

had been sitting right on the top of an active seismic fault.

Space Age Accidents: The dawn of the space age in the latter half of the 1960s brought another technological feat to the credit of man's achievements, and along with it came a host of disasters. In June 1971 during Soyuz 11, all three Soviet cosmonauts were found dead in the craft after its automatic landing. The cause of death was reported to be due to loss of pressurization in the space craft during reentry into Earth's atmosphere. Again on March 18, 1980, a Russian Vostok rocket exploded on its launch pad while being refueled, killing 50 at the Plesetsk Space Center. On January 28, 1986, the *Challenger* **s**pace shuttle exploded 73 seconds after liftoff, killing all seven American crew members. A booster leak ignited the fuel, causing the explosion. On February 1, 2003, the *Columbia* **s**pace shuttle broke up on reentering Earth's atmosphere on its way to Kennedy Space Center, killing all seven crew members. Foam insulation fell from the shuttle during launch, damaging the left wing. On reentry, hot gases entered the wing, leading to the disintegration of the shuttle.

Chemical Plant Accidents: Accidents in chemical plants have had a very long history, and they have become quite alarming in intensity. Awards totaling $717.5 million were granted to next-of-kin and injured (29 were killed and 56 were injured) following an explosion at a Pyrotechnic plant in 1971, in which, according to the legal testimony, the plant operator had previously classified the ingredients and products as "flammable" instead of "explosives". A chemical company was fined $13.2 million for illegally dumping toxic chemicals into a city waste-treatment system. The city itself was previously fined $10,000 for permitting discharge of the pollution into the river. The contamination extended downriver into a bay and resulted in a major disruption of both commercial and sport fishing through 1980. According to one estimate, the entire 65 mile stretch of the river that had to be dredged would require several years and cost up to $200 million.

In 1974, an explosion took place in Nypro UK Chemical plant at Flixbourough, in which twenty-eight people were killed and some £36 million were paid towards the fire and accident damage following this explosion. The Bhopal gas tragedy and its disastrous consequences raise doubts over man's victory over nature to satisfy his materialistic needs. This tragedy, which struck on the night of December 2-3, 1984 due to leakage of methyl isocyanate gas on the unsuspecting sleeping population near the plant, left over 3700 people dead and about 150,000 affected. The compensation paid to the victims, decided mutually between the Union Carbide Company and the Government of India through an out-of-court settlement, was $470 million.

Water-reactive chemicals also deserve special mention, since their release almost always results in water contact with the material. In Somerville, Massachusetts a tank car ruptured on April 3, 1980, leaking phosphorous tri-chloride from the car into a nearby ditch. One observer reported that the responding fire company deliberately applied water to hasten hydrolysis, and hence increased the acidity and opacity of the cloud. In this event, 23,000 persons were reported evacuated, 120 persons reported to area hospitals for treatment, and the damage from the acid gas corrosion alone was estimated at least half a million dollars.

A liquefied petroleum gas leaking from a pipeline alongside the Trans-Siberian railway in the Ural Mountains near Uta, Russia, 72 miles east of Moscow, exploded on June 3, 1989 and destroyed two passing passenger trains, killing 575 and injuring 723 of an estimated 1200 passengers on both trains.

Sometimes a deliberate act on the part of a negligent manufacturer can cause havoc to the environment and surrounding habitat, which may threaten the life support system of earth. A major electric manufacturer was fined $4 million, in addition to an agreement to conduct a research program on environmental effects of PCB in order to assist in partial clean up of the upper Hudson river, because of its contamination over many years of the PCB used in electric capacitors and transformers. The present level of control is such that the plant now discharges less than one gram *per* day into the river (according to plant management). The cost of freeing the 35.7 mile

stretch of the river above Troy, New York was estimated at $150 million, as several towns and communities draw their water supply from this river.

Fire Accidents: On May 26, 1954, an explosion and fire on aircraft carrier *Bennington* killed 103 persons on board off Quonset Point, RI., USA. Again, on July 29, 1967, a fire on U.S. carrier *Forrestal* killed 134 persons on board off North Vietnam. A power-plant fire in Caracas, Venezuela left 128 dead on December.18-21, 1982. A fire on May 10, 1993 in a doll factory near Bangkok, Thailand killed at least 187 people and injured 500 others. It was the world's deadliest factory fire.

Coal Mine Accidents: On January 21, 1960, a coal mine explosion killed 437 in Coalbrook, South Africa. On November.9, 1963, an explosion in a coal mine at Omuta, Japan killed 447. A fire in a coal mine on May 28, 1965 in Bihar, India killed 375 persons. Another disaster, caused by an explosion followed by flooding in a coal mine at Dhanbad, India, killed 372 persons on December 27, 1975. In China too, a gas explosion at a coal mine on June 20, 2002 killed 111 people. The mining industry is one of the most unsafe industries in China; it is estimated that more than 5,000 mining-related deaths occurred in 2001. Again, a gas explosion killed 209 miners at the Sujiawan mine in Liaoning Province, China on February 14, 2005. It was the single deadliest reported mine disaster in China since 1949. A methane explosion in a coal mine in March 2007 in Ulyanovskaya, Russia killed 110 people, making it the worst mine disaster in recent Russian history.

All these events from the past are just a part of the scenario, which is full of hazards of all kinds and only indicate that the technological systems will continue to be used, but the least we can do is to improve the performance of plants, systems and products and design them to be safe enough and ensure that they have a very low acceptable risk and that the ecological and economic consequences of the possible accidents are minimal.

41.1.3 Risk Perception

Risk acceptability is always a subjective matter and depends upon the perception of the decision maker about the characteristics and severity of a risk. If the decision maker is forced to trade off well-being with monetary benefits, it would be easier to establish a criterion to accept a risk by making sure that the present worth of benefits is greater than the present worth of risk. But to many this approach is not acceptable as it places a monetary value on human life and well being. Several theories have been proposed to explain why different people make different estimates of the dangerousness of risks. Another way of looking at the acceptability of risk is to compare the risk under consideration with risks which were previously judged to be acceptable. The comparison is made by a risk spectrum curve, which shows the relationship between frequency and loss level. Logarithmic scales are generally used on both axes. Farmer's curve [1] is one such method of judging the risks. Risk spectra that exhibit higher frequency at higher levels of loss are less acceptable than otherwise. However, higher frequency at low loss levels will not be considered as critical. However, generalization based on this approach may not be appropriate.

Two major families of theory have been developed by social scientists: the psychometric paradigm and cultural theory. The study of risk perception arose out of the observation that experts and laymen often disagreed about how risky various technologies and natural hazards were. For example, most experts concluded that nuclear power is relatively safe, but a substantial portion of the general public sees it as highly dangerous. The obvious explanation seemed to be that the experts, having considered the evidence carefully and objectively, have a more accurate picture of the risks than did general public. Many experts continue to believe this theory. However, social science research on risk perception has been largely challenging this and proposing alternate explanations.

Starr, in an important paper [2], as early as 1969 offered an explanation to what risks are considered acceptable by the society. He assumed that society

had reached equilibrium in its judgment of risks, so whatever risk levels actually existed in society were acceptable. His major finding was that people accept risks 1,000 times greater if they are voluntary (*e.g.*, driving a car) than if they are involuntary (*e.g.,* having a nuclear plant in the neighborhood). In fact there are more people dying of road accidents than due to nuclear accidents [4] but the general public is often averse to nuclear power.

41.1.4 Risk Communication

Risk communication is the interactive exchange of information and opinions throughout the risk analysis process and concerns risk, risk-related factors, and risk perceptions among risk assessors, risk managers, consumers, industry, the academic community, and other interested parties and also includes the explanation of risk assessment findings and the basis of risk management decisions. Risk communication is a tool for creating the understanding that:

- Every choice/decision requires an understanding of their its risks and benefits,
- Closing the gap between lay people and experts, and
- Helping people make more informed and healthier choices.

Simple steps that can ensure the success of risk communication consist of:

- Understanding the underlying cognitive processes, values, and concerns brought by various sections of the society, and likely responses of these sections to risk issues;
- Developing strategies to enhance trust and minimize conflict between these sections on risk issues; and
- Developing organizational policies and messages responsive to the risk concerns of these sections.

41.2 Quantitative Risk Assessment

No industrial activity [5, 10, 11, 15, 22, 34, 54, 58, 60, 61, 68, 70, 71, 76] is entirely free from risk, since it is not possible to eliminate every eventuality by safety measures. However, when risks are high, system designers must consider the possibilities of additional preventive or protective risk-reduction measures that can be achieved and judge whether it would be reasonable to implement these additional measures. Therefore, it becomes imperative to assess the risk of an industrial activity/plan quantitatively and ensure its safety before it is undertaken for construction or commissioning.

In fact, quantitative risk analysis [52, 76, 77] consists of seeking answers to the following questions:

- What can possibly go wrong that could lead to a hazardous outcome?
- How likely is this event?
- If that happens, what consequences can be expected?

To answer the first question, scenarios of events leading to the outcome should be defined, and to answer the second question, the likelihood of these scenarios must be evaluated. Lastly, to answer the third question, the consequences of each scenario should be evaluated. Therefore, quantitatively, the risk is defined by the following triplet:

$$R = <S_i, P_i(\text{or } Fi), C_i> \quad i=1, 2,..., n \qquad (41.1)$$

where S_i, P_i, (or Fi), and C_i are the ith scenario of events, leading to hazard exposure, likelihood (or frequency) of scenario i and the consequences of scenario i (a measure of the degree of damage or loss), respectively. The likelihood of event E_i is expressed in terms of the probability of that event, and the frequency is expressed per year or per event basis in units of time. Lastly, C_i is expressed in terms of damage to property, number of fatalities, dollars loss, *etc.*

The results of risk estimation are used to interpret various contributors to risk which can be compared and ranked. The process consists of :

1. Calculating and displaying graphically the risk profile on a logarithmic scale.
2. Calculating the total expected risk from

$$R = \sum_i P_i \; C_i . \qquad (41.2)$$

There are two ways of interpreting results. One way is to calculate expected values using (41.2) and is useful when the consequences are in financial terms. Another way is to construct a risk profile. In this case risk values are plotted against consequence values. Sometimes the logarithm of probability that the total consequence C exceeds C_i is plotted against the logarithm of C_i. This is also known as *Farmer's curve* [1] and was a landmark in reactor safety study [4].

Quantitative risk assessment usually involves [8, 15, 16, 20, 26, 68, 69, 72, 73, 74, 75, 76] three stages. These are: *risk identification* (the recognition that a hazard with definable characteristic exists); *risk estimation* (the scientific determination of the nature and level of the risks); *risk evaluation* (judgment about the acceptability or otherwise of risk probabilities and the resulting consequences).

Risk identification and estimation are both concerned with collecting information on:

- The nature and extent of the source;
- The chain of events, pathways and processes that connect the cause to the effects; and
- The relationship between the characteristics of the impact (dose) and the types of effects (response).

Through risk identification, we recognize that a hazard exists and try to define its characteristics such as chemical, thermal, mechanical, electrical, ionizing or non-ionizing radiation, biological, *etc*. Each of the identified hazards is examined to determine all physical barriers that contain it or can intervene to prevent or minimize the exposure to the hazard. Identification of each of the barriers is followed by a concise definition of the requirements for maintaining each of them.

Identification of Sources or Risk

The first step in a system risk analysis is the identification of the sources of risk to the system. In being able to identify sources of risk, it is essential for the analyst to be familiar with the system under consideration. Typically, a study or review team should be established. The team will comprise mainly managers, engineering staff, operators, and other personnel who are involved in the operation of the system or who contribute to its performance. The range of knowledge and experience of the study team is a major factor in its effectiveness and hence in the competence of the study. However, it should be recognized that it may not be possible for the team to identify all possible failure scenarios or hazards, particularly where these arise from "unforeseen" events or processes.

The following techniques have been used in the identification of sources of risk:

1. Preliminary hazard analysis (PHA) [3];
2. Failure modes and effect analysis (FMEA) [26, 56, 57];
3. Failure mode, effect and criticality analysis (FMECA) [22];
4. Hazard and operability studies (HAZOP) [3].
5. Incident databanks.

These techniques have been used for a large range of engineering systems, with the possible exception of HAZOP, which tends to be specific to the chemical and process industries. In addition, various other methods have been proposed, though these are often adoptions of the above methods to suit a specific system or problem. It will be seen that the methods to be described tend to be complementary; for example, guide lists, checklists or reference to incident databanks are often used to check that no source of risk has been omitted from the analysis. PHA is used to identify the major hazards for a system, their causes, and the severity of the consequences. Typically it is used at the preliminary design stage. The identification in a PHA of major hazards will usually invoke more detailed analyses using methods such as FMEA, FMECA and HAZOP because of its preliminary status, and it would not be expected that a PHA will identify failure of specific individual equipment which has the potential to lead to a major hazard. This is the role for FMEA, FMECA and HAZOP. FMEA is an inductive analysis because it starts at the possible outcomes and works backwards to obtain all possible causes. Hence it is essential that the identification of failure modes be as extensive as possible. This may be difficult, particularly for large systems. For this reason, generic guidelines or checklists are often

used to ensure that all failure modes are considered. The analysis involved in a FMEA generally is presented in a tabulated format in a manner similar to that used for a PHA. FMECA, or simply criticality analysis, is a logical extension of FMEA in which failure events are categorized according to the seriousness of their possible effect. In FMECA both the failure frequency (probability) and the failure effect (consequence) are assessed subjectively to determine the criticality of each failure mode. This should take account of each component and each sub-system. The failure frequency is rated in terms of a subjective likelihood such as expressed by "very low, low, medium, and high". The severity is assessed into one of a number of subjective severity levels. The HAZOP technique was developed by Lawley [3] in 1974 at ICI and is widely used in the chemical and the process industries to identify hazards or operating problems in new or existing plants. The HAZOP technique is a systematic process in which process flow diagrams are used to consider each plant item (*e.g.,* pipes, valves, computer software) in turn, so that problems which could occur with these items may be considered.

Results from a HAZOP usually are summarized in tabular worksheet form. The tables normally contain the following entries:

1. *Item:* individual components in the system (*e.g.*, pipes, vessels, relief valves);
2. *Deviation:* identify what can go wrong (*e.g.*, more pressure, no transfer, less flow);
3. *Causes:* causes of each deviation (*e.g.*, equipment failure, operator error);
4. *Consequences:* identify effects on other components, operability and hazards associated with each deviation (*e.g.*, line fracture, backflow, leakage, fire, explosion, toxic release, personnel injury); and
5. *Actions:* measures or actions required to further reduce the deviations or the severity of the consequences (*e.g.,* process design changes, equipment changes or modifications).

Risk Estimation

The next step in risk assessment is to define those scenarios in which the barriers may be breached and then make the best possible estimate of the probability or frequency for each exposure. Often, risks are measured for some time before their adverse consequences are recognized. These include the magnitude, spatial scale, duration and intensity of adverse consequences and their associated probabilities, as well as a description of the cause and effect links. Both risk estimation and identification [26] can involve modeling, monitoring, screening, and diagnosis.

Accident data, "near misses", reliability data and other statistics that describe the past performance of systems also may be used to help identify potential major hazards in a system and their causes and consequences. The techniques described above assist in the identification of those individual system elements (components and subsystems) that are potentially hazardous. This information may be used in the development of a representation of the overall system in terms of logic diagrams. These identify the sequences or combinations of events or processes necessary for system failure to occur. As noted earlier, such system representation diagrams are an aid in the understanding of the behavior of the system, and hence may suggest, without formal risk analysis, obvious measures for reducing the risk of system failure. Of course, detailed understanding of the system and its representation in a logical fashion is required for quantitative analysis of the system. Such analysis also requires quantification of system element performance. The quantification of the overall system reliability has been discussed in more detail in Chapter 19 in this handbook.

The essential (and most common) techniques used for schematic representation of a system (*i.e.*, its "modeling") are:

1. Fault trees [13, 17, 20, 21, 23, 27, 31, 32, 36, 42, 59, 63, 79] and
2. Event trees [7, 18, 26, 33, 45, 51, 76].

A decision tree is a special case of event tree. Other methods, such as fault graphs [30], cause-consequence diagrams [58], and reliability block

diagrams [59] incorporate significant features of event tree and fault tree techniques and will not be discussed. Fault trees and event trees have much in common. Whether one or the other or some combination is applied depends much on the preferences and practices within a given industry.

Fault trees and event trees have been applied extensively for qualitative and quantitative risk studies in the nuclear industry and the chemical process industries and to a lesser extent elsewhere. Automated fault tree generation [12, 13, 14, 36] has also received attention from researchers, but today expert systems can be developed to carry out FMEA, FTA and reliability and safety analysis as was discussed in Chapter 19 of this handbook. Digraphs and causal trees [64] have also been used in system safety and risk analysis. Two landmark risk analysis applications of fault trees and event trees were in the US nuclear safety study (RSS, 1975) [4]. It is the main method recommended for US nuclear risk studies [7, 46], in part because of its ability to model very complex accident sequences, including those involving dependency between events. Considerable amount of work has been done in the area of human reliability analysis [18, 19, 35, 39, 40, 43, 47, 55, 66, 73, 76]. Also, the work in the aerospace industry for human reliability analysis has made use of event tree methods extensively. Event trees and fault trees are best developed by a study team (*i.e.*, a panel of specialists), and their discussions may be likened to a "brain-storming" session where specific risks, events and scenarios and their control are suggested. It is at this stage that decisions can be made as to which risks are to be included and omitted from a risk analysis. In other words, the scope of the risk analysis can be defined.

We have included a detailed and exclusive coverage of fault trees in Chapter 38 of this handbook.

It is sometimes assumed, for ease of analysis, that any dependence between the outcomes of events may be ignored. This assumption usually is incorrect. System risk estimates calculated on the basis of assumed complete dependence between events may be considerably greater than estimates determined for the same events being assumed to be completely independent. Dependence between event failures (also known as cascade failures) can occur when more than one component in a system fails simultaneously due to a common cause. In this case the components do not fail independently of each other. For example, an external cause (such as environmental loads like wind and earthquake or man-imposed factors) may affect more than one component in the system. In general, dependent failures can have a dramatic effect on the risk associated with a project and must be properly identified and accounted for. It follows that the treatment of dependency between events is an important matter for risk analysis. There has been considerable amount of research in handling common cause failures in risk and safety analyses [6, 9, 14, 24, 28, 29, 37, 38, 44, 65, 67, 76, 78].

The estimation of system risk requires the quantitative description of both the frequency and the performance of those system elements directly influencing system risk. This means that the performance of components, items of equipment, loads, resistances, and human actions must be known, and the consequences of failure must be able to be estimated. The quantitative description of the performance of each system element usually will be a variable—either a point estimate (*i.e.*, deterministic) variable (*e.g.*, mean failure rate) or a random variable (*e.g.*, probability distribution of failure rates).

In order to cover common cause failures and human aspects of the risk assessment problem, we have included Chapter 39 exclusively on common cause failure modeling and Chapter 40 on human-system interaction for the benefit of the reader.

Risk Evaluation

The range of effects produced by exposure to a hazard may encompass harm to people, damage to equipment, and contamination of land and facilities. Therefore a third component of *risk assessment* is risk evaluation, in which judgment is made about the significance and acceptability of risk probabilities and corresponding consequences. This stage leads to policy formulation. Evaluation techniques seek to compare risks against benefits, as well as to provide ways in which the social acceptability of risks can be judged.

After the risk has been identified, estimated and evaluated (or any combination of the three), there comes a point where some kind of intervention (or deliberate decision not to intervene or to delay action) must be made. What is the course of development that is "safe enough?" A safe or less risky course of development would be one which would be compatible with the environment and can be called *eco-development*. It would not only minimize or reduce risks to acceptable levels for those who are subjected to risk, but also for those who create risks and those responsible for managing them. There is always a cost attached to the risks and the benefits flowing from a project, plant or a system. Therefore one has to work out the *risk/benefit* ratio. In considering risk/benefit trade-offs, it is essential to remember that for every benefit we usually incur some risk or cost, however small it may be.

Through safe design and better performance of these systems, we can minimize the ecological impacts and associated losses. Lastly, we have worked out the advantages accruing from these systems *vis-à-vis* the risk involved in using them. In other words, we must address the issue of acceptable risk *vis-à-vis* employing the technologies.

41.3 Probabilistic Risk Assessment

Definition of Objectives: As the first step, the objectives of probabilistic risk assessment (PRA) or probabilistic safety assessment (PSA) are set and defined. The resources required for each analytical options are evaluated, and the most effective alternative is selected.

Physical Layout of the System: The physical layout of the system or process, including facility, plant and design, administrative controls, maintenance and test procedures, as well as protective systems (those which maintain safety), is necessary to start the PRA. This will help generate all possible scenarios. All major safety and emergency systems must be identified and taken into consideration.

Identification of Initiating Events: Here we identify all those sets of events that could result in hazard exposure. The first step is to identify sources of hazards and barriers around these hazards. The next step is of course to identify events that can lead to a direct threat to the integrity of barriers.

Sequence of Scenario Development: In this step all possible scenarios are considered that encompass all the potential paths that can lead to loss of containment of the hazard, following the occurrence of an initiating event. The scenarios are often displayed by event trees.

System Analysis: The procedure followed in this step is to develop a fault tree for each event tree heading. Model dependencies and common cause failures models and all potential causes of failures, of hardware, software, test and maintenance, and human errors are included in the development of a fault tree. External events are also considered.

Data Analysis: At this point, we determine generic values of failure rates and failures on demand probabilities for each component in the fault tree. We also determine test, repair and maintenance data from generic sources or from experience; the frequency of initiating events and other component from experience or generic sources; and the common cause failures probabilities likewise.

Quantification: Fault tree and event tree sequences are quantified to determine the frequencies of scenarios and associated uncertainties in the computation.

To provide an insight of PRA to the reader, Chapter 43 on probabilistic risk assessment, including a case study, is included in this handbook. Also Chapter 71 on PRA as applied to nuclear power plants is included in this handbook to provide detailed in formation to the reader. In fact, PRA in the case of nuclear plants has three levels. Level I PRA simply calculates the core melt probability and is purely a system failure event. Level II considers the probability of failure of containment, and Level III considers the probability of release of radioactivity to the surroundings and its consequences.

41.3.1 Possibilistic Approach to Risk Assessment

We have seen there is always a gap between perceived risk and statistical risk. This is basically due to the fact that statistical risk is based on the probability theory of random ocurrences of events, whereas human thinking works on the basis of possibility. Attempts have been made to capture the subjectivity in human thinking by objectively formulating the risk assessment problem on the platform of fuzzy set theory, which appears to make this possible. Several contributions [25, 41, 49, 50, 53, 60, 62] have been made in the direction of a possibilitistic approach using fuzzy set theory, but at this moment, the researchers are transforming the problem by taking recourse to probability and possiblity compatibility principles as has been suggested in [25, 48, 50]. A better approach would be to assess system performance in a possibilitic framework directly (as is suggested in [49]), thus bringing modeling close to the way the human brain processes the situation.

Dempster–Shafer theory also provides an alternative to the probabilistic approach. For the benefit of the reader, we have included Chapter 31 on these aspects of the problem in this handbook. In fact, in the opinion of the author, fuzzy set theory provides a natural and very appropriate approach to overcome the problem of statistical risk and uncertainties associated with it and to resolve the problem of perceived and statistical risk. Human thinking is close to the possibilistic approach and does not rely on statistical values even if supported by tight confidence limits.

41.4 Risk Management

Risk management is an activity which integrates recognition of risk, risk assessment, developing strategies to manage it, and mitigation of risk using managerial resources. The strategies include transferring the risk to another party, avoiding the risk, reducing the negative effect of the risk, and accepting some or all of the consequences of a particular risk. Some traditional risk managements are focused on risks stemming from physical or legal causes (*e.g.*, natural disasters or fires, accidents, death, and lawsuits). Financial risk management, on the other hand, focuses on risks that can be managed using traded financial instruments.

The objective of *risk management* is to reduce different risks related to a pre-selected domain to the level accepted by society. It may refer to numerous types of threats caused by environment, technology, humans, organizations, or politics. On the other hand it involves all means available. In ideal risk management, a prioritization process is followed whereby the risks with the greatest loss and the greatest probability of occurring are handled first, and risks with lower probability of occurrence and lower loss are handled in descending order. In practice the process can be very difficult, and balancing between risks with a high probability of occurrence but lower loss versus a risk with high loss but lower probability of occurrence can often be mishandled.

Intangible risk management identifies a new type of risk—a risk that has a 100% probability of occurring but is ignored by the organization due to a lack of identification ability. For example, when deficient knowledge is applied to a situation, a knowledge risk materializes. Relationship risk appears when ineffective collaboration occurs. Process-engagement risk may be an issue when ineffective operational procedures are applied. These risks directly reduce the productivity of knowledge workers and decrease cost effectiveness, profitability, service, quality, reputation, brand value, and earnings quality. Intangible risk management allows risk management to create immediate value from the identification and reduction of risks that reduce productivity.

Risk management also faces difficulties allocating resources. This is the idea of opportunity cost. Resources spent on risk management could have been spent on more profitable activities. Again, ideal risk management minimizes spending while maximizing the reduction of the negative effects of risks.

Steps in the risk management process:

- Identification of risk in a selected domain of interest;
- Planning the remainder of the process;

- Mapping out the following: the social scope of risk management, the identity and objectives of stakeholders, and the basis upon which risks eventually will be evaluated (constraints);
- Defining a framework for the activity and an agenda for identification;
- Developing an analysis of risks involved in the process; and
- Mitigation of risks using available technological, human, and organizational resources.

Chapter 44 has been included in the handbook to discuss the subject of risk management in detail.

41.5 Risk Governance

It is true that individual capacities and responsibilities of different players, *viz*, government departments, the scientific community, NGOs, business community, or society at large in the arena of risk are limited, and it is absolutely desirable to have some kind of coordination and understanding between their goals, perceptions and activities, particularly to cope with disasters that require coordinated efforts of all sections and cutting across the boundaries of the countries, sectors, hierarchical levels, disciplines.

Risk governance is a concept that not only includes "risk management" or "risk analysis", it also looks at how risk-related decision-making can be affected to meet the major challenges facing society today, particularly those related to natural disasters, food safety or critical infrastructures. Risk governance also takes in view factors such as historical and legal backgrounds, guiding principles, value systems, and perceptions as well as organisational imperatives.

To put in place the framework and coordinate risk governance efforts, an independent organization named *International Risk Governance Council* (IRGC) was founded in June 2003 at the initiative of the Swiss government. The mission of IRGC is to help the understanding and management of global emerging risks that impact human health and safety, the environment, the economy, and society at large, besides developing the concepts of risk governance, anticipating major risk issues, and providing risk governance policy recommendations for key decision makers.

IRGC undertakes project work in four main areas:

- Risks associated with the mitigation of or adaptation to the effects of climate change.
- The security of energy supplies.
- Disaster risk governance.
- Risks associated with new technologies.

IRGC is a foundation funded by several governments and industries. The organizational structure comprises a Board, a Scientific and Technical Council, an Advisory Committee and a full-time Secretariat based at the foundation's headquarters located in Geneva, Switzerland.

Considering the importance of the subject, this handbook has included Chapter 45 on risk governance.

Accident Analysis of Complex Systems Based on System Control for Safety

Takehisa Kohda

Kyoto University, Kyoto, Japan

Abstract: In modern complex systems such as chemical and nuclear plants, as its hardware system reliability increases due to the advancement of technology, systemic failures such as software design errors become a significant contributor to system accidents. State-of-the-art computers have made many technology-based systems so complex that new types of accidents now result from dysfunctional interactions between system components, further adding to the number of accidents resulting from component failure. Other factors, such as management effectiveness and organizational constraints, must also be considered as part of a failure prevention strategy. Conventional event-based analysis methods such as fault trees cannot be always applied to such types of accidents. This chapter applies a concept of system control for safety to the accident analysis in two ways. The first part deals with accident cause analysis, while the second part deals with the accident analysis in the defense-in-depth approach.

42.1 Introduction

Accident analysis plays an important role in both accident investigation and risk assessment, and both aspects are required for effective risk/safety management. In the identification of accident causes, an accident model plays a fundamental role in accident investigation and accident cause analysis. The depth or resolution of an analysis result depends on its accident model. One conventional accident model is an event-based (or sequential) model, such as event trees [1], where the system accident is the end state of a cause-effect sequence initiating from a deviation caused by a failure event such as component failure, human error, or external disturbance. However, the remarkable progress in computer and information technology makes interactions among system components so complex that a new type of accident appears, namely, a deviation not corresponding to a fault can lead to an accident even though components behave as they are specified. This accident is called a systemic accident. Further, since one of the main accident contributors, human error, is greatly affected by organizational and management factors, the background factors of both human errors and component failure must be considered for effective countermeasures. Unfortunately, the event-based model cannot address these problems properly, because it stops the identification process of system accident causes at the component failure level. Root causes are rarely identified. To meet the demands in this situation, a system accident cause

analysis method based on the concept of system control for safety [2, 3] has been devised. The first part of this chapter introduced this kind of method [4] and shows the accident analysis of a railway accident [5].

In PRA (Probabilistic Risk Assessment) [1], firstly all possible accident event sequences leading to a severe accident must be identified, and then an appropriate measure must be taken for a specific accident sequence selected based on its estimated risk. Thus, the derivation of accident occurrence conditions is the most important part of PRA, whose correctness determines the validity of analysis results. However, the derivation conventionally depends on the subjective judgment of system analysts and designers, which might cause an error. To obtain an objective accident occurrence condition, the second part applies the concept of "safety control functions" to not only the derivation of accident occurrence conditions in an event tree model for a specific disturbance or initiating event, but also the analysis of their failure conditions. An illustrative example of a collision accident on a single railway track shows the applicability and effectiveness of the proposed method [6].

42.2 Accident Cause Analysis Based on Safety Control

42.2.1 Safety from System Control Viewpoint

The conventional accident model in the PRA assumes that an accident is caused by an abnormal event leading to a system failure with malfunctions of protective systems, and focus on the identification of contributing factors to the significant accident scenarios [1]. In the presented model [2, 4], system safe states are considered to be always maintained under the system control for safety, and an accident can occur due to deviation from the system boundary conditions under the safety constraints. Since the complete prevention of a failure is impossible, more attention should be paid to the entire system safety control functions than to component failure. System normal states cannot be maintained without the system control for safety. From the system control viewpoint, the system can be represented in terms of three basic concepts: safety constraints, safety control loop, and hierarchical structure.

42.2.1.1 Safety Constraints

The proposed model is based on the relationship between system components from a systems control viewpoint. Components are largely divided into two classes: controlling and controlled ones. Figure 42.1 shows a schematic relation of two components, where the upper component controls the lower component.

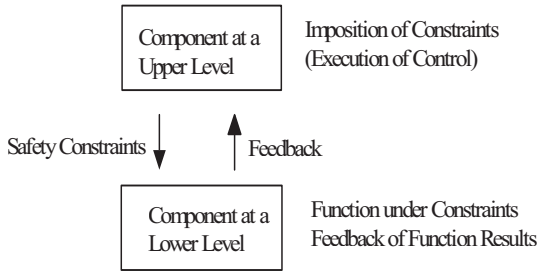

Figure 42.1. Safety constraints and feedback

Since the behavior of the lower component is constrained by the objective of the upper component, a control action of the upper component can be represented as a safety constraint imposed on the lower component. The response of the lower component can be represented as its feedback to the upper component. Based on the feedback, the upper component must modify its control action to maintain its objective. Using this control loop composed of safety constraint and feedback, the goal state of system control can be maintained. The entire system structure from the viewpoint of system safety can be reconfigured based on the interactions required to satisfy the system safety constraints.

42.2.1.2 System Control Loops

To maintain the control relation successfully, the controller must have some functions. Assume a basic system control function shown in Figure 42.2.

Based on the general theory of systems control [7], the following requirements must be satisfied

for the system control function to achieve its objective function.

1. The controller must have a goal to achieve.
2. The controller must be able to affect the state of a system to be controlled.
3. The controller must be (or have) a model of the controlled system.
4. The controller must be able to estimate the state of the system.

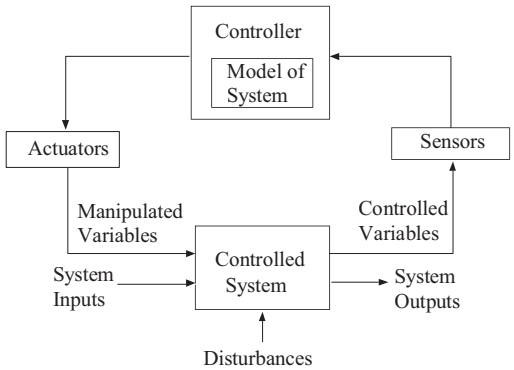

Figure 42.2. Basic control function

In Figure 42.2, controllers such as human operators and computers must obtain the information on the system state to be controlled (Requirement 4) and control the manipulated variables using the actuators to keep the controlled system within the system safety boundary conditions. Based on the system control model, a system accident can occur due to its dysfunction, which may be caused not only by its component failure, but also by an incorrect system model or incorrect control rules. The latter corresponds to systemic failure.

From the requirements for successful system control, causes of its malfunction can be classified as shown in Table 42.1 [3]. In this classification, possible factors other than component failure can be identified. Classification 1 is dysfunction related to the imposition of safety constraints, classification 2 is the dysfunction related to the execution of system control actions, and classification 3 is related to dysfunction caused by the feedback mechanism. A systemic failure can be identified as a control function error due to an incorrect system model. A system accident analysis is performed based on the assumption that dysfunction of safety control loops causes a system accident.

Table 42.1. Causes of malfunctions of system control

1. Inadequate control commands (or imposition of constraints)
1.1 Unidentified hazards
1.2 Inappropriate, ineffective or missing control for identified hazards; Design of control algorithm does not impose constraints; Inconsistent, incomplete, or incorrect system model; Inadequate coordination among controllers and decision makers
1.3 Inadequate controller operation
2. Inadequate execution of control action
2.1 Communication flaw between controller and actuator
2.2 Inadequate actuator operation
2.3 Time lag
3. Inadequate or missing feedback
3.1 No provision in system design
3.2 Communication flaw between system and controller
3.3 Time lag
3.4 Inadequate sensor operation

42.2.1.3 Hierarchical Control Structure for Safety

Based on the control relation, components can be decomposed into two classes: controlling and controlled ones. This viewpoint shows a kind of hierarchical structure. The higher level (controlling part) imposes safety constraints on the lower level (controlled part) as its safety control, while the lower level feeds the result of its performance back to the higher level. All the components in a system organization can be related to one another based on the control structure, and thus the effect of decisions at the management level on the operational level can be considered. In other words, the effect of organizational factors on an accident can be analyzed.

Figure 42.3 shows an example of the system control structure composed of design, manufacturing, operation, and maintenance of an artifact

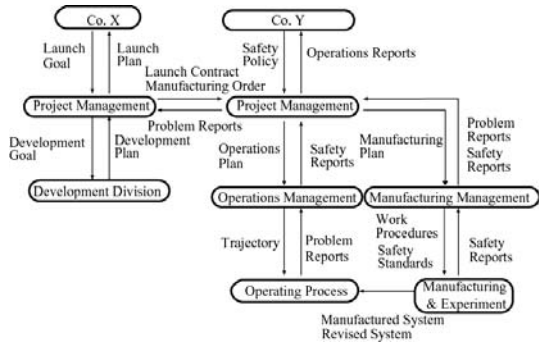

Figure 42.3. An example of hierarchical control structure

[8]. Two basic hierarchical structures, system development and operation, can be identified. An arrow shows information flow or action flow between two components: a component at an upper level imposes safety constraints on its lower component, while the lower level component gives the feedback of its performance result to its upper component. If the feedback information is not consistent with the safety constraint, the corresponding control loop may produce a dysfunction, whose effect propagates across the related hierarchical structure. Thus, based on the hierarchical structure of control loops, the effect and cause of a dysfunction of a safety control function can be analyzed.

42.2.2 Accident Analysis Procedure

To identify causal factors of a system accident to be analyzed, the general accident analysis procedure using the concept of system control for safety can be described as follows:

(1) Definition of system accident: A system accident or system danger must be defined to represent the abnormal system state condition explicitly. As shown in Figure 42.3, the system accident state generally appears as an abnormal state at the lowest level of system operation or the operating process.
(2) Identification of proximate control systems: By checking whether it can detect the abnormal state condition defined at step (1), any proximate control system related to the system accident can be identified.
(3) Identification of dysfunctions of proximate control systems: For each proximate control system obtained at step (2), all possible dysfunctions can be identified as proximate causes of the system accident by examining whether it meets any possible dysfunction condition in the checklist.
(4) Repetitive identification of dysfunctions of the related control systems: By regarding a dysfunction obtained at step (3) as an abnormal system state condition at step (1), background factors of the dysfunction can be obtained in the same way as steps (1) to (3). This procedure should be repeated until further expansion is impossible for any identified dysfunction.

Thus, the proposed method can identify background factors at the upper level by tracing related control systems sequentially from proximate control systems to control systems at upper levels. In other words, all latent problems in the hierarchical control structure can be identified step by step. Similarly, the effect of a proximate control system containing the system abnormal condition can be also investigated in the detail using the forward search in the hierarchical structure. Note that the overall hierarchical structure of control systems can be identified in two ways. One is through the step-by-step procedure in the identification process of the accident analysis. The other is based on the definition of control system specification at the system design stage.

42.2.3 Illustrative Example

Consider the train accident—a fall from an iron bridge—on 28 December 1988 in Japan [9]. Due to strong winds, seven out-of-service passenger cars of a train fell from an iron bridge accidentally, killing five workers at a food processing factory under the bridge and the train conductor, with six seriously injured persons.

42.2.3.1 System Control for Train Protection

In addition to a height of 41 m, the geographical location of the bridge—between two mountains—makes the passage of wind from the sea narrowed,

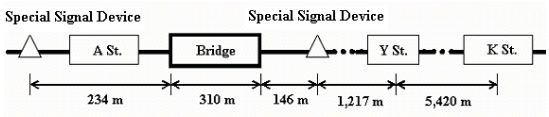

Figure 42.4. Location of special signal devices, stations and bridge

causing an increase of wind velocity. So, passenger trains can be easily exposed to strong wind conditions. Therefore, while the ordinary operating rule of the railway stops a train in case the instantaneous wind velocity is over 30 m/sec, the allowable maximum instantaneous wind velocity in this district is fixed as 25 m/s. Figure 42.4 shows position relations among the iron bridge, nearby stations, and the special signal devices.

The wind warning system was composed as follows.

1. The wind velocity on the bridge was measured by two sets of three-cup formula anemometers installed in the bridge piers, and their output signals were transmitted to the following three places: a strong wind alarm device at the CTC (Centralized Traffic Control) center, and a strong wind alarm device at Y station, and a strong wind alarm device and a wind velocity recorder at K station.
2. Depending on the larger measurement value of the two anemometers, three kinds of warning alarms can be issued. If the maximum instantaneous wind speed (MIWS) is larger than 15 m/sec, the yellow light comes on. If the MIWS is larger than 25 m/sec, the red light comes on and a buzzer sounds. The light and alarm buzzer were set to stay on for three minutes. However, if the alarm buzzer was stopped by an operator, it would not be available for three minutes, and then would be restored to run based on wind velocity measurement. Further, the alarm device does not show the wind velocity.
3. If one of the strong wind alarm devices issues the alarm with a MIWS of 25 m/sec or larger, the operator at the CTC center will change the corresponding signals to stop signals by remote control.
4. Two special signal devices, whose purpose is to stop a train in an emergency situation, are placed at both sides of the bridge: 234 m in the upside and 146 m in the downside. The operator at the CTC center operates the special signal devices by remote control.

One of two anemometers had broken down about one month before the accident, and it had not been repaired when the accident occurred. Due to the difference in their installation place, the monitored values were different. The anemometer broken at the time tended to show the larger value. Moreover, fences or frames to prevent trains from falling off the bridge were not attached at the time of the train accident due to weakness in the bridge piers.

42.2.3.2 Accident Background

In 1961, an alarm interlocked with a wind velocity transmitter was installed for upward trains, and a special signal device was installed and operated manually at Y station. Later, in 1970, the introduction of the CTC changed the operational environment. The special signal device was operated by the CTC center, and the alarm device was removed. Then, another special signal device was installed for downward trains. Before the accident, one of the anemometers was out of order. The accident occurred as follows:

9:00: Persons-in-charge were checked at the roll call.

Before 13:00: The yellow light came on, which showed that the MIWS was over 15 m/sec.

13:10: The red light and buzzer came on, which showed that the MIWS was over 25 m/sec. The CTC center made inquiries about the wind condition at K station, and K station answered, “Although the wind blew at 25 m/sec before, it is now blowing at 20 m/sec”. The CTC center did not turn on the special signal devices.

13:15: The train left K station toward the bridge.

13:21: The red light and buzzer came on, and the staff at K station telephoned the operation staff at the CTC center, “The recorder shows that the wind is now blowing at 30 m/sec or more at the moment, doesn’t it?” However, the operation staff

regarded it as a thing of the past and judged that the wind had lessened to below 25 m/sec. The train passes Y station.

13:23: The train passed by the special signal device.

13:25: The train was lashed by the strong wind and caused to fall from the bridge.

42.2.3.3 System Control for Wind Protection

The system control structure for the safe passage of a train over the iron bridge is shown in Figure 42.5. Most of relations between components have a single directed path, and there exist few control loops with safety constraints and feedback.

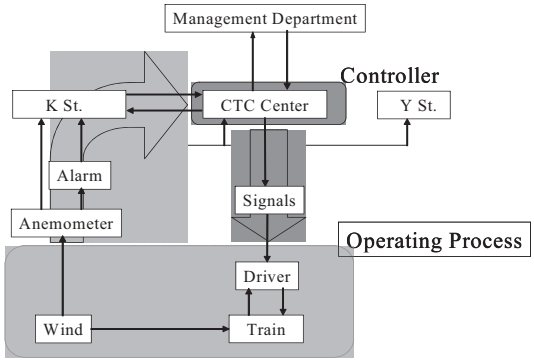

Figure 42.5. Control systems for wind protection

Although a train and its driver compose a control loop, the driver cannot directly monitor the effect of wind on the train, nor can he control it. Therefore, the protective measure against the influence of a wind is a feedback control where the CTC center plays the role of a controller. Wind is monitored by anemometers, and based on the alarm information, the CTC center gives a stop command to the driver through the special signaling device. The driver corresponds to a kind of actuator in the control loop and stops the train according to the signal devices. The management department affects the safety measures of the CTC center by giving it the operational instructions and so on. This constitutes another control loop.

42.2.3.4 Accident Cause Analysis

Since the control loop against the effect of wind cannot control the wind directly, the protective action is to stop the operation of a train when winds are strong. The control loop—which consists of wind, an anemometer, an alarm device, the CTC center, a special signaling device, a driver, and a train—is a proximate control loop related to the accident. Since the apparent cause of the accident is the inaction of the proximate control loop for the wind protection, applying the checklist about the cause of its malfunction can give the results shown in Table 42.1.

Although the accident occurred directly because the train passed through the bridge with strong winds, the incorrect judgment concerning the effect of the wind and the insufficient feedback of the wind conditions are obtained as the causal factors. For the former case, the adequate real-time information on the wind velocity was not available, and the feedback system of adequate information on wind is to be improved. The latter corresponds to the judgment error of the CTC center about the recognition of the influence of wind, but the judgment of the CTC center is affected by the

Table 42.2. Dysfunction in operating process

Check Item	Present	Note

control loop between the CTC center and the operation management department.

Applying the checklist about the cause of malfunctions of a control loop, background factors of the immediate factors are obtained as shown in Table 42.3. As the CTC center had the overarching authority on the train operation, not only the appropriate treatment at the site became difficult, but also the understanding of the current conditions at the site. These causal factors can be clarified by investigating the hierarchical control structure in the operation of wind protection from the viewpoint of the malfunction of management structure.

In this example, the accident cause analysis is examined based on the position that an accident originates in the malfunction of the system control for safety, and it is shown that the background factors are systematically identified based on the hierarchical control structure of the system from the direct cause of the accident.

42.3 Accident Occurrence Condition Based on Control Functions for Safety

In PRA, all possible accident event sequences leading to a severe accident must be identified, and then appropriate measures must be taken for a specific accident sequence, selected based on its estimated risk. Thus, the derivation of accident occurrence conditions is the most important part of PRA, the correctness of which determines the validity of analysis results. However, the derivation conventionally depends on the subjective judgment of system analysts and designers, which might cause an error. To obtain objective accident occurrence conditions, the concept of "safety control functions" is applied to not only the derivation of accident occurrence conditions in an event tree model for a specific disturbance or initiating event, but also the analysis of their failure conditions [10]. An illustrative example of a collision accident on a single track railway shows the applicability and effectiveness of the proposed method [6].

42.3.1 General Accident Occurrence Conditions

Generally speaking, to prevent and mitigate a system accident, several types of safety protective systems are installed in such large scale systems as chemical and nuclear plants and railway systems. The concept of "independent protection layers" [11] or "defence in depth" [12] is a standard approach for safety design in these complex systems. To mitigate the effect of a failure of some protective system, another independent protective system is installed in the system. Figure 42.6 shows a schematic diagram for multilayered protective systems in a chemical plant. Considering the occurrence of an accident in this kind of system, the accident occurs due to the failure of its safety control functions. Here, safety control functions mean not only safety protective systems, but also human actions to reduce the risk caused by a disturbance or component failure. A safety control system corresponds to a set of components which accomplish a safety control function. If a safety control system is normal, it can accomplish its function to prevent or mitigate a disturbance.

Thus, for a system accident to occur, the following two conditions must be satisfied:

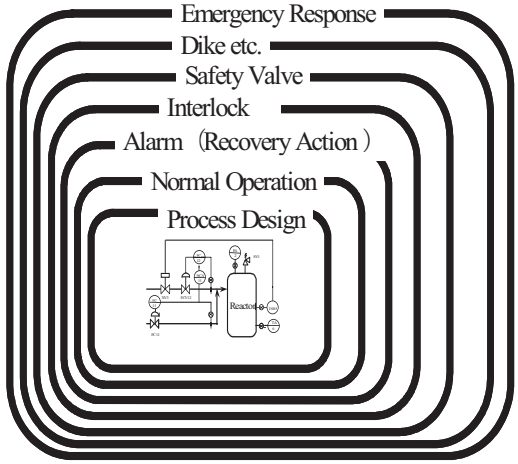

Figure 42.6. Independent protection layers

(C1) A disturbance such as human error and component failure must occur which can cause an initial deviation leading to a system accident.

(C2) Safety control systems must fail which would otherwise prevent or mitigate the disturbance.

As shown in Figure 42.7, accident occurrence conditions in the event tree can be represented as logical AND combinations of the occurrence conditions of a disturbance and the failure conditions of safety control functions related to the disturbance. To obtain the accident occurrence conditions, both disturbances leading to system accidents and safety control systems related to them must be identified.

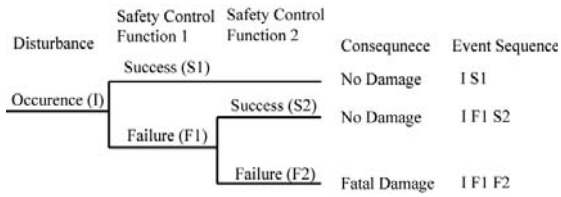

Figure 42.7. Event tree for a system accident

42.3.2 Occurrence of Disturbances

To identify a disturbance or initiating event which can cause a system accident, there are two types of approaches: bottom-up and top-down. The former corresponds to FMEA (Failure Mode and Effect Analysis) [13], while the latter corresponds to FTA (Fault Tree Analysis) [14]. In the FMEA, the possible effect of a component failure, human error, or external event is evaluated from the component level to the system level using functional relations among components in the system hierarchical structure. Based on its effect on the system, a disturbance to be considered for the safety design can be selected. On the other hand, in the FTA, an end state or a system accident to be prevented and mitigated is defined firstly, and then a logic tree is constructed step-by-step, which shows the cause-effect relationship between the system accident and basic events representing component failure and human errors. Minimal combinations of basic events (or component failures) and disturbances leading to the system accident can be obtained, each of which corresponds to an occurrence condition of the specified system accident. In the proposed method, the FMEA approach is applied to the selection of an initiating event based on the previous accident data. So, the disturbance to be mitigated is given first.

42.3.3 Safety Control Function Failure

Safety control functions, which can prevent or mitigate a specific abnormal event, are generally composed of three basic functions: detection, diagnosis, and execution. Detection consists of monitoring system states continuously or periodically to get information on the current state of the plant, and detecting any abnormality. Diagnosis is composed of identifying the cause of the system abnormality and selecting an appropriate control action. Execution corresponds to the execution of the selected control action. Corresponding to these basic functions, the safety control system can be composed of three parts: sensing part, controlling part, and executing part. The primary function of a component can show which part of a safety control system it constitutes. For each disturbance or initiating event, safety control functions which can prevent it must be identified. By examining whether its sensing part

can detect the effect of a disturbance or not, a safety control system related to the accident can be easily identified. Investigating the information flow from the sensing part, the whole structure of a safety control system can be identified, where each basic function can be achieved by a different system component such as a human operator or a computerized machine.

In obtaining the failure conditions of a safety control system, its decomposition into sensing, controlling, and executing parts can clarify what kinds of dysfunction can happen. It can, for example, obtain possible failure conditions in detecting a disturbance. The following questions must be answered: Is the subject disturbance assumed in the design? Which sensing part can detect the subject disturbance? How can the sensing part fail? In this way, all possible causes of the detection failure can be identified. For a safety control function to work successfully, all three basic functions must work successfully. Thus, the failure condition of a safety control system can be obtained as a logical OR combination of the failure conditions of each part. For example, consider an operator recovery action initiated by an alarm. The alarm corresponds to the detection of a disturbance, and the operator plays the role of diagnosis of the disturbance and execution of an appropriate action. In this case, both the normal function of the alarm and the successful performance of the human operator are essential to accomplish the safety control function. Human errors such as perceptional errors and mistakes must be considered, because the diagnosis and execution actions are required of human operators. Human factor analysis [15] should be performed by focusing on the basic functions allocated to operators, and this can also clarify the necessary interactions of human operators with system components.

42.3.4 Collision Accident Example

This section shows the details of the proposed method by analyzing a collision accident in a single track railway as shown in Figure 42.8.

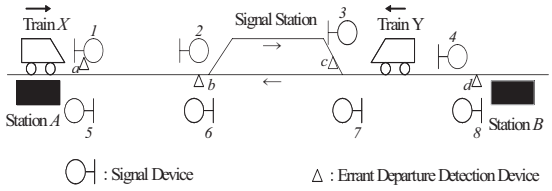

Figure 42.8. Single track railway

42.3.4.1 System Description

Consider a single track railway consisting of stations *A* and *B* and a signal station between them. At the signal station, each train always runs in the left-side track due to a turnout mechanism of points, which can make for a safe crossing of two trains at the signal station. The safety principle in a single track railway is that only one train is allowed to run in a block section. The single track between stations *A* and *B* can be largely divided into three block sections: (b1) the section between station *A* and the signal station, (b2) the section including the signal station, and (b3) the section between the signal station and station *B*. "Single track" implies that a collision accident can happen if two opposite trains exist together in block sections (b1) or (b3). To carry out the safety analysis, assume that eight signal devices and four errant departure detection devices [16] are installed as shown in Figure 42.8. Signal devices are used to keep one train in a block section. Here, signal devices are controlled by a "special automatic block" rule [16]; only one direction in a block section must be allowed for a train which enters it first. Errant departure detection devices can prevent an accident caused by the errant departure of a train ignoring the red signal. For example, if train *Y* accidentally passes across errant departure detection device *b* with signal *6* being red, signal *1* turns red to stop train *X* at station *A*. In this way, an errant departure detection device and a signal device paired together can prevent a collision accident.

42.3.4.2 Safety Control Function

In this example, a collision accident can occur if the safety principle is violated, or two trains exist together in a block section. To prevent a collision accident, the signal system and errant departure

detection devices are installed to maintain the safety principle. The signal system is regarded as a part of the safety control function, because it only gives train drivers orders to follow the safety principle. To achieve the safety control function, the final control action to stop a train must be taken by the driver. Thus, the signal system combined with train drivers constitutes a safety control system. Further, for a train to stop according to the driver action, its braking system must function successfully. Similarly, an errant departure detection device paired together with a signal device can be regarded as sensing and diagnosis parts of a safety control system to give a train driver orders to stop before entering the block section. Thus, an errant departure detection device, a signal device, and a driver with a braking system together comprise another safety control function. In both safety control systems, the final control action must be taken by a driver, whose error leads to a fatal accident even if the hardware devices are normal. Further, the frequency of human error may be much higher than the failure frequency of hardware components. Thus, the role of the driver in each safety control function is essential.

In addition to the above safety control actions, another general safety control action must be taken by drivers. A driver must stop his train if he cannot confirm its safety or if he detects an abnormal condition. This requirement implies that a driver by himself constitutes a safety control system—if he detects an abnormal condition, he must select an appropriate action to stop the train and execute that action. Similarly to the previous control actions, the braking system must be normal for the stop action to be accomplished. In this safety control procedure, detection is very important, which not only triggers the actions following it, but also limits the allowable time to take an appropriate action. In a collision accident, the available time when a driver detects a train approaching him has a large effect on the severity of an accident.

Thus, three kinds of safety control systems are assumed in this example: (s1) signal system and driver with braking system, (s2) errant departure detection device, signal, and driver with braking system, and (s3) drivers by themselves with braking systems.

42.3.4.3 Accident Occurrence Conditions

We now obtain accident occurrence conditions for a collision accident of trains *X* and *Y*. Let us assume an initiating event that train *X* accidentally departs from station *A*, neglecting signal *1* being red, after train *Y* leaves station *B* for station *A* and train *X* continues toward station *B*. Let this condition be denoted as (a0), the errant departure of train *X*.

We examine the availability of each safety control system for the errant departure of train *X*. For each safety control system to function, it must detect the occurrence of a disturbance. Firstly, this disturbance can be detected by errant departure detection device *a*, which turns signal *6* red, thereby preventing train *Y* from entering block section (b1). In safety control system (s3), drivers in trains *X* and *Y* can detect the effect of the disturbance or the possibility of a collision accident when the trains come within sight of each other. This detection can occur after the detection by errant departure detection device *a*. On the other hand, the signal system by itself cannot detect the effect of this disturbance. Thus, only safety control systems (s2) and (s3) can prevent the accident.

Next, we consider the effectiveness of safety control systems (s2) and (s3). Since safety control system (s2) prevents train *Y* from entering block section (b1), it will be of no effect if train *Y* is already in block section (b1) when errant departure detection device *a* detects the errant departure of train *X*. The initial position of train *Y* when train *X* makes an errant departure determines the effectiveness of safety control system (s2). Safety control system (s3) can be effective regardless of the initial position of train *Y*, because it functions just before a collision occurs. Thus, the initial position of train *Y* can be divided into two possible conditions:

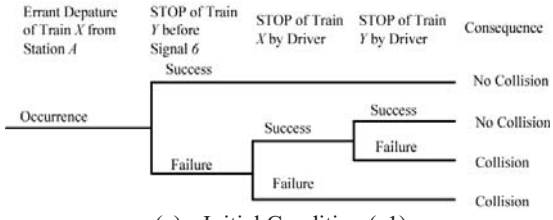
(a1) Train *Y* is running on the approach to signal *6* with a consistent signal condition, where at least signals *6* and *7* are green (to go) and signals *1* and *2* are red (to stop), and

(a2) Train *Y* is in block section (b1) after passing signal *6*.

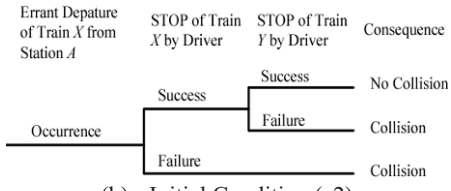
Available safety control systems can be obtained for each condition as follows.

For (a1), we obtain (s2) signal *6* with driver action and (s3) driver actions at trains *X* and *Y*.

For (a2), we obtain (s3) driver actions at trains *X* and *Y*.



(a) Initial Condition (a1)



(b) Initial Condition (a2)

Figure 42.9. Event tree representation

Figure 42.9 shows event trees for these two initial conditions. To avoid a collision accident, two countermeasures are possible in this single track railway: (c1) trains *X* and *Y* cross each other at the signal station and (c2) trains *X* and *Y* stop before the collision. In initial condition (a1), two successful event sequences are possible. The event sequence at the top represents the first case (c1), where train *Y* stops before the exit of the signal station on the right side of train *X* so that they can cross each other. Even if countermeasure (c1) fails, countermeasure (c2) can be applied as shown in the second event sequence. Each driver notices the other train approaching him and stops his train. In initial condition (a2), since train *Y* passed by signal *6* before train *X* departed from station *A* accidentally, errant departure detection device *a* was of no effect. The only available counter-measure is (c2). The top event sequence in Figure 42.9(b) corresponds to this successful case. Comparing event trees for initial conditions (a1) and (a2), the event tree for (a2) has fewer safety control systems, and the drivers must play a more important role. As this example shows, the availability of safety control systems depends on the initial condition of where a disturbance or initiating event occurs. Not only its sensing action to detect a disturbance, but also its control action must be considered for a safety control system in evaluating its effectiveness on the disturbance.

42.3.4.4 Derivation of Accident Occurrence Conditions

To obtain accident occurrence conditions of a collision accident, failure conditions must be obtained for each safety control system related to its initiating event or disturbance. Since a safety control system is considered to be a series structure of sensing, diagnosis, and execution parts, its failure condition is a logical OR combination of the failure conditions of each part. The accident occurrence conditions can be obtained as a logical AND combination of a disturbance occurrence condition and the failure conditions of its effective safety control systems.

We now obtain failure conditions of safety control system (s2). Since it is composed of errant departure detection device *a* and signal *6*, the sensing part detects the errant departure of train *X* and gives warning to the driver of train *Y*. Detection failure is due to the failed-dangerous failure (or failure-to-detect) of the errant departure detection device *a* OR the communication failure of signal *6* (or failure to communicate information to the driver). The driver plays the role of diagnosis and execution. If signal *6* is red, the driver must stop train *Y* before exiting the signal station. Otherwise, the driver will continue to run train *Y*. Generally, a driver action initiated by a signal can be divided into the detection of the signal, the judgment and selection of an appropriate operation, and the execution of it. However, since the stop/go operation depending on the signal can be considered as a kind of stimulus-response action of a well-trained driver, omitting the judgment part, its error can be evaluated as a skill-based error. Failure to detect a red signal can be evaluated as a perceptional error. Even if the driver makes no error, a braking system failure can nullify his protective action. A braking system failure in train *Y* must be included as a failure condition of the driver's stop action. Thus, the failure condition of safety control system (s2) can

be represented as a logical OR combination of the following failure conditions:

(b1) the failed-dangerous failure of errant departure detection device *a*,
(b2) the communication failure of signal *6*,
(b3) the driver at train *Y* fails to detect the red signal,
(b4) the driver at train *Y* fails to stop his train, and
(b5) the braking system at train *Y* fails to stop train *Y*.

A stop action of a driver by himself can be also divided into (1) detection of an approaching train and (2) execution of a stop action while warning the other driver. Here, the diagnosis and selection of an appropriate action in this emergency condition can be committed as a single action combined with execution, because the countermeasure to be taken is obvious for the well-trained driver to prevent an accident. Since both drivers must stop their trains, the failure conditions of safety control system (s3) are obtained as a logical OR combination of the following conditions:

(c1) the driver at train *X* fails to detect train *Y* approaching,
(c2) the driver at train *X* fails to stop his train,
(c3) the braking system at train *X* fails to stop train *X*,
(c4) the driver at train *Y* fails to detect train *X* approaching,
(c5) the driver at train *Y* fails to stop his train, and
(c6) the braking system at train *Y* fails to stop train *Y*.

In both initial conditions, the drivers' errors must be evaluated for safety control system (s3). Although the logical expressions of the failure conditions are the same under both cases, the dependency among human errors must be considered by focusing on the differences in their event sequence conditions. For example, in the third sequence of the event tree for initial condition (a1) (see Figure 42.9(a)), the driver at train *Y* commits the same type of errors twice. A more accurate evaluation of human errors is to be desired, so a more detailed analysis of the above conditions must be performed from the viewpoint of human factors [15]. For simplicity of discussion, we do not expand the above conditions further.

Accident occurrence conditions for initial condition (a1) can be obtained as:

{a0 AND a1} AND {b1 OR b2 OR b3 OR b4 OR b5} AND {c1 OR c2 OR c3 OR c4 OR c5 OR c6}

Thirty minimal cut sets are obtained. For initial condition (a2), since safety function (s2) is of no effect, accident occurrence conditions can be obtained as:

{a0 AND a2} AND {c1 OR c2 OR c3 OR c4 OR c5 OR c6}

Comparing these two cases, the number of minimal cut sets is less in initial condition (a2), which means that initial condition (a2) is more dangerous and that drivers' control actions are more serious. In particular, a human error in driver action constitutes a single component failure condition of a system accident, neglecting the occurrence of the initial condition. Even in initial condition (a1), human errors of the driver at train *Y* appear as failure conditions (b3), (b4), (c4) and (c5). Further, the failure condition of braking systems at train *Y* appears as (b5) and (c6). Though safety control systems apparently seem redundant, the common cause failures, human errors of the driver of train *Y* and failure of the braking system at train *Y*, induce the simultaneous failure occurrence of safety control systems (s2) and (s3). To prevent this condition, an alternative protection measure must be devised. In the next section, the effect of adding an automatic train stop (ATS) (or automatic train protection, ATP) [17] is considered.

42.3.4.5 Evaluation of Improvement by ATS

To mitigate the effect of a driver's erroneous omission of stop actions, assume that ATSs are installed at all signals. The basic function of an ATS is to warn a driver approaching the red signal to stop the train, and to forcibly stop the train when the driver does not make an appropriate response. If a driver stops the train appropriately, the ATS will not force his action. The ATS can take an emergency stop action in place of a driver if he fails to do it. The ATS control action is activated

by the corresponding signal turning red. Thus, the ATS can supplement a safety control function performed by a signal paired with a driver. Figure 42.9 shows general event sequences including an ATS. The addition of ATSs can reduce the contribution of drivers' errors to a collision accident. Failure of a safety control system with an ATS requires failure of the ATS, which increases the size of its minimal cut sets. In other words, it decreases its occurrence probability or frequency.

Similarly to the safety control system, an ATS can be also divided into three parts. The sensing part consists of a wayside coil on the track to send information of a red signal to the train, and a pickup coil on a train to receive the information. Thus, the sensing part fails if either the wayside coil OR the pickup coil fails. The relay circuit on the train corresponds to the diagnosis part, which triggers an appropriate command signal to the execution part depending on the driver action. A diagnosis part failure occurs if the relay circuit fails. The control actions are divided into two types: warning by alarm and compulsory stop of the train. The execution parts correspond to the alarm system, and the braking system, respectively. Depending on the situation, the failure condition of the alarm or the braking system constitutes a failure condition of the execution part. Even if the alarm system fails, the normal braking system can prevent a collision accident. In this sense, the failure conditions of the execution part correspond to those of the braking system.

From the above consideration, the ATS cannot be effective for a safety control system without signals. In the above example, the ATS is effective for safety control systems (s1) and (s2), but not for (s3) where no signal devices are available. So, the addition of ATSs is effective only for initial condition (a1) where safety control system (s2) is available. Safety control system (s2) can be improved by adding ATSs, which is denoted as safety control system (s2′). The failure conditions of safety control system (s2′) can be obtained as:

(b1′) the failed-dangerous failure of errant departure detection device *a*,
(b2′) the communication failure of signal *6*,
(b3′-1) the driver at train *Y* fails to detect the red signal AND the detection failure of the ATS,
(b3′-2) the driver at train *Y* fails to detect the red signal AND the execution failure of the ATS,

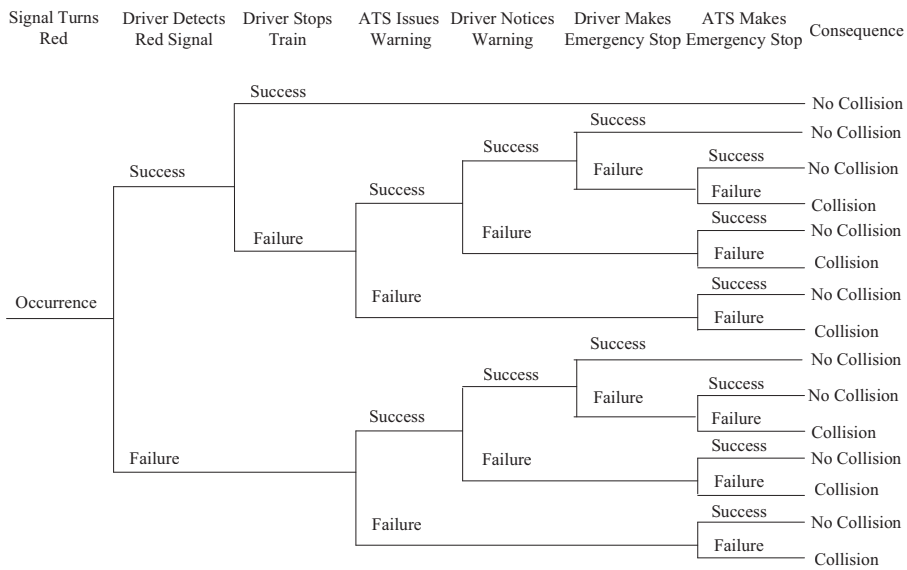


Figure 42.10. Event sequences for safety control system with ATS

(b4′) the driver at train *Y* fails to stop his train AND the execution failure of the ATS, and
(b5′) the braking system at train *Y* fails to stop train *Y*.

Compared with the previous failure conditions, the contribution of human errors in stopping the train according to the signal can be reduced by the addition of ATSs, because failure conditions of ATSs are required for the system accident to occur. Thus, a consideration from the viewpoint of safety control functions can clarify the effect of additional safety measures or devices on the safety control system.

42.4 Conclusions

This chapter considers the application of the concept of system control for safety to accident analysis. The first part of this chapter presents a system accident cause analysis based on the concept of system control for safety. By investigating the causes of malfunctions systematically according to the system hierarchical control structure, from the operating process where a system accident occurs to the top level such as management department of a company, background factors of a proximal accident cause can be identified as dysfunction of control loops at upper levels. Additional studies are being planned to improve and extend the proposed method by applying it to more practical problems such as the development of prevention measures against system accidents from the viewpoint of system control for safety.

The second part applies the concept of "safety control functions" to the derivation of accident occurrence conditions. As shown in the simple illustrative example of a collision accident, the decomposition of a safety control function into detection, diagnosis and execution can simplify not only the identification of safety control functions related to a disturbance or initiating event, but also the derivation of their failure conditions, including hardware and human actions. Safety devices and safety actions by human operators can be organized into a safety control system, which can perform a safety control function as a whole in the accident sequence. To devise an effective countermeasure, the proposed method can consider not only the cognitive aspects of human actions in a safety control function, but also the role of each component in the overall system safety control function. Depending on the initial condition when a disturbance occurs, the event sequences can be easily modified by identifying available safety control systems. Though the qualitative analysis is discussed to derive system accident occurrence conditions, the quantitative analysis is the next step in this research. Time dependency must also be considered in the evaluation of error probability. Considering the operation process of safety control functions, on-demand failure probability [10] must be utilized to evaluate the failure probability of safety control systems.

Probabilistic Risk Assessment

Mohammad Modarres

Reliability Engineering Program, A.J. Clark School of Engineering, University of Maryland, College Park, Maryland, 20742, USA

Abstract: In this chapter, the key elements of the basic methodology of probabilistic risk assessment (PRA) are presented. Starting with the enumeration of some of the strengths of PRA, the detailed steps involved in a PRA will be discussed and subsequently a case study shall be provided to highlight the various steps involved.

43.1 Introduction

Probabilistic risk assessment (PRA) is a systematic procedure for investigating how complex systems are built and operated. PRA models how human, software and hardware elements of the system interact with each other. Also, it assesses the most significant contributors to the risks of the system, and determining the value of the risk. PRA involves estimation of the degree or probability of loss. A formal definition proposed by Kaplan and Garrick [1] provides a simple and useful description of the elements of risk assessment that involves addressing three basic questions:

1. What can go wrong that could lead to exposure of hazards?
2. How likely is this to happen?
3. If it happens, what consequences are expected?

The PRA procedure involves quantitative application of the above triplets in which probabilities (or frequencies) of scenarios of events leading to exposure of hazards are estimated, and the corresponding magnitude of health, safety, environmental and economic consequences for each scenario are predicted. The risk value (*i.e.*, expected loss) of each scenario is often measured as the product of the scenario frequency and its consequences. The main result of the PRA is not the actual value of the risk computed (the so-called bottom-line number); rather it is the determination of the system elements that substantially contribute to the risks of that system, uncertainties associated with such estimates, and effectiveness of various risk reduction strategies available. That is, the primary value of a PRA is to highlight the system design and operational deficiencies and optimize resources that can be invested on improving the design and operation of the system.

43.1.1 Strength of PRA

The most important strengths of PRA as the formal engineering approach to risk assessment are:

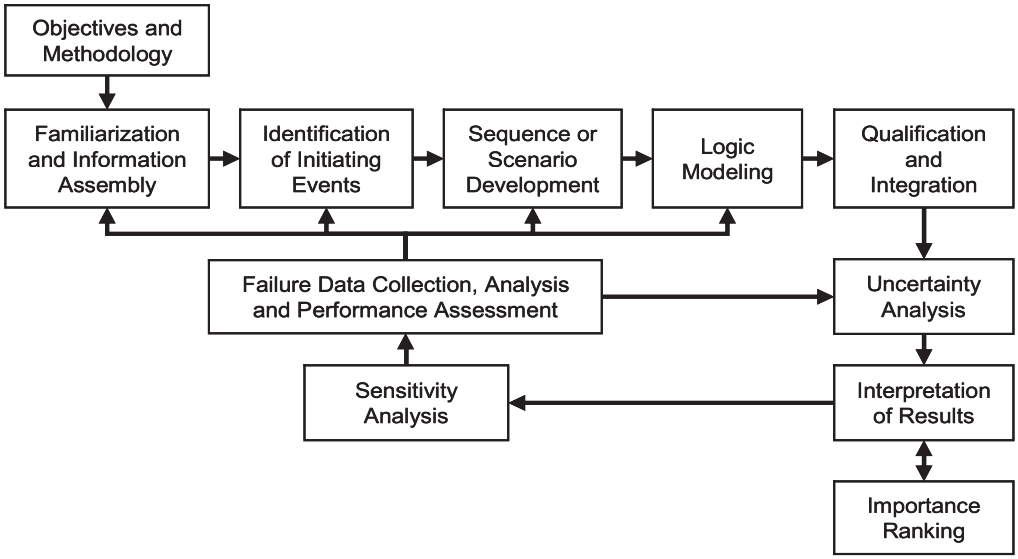

Figure 43.1. Components of the overall PRA process [2]

- PRA provides an integrated and systematic examination of a broad set of design and operational features of an engineered system,
- PRA incorporates the influence of system interactions and human-system interfaces,
- PRA provides a model for incorporating operating experience with the engineered system and updating risk estimates,
- PRA provides a process for the explicit consideration of uncertainties,
- PRA permits the analysis of competing risks (*e.g.*, of one system *vs.* another or of possible modifications to an existing system),
- PRA permits the analysis of (assumptions, data) issues via sensitivity studies,
- PRA provides a measure of the absolute or relative importance of systems, components to the calculated risk value, and
- PRA provides a quantitative measure of overall level of health and safety for the engineered system.

Major errors may results from weak or absent models, or associated data of potentially important factors in the risk of the system, including cases where

- initiating events with very low frequencies of occurrence,
- human performance models and interactions with the system are highly uncertain, and
- failures occurring from a common cause failure such as an extreme operating environment are difficult to identity and model.

43.2 Steps in Conducting a Probabilistic Risk Assessment

The following subsections provide a discussion of essential components of PRA as well as the steps that must be performed in a PRA analysis.

The NASA PRA Guide [2] describes the components of the PRA as shown in Figure 43.1. Each component of PRA will be discussed in more in the following.

43.2.1 Objectives and Methodology

Preparing for a PRA begins with a review of the objectives of the analysis. Among many objectives that are possible, the most common ones include design improvement, risk acceptability, decision support, regulatory and oversight support, and operations and life management. Once the objectives are clarified, an inventory of possible techniques for the desired analyses should be developed. The available techniques range from required computer codes to system experts and analytical experts. This, in essence, provides a road map for the analysis. The resources required for each analytical method should be evaluated, and the most effective option selected. The basis for the selection should be documented, and the selection process reviewed to ensure that the objectives of the analysis will be adequately met. See Hurtado [3] and Kumamoto and Henley [4] for the inventory of methodological approaches to PRA.

43.2.2 Familiarization and Information Assembly

A general knowledge of the physical layout of the overall system (*e.g.*, facility, design, process, aircraft or spacecraft), administrative controls, maintenance and test procedures, as well as barriers and subsystems, whose job is to protect, prevent or mitigate hazard exposure conditions, is necessary to begin the PRA. All subsystems, structures, locations, and activities expected to play a role in the initiation, propagation, or arrest of a hazard exposure condition must be understood in sufficient details to construct the models necessary to capture all possible scenarios. A detailed inspection of the overall system must be performed in the areas expected to be of interest and importance to the analysis. The following items should be performed in this step:

1. Major critical barriers, structures, emergency safety systems, and human interventions should be identified.
2. Physical interactions among all major subsystems (or parts of the system) should be identified and explicitly described. The result should be summarized in a dependency matrix.
3. Past major failures and abnormal events that have been observed in the facility should be noted and studied. Such inform ation would help ensure inclusion of important applicable scenarios.
4. Consistent documentation is critical to ensure the quality of the PRA. Therefore, a good filing system must be created at the outset, and maintained throughout the study.

With the help of the designers, operators, and owners, the analysts should determine the ground rules for the analysis, the scope of the analysis, and the configuration and phases of the operation of the overall system to be analyzed. One should also determine the faults and conditions to be included or excluded, the operating modes of concern and the hardware configuration on the design freeze date (*i.e.*, the date after which no additional changes in the overall system design and configuration will be modeled). Therefore, the results of the PRA are only applicable to the overall system at the freeze date.

43.2.3 Identification of Initiating Events

This task involves identifying those events (abnormal events or conditions) that could, if not correctly and timely responded to, result in hazard exposure. The first step involves identifying sources of hazard and barriers around these hazards. The next step involves identifying events that can lead to a direct threat to the integrity of the barriers.

A system may have one or more operational modes which produce its output. In each operational mode, specific functions are performed. Each function is directly realized by one or more systems by making certain actions and behaviors. These systems, in turn, are composed of more basic units (*e.g.*, subsystems, components, hardware) that accomplish the objective of the system. As long as a system is operating within its design parameter tolerances, there is little chance of challenging the system boundaries in such a way that hazards will escape those boundaries. These

operational modes are called normal operation modes.

During normal operation mode loss of certain functions or systems will cause the process to enter an off-normal (transient) state transition. Once in this transition, there are two possibilities. First, the state of the system could be such that no other function is required to maintain the process in a safe condition (safe refers to a mode where the chance of exposing hazards beyond the system boundaries is negligible.) The second possibility is a state wherein other functions (and thus systems) are required to prevent exposing hazards beyond the system boundaries. For this second possibility, the loss of the function or the system is considered an initiating event. Since such an event is related to the normally operating equipment, it is called an operational initiating event.

Operational initiating events can also apply to various modes of the system (if it exists). The terminology remains the same since, for each mode, certain equipment, people or software must be functioning. For example, an operational initiating event found during the PRA of a test nuclear reactor was low primary coolant system flow. Flow is required to transfer heat produced in the reactor to heat exchanges and ultimately to the cooling towers and the outside environment. If this coolant flow function is reduced to the point where an insufficient amount of heat is transferred, core damage could result (thus the possibility of exposing radioactive materials—the main source of hazard in this case). Therefore, another system must operate to remove the heat produced by the reactor (*i.e.*, a protective barrier). By definition, then, low primary coolant system flow is an operational initiating event.

One method for determining the operational initiating events begins with first drawing a functional block diagram of the system. From the functional block diagram, a hierarchical relationship is produced with the process objective being successful completion of the desired system. Each function can then be decomposed into its subsystems and components, and can be combined in a logical manner to represent operations needed for the success of that function.

Potential initiating events are events that result in failures of particular functions, subsystems, or components, the occurrence of which causes the overall system to fail. These potential initiating events are "grouped" such that members of a group require similar subsystem responses to cope with the initiating event. These groupings are the operational initiator categories.

An alternative to the use of functional hierarchy for identifying initiating events is the use of failure mode and event analysis (FMEA). (See Stamatis [5]) The difference between these two methods is noticeable; namely, the functional hierarchies are deductively and systematically constructed, whereas FMEA is an inductive and experiential technique. The use of FMEA for identifying initiating events consists of identifying failure events (modes of failures of equipment, software and human) whose effect is a threat to the integrity and availability of the hazard barriers of the system. In both of the above methods, one can always supplement the set of initiating events with generic initiating events (if known). For example, see Sattison, *et al*. [6] for these initiating events for nuclear reactors, and the NASA Guide [2] for space vehicles.

To simplify the process, after identifying all initiating events, it is necessary to combine those initiating events that pose the same threat to hazard barriers and require the same mitigating functions of the process to prevent hazard exposure.

The following inductive procedures should be followed when grouping initiating events:

1. Combine the initiating events that directly break all hazard barriers.
2. Combine the initiating events that break the same hazard barriers (not necessarily all the barriers).
3. Combine the initiating events that require the same group of mitigating human or automatic actions following their occurrence.
4. Combine the initiating events that simultaneously disable the normal operation as well as some of the available mitigating human, software or automatic actions.

Events that cause off-normal operation of the overall system and require other systems to operate so as to maintain hazards within their desired boundaries, but are not directly related to a hazard mitigation, protection or prevention function, are non-operational initiating events. Non-operational initiating events are identified with the same methods used to identify operational events. One class of such events of interest is those that are primarily external to the overall system or facility. These so called "external events" will be discussed later in more detail in this article. The following procedures should be followed in this step of the PRA:

- Select a method for identifying specific operational and non-operational initiating events. Two representative methods are functional hierarchy and FMEA. If a generic list of initiating events is available, it can be used as a supplement.
- Using the method selected, identify a set of initiating events.
- Group the initiating events having the same effect on the system, for example those requiring the same mitigating functions to prevent hazard exposure are grouped together.

43.2.4 Sequence or Scenario Development

The goal of scenario development is to derive a complete set of scenarios that encompasses all of the potential exposure propagation paths that can lead to loss of containment or confinement of the hazards following the occurrence of an initiating event. To describe the cause and effect relationship between initiating events and subsequent event progression, it is necessary to identify those functions (*e.g.*, safety functions) that must be maintained to prevent loss of hazard barriers. The scenarios that describe the functional response of the process to the initiating events are frequently displayed by event trees. The event tree development techniques are discussed in [2] and [4].

Event trees order and depict (in an approximately chronological manner) the success or failure of key mitigating actions (*e.g.*, human actions or mitigative hardware actions) that are required to act in response to an initiating event. In PRA, two types of event trees can be developed: functional and systemic. The functional event tree uses mitigating functions as its heading. The main purpose of the functional tree is to better understand the scenario of events at an abstract level, following the occurrence of an initiating event. The functional tree also guides the PRA analyst in the development of a more detailed systemic event tree. The systemic event tree reflects the scenarios of specific events (specific human actions, protective or mitigative subsystem operations or failures) that lead to a hazard exposure. That is, the functional event tree can be further decomposed to show failure of specific hardware, software or human actions that perform the functions described in the functional event tree. Therefore, a systemic event tree fully delineates the overall system response to an initiating event and serves as the main tool for further analyses in the PRA. For a detailed discussion on specific tools and techniques used for this purpose see Modarres [7].

There are two kinds of external events. First kind refers to events that originate from within the facility or the overall system (but outside of the physical boundary of the facility), which are called internal events external to the process of the system. Events that adversely affect the facility or overall system and occur external to its physical boundaries, but can still be considered as part of the system, are defined as internal events external to the system. Typical internal events external to the system are internal conditions such as fires from fuel stored within a facility or floods occurred due to rupture of tank which is part of the overall system. The effects of these events should be modeled with event trees to show all possible scenarios.

The second kind of external events are those that originate outside of the overall system, and are called external events. Examples of external events are fires and floods that originate from outside of the system. Examples include seismic events, extreme heat, extreme drought, transportation events, volcanic events, high-wind events, terrorism, and sabotage. Again, this classification

can be used in developing and grouping the event tree scenarios.

The following procedures should be followed in this step of the PRA:

- Identify the mitigating functions for each initiating event (or group of events).
- Identify the corresponding human actions, systems or hardware operations associated with each function, along with their necessary conditions for success.
- Develop a functional event tree for each initiating event (or group of events).
- Develop a systemic event tree for each initiating event, delineating the success conditions, initiating event progression phenomena, and end effect of each scenario.

For specific examples of scenario development see [2]–[4].

43.2.5 Logic Modeling

Event trees commonly involve branch points at which a given subsystem (or event) either works (or happens) or does not work (or does not happen). Sometimes, failure of these subsystems (or events) is rare and there may not be an adequate record of observed failure events to provide a historical basis for estimating frequency of their failure. In such cases, other logic-based analysis methods such as fault trees or master logic diagrams may be used, depending on the accuracy desired. The most common method used in PRA to calculate the probability of subsystem failure is fault tree analysis. This analysis involves developing a logic model in which the subsystem is broken down into its basic components or segments for which adequate data exist. For more details on how a fault tree can be developed to represent the event headings of an event tree, see Modarres *et al*. [8].

Different event tree modeling approaches imply variations in the complexity of the logic models that may be required. If only main functions or systems are included as event-tree headings, the fault trees become more complex and must accommodate all dependencies among the main and support functions (or subsystems) within the fault tree. If support functions (or systems) are explicitly included as event tree headings, more complex event trees and less complex fault trees will result. For more discussions on methods and techniques used for logic modeling see Modarres [7].

The following procedures should be followed as a part of developing the fault tree:

1. Develop a fault tree for each event in the event tree heading for which actual historical failure data does not exist.
2. Explicitly model dependencies of a subsystem on other subsystems and inter-component dependencies (*e.g.*, common cause failures). For common cause failures, see Mosleh *et al*. [9].
3. Include all potential reasonable and probabilistically quantifiable causes of failure, such as hardware, software, test and maintenance, and human errors, in the fault tree.

The following steps should be followed in the dependent failure analysis:

1. Identify the hardware, software and human elements that are similar and could cause dependent or common cause failures. For example, similar pumps, motor-operated valves, air-operated valves, human actions, software routine, diesel generators, and batteries are major components in process plants, and are considered important sources of common cause failures.
2. Items that are potentially susceptible to common cause failure should be explicitly incorporated into the corresponding fault trees and event trees of the PRA where applicable.
3. Functional dependencies should be identified and explicitly modeled in the fault trees and event trees.

43.2.6 Failure Data Collection, Analysis and Performance Assessment

A critical building block in assessing the reliability and availability of complex systems is the data on

the performance of its barriers to contain hazards. In particular, the best resources for predicting future availability are past field experiences and tests. Hardware, software and human reliability data are inputs to assess performance of hazard barriers, and the validity of the results depends highly on the quality of the input information. It must be recognized, however, that historical data have predictive value only to the extent that the conditions under which the data were generated remain applicable. Collection of the various failure data consists fundamentally of the following steps: collecting generic data, assessing generic data, statistically evaluating facility-specific or overall system-specific data, and developing failure probability distributions using test and/or facility-specific and system-specific data. Three types of events identified during the risk scenario definition and system modeling must be quantified for the event trees and fault trees to estimate the frequency of occurrence of sequences: initiating events, component failures, and human error.

The quantification of initiating events and hazard barriers and components failure probabilities involves two separate activities. First, the probabilistic failure model for each barrier or component failure event must be established; then the parameters of the model must be estimated. Typically the necessary data include time of failures, repair times, test frequencies, test downtimes, common-cause failure events. Further uncertainties associated with such data must also be characterized. Kapur and Lamberson [10], Modarres [8], and Nelson [11] discuss available methods for analyzing data to obtain the probability of failure or the probability of occurrence of equipment failure. Also, Crow [12], and Ascher and Feingold [13] discuss analysis of data relevant to repairable systems. Finally, Mosleh *et al*. [9] discusses analysis of data for dependent failures, Poucet [14] reviews human reliability issues, and Smidts [15] examines software reliability models. Establishment of the data base to be used will generally involve collection of some facility-specific or system-specific data combined with the use of generic performance data when specific data are absent or sparse. For example, References [16]–[18] describe generic data for electrical, electronic, and mechanical equipment.

To attain the very low levels of risk, the systems and hardware that comprise the barriers to hazard exposure must have very high levels of performance. This high performance is typically achieved through the use of well-designed systems with adequate margin of safety considering uncertainties, redundancy and/or diversity in hardware, which provides multiple success paths. The problem then becomes one of ensuring the independence of the paths, since there is always some degree of coupling between agents of failures such as those activated by failure mechanisms, either through the operating environment (events external to the system) or through functional and spatial dependencies. Treatment of dependencies should be carefully included in both event tree and fault tree development in the PRA. As the reliability of individual subsystems increases due to redundancy, the contribution from dependent failures becomes more important; in certain cases, dependent failures may dominate the value of overall reliability. Including the effects of dependent failures in the reliability models used in the PRA is a difficult process and requires some sophisticated, fully integrated models be developed and used to account for unique failure combinations that lead to failure of subsystems and ultimately exposure of hazards. The treatment of dependent failures is not a single step performed during the PRA; it must be considered throughout the analysis (*e.g.*, in event trees, fault trees, and human reliability analyses).

The following procedures should be followed as part of the data analysis task:

1. Determine generic values of material strength or endurance, load or damage agents, failure times, failure occurrence rate and failures on demand for each item (hardware, human action, or software) identified in the PRA models. This can be obtained either from facility-specific or system-specific experiences, from generic sources of data, or both.
2. Gather data on hazard barrier tests, repair, and maintenance data primarily from

experience, if available. Otherwise use generic performance data.
3. Assess the frequency of initiating events and other probability of failure events from experience, expert judgment, or generic sources.
4. Determine the dependent or common cause failure probability for similar items, primarily from generic values. However, when significant specific data are available, they should be primarily used.

43.2.7 Quantification and Integration

Fault trees and event trees are integrated and their events are quantified to determine the frequencies of scenarios and associated uncertainties in the calculation of the final risk values. This integration depends somewhat on the manner in which system dependencies have been handled. We will describe the more complex situation, in which the fault trees are dependent, *i.e.*, there are physical dependencies (*e.g.*, through support units of the main hazard barriers such as those providing motive, proper working environment and control functions).

Normally, the quantification will use a Boolean reduction process to arrive at a Boolean representation for each scenario. Starting with fault tree models for the various systems or event headings in the event trees, and using probabilistic estimates for each of the events modeled in the event trees and fault trees, the probability of each event tree heading (often representing failure of a hazard barrier) is calculated (if the heading is independent of other headings). The fault trees for the main subsystems, support units (*e.g.*, lubricating and cooling units, power units) are merged where needed, and the equivalent Boolean expression representing each event in the event tree model is calculated. The Boolean expressions are reduced to arrive at the smallest combination of basic failures events (the so-called minimal cut-sets) that lead to exposure of the hazards. These minimal cut sets for each of the main subsystems (barriers)—that are often identified as headings on the event trees—are also obtained. The minimal cut sets for the event tree event headings are then appropriately combined to determine the cut sets for the event-tree scenarios. If possible, all minimal cut sets must be generated and retained during this process; unfortunately in complex systems and facilities this leads to an unmanageably large collection of terms and a combinatorial outburst. Therefore, the collection of cut sets are often truncated (*i.e.*, probabilistically small and insignificant cut sets are discarded based on the number of terms in a cut set or on the probability of the cut set.). This is usually a practical necessity because of the overwhelming number of cut sets that can result from the combination of a large number of failures, even though the probability of any of these combinations may be vanishingly small. The truncation process does not disturb the effort to determine the dominant scenarios since we are discarding scenarios that are extremely unlikely.

Even though the individual cut sets discarded may be several orders of magnitude less probable than the average of those retained, the large number of them discarded may sum to a significant part of the risk. The actual risk might thus be larger than what the PRA results indicate. This can be discussed as part of the modeling uncertainty characterization. Detailed examination of a few PRA studies of very complex systems, for example nuclear power plants shows that cut set truncation will not introduce any significant error in the total risk assessment results (see Dezfuli and Modarres [19]).

Other methods for evaluating scenarios also exist that directly estimate the frequency of scenario without specifying cut sets. This is often done in highly dynamic systems whose configuration changes as a function of time leading to dynamic event tree and fault trees. For more discussion on these systems see Chang, Mosleh and Dang [20], NASA Procedures PRA Guide [2], Dugan *et al.* [21]. Employing advanced computer programming concepts, one may directly simulate the operation of parts to mimic the real system for reliability and risk analysis (see Azarkhail and Modarres [22].) The following procedures should be followed as part of the quantification and integration step in the PRA:

1. Merge corresponding fault trees associated with each failure or success event modeled in the event tree scenarios (*i.e.*, combine them in a Boolean form). Develop a reduced Boolean function for each scenario (*i.e.*, truncated minimal cut sets).
2. Calculate the total frequency of each sequence, using the frequency of initiating events, the probability of barrier failure including contributions from test and maintenance frequency (outage), common cause failure probability, and human error probability.
3. Use the minimal cut sets of each sequence for the quantification process. If needed, simplify the process by truncating based on the cut sets or probability.
4. Calculate the total frequency of each scenario.
5. Calculate the total frequency of all scenarios of all event trees.

43.2.8 Uncertainty Analysis

Uncertainties are part of any assessment, modeling, and estimation. In engineering calculations we routinely ignore the estimation of uncertainties associated with failure models and parameters, because the uncertainties are very small and more often analyses are done conservatively (*e.g.,* by using high safety factor, design margin). Since PRAs are primarily used for decision making and management of risk, it is critical to incorporate uncertainties in all facets of the PRA.

Also, risk management decisions that consider PRA results must consider estimated uncertainties. In PRAs uncertainties are primarily shown in form of probability distributions. For example, the probability of failure of a subsystem (*e.g.*, a hazard barrier) may be represented by a probability distribution showing the range and likelihood of risk values.

The process involves characterization of the uncertainties associated with frequency of initiating events, probability of failure of subsystems (or barriers), probability of all event tree headings, strength or endurance of barriers, applied load or incurred damage by the barriers, amount of hazard exposures, consequences of exposures to hazards, and sustained total amount of losses. Other sources of uncertainties are in the models used. For example, the fault tree and event tree models, stress-strength and damage-endurance models used to estimate failure or capability of some barriers, probabilistic failure models of hardware, software and human, correlation between amount of hazard exposure and the consequence, exposure models and pathways, and models to treat inter- and intra-barrier failure dependencies. Another important source of uncertainty is incompleteness of the risk models and other failure models used in the PRAs. For example, the level of detail used in decomposing subsystems using fault tree models, scope of the PRA, and lack of consideration of certain scenarios in the event tree just because they are not known or experienced before.

Once uncertainties associated with hazard barriers have been estimated and assigned to models and parameters, they must be "propagated" through the PRA model to find the uncertainties associated with the results of the PRA, primarily with the bottom-line risk calculations, and with the list of risk significant elements of the system. Propagation is done using one of several techniques, but the most popular method used is Monte Carlo simulation. The results are then shown and plotted in form of probability distributions. Steps in uncertainty analysis include:

1. Identify models and parameters that are uncertain and the method of uncertainty estimation to be used for each.
2. Describe the scope of the PRA and significance and contribution of elements that are not modeled or considered.
3. Estimate and assign probability distributions depicting model and parameter uncertainties in the PRA.
4. Propagate uncertainties associated with the hazard barrier models and parameters to find the uncertainty associated with the risk value.
5. Present the uncertainties associated with risks and contributors to risk in an easy way to understand and visually straightforward to grasp.

43.2.9 Sensitivity Analysis

Sensitivity analysis is the method of determining the significance of choice of a model or its parameters, assumptions for including or not including a barrier, phenomena or hazard, performance of specific barriers, intensity of hazards, and significance of any highly uncertain input parameter or variable to the final risk value calculated. The process of sensitivity analysis is straightforward. The effects of the input variables and assumptions in the PRA are measured by modifying them by several folds, factors or even one or more order of magnitudes one at a time, and measure relative changes observed in the PRA's risk results. Those models, variables and assumptions whose change leads to the highest change in the final risk values are determined as "sensitive". In such a case, revised assumptions, models, additional failure data and more mechanisms of failure may be needed to reduce the uncertainties associated with sensitive elements of the PRA.

Sensitivity analysis helps focus resources and attentions to those elements of the PRA that need better attention and characterization. A good sensitivity analysis strengthens the quality and validity of the PRA results. Usually elements of the PRA that could exhibit multiple impacts on the final results, such as certain phenomena (*e.g.*, pitting corrosion, fatigue cracking and common cause failure) and uncertain assumptions are usually good candidates for sensitivity analysis. The steps involved in the sensitivity analysis are:

1. Identify the elements of the PRA (including assumptions, failure probabilities, models and parameters) that analysts believe might be sensitive to the final risk results.
2. Change the contribution or value of each sensitive item in either direction by several factors in the range of 2–100. Note that certain changes in the assumptions may require multiple changes of the input variables. For example, a change in failure rate of similar equipment requires changing of the failure rates of all this equipment in the PRA model.
3. Calculate the impact of the changes in step 2 one-at-a-time and list the elements that are most sensitive.
4. Based on the results in step 3 propose additional data, any changes in the assumptions, use of alternative models, and modification of the scope of the PRA analysis.

43.2.10 Risk Ranking and Importance Analysis

Ranking the elements of the system with respect to their risk or safety significance is one of the most important outcomes of a PRA. Ranking is simply arranging the elements of the system based on their increasing or decreasing contribution to the final risk values. Importance measures rank hazard barrier, subsystems or more basic elements of them usually based on their contribution to the total risk of the system. The ranking process should be done with much care. In particular, during the interpretation of the results, since formal importance measures are context dependent and their meaning varies depending on the intended application of the risk results, the choice of the ranking method is important.

There are several unique importance measures in PRAs. For example, Fussell–Vesely [23], Risk Reduction Worth (RRW), and Risk Achievement Worth (RAW) [8] are identified as appropriate measures for use in PRAs, and all are representative of the level of contribution of various elements of the system as modeled in the PRA and enter in the calculation of the total risk of the system. For example, the Birnbaum importance measure [24] represents changes in total risk of the system as a function of changes in the basic event probability of one component at a time. If simultaneous changes in the basic event probabilities are being considered, a more complex representation would be needed.

Importance measures can be classified based on their mathematical definitions. Some measures have fractional type definitions and show changes (in the number of folds or factors) in system total risk under certain conditions with respect to the normal operating or use condition (*e.g.*, as is the case in risk reduction worth and risk achievement

worth measures). Some measures calculate the changes in system total risk as failure probability of hazard barriers and other elements of the system or conditions under which the system operates change. This difference can be normalized with respect to the total risk of the system or even expressed in a percentage change form. There are other types of measures, which account for the rate of changes in the system risk with respect to changes in the failure probability of the elements of the system. These measures can be interpreted mathematically as partial derivative of the risk as a function of failure probability of its elements (barriers, components, human actions, phenomena, *etc*.). For example, the Birnbaum measure falls under this category.

Another important set of importance measures focus on ranking the elements of the system with the most contribution to the total uncertainty of the risk results obtained from PRAs. This process is called "uncertainty ranking" and is different than component, subsystem, and barrier ranking. In this importance ranking, the analyst is only interested in knowing which of the system elements drive the final risk uncertainties, so that resources can be focused on reducing important uncertainties.

There is another classification for importance measures in which they can be divided into two major categories of absolute *vs.* relative. Absolute measures are representative of fixed importance of one element of the system, independent of the importance of other elements, while relative importance expresses significance of one element with respect to weight of importance of other elements. Absolute importance can be used to estimate the impact of component performance on the system regardless of how important other elements are, while relative importance estimates the significance of the risk-impact of the component in comparison to the effect or contribution of others.

Absolute measures are useful when we speculate on improving actions, since they directly show the impact on the total risk of the system. Relative measures are preferred when resources or actions to improve or prevent failures are taken in a global and distributed manner. For additional discussions on the risk ranking methods and their implications in failure and success domains see Azarkhail and Modarres [25]. Applications of importance measures may be categorized into the following areas:

1. (Re)Design: To support decisions of the system design or redesign by adding or removing elements (barriers, subsystems, human interactions, *etc*.)
2. Test and maintenance: To address questions related to the plant performance by changing the test and maintenance strategy for a given design.
3. Configuration and control: To measure the significance or the effect of failure of a component on risk or safety or temporarily taking a component out of service.
4. Reduce uncertainties in the input variables of the PRAs.

The following are the major steps of importance ranking:

1. Determine the purpose of the ranking and select appropriate ranking importance measure that has consistent interpretation for the use of the ranked results.
2. Perform risk ranking and uncertainty ranking, as needed.
3. Identify the most critical and important elements of the system with respect to the total risk values and total uncertainty associated with the calculated risk values.

43.2.11 Interpretation of Results

When the risk values are calculated, they must be interpreted to determine whether any revisions are necessary to refine the results and the conclusions. There are two main elements involved in the interpretation process. The first is to understand whether or not the final values and details of the scenarios are logically and quantitatively meaningful. This step verifies the adequacy of the PRA model and the scope of analysis. The second is to characterize the role of each element of the system in the final results. This step highlights additional analyses data and information gathering that would be considered necessary.

The interpretation process heavily relies on the details of the analysis to see whether the scenarios are logically meaningful (for example, by examining the minimal cut sets of the scenarios), whether certain assumptions are significant and greatly control the risk results (using the sensitivity analysis results), and whether the absolute risk values are consistent with any historical data or expert opinion available. Based on the results of the interpretation, the details of the PRA logic, its assumptions and scope may be modified to update the results into more realistic and dependable values.

The ranking and sensitivity analysis results may also be used to identify areas where gathering more information and performing better analysis (for example, by using more accurate models) is warranted. The primary aim of the process is to reduce uncertainties in the risk results.

The interpretation step is a continuous process with receiving information from the quantification, sensitivity, uncertainty, and importance analysis activities of the PRA. The process continues until the final results can be best interpreted and used in the subsequent risk management steps.

The basic steps of the PRA results interpretation are:

1. Determine accuracy of the logic models and scenario structures, assumptions, and scope of the PRA.
2. Identify system elements for which better information would be needed to reduce uncertainties in failure probabilities and models used to calculate performance.
3. Revise the PRA and reinterpret the results until attaining stable and accurate results.

43.3 Compressed Natural Gas (CNG) Powered Buses: A PRA Case Study

43.3.1 Primary CNG Fire Hazards

The fire safety hazards that should be considered in assessing the risks of using CNG fuel are:

- Fire potential from fuel leakage.
- Explosion potential from uncontrolled dispersion and mixing of CNG in the presence of an ignition source.
- Impacts and missile generated hazards due to fuel being stored at high pressure.
- Chemical hazards (gas toxicity, asphyxiation potential and higher hydrocarbons in CNG maybe considered neurotoxin even though CNG is relatively non-toxic.)
- Electrostatic discharge.

The issues of bulk transport and storage are completely different from most of the other fuel types that are typically transported to fleet storage via tanker trucks. For use as a fuel, natural gas is compressed and stored in high-pressure cylinders (tanks) on the vehicle at 2,400–3,000 psig. The containment of natural gas at such high pressures requires very strong storage tanks that are both heavy and costly. Furthermore, such tanks are subject to corrosion-fatigue, sustained load cracking, stress corrosion and fatigue failure. This distinguishing feature of CNG has the most impact on safety issues. Some important fire related incidents which include fatalities in CNG vehicles are summarized in [26].

There are two distinct categories of CNG fuel tank designs:

Metal tanks: These tanks are made of aluminum or 4130X steel. There have been some cases of fragmentation rupture in this type of cylinders. *Composite-wrapped:* These are tanks constructed with an aluminum/steel liner and E-glass wrap or carbon fiber insert with E-glass wrap. There have been several ruptures of this type of tank [27].

This PRA study only considers metal tank type.

43.3.2 The Probabilistic Risk Assessment Approach

The standard PRA approach may be applied. Fault tree and event tree modeling techniques [28] describe scenarios of events leading to fire and explosion fatalities. Frequency of occurrence of such scenarios was then quantified using the generic failure data for basic components gathered

from the process industry that experience similar components [29]. Engineering judgment and simple fire analysis methods were used to determine the likelihood of occurrence of particular fire scenarios. The main source of uncertainty is the data used in the risk model (parameter uncertainty). The uncertainty from the failure data was factored into the PRA results. Model uncertainty was not considered since the methods discussed in the literature are still evolving [30]. A universally acceptable methodology has yet to emerge. In the absence of such an approach, conservative modeling assumptions have been used in the PRA to minimize error due to model uncertainty.

Uncertainties due to failure and consequence data are propagated using a standard Monte Carlo simulation technique. The sensitivity of individual elements of the risk model (*e.g.* failure data and assumptions) was measured by varying them individually by many factors and determining the resulting change in fire fatality risk.

43.3.3 System Description

The typical CNG bus system shown in Figure 43.2 was considered for this risk study. It is comprised of the following major subsystems.

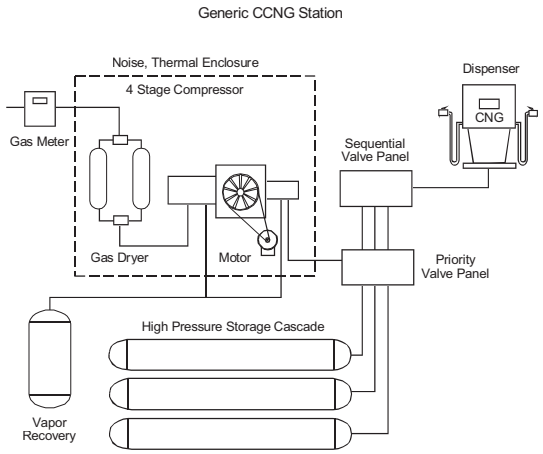

Figure 43.2. Components of a CNG station

43.3.3.1 Natural Gas Supply

Natural gas is supplied to the compressor station from a local distribution company through its pipeline system. Gas supply pressure in pipelines is typically around 25–60 psig.

43.3.3.2 The Compression and Storage Station

The compression and storage station provides CNG at different pressures to the dispenser, depending on the fueling procedure. The compression stations are designed with the flexibility to "fast fill" or regularly fill CNG bus tanks. Additionally refueling can take place directly from the compressor.

43.3.3.3 Storage Cascade

CNG is filtered after leaving the compressor and injected with methanol to reduce the moisture content. It is then sent through the priority and sequence valve panels to the low-pressure storage cascade bank, where it is stored at 1000 psig. Once the low-pressure storage bank is filled, medium (1500 psig) and high (3,600 psig) pressure banks are sequentially filled.

43.3.3.4 Dispensing Facility

The compressor and the storage tanks are connected to the dispenser through underground steel lines, which are subject to corrosion and the possibility of damage from excavation or earth movements. The dispensing equipment draws gas either from the storage cascades or from the compressor. A master shut-off valve isolates the compressor and storage cascades from the dispensing equipment for maintenance or emergency situations.

43.3.3.5 CNG Bus

The typical CNG Bus shown in Figure 43.3 is used in this study. This design is a 40 ft long bus which has six undercarriage CNG storage tanks. Only the parts of the bus relevant to the usage of CNG as a fuel and contributing to fire hazards are identified and used in this study.

The PRA develops fire scenarios and consequences due to occurrence of initiating events

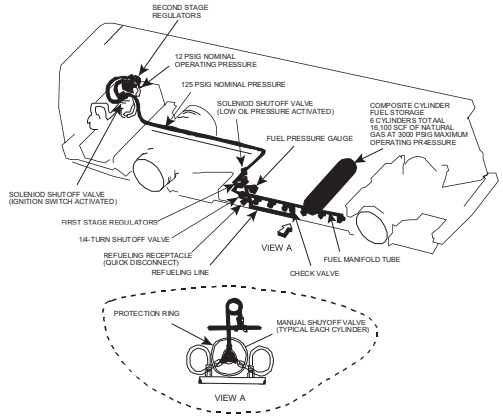

Figure 43.3. Fuel supply system of a CNG bus

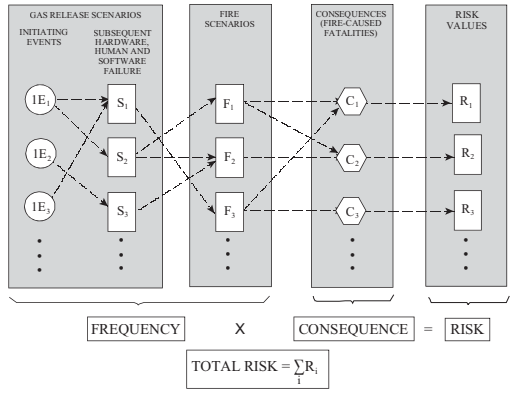

Figure 43.4. Summary of the overall PRA approach in this study

and subsequent hardware or human failures, identified as important in the qualitative risk analysis.

Generic and historical data obtained from various sources [29], [31] were used for quantifying the fault tree and event tree models, and were used to determine the frequency of occurrence of scenarios leading to fire-related fatalities. The risk was then computed from the frequency and consequence of each scenario. The steps are summarized in Figure 43.4.

43.3.4 Gas Release Scenarios

The failure modes may be grouped into six initiating event groups and subsequence hardware, human or software failures were identified to describe the scenarios of events leading to gas releases. Each scenario has an initiating event and subsequent failure events which can result in a fire or explosion with corresponding fatal consequences. The determination of the frequency of occurrence of each initiating event, the actual propagation of them into fires/explosions and consequences are part of the quantitative assessment. The classes of initiating events identified are:

1. Hardware catastrophic failures due to intrinsic failure mechanisms, leading to instantaneous release of CNG in the presence of an ignition source.
2. Hardware degraded failures resulting in gradual release, in the presence of an ignition source.
3. Hardware or human failures resulting in a CNG release with potential for electrostatic discharge ignition.
4. Accidental impact of hardware resulting in gas release in the presence of an ignition source.
5. Human error resulting in the release of CNG in the presence of an ignition source.
6. Non-CNG related fire (*e.g.*, fires due to oil or cargo burning) resulting in the release of CNG in the presence of an ignition source.

Fault Trees were used to identify and compute the probability of failure leading to a sustained gas release in the presence of an ignition source, given the occurrence of the initial failure events. A constant failure rate model was used to represent the events modeled in the fault trees. From the fault trees cut-sets were generated. Rare event approximation [29] was used to combine scenarios. Component failures were assumed independent and no common cause failure events were determined significant since very little redundancy in active components existed.

43.3.5 Fire Scenario Description

Factors that determine the kind of fire that results from gas release include:

- Type of initial gas release (leak *vs*. sudden release)
- Gas dispersion
- Gas ignition likelihood

43.3.5.1 Gas Release

The CNG release may be instantaneous or gradual. Adiabatic expansion of the gas occurs with an instantaneous release, for example from a ruptured gas tank cylinder. A gradual release occurs, as from a leaking joint or cracked fuel line. Component defects, with greater than 1/4" opening in the containment system, are determined to produce an instantaneous release of CNG. Conversely, a gradual release is produced by a crack or other defect with less than 1/4" opening.

Adiabatic expansion of CNG results in the formation of a flammable air/gas mixture with explosive potential. If the mixture is ignited immediately it results in a fireball [32]. The pressure and the volume of the CNG containment determine the extent of the fireball and explosion. Delayed ignition of the released gas results in continued mixing with a vapor cloud forming. Ignition would result in a vapor cloud explosion or flash fire. Gradual release of CNG results in a limited mixing of gas with air which, if ignited immediately, will result in a jet flame in the vicinity of the mixture. Delayed ignition leads to the accumulation of flammable air gas mixture which would produce a vapor cloud explosion or flash fire, if ignited.

43.3.5.2 Gas Dispersion

The extent of mixing of the released CNG that is not immediately ignited is best determined with computer models. In the absence of an elaborate model, the dispersion scenarios considered are dense cloud, and neutral or buoyant dispersion.

If there is an instantaneous release of CNG and the ignition is delayed, then the gas will be dispersed as a dense cloud, which will form a flash fire or would explode when ignition occurs. Gradual release of CNG in a jet, leads to buoyant dispersion and delayed ignition results in a flash fire. Following the dispersion of CNG in a dense cloud, even if delayed ignition does not occur, there are thermodynamic effects on the human body that present additional risks apart from fire or explosion hazards. This aspect of CNG dispersion is further discussed in [33].

43.3.5.3 Ignition Likelihood

If ignition can occur in less than 10 minutes of exposure then it can be considered immediate. Delayed ignition is generally considered to be greater than 10–15 minutes of exposure. Table 43.1 shows the reference values [26], [34] used for a qualitative judgment of the likelihood potential of ignition of a vapor cloud exposed to an ignition source.

Table 43.1. Qualitative ignition potential

Qualitative ranking	Quantitative likelihood range
Strong	0.25–1.00
Moderate	0.10–0.24
Weak	0.01–0.09

In this study immediate ignition of a flammable gas mixture (fireball and jet flame) is assumed to occur with a conditional probability of 0.8. Delayed ignition and dispersion (flash fire) is assumed to occur with a conditional probability of 0.95 [34]. Sensitivity of the risk results to these assumptions were assessed later in the study.

Table 43.2 summarizes the different gas release, ignition or dispersion and fire scenarios considered in this study.

Table 43.2. Summary of CNG release, ignition and fire scenario

CNG release mode	Ignition mode	Expected consequence
Instantaneous	Immediate	Fireball
	Delayed	Vapor cloud explosion or flash fire
Gradual	Immediate	Jet flame
	Delayed	Vapor cloud explosion or flash fire

43.3.6 Consequence Determination

An analytical assessment method was used to compute the number of fatalities due to the various

fire scenarios identified before. The method estimates the heat release rate and flame height, exposure temperature from fire plume modeling, and the time required to reach critical damage thresholds causing fatalities. The consequences for each event in this study are computed by assuming the following:

- Worst-case fire and explosive intensities associated with each scenario.
- Fatalities occurring when exposed to a fire heat flux of 25.0 kW/m^2 for one minute [26].

Fatalities occurring when persons are present within the distance from a point source where a radiant flux of 25.0 kW/m^2 or more is being received.

43.3.7 Fire Location

To determine the lethality of each fire event, location of the vehicle is of paramount importance. The five vehicle fire locations chosen represents normal usage. A probability factor, representing the relative frequency of a vehicle's location during normal use, is applied to the consequences. Number of people present at each location was different and was represented by distributions consistent from current experience ranging from 1–30 people exposed (no evacuation or other mitigation measures were allowed). This allows determination of the expected fatalities in each location given a fire scenario.

The locations and probability factors are based on the following assumptions:

- Garage or storage facility (0.5), (bus is parked 12 hours per day).
- Fueling station (0.06), (bus refueled maintained and repaired 1.5 hour /day).
- Urban roadway (0.21), (bus is in operation 5 hours on urban roadway).
- Rural roadway (0.21), (bus is in operation and near school, near homes and on rural roadway 5 hours).
- Tunnel, under bridges or other enclosed roadways (0.02), (bus goes through this type of roadways for 0.5 hour per day).

43.3.8 Risk Value Determination

Gas release and fire scenarios along with the consequences were combined for each initiating event to determine the risk associated with each event. The summation of each individual risk gave the total risk. Event Trees of the gas release and fire scenarios were used to combine the elements of the risk model. For this purpose, the software tool QRAS V1.6 [33] was used. This tool was used to calculate the sets of scenarios and corresponding risk values.

43.3.9 Summary of PRA Results

The PRA fire safety risk results of this study are summarized in Table 43.3. The mean total fire fatality risk for CNG buses is estimated as 0.23 per 100-million miles of operation. The study also estimates mean values of 0.16 fatalities per 100-million miles for passengers inside the CNG bus only. This would suggest that approximately 70% of the total fire related fatalities are expected to be due to the passengers of the bus.

43.3.10 Overall Risk Results

The projected mean fatalities from a typical bus due to catastrophic failures resulting in an uncontained fire are 2.7×10^{-6}/bus/year, and for all causes is 2.2×10^{-5}/bus/year. For the 8500 CNG school buses [35], [36]. in operation in the U.S. in year 2001, this would lead to a mean total risk value of approximately 0.19 deaths/year or a mean time to occurrence of 5.4 years/fatality for all existing buses in operation. If all the existing buses were to be replaced with CNG buses, then the projected fatality would be 9.9 deaths/year or a mean time to occurrence of 0.1 year/fatality.

It should be noted that some actual cases of CNG related explosions and fire from component failures have been recorded. One such incident was reported in Houston, Texas in 1998. In this case, gradual gas release and delayed ignition resulted in the explosion and a subsequent flash fire (no fatalities were reported). A CNG cylinder rupture as a result of accidental impact caused a fireball in Nassau County, NY [37] in 2001. Seven people

Table 43.3. PRA risk results

Scenarios groups leading to fire and fatality	Risk (mean fatalities/bus/year)	Risk (mean fatalities/ 100 M miles)	% of total risk
Catastrophic failure of bus or station hardware components	2.4×10^{-6}	2.5×10^{-2}	10.84
Degraded failure of bus or station hardware components	8.7×10^{-6}	9.0×10^{-2}	38.77
Electrostatic discharge of CNG	2.7×10^{-6}	2.8×10^{-2}	12.21
Accidental impacts mainly due to collision	4.9×10^{-6}	5.1×10^{-2}	21.70
Non-CNG related fires	3.4×10^{-6}	3.5×10^{-2}	14.94
Operator error	3.6×10^{-7}	3.7×10^{-3}	1.54
Total mean fire fatality risk	$\mathbf{2.2 \times 10^{-5}}$	$\mathbf{2.3 \times 10^{-1}}$	**100**

were killed in a CNG bus explosion/fire in Tajikistan and four in another accident in San Salvador [38] in 2001. As such, the evidences of some of the scenarios considered in this study have already been observed.

Analysis of the projected fatalities from all the initiating events has revealed that while the number of fatalities from CNG bus fires are low, or have not been reported to date in the U.S., this is only due to the small number of CNG buses in operation. Increasing the number of such buses will certainly increase the expected number of fatalities due to fires and explosions.

43.3.11 Uncertainty Analysis

The sources of uncertainty in the results of this study can be classified and characterized as follows:

- Generic bus system description and model used (model uncertainty)
- Major fire hazard scenarios considered (model/completeness uncertainty)
- Conservatism in fire scenario and consequence modeling techniques used (model/ assumption uncertainty)
- Failure data for hardware/human failures and estimated frequency of fires and their location (lack of sufficient data / parameter uncertainty)
- Integration of all scenarios to estimate total risk (model uncertainty).

While model uncertainties are important, due to lack of a sound model uncertainty estimation methodology, at this point only the source of uncertainty due to failure data used to quantify the PRA models are quantified. Uncertainties in the models themselves are not considered and as is the general practice in the PRA's, model uncertainties were reduced by independent peer reviews and conservatism in constructing the models. The uncertainty in failure data used in the PRA model was represented by probability distributions assigned to the component failure rate, probabilities for subsequent events and consequence of individual scenarios. Where appropriate, normal, lognormal and uniform distributions were used along with distribution parameters as suggested by the generic data sources and from engineering judgment to represent the uncertainties in failure data, parameters and assumptions.

Propagation and combination of the uncertainties in the risk analysis were performed using the QRAS V1.6, Risk Analysis software [39]. The

Table 43.4. Summary of uncertainty analysis results

CNG bus fire scenarios resulting from the following causes	Mean frequency of occurrence/bus/year	Mean risk (fatalities/bus/year)	5%	95%
Catastrophic failure of bus or station hardware components	1.4×10^{-3}	2.4×10^{-6}	2.7×10^{-7}	6.1×10^{-6}
Degraded failure of bus or station hardware components	3.7×10^{-3}	8.7×10^{-6}	5.6×10^{-7}	2.5×10^{-5}
Electrostatic discharge of CNG	1.4×10^{-5}	2.7×10^{-6}	4.1×10^{-7}	6.6×10^{-6}
Accidental impacts mainly due to collision	3.6×10^{-2}	4.9×10^{-6}	4.3×10^{-7}	1.2×10^{-5}
Non-CNG related fires	3.6×10^{-4}	3.4×10^{-6}	3.7×10^{-7}	8.5×10^{-6}
Operator error	4.0×10^{-2}	3.6×10^{-7}	2.4×10^{-8}	9.8×10^{-7}
Total fire fatality risk		**2.2×10^{-5}**	**9.1×10^{-6}**	**4.0×10^{-5}**

* Assuming 9598 miles of travel per bus per year [40]

propagation of the uncertainties relied on a Monte Carlo simulation with Latin hypercube sampling and regression analysis [40]. The results of the uncertainty analysis are summarized in Table 43.4. The mean value of the fire fatality risk computed is 2.2×10^{-5} fatalities/bus/year (see Table 43.4). The probability bounds at 5% and 95% levels are calculated as 9.1×10^{-6} and 4.0×10^{-5}, respectively.

43.3.12 Sensitivity and Importance Analysis

The sensitivity of the total risk to the input parameters was performed by changing the failure rates of important components by a factor of ten (10) and changing the outcomes of each fire by a factor of one half. Each change is done while the other parameters are kept constant. This approach allows identification of the components which contribute most to the uncertainty of the overall risk results. The sensitivity of the risk to the presence of certain ignition sources was performed by similarly varying the probability of occurrence of each ignition source and comparing the effect on the total risk result.

Sensitivity analysis shows that the total fire fatality risk is relatively insensitive to ignition sources except to the introduction of an ignition source by an operator from such activities as smoking. This result is very important and should be included in any selection and training process for operators of CNG powered equipment.

Fatality risk is sensitive to location of the fire. This study shows that the risk is highly sensitive to flash fires in urban and rural areas. The third most important fire events are fireballs in urban areas. More detailed modeling of fire scenarios would be required so that critical adiabatic flame temperatures, flame speed and burning rates can be determined analytically.

Birnbaum Importance measures [28] were also used to identify design weaknesses and component failures that are critical to the prevention of CNG release and fires. It is a good measure for identifying components and design features that contribute most to risk. Such importance measures provide insights into how one should focus risk reduction and management efforts. The components with the highest potential for risk

reduction are the CNG cylinders, pressure relief devices and bus fuel piping.

43.3.13 Case Study Conclusions

While CNG buses are more susceptible to major fires, the total average expected fire risk from CNG buses over diesel power-buses is expected to be higher by only a factor of about two. However, since most of the fire fatalities are expected to occur among the passengers of CNG school buses, the fire risk for CNG bus passengers is expected to be larger than that of diesel school bus by over two orders of magnitude. While on the average the total CNG fire safety risk is not much higher than the diesel buses, the worst possible fire scenarios may impose a far higher fatality risk in CNG buses than the worst case fire scenario from diesel powered buses.

The reliance of this study on generic models and failure data is a good approximation to screen safety risks of CNG buses. However, a more accurate physics of failure based model (such as fatigue and corrosion based life models) should be supplemented with this study to provide more accurate results. This is part of on-going research by the authors. Further, CNG-specific hardware failure data would also be needed.

Three components have been identified from the sensitivity and importance analysis to contribute most to fire fatality risk and to the uncertainty of the overall fire fatality risk. These are pressure relief valves on cylinders, CNG storage cylinders, and bus fuel piping. The failure mechanisms of these components should be modeled using a physics of failure based approach to analytically determine the failure rates.

To compare the results of CNG with diesel buses, the risk assessment should add risk of non-fatal injuries in addition to fatalities. For any policy decision making, the fire risk should be compensated for and properly characterized by integrating the safety risks of this study and the expected health and environmental benefits of using CNG powered school buses.

Risk Management

Terje Aven

University of Stavanger, 4036 Stavanger, Norway

Abstract: This chapter reviews and discusses fundamental issues in risk management, related to concepts, principles and methods used. Some of the issues addressed include:

- How we should understand risk.
- How we should express risk.
- How we should deal with uncertainties in future performance.
- How we should balance project risk management and corporate portfolio perspectives.
- How we should use expected values in risk management.
- How we should deal with cautionary and precautionary principles, as well as the ALARP principle (risk should be reduced to a level that is as low as reasonably practicable).
- How we should formulate and use goals, criteria, and requirements to stimulate performance and ensure acceptable safety standards.

44.1 Introduction

In this chapter, we first present some of the basic issues of risk management and risk analysis, as described in the literature and standards, in particular ISO [1]. These relate in particular to different perspectives on risk and key features of risk analysis. A basic distinction is made between the classical approach to risk and probability, and the Bayesian approach or paradigm.

In Section 44.2 we present and discuss the key principles of risk management and decision making, related to economic theories and perspectives, such as cost-benefit analysis and cost-effectiveness analysis, as well as cautionary and precautionary principles. The "cautionary principle" says that in the face of uncertainty, caution should be the ruling principle. The precautionary principle is a special case of the cautionary principle and expresses that caution should be the ruling principle if there is a lack of scientific certainty that will become the consequences of the action.

Special attention is given to the use of expected values in risk management. Expected values as a basis for decision making are supported by the portfolio theory and are a ruling principle among economists. Also, many safety experts view expected values as the key performance measure while making decisions in the face of uncertainties. In this section, we also review and discuss the use of risk acceptance criteria and the ALARP principle.

In Section 44.3, we highlight the key principles that we believe should form the basis of risk management.

The terminology used in this chapter is in line with the ISO standard on risk management terminology [1]. Our definition of risk is, however, slightly adjusted compared to the ISO standard, as discussed in Section 44.1.2. Our main focus is the part of risk management that addresses HES (health, environment, and safety), and in particular major accidents. However, the concepts and principles are applicable also to other areas. The chapter is to a large extent based on [2].

44.1.1 The Basis of Risk Management

The purpose of risk management is to ensure that adequate measures are taken to protect people, the environment, and assets from harmful consequences of the activities being undertaken, as well as balancing different concerns, in particular risks and costs. Risk management includes measures both to avoid the occurrence of hazards and to reduce their potential harms. Traditionally, risk management was based on a prescriptive regulating regime, in which detailed requirements were set to the design and operation of the arrangements. This regime has gradually been replaced by a more goal oriented regime, putting emphasis on what to achieve rather than on the means of doing so.

Risk management is an integral aspect of a goal oriented regime. It is acknowledged that risk cannot be eliminated but must be managed. There is an enormous drive and enthusiasm in various industries and society as a whole nowadays to implement risk management in organizations. There are high expectations that risk management is the proper framework for obtaining high levels of performance.

To support decision making on design and operation, risk analyses are conducted. The analyses include identification of hazards and threats, cause analyses, consequence analyses, and risk description. The results of the analyses are then evaluated. The totality of the analyses and the evaluations are referred to as risk assessments. Risk assessment is followed by risk treatment, which is a process involving the development and implementation of measures to modify risk, including measures designed to avoid, reduce ("optimize"), transfer or retain risk. Risk transfer means sharing with another party the benefit or loss associated with a risk. It is typically affected through insurance. Risk management covers all coordinated activities to direct and control an organization with regard to risk. The risk management process is the systematic application of management policies, procedures and practices to the tasks of establishing the context, assessing, treating, monitoring, reviewing and communicating risks, see Figure 44.1.

Risk management involves achieving an appropriate balance between realizing opportunities for gains while minimizing losses. It is an integral part of good management practice and an essential element of good corporate governance. It is an iterative process consisting of steps that, when undertaken in sequence, enable continuous improvement in decision making and facilitate continuous improvement in performance.

"Establishing the context" (see Figure 44.1) defines the basic frame in which conditions within the risks must be managed and sets the scope for the

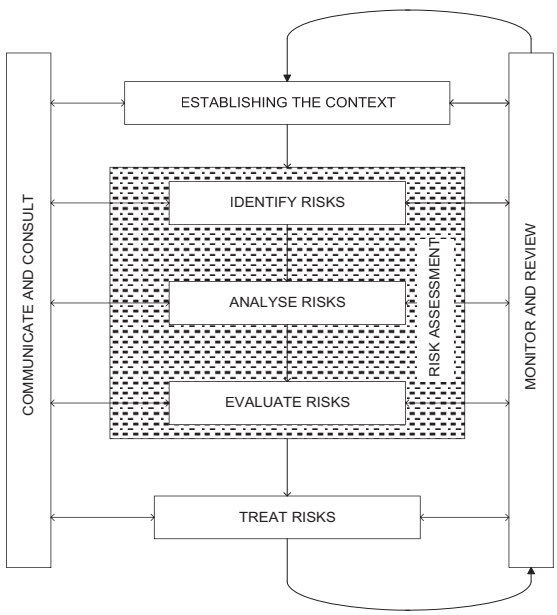

Figure 44.1. The risk management process (based on [3])

rest of the risk management process. The context includes an organization's external and internal environment, and the purpose of the risk management activity. This also includes consideration of the interface between the external and internal environments. The context means a definition of suitable decision criteria as well as structures for how to carry out the risk assessment process.

Risk analysis is often used in combination with risk acceptance criteria, as inputs to risk evaluation. Sometimes the term risk tolerability limits is used instead of risk acceptance criteria. The criteria state is what is deemed as an unacceptable risk level. The need for risk reducing measures is assessed with reference to these criteria. In some industries and countries, it is a requirement in regulations that such criteria be defined in advance of performing the analyses.

Figure 44.2 illustrates the use of risk analysis in a decision making context. The model shown in Figure 44.2 covers the following items:

1. *Stakeholders*. The stakeholders are here defined as people, groups, owners, authorities, *etc*., who have interests related to the decisions to be made. Internal stakeholders may be the owner of the installation, other shareholders, the safety manager, unions, the maintenance manager, *etc.*, whereas external stakeholders may be the safety authorities (the Norwegian Safety Petroleum Authority, the State Pollution Control Agency, *etc*.), environmental groups (Green Peace, *etc*.), research institutions, *etc*.
2. *Decision problem and decision alternatives*. The starting point for the decision process is a choice between various concepts, design configurations, sequence of safety critical activities, risk reducing measures, *etc*.
3. *Analysis and evaluation*. To evaluate the performance of the alternatives, different types of analyses are conducted, including risk analyses and cost-benefit (cost-effectiveness) analyses. These analyses may, given a set of assumptions and limitations, result in recommendations on which alternative to choose.
4. *Managerial review and judgment.* The decision support analyses need to be evaluated in the light of the premises, assumptions and limitations of these analyses. The analyses are based on a background information that must be reviewed together with the results of the analyses. Considerations should be given to factors such as:
   - The decision alternatives being analysed.
   - The performance measures analysed (to what extent do the performance measures used describe the performance of the alternatives?).
   - The fact that the results of the analyses represent judgments and not only facts.
   - The difficulty of assessing values for burdens and benefits.
   - The fact that the analysis results apply to models, *i.e.*, simplifications of the real world, and not the real world itself. The modelling entails the introduction of a number of assumptions, such as replacing continuous quantities with discrete quantities, extensive simplification of time sequences, *etc*.

In Figure 44.2 we have indicated that the stakeholders may also influence the final decision process in step (7) in addition to their stated criteria, preferences, and value tradeoffs providing input to the formal analyses in step (6).

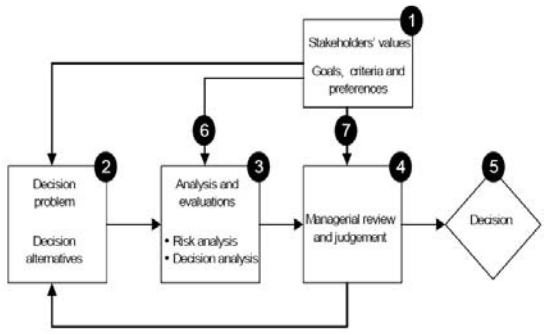

Figure 44.2. Model of the decision making process [2]

Safety management covers all coordinated activities designed to direct and control an organization with regard to safety. We use the term safety when we focus on risk related to accidents. Hence risk management includes safety management in our terminology. In the literature the terms risk and safety, as well as risk management and safety management are defined in many different ways, and often risk and risk management are used in a narrower sense than here, see, *e.g.* [4] and [5]. In safety management emphasis is often placed on aspects related to human and organizational factors, see *e.g.*, [6], [7] and [8], in contrast to risk management which has a tendency to concentrate on the more technical issues.

Similarly we define HES (health, environment, and safety) management. Safety management may be seen as a special part of uncertainty management. While uncertainty management considers all uncertainties regarding the project outcome, *i.e.*, events both with negative and positive consequences, safety management addresses only the uncertainties that can result in accidents. However, safety management is mainly concerned with low-probability and large-consequence events that normally are not considered in uncertainty management. Hence safety management goes beyond what is typically the scope of uncertainty management [9].

Following our terminology for risk, uncertainty management is a part of the risk management, although many aspects normally treated in uncertainty management is not covered by risk management.

44.1.2 Perspectives on Risk

A common definition of risk is that risk is the combination of probability and consequences, where the consequences relate to, for example, loss of lives and injuries. This definition is in line with that used in [1]. However, it is also common to refer to risk as probability multiplied by consequences (losses), *i.e.*, what is called the expected value in probability calculus. If the focus is the number of fatalities during a certain period of time, X, then the expected value is given by E[X], whereas risk defined as the combination of probability and consequence expresses probabilities for different outcomes of X, for example the probability that X does not exceed 10. Adopting the definition that risk is the combination of probability and consequence, the whole probability distribution of X is required, whereas the expected value refers only to the centre of gravity of this distribution. In the scientific risk discipline there is a broad consensus concluding that at risk cannot be restricted to expected values. We need to see beyond the expected values, for example, by expressing the probability of a major accident having a number of fatalities.

Hence risk is seen as the combination of probability and consequence. But what is a probability? There are different interpretations. Here are the two main alternatives:

a). A probability is interpreted in the classical statistical sense as the relative fraction of times the events occur if the situation analyzed were hypothetically "repeated" an infinite number of times. The underlying probability is unknown, and is estimated in the risk analysis.

b). Probability is a measure of expressing uncertainties as to the possible outcomes (consequences), seen through the eyes of the assessor and based on some background information and knowledge.

Following definition a) we produce estimates of the underlying true risk. This estimate is uncertain, as there could be large differences between the estimate and the correct risk value. As these correct values are unknown it is difficult to know how accurate the estimates are.

Following interpretation b), we assign a probability by performing uncertainty assessments, and there is no reference to a correct probability. There are no uncertainties related to the assigned probabilities, as they are expressions of uncertainties.

The implications of the different perspectives are important. If the starting point is a), there is a risk level that expresses the truth about risk, for example for an offshore installation at a given point in time. This risk level is unknown, true, but

in many cases it is difficult to see whether people are talking about the estimates of risk or the real risk.

If the starting point is b) the expert's position may be weakened, as it is acknowledged that the risk description is a judgment, and others may arrive at a different judgment. Also risk estimates represent judgments, but the mixture of estimates and real risk can often give the experts a stronger position in this case.

Depending on the risk perspective, there are different approaches to risk analysis and assessments, risk acceptance, *etc*. We will discuss this in more detail below.

Seeing risk as the combination of probability and consequence means a quantitative approach to risk. A probability is a number. Of course, a probability may also be interpreted in a qualitative way, using an interpretation such as the level of danger. We may, for example, refer to the danger of an accident occurring without reference to a specific interpretation of a probability, neither through a) nor through b). However, as soon as we address the meaning of such a statement and the issue of uncertainty, we must clarify whether we are adopting interpretation a) or b). If there is a real risk level, it is relevant to consider and discuss the uncertainties of the risk estimates compared to the real risk. If probability is a measure of the analyst's uncertainty, a risk assignment is a judgment and there is no reference to a correct and objective risk level.

In some cases we have references levels through historical records. These numbers do not, however, express risk, but they provide a basis for expressing risk. In principle, there is a huge step from historical data to risk that is a statement concerning the future. In practice, many analysts do not distinguish between the data and the risk derived from the data. This is unfortunate as the historical data may to varying degree be representative for the future, and the amount of data may often be very limited. A mechanical transformation from historical data to risk numbers should be avoided.

There are a number of other perspectives to risk than those mentioned above. Some of these are summarized below [10],[11]:

- In psychology there has been a long tradition of work that adopts the perspective to risk, that uncertainty can be represented as an objective probability. Here researchers have sought to identify and describe people's (lay-people's) ability to express the level of danger using probabilities and to understand which factors are influencing the probabilities. A main conclusion is that people are poor assessors if the reference is a real objective probability value, and that the probabilities are strongly affected by factors such as dread.
- Economists usually see probability as a way of expressing uncertainty about the outcome, and often seen in relation to the expected value. Variance is a common measure of risk. Both the interpretations a) and b) are applied, but in most cases without making it clear which interpretation being used. In economic applications a distinction has traditionally been made between risk and uncertainty, based on the availability of information. Under risk the probability distribution of the performance measures can be assigned objectively, whereas under uncertainty these probabilities must be assigned or estimated on a subjective basis [12]. This latter definition of risk is seldom used in practice.
- In decision analysis, risk is often defined as "minus expected utility", *i.e.*,− E[u(X)], where the utility function u expresses the assessor's preference function for different outcomes x.
- Social scientists often use a broader perspective on risk. Here risk refers to the full range of beliefs and feelings that people have about the nature of hazardous events, their qualitative characteristics and benefits, and most crucially their acceptability. This definition is considered useful if lay conceptions of risk are to be adequately described and investigated. The motivation is the fact that there is a wide range of multidimensional characteristics of hazards, rather than just an abstract

expression of uncertainty and loss, which people evaluate in performing perceptions - so that the risks are seen asfundamentally and conceptually distinct. Furthermore, such evaluations may vary with the social or cultural group to which a person belongs, the historical context in which a particular hazard arises, and may also reflect aspects of both the physical and human or organizational factors contributing to hazard, such as trustworthiness of existing or proposed risk management.

- Another perspective, often referred to as cultural relativism, expresses that risk is a social construction and it is therefore meaningless to speak about objective risk.

There also exist perspectives that intend to unify some of the perspectives above, see *e.g.* [13] and [14]. One such perspective, the predictive Bayesian approach [14], is based on the interpretation b), and makes a sharp distinction between historical data and experiences, future quantities of interest such as loss of lives, injuries, *etc.* (referred to as observables), and predictions and uncertainty assessments of these. The thinking is analogous to cost risk assessments, where the costs, the observables, are estimated or predicted, and the uncertainties of the costs are assessed using probabilistic terms. Risk is then viewed as the combination of possible consequences (outcomes) and associated uncertainties. This definition is in line with the definition adopted by the UK Government ([15], p. 7). The uncertainties are expressed or quantified using probabilities. Using such a perspective, with risk seen as the combination of consequences and associated uncertainties (probabilities), a distinction is made between risk as a concept and terms such as risk acceptance, risk perceptions, risk communication and risk management, in contrast to the broad definition used by some social scientists in which this distinction is not clear.

In this chapter we adopt this perspective on risk, viewing risk as the combination of possible consequences and associated uncertainties, acknowledging that risk cannot be distinguished from the context it is a part of, the aspects that are addressed, those who assess the risk, the methods and tools used, *etc*. Adopting such a perspective the risk management needs to reflect this, by

- focusing on analyses and assessments of risk by different analysts;
- addressing aspects of the uncertainties not reflected by the computed expected values;
- acknowledging that what is acceptable risk and the need for risk reduction cannot be determined simply by reference to the results of risk analyses;
- acknowledging that risk perception has a role to play to guide decision makers; professional risk analysts do not have the exclusive right to describe risk.

Such an approach to risk is in line with the recommended approach by the UK Government, see [15], and also the trend seen internationally in recent years. An example where this approach has been implemented is the Risk Level Norwegian sector project, see [16] and [14], p.122.

Let C denote the consequences or outcomes associated with an activity. Typically C would be expressed by some quantities C1, C2, on the real line, *e.g.*, economic loss, number of fatalities, number of attacks, *etc*. These quantities are examples of observable quantities, *i.e*., quantities that express states of the "world", quantities of physical reality or nature, that are unknown at the time of the analysis but will, if the system being analyzed is actually implemented, take some value in the future, and possibly become known.

A source is a situation or an event with a potential of a certain consequence. We distinguish between three categories of sources; threats, hazards, and opportunities. These terms are typically used in security, safety, and economic contexts, respectively. Here security relates to intentional situations and events, whereas safety relates to accidental situations and events. An example of an opportunity is a planned shutdown, which allows for preventive maintenance.

We define vulnerability as the combination of possible consequences and associated uncertainties given a source. Hence risk is the combination of sources (including associated uncertainties) and vulnerabilities.

Based on this definition, we refer to "vulnerability" as an aspect or feature of the system, when the combination of possible consequences and associated uncertainties is judged to give a high vulnerability, *i.e.*, is considered critical in some sense. For example, in a system without redundancy the failure of one unit may result in system failure, and consequently we may judge the lack of redundancy as vulnerability depending on the uncertainties.

44.1.3 Risk Analysis to Support Decisions

Two of the most common methods to identify hazards and risks are FMECA (failure mode and effect and criticality analysis) and HAZOP (hazard and operability studies). In FMECA categorises of the possible consequences and associated likelihoods are introduced, and the criticality is determined using a risk matrix approach. Using this approach different options may be assessed with respect to risk (criticality) and compared using the risk matrix. This is a crude risk analysis. The next level of sophistication of risk analysis is obtained when models are developed to represent cause and/or consequence scenarios. The standard tools used are FTA (fault tree analysis) and ETA (event tree analysis), and the combination of the two, CCA (cause consequence analysis). These models are important elements in a qualitative risk analysis, and provide the basis for a quantitative risk analysis. These are all standard risk analysis methods and the interested reader is referred to textbooks for their description and discussion, see *e.g.*, [5]. For further descriptions and discussions of risk analysis the reader is referred to the chapter in this book on probabilistic risk assessment.

44.1.4 Challenges

Given the above fundamentals of risk management, the next step is to develop principles and methodology that can be used in practical decision making. This is, however, not straightforward. There exist a number of challenges and some of these are addressed here:

i. Establishing an informative risk picture for the various decision alternatives.
ii. The use of this risk picture in a decision making context.

Establishing an informative risk picture means identifying appropriate risk indices, and assessments of uncertainties. Using the risk picture in a decision making context means definition and application of risk acceptance criteria, cost-benefit analyses and the ALARP principle (risk should be reduced to a level that is as low as reasonably practicable).

Risk management involves decision making in situations involving high risks and large uncertainties, and such decision making is difficult as it is hard to predict what would be the consequences (outcomes) of the decisions. A number of tools are available to support decision making in such situations, such as risk and uncertainty analyses, risk acceptance criteria (tolerability limits), cost-benefit analyses (expected net present value calculations) and cost-effectiveness analyses (addressing, *e.g.*, expected costs *per* statistical saved lives). However, these tools do not provide clear answers. They have limitations and are based on a number of assumptions and presumptions, and their uses are based not only on scientific knowledge, but also on value judgments involving ethical, strategic and political concerns. Some of the challenges related to these tools are: the assessment of uncertainties and assignment of probabilities, determination of appropriate values for quantities such as a statistical life and the discount rate, to distinguish between objective knowledge and subjective judgments, treatment of uncertainties and the way of dealing with intangibles.

Risk analyses, cost-benefit analyses and related type of analyses provide support for decision making, leaving the decision makers to apply decision processes outside the direct applications of the analyses. We speak about managerial review and judgment, see. Figure 44.2. It is not desirable to develop tools that prescribe or dictate the decision. That would mean a too mechanical approach to decision making and would fail to recognize the important role of management to

perform difficult value judgments involving uncertainty.

Nonetheless, there is a need to provide guidance and a structure for decision making in situations involving high risks and large uncertainties. The aim must be to obtain a certain level of consistency in decision making and confidence in obtaining desirable outcomes. Such guidance and structure exist to some degree, and the challenge is to find the right level. This will be discussed in more detail in the following sections.

44.2 Risk Management Principles

44.2.1 Economic and Decision Analysis Principles

This section gives a brief introduction to decision analysis theory, emphasizing expected utility theory, cost-benefit analysis, the use of expected values to support decision making, and risk aversion. The purpose of the section is not to give a comprehensive and all-including review of the field, but to highlight important issues important for risk management.

44.2.1.1 Expected Utility Theory

We consider a decision situation involving possible consequences (outcomes) that are subject to uncertainties. The problem is to make a "good" decision in such a situation. We may, for example, think of a choice between a number of different investment alternatives or development projects for an offshore installation. In theory, the optimization of the expected utility is the ruling paradigm among economists and decision analysts in such a situation, see, *e.g.*, [17],[18],[19]. The expected utility is in mathematical terms written like Eu(X), where u is the utility function and X is the outcome expressing a vector of different attributes, for example, costs and the number of fatalities. The expected utility approach is theoretically attractive, as it provides recommendations based on a logical basis. If a person is coherent both in his preferences amongst consequences and in his assessments about uncertain quantities, it can be proved that the only sensible way for him to proceed is by maximizing expected utility. For a person to be coherent when speaking about the assessment of uncertainties of events, the requirement is that he follows the rules of probability. When it comes to consequences, coherence means adherence to a set of axioms including the transitive axiom: If b is preferred to c, which is in turn preferred to d, then b is preferred to d. What we are doing is making an inference according to a principle of logic, namely that implication should be transitive. Given the framework in which such maximization is conducted, this approach provides a strong tool for guiding decision makers.

In practice it is difficult to work out a utility function. The proper specification of the utility function means the application of a lottery process, as explained in, *e.g.*, [18]. This lottery process is not straightforward to carry out in practice, and simplification procedures are presented to ease the specifications. One possible approach is to define a parametric function for the utility function, which is determined up to a certain parameter, and the value specification is reduced to assigning a number to this parameter. Examples of such procedures are found in [14]. This approach simplifies the specification process significantly, but it can be questioned whether the process imposes a too strong requirement on the specification of the utilities. Is the parametric function actually reflecting the decision maker's preferences? The decision maker should be skeptical to let his preferences be specified more or less automatically without a careful reflection of what his preferences are. Complicated value judgments are not easily transformed to a mathematical formula.

The specification of the utility function is particularly difficult when there are several attributes, and in most cases this is so. For multi-attribute utility functions simplifications can be performed by using weighted averages of the individual utility functions, see, *e.g.*, [20]. Again it is a question whether the simplification can be justified [14].

Hence methods exist that makes the specification process more feasible in practice. Nonetheless, the author of the chapter still see the expected utility theory as difficult to use in many

situations, in particular in the situations of main interest for this premise, is characterized by a potential of large consequences and relatively large uncertainties as to what the consequences will be? It is also acknowledged that even if it were possible to establish practical procedures for specifying utilities for all possible outcomes, decision makers would be skeptical to reveal these, as it would mean reduced flexibility to adapt to new situations and circumstances. In situations with many parties, as in political decision making, this aspect is of great importance.

Although the expected utility theory is the ruling paradigm for decision making under uncertainty among economists and decision analysts, experimental studies on decision making under uncertainty have revealed that individuals tend to systematically violate the independence axiom of the expected utility theory. Several alternative frameworks and theories have been established, and the rank-dependent utility theory is one of the most popular [21],[22]. The rank-dependent utility theory has been developed to better reflect how people act in real life.

The problems mentioned above in applying the expected utility theory also apply for the rank-dependent theory. However, a discussion of the suitability of the rank dependent theory compared to the expected utility theory is beyond the scope of this chapter.

There also exist other analysis approaches, and the most used in practice are cost-benefit analysis and cost-effectiveness analysis. Before we review these analyses we will briefly look into the rationale for using expected values to support decision making under uncertainty.

44.2.1.2 The Use of Expected Values to Support Decision Making. Risk Aversion

In situations with a number of independent activities, the use of expected values can provide strong guidance on how to make decisions. The justification is the law of large number saying that the average of a number of random quantities can be accurately approximated by the expected value when the number of quantities is high. In economic theory, the so-called portfolio theory plays a similar role: it justifies the use of expected values to support decision making when considering a large number of projects.

The portfolio theory expresses that the value of a portfolio of projects is equal to the expected value of the portfolio plus unsystematic and systematic risks (interpreted here as uncertainties) [23]. The systematic risk relates to general market movements, for example caused by political events, and the unsystematic risk relates to specific project uncertainties, for example, accident risks. When the number of projects is large, the unsystematic economic risk can be ignored. By diversification of the risks into many projects, the unsystematic risks are removed. A company's total cash flow (all projects are included) is approximately equal to the expected cash flow of all the projects, when ignoring the systematic risk. The difference between the portfolio's actual value and its calculated statistical expected value lies in from the portfolio theory being just dependent on the systematic risk.

However, the portfolio theory is just a theory; it has limitations. Some of these limitations and their effects are [2],[24] as follows:

1. Expected values should be used with care when an activity involves the possibility of a large accident, as large accidents have a minor effect on expected values, due to their small probabilities, but if they occur they can result in consequences that are not outweighed by other projects in the portfolio.
2. Assessments of uncertainties are difficult and the probability assignments are based on a number of assumptions and suppositions and will depend on the assessors' judgments. The expected values computed are not objective numbers.
3. Large accidents most often involve consequences that are difficult to transform to monetary values, and the expected NPV can give limited information about the consequences exceeding the strict economic values. What is the value of a life and the environment? How should the company reflect, for example, that a life has a value in itself?

Hence, uncertainty needs to be considered beyond the expected values. The important question then is how the uncertainties should be reflected in the decision making process.

When evaluating the risks, the decision maker's attitude towards risk can affect the outcome of the evaluation process. It is common to divide the decision makers into three categories: risk seeking, risk neutral and risk averse, where risk averse is the standard behavioral assumption, see [17]. The risk aversion principle is defined in decision analysis and the economic literature, see *e.g.*, [25], and reflects that we dislike negative consequences so much that these are given more weight than what is justified by reference to the expected value. Mathematically these terms are defined as follows; we call the decision maker's behavior risk averse if $E_u(X) < u(EX)$. The behavior is risk neutral if $E_u(X) = u(EX)$ and risk seeking if $E_u(X) > u(EX)$. These concepts can also be rephrased using the so-called certainty equivalent. The certainty equivalent C(X) is the value replacing the uncertain situation with C with certainty. Hence in a situation of risk aversion, the certainty equivalent is less than the expected value EC.

In the safety community, risk aversion is often referred to as an attitude to risks and uncertainties, expressing that we dislike or has antipathy against the risks and uncertainties [26]. Such an interpretation is in line with the standard dictionary definition of the word "aversion".

There seems to be a gap between the theory developed in the economic and decision analysis literature and the practical use in safety contexts. Safety people often seem to lack a basic understanding of what risk aversion means, as defined by the economic literature [27]. Following the economist interpretation, risk aversion is not a way of justifying decisions, but a way of characterizing behavioral attitudes and decisions. Two persons may both be risk averse in a specific case, but conclude in different ways on how to handle the risk.

44.2.1.3 Cost-benefit Analysis and Cost-effectiveness Analysis

A traditional cost-benefit analysis is an approach to measure benefits and costs of a project. The common scale used to measure benefits and costs is the country's currency. The main principle in transformation of goods into monetary values is to find out what the maximum amount the society is willing to pay for the project. Market goods are easy to transform to monetary values since the prices on the market goods reflect the willingness to pay. The willingness to pay for non-market goods is on the other hand more difficult to determine, and different methods such as contingent valuation and hedonic price techniques are used. The reader is referred to [28].

After transformation of all attributes to monetary values, the total performance is summarized by computing the expected net present value, the E[NPV], see, *e.g.*, [17]. To measure the NPV of a project, the relevant project cash flows (the movement of money into and out of your business) are specified, and the time value of money is taken into account by discounting future cash flows by the appropriate rate of return. The formula used to calculate NPV is:

$$\mathrm{NPV} = \sum_{t=0}^{T} \frac{X_t}{(1+r_t)^t},$$

where, X_t is equal to the cash flow at year t, T is the time period considered (in years) and r is the required rate of return, or the discount rate, at year t. The terms capital cost and alternative cost are also used for r. As these terms imply, r represents the investor's cost related to not employing the capital in alternative investments. When considering projects where the cash flows are known in advance, the rate of return associated with other risk-free investments, like bank deposits, makes the basis for the discount rate to be used in the NPV calculations. When the cash flows are uncertain, which is usually the case, they are normally represented by their expected values $E[X_t]$, and the rate of return is increased on the basis of the capital asset pricing model (CAPM) in order to outweigh the possibilities for unfavorable outcomes. The risk adjustment is based on the systematic risk only. The reader is referred to [29].

The cost-benefit analysis is based on a risk neutral behavior. However, several methods have been developed to reflect risk aversion in the

analysis. A review is given in [30]. See also Section 44.3.

We distinguish between a cost-benefit analysis and a cost-effectiveness analysis. The latter analysis is an analysis where indices of the form expected cost *per* expected saved lives (statistical life) are calculated. The analysis method does not explicitly put a value to the benefit, say a statistical life, as is required in the cost-benefit analysis.

44.2.1.4 Multi-attribute Analysis

A multi-attribute analysis is a decision support tool analysing the consequences of the various measures separately for the various attributes. Thus there is no attempt made to transform all the different attributes in a comparable unit.

As a part of the multi-attribute analysis, expected net-present values for economic measurable attributes may be reported as well as cost-effectiveness ratios.

44.2.2 The Cautionary and Precautionary Principles

The cautionary principle is a basic principle in safety management, expressing the idea that, in the face of uncertainty, caution should be a ruling principle [31]. This principle is being implemented in all industries through safety regulations and requirements. For example, in the Norwegian petroleum industry it is a regulatory requirement that in the living quarters, the walls facing process and drilling areas be protected by fireproof panels of a certain quality. This is a standard adopted to obtain a minimum safety level. This is based on established practice of many years of operation of process plants. A fire may occur, it represents a hazard for the personnel, and in the case of such an event, the personnel in the living quarters should be protected. The assigned probability for the living quarter on a specific installation being exposed to fire may be judged as low, but we know that fires occur from time to time in such plants. It does not matter whether we calculate a fire probability of x or y, as long as we consider the risks to be significant; and this type of risk has been judged to be significant by the authorities. The justification is experience from similar plants and sound judgments. A fire may occur, since it is not an unlikely event, and we should then be prepared. We need no references to cost-benefit analysis. The requirement is based on a cautionary thinking.

Risk analyses, cost-benefit analyses and similar types of analyses are tools providing insights into risks and the trade-offs involved. But they are just tools, with strong limitations. Their results are conditioned on a number of assumptions and suppositions. The analyses do not express objective results. Being cautious also means reflecting this fact. We should not put more emphasis on the predictions and assessments of the analyses than what can be justified by the methods being used.

In the face of uncertainties related to the possible occurrences of hazardous situations and accidents, we are cautious and adopt principles of safety management, such as

- robust design solutions, such that deviations from normal conditions do not leading to hazardous situations and accidents;
- design for flexibility, meaning that it is possible to utilize a new situation and adapt to changes in the frame conditions;
- implementation of safety barriers, to reduce the negative consequences of hazardous situations if they should occur, for example a fire;
- improvement of the performance of barriers by using redundancy, maintenance/testing, *etc*.;
- quality control/quality assurance;
- the precautionary principle, meaning that in the case of lack of scientific certainty on the possible consequences of an activity, we should not carry out the activity;
- the ALARP principle, meaning that the risk should be reduced to a level that is as low as reasonably practicable.

The level of caution adopted will, of course, have to be balanced against other concerns such as costs. However, all industries would introduce some minimum requirements to protect people and the environment, and these requirements can be

considered justified by the reference to the cautionary principle.

In this section we will draw special attention to the precautionary principle, whereas the ALARP principle will be discussed in Section 44.3.

There are many definitions of the precautionary principle, see *e.g.*, [32] and [33]. The most commonly used definition is probably the 1992 Rio Declaration:

> *In order to protect the environment, the precautionary approach shall be widely applied by states according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.*

Seeing beyond environmental protection, a definition such as the following reflects what we believe is a typical way of understanding this principle:

> *The precautionary principle is the ethical principle that if the consequences of an action, especially the use of technology, are subject to scientific uncertainty, then it is better not to carry out the action rather than risk the uncertain, but possibly very negative, consequences.*

The key aspect is that if there is a lack of scientific certainty as to the consequences of an action, then that action should not be carried out.

The problem with this statement is that the meaning of the term "scientific certainty" is not at all clear. As the focus is on the future consequences of the action, there would be no (or at least very few) cases with known outcomes. Hence scientific uncertainty must mean something else. Three natural candidates are:

i. knowing which type of consequences could occur,
ii. being able to predict the consequences with sufficient accuracy, and
iii. having accurate descriptions or estimates of the real risks, interpreting the real risk as the consequences of the action.

If we adopt one of these interpretations, the precautionary principle may be applied either when we do not know the type of consequences that may occur, or we have poor predictions of the consequences, risk descriptions or estimates. As an example, let us think of the issue about starting year-round petroleum activities in the Barents Sea. In December 2003 the Norwegian government considered whether year-round activities should be allowed for the areas of Lofoten and the Barents Sea, both ecologically vulnerable areas. Then following i) and using broad categories of consequences we cannot apply the precautionary principle, as we know the type of consequences of this activity. As a result of these operations, some people may be killed, some may get injured, or an oil spill may occur causing damage to the environment, *etc*. Different categories of this damage can be defined. Hence by grouping of categories and types of consequences, the possible lack of scientific certainty is "eliminated".

However, in this case, many biologists would say that there is some lack of knowledge as to what the consequences for the environment will be, given an oil spill. This lack of scientific certainty could be classified as fairly small, but that would be a value statement and people and parties could judge this differently. The point is that there is some scientific uncertainty about the consequences of an oil spill. But is this lack of scientific certainty of a different kind than uncertainty related to what will be the outcome of the oil spill? Consider the consequences of an oil spill on fish species, and let X denote the recovery time for the population of concern, with X being infinity if the population does not recover. Then there is scientific certainty according to criterion ii) if there is scientific consensus about a function (model) f such that X equals $f(Z_1, Z_2\ldots)$ with high confidence, where Z_1, $Z_2\ldots$ are some underlying factors influencing X. Such factors could relate to the possible occurrence of a blow-out, the amount and distribution of the oil spilled on the sea surface, the mechanisms of dispersion and degradation of oil components, and the exposure and effect on the fish species. For selected values of the Z_s, we can use f to predict the consequences X. The precautionary principle applies when it is difficult to establish such a

function f; the scientific discipline does not have sufficient knowledge for obtaining "scientific certainty" on how the high level performance, in this case measured by X, is influenced by the underlying factors. Models may exist, but they are not broadly accepted in the scientific community.

Scientific consensus in this sense does not mean that the consequences (X) can be predicted with accuracy, when not conditioned on the Zs. Unconditionally, the consequences (X) are uncertain, and this uncertainty is defined by the uncertainties of the factors Z.

To study the criterion iii), suppose that p represents the "real" risk, quantified by the probability distribution of X, and let p* be an estimate of p derived from a detailed risk analysis of the activity. Since the uncertainties in this estimate are considered large, relative to the real p, the precautionary principle may be applied following criterion iii). We see that using i), ii) or iii), we may obtain different conclusions.

44.2.2.1 Discussion

Among most economists and decision analysts, the theoretical framework for obtaining good decisions is the expected utility theory, based on the use of subjective probabilities. Attention should be on Eu(X), where u is the utility function and X is the outcome. In this framework there is no place for the application of the precautionary principle, as the expected utility is the appropriate guidance for the decision maker. Uncertainties and the weights put on these uncertainties are properly taken into account using this theory.

However, this is a theory, and it is difficult to prove in practice. People do not behave according to this theory. This is well known, and different alternative frameworks have been suggested. Many economists would refer to the cost-benefit analyses, as the adequate practical tool to guide the decision makers. By transforming all values to monetary values and calculating expected net present values, E[NPV]s, a consistent procedure is obtained for making decisions, which is believed to provide good decisions seen from a societal point of view.

Again, in this framework there is no place for the application of the precautionary principle, as the cost-benefit analysis is the appropriate tool for the decision maker. However, few people would conclude that the cost-benefit analyses and related tools provide clear answers. They have limitations and are based on a number of assumptions and presumptions, and their use is based not only on scientific knowledge, but also on value judgments involving ethical, strategic and political concerns. The analyses provide support for decision making, leaving the decision makers to apply decision processes outside the direct applications of the analyses. It is necessary to see beyond the expected values.

The important question then is how the uncertainties should be taken into account in the decision making process. The precautionary principle is a way of dealing with the uncertainties. The above discussion has demonstrated that the precautionary concept is difficult to understand and use, and depends on the perspective on risk applied.

To us the most meaningful definition of the precautionary principle relates to the lack of understanding of how the consequences of the activity are influenced by the underlying factors, *i.e.*, a version of criterion ii). If there is a lack of such knowledge, we may decide not to carry out the activity with references to the use of the precautionary principle. Any reference to being able to accurately measure probabilities should be avoided, as that leads to a meaningless discussion of accuracy in probability estimates. We have to acknowledge that it is not possible to establish science-based criteria for when the precautionary principle should apply. Judging when there is a lack of scientific certainty is a value judgment. In the face of uncertainty, analysts and scientists need to do a good job of expressing the uncertainties, enabling the decision maker to obtain an informative basis for his or her decision. Based on our experience, there is a large potential for improvement on risk and uncertainty descriptions and communications. Many analysts and scientists have severe problems in dealing with uncertainties, as do many statisticians. Being aware of the different perspectives on risk, and using these in the descriptions and communications, we see as a key element in improving the present situation.

Is there then a need for the concept precautionary principle? Could we not just refer to the possible consequences, the uncertainties and the probabilities, *i.e.* the risks? Well, we need a term for saying that we will not start an activity in the face of large uncertainties and risks, and we will not postpone the implementation of measures because of uncertainties. We may refer to this as a cautionary principle [34], but it would be too broad a definition for the precautionary principle. Unfortunately, this kind of broad interpretation of the precautionary principle is often seen in practice. We prefer to restrict the precautionary principle to situations where there is a lack of understanding of how the consequences (outcomes) of the activity are influenced by the underlying factors, and use the concept of caution as the broader principle saying that caution should be the ruling principle in the face of risk. Hence we adopt the cautionary principle when the criterion ii) is not met, *i.e.*, risk is present, and the precautionary principle in the special case described above.

This thinking seems to be consistent with the meaning and the use of this principle adopted by HSE [34] in the UK adheres to the following policy for using the precautionary principle.

Our policy is that the precautionary principle should be invoked where:

- there is good reason, based on empirical evidence or plausible causal hypothesis, to believe that serious harm might occur, even if the likelihood of harm is remote; and
- the scientific information gathered at this stage of consequences and likelihood reveals such uncertainty that it is impossible to evaluate the conjectured outcomes with sufficient confidence to move to the next stages of the risk assessment process.

An essential point here is that the precautionary principle is linked to outcomes and not risks.

44.2.2.2 An Example from the Offshore Oil and Gas Industry

A riser platform is installed with a bridge connection to a gas production platform. On the riser platform, there are two incoming gas pipelines and one outgoing gas pipeline. The pipelines are all large in diameter, 36 inches and above. The decision problem is whether or not to install a sub-sea isolation valve (SSIV) on the export pipeline.

We assume that the analyst has specified an annual frequency of $1x10^{-4}$ *per* year for ignited pipeline or riser failures, *i.e.*, the computed expected number of failures for a one year period is $1x10^{-4}$, which is the same as saying that there is a probability of $1x10^{-4}$ for a failure event to occur during one year. In the case of an accident, the SSIV will dramatically reduce the duration of the fire, and hence damages to equipment and exposure of personnel.

Let us assume that the computed expected number of fatalities without SSIV is 5, given pipeline/riser failure, and 0.5 with SSIV installed. Let us further assume that the expected damage cost without SSIV is 800 MNOK (million Norwegian Krones), given pipeline/riser failure, and 200 MNOK with SSIV installed. When there is no SSIV installed, the riser platform will have to be rebuilt completely, which is estimated to take two years, during which time there is no gas delivery at all. This corresponds to an expected loss of income of 40000 MNOK. With SSIV installed, the expected loss of income is 8000 MNOK.

The expected investment cost is taken as 75 MNOK, and the annual expected cost for inspection and maintenance is 2 MNOK. In the calculations of the expected net present value, 10% interest is used. All monetary values are calculated without taking inflation into account.

The total expected net present value of costs related to the valve is 93.9 MNOK, with annual maintenance costs over 30 years. The annual expected saving (*i.e.* reduced expected damage cost and reduced expected lost income) is 3.26 MNOK, and the expected net present value over 30 years is 30.7 MNOK. This implies that the expected net present value of the valve installation is a cost of 63.2 MNOK.

The expected number of averted fatalities *per* year is $4.5x10^{-4}$ fatalities. Summed over 30 years

(without depreciation of lives), this gives an expected value of averted fatalities equal to 0.0135.

Thus, the expected net present value of the costs *per* averted statistical life is 4675 MNOK, and a cursory evaluation of such a value would conclude that the cost is in gross disproportion to the benefit.

But let us examine the results more closely. It should be noted that if the frequency of ignited failure is 10 times higher, 10^{-3} *per* year, the expected net present value of the reduced costs becomes 307 MNOK (instead of 30.7 MNOK). This implies that the valve actually means an expected cost saving. In this case, the conclusion based on expected values, should clearly be to install the valve.

If we return to the base case values, the probability of experiencing a pipeline or riser failure near the platform is 0.3%, *i.e.*, the scenario is very unlikely. There is a 99.7% probability that there will never any need for the SSIV, and its installation is just a loss, without any possibility of covering any costs.

But with a small probability, 0.3 %, a highly positive scenario will occur. An ignited leak occurs, but the duration of the fire is limited to a few minutes, due to the valve cutting off the gas supply. There are still some consequences; the expected number of fatalities is 0.5, expected damage cost of 200 MNOK, and expected lost income of some months, equivalent to 8000 MNOK. These are quite serious consequences, but they would be so if an SSIV were not installed. The expected saving in this case are 4.5 fatalities, 600 MNOK damage cost, and 32000 MNOK in lost income. Note that we in the above calculations have disregarded the probability that the SSIV will not work when needed (the error introduced by this simplification is small as the assigned probability of a SSIV failure is small).

If we focus on the economy, there is a probability of 99.7% of a 63 MNOK loss (in expected net present value), and a probability of 0.3% of 32 600 MNOK reduced damage cost (in expected net present value) in a year with a pipeline/riser failure. The expected NPV, based on these conditions, becomes 63.1 MNOK. For the installation in question, the expected net present value of 63.1 MNOK is not very informative, either the scenario occurs, with an enormous cost saving (and reduced fatalities) or it does not occur, and there are only costs involved.

From the portfolio theory, and a corporate risk point of view, it is still a reasonable approach to use statistical expected values as a tool for evaluating the performance of this project. But as discussed above, we should not perform a mechanical decision making based on the expected value calculations. We need to take into account the above factors. The conclusion then becomes an overall strategic and political one, rather than one determined by the safety discipline.

44.2.3 Risk Acceptance and Decision Making

The safety regulation in industries nowadays is to large extent goal-oriented, *i.e.*, high level performance measures need to be specified and various type of analyses have to be conducted to identify the best possible arrangements and measures according to these performance measures. There has been a significant trend internationally in this direction for more than ten years. On the other hand, there are different approaches taken in order to implement this common objective, if worldwide regulatory regimes are considered.

Whereas the objective may seem simple as a principle, there are certainly some challenges to be faced in the implementation of the principle. One of the main challenges is related to the use of predetermined quantitative risk acceptance criteria, expressed as upper limits of acceptable risk.

Some examples of risk acceptance criteria used for an offshore installation, are as follows:

- The FAR value should be less than 10 for all personnel on the installation, where the FAR value is defined as the expected number of fatalities *per* 100 million exposed hours
- The individual probability that a person is killed in an accident during one year should not exceed 0.1%.

Note that in the following, when using the term "risk acceptance criteria", we always have in mind such upper limits. Now, should we use such

criteria before any analysis of the systems is conducted? The traditional textbook answer is yes. First comes the criteria, then the analysis to see if these criteria are met, and according to the assessment results, the need for risk reducing measures is determined. Such an approach is intuitively appealing, but a closer look reveals several problems, of which the following two are the most important:

1. The introduction of pre-determined criteria may give the wrong focus, meeting these criteria rather than obtaining overall good and cost-effective solutions and measures.
2. The risk analyses, the tools used to check whether the criteria are met, are not generally sufficiently accurate to permit such a mechanical use of criteria.

Item 1 is the main point. The adherence to a mechanistic use of risk acceptance criteria does not provide a good structure for management of risk to personnel, environment or assets. This is clearly demonstrated for environmental risk. Acceptability of operations with respect to environmental risk is typically decided on the results of a political process and following this process, risk acceptance is not an issue and risk acceptance criteria do not have an important role to play. Risk acceptance criteria have been required by Norwegian authorities for more than 10 years, but almost never have such criteria lead to improvement from an environmental point of view. The reader is referred to the discussion in [35].

The point here is that there are good reasons for looking at other regimes and discuss these against the one based on risk acceptance criteria. The ALARP principle as adopted in the UK represents such an alternative. This principle means that the risk should be reduced to a level which is as low as reasonably practicable. Identified improvements (risk reducing measures) should be implemented as a base case, unless it can be demonstrated that the benefits are grossly disproportionate to the costs and operational restrictions. This principle is normally applied together with a limit for intolerable risk and a limit for negligible risk. The interval between these two limits is often called the ALARP region.

In most cases, in practice risk is found to be in the ALARP region and the ALARP principle is adopted, and an ALARP assessment process is required. This will include a dedicated search for possible risk reducing measures and a subsequent assessment of these in order to determine which to be implemented.

In the UK, the ALARP principle applies in such a way that the higher a risk is, the more employers are expected to spend to reduce it. At high risks, close to the level of intolerability, they are expected to spend up to the point where further expenditure would be grossly disproportionate to the risk; *i.e.* that costs and/or operational disturbances are excessive in relation to the risk reduction. This is generally considered to be a reasonable approach as higher risks call for greater spending. More money should be spent to save a statistical life if the risk is just below the intolerability level than if the risk is far below this level.

The ALARP principle implies what could be referred to as the principle of "reversed onus of proof". This means that the base case is that all identified risk reduction measures should be implemented, unless it can be demonstrated that there is gross disproportion between costs and benefits. To verify ALARP, procedures mainly based on engineering judgments and codes are used, but also traditional cost-benefit analyses and cost effectiveness analyses. When using such analyses, guidance values as indicated above are often used, to specify what values define "gross disproportion". Such values may vary from substantially less than 1 million NOK, up to more than 100 million NOK.

A typical number for a value of statistical life used in cost-benefit analysis is 1–2 million £ [35, 36]. This number applies to the transport sector. For other areas the numbers are much higher, for example in the offshore UK industry it is common to use 6 million £ [36]. This increased number accounts of the potential for multiple fatalities and uncertainty.

The practice of using traditional cost-benefit analyses and cost effectiveness analyses to verify ALARP has been questioned [37]. The ALARP principle is an example of application of the cautionary principle. Uncertainty should be given

strong weight, and the grossly disproportionate criterion is a way of making the principle operational. However, cost-benefit analyses calculating expected net present values ignore the unsystematic risks (uncertainties) and the use of this approach to weight the unsystematic risk is therefore meaningless.

Modifications of the traditional cost-benefit analysis are suggested to solve this problem, see *e.g.,* [30]. In these methods, adjustments are made to either the discount rate or the contribution from cash flows. This latter case could be based on the use of certainty equivalents for uncertain cash flows. Although arguments are provided to support these methods, their rationale can be questioned. There is a significant element of arbitrariness associated with the methods, in particular when seen in relation to the standard given by the expected utility theory.

To explain this in more detail, say that the net present value relates to two years only, and the cash flows are X_0 and X_1. Then an approach based on certainty equivalents means an expected utility approach for the cash flows seen in isolation. The uncertain cash flows are replaced by their certainty equivalents c_0 and c_1, respectively, which means that the uncertain cash flow X_i is compared to having the money c_i with certainty, $i = 0,1$. The specification of such certainty equivalents is not straightforward, ref. the review of the expected utility theory in Section 44.2.1. However, the important point here is not this specification problem, but the fact that this procedure does not necessarily reflecting the decision maker's preferences. If we ignore the discounting for a second, the utility function of the cash flows X_0 and X_1 is not in general given by the sum of the individual utility functions. By introducing certainty equivalents on a yearly basis, we take uncertainties into account, but the way we do it has not been justified.

The alternative approach of adjusting the discount rate seems plausible as the systematic risk is incorporated in the net present value calculations through this procedure. But how large should the adjustment be? There is a rationale for the systematic risk adjustment, the CAPM model, but there is no such a rationale for the unsystematic risk. It will be impossible to find such a rationale, in fact, as the calculations are based on expected cash flows, which ignores the uncertainties. Hence we have to conclude that such an adjustment cannot be justified.

The common procedures for verifying the grossly disproportionate criterion using cost-benefit analysis therefore fail, even if we try to adjust the traditional approach. We should be careful in using an approach which is based on a conflicting perspective, ignoring unsystematic uncertainties.

So what alternative would we then suggest? In our view we have to acknowledge that there is no simple and mechanistic method or procedure for balancing different concerns. When it comes to the use of analyses and theories we have to adopt a pragmatic perspective. We have to acknowledge the limitations of the tools, and use them in a broader process where the results of the analyses are seen as just one part of the information supporting the decision making. Moreover, the results need to be subject to an extensive degree of sensitivity analyses.

44.2.3.1 Discussion

Above we have argued for the need to consider risk as a basis for making decisions under uncertainty. Such considerations however, must be seen in relation to other burdens and benefits. Care should be shown when using pre-determined risk acceptance criteria in order to obtain good arrangements, plans and measures. Pre-defined criteria driving the decisions should in general be replaced by a risk management approach highlighting risk characterization and evaluation, and a drive for risk reductions and a proper balance between burdens and benefits.

Risk analyses support decision making on choice of specific concepts, arrangements, measures, procedures, *etc*., as well as decision criteria. Such decision criteria may have the form of a requirement, for example, the system should have a probability of failure of maximum 1/1000 for a period of one year. Further detailing of this system in a later development phase, could involve risk/reliability/performance analyses to support decision making, and 1/1000 would be a boundary

condition for system performance. Some people may also refer to 1/1000 as a pre-determined risk acceptance criterion. This example illustrates the different levels of criteria that are used for supporting decision making, and the need to view the development of criteria and requirements in a time perspective. Above we have mainly focused on the high level criteria, used for the total system and not its many subsystems and components. For the latter it may be more appropriate to apply specific acceptance limits, to facilitate the design and development process, but even for such situations our main line of approach could be used. Generating alternatives and predicting their burdens and benefits, should always, in our view, be the ruling paradigm.

We see that there is a hierarchy of goals, criteria, and requirements. These can schematically be divided into four categories;

1. Overall ideal goals, for example "our goal is to have no accident".
2. Risk acceptance criteria (defined as upper limits of acceptable risk) or tolerability limits, managing the accident risk, for example, "the individual probability of being killed in an accident shall not exceed 0.1%".
3. Requirements related to the performance of safety systems and barriers, such as a reliability requirement for a safety system.
4. Requirements related to the specific design and operation of a component or subsystem, for example, the gas detection system.

Our main message can be summarized as follows:

- Focus should be on meeting defined overall objectives; which should be formulated using quantities that are observable (such as the number of fatalities, the number of injuries, the occurrence of a specific accidental event, *etc*.). Probabilistic quantities should not be used to express such objectives.
  - Safety management is a tool for obtaining confidence in meeting these objectives.
  - Emphasis should be placed on generating alternatives, to be compared with projected performance.
  - Risk acceptance criteria (level 2 above) should not be used.
- To ease the planning process for optimizing arrangements and measures, requirements related to safety systems and barriers may be useful (level 3 above).
- What is acceptable from a safety point of view and what constitutes a defensible safety level, cannot in principle be determined without incorporating all the pros and cons of the alternative, and the decision needs to be taken by personnel with formal responsibility at a sufficiently high level.

44.3 Recommendations

We recommend a risk assessment process following a structure as summarized in the following:

For a specified alternative, say A, we assess the consequences or effects of this alternative seen in relation to the defined attributes (safety, costs, reputation, *etc*.). Hence we first need to identify the relevant attributes (X_1, X_2, …), and then assess the consequences of the alternative for these attributes. These assessments could involve qualitative or quantitative analysis. Regardless of the level of quantification, the assessments need to consider both what the expected consequences are, as well as uncertainties related to the possible consequences. Often the uncertainties could be large. In line with the adopted perspective on risk, we recommend a structure for the assessment according to the following scheme:

1. Identify the relevant attributes (safety, costs, reputation, alignment with main concerns, *etc*.) .
2. What are the assigned expected consequences, *i.e.*, $E[X_i]$ given the available knowledge and assumptions?
3. Are there special features of the possible consequences? In addition to assessing the consequences on the quantities X_i, some

aspects of the possible consequences might need special attention. Examples are presented below based on the scheme developed in [38].

4. Are the large uncertainties related to the underlying phenomena, and do experts have different views on critical aspects? The aim is to identify factors that may lead to consequences Xi far from the expected consequences $E[X_i]$. A system for describing and characterizing the associated uncertainties is outlined below (based on [9]).
5. The level of manageability during project execution. To what extent is it possible to control and reduce the uncertainties, and obtain desired outcomes? The expected values and the probabilistic assessments performed in the risk analyses provide predictions for the future, but some risks are more manageable than others, meaning that the potential for reducing the risk is larger for some risks compared to others. By proper uncertainty and safety management, we seek to obtain desirable consequences. This leads to considerations on, for example, how to run processes reducing risks (uncertainties) and how to deal with human and organizational factors and obtain a good safety culture.

The structure in [38], which has been modified in [39], consists of eight consequence characteristics:

a) Potential consequences (outcomes), represented by representative performance measures (future observable quantities) such as costs, income, production volumes, deliveries, number of fatalities, *etc*.
b) Ubiquity, which describes the geographical dispersion of potential damage,
c) Persistency, which describes the temporal extension of the potential damage,
d) Delay effect, which describes the time of latency between the initial event and the actual impact of damage. The time of latency could be of physical, chemical or biological nature.
e) Reversibility, which describes the possibility to restore the situation to the state before damage occurred.
f) Violation of equity. which describes the discrepancy between those who enjoy the benefits and those who bear the risk.
g) Potential of mobilization. which is to be understood as violation of individual, social and cultural interests. and values generating social conflicts and psychological reactions by individuals and groups who feel inflicted by the risk consequences. The potential of mobilization could also result from perceived inequities in the distribution of risk and benefits.
h) The difficulty in establishing appropriate (representative) performance measures (observable quantities on a high system level).

For the uncertainties various types of uncertainty analyses can be used. The risk analysis is to be seen as an uncertainty analysis of future observable quantities and events. The analysis structures the analysts' knowledge on the risks and vulnerabilities; on what the consequences of a hazard could be. Normally a number of scenarios could possibly develop from a specific hazard. There are uncertainties present, and these uncertainties need to be assessed and described. To assess the uncertainties about the possible consequences we may adopt a classification system as follows, in addition to using probabilities to express the uncertainties related to what will be the outcomes of the various observables ([9]:

a) Insight into phenomena and systems, which describes the current knowledge and understanding about the underlying phenomena and the systems being studied.
b) Complexity of technology, which describes the level of complexity of the technology being used, reflecting, for example, that new technology will be utilized.
c) The ability to describe system performance based on its components.
d) The level of predictability, from changes in input to changes in output.

e) Experts' competence. which describes the level of competence of the experts' being used, seen in relation to for example the best available knowledge.
f) Experience data, which describes the quality of the data being used in the analysis.
g) Time frame, which describes the time frame of the project and how it influences the uncertainties.
h) Vulnerability of system, which describes the vulnerability of the system to, *e.g.*, weather conditions and human error. A more robust technical system is more likely to withstand strains and this can reduce the likelihood of negative consequences.
i) Flexibility, which describes the flexibility of the project and how this affects the uncertainty, *e.g.,* a high flexibility allows adjustments to the project plan as more information becomes available and this can reduce the potential for negative outcomes.
j) Level of detail, which describes the need for more detailed analysis to reduce the uncertainty about the potential consequences.

The uncertainty aspects a)–j) can be assessed qualitatively, and discussed, or assessed by some type of categorizations and scoring system, describing the analysts' and the experts' knowledge and judgments.

These assessments provide a basis for comparing alternatives and making a decision.

Compared to standard ways of presenting risk results, this basis is much more comprehensive. In addition, sensitivity analyses are to be performed. Of course, the depth of the analysis will be a function of the decision situation, the risks involved and the resources to be used. The full risk descriptions as outlined above would be used only in special situations, requiring a comprehensive decision support basis.

Various kinds of risk matrices can be informative. The traditional risk matrix showing combinations of possible consequences (with some defined categories) and associated probabilities is applicable in many cases.

The starting point for risk characterizations would normally be the expected value, as the expected value would give accurate predictions when considering a large population of activities. We take a portfolio perspective. We must, however, distinguish between different attributes (lives, economic quantities, *etc*.); it is not straightforward to transform all attributes to one common scale.

Let C_i be the consequence (outcome) of an activity for a given period of time, for example next year, for a specific attribute i. We may as an example let C_i denote the outage time. In the analysis we relate Ci to relevant initiating events (sources), and we may then write

$$C_i = \Sigma_j C_i \, I(A_j),$$

where, A_j denotes the source j and $I(A_j)$ is the indicator function which equals 1 if the event A_j occurs and 0 otherwise. We see that $C_i \, I(A_j)$ expresses the outage time as a result of the source j.

Hence by probability calculus, it follows that the total expected number of fatalities equals [40]

$$EC_i = \Sigma_j E[C_i \, I(A_j)] = \Sigma_j E[C_i \,|A_j] \, P(A_j),$$

i.e., the expected outage time equals the probability of event j multiplied by the expected outage time given this event, summed over all events j.

This gives a starting point for evaluating the risks. We determine $P(A_j)$ and $E[C_i \,|A_j]$ and multiply these together. We may do this by using crude categories of probability and expected values, for example consequence categories as presented in Step 1.

The consequence categories can also be based on features such as ubiquity and persistence, see list above.

This analysis is carried out for all relevant attributes, and a summarizing index can be defined based on the scores assigned for each attribute. One possible way of doing this is simply to sum the various contributions (or take an average), assuming that corresponding categories have been defined for all relevant attributes.

The derived expected values constitute a basis for the risk evaluation. However, we need to see beyond the expected values. The reason is that the actual outcomes could deviate strongly from the

expected values. The analyses are based on judgments, made by some experts, a number of assumptions and suppositions are made, and there could be large uncertainties associated with the phenomena being studied. The fact that such deviations may occur, should also be taken into account. A way of doing this is to use the approach presented in [41].

The basis is the expected value of the form EC, and we develop a matrix with components EC and U, where U are factors that could give significant deviations between the expected value and the outcomes. Such factors include the following (see. Steps 4 and 5 above)

- Vulnerabilities
- Complexity in technology
- Complexity in organizations
- Available information
- Time horizon
- Level of manageability. To what extent is it possible to control and reduce the uncertainties, and obtain desired outcomes? Some risks are more manageable than others, meaning that the potential for reducing the risk is larger for some risks compared to others. By proper uncertainty management, we seek to obtain desirable consequences.
- The thoroughness, *etc*., of the analysis. What are the experts' competences, seen in relation to the best available knowledge? Do we have available relevant experience data? To what extent would further analysis reduce the uncertainties about the potential consequences?

For each factor we give a score and based on this an index could be established.

An alternative approach for summarizing the risk picture is to use a classification scheme in line with the one used by [39] (see also [14]), and based on the system developed in [38]. The scheme is based on seven categories to represent the various combinations of the characteristics included in the scheme. The categories are based on the two main characteristics of risk; possible consequences and uncertainty about the consequences. The seven categories show a tendency of increased risk, as well as increased level of authority involvement, stakeholders' implications and treatment of societal values. The arrow in Table 44.1 is to be read as a tendency, not as a strict increasing value.

Table 44.1. Risk context classification scheme

	Category		Level of risk
	Potential consequences	**Uncertainty of consequences**	
1	Small	S/M/L	Low
2	Moderate	Small	
3	Moderate	Moderate	
4	Moderate	Large	⇓
5	Large	Small	
6	Large	Moderate	
7	Large	Large	High

Following our definition of risk, a low degree of uncertainty does not necessarily mean a low risk, and a high degree of uncertainty does not necessarily mean a high level of risk. This is important. As risk is defined as the combination of possible consequences and the associated uncertainties (quantified by probabilities), any judgment about the level of risk, needs to consider both dimensions. For example, consider a case where only two outcomes are possible, 0 and 1, corresponding to 0 and 1 fatality, and the decision alternatives are A and B, having uncertainty (probability) distributions (0.5,0.5), and (0.0, 1.0), respectively. Hence for alternative A there is a higher degree of uncertainty than for alternative B. However, considering both dimensions, we would, of course, judge alternative B to have the highest risk as the negative outcome 1 is certain to occur.

The intention of the classification scheme is to make a basis for characterization, discussion and management of risk. By this we mean that the scheme should be considered as a starting point or a basis for further handling of risk, and not as a "tool" that provide decisions of its own.

44.3.1 Research Challenges

We see the need for research in many areas, in particular related to the development of theories and methodologies for

a) structuring risk decision problems and processes,
b) analyzing vulnerabilities and risks, and
c) managing risks and making decisions under uncertainty.

Different types of classification systems for characterizing decision situations and risks are presented in the literature, see *e.g.*, [9], [38],[39] [41] and [42]. Such classification systems are designed for structuring decision problems and guide decision makers on how to deal with the problems, reflecting different stakeholder perspectives, risk assessments results, *etc*. Classification as such is not the aim, but classification can be a point of departure for clarification of relationships and behavioral patterns, *etc*. We have applied aspects of these classification systems in our framework, but further research is needed to determine the most suitable schemes.

We believe that the Bayesian approach using subjective probabilities to express uncertainties provides a sound basis for risk analyses. With limited and partially relevant data, Bayesian inference is needed. However, Bayesian analysis is not straightforward for complex problems, see, *e.g.*, [14], and further research is required. Underlying this issue is the possible use of the "rational consensus" perspective [43] on uncertainties in risk management. Is it possible to obtain a "neutral" view of uncertainties that is acceptable for all stakeholders and thereby confine stakeholder discourse to questions to preference only? To what extent is it possible to balance such a "neutral" view and the pure subjectivist position, that probability is a subjective, personal construction?

Another issue is the need for development of appropriate problem decomposition methods for risk and vulnerability identification and analysis (including extending the logic modeling techniques such as fault trees and event trees to include influence diagrams), essential for capturing different dimensions of complex risk issues. The work must be seen in relation to existing approaches such as the I-Risk [44], ARAMIS [45], the BORA projects [31], the SAM approach [47], and the HCL method [48], which develop methodology for operational risk analysis including analysis of the performance of safety barriers, with respect to technical systems as well as human [45], operational, and organizational factors.

To support the development of suitable theories and methods, there is a need for further research exploring the inter-relationships between economic theory, decision analysis, and safety science:

- How and to what extent factors other than the economic performance measures are and should be given weight, and how these factors can be measured and/or handled. Special focus should be on factors not directly related to a firms' core activity such as social responsibility and potential loss of goodwill.
- To what extent risk reducing measures are external effects for agents (firms and organizations), in the sense that they are beneficial for society but not necessarily for the agent in question.
- How these issues are influenced by public regulations and actions.

Some of the areas that need to be addressed relate to portfolio theory and safety management, the use of the cautionary and precautionary principles, the interactions between government and firms, and incentives in decision processes.

In such a context one also needs to be aware of the link between productivity growth and risk. Good risk management is generally claimed to be productivity enhancing, while the opposite is true of poorly designed schemes. If this is so, why is not risk management a higher priority both in theory and practice?

Risk Governance: An Application of Analytic-deliberative Policy Making

Ortwin Renn

University of Stuttgart and Dialogik gGmbH
Seidenstr. 36, 70174 Stuttgart
Germany

Abstract: This chapter introduces an integrated analytic framework for risk governance which provides guidance for the development of comprehensive assessment and management strategies to cope with risks, in particular at the global level. The framework integrates scientific, economic, social and cultural aspects and includes the effective engagement of stakeholders. The concept of risk governance comprises a broad picture of risk: not only does it include what has been termed "risk management" or "risk analysis", it also looks at how risk-related decision-making unfolds when a range of actors is involved, requiring co-ordination and possibly reconciliation between a profusion of roles, perspectives, goals, and activities.

45.1 Introduction

The framework's risk process breaks down into three main phases: "pre-assessment", "appraisal", and "management." A further phase, comprising the "characterization" and "evaluation" of risk, is placed between the appraisal and management phases and, depending on whether those charged with the assessment or those responsible for management are better equipped to perform the associated tasks, can be assigned to either of them—thus concluding the appraisal phase or marking the start of the management phase. The risk process has "communication" as a companion to all phases of addressing and handling risk and is itself of a cyclical nature. However, the clear sequence of phases and steps offered by this process is primarily a logical and functional one and will not always correspond to reality. The chapter will address in particular the role of public participation and stakeholder involvement.

45.2 Main Features of the IRGC Framework

The framework offers a conceptual framework to guide decisions about risks that we shall accept or refuse. This framework has been developed under the direction of the International Risk Governance Council (IRGC) and published as IRGC White Paper [1]. The concept of risk governance comprises a broad picture of risk: not only does it include what has been termed "risk management" or "risk analysis", it also looks at how risk-related decision-making unfolds when a range of actors is

involved, requiring co-ordination and possibly reconciliation between a profusion of roles, perspectives, goals and activities. Indeed, the problem-solving capacities of individual actors, be they government, the scientific community, business players, NGOs, or civil society as a whole, are limited and often unequal to the major challenges facing society today. Risks such as those related to increasingly violent natural disasters, food safety, or critical infrastructures call for co-ordinated effort amongst a variety of players beyond the frontiers of countries, sectors, hierarchical levels, disciplines and risk fields. Finally, risk governance also illuminates a risk's context by taking account of such factors as the historical and legal background, guiding principles, value systems, and perceptions as well as organizational imperatives.

The framework offers two major innovations to the risk field: the inclusion of societal context and a new categorization of risk-related knowledge.

- *Inclusion of societal context:* Besides the generic elements of risk assessment, risk management and risk communication, the framework gives equal importance to contextual aspects which are either directly integrated in a model risk process consisting of the above as well as additional elements or else form the basic conditions for making any risk-related decision. Contextual aspects of the first category include the structure and interplay of the different actors dealing with risks, how these actors may differently perceive those risks, and what concerns they have regarding their likely consequences. Examples of the second category include policy-making or regulatory style, as well as the socio-political impacts prevalent within the entities and institutions having a role in the risk process, their organizational imperatives, and the capacity needed for effective risk governance. Linking context with risk governance, the framework reflects the important role of risk-benefit evaluation and the need for resolving risk-risk tradeoffs.
- *Categorization of risk-related knowledge:* The framework also proposes a categorization of risk which is based on the different states of knowledge about each particular risk, distinguishing between "simple", "complex", "uncertain" and "ambiguous" risk problems. The characterization of a particular risk depends on the degree of difficulty of establishing the cause-effect relationship between a risk agent and its potential consequences, the reliability of this relationship, and the degree of controversy with regard to both what a risk actually means for those affected and the values to be applied when judging whether or not something needs to be done about it. Examples of each risk category include, respectively, known health risks such as those related to smoking, the failure risk of interconnected technical systems such as the electricity transmission grid, atrocities such as those resulting from the changed nature and scale of international terrorism, and the long-term effects and ethical acceptability of controversial technologies such as nanotechnologies. For each category, a strategy is then derived for risk assessment, and risk management, as well as the level and form of stakeholder participation, supported by proposals for appropriate methods and tools.

Beyond these component parts the framework includes three major value-based premises and assumptions:

- First, the framework is inspired by the conviction that both the "factual" and the "socio-cultural" dimensions of risk need to be considered if risk governance is to produce adequate decisions and results. While the factual dimension comprises physically measurable outcomes and discusses risk in terms of a combination of potential, both positive and negative, consequences and the probability of their occurrence, the socio-cultural dimension

emphasises how a particular risk is viewed when values and emotions come into play.

- The second major premise concerns the inclusiveness of the governance process, which is seen as a necessary, although not sufficient, prerequisite for tackling risks in both a sustainable and acceptable manner and consequently imposes an obligation to ensure the early and meaningful involvement of all stakeholders and, in particular, civil society.
- A third major premise involving values is reflected in the framework's implementation of the principles of "good" governance: beyond the crucial commitment to participation, these principles include transparency, effectiveness and efficiency, accountability, strategic focus, sustainability, equity and fairness, respect for the rule of law, and the need for the chosen solution to be politically and legally realizable as well as ethically and publicly acceptable.

45.3 The Core of the Framework: Risk Governance Phases

The framework's risk process, or risk handling chain is illustrated in Figure 45.1. It breaks down into three main phases: "pre-assessment", "appraisal", and "management". A further phase, comprising the "characterization" and "evaluation" of risk, is placed between the appraisal and management phases and, depending on whether those charged with the assessment or those responsible for management are better equipped to perform the associated tasks, can be assigned to either of them—thus concluding the appraisal phase or marking the start of the management

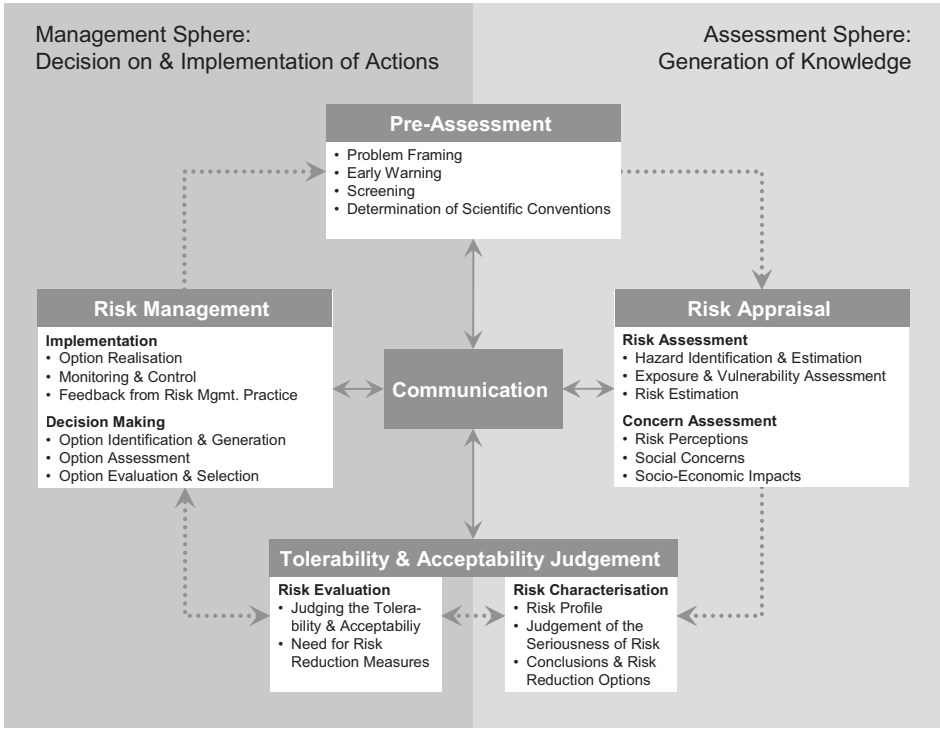

Figure 45.1. IRGC risk governance framework

phase. The risk process has "communication" as a companion to all phases of addressing and handling risk and is itself of a cyclical nature. However, the clear sequence of phases and steps offered by this process is primarily a logical and functional one and will not always correspond to reality.

The purpose of the *pre-assessment* phase is to capture both the variety of issues that stakeholders and society may associate with a certain risk and also existing indicators, routines, and conventions that may prematurely narrow down, or act as a filter for, what is going to be addressed as risk. What counts as a risk may be different for different groups of actors. The first step of pre-assessment, risk framing, therefore places particular importance on the need for all interested parties to share a common understanding of the risk issue(s) being addressed or, otherwise, to raise awareness amongst those parties of the differences in what is perceived as a risk. For a common understanding to be achieved, actors need both to agree with the underlying goal of the activity or event generating the risk and to be willing to accept the risk's foreseeable implications on that very goal. A second step of the pre-assessment phase, early warning and monitoring, establishes whether signals of the risk exist that would indicate its realization. This step also investigates the institutional means in place for monitoring the environment for such early warning signals.

The third step, pre-screening, takes up and looks into the widespread practice of conducting preliminary probes into hazards or risks and, based on prioritization schemes and existing models for dealing with risk, of assigning a risk to pre-defined assessment and management "routes", The fourth and final step of pre-assessment selects major assumptions, conventions and procedural rules for assessing the risk as well as the emotions associated with it.

The objective of the *risk appraisal* phase is to provide a knowledge base for the societal decision on whether or not a risk should be taken and, if so, how the risk can possibly be reduced or contained. Risk appraisal thus comprises a scientific assessment of both the risk and of questions that stakeholders may have concerning its social and economic implications.

The first component of risk appraisal, risk assessment, seeks to link a potential source of harm, a hazard, with likely consequences, specifying probabilities of occurrence for the latter. Depending on the source of a risk and the organizational culture of the community dealing with it, many different ways exist for structuring risk assessment. Despite such diversity, three core steps can be identified. These are: the identification and, if possible, estimation of the hazard; an assessment of related exposure and/or vulnerability; and an estimation of the consequent risk. The latter step, risk estimation, aggregates the results of the first two steps and states, for each conceivable degree of severity of the consequence(s), a probability of occurrence. Confirming the results of risk assessments can be extremely difficult, in particular when cause-effect relationships are hard to establish, when they are instable due to variations in both causes and effects and when effects are both scarce and difficult to understand.

Depending on the achievable state and quality of knowledge, risk assessment is thus confronted with three major challenges that can best be summarized using the risk categories outlined above—"complexity", "uncertainty", and "ambiguity". For a successful outcome to the risk process and, indeed, to overall risk governance, it is crucial that the implications of these challenges are made transparent at the conclusion of risk assessment and throughout all subsequent phases. Equally important to understanding the physical attributes of the risk is detailed knowledge of stakeholders' concerns and questions—emotions, hopes, fears, apprehensions—about the risk as well as likely social consequences, economic implications, and political responses. The second component of risk appraisal, concern assessment, thus complements the results from risk assessment with insights from risk perception studies and interdisciplinary analyses of the risk's (secondary) social and economic implications.

The most controversial phase of handling risk, *risk characterization and evaluation,* aims at judging a risk's acceptability and/or tolerability. A risk deemed "acceptable" is usually limited in terms of negative consequences so that it is taken

on without risk reduction or mitigation measures being envisaged. A risk deemed "tolerable" links undertaking an activity which is considered worthwhile for the value-added or benefit it provides with specific measures to diminish and limit the likely adverse consequences. This judgment is informed by two distinct but closely related efforts to gather and compile the necessary knowledge which, in the case of tolerability, must additionally support an initial understanding of required risk reduction and mitigation measures. While risk characterization compiles scientific evidence based on the results of the risk appraisal phase, risk evaluation assesses broader value-based issues that also influence the judgment. Such issues, which include questions such as the choice of technology, societal needs requiring a given risk agent to be present, and the potential for substitution as well as for compensation, reach beyond the risk itself and into the realm of policy-making and societal balancing of risks and benefits.

The *risk management* phase designs and implements the actions and remedies required to tackle risks with an aim to avoid, reduce, transfer, or retain them. Risk management thereby relies on a sequence of six steps which facilitates systematic decision-making. To start with, and based on a reconsideration of the knowledge gained in the risk appraisal phase and while judging the acceptability and/or tolerability of a given risk, a range of potential risk management options is identified. The options are then assessed with regard to such criteria as effectiveness, efficiency, minimization of external side effects, sustainability, *etc*. These assessment results are next complemented by a value judgment on the relative weight of each of the assessment criteria, allowing an evaluation of the risk management options. This evaluation supports the next step in which one (or more) of the of risk management options is selected, normally after consideration of possible trade-offs that need to be made between a number of second-best options. The final two steps include the implementation of the selected options and the periodic monitoring and review of their performance.

Based on the dominant characteristic of each of the four risk categories ("simple", "complex", "uncertain", "ambiguous") it is possible to identify specific safety principles and, consequently, design a targeted risk management strategy (*see* Table 45.1). "Simple" risk problems can be managed using a "routine-based" strategy which draws on traditional decision-making instruments and best practice, as well as time-tested trial-and-error. For "complex" and "uncertain" risk problems, it is helpful to distinguish the strategies required to deal with a risk agent from those directed at the risk-absorbing system: complex risks are thus usefully addressed on the basis of "risk-informed" and "robustness-focused" strategies, while uncertain risks are better managed using "precaution-based" and "resilience-focused" strategies. Whereas the former strategies aim at accessing and acting on the best available scientific expertise and at reducing a system's vulnerability to known hazards and threats by improving its buffer capacity, the latter strategies pursue the goal of applying a precautionary approach in order to ensure the reversibility of critical decisions and of increasing a system's coping capacity to the point where it can withstand surprises. Finally, for "ambiguous" risk problems the appropriate strategy consists of a "discourse-based" strategy which seeks to create tolerance and mutual understanding of conflicting views and values with a view to eventually reconciling them.

The remaining element of the risk process is *risk communication*, which is of major importance throughout the entire risk handling chain. Not only should risk communication enable stakeholders and civil society to understand the rationale of the results and decisions from the risk appraisal and risk management phases when they are not formally part of the process, but it should also help them to make informed choices about risk, balancing factual knowledge about risk with personal interests, concerns, beliefs, and resources, when they are themselves involved in risk-related decision-making. Effective risk communication consequently fosters tolerance for conflicting viewpoints and provides the basis for their means for assessing and managing risk and related concerns. Eventually, risk communication can have a major impact on how well society is

Table 45.1. Risk characteristics and their implications for risk management

Knowledge Characterization	Management Strategy	Appropriate Instruments	Stakeholder Participation
1 "Simple" risk problems	*Routine-based:* (tolerability/ acceptability judgment)	→ Applying "traditional" decision-making – Risk-benefit analysis – Risk-risk trade-offs	Instrumental discourse
	(risk reduction)	– Trial and error – Technical standards – Economic incentives – Education, labeling, information – Voluntary agreements	
2 Complexity-induced risk problems	*Risk-informed:* (risk agent and causal chain)	→ Characterizing the available evidence – Expert consensus seeking tools: - Delphi or consensus conferencing - Meta analyses - Scenario construction, *etc*. – Results fed into routine operation	Epistemological discourse
	Robustness-focused: (risk absorbing system)	→ Improving buffer capacity of risk target through: – Additional safety factors – Redundancy and diversity in designing safety devices – Improving coping capacity – Establishing high reliability organisations	
3 Uncertainty-induced risk problems	*Precaution-based:* (risk agent)	→ Using hazard characteristics such as persistence, ubiquity, *etc*., as proxies for risk estimates Tools include: – Containment – ALARA (as low as reasonably achievable) and ALARP (as low as reasonably possible) – BACT (best available control technology), *etc*.	Reflective discourse
	Resilience-focused: (risk absorbing system)	→ Improving capability to cope with surprises 1. Diversity of means to accomplish desired benefits 2. Avoiding high vulnerability 3. Allowing for flexible responses 4. Preparedness for adaptation	

prepared to cope with risk and to react to crises and disasters. Risk communication has to perform these functions both for the experts involved in the overall risk process—requiring the exchange of information between risk assessors and managers, between scientists and policy makers, between academic disciplines, and across institutional barriers—and for the "outside world" of those affected by the process.

45.4 Stakeholder Involvement and Participation

The classification of risk knowledge into four risk classes, *i.e.*, simple, complex, uncertain, and ambiguous, suggests some generic suggestions for participation:

- *Simple risk problems:* For making judgments about simple risk problems, a sophisticated approach to involve all potentially affected parties is not necessary. Most actors would not even seek to participate, since the expected results are more or less obvious. In terms of cooperative strategies, an "*instrumental discourse"* among agency staff and directly affected groups (such as product or activity providers and immediately exposed individuals), along with enforcement personnel is advisable. One should be aware, however, that often risks that appear simple turn out to be more complex, uncertain or ambiguous than originally assessed. It is therefore essential to revisit these risks regularly and monitor the outcomes carefully.
- *Complex risk problems:* The proper handling of complexity in risk appraisal and risk management requires transparency over the subjective judgments and the inclusion of knowledge elements that have shaped the parameters on both sides of the cost-benefit equation. Resolving complexity necessitates a discursive procedure during the appraisal phase, with a direct link to the tolerability and acceptability judgment and risk management. Input for handling complexity could be provided by an "*epistemological discourse"* aimed at finding the best estimates for characterising the risks under consideration. This discourse should be inspired by different science camps and on the participation of experts and knowledge carriers. They may come from academia, government, industry, or civil society, but their legitimacy to participate is their claim to bring new or additional knowledge to the negotiating table. The goal is to resolve cognitive conflicts. Exercises such as Delphi, Group Delphi, and consensus workshops would be most advisable to serve the goals of an epistemological discourse.
- *Risk problems due to high unresolved uncertainty:* Characterising risks, evaluating risks, and designing options for risk reduction pose special challenges in situations of high uncertainty about the risk estimates. How can one judge the severity of a situation when the potential damage and its probability are unknown or highly uncertain? In this dilemma, risk managers are well advised to include the main stakeholders in the evaluation process and ask them to find a consensus on the extra margin of safety in which they would be willing to invest in exchange for avoiding potentially catastrophic consequences. This type of deliberation, called *reflective discourse* relies on a collective reflection about balancing the possibilities for over- and under-protection. If too much protection is sought, innovations may be prevented or stalled; if we go for too little protection, society may experience unpleasant surprises. The classic question of "how safe is safe enough" is replaced by the question of "how much uncertainty and ignorance are the main actors willing to accept in exchange for some given benefit". It is recommended that policy-makers, representatives of major stakeholder groups, and scientists take part in this type of discourse. The reflective discourse can take different forms: round tables, open space forums, negotiated rule-making exercises, mediation, or mixed advisory committees including scientists and stakeholders.
- *Risk problems due to high ambiguity:* If major ambiguities are associated with a risk problem, it is not enough to

demonstrate that risk regulators are open to public concerns and address the issues that many people wish them to address. In these cases the process of risk evaluation needs to be open to public input and new forms of deliberation. This starts with revisiting the question of proper framing. Is the issue really a risk problem or is it in fact an issue of lifestyle and future vision? The aim is to find consensus on the dimensions of ambiguity that need to be addressed in comparing risks and benefits and on balancing the pros and cons. High ambiguities require the most inclusive strategy for participation, since not only directly affected groups but also those indirectly affected have something to contribute to this debate. Resolving ambiguities in risk debates requires a "participative discourse", a platform where competing arguments, beliefs, and values are openly discussed.

The opportunity for resolving these conflicting expectations lies in the process of identifying common values, defining options that allow people to live their own vision of a "good life" without compromising the vision of others, finding equitable and just distribution rules when it comes to common resources, and activating institutional means for reaching common welfare so all can reap the collective benefits instead of a few (coping with the classic commoners' dilemma). Available sets of deliberative processes include citizen panels, citizen juries, consensus conferences, ombudspersons, citizen advisory commissions, and similar participatory instruments.

Categorizing risks according to the quality and nature of available information on risk may, of course, be contested among the stakeholders. Who decides whether a risk issue can be categorized as simple, complex, uncertain or ambiguous? It seems prudent to have a screening board perform this challenging task. This board should consist of members of the risk and concern assessment team, of risk managers and key stakeholders (such as industry, NGOs, and representatives of related regulatory or governmental agencies). The type of discourse required for this task is called design discourse. It is aimed at selecting the appropriate risk and concern assessment policy, defining priorities in handling risks, organising the appropriate involvement procedures, and specifying the conditions under which the further steps of the risk handling process will be conducted.

Figure 45.2 provides an overview of the different requirements for participation and stakeholder involvement for the four classes of risk problems and the design discourse. As is the case with all classifications, this scheme shows an extremely simplified picture of the involvement process. In addition to the generic distinctions shown in the graph below, it may for instance be wise to distinguish between participatory processes based on risk agent or risk absorbing issues. To conclude these caveats, the purpose of this scheme is to provide general orientation and explain a generic distinction between ideal cases rather than to offer a strict recipe for participation.

45.5 Wider Governance Issues: Organizational Capacity and Regulatory Styles

The white paper also addresses wider governance issues pertinent to the context of a risk and the overall risk process, thus acknowledging the many different pathways that different countries—or, indeed, risk communities—may pursue for dealing with risk. The discussion of these wider issues begins with an assessment of the very notion of "risk governance" which builds on the observation that collective decisions about risks are the outcome of a "mosaic" of interactions between governmental or administrative actors, science communities, corporate actors, and actors from civil society at large, many of the interactions taking place in and relevant to only individual parts of the overall process. The interplay of these actors has various dimensions, including public participation, stakeholder involvement, and the formal (horizontal and vertical) structures within which it occurs. The white paper additionally investigates organizational prerequisites for

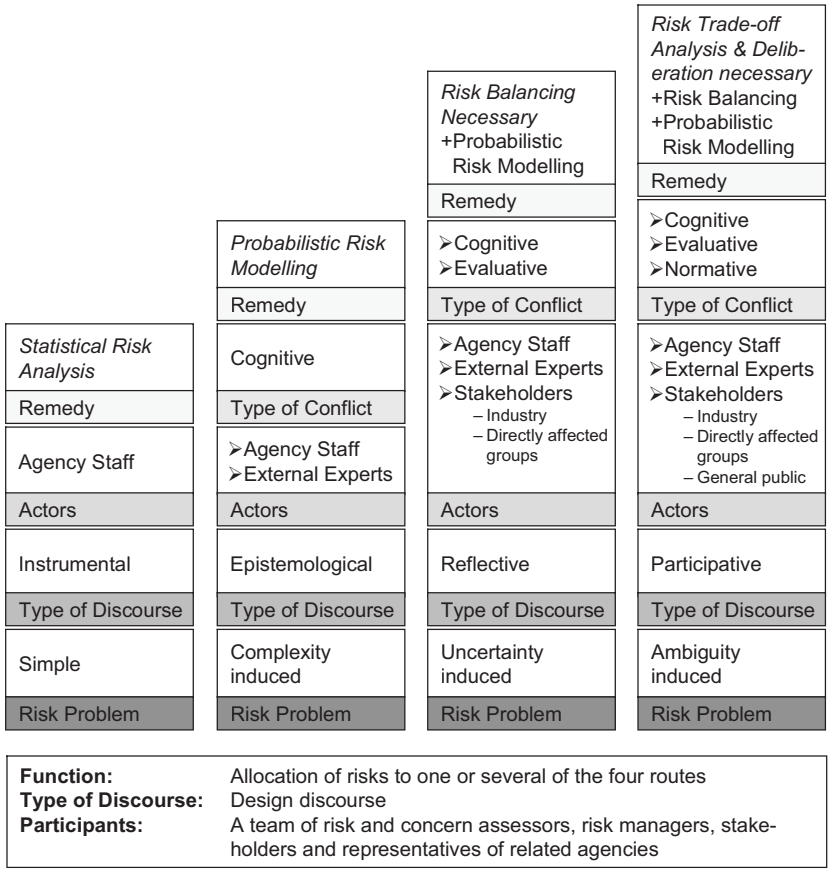

Figure 45.2. The risk management escalator and stakeholder involvement (from simple *via* complex uncertain to ambiguous phenomena)

effective risk governance, which are at the crossroads of the formal responsibilities of actors and their capability and authority to successfully fulfill their roles, and makes a very short case for risk education. The organizational prerequisites are summarized under the term "institutional and organizational capacity" and include both intellectual and material "assets", "skills", and also the framework of relations, or "capabilities", required to make use of the former two.

Risk management depends, however, not only on scientific input. It rather rests on three components: *systematic knowledge, legally prescribed procedures, and social values.* Even if the same knowledge is processed by different risk management authorities, the prescriptions for managing risk may differ in many aspects (*e.g.*, with regard to inclusion and selection rules, interpretative frames, action plans for dealing with evidence, and others). National culture, political traditions, and social norms furthermore influence the mechanisms and institutions for integrating knowledge and expertise in the policy arenas. Policy analysts have developed a classification of governmental styles that address these aspects and mechanisms. While these styles have been labeled inconsistently in the literature, they refer to common procedures in different settings. They are summarized in Table 45.2.

Table 45.2. Characteristics of policy making styles

Style	Characteristics	Risk Management
1 *Adversarial approach*	• open to professional and public scrutiny • need for scientific justification of policy selection • precise procedural rules • oriented towards producing informed decisions by plural actors	• main emphasis on mutual agreements on scientific evidence and pragmatic knowledge • integration of adversarial positions through formal rules (due process) • little emphasis on personal judgment and reflection on the side of the risk managers • stakeholder involvement essential for reaching communication objectives
2 *Fiduciary approach (patronage)*	• closed circle of ”patrons” • no public control, but public input • hardly any procedural rules • oriented towards producing faith in the system	• main emphasis on enlightenment and background knowledge through experts • strong reliance on institutional in-house “expertise” • emphasis on demonstrating trustworthiness • communication focused on institutional performance and “good record”
3 *Consensual approach*	• open to members of the “club” • negotiations behind closed doors • flexible procedural rules • oriented towards producing solidarity with the club	• reputation most important attribute • strong reliance on key social actors (also non-scientific experts) • emphasis on demonstrating social consensus • communication focused on support by key actors
4 *Corporatist approach*	• open to interest groups and experts • limited public control, but high visibility • strict procedural rules outside of negotiating table • oriented towards sustaining trust to the decision making body	• main emphasis on expert judgment and demonstrating political prudence • strong reliance on impartiality of risk information and evaluation • integration by bargaining within scientifically determined limits • communication focused on fair representation of major societal interests

- The *adversarial approach* is characterized by an open forum in which different actors compete for social and political influence in the respective policy arena. The actors in such an arena use and need scientific evidence to support their position. Policy-makers pay specific attention to formal proofs of evidence because their decisions can be challenged by social groups on the basis of insufficient use or negligence of scientific knowledge. Risk management and communication is essential for risk regulation in an adversarial setting because stakeholders demand to be informed and consulted. Within this socio-political context, stakeholder involvement is mandatory.

- In the *fiduciary approach*, the decision-making process is confined to a group of patrons who are obliged to make the "common good" the guiding principle of their actions. Public scrutiny and involvement of the affected public are alien to this approach. The public can provide input to and arguments for the patrons but is not allowed to be part of the negotiation or policy formulation process. The system relies on producing faith in the competence and the fairness of the patrons involved in the decision making process. Advisors are selected according to national prestige or personal affiliations. In this political context, stakeholder involvement may even be regarded as a sign of weakness or a diffusion of personal accountability.
- The *consensual approach* is based on a closed circle of influential actors who negotiate behind closed doors. Social groups and scientists work together to reach a predefined goal. Controversy is not present and conflicts are reconciled on a one-to-one basis before formal negotiations take place. Risk communication in this context serves two major goals: it is supposed to reassure the public that the "club" acts in the best interest of the public good and to convey the feeling that the relevant voices have been heard and adequately considered. Stakeholder participation is only required to the extent that the club needs further insights from the affected groups or that the composition of the club is challenged.
- The *corporatist approach* is similar to the consensual approach but is far more formalized. Well-known experts are invited to join a group of carefully selected policy-makers representing the major forces in society (such as employers, unions, churches, professional associations, and environmentalists). Similar to the consensual approach, risk communication is mainly addressed to the outsiders: they should gain the impression that the club is open to all "reasonable" public demands and that it tries to find a fair compromise between public protection and innovation. Often the groups represented within the club are asked to organize their own risk management and communication programs as a means of enhancing the credibility of the whole management process.

Although these four styles cannot be found in pure form in any country they form the backdrop of socio-political context variables against which specific risk governance structures are formed and operated. These structures, along with the individual actors' goals and the institutional perspectives they represent, would need more specific attention and, for the time being, are difficult to classify further.

45.6 Conclusions

The IRGC risk governance framework described in this chapter has been designed, on one hand, to include enough flexibility to allow its users to do justice to the wide diversity of risk governance structures and, on the other hand, to provide sufficient clarity, consistency, and unambiguous orientation across a range of different risk issues and countries.

The framework includes a comprehensive risk handling chain, breaking down its various components into three main phases: "pre-assessment", "appraisal", and "management". The two intermediate and closely linked stages of risk characterization and evaluation have been placed between the appraisal and management phases and can be assigned to either of them, depending on the circumstances: if the interpretation of evidence is the guiding principle for characterising risks, then risk and concern assessors are probably the most appropriate people to handle this task; if the interpretation of underlying values and the selection of yardsticks for judging acceptability are the key problems, then risk managers should be responsible. In an ideal setting, however, this task of determining a risk's acceptability should

be performed in a joint effort by both assessors and managers.

At any rate, a comprehensive, informed, and value-sensitive risk management process requires a systematic compilation of results from risk assessment, risk perception studies and other context-related aspects as recommended and subsumed under the category of risk appraisal. Risk managers are thus well advised to include all the information related to the risk appraisal in evaluating the tolerability of risks and in designing and evaluating risk reduction options. The crucial task of risk communication runs parallel to all phases of handling risk: it assures transparency, public oversight, and mutual understanding of the risks and their governance.

Maintenance Engineering and Maintainability: An Introduction

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: Maintenance is another important aspect of system performance after reliability. There are several facets of maintenace management, and in this introductory chapter we would like to have these surveyed. Broadly speaking, maintenance is the process of maintaining equipment in its operational state either by preventing its transition to a failed state or by restoring it to an operational state following a failure. This leads to various types of maintenace activities that can be planned to realize the objective of maitenance, such as preventive, predictive, or corrective. Recent developments in maintenance engineering and management are also discussed in this chapter.

46.1 Introduction

The Oxford dictionary meaning of "to maintain" is to "cause something to continue" or "to keep something in existence at the same level". Therefore, maintenance does extend the useful life of a product or system. Also the necessity of "upkeep" arises to oppose the forces of degradation. Degradation can be due to deterioration caused by the environment to which the equipment is exposed or due to deterioration of equipment arising from its actual use. From British Standard BS4778-3.1:1991 or BS3811:1993 (or MIL-STD-721B), one settles for the definition of maintenance as: "Maintenance is the process of maintaining an item in an operational state by either preventing a transition to a failed state or by restoring it to an operational state following failure". Therefore the primary aim of a maintenance system is to prolong the state of functioning of equipment or a system by not allowing it to deteriorate in condition.

There is an interesting philosophical paper by Rao [25], who postulates 14 laws for the subject of universal theory of failures. But more interesting and of concern to maintenance engineers is the section on the anatomy of failures in this article, which makes it an interesting reading, particularly in relation to fault and failure and the warning time to failures, as catastrophic failures do not occur instantaneously without a warning time. This allows us to take proactive measures to avoid them.

46.1.1 Maintenance System

An effective maintenance system involves three separate entities of work, *viz.*, maintenance, inspection, and verification, which can be done by different groups in the same company or different companies specifically subcontracted for the purpose.

Maintenance task: Maintenance tasks [12, 13, 15] are generally of two types, *viz.*, *planned* and

unplanned. *Planned maintenance* can be *preventive* or *corrective* (including deferred maintenance), whereas *unplanned maintenance* is mainly *corrective,* which includes any *emergency maintenance*. Again the preventive maintenance can be *scheduled maintenance*, and the other can be based on the condition of the equipment—known as *condition-based maintenance*. Therefore, the form of the maintenance can be:

1. *Pre-planned maintenance:* This includes early maintenance tasks such as cleaning, greasing, lubricating, zero-setting, and recording key measurements. This is often conducted by non-maintenance staff and observed equipment deterioration that cannot be corrected will be reported to regular maintenance staff. This is also called first-line maintenance.
2. *Planned maintenance:* This is also known as scheduled maintenance, and its timing and scope are both known in advance.
3. *Shutdown maintenance:* It is a planned maintenance but is carried out when production or plant is shut down.
4. *Breakdown maintenance:* This is carried out when equipment fails to meet its desired function. This may involve repairs, replacements, or adjustments as considered necessary.
5. *Emergency maintenance:* This is carried out only when either inspection or breakdown maintenance has identified its necessity.

Inspection: All plant machines, equipment, and structures are subjected to regular inspection scheduled to detect performance or safety problems and to ensure that all items receive necessary maintenance.

Verification: Verification is a process, not a measurement, and it has two primary objectives:

- To check that the maintenance work is being done, and
- To confirm that maintenance standards have not been compromised.

Verification is usually performed by or supplemented by (in addition to in-house verification) a third party (to be completely impartial or fair). One of the key parameters to verify if the maintenance was up to standard is to determine the availability of the system, since the maintenance is result dependent and the test lies in *effectiveness* rather than *efficiency*.

46.1.2 Maintenance Philosophy

Based on the timing and the work contents involved in the maintenance task, different maintenance philosophies [13, 15] can be put in the following categories, *viz.:*

1. *Timing known, content known:* preplanned maintenance (PPM), planned shutdowns, routine inspections, and scheduled change-outs fall in this category;
2. *Timing known, content unknown:* statutory surveys, third party inspections, and condition-based maintenance;
3. *Timing unknown, content known:* anticipated maintenance work, contingency work awaiting shutdown, and run to destruction; and
4. *Timing unknown, content unknown:* breakdown maintenance, immediate repairs arising from inspection, and run to failure.

From the point of view of work management, activities falling in category 1 are most welcome and those in category 4 are least welcome. It is always advantageous to shift work to a more manageable category. By using an effective maintenance regime, the intention should be to keep category 4 as empty as possible. It is worthwhile to observe that in "run to failure" in which equipment is run until it fails and then is repaired, work content is unknown. However, in the "run to destruct" category, in which equipment is run till it fails and then is discarded, a replacement is required; thus work content is known. Also, by careful evaluation of maintenance histories and shutdown programs, the timing uncertainty in category 3 can be minimized. Such work followed by full job preparation can provide a fast response when a situation finally requires it. Also, the requirements in category 2 can be anticipated with care once operations are routinely established.

Out of all maintenance work, preplanned maintenance (category 1) is most widely used, but it is often argued that this method requires work to be done that is not necessary since it is done on the basis of calendar irrespective of machine condition.

In run to destruct (category 3), the equipment is usually used until it fails and is discarded or replaced. The work requires switching off the machinery or isolating it, then removing or replacing the old unit and connecting the new unit. Work management is straightforward, as technical content is all known.

Breakdown maintenance (category 4) is simple and can be applied quickly with limited resources and information, but work arising from an unexpected breakdown is difficult to manage and may involve high costs. Breakdown maintenance is not safe and may sometimes involve danger to life.

46.1.3 Maintenance Scope Changed with Time

Over the past several decades starting from the pre-World War II period, the concept and scope of maintenance has changed considerably—more than any other management discipline. These changes can basically be attributed to the advent of more complex designs of systems requiring new maintenance techniques.

This is resulting in change in the concept of maintenance organization and responsibilities. There is a tremendous increase in the number, size and variety of physical assets (plants, equipment, and buildings) which have maintained.

There is a rapidly growing awareness of product quality affecting maintenance activities and of the extent to which equipment failure can affect safety and the environment, coupled with the requirement of achieving high plant availability at reduced costs. With the increase in complexity and sophistication, along with organizational changes, the maintenance work carried out today itself is undergoing changes. These changes are testing the attitudes and skills to their limits in all sectors of industry. Management and engineers [7, 11] are beginning to adopt completely new ways of thinking and strategies towards maintenance, so that they can evaluate them sensibly and apply those likely to be useful to them and their companies. In fact, the changes that have taken place during this period are well documented by Moubray [14], who split this period into three distinct periods (which Moubray [14] calls *generations I, II and III*) and are summarized in Table 46.1.

During the period 1930 to 1950 (first generation), industry was not so mechanized, so downtime did not matter much to them. Maintenance was conducted only when equipment actually failed. The work was more "fix-it" than maintenance. Moreover, most equipment was simple and was usually over-designed, which made

Table 46.1. Changing Maintenance Requirement over Time

Characterized by	Period		
	From 1930 to 1950	From 1950 to 1975	From 1975 to present
Expectations of maintenance	Failure-based maintenance	Higher plant availability Longer equipment life Lower costs	Higher plant availability and reliability Greater safety and better quality Environmentally friendly Longer life Greater cost effectiveness
Pattern of failure	Old age failures	Infant mortality and old age	Various patterns of hazard rates
Maintenance techniques	Reactive maintenance Fix it when it broke	Calendar-based maintenance Scheduled overhauls Systems for planning and controlling work -Big but slow computers	Condition monitoring Design for reliability and maintainability Hazard studies Small but fast computers Expert systems Multi-skilling and teamwork

it reliable and easy to repair. This meant that the prevention of equipment failure was not considered a priority by the management. Therefore there was no need for systematic maintenance [2, 14] of any sort beyond occasional cleaning, servicing, and lubrication. Obviously, the skill requirement was also lower than it is today.

But things changed dramatically during and after World War II. Wartime pressure accelerated mechanization, and by the 1950s machines had become more complex and numerous. As industry became more and more dependent on them, the concern for the uptime of these machines became the priority of the industry, and the management considered it advantageous and in their interest to prevent equipment failures. This became the rallying point for the concept of preventive maintenance with the realization that performing regular maintenance and refurbishment could keep equipment operating longer between failures. This came to be known as *periodic maintenance* or *calendar based maintenance* or *preventive maintenance* (PM). The goal was to have most of the equipment able to operate most of the time until the next scheduled maintenance outage. This approach provided more control over the maintenance schedule; however, the system was still susceptible to failure between maintenance cycles.

However, even by the 1960s, this concern was mainly confined to overhauls of equipment done at fixed intervals. Then as the cost of maintenance increased, the necessity of maintenance planning and control systems was felt. In fact, the amount of capital tied up in fixed assets increased enormously, and the necessity of maximizing the life of these assets was felt more acutely.

As downtime reduced output, it affected the productive capability of physical assets by increasing operating costs and interfering with customer service, and by the 1970s this was further aggravated by the worldwide move towards just-in-time systems—where reduced stocks of work-in-progress meant that quite small breakdowns could stop the whole plant. Instead of waiting for a machine to fail before working on it, or performing maintenance on a machine regardless of its condition (PM), the idea of performing maintenance on equipment only when it indicates impending faults—*predictive maintenance* (PdM)—took hold, and the idea of using PdM to perform maintenance on machines only when they exhibit signs of mechanical failure had come to be known as *condition-based maintenance* (CBM). This process of maintenance has become more *proactive* than *reactive* in maintenance tasking.

In recent times, however, with extensive automation, reliability, availability, and safety of production processes have become serious issues, since failures can affect our ability to sustain satisfactory quality standards and may have severe environmental consequences. This necessitates the integrity of our physical assets, which goes beyond cost and becomes a matter of survival for the organization. Today, as the dependence on physical assets is growing, in order to secure maximum return on their investment they must be kept in efficiently working condition for as long as possible.

Moreover, the cost of maintenance is also rising, in absolute terms and as a proportion of total expenditure. In some industries, it is the highest or the second highest element of operating costs. Consequently, in the last thirty years it has moved from almost nowhere to the top of the cost control priority. Also it is becoming apparent that there is less and less connection between the operating age of assets and how likely they are to fail.

In recent times, there has been tremendous growth in maintenance concepts and techniques. The change in emphasis includes:

- Decision support tools, such as hazard studies, failure modes and effects analyses, and expert systems.
- New maintenance techniques such as condition monitoring or CMMS.
- Designing equipment with emphasis on reliability and maintainability.
- A major shift in organizational thinking towards participation, teamwork and flexibility.

A major challenge facing maintenance people nowadays is not only to learn what these techniques are, but to decide which are worthwhile and which are not in their own organizations. If we

make the right choices, it is possible to improve asset performance and at the same time contain and even reduce the cost of maintenance. If we make the wrong choices, new problems are created while existing problems only get worse.

In fact, RCM provides a framework which enables users to respond to these challenges quickly and easily. Since every physical asset is put into service because someone wants it to do something, they expect it to fulfill a specific function or functions. When an asset is maintained, obviously the state we wish to preserve is the one in which it continues to do whatever its users want it to do.

Of late, emphasis is being placed on *core business* by several major companies of the world, and under this thinking companies are transferring previously in-house functions to external specialist companies. Use of experts or specialists, as well as choosing *in-house* teams *on-site*, accommodated teams, or *manned-up* technicians brought from outside for the completion of a job, is becoming routinely common these days. Subcontracting for maintenance jobs is also becoming quite common in the globalizing world of trade these days, and the number and size of companies engaged in maintenance work is growing very fast.

46.2 Approaches to Maintenance

There are several approaches to maintenance, and different approaches are applicable based on the expected use and maintenance schedule of an item. Economic considerations are tightly related to maintenance and the system lifecycle; it is clear that failure to consider a design's effects on maintenance, and *vice versa*, can have adverse effects on profit. Therefore, design and maintenance must be simultaneously planned in order to ensure an efficient and cost-effective operation over the life of a product.

Maintenance has been categorized based on the nature and purpose of the maintenance work and on its frequency. Generally, there are four types of maintenances in use, *viz.*, preventative, corrective, predictive, and fault-finding.

Maintenance can also be classified according to the degree to which the maintenance work is carried out to restore the equipment relative to its original state. This leads to the following categorization:

Perfect maintenance is maintenance which restores the equipment to *as good as new* condition.

Minimal maintenance results in equipment having the same failure rate as it had before the maintenance action was initiated. This is also called the *as bad as old* state.

Imperfect maintenance is maintenance in which the equipment is not restored to *as good as new*, but to a relatively *younger* state (a state in between *as good as new* and *as bad as old*).

Worse maintenance: This type of maintenance results (unintentionally) in an increase of the equipment's failure rate or actual age but does not result in breakdown.

Worst maintenance: This type of maintenance results (unintentionally) in the equipment's breakdown.

In the foregoing classification, maintenance can be preventive (PM) or corrective (CM), and accordingly the PM or CM would be belong to one of the above categories. These have been discussed nicely in several texts [20, 22, 24].

In this handbook, we have included Chapters 47 and 48 on some aspects of maintenance modeling and optimization as well as on the trends on maintenance technology and management.

46.2.1 Preventive Maintenance

Preventative maintenance, as the name itself indicates*,* is a schedule of planned maintenance aimed to prevent future breakdowns and failures of a system that is functioning properly. In fact, preventive maintenance is performed to prevent equipment failure before it actually occurs and to keep the equipment working and/or extend the life of the equipment. Usually, it is performed on equipment on a regular basis based on the expected life of the equipment, and the frequency of the maintenance is generally constant. Preventive maintenance is a schedule of planned maintenance actions aimed at the prevention of breakdowns and failures, since the primary objective of preventive maintenance is to prevent the failure of equipment before it actually occurs. For example, lubrication of mechanical systems is done after a certain

number of operating hours, or replacement of lightning arresters in jet engines after a certain number of lightning strikes. It is designed to enhance equipment reliability by replacing worn components before they actually fail. Preventive maintenance activities include equipment checks, partial or complete overhauls at specified periods, oil changes, lubrication, and so on. In addition, workers can record equipment deterioration, so they know which worn out parts to replace or repair before they can cause system failure. Technological advances in tools for inspection and diagnosis have enabled even more accurate and effective equipment maintenance. The ideal preventive maintenance program would prevent *all* equipment failures before they occur.

Preventive maintenance [17] is a logical alternative if the following two conditions are satisfied:

- The equipment in question has an increasing hazard rate. In other words, the hazard rate of the equipment increases with time, implying a wear-out situation. Preventive maintenance of a component that is assumed to have an exponential distribution (which implies a constant failure rate) does not make sense!
- The overall cost of the preventive maintenance action must be less than the overall cost of a corrective action. The overall cost for a corrective action includes ancillary tangible and/or intangible costs such as downtime costs, loss of production costs, lawsuits over the failure of a safety-critical item, loss of goodwill, *etc*.

As stated earlier, if the unit has an increasing failure rate, then a carefully designed preventive maintenance program may improve system availability. Otherwise, the costs of preventive maintenance might actually outweigh the benefits. It is important to make it explicitly clear that if a component has a constant failure rate (*i.e*., defined by an exponential distribution), then preventive maintenance of the component will have no effect on the component's failure occurrences.

In fact, the objective of a good preventive maintenance program is to either minimize the overall costs (or downtime, *etc*.) or to meet reliability-availability goals. In order to achieve this, an appropriate interval of time must be determined for the scheduled maintenance. One way to do that is to use the optimum age replacement model, where the model satisfies the conditions mentioned previously, *viz.*:

- The unit is exhibiting behavior associated with a wear-out mode. That is, the failure rate of the unit is increasing with time, and
- The cost for planned replacements is significantly less than the cost for unplanned replacements.

Long-term benefits of preventive maintenance include:

- Improved system reliability.
- Decreased cost of replacement.
- Decreased system downtime.
- Better spares inventory management.

Thus long-term effects and cost comparisons usually favor preventive maintenance over performing maintenance actions only when the system fails.

Maintenance Policies

The literature is full of numerous maintenance models [22] that have been presented by researchers using various assumptions and cost structures, but all of them can be broadly categorized under certain maintenance policies. These policies, however, are with regard to a single piece of equipment.

Age-dependent PM policy: Under this policy, PM is carried out at some predetermined age or repaired (CM) upon failure. PM or CM can be perfect, minimal or imperfect.

Periodic PM policy: Under this policy, the equipment's PM is carried out at fixed time intervals regardless of its failure history.

Failure limit policy: Under this policy, the PM is performed only when the failure rate (or some index of performance) reaches a predetermined level, and the intervening failures are repaired when they occur.

Sequential PM policy: Under this policy, the equipment's PM is carried out at unequal time intervals, which become shorter with age.

Repair limit policy: Under this policy, two cases arise, *viz.*, *repair cost limit policy* and *repair time limit policy*. Under the former, the repair cost is assessed when the equipment fails and repair is performed only if the repair cost is less than a predetermined limit. Otherwise the equipment is replaced. Under the repair time limit policy, the limit is set on the repair time instead of cost.

Repair number counting policy: Under this policy, the equipment is replaced at kth failure and the first $(k-1)$ failures are removed by minimal repair. Upon replacement the process repeats.

As said before, the foregoing maintenance policies were applicable to a single piece of equipment with an increasing failure rate. Recently, there has been increasing interest in multi-equipment maintenance models. In fact, maintenance of a multi-equipment system differs from that of single equipment in that there exists *economic* or *failure* dependence. Due to the former, the PM of non-failed subsystems can be performed at reduced cost while the failed subsystems are being repaired. In case of failure dependence or *correlated failures*, failure of one of the subsystems may affect the functioning of other subsystems. In case of a system with a number of subsystems or equipment, the following maintenance policies are applicable.

Group maintenance policy: Under this policy, there are three different cases:

- *T-age group replacement policy:* The units or equipment are replaced when the system is of age T.
- *m-failure group policy:* This calls for a system inspection after m failures have occurred.
- *m-failure* and *T-age policy*: This policy combines the advantages of the *m*-failure and *T-age* policies and calls for a group replacement when the system is of age T or when m failures have occurred, whichever comes first. This policy requires inspection at either the fixed age T or the time when m failures have occurred, whichever comes first. At inspection, all failed equipment are replaced with new ones and all functioning equipment are serviced so that they become as good as new.

Opportunistic maintenance policies: Under this policy in multi-component systems, it is possible to do PM of non-failed equipment at a reduced additional cost while failed equipment is being repaired. There are many variations in strategy under this category.

Warranty models: Maintenance needs to be incorporated in the warranty models so that if warranted equipment fails, the failed components that caused the equipment failure will be replaced, and in addition PM can be carried out to reduce the chances of failure in the future. Therefore, warranty policies [23] with integrated PM should be preferable.

It can easily be shown that corrective replacement costs increase as the replacement interval increases. In other words, the less often we perform PM, the higher will be the corrective costs. Obviously, the longer we let a piece of equipment operate, its failure rate increases to a point where it is more likely to fail, thus requiring corrective action. However, just the opposite is true for the preventive replacement costs. The longer we wait to perform PM, less shall be the costs. On the other hand, if we do PM too frequently, the cost would go up. If we combine both costs, it is easy to realize that there is an optimum point that minimizes the costs. In other words, one must strike a balance between the risk (costs) associated with a failure, while maximizing the PM interval analysis.

Generally, preventive maintenance (PM) is considered beneficial, but it must be mentioned that there are risks of equipment failure and human errors committed while performing PM, just as in any other maintenance operation. This logic dictates that it would cost more for regularly scheduled downtime and maintenance than it would normally cost to operate equipment until repair is absolutely necessary. This may be true for some components; however, one should compare not only the costs but the long-term benefits and savings associated with preventive maintenance. Without preventive maintenance, for example, costs for lost production time from unscheduled equipment breakdown will be incurred. Also, preventive maintenance results in savings due to an increase of effective system service life.

There are several excellent references available for preventive maintenance modeling and analysis, but the books by Nakagawa [20], Wang and Pham [22], and Jardine and Tsang [24] stand out distinctly. The book by Jardine and Tsang [24] presents different optimal replacement policies and models and spare parts provisioning, besides discussing optimal inspection policies under various conditions. Additionally, capital equipment replacement decisions and maintenance resource requirements are also presented. Nakagawa and Wang and Pham [20, 22] describe perfect and imperfect preventive maintenance models and several optimum preventive maintenance policies: inspection models, with different types of units such as standby and storage, and different types of failures such as extended failures (catastrophic, partial or degraded) and intermittent failures. Faults revealed or unrevealed are also considered. In fact, both these books present an up-to-date status of various models that have been available so far.

In this handbook, we have included Chapter 49 by Nakagawa on replacement and preventive maintenance models.

46.2.2 Predictive Maintenance

Predictive maintenance (PdM) or condition-based maintenance (CBM) is carried out only after collecting and evaluating enough physical data on performance or condition of equipment, such as temperature, vibration, particulate matter in oil, *etc.*, by performing periodic or continuous (on-line) equipment monitoring. Analysis is then performed on the collected data to prepare an appropriate maintenance plan. PdM technologies used to collect information of equipment conditions can include infrared, acoustic (partial discharge and airborne ultrasonic), corona detection, vibration analysis, sound level measurements, oil analysis, and other specific online tests.

The basic aim in PdM [18] is to perform maintenance at a scheduled point in time when the maintenance activity is most cost effective but before the equipment fails in service. Most PdM inspections are performed while equipment is in service, thereby minimizing disruption of normal system operations. This type of maintenance is generally carried out on mechanical systems where historical data is available for validating the performance and maintenance models for the systems and the failure modes are known. Predictive maintenance (PdM) helps determine the condition of in-service equipment in order to predict when maintenance should be performed. The *predictive* component of the term predictive maintenance comes from the goal of predicting the future trend of the equipment's condition. This approach uses principles of statistical process control to determine at what point in the future maintenance activities will be appropriate.

In fact, for condition monitoring or predictive techniques, any relevant means is acceptable to determine equipment conditions and to predict potential failure. This may even include the use of the human senses (appearance, sound, feel, smell, *etc.*), machine performance monitoring, and statistical process control techniques. Other sophisticated technologies used in monitoring include:

- Vibration measurement and analysis,
- Acoustic emission (ultrasonics),
- Oil analysis,
- Infrared thermography, and
- Motor current analysis.

These will be explained in some detail in the following paragraphs.

46.2.2.1 Vibration Measurement and Analysis

This technology owes its popularity to the fast Fourier transform (FFT) technique developed in 1964, when spectrum analyzers became available that could be used with special transducers to measure machine vibrations. When portable FFT-based data collectors became available around 1980, the use of vibration as a tool for machinery fault diagnosis underwent a sea of change and found applications in the petrochemical, electrical power, paper, and other process industries. Today, the *on-line vibration analysis system* (rather than portable analyzers) is widely used for monitoring vibrations with piezoelectric accelerometers as vibration probes and computer-based specialized

data acquisition systems for collecting, storing, and archiving FFT data. The on-line dynamic vibration monitoring system enables mechanical fault detection at the earliest detectable time. But the system installation costs are usually high because of the capital cost of the hardware as well as the installation labor. However, vibration analysis is the most appropriate solution on high speed rotating machines and can be the most expensive part of a PdM program. It still remains the most widely used method for detecting rubbing in rotating machines such as electrical power generating turbines through changes in amplitude and phase of the 1X (rotating frequency) vibration component.

46.2.2.2 Acoustic Emission

Acoustic emission (AE), particularly for bearing diagnosis, is becoming quite indispensable. Sometimes acoustical analysis may also be done at sonic or ultrasonic levels. Sonic technology is useful for mechanical equipment, whereas ultrasonic equipment is useful for detecting electrical problems. Ultrasonic testing is a relatively new predictive technology. It is capable of detecting sounds that lie outside the human hearing range and are indicators of failing mechanical conditions. As a result, ultrasonic testing has become an essential part of a predictive maintenance program. Ultrasonic inspections can help detect leaking gases or fluids in heat exchangers, compressors, and valves. This technique not only locates leaks in steam traps and valves, but can also be helpful in detecting certain electrical faults, such as arching and corona.

46.2.2.3 Oil Analysis

Oil analysis in relevant cases can be a more reliable technique in predictive maintenance. The early use of oil analysis dates back to the early 1940s by the railway companies in the western United States, where technicians used simple spectrographic equipment and physical tests to monitor locomotive engines. When diesel locomotives came in use, oil analysis practices by railways became very frequent. By the 1980s, oil analysis formed the basis of condition-based maintenance (CBM) in most railways in North America.

Lubricating oil contains a good deal of information about the envelope in which it circulates. Wear of metallic parts, for example, produces a lot of minute particles which are carried by the lubricant. Wear means the loss of solid material due to the effects of friction of contacting surfaces. These small metal particles can give information about the machine parts that are wearing, and they can be detected by various methods such as atomic emission spectrometry. Determination of larger particles can be done using optical or electronic microscopy, or ferrography. The acidity of oil can indicate whether the oil has been oxidized as a result of operation at high temperature, if there is a high percentage of moisture, or due to oil having been in service for a long period.

The viscosity of the oil is also an important parameter and must conform to the requirements of the machine. The loss of alkalinity of the oil indicates whether the oil is in contact with some inorganic acids such as sulfuric or nitric acid. Oil undergoes destructive changes in property when it is subjected to oxygen, combustion gasses, and high temperatures. Viscosity change, as well as additive depletion and oxidation, occur to degrade the oil.

Several methods are used to analyze oil condition and contamination. These analyses may include spectrometry, viscosity analysis, dilution analysis, water detection, acid number assessment, base number assessment, particle counting, and microscopy. Oil and wear particle analysis is a combination of spectrometric, ferrographic, and filter analysis. Oil and wear particle analysis can detect abnormal wear modes, particularly in aviation systems, long before the wear can cause any serious damage.

Oil data modeling and analysis can be of great help in fault detection procedures, and we have included Chapter 50 in this handbook on this aspect.

46.2.2.4 Infrared (IR) Thermography

Infrared (IR) thermography is used to detect temperature changes in bearings and shafts. IR thermographic analysis detects abnormal temperatures

that may signify corrosion, damaged wiring, loose connections, and/or insulation breakdown and hot spots. Infrared monitoring and analysis help reduce unexpected failures in electrical and mechanical equipment (from high to low speed equipment). This vital information can alert in advance of the catastrophic failures and is considered a cost-effective technique of monitoring.

46.2.2.5 Motor Current Analysis

Motor diagnostic technologies have become more prevalent through the 1990s to recent times. The technologies include: motor circuit analysis (MCA) and motor current signature analysis (MCSA) applied to both energized and de-energized electric motor systems. Motor current analysis techniques are non-intrusive methods of detecting mechanical and electrical problems in motor driven rotating equipment. Motor current monitor (MCM) uses the electric motor of the equipment as a sensor, and the information about the equipment is extracted from the line current of the motor. The MCM first learns the motor-based system for a certain period of time and acquires and processes the motor data. These data are stored in an internal database, and a reference model, which consists of parameters and their means and standard deviations, is established. Now during actual monitoring, the data being acquired is compared with the results stored in the internal database. If the acquired data is significantly different from the reference model, it indicates a fault level that is determined by the magnitude and the time duration of the difference. This approach is used for diagnostics of electrical equipment, especially those with rotating components. The main advantages lie in its being a noninvasive methodology for diagnosing health and operations of motor-actuated valves, generators, electric motors, and other types of electric equipment.

With new, inexpensive RF components and integration techniques, along with advances in microprocessor technology, it is possible to provide an economic solution for wirelessly monitoring motor operating parameters – such as temperature, vibration, current, *etc*. – for all classes of motors. The generic technology will find applications in areas where motors, pumps, gearboxes or drive chains need to be monitored on a continuous basis, such as fluids processes in chemical industries, motor generator systems, serial trunk conveyor systems, and general line production in manufacturing industries.

Motor current signature analysis (MCSA) is a technique used to determine the operating condition of AC induction motors without interrupting production. MCSA techniques can be used in conjunction with vibration and thermal analysis to confirm key machinery diagnostic decisions.

MCSA works on the principle that induction motor circuits can actually be viewed as a transducer. By clamping a Hall Effect current sensor on either the primary or the secondary circuit, fluctuations in motor current can be observed. It has been observed that if a high resistance exists, (for example due to broken rotor bars) harmonic fluxes are produced in the air gap. These fluxes induce current components in the stator winding that can cause modulation of the supply current at ± the number of motor poles times slip. Available signal processing techniques can help extract the modulating frequency and represent the amplitude relationship of modulating frequency to line frequency. This relationship allows one to estimate the presence and severity of the defect.

46.2.2.6 Problems in Condition Monitoring

Although many organizations use sophisticated techniques for condition monitoring these days, there are still many problems that remain unresolved. For example, it is known that the main determinant of the frequency of condition monitoring is the lead time to failure (or PF interval), which is from the time at which an incipient failure can first be detected until functional failure occurs. For example, in the case of a bearing, the PF interval is the time interval from when overall bearing vibration levels reach an alarming limit until the bearing seizes completely. In order to be sure that the failure is detected prior to functional failure; the bearing must be monitored at a frequency less than the PF Interval. But the PF interval can hardly be determined accurately. For instance, in the case of a bearing, the PF Interval may vary depending on the type of bearing

installed, the severity of its operating cycle, the type of lubrication applied, ambient temperature conditions, the type of failure detected, and many other factors.

Even today, the PF Interval can only be approximately estimated. Any error tends to be on the conservative *(i.e.,* too frequent) side. However, there are cases of bearing failures that have occurred undetected, despite these bearings being monitored at these conservative frequencies. However, the situation is not that bad, as smart sensor technology will greatly reduce the complexity of linking the outputs of these sensors to current process control systems, and thereby more and more equipment can be monitored continuously, -on-line, -and the control room operators will be able to assess quickly and easily, the current condition of the bearings, or alignment, or balance, or gears on a particular machine. Several expert systems for fault diagnosis are available today. However, at present these expert systems are still essentially rule-based systems, and like all rule-based systems, the results are only as good as the rules that have been established within the system.

Several articles have been published on the performance monitoring of steam turbines, using measurements of temperature, pressure, and power output and along with other techniques to determine the turbine condition, and the specific faults that may require attention. In the future, it is likely that this type of monitoring will be used on large diesel engines, pumps, and other sophisticated equipment. It is expected that sophisticated techniques such as ultrasonic flow measurement will be used to assist with the cost-effective application of performance monitoring techniques to a wider range of equipment.

The major trends one may expect to see in the future are:

- The development of smart sensors and other low-cost on-line monitoring systems that will permit the cost-effective continuous monitoring of important equipment.
- The increasing provision of built-in vibration sensors as standard features in large motors, pumps, turbines and other large equipment items.
- Increasingly sophisticated condition monitoring software, with rapidly developing *expert* diagnosis capabilities.
- Increasing integration and acceptance for interfacing condition monitoring software with CMMS and process control software.
- More focus on the applications of condition monitoring technologies to improve equipment reliability and performance, rather than just to predict component failure.
- A reduction in the cost of applying condition monitoring technologies.

In any case, adoption of PdM in the maintenance of equipment can result in substantial cost savings and higher system reliability. This approach offers cost savings over routine or time-based preventive maintenance because tasks are performed only when considered necessary, in contrast to time and/or operation count based maintenance where a piece of equipment gets maintained whether it needs it or not. Time based maintenance is labor intensive and ineffective in identifying problems that develop between scheduled inspections, and it is not cost effective.

46.2.3 Failure-finding Maintenance

Failure-finding maintenance involves checking a (quiescent) part of a system to see if it is still working. This is often performed on subsystems of a system dedicated to safety—protective devices. This is an important type of maintenance check because failures in safety systems can have more catastrophic effects if other parts of the system fail. Inspections are usually carried out in order to uncover hidden failures (also called dormant failures). In general, no maintenance action is performed on the component during an inspection unless the component is found failed, in which case a corrective maintenance action can be initiated.

46.2.4 Corrective Maintenance

Corrective maintenance consists of the actions taken to restore a failed piece of equipment or system to an operational state. This maintenance usually involves replacing or repairing the

component that caused the failure of the overall system. Corrective maintenance is performed at unpredictable intervals because a component's failure time is not known *a priori*. The equipment becomes operational after corrective maintenance or repairs have been performed. Corrective maintenance is actually carried out in three steps:

1. *Diagnosis of the fault*: The repairmen must take time to locate the fault or failed parts or otherwise satisfactorily assess the cause of the equipment or system failure.
2. *Repair or replacement of faulty components:* Once the cause of equipment failure has been established, action is taken to remove the cause, usually by replacing or repairing the components that caused the equipment to fail.
3. *Verification of the repair action:* After the faulty components have been repaired or replaced, the repair crew must verify that the system is again successfully operating.

The total time taken to repair the equipment is called *downtime,* as during this period the equipment is not available or operating. By the same logic, the *uptime* of an equipment or system is the time during which it is available or operating. Further, *cycle time* is the sum of *uptime* and *downtime*. In fact a repairable or maintainable equipment or system undergoes several such cycles of *operating state* and *down state* during its entire *lifetime* before it is discarded or decommissioned.

Actually, downtime is the sum of the *administrative time*, the *logistic time* and the *actual repair time*. The *administrative time* is the time spent in organizing repairs and is the time lost between the occurrence of a fault and the instant repairmen initiate repair action. This should exclude the *logistic time,* which is the portion of down time during which the repair activity is suspended or delayed on account of non-availability of spare parts or replacements.

The *actual repair time* or *active repair time* is the time during which the repairmen are working on the equipment to effect the repairs. This time is in fact the sum of the time to locate the fault or faults and for identification of the fault, fault correction time, and finally the time taken for testing and recommissioning the equipment. It is apparent that *repairability*, which is the probability that the equipment or system will be restored to operable state within a specified *active repair time*, depends on the training and skill of the repair crew as well as on the design of the equipment. For example, the ease of accessibility of components in equipment has a direct effect on the active repair time. However, human factors (covered in Chapter 40 of this handbook) to a large extent govern the duration of active repair time.

46.2.4.1 Maintainability

In contrast with repairability [4, 13, 19], *maintainability* is defined as the probability that the equipment or a unit will be restored to operable state within a specified downtime and depends on all the elements of downtime, *viz., administrative*, *logistic*, and *active repair* times. The downtime is a random variable and has its own distribution, called the repair distribution. If the repair distribution is exponentially distributed and we denote maintainability by $M(t)$, it will be given by

$$M(t) = 1 - e^{-\mu t} \quad ,$$

where μ is the repair rate and t denotes the time to repair (or rather downtime). One can also compute the mean of the repair distribution (MTTR) as:

$$MTTR = 1/\mu \, .$$

If we change the repair distribution to lognormal, Weibull, or gamma, *etc*, the expression for maintainability and mean time to repair would also change. One can find a discussion of repair time distributions in texts like [4, 8, 9, 10].

From the point of view of assessing the performance of such repairable equipment which undergoes several cycles of uptimes and downtimes, a question that naturally arises is what percentage of time on an average (over its entire life) the equipment is available or operating. Thus averaging over a long period of time, one can assess the performance of a repairable or maintained equipment or system, and this average characteristic is called *steady state availability* or *inherent availability* or just *mean uptime ratio*.

46.2.4.2 Availability

Statistically speaking, the uptimes and downtimes are random variables and will have their distributions. Based on these distributions, one can compute *mean uptime* and *mean downtime.* Actually mean uptime reflects how good the inherent design or built-in reliability is, and mean downtime reflects how good the maintainability is. If the steady state availability (SSA) is to be kept high, one should try to design for a high value of mean uptime (MUT) and mean down time (MDT) to be as low as possible, since SSA is the ratio of mean uptime to *mean cycle time* which is the sum of mean uptime and mean downtime. There can be several combinations of MUT and MDT which can offer the same value of availability. Thus availability is dependent on reliability and maintainability, and by clever manipulation one can get the desired value of availability. But the life cycle costs must not be lost sight of while designing a maintained equipment or system.

There are other measures of performance of the maintained equipment, such as *point availability* and *interval availability*.

Point availability is defined as the probability that the equipment or system is available at a given point of time, and *interval availability* is defined as the expected fraction of an interval of specified length that the equipment or system is in an up state. Naturally if the interval becomes very large, the interval availability would approach steady state availability. There are other measures, such as *frequency of failures* and *mean duration of failure*, of interest in the case of maintained systems. The frequency of failures can also be further classified as interval frequency and steady state frequency. The interval frequency of failure is defined as the expected number of times a failure state is encountered in a specified interval, whereas the steady state frequency of failure, or simply the frequency of failure, is defined as the expected number of times a failure state is encountered over a long period of time.

46.2.4.3 Assessment Techniques

For quantitative analysis of performance measures like reliability, availability, or any other measure mentioned in earlier sections, it is necessary to have the following information about the equipment or system:

- *System configuration:* the number of units (identical or non-identical), series, parallel, standby, nature of redundancy (such as warm, cold, or active, *etc*.);
- *Failure and repair data:* failure modes, failure and repair distributions; and
- *Repair strategy:* number of repair crews, independent repair facilities inspection or overhaul schedules, *etc*.

Once the above information is available, one can proceed using any of the following techniques:

- State space approach or Markov method,
- Block diagram approach,
- Conditional probability approach, or
- Monte Carlo approach

Detailed information on these approaches can be found in the references quoted above or in [4]. The Markov method appears to be a more popular technique to analyze maintained systems, although it suffers the disadvantage of the dimensionality of the formulation even for a moderately sized system. However, with fast computing facilities having large memories available, this should not be considered a disadvantage any more. In any case, one can always decompose a large problem into manageably sized problems and also use a combination of solution techniques, rather than using just one technique.

46.2.4.4 Availability Trade-offs

In designing repairable systems, it is generally desired to optimize system availability subject to some cost constraints. Alternatively, a designer may be specified a value of availability to achieve and must determine the optimal pair of mean time between failures (MTBF) and the mean time to repair (MTTR), while minimizing the cost of the system. These formulations are discussed in Chapter 32 of this handbook and the several models are discussed in texts like [1, 8]. However, it is necessary to have some relationship between the variables MTBF and cost and MTTR *versus* cost before any tradeoff can take place. Also, the lower and upper limits on MTBF and MTTR

should be established from practical considerations as well as the state-of-the-art of the available technology. This will help establish the feasibility pairs for MTBF and MTTR.

46.3 Reliability Centered Maintenance

Reliability centered maintenance (RCM) is an approach that helps in deciding what maintenance tasks must be performed at any given point of time. RCM methodology [3, 5 ,6, 16, 21] was initially used in the aviation industry during the 1960s to reduce maintenance costs and to increase safety and reliability. Today it is used in a variety of industries and has benefits applicable to dependable embedded systems. In fact RCM covers a wide range of steps, starting from the product design phase to the deployment and maintenance of a system. The first step in applying RCM techniques is to establish the user's expectations about various characteristics of the system on which RCM will be performed. Then, all the modes that the system can fail in must be identified, and an FMEA or FMECA is performed to identify root causes of these failure modes. From that information, an appropriate combination of types of maintenance is selected, and an appropriate schedule of those maintenance actions is planned. The maintenance plan is then implemented, and data is collected to refine and improve the maintenance schedule.

RCM is a systematic process of preserving a system's or asset's function by selecting and applying effective preventive maintenance (PM) tasks. However, it differs from PM in focusing on function rather than equipment. RCM governs the maintenance policy at the level of plant or equipment type. In general, the concept of RCM is applicable to large and complex systems such as large passenger aircraft, chemical plants, oil refineries, electrical power stations, *etc*.

The main features of RCM are:

- A focus on the preservation of system function;
- Identification of specific failure modes to define loss of this function;
- Prioritizating the failure modes, as not all functions or functional failures have the same importance; and
- Identification of effective and applicable PM tasks that will prevent, and discover or detect the onset of appropriate failure modes based on cost-effective options.

The following process is followed as RCM:

1. The objectives of maintenance with respect to a particular asset are defined by the functions of the asset and its associated desired performance standards.
2. Functional failures are identified.
3. Failure modes which are likely to cause loss of each function are also identified.
4. Failure effects are assessed.
5. Failure consequences are quantified to identify the criticality of failure in terms of the following categories: hidden failure, safety and environmental, operational and non-operational.
6. Functions, functional failures, failure modes, and criticality are analyzed to identify opportunities for improving performance and/or safety.
7. Preventive tasks are established. These may be one of three main types: scheduled on-condition tasks which employ condition-based or predictive maintenance, scheduled restoration, and scheduled discard tasks.

Although the main aim of using RCM is to reduce the total costs associated with system failure and downtime, evaluating the returns from an RCM program solely by measuring its impact on costs may hide many other less tangible benefits such as:

- Improving the system availability,
- Optimizing spare parts inventory,
- Identifying component failure significance and hidden failure modes as well as previously unknown failure scenarios,
- Providing training opportunities for system engineers and operations personnel,
- Identifying areas for potential design enhancement, and
- Providing detailed review and improvement where necessary.

The RCM implementation generally involves high initial costs and quite often results in successful investment, but there have been some cases of unsuccessful implementation, which makes a prior economic evaluation of RCM an important step before it is adopted. In fact, RCM should not be undertaken if the financial benefits cannot be demonstrated to outweigh the involved costs. However, the financial benefits and costs associated with RCM are difficult to assess due to the fact that areas of savings are vague; there are no clear cause and effect relationships in the evaluation process. Costs can more easily be identified than benefits. Costs include initial outlays, primarily for training, and ongoing costs, including maintenance and support personnel and expenditures associated with the maintenance introduced as a result of RCM findings. Benefits can also be identified through a series of steps. Firstly, one can start by identifying the current problems that can be resolved through RCM. Secondly, one can estimate how much improvement would result through the adoption of RCM for the identified problems. Lastly, one should quantify each of the improvements in the larger sense of company's performance (profits, plant availability, personnel cost, *etc*.). When that quantification is done, then the economic benefits of RCM can be evaluated to see if its adoption is justified or not.

The value of RCM lies in the fact that it recognizes that the consequences of failures are far more important than their technical characteristics. In fact, it recognizes that the only reason for doing any kind of proactive maintenance is not to avoid failures *per se*, but to avoid or at least minimize the consequences of failures. In fact, the RCM process classifies these consequences into the following four groups:

- *Hidden failure consequences*: Hidden failures have no direct impact, but they may lead to multiple failures, often with catastrophic consequences. (Often these failures are associated with protective devices which are not fail-safe.)
- *Safety and environmental consequences:* A failure has safety consequences if it has the potential to injure or kill someone. It has environmental consequences if it breaches any environmental standard.
- *Operational consequences:* A failure has operational consequences if it affects production, product quality, customer service, or operating costs or cost of repairs.
- *Non-operational consequences:* Failures belonging to this category neither affect safety nor production, but involve only the direct cost of repair.

46.4 Total Productive Maintenance

It is a well-known fact that in many factories, the operating time is less than 50% of the gross available hours per year; this obviously shows that assets are not being used to the fullest extent. This is partly due to *scheduled downtime*, which includes holidays, no production planned due to limited load, spare capacity to cope with volume flexibility, *etc*. The other part is caused by the fact that production is not wholly efficient. The reasons for this can be categorized into losses, which can be influenced during development and production phase. The total productive maintenance is a proactive equipment maintenance strategy designed to improve overall equipment effectiveness. It actually breaks the barrier between the maintenance department and the production department of a company.

Total Productive Maintenance: This is an approach to optimize the effectiveness of production means in a structured manner. TPM focuses on improving the planned loading time. The gap (losses) between 100% and actual efficiency can be categorized into three categories: availability, performance and yield (quality rate).

- *Availability losses:* These include breakdowns and changeover situations when the line is not running while it should be.
- *Performance losses:* These are basically due to speed losses and small stops, idling, or empty positions when the line is running but is not providing the quantity it should.
- *Yield losses:* These occur when the line is producing products, but there are losses due to rejects and start-up quality losses.

These losses lead to the overall equipment effectiveness (OEE) indicator, which tells how efficiently the planned production process is. TPM helps to improve the OEE by providing a structure to quantify these losses, and by subsequently giving priority to the most important ones. TPM provides concepts and tools to achieve both short and long term improvements.

Total productive maintenance is not the same as a maintenance department that repairs breakdowns (breakdown maintenance). TPM is a critical adjunct to lean manufacturing. If machine uptime is not predictable and if process capability is not sustained, we cannot produce at the velocity of sales. One way to think of TPM is *deterioration prevention* and *maintenance reduction*, not fixing machines. For this reason many people refer to TPM as *total productive manufacturing* or *total process management*. TPM is a proactive approach that essentially aims to prevent any kind of slack before occurrence. Its motto is "*zero error, zero work-related accident, and zero loss*". TPM has five goals:

1. Maximize equipment effectiveness;
2. Develop a system of productive maintenance for the life of the equipment;
3. Involve all departments that plan, design, use, or maintain equipment in implementing TPM;
4. Actively involve all employees; and
5. Promote TPM through motivational management.

For this concept to function properly, the machines must be ready when they are needed, and they must be shut down in such a fashion as to be ready the next time. Key measures include efficiency while running and quality. Overall equipment effectiveness (or OEE) tells us how TPM is working, not just the typical measures of uptime and throughput. OEE is actually the product of availability, performance efficiency, and the quality rate. Operators know what maintenance tasks are theirs; they also know what tasks are appropriate for the skilled trades' maintenance crews. TPM is a philosophy that helps create ownership of the manufacturing process among all employees. Teamwork is vital to the long-term success of TPM. The maintenance group performs equipment modifications that would improve reliability. These modifications are then incorporated into new equipment. The work of the maintenance group is then to make changes that will lead to maintenance prevention. Thus *preventive maintenance* along with *maintenance prevention* and *maintainability improvement* are grouped as *productive maintenance*. The aim of productive maintenance is to maximize plant and equipment effectiveness and to achieve the optimum life cycle cost of production equipment.

Nippondenso of Japan was first to implement TPM. It had already had quality circles which involved the employees in changes. Therefore, all employees took part in implementing productive maintenance. Based on these developments, Nippondenso was awarded the distinguished plant prize for developing and implementing TPM by the Japanese Institute of Plant Engineers (JIPE). Thus Nippondenso of the Toyota group became the first company to obtain the TPM certification.

TPM identifies sixteen types of wastes (*Muda*) and then works systematically to eliminate them by making improvements (*Kaizen*). TPM has eight pillars of activity, each being set to achieve a "*zero*" target. These pillars are:

1. Focused improvement (*Kobetsu-Kaizen*): for eliminating waste,
2. Autonomous maintenance (*Jishu-Hozen*): involves daily maintenance activities carried out by the operators themselves (the key players) which prevent the deterioration of the equipment,
3. Planned maintenance: for achieving zero breakdowns,
4. Education and training: for increasing productivity,
5. Early equipment/product management: to reduce waste occurring during the implementation of a new machine or the production of a new product,
6. Quality maintenance (*Hinshitsu-Hozen*): actually "*maintenance for quality*", it includes the most effective quality tool of TPM, "*poka-yoke*", which aims to achieve zero loss by taking necessary measures to prevent loss,

7. Safety, hygiene, and environment: for achieving zero work-related accidents and for protecting the environment, and
8. Office TPM: for involvement of all parties to TPM since office processes can be improved in a similar manner as well.

46.5 Computerized Maintenance Management System

Computerized maintenance management system (CMMS) is also known as *enterprise asset management* (EAM). A CMMS is a stand-alone computer program used to manage maintenance work, labor, and inventory in a company, whereas EAM not only does all the functions of a CMMS, but also integrates with the company's financial, human resource, material management, and other ERP (enterprise resource planning) applications. In the past, stand alone CMMS had an advantage over EAM in terms of features, ease of use and functionality.

A CMMS maintains a computer database of an organization's complete maintenance operations. This database is intended to help maintenance staff do their jobs more effectively (for example, determining which storerooms contain the spare parts they may need) and to help management make informed decisions, such as in calculating the cost of maintenance for each piece of equipment used by the organization and in allocation of resources judiciously. This information can also be helpful in dealing with third parties. For instance, if the organization is involved in a liability suit, the database information available with the CMMS can be used as evidence to support that proper safety maintenance was performed. CMMS can be used by any organization that must perform maintenance on equipment and property. Some CMMS products focus on particular industry sectors (*e.g.*, the maintenance of vehicle fleets or health care facilities, *etc.*). Other products aim to be more general. To identify CMMS vendors, a search for CMMS using any internet search engine can be performed.

Different CMMS packages offer a wide range of capabilities. A typical package may have the following features:

- Work orders: Scheduling jobs, assigning personnel, reserving materials, recording costs, and tracking relevant information such as the cause of the problem, record of downtime, and suggestions for further action required.
- Preventive maintenance (PM): Keeps track of PM inspections and jobs, including step-by-step instructions or check-lists, lists of materials required, and other pertinent details. Typically, the CMMS schedules PM jobs automatically-different software packages offer different techniques for reporting when a job should be performed.
- Asset management: Recording data about equipment and property including specifications, warranty information, service contracts, spare parts, purchase date, expected lifetime, *etc*. that might be of help to management or maintenance workers.
- Inventory control: Management of spare parts, tools, and other materials including the specification of materials required for particular jobs, records of where materials are stored, determining when more materials should be purchased, tracking shipment receipts, and taking inventory.

CMMS can produce status reports and documents giving details or summaries of maintenance activities. The more sophisticated the package is, the more analysis facilities are possible. Many CMMS packages can also be hosted by the company selling the product on an outside server, meaning that the company buying the software hosts the product on their own server or LAN. CMMS packages are closely related to facility management system packages (also called facility management software).

By adding some powerful reliability management tools, one can manage the information around maintenance, reliability, and ultimately a physical asset management (PAM). In fact, it can begin with the selection, implementation, data accuracy, failure coding, asset hierarchy, work order history,

user adoption, training, enforcement, reporting, key performance indicators (KPIs), dashboards, budgeting, planning, scheduling, mobile options, material management, and many more factors and will determine the result one can get with CMMS or EAM.

Last but not least, one must realize that these software systems are simply automating the underlying maintenance process, so if one is dealing with a poor maintenance process, adding CMMS will not make it better.

System Maintenance: Trends in Management and Technology

Uday Kumar

Division of Operation and maintenance Engineering, Luleå University of Technology,
S-97187, Luleå, Sweden

Abstract: Modern day systems are large, complex and automated. The high demands on the performance of such systems has created a need for new management and engineering solutions in the area of the maintenance of the complex systems. This need is mainly motivated by the steeply increasing cost of downtime. This chapter presents an overview of the recent trends in management of maintenance function and maintenance technology.

47.1 Introduction

Maintenance is necessary when a component (or system) is likely to fail or fails to fulfil its required function and involves servicing, replacement or repair. Some failures directly affect the operational capability and performance of the system. The main purpose of the maintenance function is to avoid these failures or to restore the system to its operating state after it has failed to fulfil the required function. In short, the maintenance function can be defined as activities for retaining a system in an operating state or restoring it to a state that is considered necessary for its operation and utilization. Therefore, the fundamental step in the effective management of the maintenance process is the accurate determination of the maintenance need of the system, which in turn is determined by the state of the equipment, and the actions that must be taken to restore it or retain it in an operating condition [1]. Furthermore, the maintenance needs are quantified by the consequences of the corresponding failures. Therefore, the driving element in all maintenance decisions is not the failure of the given item or system, but the consequences of the failure of that particular item or system [2].

The increased level of automation and the high demands on system performance have created a need for a new engineering approach and new managment techniques in the field of equipment and asset management. This need is mainly motivated by the steeply increasing cost of maintenance and downtime. For example, the amount spent on the maintenance budget for Europe is around 1500 billion Euros *per* year [3], and for a small country like Sweden it is about 20 billion Euros *per* year if only the direct cost of maintenance is taken into account [4]. Besides, breakdowns and downtime also result in a loss of product quality and production, as well as having a negative impact on health, safety, and the environment. A safety-related example from the recent past is the accident at British Petroleum's Texas refinery in the USA, which killed 15 and injured about 500 persons, apart from costing a

billion dollars in repair and compensation [5]. Prevention of such accidents could have enhanced BP's image, besides saving billions of dollars. In short, the discipline of maintenance has evolved over the years to become an indispensable field in engineering.

In general, the maintenance approaches implemented and practised by companies can be classified into two major groups, namely planned maintenance and unplanned maintenance. These approaches can be further subdivided into the preventive and the corrective maintenance approaches. The corrective maintenance approach is reactive in nature, whereas preventive maintenance is a form of proactive maintenance activity (see Figure 47.1). The preventive maintenance approach can be time-based or condition-based.

The traditional aim of the condition monitoring technique has been the early prediction of failures by monitoring certain critical system parameters, and now it is an established fact that the judicious application of condition monitoring techniques can help in controlling and optimizing the colossal maintenance problem. The dream figure of 80% planned maintenance and 20% emergency or running repairs looks realistic today, if one believes in the capability of "on-line" and "off-line" condition monitoring devices and instrumentation. Figure 47.1 illustrates the evolution of the business of maintenance through the years [6]. In the past maintenance was not an issue, but now we are talking about self-maintenance and maintenance-free systems.

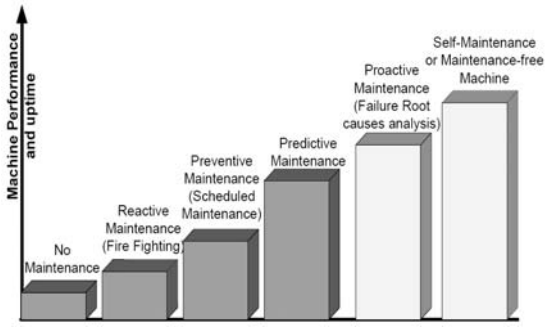

Figure 47.1. Development and evolution of the concept of maintenance with time [6]

47.2 Why Does a Component or a System Fail and What Is the Role of Maintenance?

To understand the evolution and developments taking place in maintenance engineering and management, it is essential to understand why we need to think about maintenance and what role it plays in the achievement of business goals.

Most physical products and systems wear, tear, and deteriorate with age and usage. In general, due to cost and technological considerations, it is almost impossible to design a system that is maintenance-free. In fact, maintenance requirements come into consideration mainly due to a lack of properly designed reliability and quality for the tasks or functions to be performed. Thus, the role of maintenance and product support can be perceived as the process that compensates for deficiencies in design both in terms of product reliability and product output quality. These shortcomings in design are compensated for through appropriate maintenance and product support programs (Figures 47.2 and 47.3).

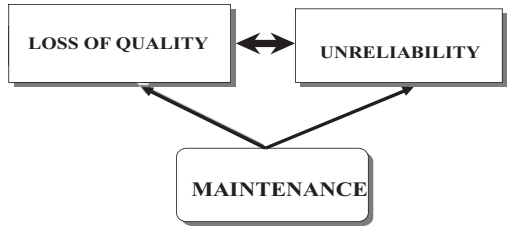

Figure 47.2. Maintenance compensates for the unreliability and loss of quality in the designed product

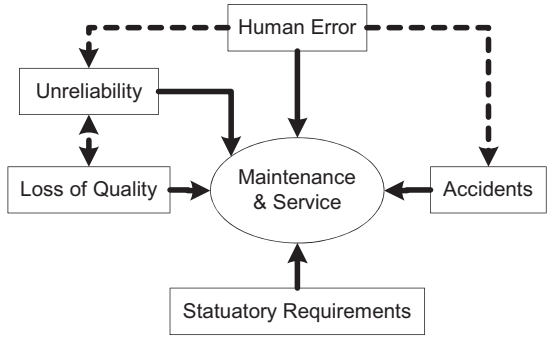

Figure 47.3. Root causes of product support and maintenance

Apart from unreliability and poor quality, other factors such as human error, statutory requirements, accidents, *etc.*, also influence the design and development of product support and the maintenance concepts [7].

In the following sections we present a brief review of recent trends in maintenance management and maintenance technology. The first section introduces the subject area; the second section presents a review of the recent developments being made for effective control and management of the maintenance function by companies and researchers. The third section presents a brief overview of the recent advances in condition monitoring and maintenance engineering approaches being adopted and implemented by companies all over the world.

47.3 Trends in Management of the Maintenance Process

It is obvious that maintaining equipment and plants is a very costly and time-consuming activity. Maintenance is also important for health and safety, since records show that inadequate maintenance activities are closely associated with excessive accident rates [8]. As a result, there has been a major paradigm shift in the maintenance philosophy of many companies aiming at a high degree of mechanization and automation. Maintenance is no longer a necessary evil "that costs what it costs", but an important function that creates additional value (see [9]) in the business process as illustrated in Figure 47.4.

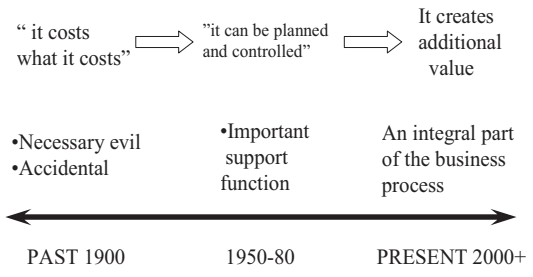

Figure 47.4. Paradigm shift in asset managers' views of the maintenance discipline

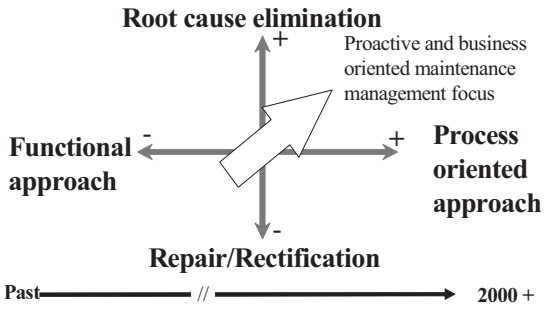

Figure 47.5. Paradigm shift in maintenance work culture

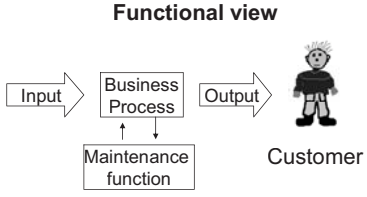

Figure 47.6. Functional approach of the maintenance discipline

Accordingly, the focus of senior asset managers has shifted from "fail and fix" to root cause elimination, and from functional thinking (we and them) to a process-oriented approach that encourages a process-oriented work culture in maintenance (*i.e.*, a focus on the end customer), see Figure 47.5. Furthermore, a closer look at the style of maintenance management reveals that many companies are treating maintenance as an integral part of their business process, and not as a standalone support function. Accordingly, the focus of maintenance management has shifted from merely being responsible for the delivery of agreed reliability and availability to supplying services to fulfill the requirements of customers and stakeholders [10].

This has brought about a change in the attitude of maintenance engineers and managers and their focus has shifted to the end customers, apart from meeting set availability and equipment capacity targets (see Figures 47.6 and 47.7).

47.4 TPM Implementation

The search for appropriate techniques for achieving excellence in maintenance with the involvement of

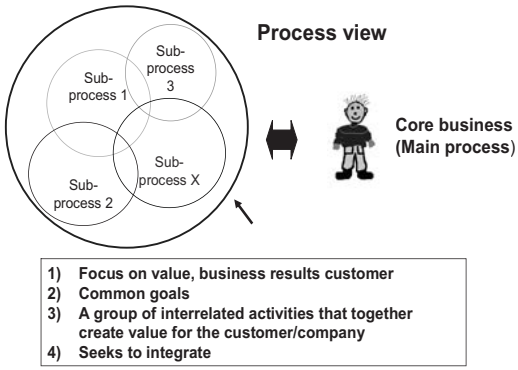

Figure 47.7. Process-oriented approach of the maintenance discipline

all the employees in the organization has led to many companies implementing the Total Productive Maintenance (TPM) philosophy in some form or another. The strategy of dividing up the maintenance tasks between operators and maintenance specialists has made the TPM approach quite popular in the manufacturing industry. TPM combines the conventional practice of preventive maintenance with the concept of total employee involvement through small group activities. The result is an innovative system for equipment maintenance that optimizes productivity, eliminates breakdowns and promotes the philosophy of autonomous maintenance through continuous improvement. In general, the key to the success of the TPM approach is the fact that the operator performs the first line maintenance and specialized jobs are carried out by experts.

TPM seriously takes into account the social factors and cultural background in its endeavour to achieve the overall effectiveness of the operating system. See [11] for a detailed discussion of TPM philosophy. Since social factors and employees' backgrounds play an important role, TPM is not a stereotype implementation of some set rules. The management effort needs a human touch to achieve the best out of the existing production system. The success of TPM is dependent on the success of team work between the operation and the maintenance department. In TPM, these teams are also referred to as total quality circles (TQC) in maintenance.

TPM is based on the application of five S's, namely seiri-organization, seiton- neatness, seiso-purity, seiketsu-cleanliness and shitsuke-discipline, which are central to all the Japanese methods that have evolved since the early 1950s.

It is appropriate to mention that the results of TPM take around three to four years to become visible, as it involves the soft side of human nature. Since it takes a long time to implement TPM, many companies are adopting a lean version of TPM, *i.e.*, they are focusing on a partial implementation.

To manage the maintenance function effectively, one needs to plan and predict the future maintenance requirement while keeping in view the strategic production and operation goal of the company. The main challenge is to implement a decision support system that facilitates correct decision making when dealing with maintenance-related issues. One such approach is risk-based decision making.

47.5 Application of Risk-based Decision Making in Maintenance

The main purpose of maintenance is to reduce the business risk. Taking decisions concerning the selection of a maintenance strategy using risk-based criteria is essential to develop cost-effective maintenance policies for mechanized and automated systems, because in this approach technical features (such as reliability and maintainability characteristics) are analyzed considering the economic and safety consequences of each alternative at hand. Therefore, it is natural that an increasing number of assets and plant managers are adopting risk assessment procedures as an integral part of the maintenance planning [2]. This approach provides a holistic view of the various decision scenarios concerning the maintenance strategy where the cost consequences of every possible solution can be assessed quantitatively.

Risk analysis is a technique for identifying, characterizing, quantifying, and evaluating the loss due to an event. In system risk analysis, reliability and maintainability (see the section on design-out maintenance) are integrated at various stages of the

analysis. Risk can be formally defined as the potential of loss or injury resulting from exposure to a hazard or failure. Risk can be viewed both qualitatively and quantitatively. In general, risk analysis consists of answers to the following questions [12]:

- What can go wrong and lead to a system failure?
- How likely is this to happen?
- If it happens, what consequences are to be expected?

Therefore, risk can be defined qualitatively as the following set of triplets

$$R = E_i P_i C_i,$$

where

E_i is the scenario of events that leads to a failure,
Pi is the probability of the occurrence of event i, and C_i is the consequence of scenario i. For a particular failure mode, risk can be quantified by (see also Figure 47.8):

Risk = the probability of occurrence x the consequences of the failure

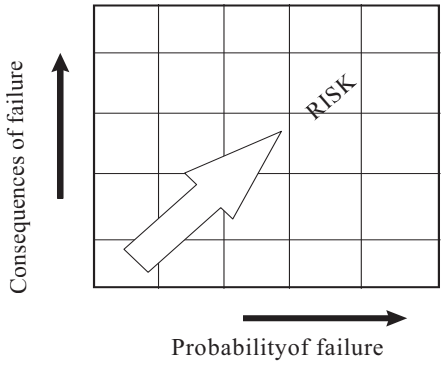

Figure 47.8. Illustration of the risk concept

In general, three classes of consequences are relevant for system namely safety consequences, economic consequences and environmental consequences. To deal with the estimated risk, preventive maintenance programmes are implemented to control the occurrence of failures and at the same time efforts are also made to contain the intensity and effect of consequences through various damage control measures. Figure 47.9 illustrates the approach.

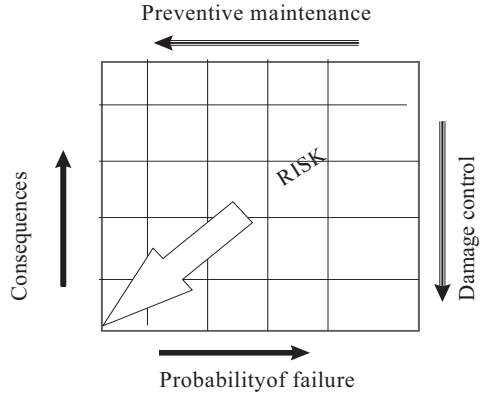

Figure 47.9. Risk and its control measures

For each of the potential design changes or modifications that are to be identified by the experts, a cost-benefit comparison can be used to select the viable modification options based on a comparison of expected benefits versus estimated costs. In fact the cost, the level of risk and the benefits from risk control are closely linked and they cannot be evaluated separately. In other words, any anticipated increase in benefit from a decision may increase the risk if the cost is kept constant, or any reduction in risk may reduce the benefit as the cost may increase. Such analysis clearly shows the rate of cost intensity of risk elimination.

47.6 Outsourcing of Maintenance and Purchasing of the Required Functions

It is being argued by many asset managers and leading companies that it is preferable to concentrate on the core business and that the business of maintenance, which has been expanding critically with the evolution of technology, should be taken care of by the specialists. This way of thinking is gradually spreading and many managers are willing to contract out the maintenance function to the authorised service providers or the original equipment manufacturer (OEM). This approach has helped many companies

to maintain a lean and flat maintenance organization. Another trend in maintenance management is for the equipment operator to enter into a contractual agreement with the equipment supplier whereby the supplier is responsible for repair and maintenance, including the storage of spare parts, *etc.* In such a contract, a specified level of availability is usually demanded and failure to meet it results in the supplier being stiffly penalized. It is the firm belief of senior asset managers that the development of a sound subcontracting system for maintenance can reduce the cost of maintenance manifold, and this practice is on the increase in many industries. However, it is also being criticized, because control of the availability of machines is shifted to some external organization over which one has little control.

Types and forms of maintenance and service contract:

- Contracting-out of the routine maintenance tasks
- Outsourcing
- Partnering

47.6.1 Contracting-out of the Maintenance Tasks

Many asset managers adopt the practice of contracting out a part of their maintenance work load to service providers or to original equipment manufacturers (OEM) to cut down their cost and maintain a lean organization. The exchange of data and information is limited with such an approach and such a relationship with the service provider and is mainly governed by the written contact. Such a form of service outsourcing does not facilitate a long-term relationship, as it is mostly based on the premise, "I win and do not care what happens to you."

47.6.2 Outsourcing

Outsourcing is a more developed form of traditional contracting-out. In the outsourcing process one establishes a form of relationship with the service provider where the service receiver on a case-to-case basis does not hesitate to share even confidential information [13].

47.6.2.1 Partial Outsourcing

In this approach, an OEM sells a system accompanied by an attractive bundle of service and maintenance provisions. The maintenance work is partially outsourced to the OEM or a service supplier. While the operator out sources some or all of the maintenance work, they still own the product and their employees operate it. For example, in the case of a drill machine, a mine-operator can choose to outsource the maintenance of the hydraulics and IT-related services to the OEM or to some independent service provider.

Alternatively, a mine operator/user may choose to outsource all the maintenance work to an OEM or to an authorized service and maintenance supplier. Due to the probability of fast technological developments, a management may prefer to focus its attention and resources upon core business activities. Fewer and fewer companies seem willing to buy a system, use it and maintain it; the preference is to outsource maintenance/ services so as to share business responsibilities with an OEM/supplier. Outsourcing is viewed as a means to ensure far greater cost discipline while at the same time improving the quality of service and the product delivery capability. For instance, returning to the drill machine, a mine operator may outsource all the maintenance-related work (not only the maintenance of hydraulics or a particular drilling machine part). Managers and operators/ companies use outsourcing as a means to focus on the core business and thereby minimize the business risk, in addition to increasing competitiveness. Outsourcing has changed not just the face of the workplace but also societal attitudes towards work and employment.

The decision to outsource is usually based on the premise that an OEM/supplier has some inherent advantage over the host company in varying forms of shared supervision. This can cause conflict between the workers of an OEM/supplier/ contractor and a host company, since officially these workers are under the administrative control of the contractor, while in

reality the host company controls them. Therefore, the terms and conditions related to the role and responsibilities of all the actors should be clearly defined in the contract (negotiated agreement) to avoid a loss of control, reduced competence, and decreased operational flexibility. Recently conducted surveys report high levels of dissatisfaction with outsourcing [14]. On the other hand, outsourcing, when carefully managed, offers excellent potential in the sharing of business risk and the enhancement of business performance between partners. Outsourcing is often a matter of trust and cooperation between the parties involved. The main driver of outsourcing is the aim of achieving cost benefits. The available literature [15], [16] offers details on the management of different elements in outsourcing.

47.6.2.2 Full Outsourcing

With this newest type of strategy a customer/mine operator owns a system but all the support required for the mining equipment and the equipment operators' related services is provided by the OEM or equipment supplier at agreed prices or as part of the original selling price. This combination of system, services, support and knowledge from an OEM to a mine operator means that full service is provided. Full service in the mining industry usually means that the OEM/service provider executes all the corrective, preventive and predictive maintenance activities, as well as all the support to the equipment operator/customer (for details see [17] and [18]. Such support ranges from training to machine maintenance. A critical element is the fact that support is given to a mine operator for using the drill machine effectively and efficiently. In this form of full outsourcing an OEM/service provider is responsible for providing an agreed level of availability and reliability. The knowledge provided includes when, why, and how a drill machine is to be used to achieve the maximum profit. This is more or less an individualized problem solving service sold to a mine operator/customer as part of a package.

47.6.2.3 Partnering

This is the most developed form of contracting-out of jobs and in such a form the problem is owned by both the partners with some form of incentive to stimulate development and innovation in the services. Here asset managers share everything with service providers (partners) including the profit and losses, and mostly this is based on long-term understanding of each other's business processes, which are mainly focused on creating a WIN–WIN situation for both the partners (see Figure 47.10). For details see [19].

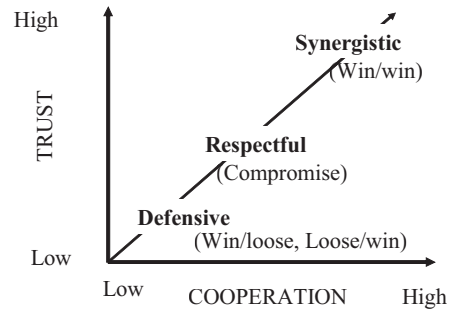

Figure 47.10. Outsourcing model built on cooperation and trust(adapted from [20])

The trend in maintenance can be illustrated as shown in Figure 47.11 from situation I to II but the business is drifting towards type II (leasing and functional product).

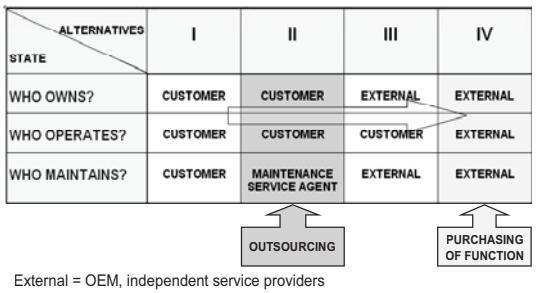

Figure 47.11. Trends in outsourcing leading to the concepts of functional products

47.6.3 Purchasing the Required Function: The Concept of Functional Products

Functional products: Modern-day industry is becoming less physical and more cognitive as manual labor is gradually being replaced by machine operation. The machines involved are expected to perform round the clock. However, due to design problems, these systems are not able to meet customers' requirements in terms of system performance and effectiveness. This is often due to poorly designed reliability and maintainability characteristics, combined with poor maintenance and product support strategy, which often lead to unscheduled stoppages (failures). This has given a new dimension to the problem of effective and efficient management of maintenance and service processes. To avoid the complexities of maintenance management, many customers/users prefer to purchase only the required function, not the machines or systems, so that the responsibility of maintenance and product support lies with the organization delivering the required function. With the advent of this trend, the focus has shifted to the design of functional products (see Figure 47.11).

A functional product may be defined as a product whose function is purchased by the user and not the actual machine/system delivering the function. For details see [21] and [22]. Often designers and manufacturers develop systems and sell them to users (the continuous line). This is also called a technological push, *i.e.* one develops a system and creates a need for it. However, systems should be developed keeping in view the application type customer-pull. The designed product characteristics define the types of application which the product can be subjected to and the type of product support needed to achieve the expected function and performance.

Without any formal measures of performance, it is difficult to plan control and improve the outcome of the maintenance process. Today, maintenance performance measurement (MPM) is receiving a great amount of attention from asset managers and maintenance engineers, mainly due to its newly found role in the prevalent business environment [23] and [24].

47.6.4 Maintenance Performance Measurement

Measuring maintenance process activity is nothing new and previously used to be carried out with scorecards or with indicators like maintenance cost per unit, maintenance budget, overtime costs and non-availability index due to maintenance, *etc.* However, these maintenance indicators are found to be stand-alone indicators, mostly localized to the shop floor or operational area only and not linked to the corporate business level. With the current paradigm shift in maintenance, today senior management can visualize the linkage and are keen to know the value created by the maintenance process.

In the 1980s, the term "productivity" was replaced with "performance", as the criteria of the productivity paradigm were unable to satisfy various stakeholders. It was realized that the shortcomings of the prevailing performance measurement systems, most of which were based on financial measures. Traditional financial performance measures provide little indication of future performance and encourage short-termism [25]; they are internally rather than externally focused, with little regard for competitors or customers [26], [27]. Moreover, the traditional performance measures lack a strategic focus and do not encourage innovation. Normally, most organizations measure what is easy to measure, collecting all sorts of data, which ultimately leads to data overload.

A PM system is defined as the set of metrics used to quantify the efficiency and effectiveness of actions [27]. The MPM concept adopts the PM system, which is used for the strategic and day-to-day running of the organization, and for planning, controlling and implementing improvements, including monitoring changes. A key performance indicator (KPI) needs to be defined for each element of a strategic plan and the KPI can be converted into the PI at the basic shop floor or operational level.

Presently, maintenance performance measurement forms an integral part of performance management in any production or manufacturing organization. In the MPM system, the corporate

goals need to be cascaded down into operational targets at the shop floor level, and the outcome results or actual lagging indicators need to be aggregated at a higher level. The real challenge is how to cascade the goal vertically down the organization and aggregate the outcome at various levels upwards. It is also a challenge to integrate activities amongst various departments within organizations horizontally so that the total maintenance effectiveness and desired business objectives is achieved. An all-out effort is currently being made to create a link and effect model to measure the contribution of maintenance to the company's business goals [23]. Today, researchers have developed a multiple criteria and hierarchical MPM framework which is balanced and integrated. For details see [28]. With the application of information and communication technology (ICT) and e-Maintenance, companies can look forward to having an efficient MPM system based on server-based software applications, the latest embedded internet interface devices and state-of-the-art data security. The application of ICT and e-Maintenance has facilitated real-time data collection and analysis, and cost-effective decision making [23].

47.7 Trends in Maintenance Technology and Engineering

The different concepts and tools used in maintenance engineering have evolved over the years with the objective of continuous improvement in maintenance planning and management. With the introduction of the functional product to the market, OEMs have directed their focus on tackling the maintenance needs of a system, which can minimize the life cycle cost of the system. In this connection many designers have two alternatives: either to design out maintenance using available or innovative engineering solutions or, in cases where this is not possible, to opt for the design for maintainability alternatives.

47.7.1 Design out and Design for Maintenance

More often than not it is becoming standard practice to use risk analysis in combination with LCC analysis to arrive at a correct decision as to whether to design out the maintenance need or design the system for maintenance, if the option of designing out is either technically unfeasible or economically unviable. For such exercises, knowledge of reliability and maintainability engineering is a must. It is important to consider system reliability and maintainability issues in all the phases of a system's conception, design, construction (manufacturing) and operation. Not only does this raise our consciousness of the issues in question, but it also usually results in real improvements in the reliability of the system, thereby reducing the risk of failure and leading to subsequent saving in maintenance.

47.7.2 Reliability

The reliability of equipment is the probability that it will perform its required function without failure under given conditions for an intended period of operation. The decision regarding the reliability characteristics of equipment is taken during the drawing board stage of equipment development. The aim is to prevent the occurrence of failures and also to eliminate their effects on the operational capability of systems. Among the factors which have an important influence on equipment reliability are:

- the period of use
- the environment of use

The mean time to failure (MTTF) is a measure commonly used to express the reliability of components or systems [29], [12].

47.7.3 Maintainability

The maintainability of equipment can be defined as the probability that it will be restored to a specified condition within a given time period using specified resources. High maintainability performance is obtained when the system is easy to maintain and repair. In general, maintainability is measured by the mean repair time, often called the mean time to repair (MTTR), which includes the total time for fault finding and the actual time spent carrying out the repair. Maintainability considerations are also

very important for units operating under tough conditions, for instance mining equipment [30].

Some of the prerequisites for a good maintainability standard are:

- interchangeability
- easy accessibility
- modular design

When considering maintenance in design, one generally has two options: one can either try to design out maintenance (Figure 47.12) and if this alternative is not feasible economically or due to lack of technology, then design for maintainability approach is adopted (see Figure 47.13).

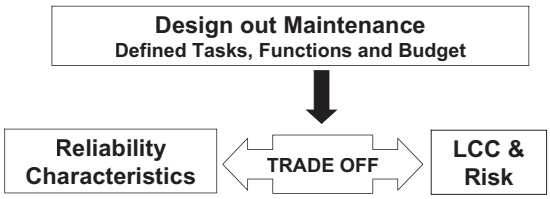

Figure 47.12. Designing out maintenance

However, if maintenance is to be designed out, one has to consider the reliability characteristics of the components and system *vis-à-vis* the task and function to be performed by them. In fact designing out maintenance is very much synonymous with designing for reliability. Besides the reliability characteristics of the component and system, one also has to consider the state of the art of the technology – a lack of available technology might not allow the elimination of maintenance need, or might make it too costly.

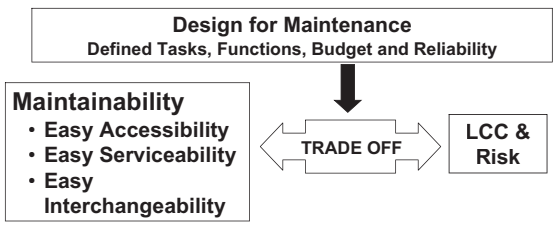

Figure 47.13. Designing for maintainability

There are also other factors to evaluate, such as product capacity, design alternatives, and payback of development costs, *etc.* There will always be a trade-off between these considerations. LCC analysis might be used to compare the design alternatives. The LCC analysis results have to be balanced against the market need, the customer's willingness to pay, customer preferences, *etc* [31].

In designing out maintenance, one has to use RAMS tools like FMECA (failure mode effects and criticality analysis), FTA (fault tree analysis), and risk analysis to arrive at the best LCC alternative. If the life cycle cost of *designing out maintenance* is higher compared to the alternative *designing for maintenance*, then we should naturally prefer the latter. The objectives of maintainability analysis are to reduce the product maintenance time and cost, and to determine labour and other related costs by using maintainability data to estimate item availability. The results should be reduced downtime, more efficient restoration of the product to an operating condition, and a maximization of operational readiness. If the reliability is too low, maintainability issues such as accessibility to parts that need to be maintained, and the serviceability and interchange ability of parts and systems have to be considered [29], [32]. Warranty and the life span are also issues to be evaluated.

Often it is not possible to design out maintenance because of a lack of technology, and one ends up trying to balance reliability, cost, and availability. Other ways to reduce the future maintenance need are to reduce the capacity, to substitute/eliminate the weak functions, or to replace weak components with ones that are more robust. If one allows the system/component to fail due to various limitations, then one needs to make provision for easy and quick repair/replacement. Thus, when designing for maintenance, one will first have to examine the reliability characteristics, and thereafter decide the maintainability characteristics. Both R and M are traded off to meet the design requirement. LCC analysis, in combination with risk analysis methods, could be a viable tool for evaluating these issues [33], [34].

47.7.3.1 Design for Data Collection, Diagnostics, Prognostics, Internet Applications, etc.

As products become more complex, failures and faults become harder and more time-consuming to diagnose. The designer's goal with respect to design for diagnosability is to facilitate the process of determining the parameters that are not in the designated state. Once the parameters that are not in the intended state are isolated, a repair action can take place to return the parameters to the design state. Automated sensor-based diagnostics systems have been the focus in research on diagnostics in mechanical systems [7].

47.8 Condition Monitoring and Condition-based Maintenance Strategy

A closer look at recent advances in maintenance in different parts of the world suggests that most companies are increasingly using some type of condition monitoring device on their critical units. Most equipment manufacturers have developed some form of condition monitoring device in close cooperation with the users of the equipment. Usually in such systems, the performance data from the machine is collected automatically. The collected data is analyzed either by using professional software or manually to extract information from the data. By the judicious use of information, new knowledge of system health is generated, which provides a basis for decision making in maintenance (Figure 47.14).

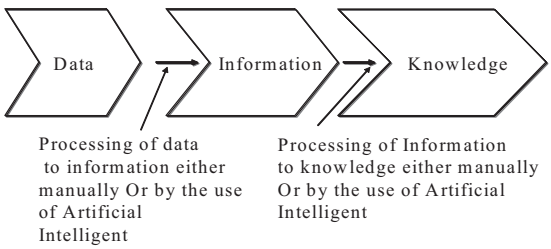

Figure 47.14. Processing of raw data into useful information and knowledge

A close examination of the development trends in condition monitoring technologies clearly shows that the focus has shifted from fault diagnostics to prognostics. In fact, equipment users are demanding zero breakdowns during operation and production, leading to more focus on prognostics technologies. This trend has stimulated R and D in the field of sensor technology and also in the area of future and emerging technology. Today operators are demanding production systems with a self-healing and self-maintaining ICT infrastructure. The intelligent application of a prognostics model can detect failures before they occur.

Currently many suppliers are offering so-called "expert" systems for fault diagnosis and prognosis. At present, these expert systems are still essentially rule-based systems, and like all rule-based systems, the results are only as good as the rules that have been established within the system. The reality is that these rule-based expert systems are still significantly weaker than even a moderately experienced maintenance engineer or analyst in identifying and diagnosing faults. Nevertheless, an imperative, if smart sensor technology is to work, and if widespread on-line vibration monitoring is to proliferate, is the development of better and more accurate "expert" software. Further advances can be made through the use of fuzzy logic and neural network processes in condition monitoring software.

47.8.1 Sensor to Sensor (S2S)

In expert systems the data is transmitted from sensor to sensor at the plant and equipment level. Sensors are embedded in the system or subsystem for collecting data which is converted to the e-health information of the plant and machinery. This e-health information provides support for the management for monitoring and control of the productivity, besides correct decision making.

47.8.2 Sensor to Business (S2B)

Today researchers and companies are busy developing Web-enabled remote monitoring sensor-to-business device platforms for the remote monitoring and prognostics of diversified products

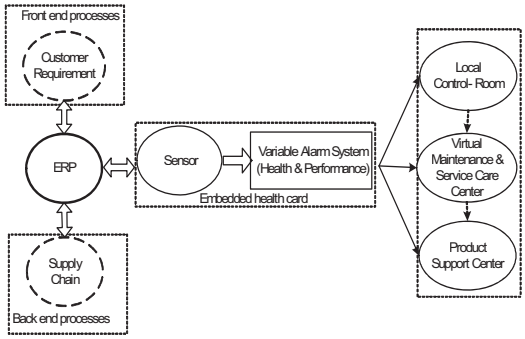

Figure 47.15. A schematic diagram of sensor to business communication

[6]. The rapid development of smart sensors and Web-enabled technologies is an important enabler for remote monitoring and prognostics. Figure 47.15 illustrates one sensor-to-business scenario where embedded sensors in machines and systems will only trigger alarms regarding impending failures after evaluating the total business risk using information and data from an enterprise resource planning (ERP) system.

Such sensors are smart and make provision for variable alarms depending on the evaluated business risk for each viable alternative for the situation encountered.

47.9 ICT Application in Maintenance: e-Maintenance 24-7

With the emergence of intelligent and smart sensors to measure and monitor the health state of components and the implementation of information and communication technologies (ICT), the conceptualization and implementation of e-Maintenance are becoming a reality. e-Maintenance facilitates decision making in real time by monitoring plant and systems health and its behaviour in real time, by benchmarking the status against the specified standards and by evaluating the associated business risks with various alternatives at hand, using embedded intelligent sensors and internet-based technology. To benchmark the health state and the performance characteristics, the experts invariably envision the generation and implementation of different types of performance trend charts and indicators when making decisions in maintenance. Although e-Maintenance shows a great deal of promise, the seamless integration of ICT into the industrial environment and setting remains a challenge. Understanding the requirements and constraints from the perspective of maintenance performance and ICT is essential for the effective implementation of such concepts. The related issues need to be addressed for the successful use of ICT and e-Maintenance for measuring maintenance performance.

The main problem for decision-making in the operation and maintenance process is the non-availability of relevant data and information. The recent application of information and communication technology (ICT) and other emerging technologies facilitates the easy and effective collection of data and information. E-condition monitoring, using intelligent health monitoring techniques like embedded intelligent sensors through a wireless communication system, is integrated with the maintenance process, to monitor and control the health status of plant and machinery. This is achieved by analyzing the data after it has been collected and effective decision making. The most important application of the measurement is the identification of opportunities to improve the state of existing equipment and plants before new investment or to promote improved supplier performance.

e-Maintenance provides the organization with intelligent tools to monitor and manage assets like machines and plant proactively through ICT. e-Maintenance creates a virtual knowledge centre consisting of users, technicians/experts and manufacturers, and specializing in operation and maintenance in the manufacturing, process and service industries. Moreover, e-Maintenance provides a holistic solution for the process industry with the objectives of reducing the overall costs and achieving savings in resources through maintenance performance indicators (MPIs). Condition monitoring techniques generally include one or several alarms that are triggered if a tolerance limit is exceeded or if a trend deviates from the expected values in time. References of the working points of signals are provided by knowledge-based systems and by comparison with a model of the system. These signals are acquired

by a sensor system [35]. An e-Maintenance solution consists of the virtual connectivity of:

- Plant/equipment fitted with intelligent and wireless sensors
- On-line (wireless) connectivity to out-sourcing contractors/stakeholders
- Operation/control platform of an online and wireless warning system
- Virtual maintenance team or expert support

Real-time connectivity amongst all the stake-holders concerned is a factor which facilitates the collection of system health and performance information. US companies have a substantial lead in the area of interoperable maintenance-oriented tools with MIMOSA (Machinery Information Management Open System Alliance), which has elaborated a set of standards [36]. In Europe, there are organizations like ITEA (Information Technology for European Advancement), which was established in 1999 and is conducting the PROTEUS project (ITEA 01011) to provide a fully integrated platform to support any broad e-Maintenance strategy [37]. Other e-Maintenance platforms which are trying to standardize are CASIP [38] and GEM@WORK [39].

47.9.1 The e-Maintenance Framework

Some of the existing e-Maintenance solutions provide server-based software and equipment-embedded internet interface devices (health management cards) for condition monitoring. These e-Maintenance solutions provide 24 x 7 (24 hours a day and 7 days a week) real-time monitoring, control and alerts at the operating centre. This type of system converts data into information that is available to all the stakeholders concerned for decision-making and predicting the performance condition of the plant and machinery on a real-time basis. This enables the system to make a match with the e-business and supply chain requirements. For example, once the supervisor knows the plant degradation condition and its related effects on material and inventory, then the delivery status can be planned and coordinated with greater speed to satisfy the customer.

A broad e-Maintenance framework indicating different stakeholders and their role is given in Figure 47.16. A stakeholder is a party having a right, share or claim in a system or in its possession of characteristics that meet that party's needs and expectations [40]. In this framework, the internal stakeholders are, *e.g.*, the management, employees, and different groups or departments, and external stakeholders are the customers, suppliers, out-sourcing agencies and partners, regulating authorities, and virtual consultants/experts, *etc.* The health condition data of the plant/machinery is collected through the e-health card/intelligent embedded sensors and compared with the pre-specified MPI limits. Accordingly, once the warning or alarm level is reached, all the affected parties receive a signal telling them to have a look and take appropriate preventive/predictive action. The maintenance control centre (MCC) controls, monitors and coordinates all the maintenance activities in-house or through the on-line help of the experts and virtual repair teams.

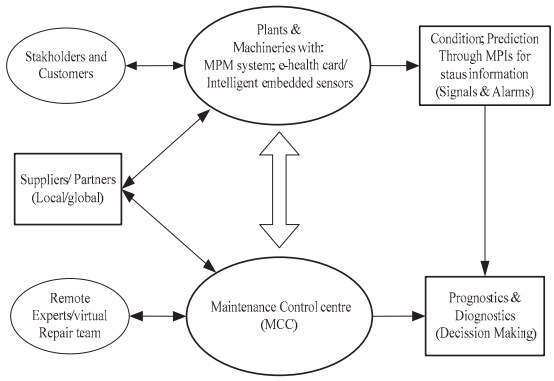

Figure 47.16. e-Maintenance framework (MPM –maintenance performance measurement, MPIs – maintenance performance indicators)

The suppliers or the outsourcing partners are also part of this e-Maintenance network and provide real-time support as and when required. Since the customers and other stakeholders are receiving real-time information and support as well, the e-Maintenance framework can take care of all the stakeholders. As can be seen, e-Maintenance creates a virtual knowledge centre consisting of users, technicians/experts and manufacturers, and specializing in operation and maintenance. E-Maintenance can provide a holistic solution for the

process industry with the objectives of reducing the overall costs and achieving savings in resources through MPIs like OEE and ROMI, *etc.* The problem today in a plant health management system is the existing information islands, *i.e.,* the different specialized systems within an organization speaking a different data and information language.

Maintenance has come a long way from the mechatronics to the infotronics stage. Adopting the emerging condition-based component degradation and monitoring system, integrated with an appropriate e-Maintenance model, organizations can achieve effective maintenance monitoring and control through measuring maintenance performance. Managing varieties of condition monitoring information demands effective methods in order to achieve the desired maintenance performance. With the development and emergence of intelligent e-Maintenance in the manufacturing and process industries, the objective of managing the maintenance information system is to convert the field data into useful information, so that decisions aiming to achieve the desired maintenance performance can be made on-line and/or remotely through wireless communication.

However, various constraints and challenges are to be resolved, as is appropriate to the different organizations, prior to the e-Maintenance system's adoption and implementation. The e-Maintenance real-time measuring system can act as a performance driver and help the organizations to know the plant/equipment health state and take prognostic action well in advance. This integrated approach of the e-Maintenance system, using ICT for measuring maintenance performance, can support and facilitate the organization in achieving transparency and good corporate governance, while taking care of the health, safety (accident prevention), economic, and environmental issues.

47.10 Conclusions

In this chapter the author has focused on the application of and future trends in ICT and e-Maintenance, besides purchasing the maintenance function as a functional product. It is essential that the engineers, managers and researchers involved in the operation and maintenance of systems are aware of the development of these trends in technology and management, so as to update their know how and keep pace with the technology and global competition.

Maintenance Models and Optimization

Lirong Cui

School of Management and Economics,
Beijing Institute of Technology, Beijing, 100081, P.R. China

Abstract: In this chapter, maintenance models and policies, optimal problems, and related techniques are summarized, based on two recent survey papers and the latest research papers. The summary is done in terms of classification of the discussed problems, but some important ones are emphasized in detail. Finally, future developments and some new trends in the subject of maintenance are presented. The use effectiveness of a system depends not only on its reliability but also on maintainability, which makes the products or systems more competitive. In this chapter, we shall give a review for maintenance models and their optimization.

48.1 Introduction

Nowadays many systems, such as production lines, weapon equipment, nuclear power stations, devices, vehicles, aircraft, *etc*., have become more and more complex. The costs of their usage are also getting even higher than before. Maintenance has to be carried out in order to keep these systems' performance close to the level of the original design. Most systems used in practice are subject to deterioration with usage and age. For those deteriorated systems, maintenance, such as monitoring, repairs, and replacements, can result in extending their usage lifetimes and keeping the quality of operations, reducing the cost of operations and preventing the occurrence of system failures. Thus the study of maintenance has become more interesting over the past decades.

The subject of maintenance has been widely studied over the past several decades, and it is still an interesting topic because of its importance and usefulness. Maintenance models are the basis of any maintenance quantitative analysis, which can be used to analyze and evaluate the performances of systems. There has been a lot of literature on research into maintenance problems so far. Several scholars have published survey or review papers to summarize maintenance research results. In this chapter, in order to present some new points of view on maintenance models and their optimization, the author will focus more on recent research papers on maintenance and two recent review papers, one by Wang [53] and another by Dekker *et al*. [18].

The aims of the chapter are to survey the important research on maintenance problems, including maintenance models, maintenance polices, maintenance optimization, and others. Based on those and the author's point of view, the chapter will point out some new trends in the subject.

In practice, maintenance is divided into two major classes: one is so-called corrective maintenance (CM), the other preventive maintenance (PM). Corrective maintenance aims to restore the system to a specified condition when the system fails. Preventive maintenance aims to retain or restore the system in a specified condition when the system is operating. Here maintenance will be a general term and may represent either corrective maintenance or preventive maintenance. In this chapter, many terms used in the subject of maintenance are well known and are not here defined, otherwise they are defined before they are used.

Maintenance models are the basis of any maintenance quantitative analysis, so first let us look at which factors will affect the maintenance models. The following ten factors are often discussed, which distinguish the maintenance models in essential.

1. Maintenance polices: for example, age replacement, block replacement, failure limit, *etc*.;
2. System structures: for example, series structure, parallel structure, *k*-out-of-*n* structure, *etc*.;
3. Maintenance degree: for example, perfect maintenance, imperfect maintenance, minimal maintenance, *etc*.;
4. Optimization criteria: for example, minimize cost rate, maximize availability, maximize reliability, *etc*.;
5. Distributions of components: for example, exponential distribution, Weibull distributions, gamma distributions, *etc*.;
6. Shut-off rules: for example, for multi-unit systems, when some units fail, some other units may continue to operate or be in states of suspended animation with the system down—a different shut-off rule results in different availability;
7. System information: for example, perfect, imperfect, continuous, inspection and monitoring, *etc*.;
8. Model types: for example, continuous and discrete;
9. Maintenance action distributions: for example, exponential distribution, Weibull distributions, phase-type distribution, *etc*.; and
10. Other assumptions: for example, independence or dependence among distributions or factors.

Systems we shall discuss in this chapter consist of units (components), which may be of two kinds: single-unit systems and multi-unit systems. If a system can be maintained we call it a repairable system. We assume that any system discussed in the chapter has only two possible kinds of states: working state and failure state: this applies to the components of the system as well. The maintenance indexes for the system are usually as follows,

1. *Availability:* There are several kinds of availability indexes. For example,

2. *Point availability:*

$A(t) =$

$P\{$*the system is in a working state at time* $t\}$.'

Limit availability:

$$A = \lim_{t\to\infty} A(t)$$
$$= \lim_{t\to\infty} P\{\text{the system is in a working state at time } t\},$$

if the limit exists,

Average availability over (t_1, t_2):

$$A_{(t_1,t_2)} = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} A(u)du \text{ , and}$$

Limit average availability:

$$A_{AV\infty} = \lim_{t\to\infty}\frac{1}{t}\int_0^t A(u)du,$$

if the limit exists.

3. *Reliability:* Several indexes have been used to describe the system reliability related performances. For example, *repairable system reliability:*

$R(t) = P\{$*the system never fails before time* $t\}$.

Mean time to first failure MTTFF

Mean time to failure MTTF
Mean up time MUT
Mean down time MDT
Mean time between failures MTBF

4. *Capacity of repair:* How many repairmen or devices can be used in the repairable system? In general, the following indexes are used:
   Pointwise busy probability of repairmen:
   $B(t) = P\{\text{the repairmen or devices are busy at time } t\}$,
   Steady-state busy probability of repairmen:
   $B = \lim_{t\to\infty} B(t)$
   $= P\{\text{the repairmen or devices are busy at time } t\}$,
   if the limit exists.
   Mean time to repair: MTTR.

5. *Failure frequency:* This reflects the frequency of failures occurring in the repairable systems, which can be depicted by the following indexes:
   The average number of failures occurring in the time interval $(0,t]$, :
   $M_i(t) = E\{N(t) \mid X(0) = i\}$,
   Pointwise failure frequency:
   $$m_i(t) = \frac{d}{dt} M_i(t), \text{ , and}$$
   Steady-state failure frequency:
   $$m_i = \lim_{t\to\infty} m_i(t) = \lim_{t\to\infty} \frac{d}{dt} M_i(t),$$
   if the limit exists.

   Here, $N(t)$ is the number of failures of the system occurring in the time interval, and $\{X(t), t \geq 0\}$ is a stochastic process describing the repairable system.

The remainder of this chapter is organized as follows. Section 48.2 reviews the previous important contributions to the subject of maintenance. In this chapter the author mainly focuses on recent papers and the two recent survey papers mentioned above. In Section 48.3, maintenance models are presented and summarized in some categories for both single-unit and multi-unit systems. Section 48.4 presents the maintenance policies in terms of classes. Section 48.5 reports on maintenance optimization for various categories of maintenance problems; also techniques of optimization are discussed. In Section 48.6 other issues related to the subject of maintenance are considered. Section 48.7 discusses future developments and new trends, based on a literature survey and the author's point of view.

48.2 Previous Contributions

During the past several years, the subject of maintenance has continued to be a topic of growing interest. For example, some papers appeared in the journal IEEE Transactions on Reliability. Zhang [56, 57] uses a geometric process to describe a deteriorating simple repairable system with two and three states, respectively, and then the optimal policies are given in terms of the minimal average cost. Bunea and Bedford [9] consider the effect of model uncertainty on maintenance optimization; they point out that the optimal replacement interval and optimal replacement cost can be dramatically non-optimal when the wrong model is used. Cui *et al.* [16] study optimal maintenance problems to maximize the expected system lifetime under fixed resources when repair actions can only be selected between perfect and minimal repairs. Perez-Ocon and Montoro-Cazorla [37] consider a repairable system with phase-type distributions for lifetime of system and repair times. Cassady *et al*. [10] use the simulation method to analyze a generic model of system availability under imperfect maintenance, in which Kijima's first virtual age model is used. Attardi and Pulcini [3] discuss statistical inference on a repairable model with bounded failure intensity. Wang and Trivedi [52] study the computation for steady-state mean time to failure for non-coherent repairable systems. Wu and Clements-Croome [55] study optimal maintenance policies under different operational schedules, in which three models are presented and cost functions are more developed. Zheng *et al.* [59] consider single-unit Markov repairable models with repair time omission, in which some ideas

result from the modeling of ion channels. Jiang *et al.* [27] give a review of the assessment of repairable-system reliability using proportional intensity models.

Some papers appeared in the European Journal of Operational Research. For example, Chien and Sheu [13, 14] discuss an extended optimal age-replacement policy with minimal repair of a system subject to shocks. Smidt-Destombes *et al.* [47] study the system availability which depends on maintenance policy, spare part inventory level, repair capacity and repair job priority setting. Jaturonnatee *et al* [26] consider optimal preventive maintenance of leased equipment with corrective minimal repairs, in which the optimal parameters of preventive maintenance policy are given. Grigoriev *et al.* [22] deal with a scheduling maintenance service system to model and solve its periodic maintenance problem. Zhang [58] corrects Sheu's [46] wrong statement for a bivariate optimal replacement policy for a repairable system. Quan *et al* [41] use an evolutionary algorithm to discuss the multi-objective preventive maintenance schedules. Crowder and Lawless [15] discuss preventive maintenance using wear process to describe system degradation. Bai and Pham [4] present some results for multi-component systems on renewable full-service warranty policies. Tang and Lam [50] propose a δ-shock maintenance model for a deteriorating system, in which it is assumed that shocks arrive according to a renewal process and the inter-arrival times of shocks have a Weibull or gamma distribution. The threshold values follow an increasing geometric process. In this model, attention is paid to the "frequency" of shocks rather than the accumulated amount of damage of shocks, which is different from other shock models. Ribeiro *et al.* [43] study the joint optimization of maintenance and buffer size in a manufacturing system using a mixed integer linear programming model. Glazebrook *et al* [21] discuss maintenance policy for a team of R repairmen and M non-identical machines by using a Markov decision process. Liao *et al.* [33] study the condition-based maintenance policies in which monitoring is performed continuously for a degrading system. Chien *et al.* [13, 14] consider an extended optimal replacement model of systems subject to shocks, in which the probability of a type II failure is permitted to depend on the number of shocks since the last replacement. Wang and Pham [54] study the availability and maintenance of series systems subject to imperfect repair and in which the failures and repairs are correlated. Vaughan [51] addresses inventory policy for spare parts under failure replacement and preventive maintenance. Juang and Anderson [28] consider a Bayesian theoretic approach to determine an optimal adaptive maintenance policy with minimal repair, in which some statistical inferences are given for maintenance problems. Apeland and Scarf [1] use the fully subjective approach to modeling inspection maintenance. Hsieh and Chiu [25] discuss the optimal maintenance policy for a multi-state deteriorating standby system, in which the optimal number of standby components required in the system is given. Bloch-Mercier [8] proposes a preventive maintenance policy with sequential checking procedure for a Markov deteriorating system, in which the deteriorating degree is measured with a finite discrete scale; repairs follow general distributions, and failures are instantaneously detected.

In the journal Reliability Engineering and System Safety there also are some papers related to maintenance. For example, Qu *et al.* [40] discuss the problems of enhanced diagnostic certainty using information entropy theory. Kim *et al.* [30] deal with the warranty and discrete preventive maintenance problem, in which the model determines when preventive maintenance actions should be carried out at discrete time instants over the warranty period. Castro and Alfa [11] consider two models to describe maintenance policy based on the lifetime of a system, in which the phase type distribution is used as the system lifetime distribution. Perez-Ocon and Montoro-Cazorla [38] discuss the cold standby repairable system with operational and repair times also following phase type distributions. Doyen and Gaudoin [19] consider two models for imperfect repair of systems, in which the repair effects are described by failure intensity and system virtual age. Smidt-Destombes *et al*. [48] study the interaction between preventive maintenance policy, spare part

inventories and repair capacity for a *k*-out-of-*n* system with exponentially distributed component lifetimes and repair times. Moustaf *et al* [35] deal with a maintenance model for a multi-state semi-Markovian deteriorating system, in which the control limit policy and the policy-iteration algorithm are used to find optimal maintenance policies that minimize the expected long-run cost rate of the system. Pongpech and Murthy [39] study the leased equipment periodic preventive maintenance policy, in which the tradeoff between penalty and maintenance costs is achieved. Rajpal *et al.* [42] propose an artificial neural network for modeling the reliability, availability, and maintainability of a repairable system.

Of course, in addition to the papers appearing in the three main reliability journals, many articles related to the subject of maintenance have been published. Because of the limitation of contents of this section, they can not be listed totally, even some papers that appeared in the three journals. The author will try his best to consider these contributions, including those important ones before 2002, in the next sections. In fact, the maintenance problems discussed in published papers are mostly related to the ten factors stated in Section 48.1, the different factors considered result in the different papers.

48.3 Maintenance Models

Since there have been numerous papers and books on maintenance models in the past decades, in this chapter the author will divide them into several categories in order to describe them clearly and concisely. At the same time, some very important maintenance models will be emphasized as typical representations. In this chapter, maintenance models are classified in terms of the following categories:

1. Time models,
2. Degradation degree models,
3. Cost models,
4. Shock models,
5. Inspection models.
6. Reliability/availability models
7. Warranty models.

The systems related to maintenance problems consist of a single unit or multi-units. The single-unit system is a special case of a multi-unit system, but there exist some different aspects for repairable systems. The maintenance models for these systems have some different points shown in Table 48.1.

Table 48.1. Different points for both systems

System No	Single-unit System	Multi-unit System
1	Non-structure	Structure
2	Without shut-off rules	Shut-off rules
3	Non-dependence, or failure dependence or block/opportunistic policies, exists	Dependence, Interactions—some dependences can be assumed among units (components)
4	One repair facility	One or more repair facilities
5	Non-repair priority	Some repair priority may exist
6	Non-detecting	Sometimes, need to detect which component fails

In the following, the models classified above are detailed, but single-unit and multi-unit repairable systems will not be distinguished.

1. *Time model*. In this model some units of the repairable system are repaired or replaced at a specified time instant, such as the so-called age-dependence model including PM and CM, the periodic repair model, *etc*. The characteristic of this kind of model is a specified repair time instant. In this model, the repair effects are used extensively, in which the concepts of minimal, imperfect and perfect repair are employed. The effects of maintenance can

be described by the lifetime (such as virtual age), reliability, or failure rate of the system or component. The optimization of problems based on the time model is to find optimal repair time instants to minimize some objective function, usually on cost concerns, or maximize some reliability/ availability function. A typical paper on this kind of model is by Barlow and Hunter [5]. Later, many extensions have been done on this kind of model, however, these extensions are with two decision variables at most for optimization.

2. *Degradation degree models*. In this model units can be repaired or replaced at a predetermined system or component deteriorating level, such as the so-called failure limit model, failure number limit model, *etc*. As mentioned before, the degree of deterioration can be described by the failure rate, reliability, age or virtual age, accumulated damage, *etc*. The idea of the model is very natural, because when the system deteriorates, it should be repaired in order to maintain the system reliability or availability. The various measurements of degree of deterioration used result in different detailed models, but they should be equivalent to each other in essence: for example, a predetermined failure rate corresponds to a predetermined age or virtual age, and *vice versa*. The difference is only in the measure of the degree of deterioration for these kinds of models, perhaps needing different efforts of computation and discussions on properties of the models. An early example of this kind of model was presented by Bergman [7].
3. *Cost models*. In this model the main focus is on maintenance costs, and the maintenance actions, strategies, and optimizations depend strongly upon the costs. For example, Seo and Ahn [44] build an artificial neural network with 24 product attributes as input layer nodes, two hidden layers with 20 and 18 nodes respectively, and one output layer node to describe maintenance costs. Other examples of this kind of model are regression models for maintenance related costs, which have appeared in many books. Although many maintenance models put some costs as optimal objective functions, the author does not want to classify them as cost models in general, because these models focus mainly on maintenance actions and strategies. Of course, the model classification depends on the purpose of discussion and any classification rules can be changed depending on the situation.
4. *Shock models*. In general, there are two ways to describe the rules of occurrences of failures for repairable systems. One is to assume that the lifetime(s) of system (components) have followed some distribution(s); another is to assume that the system (components) is (are) subject to shocks arriving according to some stochastic process. The second way has attracted more attention recently, because many practical situations can be suitably described by these assumptions. The shock models are formed this way. For example, Lam [32] introduces so-called 'geometric processes' to describe these phenomena. For another example, the physical damage measure process $\{X(t), t \geq 0\}$ is a compound process,

$$X_t = \sum_{i=1}^{N(t)} Y_i,$$

where $\{N(t), t \geq 0\}$ is a counting process and Y_i is the damage measure for the ith shock arriving for the system. This kind of model is usually more complicated in its mathematical description and manipulation.
5. *Inspection models*. To apply any maintenance actions we first need to find which component fails or decide how to know whether the repairable system operates or not. Inspection models focus on the inspection procedure, inspection method, inspection input, information from inspection, *etc*. The inspection factor in both theory and

practice is more important for maintenance actions and optimal strategy options. In general, there are two kinds of inspections: continuous and discrete inspections. For example, the classical failure (hazard) rate is defined as

$$\lambda(t) = \lim_{t\to\infty} \frac{1}{h} P\{T \in [t, t+h] \mid T > t\},$$

where T denotes the system lifetime. Arjas [2] proposed a so-called hazard rate process which describes a multi-unit system's failure rate. The process is defined as follows:

$$\Lambda_t = \lim_{t\to 0} \frac{1}{h} P\{T \in [t, t+h] \mid \{T > t\} \cap \mathcal{F}_t\}.$$

Where filtration is given by

$$\mathcal{F}_t = \sigma(T \le t, Z \le t, T_i \le t, i = 1, 2, \cdots, n),$$

and $T_i, 1 \le i \le n,$ are the unit failure times, n is the number of units, and Z is the occurrence time of a shock. He also defined (and referred to as "observed hazard rate"):

$$\Lambda_t^0 = \lim_{h\to 0} \frac{1}{h} P\{T \in [t, t+h] \mid \{T > t\} \cap \mathcal{F}_t^0\},$$

where the filtration $\mathcal{F}_t^0$ is determined by other observed information. Another example is Barros *et al*. [6] who study optimal replacement times using imperfect monitoring information. Inspection models can be extended in many ways, but perhaps the models become more and more complicated, which is inconvenient in theoretical analysis and practical use.

6. *Reliability/availability models*. In this model, the reliability or availability is found for repairable systems under some maintenance assumptions. The characteristic of the model is the focus on the system reliability or availability in most situations. This model is a basis for many maintenance optimization questions, and it has been studied a lot over the past decades. Research interest in this direction is still hot now. For example, Zheng *et al.* [57] establish some new maintenance models in which reliability and availability are mainly concerned, because people must pay more attention to reliability and availability for any new maintenance models. The author believes that this kind of model can be extended greatly, driven by practical situations and theoretical interest. Further examples are various virtual age models, in which the virtual age receives attention in order to track system reliability. Table 48.2 lists various models.
7. *Warranty models*. The model is built in terms of problems related to maintenance during a product warranty period. The research into this kind model has been greatly driven by practical situations, and it can be used in making practical product warranty policies. As Kim *et al.* [30] pointed out, the warranty period offered has been progressively getting longer. The warranty periods for cars have been changed from three months, one year, and three or five years since the thirties, sixties, and currently, respectively. Many maintenance actions can be carried out in order to reduce the costs of buyers and manufacturers, so that the related models must be studied more. For example, Murthy and Djamaludin [36] give a review on warranty literature over the period 1990–2001. Maintenance is one of most important factors in warranty study, and our warranty models focus on maintenance actions and strategies in the product warranty period instead of other warranty considerations.

The classification of maintenance models given above differs from that in the previous literature, and the maintenance models for single-unit and multi-unit systems are not partitioned on the basis of different points for the two systems.

Similar to other literature, Wang [53] lists the maintenance models for repairable systems in the following categories:

1. Age-dependent PM model,
2. Periodic PM model,

Table 48.2. Various virtual age models

Proposed by	Virtual age after repair $v(t_i+0)$	Notes
Kijima [29]	$v(t_{i-1})+\theta_i X_i$	θ_i —degree of repair
Kijima [29]	$\theta_i[v(t_{i-1})+X_i]$	X_i —lifetime during the ith operating phase
Stadje and Zuckerman [49]	$v(t_{i-1})+X_i-d$	d —between 0 and $v(t_{i-1})$
Finkestein [20]	$g(v(t_{i-1})+X_i)$	$g(\bullet)$ —general positive function
Guo and Love [24]	$(1-w_i)v(t_{i-1})+\theta_i X_i$	$h(\bullet)$, $\psi(\bullet)$, $q(\bullet)$ are positive functions
Dagpunar [17] Makis [34]	$f(v(t_{i-1}), X_i)$	
Guo *et al*. [23]	$h(\psi[v(t_{i-1})]+q(X_i))$	

3. Failure limit model,
4. Sequential PM model,
5. Repair limit model,
6. Distribution-free and semi-parametric model, and
7. Effects of repair model.

The classification of maintenance models may be done in many ways, but the criterion of better maintenance models is whether they can describe the practical situation correctly and be used conveniently. Each class of maintenance model has its own focus and characteristic, which are real points to be considered in both theory and practice.

48.4 Maintenance Policies

As mentioned before, the maintenance policy, *i.e.*, when and how to repair the failed system, is one of the important factors which affect the maintenance results. The meanings of terms for policy and strategy are the same as for maintenance problems in this chapter. Before classification, some important definitions need to be made. The repair action in general contains replacement and mending actions. The effects of repair for a failed system or components can be measured by the degree of repairs. The degree of repairs, denoted by θ, is between 0 and 1, and when $\theta=0$, it is called maximal repair or perfect repair, or replacement. When $\theta=1$, it is called minimal repair, *i.e.*, under minimal repair the failure rate after repair is the same as that just before failure. When $0<\theta<1$, it is called imperfect repair. Another important concept is so-called virtual age, which was first proposed by Kijima [29]. The maintenance policy (strategy) can be classified into the following classes. Of course, like maintenance models, the different classification standards result in different classes.

1. Time-dependent maintenance policy,
2. Degradation degree-dependent maintenance policy,
3. Mixed time and deteriorating degree dependent maintenance policy,
4. Detecting information-dependent maintenance policy,
5. Block maintenance policy,
6. Priority maintenance policy, and
7. Other maintenance policy.

In the following, the listed models above will be detailed according to their characteristic, advantages, and possible extension directions, *etc*.

1. *Time-dependent maintenance policy*. Under this policy, maintenance actions can be done at specified time instants; examples include age-dependent policy, periodic policy, sequential policy, *etc*. This policy has been studied more because of its intuitive and practical operation; on the other hand, it can be dealt with relatively easily in theory. It also may be extended to more than two time instants. For example, the maintenance action is done when the first, second, or third time-event happens, whichever occurs first. The detailed models may have more, but the simplest maintenance policies depend on a single time instant. This given time instant may be constant or a random variable. For example, the preventive maintenance time instant is given by

$$T = \begin{cases} X, & X \le t_0, \\ t_0, & X > t_0, \end{cases}$$

where t_0 is a predetermined time, and X is the lifetime of system. Thus, T is a random variable.

2. *Degradation degree-dependent maintenance policy*. Under this policy, the maintenance actions will be done at the time instant when the system degradation degree reaches a specified level. Examples include failure limit policy, repair limit policy, *etc*. This maintenance policy is very natural because when the deteriorating system becomes older or has accumulated more damage, maintenance actions should be carried out to rejuvenate the system. The threshold of degradation degree may be measured by the failure rate (hazard rate), reliability, age or virtual age, availability, number of failures, interval times of failures, *etc*. For example,

$$T = \inf_{t \ge 0} \{t : r(t) \ge r_0\},$$

is a time instant of maintenance action taken, where $r(t)$ is the failure rate of system and r_0 is a predetermined constant. In general, it is assumed that $r(t)$ is an increasing function in t.

3. *Mixed time and deteriorating degree dependent maintenance policy*. Under this policy, maintenance actions can be done at specified time instants or at the time instant when the system degradation degree reaches a specified level, whichever occurs first. For example, maintenance actions can be done at the following time instant T,

$$T = \min\{T_1, T_2\},$$

where

$$T_1 = \inf_{t \ge 0} \{t : r(t) \ge r_0\},$$

$$T_2 = XI_{\{X \le t_0\}} + t_0 I_{\{X > t\}}.$$

The characteristic of the policy is the combination of time dependent and degradation degree maintenance policies.

4. *Detecting information-dependent maintenance policy*. Under this policy, the maintenance action is carried out at a time instant which is determined in terms of detected information about the system. The information detected may be of various kinds, such as complete information or partial information. For example, for an imperfect monitored two-unit parallel system consisting of statistically dependent units, the preventive maintenance policy is determined by a stopping rule in which the observed failure rate is a stochastic process. For details see Barros *et al.* [6]. This policy may be extended more in the future, because it is based on observed information, which is more realistic.

5. *Block maintenance policy*. This policy specifies that the maintenance action will be done when more than two components are maintained together. Examples include group and opportunistic maintenance policies. Here the meaning of block is not necessarily a real block of physically adjacent components but may instead be any set of components, regardless of their physical constitution, which is convenient to treat together. Thus, the characteristic of the policy is to carry out maintenance actions together for several components, although the individual components may

receive different maintenance actions. For example, for a repairable parallel system consisting of five independent subsystems, the maintenance actions can be done at time

$$T = \min_{i \neq j \neq k} \max\{T_i, T_j, T_k\},$$
$$i, j, k \in \{1, 2, 3, 4, 5\},$$

where $T_1, T_2, \cdots, T_5$ are failure time instants for subsystems 1,2,…,5, respectively. The detailed maintenance actions are as follows, because of physical limitations such as the failed subsystem's temperature. The first and second failed subsystems are repaired, and the third failed subsystem is replaced. This policy is adopted perhaps because of costs, limitations of real situation, *etc*. The policy may be more applicable in real situations, because of dependence among costs, failures and other factors. Of course, the policy is just for multi-unit systems. Extensions of the policy may be done in terms of classes of units, relationship among costs, different mission phases, *etc*.

6. *Priority maintenance policy*. For multi-unit repairable systems, the repair facility may face several failed components at one time instant. Under this policy, it is specified which failed component should be repaired first, second, *etc*. That is, some components have priority to be treated in maintenance actions. For example, for a repairable consecutive-*k*-out-of-*n* system, the positions of failed components play important roles for maximizing the system availability, so that there necessarily exist some priority rules for this kind of repairable system. System performance, such as reliability or availability, may be improved greatly through such a policy. In fact, in any maintenance policy, some order of treatments for failed components exists, although in most situations people do not specify it explicitly. The policy may be extended to various priority rules like that in queuing theory and practical operation sequences.
7. *Other maintenance policies*. In addition to the policies mentioned above, here we classify the remaining maintenance policies as "other maintenance policy". In fact, many policies have appeared in the literature, which are driven by both practical applications and theoretic researches. Since maintenance policies involve many factors, which can be combined in a variety of ways, numerous maintenance policies are possible, although the class of maintenance policies may not increase greatly. On the other hand, a maintenance policy can be classified using a variety of criteria, such as continuous maintenance policy and discrete maintenance policy, PM policy and CM policy, replacement maintenance policy and imperfect repair maintenance policy, *etc*.

For most maintenance policies, there exist optimal maintenance policies, which maximize the system reliability and availability or minimize the failure frequency and downtime, maintenance costs, *etc*. It is clear that the optimal maintenance policy depends on the objective function, *i.e.*, the system improvement objectives determine the optimal maintenance policy parameters.

Figure 48.1 shows various factors about which a maintenance policy should mainly be concerned.

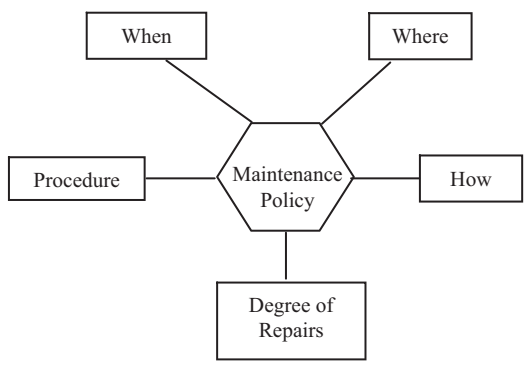

Figure 48.1. Various main factors concerned in a maintenance policy

48.5 Maintenance Optimization and Techniques

When various factors including maintenance policy and various assumptions which determine the maintenance models are defined, a maintenance model may be established after some efforts. Once a maintenance model is known, people can work on it in a mathematical way, *i.e.*, to find solutions and explain the real physical problems in terms of the solutions. In maintenance problems, it is usual to do some optimizations, and before finding the optimal solutions, we need to know the objective functions. The objective functions are usually determined by the maintenance purposes. Generally speaking, there are two kinds of optimization function: single-objective function and multi-objective functions. In addition, before finding optimal solutions, all constraints need to be considered, and then a set of constraint equations is built. In the literature, many objective functions are related to maintenance costs, such as the total average cost per time unit, the system reliability measures, *etc*.

For example, the following problem (refer to Kuo *et al.* [31], p. 333) is a single-objective function without constraints, which is an optimal planned-maintenance policy to be determined for preventive replacement of systems, the objective function is the replacement cost-rate. That is, find

$$\min_{t_p} C(t_p) = \frac{C_{pr}R(t_p) + C_{fr}(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)},$$

where

$C(t_p)$ --- *total expected replacement cost-rate*,

C_{pr} --- *cost of a preventive replacement*,

C_{fr} --- *cost of a failure replacement*,

$M(t_p)$ --- *mean-life during cycle* $[= \int_0^{t_p} R(t)dt]$,

$R(x)$ --- *reliability function* $[= 1 - F(x)]$,

t_{dpr} --- *mean down time for preventive replacement*,

t_{dfr} --- *mean down time for failure replacement*,

and

t_p --- *preventive replacement age.*

The optimal times t_p and t_p^* are found by minimizing $C(t_p)$ by the usual calculus method.

A problem involving a single-objective function with constraints is as follows. Find

$$\min_{t_p} C(t_p) = \frac{C_{pr}R(t_p) + C_{fr}(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)},$$

subject to

$$A(t_p) = \frac{\text{exp}ected\ operating\ time\ in\ the\ cycle}{\text{exp}ected\ cycle} = \frac{M(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)} \geq A_0.$$

where A_0 is the required minimal availability. For another example, Chelbi and Rezg [12] consider a repairable production unit subject to random failures, in which the buffer stock and optimal maintenance time are given for minimizing the total average cost per time unit and satisfying the availability constraint.

Similarly, a problem involving a multi-objective function without constraints, for example, is as follows. Find

$$\min_{t_p} C(t_p) = \frac{C_{pr}R(t_p) + C_{fr}(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)},$$

$$\max_{t_p} A(t_p) = \frac{M(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)}.$$

A problem involving a multi-objective functions with constraints, for example, is as follows. Find

$$\min_{t_p} C(t_p) = \frac{C_{pr}R(t_p) + C_{fr}(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)},$$

$$\max\ R(x,h) = \frac{R(x+h)}{R(x)}.$$

subject to

$$A(t_p) = \frac{M(t_p)}{M(t_p) + t_{dpr}R(t_p) + t_{dfr}F(t_p)} \geq A_0.$$

where $R(x,h)$ is mission reliability, *i.e.*, the probability that a system finishes a mission of length h which begins at age x.

The techniques for optimization in maintenance problems have received some attention. In general, there are two ways to find the optimal solutions. One way is by metaheuristic algorithms, such as genetic algorithms, tabu search, and simulated annealing techniques. Here the author wants to emphasize the genetic algorithm which has been used more recently. For example, in 2006, the journal Reliability Engineering and System Safety published a special issue on the applications of genetic algorithms in reliability problems. There is no doubt that genetic algorithms can be used in optimal maintenance problems. Another method uses exact algorithms, such as dynamic programming, implicit enumeration, lexicographic search procedure, integer programming, mixed integer programming, nonlinear programming techniques, *etc*. Even though many optimal techniques have been known, new optimal techniques are still developed, because each individual optimal problem has its own characteristics. Some optimal techniques can be proposed in terms of some individual special characteristic. On the other hand, we can list the optimal techniques in another way as follows:

1. Conventional approaches such as the usual calculus method,
2. Simulation approaches,
3. Algorithms,
4. Artificial neural networks,
5. Programming methods such as linear programming,
6. Fuzzy theory approaches.

When the objective and constraints of a practical problem are precisely known, then the model can be built in a precise manner. However, in most real-life situations, the objectives and the constraints are not precisely defined; sometimes the resource constraints are not very rigid. Under such imprecise conditions, the classical optimization approach does not serve much purpose. The fuzzy approach is very useful in dealing with qualitative statements, vague objectives, and imprecise information. For details on this approach, one can refer to Kuo *et al.* [31].

To summarize the section: if the optimal problem has been built, then it becomes an optimal mathematical problem; one can find solutions to the problem by using any optimal technique. Sometimes, for optimal problems involving multi-objective functions, one needs to understand the meaning of the optimal solutions, because these so-called optimal solutions differ from those of the optimal problems involving a single-objective function.

48.6 Maintenance Miscellanea

Maintenance models involve many factors. Any maintenance model is established under a particular environment or situation. In this section, we will discuss practical factors which may affect the maintenance model, such as maintenance management system, spares, maintenance software, maintenance costs, *etc*. We will also consider some other evaluation methods such as stochastic order for stochastic behaviors, optimal criterion, *etc*.

Now in many practical situations, the ERP (enterprise resource planning) system has been more and more used. As an important resource, the subject of maintenance can be included in the ERP system, or some software modules for maintenance models may be integrated into the ERP system. The decision-making on maintenance matters may be greatly affected by the ERP system. On the other hand, some new developments in the subject of maintenance can be input the ERP system, which may be more useful in practice. In a broad sense, the maintenance management system has more and more effect on maintenance decisions.

For inventory spares, it is no doubt that the quantity of spares and inventory allocation of spares have more effect on maintenance models if the models contain these factors. In fact, there is a great deal of research in the literature in this direction, and many companies have their own way to specify the related factors of spares. The study of spares still creates challenges in theory and practice in order to fit a variety of practical situations.

The cost factor for maintenance has been widely studied. Most maintenance related literature involves cost, but it seems that few maintenance models can be universal or fit many practical situations; they are more of theoretical interest. The author believes that more practical maintenance models related to costs need to be developed, because it is not that maintenance cost models are too complicated, rather they are too simple to describe real world situations properly. For example, different maintenance phases need different cost input intensities: changes in the optimal objective functions result in variable optimal cost solutions. Such examples can be given easily.

Comprehensive maintenance models need to consider more factors, which may increase the complexity of the models, but in the era of information this difficulty can be overcome. In fact, the use of maintenance models in most situations needs the help of computer programming, which is at least one of the reasons for the existence of much maintenance software in today's market.

Besides the factors mentioned above, we definitely need to consider some evaluation factors/methods which are not studied in detail in the previous sections.

In maintenance models, some indexes, such as the number of failures, age or virtual age, *etc.*, have random properties; they may be random variables or stochastic processes. Sometimes a comparison is needed among the various cases. For example,

$$N_1(t) \geq_{st} N_2(t), \text{ or } T_n^A \geq_{LR} T_n^B,$$

where $N_i(t)$ $(i = 1, 2)$ is the number of failures by time t for the ith maintenance policy. T_n^A *and* T_n^B are the virtual ages of a system under maintenance policies A and B, respectively, after the nth maintenance action.

The above inequalities can provide some information which the conventional comparison methods cannot. The stochastic order is a most useful approach to this kind of comparison, bringing new insight to understand the maintenance policy comparison. In addition, sometimes evaluation of the (joint) distribution function is difficult in maintenance models. We can study its stochastic properties, such as monotonicity, through the stochastic order. Although stochastic behaviors are sometimes studied by a distribution function and their characteristic values, the stochastic order is another effective approach. The stochastic order has many definitions. In general, the larger stochastic order, the hazard rate order, and the likelihood ratio order are used more often—one can refer to the book of Shaked and Shanthikumar [45]. The applications of stochastic order in maintenance models can provide more useful information for the related decision-making problems.

Multiple optimal criteria in maintenance models, for example, such as the joint consideration of cost, reliability and availability, can be studied more, which also makes the problems more complicated. Sometimes, some of the objective functions, for example g_i, g_j, g_k, should be maximized, whereas others, for example g_l, g_m, should be minimized. Then they can be put together as maximal (minimal) objective functions of the form

$$\max(g_i, g_j, g_k, -g_l, -g_m), \text{ or}$$

$$\min(-g_i, -g_j, -g_k, g_l, g_m).$$

Under the unified form, optimizing techniques such as algorithms can be used to find solutions. In this case, the solutions can be divided into four classes as follows.

1. *Optimal (positive-ideal) solution:* simultaneously results in the optimal value of each objective function,
2. *Nondominated (Pareto-optimal) solution:* denotes a noninferior solution and an efficient solution,
3. *Preferred solution:* a nondominated solution chosen by the decision maker through some additional criteria, and
4. *Satisfying solution:* a solution in a reduced subset of the feasible set.

Although several factors related to maintenance models have been discussed, there are some elements we have not mentioned or recognized in practical maintenance problems. The more factors

that are involved in maintenance models, the more applicable the models are, although the complexity, including finding the optimal solutions and description of models, becomes higher. The ideal maintenance model should be at least practically applicable and easily dealt with in mathematical sense. However, what constitutes an ideal maintenance model is a very debatable issue.

48.7 Future Developments

Maintenance models and their related problems have been discussed or reviewed in this chapter. As mentioned previously, the topic receives much attention because it has wide scope for research and study. On the other hand, maintenance models are the basis of any maintenance research. The classification of maintenance models made by the author in this chapter is different from that which has appeared in the literature, because each classification has its own criterion to distinguish the maintenance models. The author believes that some of the most important future developments in the subject of maintenance should be in the following directions.

1. *New models:* New maintenance models, such as those involving probability and fuzzy or vague set theory, can be developed to meet various real situations and extend the range of theoretical applications. On the other hand, as high-tech product applications, such as IC manufacture systems and bio-product manufacturing devices, become widespread, the new situations will bring some new maintenance policies and models naturally. The invention of new maintenance models can extend the old models and stimulate new maintenance techniques.
2. *New processes:* The description of lifetimes of components or a system is an important factor in considering maintenance problems. New distributions or new stochastic processes are definitely needed to meet this requirement. For example, shock models have been paid more attention recently; some new stochastic processes, such as aggregated stochastic processes, are presented in repairable system analysis. It is no doubt that new stochastic processes or newly extended stochastic processes are bringing some new light on the subject of maintenance. Here the author wants to mention that the hazard rate process (for example, Arjas [2]) has provided new understanding for repairable systems in terms of different information levels. This direction may be an interesting future development, although it may need good probability and stochastic process knowledge. Martingale techniques in particular may be used more in this approach.
3. *New techniques/approaches:* The techniques for establishing models and optimization of models are driven by the development of new maintenance models and problems. As new maintenance models are invented, the conventional approaches may not meet the changed situations, and new techniques will be proposed naturally. On the other hand, techniques in other disciplines may be transferred into the subject of maintenance in order to solve maintenance problems, including establishing new models and finding the optimal solutions for new maintenance problems. Here the author emphasizes that some new algorithms may be developed for finding quick solutions and easy handling.
4. *New optimization criteria:* The same problem can obtain totally different optimal solutions under different optimal criteria. New optimal criteria will definitely be developed in the future. Because the targets people aspire are changing, the criteria of problems need to be adjusted; thus new optimal criteria, especially multiple criteria, will be born naturally. In some situations, the optimal criteria are in contradiction with each other, which gives rise to the need to develop new so-called optimal or satisfying solutions. Meta-heuristic algorithms may be developed

further, although in general they cannot guarantee that the real optimal solutions will be obtained. In fact, heuristic algorithms are more versatile, which can fit more problems in various optimal criteria.

5. *Statistical inferences on repairable systems:* So far most research work on the subject of maintenance is on the application of probability and stochastic processes to maintenance problems, with little work on statistical inference on maintenance problems. In practice, maintenance systems have a lot of operation and repair data, which should be used more to analyze the maintenance systems. The author believes that statistical inference work has a large scope for development. Statistical work can correct maintenance models and analyze the properties of maintenance models, such as robustness, goodness-of-fit test, and model selection based on real data. This approach may need much more relation with computer simulation in the subject of maintenance. The difficulty of applying statistical methods may be one of the reasons that statistical inference work on maintenance has not been developed more, so that computer simulation may be a powerful approach in dealing with the data. In theory, any stochastic environment or situation can be simulated properly by computer. Of course, the simulation method can not give a precise solution, but a reasonably accurate one will usually be sufficient—better an approximate answer to the right question than an exact answer to the wrong one!
6. *Analysis of maintenance models:* Thousands of maintenance models have been proposed, but properties such as model robustness, models' sensitivity analysis, models' random properties, *etc*., are often not fully discussed. This kind of work may attract future research. The equivalence property of maintenance models should be studied, because many current maintenance models are equivalent to each other in some sense. For example, the effects of repairs can be described by failure rate, virtual age, reliability, *etc*, but these indexes have some well-known relationships, which reveals that related maintenance models are the same in some sense.
7. *Dependence among the model factors:* Dependence exists in real world maintenance, such as economic dependence, structural dependence, and stochastic dependence, which is pointed out by Dekker *et al.* [18]. In fact, more factors are now considered and the dependence among them can be discussed more too, which is the direction of further research in the subject of maintenance. Here the author emphasizes that modeling stochastic dependence is a very broad subject. One useful tool in this aspect is the Copula.

The author has tried to give a reasonably complete and an advanced chapter. However, inevitably, there will be some points of view of the researchers that have been overlooked, not included, or inadvertently not referenced. However, it is hoped that important points are at least not omitted.

Acknowledgement

The author would like to thank Professor Alan G. Hawkes for his help with the English of this chapter, but the responsibility rests with the author, if some errors still exist.

Abstract: This chapter summarizes concisely optimum maintenance policies for reliability models without detailed mathematical explanations: First, standard replacement models such as age, block, and periodic replacements are taken up, and are converted to modified models with finite operating times and random replacement times. Furthermore, replacement policies for inspection models, cumulative damage models, and a parallel system are proposed. Secondly, preventive maintenances (PMs) of one-unit and two-unit systems are discussed. Modified models with periodic PM times, imperfect PM, and repair limit are proposed. Optimum policies that minimize the expected costs or maximize availabilities are summarized. Finally, as applications of maintenance models, optimum policies for computer systems with intermittent faults, imperfect maintenance, and restart are discussed. These results should be very helpful in applications of maintenance models and studies of reliability theory.

49.1 Introduction

Most units or systems such as parts, equipment, components, devices, materials, structures, and machines are replaced or repaired immediately when they fail. However, *corrective maintenance* of units after failure may be costly, and sometimes requires a long time. It is an important problem to determine when to preventively maintain operating units before failure. However, it is unwise to maintain units very frequently. From this viewpoint, the commonly considered maintenance policies are *preventive replacement* for units without repair and *preventive maintenance* (PM) for units with repair on a specific schedule.

Suppose that a unit has to operate for an infinite or a specified time span. Then, as an objective function, it is appropriate to adopt the expected cost *per* unit of time for an infinite time span, that is called *expected cost rate*, and the total expected cost for a finite time span from the viewpoint of economics. Furthermore, it is appropriate to adopt mean time to failure from reliability and *availability* for units with non-negligible replacement or repair time.

We summarize the theoretical results of optimum policies that minimize or maximize the above quantities without detailed explanations and proofs, which are available in the literature [1, 2]. In Section 49.2, we first introduce simple replacement policies for an operating unit. Next, we take up standard replacement models such as age, block, and periodic replacements, convert them to replacement models for a finite time

interval, and consider extended models in which a unit is replaced at a random time. Furthermore, we propose the replacement policies for inspection models, cumulative damage models, and a parallel redundant system. In Section 49.3, we obtain the availabilities of a one-unit system and a two-unit system with PM, and consider the modified PM models where PMs are done at periodic and sequential times. Furthermore, we propose imperfect PM models, where a unit is not always like new at PM times, and a repair limit model as one modified model of PM models. In Section 49.4, as applications of replacement and PM models, we discuss optimum policies for a computer system with intermittent faults and with imperfect maintenance. Finally, we also derive an optimum number of restarts for a computer system.

The known results of replacement, preventive maintenance, and associated models have been summarized in [1]. Since then, many papers and books have been published and reviewed [3–12].

Recently published books [13–17] have collected many reliability and preventive maintenance models. Some chapters in these books have discussed and applied these models to actual systems [18–21]. Many maintenance policies from standard to advanced ones for system reliability models have been extensively discussed [2, 22].

We use the following notations throughout this chapter: Suppose that a unit has to operate for an infinite time span and a specified time span. The unit fails according to a general distribution $F(t) \equiv \int_0^t f(u)du$ with a finite mean μ and a density function $f(t)$, *i.e.*, $f(t) \equiv dF(t)/dt$ and $\mu \equiv \int_0^\infty \overline{F}(t)dt$, where $\overline{\Phi}(t) \equiv 1-\Phi(t)$ for any function $\Phi(t)$. It is assumed that the *failure rate* is $h(t) \equiv f(t)/\overline{F}(t)$ and the *renewal density* is $m(t) \equiv \sum_{j=1}^\infty f^{(j)}(t)$, where $\Phi^{(j)}(t)$ is the j-fold convolution of $\Phi(t)$ with itself and $\Phi^{(0)}(t) \equiv 1$ for $t \geq 0$. In addition, $H(t) \equiv \int_0^t h(u)du$ and $M(t) \equiv \int_0^t m(u)du$, *i.e.*, $F(t) = 1-e^{-H(t)}$ and $M(t) \equiv \sum_{j=1}^\infty F^{(j)}(t)$ that are called a *cumulative hazard rate* and a *renewal function*, respectively. When the unit fails and undergoes minimal repair at failures [2], it is said that failures occur in a nonhomogeneous Poisson process with a *mean value function* $H(t)$ and an *intensity function* $h(t)$.

49.2 Replacement Models

Suppose that an operating unit is replaced after failure or before failure. Then, replacement is roughly classified into two replacements after failure and before failure that are called *corrective replacement* and *preventive replacement*, respectively.

First, we introduce simple replacement policies [2]. Next, as the preventive replacement policies, we take up three policies for age, block, and periodic replacements, and derive analytically optimum policies that minimize the expected cost rates [1, 2]. We extend these policies to replacement models for a finite time interval and with random replacement interval [2, 23]. Furthermore, we propose the replacement policies for inspection models [2], cumulative damage models [24], and a parallel redundant system [2, 24].

49.2.1 Simple Replacement Models

As simple reliability measures of replacement, there are a mean failure time μ and a characteristic life T_1 such that $H(T_1) = 1$. If we estimate only the mean failure time, we may replace a unit before failure when it operates for a $p\mu$ time interval at the rate of p. Because $H(T_1)$ represents the expected number of failures in $[0, T_1]$, time T_1 is the time until the expected number of failures is equal to 1 and $F(T_1) = 1-e^{-1}$, *i.e.*, T_1 is also the approximate time that the unit fails with a probability of 63.2%.

Next, consider a unit that is replaced at time T: Suppose that an operating unit has some earning per unit of time if it does not fail in time T,

otherwise it has no earning. Then, the average time during $[0,T]$ in which we have some earning is

$$l(T) = 0 \times F(T) + T\overline{F}(T) = T\overline{F}(T).$$

Thus, an optimum time T_2 that maximizes $l(T)$ is given by $h(T_2) = 1/T_2$. In particular, when $F(t) = 1 - e^{-\lambda t}$, $T_1 = T_2 = 1/\lambda$.

Finally, introduce simple preventive replacement policies: The first one is that the unit is replaced before failure at time T_p such that $F(T_p) = p \quad (0 < p \le 1)$, where T_p is called a p th percentile point of $F(t)$. Secondly, let c_1 and c_2 $(c_1 > c_2)$ be the respective replacement costs after failure and before failure. Then, we balance the cost of replacement after failure against that before failure such that $c_1 F(T) = c_2 \overline{F}(T)$. In this case,

$$F(T) = \frac{c_2}{c_1 + c_2},$$

and a solution T_p to satisfy it represents a $p(= c_2/(c_1 + c_2))$ th percentile point of $F(t)$.

49.2.2 Standard Replacement

Suppose that a unit must operate for an infinite time span. Then, we consider the standard three replacement policies; age, block, and periodic replacements.

The unit is replaced at failure or at a planned time $T \quad (0 \le T \le \infty)$, whichever occurs first. Then, the expected cost rate is

$$C_1(T) = \frac{(c_1 - c_2)F(T) + c_2}{\int_0^T \overline{F}(t)dt}, \qquad (49.1)$$

where $c_1 =$ cost of replacement at failure and $c_2 =$ cost of replacement at time T with $c_2 < c_1$. If $T = \infty$, then this corresponds to the replacement only at failures, and the resulting cost rate is $C_1(\infty) = c_1/\mu$. If the failure rate $h(t)$ is strictly increasing and $h(\infty) = \lim_{t\to\infty} h(t) > c_2/[\mu(c_1 - c_2)]$, then there exists a finite and unique $T^* \quad (0 < T^* < \infty)$ that satisfies

$$h(T)\int_0^T \overline{F}(t)dt - F(T) = \frac{c_2}{c_1 - c_2}, \qquad (49.2)$$

and the resulting cost rate is

$$C_1(T^*) = (c_1 - c_2)h(T^*). \qquad (49.3)$$

Next, the unit is replaced at periodic times kT $(k = 1,2,\ldots)$ and is also replaced at any failures between replacements. Then, the expected cost rate is

$$C_2(T) = \frac{1}{T}[c_1 M(T) + c_2], \qquad (49.4)$$

where $c_1 =$ cost of replacement at each failure and $c_2 =$ cost of replacement at time T . A necessary condition for a finite T^* to exist is that T^* satisfies

$$Tm(T) - M(T) = \frac{c_2}{c_1}, \qquad (49.5)$$

and the resulting cost rate is

$$C_2(T^*) = c_1 m(T^*). \qquad (49.6)$$

Further, the unit is replaced at periodic times $kT \quad (k = 1,2,\ldots)$ and undergoes only minimal repair at failures between replacements. Minimal repair means that the failure rate remains undisturbed by any minimal repair. Then, the expected cost rate is

$$C_3(T) = \frac{1}{T}[c_1 H(T) + c_2], \qquad (49.7)$$

where $c_1 =$ cost of minimal repair at each failure and $c_2 =$ cost of replacement at time T . If the failure rate $h(t)$ is strictly increasing and $\int_0^\infty t\, dh(t) > c_2/c_1$, there exists a finite and unique $T^* \quad (0 < T^* < \infty)$ that satisfies

$$Th(T) - H(T) = \frac{c_2}{c_1}, \qquad (49.8)$$

and the resulting cost rate is

$$C_3(T^*) = c_1 h(T^*). \qquad (49.9)$$

Clearly, if $h(t)$ is strictly increasing to infinity, a finite T^* exists uniquely.

Finally, the unit is replaced only at times kT $(k = 1,2,\ldots)$ and remains failed for the time interval from its failure to a planned replacement. Then, the expected cost rate is

$$C_4(T)=\frac{1}{T}\left[c_1\int_0^T F(t)dt+c_2\right], \qquad (49.10)$$

where c_1 = cost for the time elapsed between a failure and the replacement per unit of time. If $\mu > c_2/c_1$, there exists a finite and unique T^* $(0<T^*<\infty)$ that satisfies

$$TF(T)-\int_0^T F(t)dt=\frac{c_2}{c_1}, \qquad (49.11)$$

and the resulting cost rate is

$$C_4(T^*)=c_1F(T^*). \qquad (49.12)$$

49.2.3 Replacement for a Finite Interval

A unit has to be operating for a finite time interval $[0,S]$, *i.e.*, the working time of a unit is given by a specified value S. For the maintenance of an operating unit, an interval S is partitioned equally into N parts in which it is replaced at periodic times kT $(k=1,2,\ldots,N)$, where $NT=S$.

The unit is replaced at periodic times kT $(k=1,2,\ldots,N)$ and any unit is as good as new at each replacement. First, the unit is always replaced at any failures between replacements. Then, the expected cost of one interval $[0,T]$ is, from (49.4),

$$\tilde{C}_2(1)\equiv c_1M(T)+c_2=c_1M\left(\frac{S}{N}+c_2\right).$$

Thus, the total expected cost until time S is

$$C_2(N)\equiv N\tilde{C}_2(1)=N\left[c_1M\left(\frac{S}{N}\right)+c_2\right]$$
$$=\frac{S}{T}\left[c_1M(T)+c_2\right] \quad (N=1,2,\ldots). \qquad (49.13)$$

Therefore, we have the optimum policy [2]:

(i) If $T^*<S$, then we set that $\left[S/T^*\right]\equiv N$ and calculate $C_2(N)$ and $C_2(N+1)$ from (49.13). If $C_2(N)\le C_2(N+1)$, then $N^*=N$, and conversely, if $C_2(N)> C_2(N+1)$, then $N^*=N+1$.

(ii) If $T^*\ge S$, then $N^*=1$.

Next, the unit undergoes only minimal repair at failures between replacements. Then, the expected cost of one interval $[0,T]$ from (49.7) is

$$\tilde{C}_3(1)\equiv c_1H(T)+c_2=c_1H\left(\frac{S}{T}\right)+c_2.$$

Thus, the total expected cost until time S is

$$C_3(N)\equiv N\tilde{C}_3(1)=N\left[c_1H\left(\frac{S}{N}\right)+c_2\right]$$
$$=\frac{S}{T}\left[c_1H(T)+c_2\right] \quad (N=1,2,\ldots). \qquad (49.14)$$

Therefore, by obtaining T^* that satisfies (49.8) and applying it to the optimum policy, we can obtain an optimum number N^* that minimizes $C_3(N)$ in (49.14).

Finally, the unit is replaced only at periodic times kT. Then, from (49.10), the expected cost of one interval $[0,T]$ is

$$\tilde{C}_4(1)\equiv c_1\int_0^T F(t)dt+c_2$$
$$=c_1\int_0^{S/N}F(t)dt+c_2.$$

Thus, the total expected cost until time S is

$$C_4(N)\equiv N\tilde{C}_4(1)=N\left[c_1\int_0^{S/N}F(t)dt+c_2\right]$$
$$=\frac{S}{T}\left[c_1\int_0^T F(t)dt+c_2\right]. \qquad (49.15)$$

Therefore, using the optimum policy, we can obtain an optimum replacement number N^* that minimizes $C_4(N)$ in (49.15).

49.2.4 The Random Replacement Interval

When a unit has a variable working cycle and processing time, it would be better to do some maintenance after it has completed its work and process. It is assumed that a unit is replaced before failure at either a planned time T or a random time Y, where Y is distributed according to a general distribution $G(t)$, where $\overline{G}(t)\equiv 1-G(t)$.

First, the unit is replaced at time T, at random time Y or at failure, whichever occurs first. Then, from (49.1), the expected cost rate is

$$C_1(T) = \frac{(c_1 - c_2)\int_0^T \overline{G}(t)dF(t) + c_2}{\int_0^T \overline{G}(t)\overline{F}(t)dt}. \quad (49.16)$$

If the failure rate $h(t)$ is strictly increasing, and

$$h(\infty)\int_0^T \overline{G}(t)\overline{F}(t)dt - \int_0^\infty \overline{G}(t)dF(t) > \frac{c_2}{c_1 - c_2},$$

there exists a finite an unique T^* $(0 < T^* < \infty)$ that satisfies

$$h(T)\int_0^T \overline{G}(t)\overline{F}(t)dt - \int_0^T \overline{G}(t)dF(t) = \frac{c_2}{c_1 - c_2}, \quad (49.17)$$

and the resulting cost rate is given in (49.3).

Secondly, the unit is replaced at time T or at time Y, whichever occurs first, and is also replaced at any failures between replacements. Then, from (49.4), the expected cost rate is

$$C_2(T) = \frac{c_1\int_0^T \overline{G}(t)dM(t) + c_2}{\int_0^T \overline{G}(t)dt}. \quad (49.18)$$

A necessary condition for a finite T^* to exist is that T^* satisfies

$$m(T)\int_0^T \overline{G}(t)dt - \int_0^T \overline{G}(t)dM(t) = \frac{c_2}{c_1}, \quad (49.19)$$

and the resulting cost rate is given in (49.6).

Further, the unit is replaced at time T or at time Y, whichever occurs first, and undergoes only minimal repair at failures between replacements. Then, from (49.7), the expected cost rate is

$$C_3(T) = \frac{c_1\int_0^T \overline{G}(t)dH(t) + c_2}{\int_0^T \overline{G}(t)dt}. \quad (49.20)$$

If the failure rate $h(t)$ is strictly increasing, and $\int_0^\infty [\int_0^t \overline{G}(u)du]dh(t) > c_2/c_1$, there exists a finite an unique T^* $(0 < T^* < \infty)$ that satisfies

$$h(T)\int_0^T \overline{G}(t)dt - \int_0^T \overline{G}(t)dH(t) = \frac{c_2}{c_1}, \quad (49.21)$$

and the resulting cost rate is given in (49.9).

Finally, when the unit fails between replacements, it remains failed for the time interval from a failure to its replacement. Then, from (49.10), the expected cost rate is

$$C_4(T) = \frac{c_1\int_0^T \overline{G}(t)dF(t) + c_2}{\int_0^T \overline{G}(t)dt}. \quad (49.22)$$

If $\int_0^\infty \overline{G}(t)\overline{F}(t)dt > c_2/c_1$, then there exists a finite and unique T^* $(0 < T^* < \infty)$ that satisfies

$$F(T)\int_0^T \overline{G}(t)dt - \int_0^T \overline{G}(t)F(t)dt = \frac{c_2}{c_1}, \quad (49.23)$$

and the resulting cost rate is given in (49.12). In particular, when $\overline{G}(t) \equiv 1$ for any $t \geq 0$, the above results correspond to those of Section 49.2.2.

Next, suppose that the unit is replaced at a planned time T or at the N th random time $(N = 1, 2, \ldots)$. Then, the expected cost rates of each model can be rewritten as

$$C_1(T,N) = \frac{(c_1 - c_2)\int_0^T [1 - G^{(N)}(t)]dF(t) + c_2}{\int_0^T [1 - G^{(N)}(t)]\overline{F}(t)dt}, \quad (49.24)$$

$$C_2(T,N) = \frac{c_1\int_0^T [1 - G^{(N)}(t)]dH(t) + c_2}{\int_0^T [1 - G^{(N)}(t)]dt}, \quad (49.25)$$

$$C_3(T,N) = \frac{c_1\int_0^T [1 - G^{(N)}(t)]dM(t) + c_2}{\int_0^T [1 - G^{(N)}(t)]dt}, \quad (49.26)$$

$$C_4(T,N) = \frac{c_1\int_0^T [1 - G^{(N)}(t)]F(t)dt + c_2}{\int_0^T [1 - G^{(N)}(t)]dt}. \quad (49.27)$$

49.2.5 Inspection with Replacement

A unit should operate for an infinite time span and is checked at successive times $T_k \quad (k=1,2,\ldots)$, where $T_0=0$. Any failure is detected at the next checking time and is replaced immediately. It is assumed that all times needed for checks are negligible and the failure rate $h(t)$ is unchanged by any check. Then, the total expected cost until the replacement is

$$C_1(T_1,T_2,\ldots)=\sum_{k=0}^{\infty}\int_{T_k}^{T_{k+1}}[c_1(k+1)+c_2(T_{k+1}-t)]dF(t)+c_3, \qquad (49.28)$$

where c_1 = cost of one check, c_2 = loss cost *per* unit of time for the time elapsed between a failure and its detection at the next checking time, and c_3 = replacement cost of a failed unit.

Differentiating $C_1(T_1,T_2,\ldots)$ with T_k and setting it equal to zero,

$$T_{k+1}-T_k=\frac{F(T_k)-F(T_{k-1})}{f(T_k)}-\frac{c_1}{c_2} \quad (k=1,2,\ldots). \qquad (49.29)$$

Algorithm 1 for computing the optimum inspection schedule is [1]:

1. Choose T_1 to satisfy $c_1=c_2\int_0^{T_1}F(t)dt$.
2. Compute $T_2,T_3,\ldots$ recursively from (49.29).
3. If any $\delta_k>\delta_{k-1}$, reduce T_1 and repeat, where $\delta_k\equiv T_{k+1}-T_k$. If any $\delta_k<0$, increase T_1 and repeat.
4. Continue until $T_1<T_2<\cdots$ are determined to the degree of accuracy required.

Next, a unit should operate for a finite time interval $[0,S]$ and is checked at successive times $T_k \quad (k=1,2,\ldots,N)$, where $T_0\equiv 0$ and $T_N=S$. Then, the expected cost is

$$C_2(T_1,T_2,\ldots,T_N)=\sum_{k=0}^{N-1}\int_{T_k}^{T_{k+1}}[c_1(k+1)+c_2(T_{k+1}-t)]dF(t)+c_1N\overline{F}(T_N)+c_3 \quad (N=1,2,\ldots). \qquad (49.30)$$

Setting $\partial C_2(T_1,T_2,\ldots,T_N)/\partial T_k=0$, we have (49.29) for $k=1,2,\ldots,N-1$, and the resulting cost is

$$\begin{aligned}\tilde{C}_2(T_1,T_2,\ldots,T_N)&=C_2(T_1,T_2,\ldots,T_N)+c_2\int_0^S\overline{F}(t)dt-c_3\\&=\sum_{k=0}^{N-1}[c_1+c_2(T_{k+1}-T_k)]\overline{F}(T_k)\end{aligned} \quad (N=1,2,\ldots). \qquad (49.31)$$

Therefore, we may solve the simultaneous equations (49.29) for $(k=1,2,\ldots,N-1)$ and $T_N=S$, and obtain the expected cost $\tilde{C}_2(T_1,T_2,\ldots,T_N)$ in (49.31). Next, comparing $\tilde{C}_2(T_1,T_2,\ldots,T_N)$ for all $N\geq 1$, we can obtain the optimum checking number N^* and times T_k^* $(k=1,2,\ldots,N^*)$.

Finally, suppose that a unit is checked at time T_k and random times $Y_k \quad (k=1,2,\ldots)$, where $Y_0\equiv 0$ and $Z_k\equiv Y_k-Y_{k-1} \quad (k=1,2,\ldots)$ are independently and identically distributed random variables, and also independent of its failure time. It is assumed that Z_k has an identical distribution $G(x)$ and the distribution of Y_k is denoted by the j-fold convolution $G^{(j)}(x)$ of $G(x)$ with itself. Then, the total expected cost until replacement is

$$\begin{aligned}C_3(T_1,T_2,\ldots)&=c_1\sum_{k=0}^{\infty}\overline{F}(T_k)\\&+c_4\sum_{k=0}^{\infty}k\int_0^{\infty}[G^{(k)}(t)-G^{(k+1)}(t)]dF(t)\\&-(c_1-c_4)\sum_{k=0}^{\infty}\int_{T_k}^{T_{k+1}}\{G(T_{k+1})-G(t)\\&+\int_0^t[G(T_{k+1}-x)-G(t-x)]dM_G(x)\}dF(t)\\&+c_2\sum_{k=0}^{\infty}\int_{T_k}^{T_{k+1}}\{\int_t^{T_{k+1}}\overline{G}(y)dy\\&+[\int_0^t(\int_{t-x}^{T_{k+1}-x}\overline{G}(y)dy)dM_G(x)]\}dF(t)\\&+c_3,\end{aligned} \qquad (49.32)$$

where c_4 = cost of the random check and $M_G(x)$ represents the expected number of random checks during $[0,x]$.

In particular, when $G(x) = 1 - e^{-\theta x}$, the total expected cost in (49.32) can be simplified as

$$C_3(T_1, T_2, \ldots) = c_1 \sum_{k=0}^{\infty} \overline{F}(T_k) + c_4 \theta \mu - \left(c_1 - c_4 - \frac{c_2}{\theta} \right) \sum_{k=0}^{\infty} \int_{T_k}^{T_{k+1}} [1 - e^{-\theta(T_{k+1} - t)}] dF(t) + c_3. \quad (49.33)$$

49.2.6 The Cumulative Damage Model

Consider the following cumulative damage model: A unit should operate for an infinite time span. Shocks occur at random times and each shock causes a random amount of damage to the unit. It is assumed that the total damage is additive, and the unit fails when it has exceeded a failure level K.

First, suppose that shocks occur in a renewal process with a general distribution $F(t)$ with finite mean μ. Letting $N(t)$ be the number of shocks in time t, the probability that j shocks occur exactly in $[0, t]$ is

$$\Pr\{N(t) = j\} = F^{(j)}(t) - F^{(j+1)}(t) \quad (j = 0, 1, 2, \ldots).$$

Further, an amount W_j of damage due to the jth shock has an identical distribution $G(x) \equiv \Pr\{W_j \le x\}$.

The unit is replaced before failure at time T, at shock N, or at damage Z, whichever occurs first. Then, the expected cost rate is

$$C(T, N, Z) = \left[c_1 - (c_1 - c_2) \sum_{j=0}^{N-1} [F^{(j)}(T) - F^{(j+1)}(T)] G^{(j)}(Z) - (c_1 - c_3) F^{(N)}(T) G^{(N)}(Z) - (c_1 - c_4) \sum_{j=0}^{N-1} F^{(j+1)}(T) \times \int_0^Z [G(K - x) - G(Z - x)] dG^{(j)}(x) \right] \Big/ \left[\sum_{j=0}^{N-1} G^{(j)}(Z) \int_0^T [F^{(j)}(t) - F^{(j+1)}(t)] dt \right], \quad (49.34)$$

where c_1 = cost of replacement at failure, c_2 = cost of replacement at time T, c_3 = cost of replacement at shock N, and c_4 = cost of replacement at damage Z.

When the unit is replaced at time T $(0 < T \le \infty)$ or at failure, whichever occurs first, the expected cost rate in (49.34) is

$$C_1(T) = \frac{c_1 - (c_1 - c_2) \sum_{j=0}^{\infty} [F^{(j)}(T) - F^{(j+1)}(T)] G^{(j)}(K)}{\sum_{j=0}^{\infty} G^{(j)}(Z) \int_0^T [F^{(j)}(t) - F^{(j+1)}(t)] dt}. \quad (49.35)$$

When the unit is replaced at shock N $(N = 1, 2, \ldots)$ or at failure, whichever occurs first, the expected cost rate in (49.34) is

$$C_2(N) = \frac{c_1 - (c_1 - c_3) G^{(N)}(K)}{\mu \sum_{j=0}^{N-1} G^{(j)}(K)} \quad (N = 1, 2, \ldots). \quad (49.36)$$

Finally, when the unit is replaced at damage Z $(0 < Z \le \infty)$ or at failure, whichever occurs first, the expected cost rate in (49.34) is

$$C_3(Z) = \frac{c_1 - (c_1 - c_4) \left[G(K) - \int_0^Z \overline{G}(K - x) dM_G(x) \right]}{\mu [1 + M_G(Z)]}. \quad (49.37)$$

The optimum policies that minimize the expected cost rates in (49.35), (49.36), and (49.37) have been discussed analytically [24].

For example, an optimum damage level Z^* that minimizes $C_3(Z)$ in (49.37) for $c_1 > c_4$ is given as follows: If $M_G(K) > c_4/(c_1 - c_4)$, then there exists a finite and unique Z^* $(0 < Z^* < K)$ that satisfies

$$\int_{K-Z}^{K} [1 + M_G(K - x)] dG(x) = \frac{c_4}{c_1 - c_4}, \quad (49.38)$$

and the resulting cost rate is

$$\mu C_3(Z^*) = (c_1 - c_4) \overline{G}(K - Z^*). \quad (49.39)$$

Conversely, if $M_G(K) \le c_4/(c_1 - c_4)$, then $Z^* = K$, *i.e.*, the unit should be replaced only at failure, and the expected cost rate is

$$\mu C_3(K) = \frac{c_1}{1 + M_G(K)}. \quad (49.40)$$

Next, suppose that shocks occur in a nonhomogeneous Poisson process with a mean value function $H(t)$, *i.e.*, $p_j(t) \equiv \Pr\{N(t) = j\} = \left[H(t)^j / j!\right] e^{-H(t)}$ $(j = 0,1,2,\ldots)$. Then, the expected cost rate in (49.34) is rewritten as

$$C(T,N,Z) = \frac{\begin{aligned} &c_1 - (c_1 - c_2)\sum_{j=0}^{N-1} G^{(j)}(Z)\, p_j(T) \\ &-(c_1 - c_3) G^{(N)}(Z) \sum_{j=N}^{\infty} p_j(T) \\ &-(c_1 - c_4)\sum_{j=0}^{N-1} \int_0^Z [G(K-x) - G(Z-x)] \\ &\times dG^{(j)}(x) \sum_{i=j+1}^{\infty} p_i(T) \end{aligned}}{\sum_{j=0}^{N-1} G^{(j)}(Z) \int_0^T p_j(t)\,dt}. \quad (49.41)$$

When shocks occur in a Poisson process, the two costs of (49.34) and (49.41) agree with each other.

49.2.7 The Parallel Redundant System

Consider a parallel redundant system that consists of n $(n \geq 2)$ identical units and fails when all units fail. It is assumed that each unit has a failure distribution $F(t)$ with finite μ.

Suppose that the system is replaced at failure or at time T $(0 < T < \infty)$, whichever occurs first. Then, the expected cost rate is

$$C_1(T) = \frac{(c_1 - c_2)F(T)^n + c_2 + c_0 n}{\int_0^T \left[1 - F(t)^n\right] dt}, \quad (49.42)$$

where $\mu_n \equiv \int_0^\infty \left[1 - F(t)^n\right] dt$, c_1 = cost of replacement at system failure, c_2 = cost of replacement at time T with $c_2 < c_1$, and c_0 = acquisition cost of one unit. By a method similar to that in Section 49.2.2, if the failure rate $h(t)$ is strictly increasing, and $h(\infty) > (c_1 + nc_0)/\left[\mu_n (c_1 - c_2)\right]$, then there exists a finite and unique T^* $(0 < T^* < \infty)$ that satisfies

$$\frac{nh(T)\left[F(T)^{n-1} - F(T)^n\right]}{1 - F(T)^n} \int_0^T \left[1 - F(t)^n\right] dt - F(T)^n = \frac{c_2 + nc_0}{c_1 - c_2}, \quad (49.43)$$

and the resulting cost rate is

$$C_1(T^*) = n(c_1 - c_2)h(T^*)\frac{F(T^*)^{n-1} - F(T^*)^n}{1 - F(T^*)^n}. \quad (49.44)$$

If the system is replaced only at failure, then the expected cost rate in (49.42) is

$$C_2(n) \equiv \lim_{T \to \infty} C_1(T) = \frac{c_0 n + c_2}{\int_0^\infty \left[1 - F(t)^n\right] dt} \quad (n = 1,2,\ldots). \quad (49.45)$$

An optimum number n^* is given by a finite unique minimum that satisfies

$$\frac{\int_0^\infty \left[1 - F(t)^n\right] dt}{\int_0^\infty \left[F(t)^n - F(t)^{n+1}\right] dt} - n \geq \frac{c_2}{c_0} \quad (n = 1,2,\ldots). \quad (49.46)$$

In particular, when $F(t) = 1 - e^{-\lambda t}$, an optimum n^* is a unique minimum such that

$$(n+1)\sum_{j=1}^{n} \frac{1}{j} - n \geq \frac{c_2}{c_0} \quad (n = 1,2,\ldots). \quad (49.47)$$

Finally, consider a parallel redundant system with n units in which units fail subject to shocks at a mean interval μ. It is assumed that the probability that each unit fails at shock j is constant p, where $q \equiv 1 - p$. Suppose that the system is replaced before failure when the total number of failed units is $N+1, N+2, \ldots, n-1$, or it is replaced when all units have failed, otherwise it is left alone. Then, the expected cost rate is

$$C_3(N) = \frac{\begin{aligned} &(c_1 - c_2)\sum_{j=0}^{N} \binom{n}{j} (-1)^j p^{n-j} \\ &\times \sum_{i=0}^{j} \binom{j}{i} (-1)^i \left[1/(1 - q^{n-i})\right] + c_2 \end{aligned}}{\mu \sum_{j=0}^{N} \binom{n}{j} (-1)^j \sum_{i=0}^{N-j} \binom{n-j}{i} \left[1/(1 - q^{n-i})\right]} \quad (N = 0,1,\ldots,n-1), \quad (49.48)$$

where c_1 = cost of replacement at system failure and c_2 = cost of replacement before failure with $c_2 < c_1$. In particular, when $n = 2$,

$$C_3(0) = \frac{c_1 p^2 + c_2(1-p^2-q^2)}{\mu},$$

$$C_3(1) = \frac{c_1}{\mu}\frac{1-q^2}{1+2q}. \tag{49.49}$$

Thus, if $c_2/c_1 < q/(1+2q)$, then the system is replaced when one unit fails at some shock, and if $c_2/c_1 \geq q/(1+2q)$, then it is replaced when two units have failed.

49.3 Preventive Maintenance Models

A unit is repaired upon failure. If a failed unit undergoes repair, it needs a repair time that may not be negligible. After the completion of repair, the unit begins to operate again. When the unit is repaired after failure, it may require much time and high cost. To prevent such failure, we need to undergo preventive maintenance before failure, but not to do it too late from the viewpoint of reliability or cost.

First, this section considers a one-unit system and a two-unit system, and derives optimum PM times that maximize the availabilities [2, 25]. Next, we modify the standard model in which the PM is planned at periodic times and it is done at the next time when the number of failures and the total damage have exceeded a threshold level [2, 26]. Furthermore, we consider the PM model, where PM times are done at sequential times, and derive analytically optimum times that minimize the expected cost rate [2, 27]. We propose imperfect PM models, where the unit may be younger at each PM time, and the repair limit model, where the repair of a failed unit is stopped when it is not completed in time T [2, 22, 28, 29].

49.3.1 The Parallel Redundant System

When a unit fails, it undergoes repair immediately, and once repaired it is returned to the operating state. It is assumed that the failure time X has an identical distribution with mean μ, and the repair time Y_1 has an identical distribution $G_1(t)$ with finite mean θ_1. Further, the unit undergoes PM before failure at a planned time T and the time for PM is θ_2. Then, the availability is

$$A(T) = \frac{\int_0^T \overline{F}(t)dt}{\int_0^T \overline{F}(t)dt + \theta_1 F(T) + \theta_2 \overline{F}(T)}. \tag{49.50}$$

Thus, the PM policy maximizing the availability is the same as minimizing the expected cost rate $C_1(T)$ in (49.1).

Next, suppose that the repair of a failed unit is not completed in time T $(0 \leq T \leq \infty)$, which is called a *repair limit policy*, then it is replaced with a new one. Then, the expected cost rate is

$$C(T) = \frac{c_1 \overline{G}_1(T) + \int_0^T \overline{G}_1(t)dc_r(t)}{\mu + \int_0^T \overline{G}_1(t)dt}, \tag{49.51}$$

where c_1 = replacement cost of a failed unit and $c_r(t)$= repair cost during $(0,t]$.

Let $g_1(t)$ be a density function of $G_1(t)$ and $r_1(t) \equiv g_1(t)/\overline{G}_1(t)$ be the repair rate. In particular, when $c_r(t) = c_2 t$, the expected cost rate in (49.51) is rewritten as

$$C(T) = \frac{c_1 \overline{G}_1(T) + c_2 \int_0^T \overline{G}_1(t)dt}{\mu + \int_0^T \overline{G}_1(t)dt}. \tag{49.52}$$

Then, we have the optimum policy when $r_1(t)$ is strictly decreasing: If $r_1(0) \leq k$, then $T^* = 0$, *i.e.*, no repair should be made. If $r_1(0) > k$ and $r_1(\infty) \leq K$, then there exists a finite and unique T^* that satisfies

$$r_1(T)\left[\mu + \int_0^T \overline{G}_1(t)dt\right] + \overline{G}_1(T) = \frac{c_2\mu}{c_1}, \tag{49.53}$$

and the resulting cost rate is

$$C(T^*) = c_2 - c_1 r_1(T^*). \tag{49.54}$$

If $r_1(\infty) \geq K$, then $T^* = \infty$, *i.e.*, no repair should

be made, where

$$k \equiv \frac{c_2\mu - c_1}{c_1\mu}, \qquad K \equiv \frac{c_2\mu}{c_1(\mu+\theta_1)}.$$

49.3.2 The Two-unit System

Consider a two-unit standby system where two units are statistically identical. Suppose that when an operating unit operates for a specified time T without failure, we stop its operation and undergo its PM. It is assumed that an operating unit has a failure distribution $F(t)$ with finite mean μ, a failed unit has a repair distribution $G_1(t)$ with finite mean θ_1, and the time for PM has a general distribution $G_2(t)$ with finite mean θ_2. Then, the availability is

$$A(T) = \frac{\left[\gamma_1 + \int_0^T G_1(t)\overline{F}(t)dt\right]\left[1 - \int_T^\infty G_2(t)dF(t)\right] + \left[\gamma_2 + \int_0^T G_2(t)\overline{F}(t)dt\right]\int_T^\infty G_1(t)dF(t)}{\left[\theta_1 + \int_0^T G_1(t)\overline{F}(t)dt\right]\left[1 - \int_T^\infty G_2(t)dF(t)\right] + \left[\theta_2 + \int_0^T G_2(t)\overline{F}(t)dt\right]\int_T^\infty G_1(t)dF(t)}, \tag{49.55}$$

where

$$\gamma_i \equiv \int_0^\infty \overline{G}_i(t)\overline{F}(t)dt \quad (i=1,2).$$

When $G_1(t) < G_2(t)$ for $0 < t < \infty$ and the failure rate $h(t)$ is strictly increasing, we have the following optimum policy: If $\rho_1\theta_2 > \rho_2\theta_1$ and $h(0) \geq k$, then $T^* = 0$, and the availability is

$$A(0) = \frac{q_2\gamma_1 + (1-q_1)\gamma_2}{q_2\theta_1 + (1-q_1)\theta_2} \tag{49.56}$$

If $\rho_1\theta_2 > \rho_2\theta_1$, $h(\infty) > K$, and $h(0) < k$, or $\rho_1\theta_2 \leq \rho_2\theta_1$ and $h(\infty) > K$, then there exists a finite and unique T^* $(0 < T^* < \infty)$ that satisfies

$$h(T)\left[\int_0^T L(t)\overline{F}(t)dt + \int_0^\infty \overline{L}(t)dt\right] - \int_0^T L(t)dF(t) = \frac{\rho_1\int_0^\infty \overline{L}(t)dF(t) + \rho_2\int_0^T L(t)dF(t)}{\rho_1 - \rho_2}. \tag{49.57}$$

If $h(\infty) \leq K$, then $T^* = \infty$, *i.e.*, no PM is done, and the availability is

$$A(\infty) = \frac{\mu}{\mu + \theta_1 - \gamma_1},$$

where

$$q_i \equiv \int_0^\infty \overline{G}_i(t)dF(t),$$

$$\rho_i \equiv \int_0^\infty \overline{G}_i(t)F(t)dt = \theta_i - \gamma_i \quad (i=1,2),$$

$$L(t) \equiv \frac{\rho_1 G_2(t) - \rho_2 G_1(t)}{\rho_1 - \rho_2},$$

$$k \equiv \frac{\rho_1 q_2 + \rho_2(1-q_1)}{\rho_1\theta_2 - \rho_2\theta_1}, \quad K \equiv \frac{\rho_1}{\mu(\rho_1 - \rho_2)}.$$

49.3.3 The Modified Discrete Policy

Consider a unit that should operate for a certain time span. It is assumed that failures occur in a nonhomogeneous Poisson process with an intensity function $h(t)$ and a mean value function $H(t) \equiv \int_0^t h(u)du$. Then, the expected number of failures during $[0,t]$ is $p_j[H(t)] \equiv \left[H(t)^j / j!\right] \times e^{-H(t)}$ $(j = 0,1,2,\ldots)$. Suppose that the PM is planned at periodic times kT $(k = 1,2,\ldots)$, where a positive T $(0 < T < \infty)$ is given. If the total number of failures has exceeded a specified number N $(N = 1,2,\ldots)$, the PM is done at the next planned time and the unit becomes like new, otherwise the unit is left as it is. The unit undergoes minimal repair at each failure between PMs.

Under the above assumptions, the expected cost rate is

$$C_1(N) = \frac{c_1\sum_{k=0}^\infty [H((k+1)T) - H(kT)] \times \sum_{j=0}^{N-1} p_j[H(kT)] + c_2}{T\sum_{k=0}^\infty \sum_{j=0}^\infty p_j[H(kT)]} \quad (N = 1,2,\ldots), \tag{49.58}$$

where c_1 = cost of minimal repair at each failure and c_2 = cost of planned PM.

When an intensity function $h(t)$ is strictly increasing, if $L_1(\infty) > c_2/c_1$, then an optimum number N^* is given by a finite and unique minimum that satisfies

$$L_1(N) \geq \frac{c_2}{c_1} \qquad (N = 1, 2, \ldots), \qquad (49.59)$$

where

$$L_1(N) \equiv q_1(N) \sum_{k=0}^{\infty} \sum_{j=0}^{N-1} p_j[H(kT)] - \sum_{k=0}^{\infty} [H((k+1)T) - H(kT)] \sum_{j=0}^{N-1} p_j[H(kT)],$$

$$q_1(N) \equiv \frac{\sum_{k=0}^{\infty} [H((k+1)T) - H(kT)]\, p_N[H(kT)]}{\sum_{k=0}^{\infty} [p_N[H(kT)]]}.$$

Next, consider the cumulative damage model where shocks occur in a nonhomogeneous Poisson process with a mean value function $H(t)$ and each damage due to shocks has an identical distribution $G(x)$. The total damage is additive, and the unit fails when it has exceeded a failure level K and the CM is done. If the total damage has exceeded a threshold level Z $(0 \leq Z \leq K)$ during $(kT, (k+1)T]$ $(k = 0, 1, 2, \ldots)$, then the PM is done at time $(k+1)T$. Then, the expected cost rate is

$$C_2(Z) = \frac{\begin{array}{l} c_2 + (c_1 - c_2) \sum_{k=0}^{\infty} \sum_{j=0}^{\infty} p_j[H(kT)] \\ \times \sum_{i=0}^{\infty} p_i[H((n+1)T) - H(nT)] \\ \times \int_0^Z [1 - G^{(i)}(K-x)]\, dG^{(j)}(x) \end{array}}{\begin{array}{l} \sum_{k=0}^{\infty} \sum_{j=0}^{\infty} p_j[H(kT)] \\ \times \int_0^Z G^{(i)}(K-x)\, dG^{(j)}(x) \\ \times \int_{kT}^{(k+1)T} p_i[H(t) - H(nT)]\, dt \end{array}}, \qquad (49.60)$$

where c_1 = CM cost after failure and c_2 = PM cost before failure.

When shocks occur in a Poisson process with rate λ, *i.e.*, $p_j[H(kT)] = [(k\lambda T)^j / j!] e^{-k\lambda T} \equiv p_j(k\lambda T)$ $(j = 0, 1, 2, \ldots)$, an optimum damage level Z^* is given as follows: If $M_G(K) > c_2/(c_1 - c_2)$, then there exists a unique Z^* $(0 < Z^* < K)$ that satisfies

$$\begin{aligned} & q_2(Z) \sum_{k=0}^{\infty} \sum_{j=0}^{\infty} p_j(k\lambda T) \sum_{i=0}^{\infty} \int_0^T p_i(\lambda t)\, dt \\ & \times \int_0^Z G^{(i)}(K-x)\, dG^{(j)}(x) \\ & - \sum_{k=0}^{\infty} \sum_{j=0}^{\infty} p_j(k\lambda T) \sum_{i=0}^{\infty} p_i(\lambda T) \\ & \times \int_0^Z [1 - G^{(i)}(K-x)]\, dG^{(j)}(x) = \frac{c_2}{c_1 - c_2}, \end{aligned} \qquad (49.61)$$

and the resulting cost rate is

$$C_2(Z^*) = (c_1 - c_2) q_2(Z^*), \qquad (49.62)$$

where

$$q_2(Z) \equiv \frac{\sum_{i=0}^{\infty} p_i(k\lambda T)[1 - G^{(i)}(K-Z)]}{\sum_{i=0}^{\infty} \int_0^T p_i(k\lambda T)\, dt\, G^{(i)}(K-Z)}.$$

Conversely, if $M_G(K) \leq c_2/(c_1 - c_2)$, then $Z^* = K$, and the PM is done after failure, and the expected cost rate is

$$C_2(K) = \frac{c_1}{\mu[1 + M_G(K)]},$$

which agrees with (49.40).

49.3.4 Periodic and Sequential Policies

A unit must operate for an infinite time span. The PM is done at successive times $0 < T_1 < T_1 + T_2 < \cdots < T_1 + T_2 + \cdots + T_N$, and the unit is replaced at time $T_1 + T_2 + \cdots + T_N$. It is assumed that the unit has the failure rate $h_k(t)$ in the k-th period of PMs and $h_k(t) < h_{k+1}(t)$ for any $t > 0$, *i.e.*, the failure rate increases with the number of PMs. Further, the unit undergoes minimal repair at failures between PMs. Then, the expected cost rate is

$$C(T_1, T_2, \ldots, T_N) = \frac{c_1 \sum_{k=1}^{\infty} \int_0^{T_k} h_k(t)\, dt + c_2 + (N-1)c_3}{T_1 + T_2 + \cdots + T_N}, \qquad (49.63)$$

where c_1 = cost of minimal repair at each failure, c_2 = cost of replacement, and c_3 = cost of PM with $c_3 < c_2$. When $N = 1$, (49.63) agrees with (49.7). Differentiating $C(T_1,T_2,\ldots,T_N)$ with respect to T_k and setting it equal to zero implies

$$h_1(T_1) = h_2(T_2) = \cdots = h_N(T_N), \qquad (49.64)$$

$$c_1 h_k(T_k) = C(T_1,T_2,\ldots,T_N). \qquad (49.65)$$

Thus, we can specify the following computing procedure for obtaining an optimum PM policy:

1. Solve $h_k(T_k) = A$ and express T_k $(k = 1,2,\ldots,N)$ by a function of A.
2. Substitute T_k in (49.65) and solve it with respect to A.
3. Determine N^* that minimizes A.

Suppose that $h_k(t) = \lambda_k m t^{m-1}$ $(m > 1)$ and $\lambda_k < \lambda_{k+1}$, *i.e.*, the failure rate $h_k(t)$ becomes greater with the number of PMs and is strictly increasing to ∞ as $t \to \infty$. Then, solving $h_k(T_k) = A$, we have

$$T_k = \left(\frac{A}{\lambda_k m}\right)^{1/(m-1)}.$$

Substituting T_k in (49.65) and rearranging it,

$$A\sum_{k=1}^{N}\left(\frac{A}{\lambda_k m}\right)^{1/(m-1)} - \sum_{k=1}^{N}\lambda_k\left(\frac{A}{\lambda_k m}\right)^{m/(m-1)} = \frac{c_2 + (N-1)c_3}{c_1},$$

i.e.,

$$A = \left\{\frac{c_2 + (N-1)c_3}{c_1\left[1-(1/m)\right]\sum_{k=1}^{N}\left[1/(\lambda_k m)\right]^{1/(m-1)}}\right\}^{(m-1)/m}.$$

Next, solve the problem that minimizes

$$B(N) = \frac{c_2 + (N-1)c_3}{\sum_{k=1}^{N}\left(1/\lambda_k\right)^{1/(m-1)}} \quad (N = 1,2,\ldots).$$

An optimum N^* that minimizes *B(N)* is given as follows: If $L(\infty) > c_2/c_3$, then there exists a finite and unique N^* that satisfies

$$L(N) \ge \frac{c_2}{c_3} \qquad (N = 1,2,\ldots),$$

where

$$L(N) \equiv \sum_{k=1}^{N}\left(\frac{\lambda_{N+1}}{\lambda_k}\right)^{1/(m-1)} - (N-1).$$

Therefore, we have the following optimum policy:

$$A = \left\{\frac{c_2 + (N^*-1)c_3}{c_1\left[1-(1/m)\right]\sum_{k=1}^{N^*}\left[1/(\lambda_k m)\right]^{1/(m-1)}}\right\}^{(m-1)/m},$$

$$T_k^* = \left(\frac{A}{\lambda_k m}\right)^{1/(m-1)},$$

and the expected cost rate is $c_1 A$.

49.3.5 Imperfect Policies

Consider four imperfect policies for the same periodic PM model as that in Section 49.3.4, *i.e.*, the PM is done at periodic times kT $(k = 1,2,\ldots)$. It is assumed that the unit undergoes only minimal repair at failures between PMs, and the failure rate is strictly increasing and remains undisturbed by minimal repair.

First, suppose that the unit after PM has the same failure rate as it had before PM with probability p $(0 \le p < 1)$ and that it becomes as good as new with probability $q \equiv 1 - p$. Then, the expected cost rate is

$$C_1(T) = \frac{1}{T}\left[c_1 q^2 \sum_{j=1}^{\infty} p^{j-1}\int_0^T h(t)\,dt + c_2\right], \qquad (49.66)$$

where c_1 = cost of minimal repair at each failure and c_2 = cost of each PM. If $\int_0^T t\,dh(t) > c_2/\left(c_1 q^2\right)$, then there exists a finite and unique T^* that satisfies

$$\sum_{j=1}^{\infty} p^{j-1}\int_0^{jT} t\,dh(t) = \frac{c_2}{c_1 q^2}. \qquad (49.67)$$

Secondly, suppose that the age becomes x $(0 \le x \le T)$ units younger at each PM and is

replaced if it operates for the time interval NT. Then, the expected cost rate is

$$C_2(N) = \frac{1}{NT}\left[\begin{array}{l} c_1 \sum_{j=0}^{N-1} \int_{j(T-x)}^{T+j(T-x)} h(t)dt \\ +c_2 + (N-1)c_3 \end{array}\right] \quad (N = 1, 2, \ldots), \quad (49.68)$$

where c_1 = cost of minimal repair, c_2 = cost of replacement at time NT, and c_3 = cost of each PM with $c_3 < c_2$. Then, an optimum N^* that minimizes $C_2(N)$ is given as follows: If $L_2(\infty) > (c_2 - c_3)/c_1$, then there exists a finite and unique minimum such that

$$L_2(N) \geq \frac{c_2 - c_3}{c_1} \quad (N = 1, 2, \ldots), \quad (49.69)$$

where

$$L_2(N) \equiv \sum_{j=0}^{N-1} \int_0^T \left[h(t + N(T-x)) - h(t + j(T-x))\right] dt.$$

Thirdly, suppose that the age after PM reduces to at $(0 < a \leq 1)$ when it was t before PM, *i.e.*, the age becomes $t(1-a)$ units of time younger at each PM. Then, the expected cost rate is

$$C_3(N) = \frac{1}{NT}\left[c_1 \sum_{j=0}^{N-1} \int_{A_j T}^{(A_j+1)T} h(t)dt + c_2 + (N-1)c_3\right] \quad (N = 1, 2, \ldots), \quad (49.70)$$

where $A_j \equiv a + a^2 + \cdots + a^j$ $(j = 1, 2, \ldots)$, $A_0 \equiv 0$, and the costs are the same ones as those in (49.66). If $L_3(\infty) > (c_2 - c_3)/c_1$, then there exists a finite and unique minimum such that

$$L_3(N) \geq \frac{c_2 - c_3}{c_1} \quad (N = 1, 2, \ldots), \quad (49.71)$$

where

$$L_3(N) \equiv N \int_{A_N T}^{(A_N+1)T} h(t)dt - \sum_{j=0}^{N-1} \int_{A_j T}^{(A_j+1)T} h(t)dt.$$

Finally, when the failure rate after PM reduces to $bh(t)$ $(0 < b \leq 1)$ when it was $h(t)$ before PM, the expected cost rate is

$$C_4(N) = \frac{1}{NT}\left[c_1 \sum_{j=0}^{N-1} b^j \int_{jT}^{(j+1)T} h(t)dt + c_2 + (N-1)c_3\right] \quad (N = 1, 2, \ldots). \quad (49.72)$$

If $L_4(\infty) > (c_2 - c_3)/c_1$, then there exists a finite and unique minimum such that

$$L_4(N) \geq \frac{c_2 - c_3}{c_1} \quad (N = 1, 2, \ldots), \quad (49.73)$$

where

$$L_4(N) \equiv N b^N \int_{NT}^{(N+1)T} h(t)dt - \sum_{j=0}^{N-1} b^j \int_{jT}^{(j+1)T} h(t)dt.$$

Note that the four models are identical and agree with the standard model in (49.7) when $p = 0$ and $N = 1$.

49.4 Computer Systems

A computer system has usually two types of failures: The system stops because of intermittent faults due to transient faults from noise, temperature, power supply variations, and poor electric contacts. Such faults are often automatically detected by the error correcting code and corrected by the error control, and the system begins to operate again. If the faults cannot be corrected, the system is restarted. On the other hand, the system stops subject to hardware failures or software errors, and then, it breaks down and needs corrective maintenance.

First, we apply the inspection policy to intermittent faults where the test is planned at periodic times to detect faults. We obtain the expected cost until fault detection and derive an optimum test time [2, 30, 31]. Next, we consider a computer system that is restarted when it stops, and discuss optimum PM policies that maximize the availabilities [32]. Furthermore, we apply the imperfect PM policy to a computer system with three imperfect cases, and derive an optimum PM time [2, 33].

49.4.1 Intermittent Faults

Suppose that faults occur intermittently, *i.e.*, a computer system repeats the operating state (state 0) and fault state (state 1) alternately. The times of respective operating and fault states are independent and have identical exponential distributions $(1-e^{-\lambda t})$ and $(1-e^{-\theta t})$ with $\theta > \lambda$. The periodic test to detect faults is planned at times kT $(k = 1, 2, \ldots)$. It is assumed that faults are investigated only through test and are always detected at tests when they have occurred.

The transition probabilities from state 0 to state j $(j = 0, 1,)$ are [1]

$$P_{00}(t) = \frac{\theta}{\lambda+\theta} + \frac{\lambda}{\lambda+\theta} e^{-(\lambda+\theta)t},$$

$$P_{01}(t) = \frac{\lambda}{\lambda+\theta}\left[1 - e^{-(\lambda+\theta)t}\right].$$

Thus, the expected number of $M(T)$ of tests to detect a fault is

$$M(T) = \sum_{j=0}^{\infty} (j+1)\left[P_{00}(T)\right]^j P_{01}(T) = \frac{1}{P_{01}(T)}, \tag{49.74}$$

and the mean time $l(T)$ to detect a fault is

$$\begin{aligned} l(T) &= \sum_{j=0}^{\infty} \left[(j+1)T\right]\left[P_{00}(T)\right]^j P_{01}(T) \\ &= \frac{T}{P_{01}(T)} = TM(T). \end{aligned} \tag{49.75}$$

Further, the probability $P(T)$ that the first occurrence of faults is detected at the first test is

$$\begin{aligned} P(T) &= \int_0^T e^{-\theta(T-t)} \lambda e^{-\lambda t} dt \\ &= \frac{\lambda}{\theta-\lambda}\left(e^{-\lambda T} - e^{-\theta T}\right). \end{aligned} \tag{49.76}$$

The total expected cost until fault detection is, from (49.74) and (49.75),

$$C(T) \equiv c_1 M(T) + c_2 l(T) = \frac{c_1 + c_2 T}{P_{01}(T)}, \tag{49.77}$$

where $c_1 =$ cost of one test and $c_2 =$ operational cost rate of a computer system. Then, an optimum test time T_1^* that minimizes $C(T)$ is given by a finite and unique solution of the equation:

$$\frac{1}{\lambda+\theta}\left[e^{(\lambda+\theta)T} - 1\right] - T = \frac{c_1}{c_2}.$$

Furthermore, an optimum time T_2^* that maximizes $P(T)$ is given by

$$T_2^* = \frac{\log\theta - \log\lambda}{\theta - \lambda}. \tag{49.78}$$

49.4.2 Imperfect Maintenance

A computer system begins to operate at time 0 and has to operate for an infinite time span. When the unit fails, it is repaired immediately and its mean repair time is θ_1. To prevent failures, the unit undergoes PM at periodic times kT $(k = 1, 2, \ldots)$. Then, one of the following three cases after PM results:

(1) The system is not changed with probability p_1, *i.e.*, PM is imperfect.

(2) The system is as good as new with probability p_2, *i.e.*, PM is perfect.

(3) The system fails with probability p_3, *i.e.*, PM becomes failure, where $p_1 + p_2 + p_3 = 1$ and $p_2 > 0$. In this case, the mean repair time for PM failure is θ_2.

The probability that the system is renewed by repair upon actual failures is

$$\sum_{j=1}^{\infty} {p_1}^{j-1} \int_{(j-1)T}^{jT} dF(t) = (1-p_1) \sum_{j=1}^{\infty} {p_1}^{j-1} F(jT), \tag{49.79}$$

the probability that it is renewed by perfect PM is

$$p_2 \sum_{j=1}^{\infty} p_1^{j-1} \overline{F}(jT), \tag{49.80}$$

and the probability that it is renewed by repair upon PM failure is

$$p_3 \sum_{j=1}^{\infty} p_1^{j-1} \overline{F}(jT), \tag{49.81}$$

where (49.79) + (49.80) + (49.81) = 1.

Further, the mean time until the unit is renewed by either repair or perfect PM is

$$\sum_{j=1}^{\infty} p_1^{j-1} \int_{(j-1)T}^{jT} t\,dF(t) + (p_2+p_3)\sum_{j=1}^{\infty} p_1^{j-1}\overline{F}(jT)$$
$$= (1-p_1)\sum_{j=1}^{\infty} p_1^{j-1} \int_0^{jT} \overline{F}(t)dt. \quad (49.82)$$

Therefore, from (49.79)–(49.82), the availability is

$$A(T) = \frac{(1-p_1)\sum_{j=1}^{\infty}\int_0^{jT}\overline{F}(t)dt}{(1-p_1)\sum_{j=1}^{\infty} p_1^{j-1}\int_0^{jT}\overline{F}(t)dt + [(1-p_1)\theta_1]\sum_{j=1}^{\infty} p_1^{j-1}F(jT) + (p_3\theta_3)\sum_{j=1}^{\infty} p_1^{j-1}\overline{F}(jT)}. \quad (49.83)$$

Then, an optimum time T^* that maximizes the availability $A(T)$ is given as follows: Suppose that

$$Q(T) \equiv \frac{\sum_{j=1}^{\infty} p_1^{j-1} j f(jT)}{\sum_{j=1}^{\infty} p_1^{j-1} j\overline{F}(jT)}$$

is strictly increasing and $K \equiv (1-p_1)/(p_2\mu)$. Then, if $Q(\infty) > K$ and $(1-p_1)\theta_1 < p_3\theta_2$, there exists a finite and unique T^* that satisfies

$$Q(T)\sum_{j=1}^{\infty} p_1^{j-1}\int_0^{jT}\overline{F}(t)dt - \sum_{j=1}^{\infty} p_1^{j-1}F(jT) = \frac{p_3}{1-p_1}\frac{\theta_2}{(1-p_1)\theta_1 - p_3\theta_2}, \quad (49.84)$$

and the resulting availability is

$$A(T^*) = \frac{1}{1+[\theta_1 - p_3\theta_2/(1-p_1)]Q(T^*)}. \quad (49.85)$$

49.4.3 Optimum Restart

Consider a computer system where restarts due to system failures occur in a nonhomogeneous Poisson process with a mean value function $H(t)$: When the system stops, it is restarted. The restart succeeds with probability q $(0 < q \le 1)$. In this case, the system returns to its initial condition and the intensity function remains undisturbed by restart. Conversely, the restart fails with probability $p \equiv 1-q$. In this case, the system breaks down and undergoes CM with mean time θ_1. The system undergoes PM with mean time $\theta_2 < \theta_1$ at time T. Then, the probability that the system needs CM in time T is

$$F_p(T) \equiv \sum_{j=0}^{\infty}\left(q^j p\right) p_j[H(T)] = 1 - e^{-pH(T)}. \quad (49.86)$$

Thus, replacing $F(t)$ in (49.83) with $F_p(t)$, we can obtain the availability $A_1(T)$.

Next, suppose that the system undergoes PM when the N th restart succeeds. Then, because the mean time to the Nth restart is $\sum_{j=0}^{N-1} q^j \int_0^{\infty} p_j[H(t)]dt$, the availability is:

$$A_2(N) = \frac{\sum_{j=0}^{N-1} q^j \int_0^{\infty} p_j[H(t)]dt}{\sum_{j=0}^{N-1} q^j \int_0^{\infty} p_j[H(t)]dt + (1-q^N)\theta_1 + q^N\theta_2} \quad (N = 1,2,\ldots). \quad (49.87)$$

If $h(t)$ is strictly increasing and $h(\infty)p\int_0^{\infty} e^{-pH(t)}dt > \theta_1/(\theta_1-\theta_2)$, then there exists a finite and unique minimum such that

$$\frac{p\sum_{j=0}^{N-1} q^j \int_0^{\infty} p_j[H(t)]dt}{\int_0^{\infty} p_N[H(t)]dt} - (1-q^N) \ge \frac{\theta_2}{\theta_1-\theta_2} \quad (N = 1,2,\ldots). \quad (49.88)$$

Finally, the PM is planned only at times kT $(k = 1,2,\ldots)$ as shown in Section 49.3.3. If the total number of successful restarts exceeds a specified number N, the PM is done at the next PM time, otherwise no PM is done. Then, the availability is

$$A_3(N) = \frac{\sum_{k=0}^{\infty}\int_{kT}^{(k+1)T}\overline{F}_p(t)dt\sum_{j=0}^{N-1} p_j[qH(kT)]}{\sum_{k=0}^{\infty}\int_{kT}^{(k+1)T}\overline{F}_p(t)dt\sum_{j=0}^{N-1} p_j[qH(kT)] + \theta_2 + (\theta_1-\theta_2)\left[F_p((k+1)T) - F_p(kT)\right] \times \sum_{j=0}^{N-1} p_j[qH(kT)]}. \quad (49.89)$$

In this case, (49.88) is rewritten as

$$\frac{\sum_{k=0}^{\infty}\int_{kT}^{(k+1)T}\overline{F}_p(t)dt\sum_{j=0}^{N-1}p_j\left[qH(kT)\right]}{\sum_{k=0}^{\infty}\int_{kT}^{(k+1)T}\overline{F}_p(t)dt\,p_N\left[qH(kT)\right]}$$

$$\times\sum_{k=0}^{\infty}\left[F_p((k+1)T)-F_p(kT)\right]p_N\left[qH(kT)\right]$$

$$-\sum_{k=0}^{\infty}\left[F_p((k+1)T)-F_p(kT)\right]\sum_{j=0}^{N-1}p_j\left[qH(kT)\right]$$

$$\geq\frac{\theta_2}{\theta_1-\theta_2}\qquad(N=1,2,\ldots).\qquad(49.90)$$

Effective Fault Detection and CBM Based on Oil Data Modeling and DPCA

Viliam Makis and Jianmou Wu

University of Toronto, Department of Mechanical and Industrial Engineering
5 King's College Rd., Toronto, Canada M5S 3G8

Abstract: This chapter presents two methodologies for effective equipment condition monitoring and condition-based maintenance (CBM) decision-making. The first method is based on multivariate modeling of data obtained from condition monitoring (CM data), dimensionality reduction using dynamic principal component analysis (DPCA), and constructing and using on-line a multivariate statistical process control (MSPC) chart based on the DPCA. The second method is based on vector autoregressive (VAR) modeling of CM data, DPCA, and building a proportional hazards (PH) decision model using the retained principal components as covariates. These methodologies are illustrated by an example using real oil data histories obtained from spectrometric analysis of heavy-hauler truck transmission oil samples taken at regular sampling epochs. The performances of the MSPC chart-based policy and the PH model-based optimal control limit policy are evaluated and compared with the traditional age-based policy.

50.1 Introduction

High complexity and sophistication of modern manufacturing systems has increased the impact of unplanned downtime caused by system failures. Unplanned downtime reduces productivity, increases product or service variability, and results in an increased maintenance spending due to breakdown maintenance. Effectively planned maintenance activities are becoming more and more important in modern manufacturing. Various maintenance schemes have been widely applied in industry, from corrective and time-based maintenance to condition-based maintenance (CBM). CBM is a maintenance strategy based on collected condition data that are related to the system health or status [1]. A CBM policy is based on monitoring an equipment condition on-line (*e.g.*, machine vibration monitoring or spectrometric analysis of oil samples) and making maintenance decisions based on the partial information obtained from the observation process. The concept of CBM has been widely accepted in maintenance practice due to the availability of advanced condition-monitoring technology capable of collecting and storing a large amount of data when the equipment is in operation. Several CBM models have appeared in the maintenance literature, such as a proportional hazards model in [2], a random coefficient regression model in [3], a counting-process model in [4], a state-space model in [5], an optimal-stopping

model in [6], and a hidden Markov model in [7], among others.

This chapter presents two novel methodologies for effective equipment condition monitoring and condition-based maintenance (CBM) decision-making based on multivariate modeling of CM data, dimensionality reduction using dynamic principal component analysis (DPCA), constructing a multivariate statistical process control (MSPC) chart based on the DPCA results, and building a proportional hazards (PH) model using the retained principal components as covariates.

Statistical process control (SPC) concepts and methods are very useful in industrial practice for process condition monitoring and fault detection. SPC uses statistically based methods to evaluate and monitor a process or its output in order to achieve or maintain a state of control [8]. It is still common in many industries to apply univariate SPC methods, such as Shewhart, CUSUM and EWMA charts, to a small number of variables and examine them one at a time. Due to the availability of advanced condition-monitoring technologies that are able to collect and store a large amount of process data, these univariate approaches should be replaced by multivariate methods. The multivariate process data should be used to extract information in an effective manner for monitoring operating performance and failure diagnosis. Various multivariate SPC (MSPC) charts, such as χ^2, T^2, multivariate CUSUM and EWMA have been developed and can be used for this purpose.

Although the MSPC charts have been applied in industrial practice, the main focus has been on multivariate quality control. Little attention has been paid to the implementation of MSPC for fault detection and maintenance decision-making. Considering the similarity between on-line quality control and condition monitoring for maintenance purposes, the application of multivariate SPC tools to CBM seems to be very appealing. The advantage of this approach when compared with the previously developed CBM models is the relative simplicity of the multivariate charting methods and an easy implementation in industrial practice. Some recent attempts to integrate SPC and maintenance control can be found in the literature (see, *e.g.*, [9], [10], [11], and [12]). However, in these studies only relatively simple univariate SPC approaches have been used. To our knowledge, there has been no SPC application based on real data in the maintenance literature.

Using the T^2 control chart, Jackson and Mudholkar [13] investigated PCA as a multivariate SPC tool for the purpose of dimensionality reduction and introduced residual analysis. The PCA-based (T_A^2, Q) control charts are very useful for monitoring multivariable industrial processes, but they cannot be directly applied in CBM because PCA assumes independence of successive samples, whereas the maintenance data typically exhibit both cross and auto-correlation. Dynamic PCA, an extension of PCA, can be successfully applied to such data, and therefore a DPCA version of the combined T_A^2 and Q, charts would be appropriate for a maintenance application. In this chapter, we apply the DPCA-based (T_A^2, Q) charts to the CM data and illustrate the method using real heavy hauler truck transmission oil data for failure prevention and CBM decision-making.

PHM, first proposed by Cox in 1972, has become very popular to model the lifetime data in biomedical sciences, and recently also in reliability and maintenance applications. In CBM modeling, PHM integrates the age information with the condition information to calculate the risk of failure (hazard rate) of a system. In the paper by Makis and Jardine [2], a PH decision model was considered and the structure of the optimal replacement policy minimizing the total expected average maintenance cost was obtained. The computational algorithms for this PH decision model were published by Makis and Jardine [14].

In this chapter, the CBM modeling is based on the above PH model. The sampling data gained from condition monitoring can be represented in a vector form and the components in a data vector are termed as covariates in PH modeling. Usually the covariates are both cross-correlated and auto-correlated because they are related to the same deterioration process. The amount of data collected at a sampling epoch is usually very large and it is therefore important to reduce data dimensionality and capture most of the information contained in the original data set. Therefore, we first apply the

multivariate time series methodology to fit a vector autoregressive (VAR) model to the whole oil data histories. Then, a DPCA is performed and the principle components capturing most of the data variability are selected. These principal components are then used as the covariates to build a PH model for CBM purposes.

50.2 Fault Detection Using MSPC, VAR Modeling and DPCA

50.2.1 Hotelling's T^2 Chart and PCA-based (T_A^2, Q) Charts

The best-known control charts for monitoring multivariate processes are Hotelling's χ^2 and T^2 charts [15]. Assume that when the process is in control, a *k*-dimensional vector Y_t of measurements has a multivariate normal distribution with mean vector μ and covariance matrix Σ. The following statistic

$$\chi_t^2 = (Y_t - \mu)'\Sigma^{-1}(Y_t - \mu) \qquad (50.1)$$

is plotted on the chart for which the upper control limit (UCL) is $\chi_{\alpha,k}^2$, where α is the selected probability of false alarm.

When the in-control mean vector μ and covariance matrix Σ are unknown and must be estimated from a sample of data, the Hotelling's T_t^2 statistic is used:

$$T_t^2 = (Y_t - \hat{\mu})'S^{-1}(Y_t - \hat{\mu}), \qquad (50.2)$$

where $\hat{\mu}$ and S are the estimates of the process mean μ and the covariance matrix Σ, respectively. The upper control limit T_{UCL}^2 is obtained from the *F* distribution with k and $N-k$ degrees of freedom, where N is the size of the sample used to estimate μ and Σ,

$$T_{UCL}^2 = \frac{(N^2-1)k}{N(N-k)}F_\alpha(k, N-k). \qquad (50.3)$$

Principal component analysis (PCA) is a linear transformation method that can obtain a set of uncorrelated variables, termed principal components (PCs), from the original set of variables. The obtained PCs have special properties in terms of variances. For example, the first PC is the standardized linear combination with maximum variance. The second PC has maximum variance of all linear combinations uncorrelated with the first PC, *etc.* [16]. When the PCA is used to characterize the multivariable observation process, Hotelling's T^2 can also be expressed in terms of PCs:

$$T_t^2 = \sum_{a=1}^{k}\frac{z_{t,a}^2}{l_a}, \qquad (50.4)$$

where $z_{t,a}$ are the PC scores from the principal component transformation and l_a, $a = 1, 2, \cdots, k$, are the eigenvalues of the correlation matrix estimate of the original data.

Furthermore, the PC score vector Z_t can be expressed as Y_t

$$Z_t = (z_{t,1}, z_{t,2}, \cdots z_{t,k})' = (u_1, u_2, \cdots u_k)' \cdot O_t, \qquad (50.5)$$

where $u_1, u_2, \cdots, u_k$ are the eigenvectors of the correlation matrix estimate of the original data set Y_t and the vector O_t is the standardized vector obtained from $O_t = (\frac{Y_{t,1}-\bar{Y}_1}{s_1}, \frac{Y_{t,2}-\bar{Y}_2}{s_2}, \cdots, \frac{Y_{t,k}-\bar{Y}_k}{s_k})'$, with $\bar{Y}_i$ and s_i denoting the sample mean and standard deviation for variable $i, (i = 1, \cdots, k)$.

When PCA is used to reduce dimensionality, the T^2 chart based on the first A selected principal components is constructed as follows:

$$T_{A,t}^2 = \sum_{a=1}^{A}\frac{z_{t,a}^2}{l_a} = \sum_{a=1}^{A}\frac{(u_a' \cdot O_t)^2}{l_a}. \qquad (50.6)$$

Then, based on the above formula, we can rewrite the T_t^2 statistic as follows [8], [17]

$$T_t^2 = \sum_{a=1}^{A}\frac{z_{t,a}^2}{l_a} + \sum_{a=A+1}^{k}\frac{z_{t,a}^2}{l_a^2} = T_{A,t}^2 + \sum_{a=A+1}^{k}\frac{z_{t,a}^2}{l_a^2}. \qquad (50.7)$$

The T_A^2 statistic based on the first A uncorrelated PCs provides a test for deviations in the condition monitoring variables that contribute most to the variance of the original data set Y_t. The upper control limit of T_A^2 can be calculated from (50.3) with k replaced by A [17].

However, only monitoring the process via T_A^2 is not sufficient. This method can only detect whether the variation in the condition monitoring variables in the space defined by the first A principal components exceeds UCL or not. In case a totally new type of special event occurs, which can cause the machine failure and was not presented when developing the in-control PCA model, then new PC's will appear and the new observation will move off the space defined by the in-control PCA model. Such new events can be detected by monitoring the squared prediction error (SPE) of the observation residuals, which gives a measure of how close an observation is to the A-dimensional space defined by the in-control PCA model:

$$SPE_t = \sum_{i=1}^{k} (O_{t,i} - \hat{O}_{t,i})^2 , \qquad (50.8)$$

where $\hat{O}_t = \sum_{a=1}^{A} Z_{t,a} \cdot u_a$ is computed from the in-control PCA model.

The SPE statistic is also referred to as a Q statistic [18]. The upper control limit for the Q statistic can be computed using approximate results for the distribution of quadratic forms [18], [19]. With significance level α, the UCL can be computed from the following formula:

$$Q_\alpha = \theta_1 [1 - \theta_2 h_0 (1 - h_0) / \theta_1^2 + z_\alpha (2\theta_2 h_0^2)^{1/2} / \theta_1]^{1/h_0} \qquad (50.9)$$

where z_α is the $100(1-\alpha)$ normal percentile, $\theta_i = \sum_{j=A+1}^{k} l_j^i, i = 1, 2, 3,$ and $h_0 = 1 - 2\theta_1\theta_3 / 3\theta_2^2$ [20]. When the process is in control, Q represents unstructured fluctuations (noise) that cannot be accounted for by the PCA model. When an unusual event occurs that results in a change in the covariance (or correlation) structure of the original data set, it will be detected by a high value of Q. In this case, the PCA model may no longer be valid.

A T_A^2 chart on the A dominant orthogonal PCs plus a Q chart is an effective set of multivariate SPC charts. On one hand, because the T_A^2 statistic is not affected by the smaller eigenvalues of the correlation matrix, it provides a more robust fault detection measure. T_A^2 can be interpreted as measuring the systematic variation in the PCA subspace, and a large value of T_A^2 exceeding the threshold would indicate that the systematic variation is out of control [20]. On the other hand, the T^2 chart is overly sensitive in the PCA space because it includes the scores corresponding to the small eigenvalues representing noise which may contribute significantly to the value of the T^2 statistic. The Q (SPE) statistic represents the squared perpendicular distance of a new multivariate observation from the PCA subspace and it is capable of detecting a change in the correlation structure when a special event occurs.

50.2.2 The Oil Data and the Selection of the In-control Portion

The data used in this chapter are the histories of the diagnostic oil data obtained from the 240-ton heavy hauler truck transmissions. Oil samples are taken roughly every 600 hours and the results of the spectrometric analysis consisting of the measurements of 20 metal elements in ppm are recorded. The total number of oil data histories considered is 51, 20 of them ended with a failure and the remaining 31 were suspended. A preliminary analysis by using EXAKT software (http://www.mie.utoronto.ca/labs/cbm) and also the results obtained previously [21] indicate that it is sufficient to consider only 6 out of the total of 20 metal elements, namely potassium, iron, aluminum, magnesium, molybdenum and vanadium for maintenance decision-making.

Since it is a set of six-dimensional data and the in-control covariance matrix is unknown, we decided to calculate and plot the T^2 statistic in order to determine the portions of the histories when transmission was in a healthy state. Before plotting the T^2 statistic and selecting the in-control portion of the oil data, it was necessary to pre-process the raw oil data. To satisfy the equal sampling interval condition, we discarded six histories that have sampling intervals far greater than 600 hours. In the remaining 45 histories, the sampling records were excluded when the sampling intervals were far less than 600 hours. There were also nine short histories that have less than six records. Since it does not make much sense to select the in-control portions from these short histories, we discarded them too. Finally, we considered 36 histories that are long enough and equally spaced. The total number of the oil data records is 527. The T^2 statistic was calculated and plotted and the in-control portion of the data was identified.

The sample mean and covariance matrix were estimated from the data and the T_t^2 values were calculated using (50.2). For the upper control limit T_{UCL}^2, we set k=6 and N=527 in (50.3) because our oil data is 6-dimensional and we have totally 527 observations in the remaining 36 histories. Choosing the significance level $\alpha = 0.025$, we found $F_\alpha(k, N-k) = 2.4325$ and $T_{UCL}^2 = 14.763$.

On selecting the healthy portion of the oil data, the following three working states of the transmissions were considered: initial state, healthy state and deteriorating state. Also, we note that the transmission oil was changed every 1200 hours, which dramatically affected the cumulative increasing trend of the T_t^2 series. We have decided to apply the following criteria to find out the in-control portion of the oil data. When the T_t^2 value exceeded the upper control limit T_{UCL}^2 during the first three observations of a history, we assumed the transmission was in the initial run-in state before reaching the normal operating state. We excluded all the initial records in the histories up to and including the ones that exceeded the upper control limit. On the other hand, when an abnormal value of T_t^2 appeared later in the history ($t \geq 6$), it was assumed that the transmission reached a deteriorating state and all the following observations were excluded. The remaining observations are the portions of the histories when transmission was in a healthy state. Following this procedure, we selected 409 out of 527 records as the healthy portion of the oil data histories.

50.2.3 Multivariate Time Series Modeling of the Oil Data in the Healthy State

We assume that the evolution of the observation process is described by a VAR model which proved to be a good representation of the oil data obtained from condition monitoring in our previous research [22], [23]. Using the in-control portion of the oil data, we can build a stationary VAR model to describe the observation process.

We have applied the Yule–Walker estimation method to calculate the model parameter estimates. The model order was determined by a test using Wald statistic. After fitting the VAR model, we also checked the model stationarity condition in order to confirm that our method of selecting the in-control portion of the data histories is appropriate. The details of the Yule–Walker methodology, Wald statistic and the stationarity condition check can be found in [24].

By extending the Yule–Walker estimator formulae and the Wald statistic formula to a multi-history case and applying them to the in-control portion of the oil data, we have the following modeling results. For m = 2, 3, 4, 5 the order test Wald statistic values are W_2 = 59.6080, W_3 = 29.8101, W_4 = 21.8461, and W_5 = 13.6612. We can see that there is a clear drop in these values between W_2 and W_3. By setting the significance level $\alpha = 0.025$, we find the critical value $C = X_{36,0.025}^2 = 54.437$ from the chi-square distribution with $k^2 = 36$ degrees of freedom. Since $W_2 > C$ and $W_3 < C$, we reject $H_0 : \Phi_{22} = 0$ and fail to reject $H_0 : \Phi_{33} = 0$. Thus, we conclude that an AR(2) model is adequate to model the in-control portion of the oil data. The order of the AR

model is also used in the dynamic principle component analysis (DPCA) later in the chapter as the time lag value.

For the fitted AR(2) model $(Y_t - \mu) = \Phi_{12}(Y_{t-1} - \mu) + \Phi_{22}(Y_{t-2} - \mu) + \varepsilon_t$, the estimates of the parameters are as follows,

$$\hat{\mu}_6 = (2.3899 \quad 8.9342 \quad 1.3215 \quad 8.2506 \quad 0.5114 \quad 0.1038)'$$

$$\hat{\Phi}_{12} = \begin{bmatrix} 0.7150 & -0.0237 & 0.1045 & 0.0008 & -0.1016 & -0.0433 \\ 0.2618 & 0.4857 & -0.8588 & -0.0211 & 0.4640 & -0.3494 \\ 0.0145 & 0.0082 & 0.2323 & 0.0003 & -0.0942 & 0.0196 \\ -0.2546 & -0.0100 & 0.9894 & 0.4606 & 0.7465 & -1.2370 \\ 0.0142 & 0.0012 & -0.0081 & -0.0025 & 0.0996 & -0.0034 \\ -0.0149 & 0.0023 & 0.0546 & -0.0012 & -0.0493 & 0.0625 \end{bmatrix}$$

$$\hat{\Phi}_{22} = \begin{bmatrix} -0.1385 & 0.0003 & -0.2326 & 0.0014 & 0.0591 & 0.2485 \\ -0.1378 & 0.1302 & 0.7855 & 0.0099 & 0.0037 & 0.7663 \\ -0.0300 & -0.0039 & 0.2115 & -0.0031 & -0.0626 & -0.0538 \\ 0.2238 & -0.0209 & 0.1360 & -0.0063 & 0.3450 & -0.9185 \\ -0.0119 & -0.0062 & -0.0377 & -0.0001 & 0.1411 & -0.0023 \\ 0.0143 & -0.0057 & -0.0188 & 0.0006 & 0.0899 & 0.0384 \end{bmatrix}$$

$$\hat{\Sigma}_2 = \begin{bmatrix} 6.6044 & 1.1622 & 0.0802 & -2.8131 & 0.0168 & 0.1088 \\ 1.1622 & 25.3816 & 0.2222 & 1.9658 & 0.4041 & 0.0739 \\ 0.0802 & 0.2222 & 0.2333 & -0.3565 & 0.0974 & 0.0245 \\ -2.8131 & 1.9658 & -0.3565 & 75.2260 & 0.0304 & -0.1669 \\ 0.0168 & 0.4041 & 0.0974 & 0.0304 & 0.2686 & 0.0211 \\ 0.1088 & 0.0739 & 0.0245 & -0.1669 & 0.0211 & 0.2239 \end{bmatrix}$$

The eigenvalues of Φ_2 are (−0.4261, −0.2512 + 0.1343*i*, −0.2512 − 0.1343*i*, −0.1792, −0.0000, 0.2915 + 0.2170*i*, 0.2915 −0.2170*i*, 0.6724, 0.6135, 0.4358 + 0.0667i, 0.4358 −0.0667*i*, 0.4230), where Φ_2 is described as $\Phi_2 = \begin{bmatrix} \Phi_{12} & \Phi_{22} \\ I & 0 \end{bmatrix}$. Since the eigenvalues are all less than one in absolute value, the fitted AR(2) model is stationary. This result indicates that choosing the relatively simple Yule–Walker method for the AR model parameters estimation and Wald statistic for the model order selection is appropriate.

50.2.4 Dynamic PCA and the DPCA-based $(T^2_{4,t}, Q_t)$ Charts for the Oil Data

The readings of the six metal elements representing the oil data are both cross and auto-correlated. Since the oil data does not satisfy the assumption of independence of samples collected at different time epochs, the original PCA method is not suitable here. Directly applying PCA to the oil data will not reveal the exact relations between the variables of the process. DPCA, an extension of the PCA method, is used to process the oil data. The correlation relationship in the oil data is represented by the cross-covariance and the auto-covariance matrices. The correlation relationship can be represented by the covariance matrices $\Gamma(0), \Gamma(1)$ and $\Gamma(2)$. $\Gamma(0)$ is the cross-covariance matrix and $\Gamma(i)$ is the auto-covariance matrix of time lag $i, i = 1, 2$. These covariance matrices are used when applying DPCA to the oil data. Unlike the PCA method, when DPCA is applied, the data matrix is composed of the time-shifted data vectors (see, *e.g.*, [25]).

DPCA is based on conducting singular value decomposition on an augmented data matrix containing time lagged process variables. It is essentially the same as PCA except that the data vectors of the variables consist of the current data vector Y_t and the time-shifted vectors $Y_{t-1}, Y_{t-2}, \cdots$. For example, in the case of our oil data, the process dynamics is described by a vector AR(2) model so that the data vector considered in the DPCA is $(Y'_t, Y'_{t-1}, Y'_{t-2})'$ instead of Y_t which would be considered in the PCA.

The starting point for DPCA is to obtain the sample covariance matrix $\hat{\Gamma}$. In our vector AR(2) model, the covariance matrix Γ consists of $3 \times 3 = 9$ blocks, each of dimension 6×6, where the $(i, j)th$ block matrix is $\Gamma(i - j)$, $\Gamma(i - j) = \Gamma(j - i)'$ if $i - j < 0$, for $i, j = 1, 2, 3$. In this section, $\Gamma(i)$ denotes the sample covariance matrix of time lag i. If the original variables are in different units, or their means vary widely, as is the case for our oil data, it is more appropriate to use the correlation matrix rather than the covariance

matrix. The lag i correlation matrix can be obtained from the covariance matrix directly by $R(i) = D^{-1}\Gamma(i)D^{-1}, i = 0,1,2$, where D is the diagonal matrix of standard deviations of the original variables. The structure of the sample correlation matrix used in DPCA is the same as the structure of the sample covariance matrix Γ, *i.e.*, the $(i, j)th$ block matrix is $R(i-j)$, where $R(i-j) = R(j-i)'$ if $i-j<0$, $i, j = 1,2,3$. Replacing O_t by $D_t = (O'_t, O'_{t-1}, O'_{t-2})'$ in (50.5), we can obtain the PC scores from the original oil data.

The eigenvalues $\{l_i\}$ of the sample correlation matrix R ordered from the largest to the smallest are the sample variances of the (sample) principal components. The purpose of DPCA is to generate a reduced set of variables (PCs) that accounts for most of the variability in the original oil data. A number of procedures for determining how many components to retain have been suggested in [26]. Here we apply the scree test, an approach first proposed by Cattell [27]. In the scree test, the eigenvalues are plotted in successive order of their extraction and then an "elbow" in the curve is identified such that the bottom portion of the eigenvalues after the "elbow" forms an approximate straight line. The points above the straight line in the curved portion of the plot correspond to the retained PCs. The result of the scree test for the in-control oil data DPCA is shown in Figure 50.1. The eigenvalues obtained after applying DPCA are listed in Table 50.1.

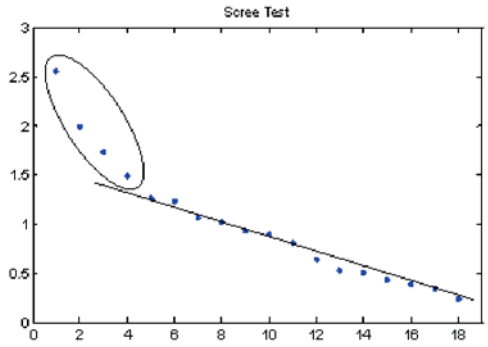

Figure 50.1. Scree test of DPCA for the oil data

The scree test plot in Figure 50.1 clearly shows that there is a break (an elbow) between the first four and the remaining 14 eigenvalues that form approximately a straight line. This result indicates that we should retain the first four PCs to construct our DPCA model.

After applying the DPCA and selecting the principle components accounting for most of the process variation, we obtained a four-dimensional PC scores series. Putting $A = 4$ in (50.6) and (50.8), we calculated the $T^2_{4,t}$ and Q_t values. Setting the significance level as $\alpha = 0.025$, we obtained: $T^2_{4,UCL} = 11.4305$, $Q_{UCL} = 23.2147$ from (50.3) and (50.9). We then plotted the $T^2_{4,t}$ and the Q_t values on the corresponding charts. The T^2_4 chart shows too many false alarms and misses most of the impending failures. The reason is that the four-dimensional PC score series is still highly serially correlated, which makes the T^2_4 chart in-

Table 50.1. Successive eigenvalues l_i and eigenvalues diffenerce l_i-l_{i+1}

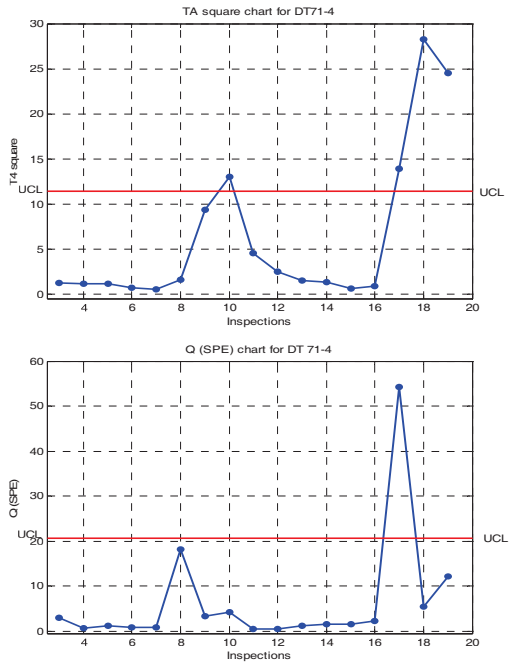

Figure 50.2. An example of the DPCA-based T_4^2 chart and Q chart

effective. On the other hand, the Q chart is based on the residuals of the DPCA model and serial correlation is not significant when the process is in control. In the Q chart, false alarms are significantly reduced and the true alarms coincide with the impending transmission failures.

For example, Figure 50.2 compares the DPCA-based T_4^2 chart and Q charts applied to history DT 71-4 which ended with suspension. On the T_4^2 chart, out-of-control alarms appear at the 10th, 17th, 18th and 19th sampling points. It is clear that the 17th sampling point alarm in the T_4^2 chart has an effect on the next two $T_{4,t}^2$ values because of the high serial correlation of the PC scores and two subsequent alarms appeared that should not be there. On the Q chart, only one alarm appears at the 17th sampling point. Because this history ended with suspension, which means the transmission worked properly until it was suspended, all these alarms are false alarms although the alarm generated by the Q chart is much closer to the suspension time than the alarms on the T_4^2 charts. Therefore, it is obvious that the T_4^2 chart is not appropriate for transmission condition monitoring due to the serial correlation of the oil data, and the Q chart shows a better performance. Note that the T_4^2 chart and the Q chart begin with the third sample because the time shift in DPCA makes the first two $T_{4,t}^2$ and Q_t values unavailable.

50.2.5 Performance Comparison of Fault Detection and Maintenance Cost

In this section, we check the fault detection performance of the DPCA-based Q chart, denoted as Q_{DPCA} chart and perform a maintenance cost comparison between the Q_{DPCA} chart-based policy and the age-based policy.

By setting the significance level $\alpha = 0.025$, we first applied the Q_{DPCA} chart to the 23 histories that ended with suspension. In these cases, the histories ended with suspensions and the transmissions were replaced applying the age-based policy after about 12,000 working hours regardless of their actual conditions. Thus, we only focused on the false alarms in the chart. One can assume that the out-of-control signals occurring at the first three samplings are run-in period alarms. After the run-in period any subsequent signals can be considered to be false alarms. The out-of-control signals and the false alarms (in bold font) are summarized in Table 50.2. Totally, there are only 6 false alarms in the Q_{DPCA} chart for the 23 suspended histories.

For the failure histories, our main goal is to compare the failure detection capability of the two charting methods. If the out-of-control signal occurs just before failure, *i.e.*, at the last sampling point, the SPC chart indicates the impending failure perfectly and triggers a preventive replacement which avoids failure. Furthermore, in case the Q_{DPCA} statistic value dramatically

DT 78-1	15	–
DT 79-3	7	–

increases, even if it does not exceed the control limit, this can also be considered as an alarm indicating the impending failure. Examples of the Q_{DPCA} chart applied to the failure histories, DT 68-2 and DT 72-2, are given in Figure 50.3. The trends of the Q_{DPCA} are increasing in both plots and engineers can easily figure out that the signals indicate transmission impending failures.

The alarms which occur in the middle part of the failure histories (excluding the first three samples) are treated as false alarms and the significance level is $\alpha = 0.025$. The results for the Q_{DPCA} chart applied to the failure histories are

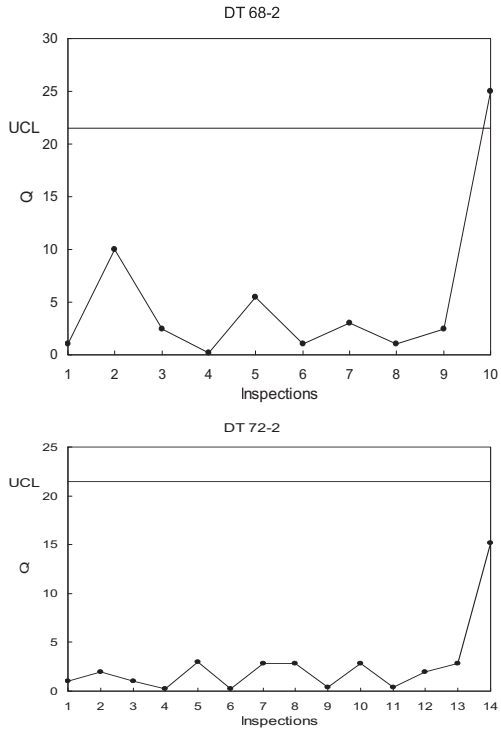

Figure 50.3. Examples of Q_{DPCA} chart applied to the failure histories

given in Table 50.3. The Q_{DPCA} chart triggers 7 preventive replacements without giving any false alarm for the 13 failure histories.

From the results in Tables 50.2 and 50.3, we can conclude that the Q_{DPCA} chart is an effective SPC charting method which can prevent considerable number of failures in a timely manner without generating an excessive number of false alarms. Next, we perform a maintenance cost analysis between the Q_{DPCA} chart-based policy and the age-based policy in order to confirm the effectiveness of the Q_{DPCA} chart.

When the chart signals, the transmission is inspected by a technician to find out whether it is a false alarm or an indication of impending failure. Therefore, every alarm incurs a sampling cost, which includes also the cost related to machine downtime. In case the alarm occurs at the last sampling point before failure, preventive replacement is considered. The preventive replacement

Table 50.3. Application of the Q_{DPCA} chart to the failure histories

Histories	Number of samplings	Alarms in Q_{DPCA} chart

DT 74-2	–	–
DT 77-1	7	7th
DT 79-2	–	–

cost includes inspection cost, downtime cost, a transmission re-installation cost and so on. Therefore, in the maintenance cost analysis, only the alarms in the middle of the histories will result in incurring a false alarm cost since the sampling cost is included in the preventive replacement cost.

The following parameters are needed to calculate the total maintenance cost for a particular policy: the preventive replacement cost C, the failure replacement cost $C+K$, and the false alarm cost F. For this study, we consider the estimates used in our previous research [22], [23], namely C=\$1,560 and $C+K$=\$6,780. In this chapter, the false alarm cost F is considered to be \$450. A comparison of the two maintenance policies (the currently used age-based policy and the Q_{DPCA} chart-based policy) is in Table 50.4.

From Table 50.4, the chart-based maintenance policy can avoid 7 out of 13 transmission failures. Considering the transmission oil changes that eliminate any cumulative increase in the control

Table 50.4. Comparison of maintenance policies using oil data histories

Policy	Age-based	Q_{DPCA} Chart-based
Sample size	36	36
Failures	13	6
Preventive replacements	23	30
Prev. repl.	63.89%	83.33%
Total false alarms	–	6
Total maintenance cost	\$124020	\$90180
Savings	–	\$33840
Savings %	–	27.29%

statistics, which makes it very difficult to indicate impending failures in condition monitoring, the fault detection capability of the Q_{DPCA} chart is excellent. On the other hand, the Q_{DPCA} chart gives only six false alarms. Thus the Q_{DPCA} chart based policy leads to significant cost savings, \$33840 or 27.29%.

50.3 CBM Cost Modeling and Failure Prevention

50.3.1 The Proportional Hazards Model and the CBM Software EXAKT

The CBM model presented in this chapter is the PH decision model considered by Makis and Jardine [2], controlled by the optimal replacement policy. It was proved in [2] that the average cost optimal policy is a control limit policy, *i.e.* the system is replaced (overhauled) when the value of the hazard function exceeds some optimal limit.

In the general PHM [28], the hazard rate is assumed to be the product of a baseline hazard rate $h_0(t)$, and a positive function $\psi(z,\gamma)$ representing

the effect of the operating environment on the system deterioration, where z is a covariate vector and γ is the vector of the unknown parameters.

In maintenance and reliability applications, some covariates are usually time-dependent stochastic processes and a dynamic PHM is more appropriate to describe the time-to-failure distribution. Thus, the hazard function for the dynamic PHM has the form: $h(t, z_t) = h_0(t, \omega)\psi(z_t, \gamma)$, where z_t is a covariate vector process and (ω, γ) is a vector of unknown parameters. In real applications, the system condition is usually monitored at regular sampling epochs and it is thus assumed that the values of $\{z_t\}$ are available only at these discrete sampling times. The system deterioration process is assumed to be continuous and the system can fail at any time. The covariate vector process $\{z_t\}$ is assumed to be a continuous time Markov process. Each replacement costs C and the failure replacement cost is C+K, C>0, K>0. The optimal policy minimizes the long-run expected average cost per unit time.

The condition-based maintenance (CBM) modeling is conducted by using the software called EXAKT, which was developed by the CBM lab at the Department of Mechanical and Industrial Engineering, University of Toronto.

EXAKT is a software package for CBM data pre-processing, PH modeling and maintenance decision-making. It utilizes recent oil or vibration data histories obtained from an equipment condition monitoring to build a Weibull PH model off-line, calculates the average cost optimal preventive replacement policy and then processes the data obtained from an on-line condition monitoring system to make optimal maintenance decisions.

The PH model in EXAKT uses the Weibull hazard function, which has the form:

$$h(t, Z(t)) = \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1} Exp(\gamma_1 z_1(t) + \gamma_2 z_2(t) + \cdots + \gamma_k z_k(t)) \tag{50.10}$$

where β and η are unknown shape and characteristic life parameters, respectively, and $\gamma = (\gamma_1, \gamma_2, \cdots, \gamma_k)'$ is the vector of unknown regression coefficients, $Z(t) = (z_1(t), z_2(t), \cdots, z_k(t))'$ is the vector of covariates assumed to be a multivariate non-homogeneous Markov process. The decision model in EXAKT calculates the average-cost optimal preventive replacement policy using the PH model fitted to recent data histories. It was proved in [2] that the structure of the optimal replacement policy is a control-limit policy, *i.e.*, a preventive replacement is recommended when the calculated value of the hazard function in (50.10) exceeds some optimal critical value.

50.3.2 Multivariate Time Series Modeling of the Oil Data

The oil data set used here is the same as what was used in the previous section. However, in this section, the modeling is not based on the healthy portion of the histories but using the whole data histories. Thus, we only discard the histories with the sampling interval far greater than 600 hours or much smaller than 600 hours in the multivariate time series modeling. There were two other data histories with only two records, which were too short for time series modeling and they were also discarded. Thus, our time series modeling is based on the 43 of the original 51 histories (totally 563 sampling records).

We have applied the least-square (LS) estimation method to calculate the model parameter estimates. The model order was determined by a test using likelihood ratio (LR) statistic. After fitting the VAR model, we also checked the model stationarity condition. The details of the LS estimation method, LR statistic and the stationarity condition check can be found in [24].

Based on the 43 of the selected oil data histories, we have the following modeling results. For m=2,3, the order test LR statistic M_2= 87.938, M_3=50.286. From the chi-squared distribution, with k^2=36 degrees of freedom and taking the significance level as 0.05, we find

$X^2_{36,0.05} = 50.998 = C$. Since $M_2 > C$ and $M_3 < C$, we reject H_0: $\Phi_{22} = 0$ and fail to reject H_0: $\Phi_{33} = 0$. Thus, we conclude that an AR(2) model is adequate for the oil data. Thus, the correlation relationship is represented by the covariance matrices $\Gamma(0), \Gamma(1)$ and $\Gamma(2)$. $\Gamma(0)$ is the cross-covariance matrix while $\Gamma(1)$ and $\Gamma(2)$ are the auto-covariance matrices of time lag one and two respectively. For the fitted AR(2) model $Y_t = \Phi_{12} Y_{t-1} + \Phi_{22} Y_{t-2} + \delta + \varepsilon_t$, the estimates of the parameters are as follows:

$$\hat{\delta}' = [0.6217,\ 2.3614,\ 0.8288,\ 5.9734,\ 0.5074,\ 0.3047]$$

$$\hat{\Phi}_{12} = \begin{bmatrix} 0.3946 & -0.5443 & 0.0175 & -0.3526 & -0.0060 & 0.1368 \\ -0.0000 & 0.6668 & 0.0052 & -0.1179 & 0.0044 & -0.0034 \\ 0.0285 & -0.2587 & 0.1776 & 7.1550 & -0.0733 & -0.0517 \\ 0.0020 & -0.0100 & 0.0007 & 0.2410 & -0.0008 & 0.0036 \\ -0.1571 & 0.6021 & -0.0498 & -5.0252 & 0.2169 & -0.1450 \\ 0.0040 & -0.0516 & 0.0041 & 0.9885 & -0.0206 & 0.0378 \end{bmatrix}$$

$$\hat{\Phi}_{22} = \begin{bmatrix} 0.1613 & 0.5135 & -0.0301 & 0.0774 & 0.0016 & -0.0357 \\ -0.0111 & 0.0617 & -0.0048 & 0.0479 & -0.0006 & 0.0049 \\ -0.0923 & 0.1459 & 0.2555 & -2.6052 & -0.0730 & -0.1901 \\ 0.0014 & 0.0132 & -0.0004 & 0.0742 & 0.0009 & 0.0051 \\ 0.0748 & 0.0051 & -0.0263 & 3.0802 & 0.2134 & 0.1781 \\ -0.0791 & -0.1721 & -0.0002 & -1.1693 & 0.0113 & -0.0601 \end{bmatrix}$$

$$\hat{\Sigma}_2 = \begin{bmatrix} 2.6322 & 1.4876 & 0.1178 & 0.4422 & 0.0237 & 0.1261 \\ 1.4876 & 78.4428 & 0.1926 & 3.5132 & 0.4981 & 1.8616 \\ 0.1178 & 0.1926 & 0.2697 & 0.9228 & 0.0901 & 0.1233 \\ 0.4422 & 3.5132 & 0.9228 & 715.5363 & 0.2702 & 3.2791 \\ 0.0237 & 0.4981 & 0.0901 & 0.2702 & 0.3806 & 0.1079 \\ 0.1261 & 1.8616 & 0.1233 & 3.2791 & 0.1079 & 2.7440 \end{bmatrix}$$

To check the stationarity condition for this fitted AR(2) model, we found that the eigenvalues of Φ_2 are (−0.4755, −0.3717, −0.2068 + 0.0647i, −0.2068 − 0.0647i, 0.0040 + 0.1866i, 0.0040 − 0.1866i, 0.0500, 0.7449, 0.6766, 0.6474, 0.3539, 0.5145), where Φ_2 is described as $\Phi_2 = \begin{bmatrix} \Phi_{12} & \Phi_{22} \\ I & 0 \end{bmatrix}$. Since the eigenvalues are all less than one in absolute value, the fitted AR(2) model is stationary.

50.3.3 Application of DPCA to the Oil Data

The readings of the six metal elements representing the oil data are both cross and auto-correlated. The correlation relationship among them is represented by the cross-covariance and the auto-covariance matrices. It follows from the analysis in the previous section that the correlation relationship can be represented by the covariance matrices $\Gamma(0), \Gamma(1)$ and $\Gamma(2)$. $\Gamma(0)$ is the cross-covariance matrix and $\Gamma(i)$ is the auto-covariance matrix of time lag $i, i = 1, 2$. These covariance matrices are used when applying DPCA to reduce the dimensionality of oil data. DPCA is an extension of the original PCA method applied to the matrix composed of the time-shifted data vectors (see, *e.g.*, [25] for an application of DPCA to a chemical process data analysis).

Following the DPCA procedures described in the previous section and using the new VAR modeling results in this section, we obtain the following DPCA results: the eigenvalues $\{l_i\}$ of the sample correlation matrix R in Table 50.5 and scree plot in Figure 50.4. The plot in Figure 50.4 clearly shows that there is a break (an elbow) between the first three and the remaining fifteen eigenvalues which form approximately a straight line. This indicates that we should retain the first three PCs for the subsequent CBM model building.

50.3.4 CBM Model Building Using DPCA Covariates

It follows from the analysis in the previous sub-sections that the three selected principal components calculated at each sampling epoch are uncorrelated, but since it is an AR(2) model, the resultant multivariate time series consisting of the three PCs at different time epochs is autocorrelated. To represent the covariate vector $Z(t)$ in (50.10) for PH modeling as a multivariate Markov process, we define

$$Z(t) = (pc1_t, pc2_t, pc3_t, pc1_{t-1}, pc2_{t-1}, pc3_{t-1}). \tag{50.11}$$

It follows from (50.5) that the portion of the U matrix needed for the calculation of the selected three PCs at each sampling epoch has the form $U = [u_1, u_2, u_3]$, where (u_1, u_2, u_3) are the eigenvectors corresponding to the first three largest eigenvalues of the sample correlation matrix R. For the oil data, the matrix U was calculated in the previous sub-section.

In EXAKT, in order to represent the covariate process as a discrete state Markov process, the covariate values are discretized and EXAKT provides routines for determining the covariate bands automatically. The covariate Markov process is generally assumed to be non-homogeneous. The length of the process histories is divided into several intervals and the process is assumed to be homogeneous within an interval, fully determined by the transition rates, which are estimated from the data together with the vector of the unknown PH model parameters. For the oil data considered in this chapter, two time intervals were suggested in [21], namely $[0, 2000)$ and $[2000, +\infty)$, and the covariate Markov process is assumed to be homogeneous in each interval.

The following three parameters are needed to calculate the average cost optimal replacement policy: the preventive replacement cost C, the failure replacement cost C+K, and the length of the interval between two subsequent samplings, Δ. For this study, we consider the estimates obtained in [21], namely C=\$1,560, C+K=\$6,780, and $\Delta = 600$ hours. After estimating the PH model parameters and the transition rates for the covariate Markov process, EXAKT builds a PH model by testing two kinds of hypotheses. The first null hypothesis states that the shape parameter β in the hazard function given by (50.10) is equal to one, *i.e.*, the baseline hazard function is a constant, indicating that the time effect is not significant and an exponential baseline hazard function is appropriate. The second set of hypotheses tests the significance of the individual covariates, *i.e.*, if the null hypothesis $H_0^i : \gamma_i = 0$ is rejected, the *i*th covariate $Z_i(t)$ is retained in the model. The summary of the PH model building using EXAKT is in Table 50.6.

From the results of the analysis, as presented in Table 50.6, only $PC1_t$, $PC1_{t-1}$ and $PC2_t$ are significant covariates to be retained in the model. Also, the estimate of the shape parameter β equal to 1.723 is considerably different from the hypothesized value of one, indicating that the time effect is significant and the exponential baseline model is not appropriate. A comparison of the

Table 50.6. The results of the PH model building using EXAKT

Parameter	Estimate	Significant	Standard Error	P-value
Scale (η)	1.755e+004	–	3564	–
Shape (β)	1.723	Y	0.3326	0.02982

pc1_1 (γ_2)	0.9909	Y	0.2584	0.0001253
Pc2 (γ_3)	0.545	Y	0.2526	0.03093

Table 50.7. Policy comparison

	Cost [$/hr]	Prev. repl. Cost [$/hr]	Failure repl. cost [$/hr]	Prev. repl. [%]	Failure repl. [%]
DPCA PHM optimal policy	0.258752	0.121589 (47.0%)	0.137162 (53.0%)	79.4	20.6
Failure replacement only	0.474628	0 (0.0%)	0.474628 (100%)	0	100
Savings	0.215876 (45.5%)	-0.121589	0.337466	−79.4	79.4

optimal maintenance policy for the fitted PH model summarized in Table 50.6, and the policy which replaces only upon failure is in Table 50.7. From Table 50.7, 79.4% of the replacements are preventive replacements and only 20.6% are failure replacements, *i.e.*, a substantial portion of failure is avoided by preventive maintenance actions. Also, the average cost per hour is substantially reduced by applying the optimal policy, resulting in the savings of 45.5% when compared with the average cost associated with the failure replacement policy.

50.3.5 Failure Prevention Performance and the Maintenance Cost Comparison

Next, we will check the failure prevention performance of the CBM model using DPCA covariates by applying the optimal policy to the oil data histories. The results will also be compared with the current maintenance policy of the company, which is a simple age-based replacement policy, *i.e.*, a transmission is replaced after 12,000 working hours, or upon failure, whichever occurs first. The results are summarized in Table 50.8.

From the results in Table 50.8, we can again conclude that when applied to the 48 real data histories (18 ended with failure and 30 ended with suspension), the optimal policy for the DPCA PHM gives the lower average cost (0.349 *vs*, 0.432), smaller number of failures, and the higher percentage of preventive replacements, compared to the simple age-based policy. Since only 8 out of the 18 failures occurred when applying the DPCA PHM optimal policy, it is clear that the optimal policy correctly suggested 10 preventive replacements before the machine failure. Thus, in the 21 “replaced” histories of the PHM policy, there are 10 cases for which impending failures were avoided and in the other 11 cases preventive replacement decision was suggested before suspension. The remaining 19 histories ended with suspension when applying the age-based policy, but the optimal DPCA PHM policy suggested that these transmissions should continue operating and the suspension was possibly performed too early.

Table 50.8. Policy comparison using real data histories

Policy	Current age-based	DPCA PHM
Sample size	48	48
Failed	18	8
Replaced	30	21
Undecided	0	19
Cost per unit time	0.432	0.349
Prev. repl.	62.50%	83.33%

These 19 cases are marked as "undecided" in Table 50.8. When we compute the average cost and preventive replacement percentage, these 19 "undecided" histories are treated as suspensions followed by a preventive replacement.

For further failure prevention performance check, we applied the optimal policy for the DPCA PHM model to all the 20 data histories that ended with failure out of the whole 51 histories considered. As shown in Table 50.9, the optimal policy using DPCA PHM recommends 8 preventive replacements to be made at a sampling time before the actual failure occurred. If the decision is not to replace immediately, the software calculates the expected replacement time. For the three histories (ID 69-2, ID 77-2 and ID 79-2), the policy recommended replacements 30 hours after taking the sample. Since 30 hours is a very short time compared to the roughly 600 hours sampling interval, the transmissions will be replaced immediately before the actual failure occurs. To summarize, the policy which uses the DPCA PHM recommends ten preventive replacements for 20

Table 50.9. Replacement recommendation for failure histories using DPCA PHM

ID	Failure time [h]	Last Sampling time [h]	Recommend replace (Y or N)?	Expected to replace in [h]

histories which ended with failure. Compared with the current policy used by the company, the policy which uses the DPCA PHM can avoid 50% of failures.

50.4 Conclusions

In this chapter, we have applied the multivariate time series modeling and DPCA to the transmission oil data. The models have been used for maintenance decision-making using a DPCA-based Q chart and the optimal policy for a DPCA PHM-based CBM model. The effectiveness of both methodologies was demonstrated by evaluating the fault detection capability and cost benefit when compared with the currently used age-based maintenance policy.

First, we presented the methodology which uses the DPCA-based Q chart for maintenance decision-making and used the real truck transmission oil data for testing its performance. Since the transmission oil data exhibits both cross and auto-correlation, the PCA-based (T_A^2, Q) charts cannot be used and we considered the DPCA-based (T_A^2, Q) charts. After applying the DPCA transformation, serial correlation still exists in the PC scores, which considerably reduces the effectiveness of the DPCA-based T_A^2 chart. On the other hand, for the DPCA-based Q chart, no such autocorrelation effect exists. It has been demonstrated that the fault detection ability of the Q_{DPCA} chart is excellent and the application of the Q_{DPCA} chart-based policy resulted in a significant maintenance cost savings compared with the currently used age-based policy.

Next, based on the results of the multivariate time series modeling of transmission oil data and subsequent dimensionality reduction using DPCA, we have built a proportional hazards-based CBM model using the significant three PCs as the covariates. The theoretical results showed that the optimal policy for the CBM model leads to considerable maintenance cost savings compared to the "replace only upon failure" policy. When applied to the oil data histories, the CBM model based policy resulted in a significant cost reduction compared to the current age-based policy.

From the two case studies presented in this chapter and summarized above, we have demonstrated effectiveness of the multivariate time series modeling and DPCA applied to CM data and used for an on-line maintenance decision-making.

Sustainability: Motivation and Pathways for Implementation

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: Sustainability is a characteristic of a process or state that can be maintained at a certain level indefinitely. Sustainability focuses on providing the best outcomes for both human and natural environments now, and indefinitely into the future. In recent years, academic interest and public discussion has led to the use of the word sustainability in reference to how long human ecological systems can be expected to be usefully productive. This chapter first examines the threats and then provides how the environmental threats can be assessed and mitigated.

51.1 Introduction

There is no industrial activity that is entirely free from risks and it is not possible to eliminate every eventuality of mishap by safety precautions. However, when risks are high, system designers must consider the possibilities of additional preventive or protective measures to reduce the risk, and judge whether it would be worthwhile to implement these additional measures, particularly when consequences affect the environment. The industrial accidents that have "*environmental consequences*" for man in some way or the other and are transmitted through the air, water, soil or biological food chains, are known as *environmental risks*. Their causes and characteristics, however, can be very diverse. Some are created by man through the introduction of new technology; product or chemicals while others, such as natural hazards, result from natural processes, which happen to interact with human activities and settlements. Some of these, such as pollution from a smelter, can be anticipated, others, such as the possible effects on the Earth's ozone layer of fluorocarbon sprays or nitrogen fertilizers, have wholly unsuspected effects at the time the technologies or activities were developed.

With chemical industries [8], there is always the risk of toxic substances, fluids or gases getting released to the surrounding environment due to and accident. Therefore it is necessary to assess the risks in all such cases where environmental consequences are possible incase of any mishap. Moreover, there are other sources of environmental degradation due to their even normal operation such as in mining industry where landspoils occur in abundance or in the case of vehicular exhaust where air gets polluted constantly. In such cases, environmental impact assessment [3] should be carried out to plan preventive measures for the public.

In addition to having a common feature of being transmitted through environmental media, environmental risks can cause harm to people who have voluntarily or specifically not chosen to suffer their consequences; therefore they require control or

management. Environmental risk management involves the search for a "*best route*" between social benefit and environmental risks. It is actually a trade-off between various combinations of risks and social and economic gain that usually decides the acceptability of a technological development or a system.

51.2 Environmental Risk Assessment

Environmental risk assessment has acquired importance and emphasis over the past few decades after the public experienced several industrial and nuclear accidents and realized that the actions of humans can have adversely affect the environment. It was due to this realization that the once widely-used pesticide DDT was banned when it was found to have negative effects on the environment (including humans). The 1970s saw the passing of environmental protection legislation such as the Clean Water Act, the Clean Air Act and the Superfund environmental cleanup regulations (the Comprehensive Environmental Response, Compensation and Liability Act). All these legislations required risk assessments.

Two types of approaches are applied to environmental risk assessment, *viz.*, *predictive* and *retrospective*. Predictive assessments deal with proposed actions, such as the introduction of new chemicals, new sources of environmental releases, or possible accidents.

In general, the predictive approach follows a four-step paradigm, *viz.*, *hazard identification, dose-response assessment, exposure assessment,* and *risk characterization*. Hazard identification includes selecting the endpoints, describing the environment under consideration, and determining the pollutant sources. Dose-response assessment replaces effects assessment, which includes the use of models to project the effects of stresses on selected endpoints. Exposure assessment and risk characterization follow.

51.2.1 Hazard Identification

This is the recognition that a hazard with definable characteristic exists. It is a step to ascertain if there is the potential for an exposure of an organism (including a human) or ecosystem [4] to an environmental stressor; the identification of what is at risk. Hazard identification involves the use of exposure and effects data from the laboratory and the field to determine whether the agent of concern can cause a particular adverse health effect. The breadth and complexity of most ecological systems may initially require considerable effort to define the scope of the problem, including identifying the stresses involved (whether chemical or non-chemical), the type of ecosystem(s) involved (aquatic, terrestrial, wetlands, *etc*.), and spatial and temporal scaling factors.

The identification of what is at risk, also referred to as endpoint (or receptor) selection, is critical to the environmental risk assessment process. Ecological endpoints can be chosen at any of several organizational levels, from biochemical and cellular level through individuals, populations, communities, and ecosystems. Endpoint selection is dependent upon both the ecosystem and stresses of concern. Thus, it is important to define these endpoints at the beginning of an environmental risk assessment.

51.2.2 Dose-response Assessment

Dose-response assessment characterizes the relationship between administered dose to a receptor (organism or ecosystem), and the incidence of an adverse effect on that receptor. In human health risk assessment, when administered doses are plotted against the measured responses, extrapolation methods are typically used to estimate the response at low doses. *Stress-response* may be a better term than *dose-response* when dealing with environmental risk assessment, since ecosystems can be adversely affected by many different types of anthropogenic stresses, not only toxic chemicals. A stress response assessment can be conducted once the appropriate assessment and measurement endpoints have been selected. Data used can vary widely depending upon the test protocol; whether the experimental design includes structure-activity relationship analysis, laboratory tests with single species, laboratory microcosms, or full-scale field tests.

51.2.3 Exposure Assessment

An exposure assessment is done to measure or estimate the magnitude, frequency, and duration of exposure, and to characterize the human populations that are subject to exposure. In an ecological context, exposure more frequently refers to the concentration or magnitude of a contaminant or stress in the environment currently or may be present in the future. Characterization of the exposed population is particularly problematic in ecological risk assessments. While demographics and activity patterns are frequently available for human populations, ecological risk assessment generally deals with a diverse group of species, about which relatively little is known. There is also a tremendous diversity of habitats, ranging from aquatic environments (sediment, freshwater, and marine) to wetland and terrestrial environments.

Ecological exposure assessments are generally based on the frequency and duration of inputs of a chemical, its fate and transport in the environment, and any chemical transformations. One can integrate the probabilistic properties of pollutant release into transports and fate models that would give estimates of the concentrations and persistence of the pollutant in different environmental media (soil, water, *etc*.).

The ability of ecosystem to recover from stress is another important factor that must be considered. The ultimate effects of stress on an ecosystem depend not only upon the strength and duration of the initial stress, but also the ecosystem's ability to regenerate.

51.2.4 Risk Characterization

In characterizing risk, one estimates the incidence of adverse human health effect under conditions stated in the exposure assessment. In an environmental risk assessment, the probabilities of adverse effects at estimated exposure levels are not usually determined.

Retrospective risk assessment: In addition to predicting the potential effects of proposed actions, one is frequently faced with the problem of determining whether adverse ecological effects have occurred as a result of previous actions, through a *retrospective risk assessment*. For example, a retrospective risk assessment can be used at an abandoned hazardous waste site to determine whether ecological impacts have occurred. On the other hand, in retrospective assessments both the sources of pollution and the polluted environment may be observed directly. The purpose of a retrospective study is to define the relationship between pollution source, ecosystem exposure, and ecosystem effects.

Each of the steps mentioned in the foregoing sections requires the collection of data (such as the collection of lead concentrations in soil or water) and/or the use of mathematical models (such as ones that describe the movement of contaminants in the environment or define the cancer incidence from exposure to levels of uranium). Risk assessments have now become part of the analysis that a proposed new chemical or other product must undergo before it may be placed on the market.

As is obvious, the successful environmental risk assessment will require the experts from several disciplines, *viz.,* chemistry, physics, biology, ecology, geology, hydrology and engineering. Because of their skills in analyzing data and computations including risk and handling uncertainties, statisticians will play a key role in each one of the above steps. Data or modeling uncertainty in any one of the steps may have a significant effect on the results and meaning of the assessment.

51.3 Ecological Risk Assessment

Ecological risk from chemicals is much more difficult to assess than the estimation of risks to humans. In the first place, we are dealing with only one kind of living creature, humans, while in ecological risk assessment, we must consider the whole range of organisms that exists in nature from the very small to the very large; all those which live in water or in the air or on the ground; and those which have very long or very short life spans. These organisms vary not only in size and life span but also in sensitivity to particular chemicals and to how these chemicals are broken down after being absorbed into the organism.

The goal of ecological risk assessment [4] is not as clearly defined. While some scientists suggest that the focus should be on the individual organism, others think that the focus should be on the survival of the population of animals rather than any single organism. Still others have another view that the larger body of ecosystem, such as a lake or river, should be protected.

Therefore, there is no standard procedure for assessing overall ecological risk. There are intense efforts currently underway to improve upon this situation, but it will undoubtedly take some time before such procedures are standardized and are applicable to all contaminants and sites of interest. However, a large number of studies have been done on the adverse effects that specific chemicals can have on the environment. In addition, there are many studies that have investigated other adverse effects, especially changes in reproductive capacity. Besides the research on PCBs and terrestrial organisms, other investigations have shown a relationship between reproduction and tributyltin, a pesticide often added to marine paints. Other work relating fish tumors to contaminants is not as well advanced, and many tumors have been shown to be caused by naturally occurring viruses. A number of these effects, especially death and decreased reproductive capacity, have impacts on populations as well as individuals and also have the potential to affect ecosystem health.

While these studies provide a great deal of important information, there are a variety of uncertainties associated with the results. When the studies are done in the field one significant source of uncertainty is determining the degree of exposure of the animal to various agents, both chemical and physical, as it moves from place to place and as the environment around it changes. This can be especially problematical when dealing with animals that migrate and so face radically different environments at different times of the year.

To best manage the environment, it is necessary to assess the extent of current and future risks to the biota of the environment and to characterize the causative agents. Increased understanding by public is critical to the development and implementation of policies that are responsive to the concerns of the people inhabiting the ecosystem.

51.4 Sustainability

We have seen in Chapter 1, how in our effort to make the Earth to yield more for the increasing human population through industrialization, we degraded the environment of the planet that we live on and our future generations have to survive on. Unless some urgent drastic steps are taken to contain further deterioration and to maintain *status quo*, if not to regenerate the spoiled environment, the situation is likely to get out of control, and we may be leading our planet towards the doomsday. Ever-increasing deforestation, large scale mining, depletion of mineral resources and fossil fuel reserves, green house gases, ozone layer depletion, waste dumps including radio-active waste, air pollution due to vehicular exhaust, acidification, pollution of water bodies (lakes, rivers, sea, *etc.*), noise, and energy losses are all leading to increase our woes and disrupt the delicate ecological balance that existed on Earth to sustain life on this planet. Thoughtless planning, execution and use have also added to ecological problems. Thus the only pathway that is feasible and practicable seems to lie in the strategy of pollution prevention of all kinds and in sustainable development. Unless all our industrial activities conform [32] to sustainability principles and all products, systems, and services are redesigned to be sustainable, we cannot possibly stop the march to doomsday and future generations will hold the present generation responsible for this lapse if we do not act while there is still time.

The United Nations has taken an initiative in this direction by declaring a *Decade of Education for Sustainable Development* that started in January of 2005. In the US also a non-partisan multi-sector group called the *U.S. Partnership for the Decade of Education for Sustainable Development* has been constituted. Any organization and individuals or groups of youth, business, religion, *etc.*, can join and share resources and success stories for creating a sustainable future.

However, there are lots of impediments in the way of achieving an environmentally sustainable future. A new sustainability paradigm is possible, if all progressive elements of civil society, governments, and businesses, share the information and work together to create an alternative vision of globalization centered on the quality of life, human solidarity, and environmental resilience. The Tellus Institute [26, 34] has brought out some useful publications like "Great Transition" to examine these aspects.

51.4.1 Definition

The simplest definition of sustainability that can be given is: It is a characteristic of a process or state that can be maintained at a certain level indefinitely. The oft-cited definition of sustainability is the one given by the Brundtland Commission [5], which defined *sustainable development* as development that "meets the needs of the present without compromising the ability of future generations to meet their own needs". Sustainability can be defined as: "Humanity's investment in a system of living, projected to be viable on an ongoing basis that provides quality of life for all individuals of sentient species and conserves natural ecosystems".

Sustainability focuses on providing the best outcomes for both the human and natural environments now, and into the indefinite future. In recent years an academic and public discourse has led to the use of the word sustainability in reference to how long human ecological systems can be expected to be usefully productive.

Sustainability relates to the continuity of economic, social, institutional and environmental aspects of human society, as well as the non-human environment. Sustainability is one of the four Core Concepts behind the 2007 Universal Forum of Cultures. Sustainability can be defined both qualitatively in words, as an ethical/ecological proposition such as the Brundtland definition above, and quantitatively in terms of system life expectancy and the trajectory of certain factors or terms in the system. Quantitative analysis in sustainability thinking typically uses system dynamics modeling, as systems are often non-linear and so-called feedback loops are key factors. So, for instance, important human ecological sub-systems that could be analyzed or modeled in this way might include the nitrogen cycle in sustainable agriculture, or the depletion of oil reserves.

In order to distinguish quantitatively and qualitatively which human economic activities are destructive and which are benign or beneficial, various definitions/models of sustainability have been developed. The following list is not exhaustive but contains the major points of view:
In 1996, the International Institute for Sustainable Development, Canada, proposed a *Sample Policy Framework,* according to which a sustainability index need to be developed to provide decision-makers tools to compare various alternative policies and programs and to establish measurable entities or metrics that can be used to assess progress towards sustainability. Accordingly, there have been several efforts [23, 24, 30, 35] in that direction.

51.4.2 The Social Dimension to Sustainability

It may be worthwhile to mention that values vary considerably within and between cultures, as well as between economists and ecologists [6]. The introduction of social values to sustainability goals is a much more complex aspect and the non-ecological interpretations are strongly opposed by those focused on the side of ecological impacts. However, one may like to interpret sustainability in the light of value set which gives "parallel care and respect for the ecosystem and for the people within the ecosystem". From this value set emerges the social goal of sustainability*, i.e.,* to achieve the well-being of human and ecosystem, together. In this context, the concept of sustainability becomes much wider than just a means for environmental protection. It is a positive concept that has as much to do with achieving well-being of people and of ecosystems by reducing ecological stresses or environmental impacts.

At its least, sustainability implies paying attention to comprehensive outcomes of events and actions insofar as they can be anticipated at present. This is known as *full cost accounting*, or *environmental accounting*. This kind of accounting

assumes that all aspects of a system can be measured and audited (*environmental audits*).

Environmental accounting can have a limited biological interpretation as in ecological footprint analysis, or may include social factors as in the case of urban and community accounts.

At most, sustainability is intended as a means of configuring civilization and human activity so that society, its members, and its economies are able to meet their needs and realize their greatest potential in the present, while preserving biodiversity and natural ecosystems, and planning and acting for the ability to maintain these ideals over a very long period – typically, at least seven generations.

However, no one has ever underestimated the importance of the ecological interpretation of sustainability. All advocates of sustainability accept that ecological, not social factors, can be effectively measured and are universal indicators of sustainability. Sustainability outcomes can be investigated at every level of organization, from the local neighborhood to the entire planet.

51.4.3 Sustainability Assessment

Sustainability requires an integrated view of the world, in which close links between environment, economy, and society exist. The natural resources provide the raw materials for production on which jobs and stockholder profits depend. Jobs affect the poverty rate and the poverty rate affects crime. Air quality, water quality, and materials used for production have an effect on health and on stockholder profits: if a process requires clean water as an input, cleaning up poor quality water prior to processing is an extra expense, which reduces profits. Likewise, health is related to general air quality or exposure to toxic materials, and will have an effect on worker productivity and contribute to the rising costs of health insurance. Therefore, sustainability requires multidimensional indicators that show the links between a community's economy, environment, and society. Ness *et al* [36] discuss in detail the assessment tools for sustainability which may be based on indicators, or product related assessment or integrated assessment. The first set of sustainability assessment tools consists of indicators and indices. Indicators are simple measures representing quantitatively a state of economic, social and/or environmental development in a specified region-often the national level. If indicators are aggregated in some manner, the resulting measure is called an index. Indicators and indices, which are continuously measured and calculated, allow for the tracking of longer-term sustainability trends from a retrospective point of view. Understanding these trends allows us to make short-term projections and relevant decisions for the future. The tools in the category of indicators and indices are either *non-integrated*, meaning they do not integrate nature–society parameters, or *integrated*, meaning the tools aggregate the different dimensions. There is also a subcategory of non-integrated tools that focuses specifically on regional flow indicators. An example of non-integrated indicators is environmental pressure indicators (EPIs), developed by the Statistical Office of the European Communities (Eurostat). EPIs consist of 60 indicators, six in each of the ten policy areas under the Fifth Environmental Action Program. Another example is the set of 58 national indicators used by the United Nations Commission on Sustainable Development (UNCSD). These indicators are not integrated or aggregated in any manner. UNCSD indicators include water quality levels for the environmental category, national education levels, and population growth rates as social determinants, GNP per capita for the economic sphere, and the number of ratified global agreements in the category of institutional sustainability. Recently, considerable attention has been paid to *composite* indicators. Chapter 54 in this handbook deals with this aspect.

51.4.4 Metrics of Sustainability

Just as we have indicators in every field to show how well a particular system is working, we also have indicators for sustainability. Indicators are as varied as the types of systems they monitor. Very many indicators have been suggested by organizations and experts. However, there are certain characteristics that effective indicators must have in common. An effective indicator should be based on accessible data so that checks are possible

and should be relevant, easy to understand, and reliable.

Based on Brundtland's definition of sustainability [5], Robèrt [25] described the conditions of sustainability in the *natural step framework* that a sustainable society is one which does not systematically increase concentrations of substances extracted from the Earth's crust, or substances produced by society, does not degrade the environment, and in which people have the capacity to meet their needs worldwide.

Another composite measure of sustainability is through life cycle assessment. It analyses the environmental performance of products and services through all phases of their life cycle; extracting and processing raw materials, manufacturing, transportation and distribution; use, re-use, maintenance; recycling, and final disposal.

Yet another way to look at the sustainability index is through ecological footprint analysis, which is the estimate of the amount of land area a human population, based on existing technology, would need if the current resource consumption and pollution by the population were matched by the sustainable (renewable) resource production and waste assimilation by such a land area. Zhao *et al.* [31] developed algorithms based on ecological footprint model in combination with the emergy methodology and a sustainability index has been derived from the latter. They have also been combined with an index of quality of life (Marks *et al.* [33]), and an index called the *(Un)Happy Planet Index* (HPI) was derived for 178 nations.

Very often a country's economic power and success is judged by the *gross domestic product* (GDP) and is an indicator of prosperity, as it is defined as the total value of a country's annual output of goods and services. However, it is obvious that the welfare of a nation can hardly be judged from the national income. For example, GDP reflects only the amount of economic activity, regardless of the effect of that activity on the community's social and environmental health, it is possible for GDP to go up when overall community health actually goes down. A comparable sustainability indicator is the Index of Sustainable Economic Welfare, which subtracts from the GDP corrections for harmful bases or consequences of economic activity and adds to the GDP corrections for significant activities such as unpaid domestic labor in order to get a more complete picture of the economic progress. For instance, the ISEW accounts for air pollution by estimating the cost of damage per ton of five key air pollutants. It accounts for depletion of resources by estimating the cost to replace a barrel of oil equivalent with the same amount of energy from a renewable source. It estimates the cost of climate change due to greenhouse gas emissions per ton of emissions. The cost of ozone depletion is also calculated per ton of ozone depleting substance produced. Additionally, adjustments are made to reflect concern about unequal income distribution. The correction for unpaid domestic labor is based on the average domestic pay rate. Some health expenses are considered as not contributing to welfare, as well as some education expenses.

The Living Planet Report 2002 by WWF shows that humans are currently using over 20% more natural resources each year than can be regenerated and this deficit is growing each year. Projections based on likely scenarios of population growth, economic development and technological change, indicate that by 2050, humans will consume between 180% and 220% of the Earth's biological capacity, which means that unless governments take urgent action, by 2030, human welfare, as measured by average life expectancy, educational level, and world economic product will go into decline.

Another indicator of sustainability is the *Living Planet Index,* which actually indicates the state of Earth's biodiversity. It tracks populations of 1,313 vertebrate species (fish, amphibians, reptiles, birds, mammals) from all around the world. Separate indices are produced for terrestrial, marine, and freshwater species, and the three trends are then averaged to create an aggregated index. Although vertebrates represent only a fraction of known species, it is assumed that trends in their populations are typical of biodiversity overall. By tracking wild species, the Living Planet Index is also monitoring the health of ecosystems. Between 1970 and 2003, the index fell by about 30%. This global trend suggests that we are degrading natural

ecosystems at a rate unprecedented in human history.

Several other indicators of development to GDP exist such as UN's *Human Development Index* (HDI), but this also fails to assess the success at achieving the ultimate aim of people's happiness in terms of health and happiness for themselves and their families. It is important that the resources provided by our planet also be available to future generations. HPI estimates the ecological efficiency with which nations ensure happy and long lives for their people. The wealthiest nations according to this index are grossly inefficient and no nation scores well on all counts. In actual fact,, HPI involves three distinct indicators, *viz.,* ecological foot prints, self-reported life satisfaction, and life expectancy. It is defined as:

$$HPI = \frac{LifeSatisfaction \times LifeExpectancy}{EcologicalFootprint}$$

Thus HPI is a measure of the ecological efficiency of delivering human well-being. It indicates the average years of happy life produced by a given society or nation per unit of planetary resources consumed. The startling conclusion from ecological footprint analyses was that it would be necessary to have four or five back up planets exclusively engaged in agriculture to sustain the current population to maintain a Western lifestyle.

In 1997, Brown and Ulgiati [17, 20] defined a new sustainability index (SI) called *emergy sustainability index* (ESI) as a ratio of the emergy (embodied energy) yield ratio (EYR) to the environmental loading ratio (ELR). This index accounts for yield, renewability, and environmental load. It is the incremental emergy yield compared to the environmental load.

$$SustainableIndex = \frac{EmergyYieldRatio\,(EYR)}{EnvironmentalLoadingRatio\,(ELR)}$$

It may be noted here that the numerator is not *energy yield ratio*, but *emergy yield ratio*, which is a different concept. This method of valuation, called emergy accounting [15, 19, 23] uses the thermodynamic basis of all forms of energy and materials, but converts them into equivalents of one form of energy, usually sunlight. Emergy accounting is a technique of quantitative analysis, which determines the values of non-monied and monied resources, services, and commodities in common units of the solar energy that it took to make them. The units of emergy are emjoules, to distinguish them from joules. Most often emergy of fuels, materials, services, *etc*., is expressed in solar emjoules (abbreviated *sej*). Emergy then, is a measure of the global processes required to produce something expressed in units of the same energy form. To derive solar emergy of a resource or commodity, it is necessary to trace back through all the resources and energy that are used to produce it and express each in the amount of solar energy that went into their production

51.4.5 The Economics of Sustainability

The World Business Council for Sustainable Development was founded in 1995. It came about through the merging of the Business Council for Sustainable Development and the World Industry Council for the Environment and is based in Geneva, Switzerland, has a North American Office in Washington DC, and has the membership of leading companies like DuPont, General Motors, 3M, Deutsche Bank, Coca-Cola, Sony, Oracle, BP, *etc*.). The World Business Council for Sustainable Development has advocated a business case for sustainable development and advises companies that "sustainable development is good for business and business is good for sustainable development". This view is also shared by proponents of industrial ecology. The theory of industrial ecology suggests that industry should be viewed as a series of interlocking man-made ecosystems interfacing with the natural global ecosystem.

According to some economists [7], it is possible for the concepts of sustainable development and competitiveness to merge if enacted wisely, so that there is no inevitable trade-off. This merger is motivated by the following facts put forward by Hargroves and Smith [28]:

1. Throughout the economy there are widespread untapped potential resource productivity improvements to be made to be coupled with effective design.

2. There has been a significant shift in understanding over what creates the lasting competitiveness of a firm.
3. There is now a critical mass of enabling technologies in eco-innovations that make integrated approaches to sustainable development economically viable.
4. Since many of the costs of what economists call "environmental externalities" are passed on to governments, in the long-term sustainable development strategies can provide multiple benefits to the tax payer.
5. There is a growing understanding of the multiple benefits of valuing social and natural capital, for both moral and economic reasons, and these are being included now in measures of national well-being.
6. There is mounting evidence to show that a transition to a sustainable economy, if done wisely, may not harm economic growth significantly; in fact it could even help it.

However, according to The *Stern Review on the Economics of Climate Change*, which is a 700-page report released on October 30, 2006 by economist Nicholas Stern for the British government, discusses the effect of climate change and global warming on the world economy. This is the most widely known and discussed report of its kind. Its main conclusions are that 1% of the global gross domestic product (GDP) *per annum* is required to be invested in order to avoid the worst effects of climate change, and that failure to do so could risk global GDP being up to 20% lower than it might otherwise be. Stern's report suggests that climate change threatens to be the greatest market failure ever seen, and it suggests prescriptions including environmental taxes to minimize the economic and social disruptions. Stern states that "our actions over the coming few decades could create risks of major disruption to economic and social activity, later in this century and in the next, on a scale similar to those associated with the great wars and the economic depression of the first half of the 20th century".

The debate currently focuses on the sustainability between economy and the environment, which can in other words be considered as between "natural capital" and "manufactured/man-made capital". This is also captured in the "*weak*" versus "*strong*" *sustainability* discussions. Weak sustainability is explained by Hartwick's rule [2], which states that under certain conditions, the amount of investment in produced capital (buildings, roads, knowledge stocks, *etc*.) is needed to exactly offset declining stocks of non-renewable resources. This investment is undertaken so that the standard of living of society does not fall as society moves into the indefinite future. In other words, Hartwick's rule states that so long as total capital stays constant, sustainable development can be achieved.

As long as the diminishing natural capital stocks are being substituted by gains in the man-made stock, total capital will stay constant and the current level of consumption can continue. The proponents believe that economic growth is beneficial as increased levels of income lead to increased levels of environmental protectionism. This is also known as the "substitutability paradigm". Conversely, strong sustainability, as supported by Herman Daly [16], believes that natural capital and man-made capital are only complementary at best. In order for sustainable development to be achieved, natural capital has to be kept constant independently from man-made capital. This is known as the "non-substitutability paradigm".

51.4.6 Resistance to Sustainability

There is a strong resistance to adopting sustainable practices. According to Unruh [21, 22], this is primarily due to the fact that today's technological systems and governing institutions were designed and built for permanence and not to change. In the case of fossil fuel-based systems, this is termed "carbon lock-in" and inhibits many efforts to change.

The whole world is aware that it must live sustainably. There are numerous practical, proven ways to do this, which is the *technical side* of the problem. However, society does not want to take the final step and adopt these practices, which is the resistance to change or the *social side* of the problem. *Therefore, the social side of the problem* prevails. Meadows *et al.* [27] in *Limits to Growth*

have put it very appropriately: "*Beyond the Limits* was published in 1992, the year of the global summit on environment and development in Rio de Janeiro. The advent of the summit seemed to prove that global society had decided to deal seriously with the important environmental problems. But we now know that humanity failed to achieve the goals of Rio. The Rio plus ten conferences in Johannesburg in 2002 produced even less; it was almost paralyzed by a variety of ideological and economic disputes, by the efforts of those pursuing their narrow national, corporate, or individual self-interests. … humanity has largely squandered the past 30 years…"

The failure of governments and individuals to act on the available information can be attributed to personal greed (deemed to be inherent in human nature) especially on the part of international capitalists. However, two things seem to be obvious from our discussion:

1. It is necessary to follow up the study of the socio-cybernetic, or systems processes, which, seem to control what happens in society.
2. We should use social-science-based insights to evolve forms of public management that will act on information in the long term public interest.

51.5 Pathways to Sustainability

With the ever-growing world population, we must have efficient mass production systems. At the same time people must have better life style and living standards. This imposes severe strain on the health of Earth's environment. Therefore, it is time that motivation for performance improvement must also change from economic compulsion to environmental compulsion. It is also true that no development activity for the benefit of human beings can possibly be carried out without incurring a certain amount of risk. This risk may be in terms of environmental degradation in terms of pollution of land, water, air, depletion of resources, and cost of replenishment or restoration to acceptable levels both during normal operating conditions and under the conditions of sudden hazardous releases on account of catastrophic failures or accidents. In the past, we have witnessed several technological (man-made) disasters, which had their origin in our underscoring the importance of ensuring the best level of system performance and its linkages with environmental risk**.**

There is a severe requirement of material conservation, waste minimization energy efficient systems than before. Instead of mining; recycling, recovery, and reuse should become more and more common, as these are not only cost effective but less energy intensive and less polluting. Recycling and reuse must be given serious consideration if nonrenewable resource consumption is to be minimized or energy use associated with material extraction is to be conserved. Use of renewable energy sources has to become the order of the day. The same is true about the prevention of pollution of *free resources* like water and air, which are also required for sustaining life support system of the planet we live on.

One of the important strategies of implementing sustainability is to prevent pollution (*rather than control* it) and this by itself cannot be viewed in isolation with the system performance. A better system performance would necessarily imply less environmental pollution on account of system longevity and optimum utilization of material and energy for limited resources scenario that governs the development of future systems. It is also naturally an economic proposition. In other words, sustainability depends very heavily on the performance characteristic of a system. Therefore, the objective of a system designer should be to incorporate the strategy of sustainability in all future system performance improvement programmes and designs.

The other pathways to achieve sustainable development and to minimize environmental impacts would be to use the concept of *industrial ecology* [18], which would entail to cluster a set of industries and have their *inputs* and *outputs* interlinked and mutually supported in order to preserve energy and materials including wastes. We have to work out methods of efficient energy generation and utilization, cleaner transportation, improved materials. Use of biotechnology for improving products and cleanup process for taking

care of effluents, molecular manufacturing, extensive use of biodegradable materials and plastics would have to become quite common in future.

In summary, the key issues associated with the implementation of sustainability characteristic appear to revolve around:

- The need to conserve essential natural resources, minimize the use of materials, develop renewal energy sources, and avoid over exploitation of vulnerable resource reserves.
- The need to minimize the use of processes and products that degrade or may degrade the environmental quality.
- The need to reduce the volume of waste produced by economic activities entering the environment.
- The need to conserve and minimize the use of energy
- The need to reduce or prevent activities that endanger the critical ecological processes on which life on this planet depends.

In this Handbook, we have tried to include Chapters 52, 53, 54 and 55 to cover the several important facets of sustainability problem.

51.6 Sustainable Future Technologies

As of now, two technologies appear to hold promise to revolutionize the way products and systems would be designed, built or used in the near future (within one or two decades), which will not only be highly dependeable but also sustainable. They are nanotechnology or molecular manufacturing and biotechnology. In the opinion of the author one is going to inflence the other and *vice versa.* As of today, nanotechnology is parallel to bioprocesses, which instead of consuming fossil fuels and emitting CO_2, uses CO_2 and sunlight to convert them into products and thus act as a net CO_2 consumer.The parallelism does not go beyond this and nonotechnology should not be considered a form of biotechnology, and molecular technology would not use ribosomes but robotic assembly; not veins but conveyors; not muscles but motors; not genes but computers; not cells dividing but small factories making products including factories. What molecular nanotechnology has in common with biology is the use of system of molecular machinery to guide molecular aasembly with clean and rapid precision.

51.6.1 Nanotechnology

Nanotechnology comes from the word nanometer, which is 10^{-9}. The idea behind nanotechnology is to custom design atom by atom. Feynman [1] in his classic talk in 1959 (at the annual meeting of American Physical Society at Caltech, on December 29, 1959) said: “The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom”. Nanotechnology just aims to achieve that. All manufactured products are made from atoms. The properties of those products depend on how those atoms are arranged. For example, if we can rearrange the atoms in coal in a definite way, we probably will make diamond.

Nanotechnology will achieve to:

- Get essentially every atom in the right place.
- Make almost any structure consistent with the laws of physics that we can specify in molecular detail.
- Have manufacturing costs not greatly exceeding the cost of the required raw materials and energy.

There are two more concepts commonly associated with nanotechnology:

- Positional assembly.
- Massive parallelism.

However, without using some form of positional assembly (to get the right molecular parts in the right places) this seems difficult and we need some form of massive parallelism (to keep the costs down). The need for positional assembly implies an interest in molecular robotics, *e.g.,* robotic devices that are molecular in their size and precision. These molecular scale positional devices are likely to resemble very small versions of their everyday macroscopic counterparts. Positional assembly is frequently used in normal macroscopic

manufacturing today, and provides tremendous advantages. Nanotechnology will require complete control of the structure of matter building complex objects with molecular precision. The research at present falls in two categories, *viz.*, theoretical and enabling technologies.

The problems of atomically-precise and nanometer-scale electronic systems, which includes studies of assemblers, replicators and nanocomputers need to be addressed. One robotic arm assembling molecular parts is going to take a long time to assemble anything large, so many robotic arms are required: this is what is meant by massive parallelism. While earlier proposals achieved massive parallelism through self replication, today's "best guess" is that future molecular manufacturing systems will use some form of convergent assembly. One of the concepts that is essential to molecular manufacturing is that of a self-replicating manufacturing system. And that concept has lagged behind in its acceptance even though it is fairly obvious that such things are feasible. So in order to produce the economies that we are talking about, in order to economically produce complex products we are basically going to adopt a strategy that has been demonstrated by agricultural products.

Molecular manufacturing [10, 12, 14] is the ultimate goal of nanotechnology. The benefits that will flow from the use of nanotechnology in making products or systems sustainable are as follows:

Less material, higher performance capabilities, low cost, waste minimization, and less energy requirement. The products would be lighter and stronger. For example, a diamond is light and strong. The strength-to-weight ratio of a diamond is over 50 times that of steel. Great strength and light weight is not exclusive to diamonds; graphite can also be strong. Aeroplanes or rockets would benefit immensely from having lighter and stronger materials. This would reduce the cost of air travel, and it would reduce the cost of rockets and allow space travel or exploration at literally orders of magnitude lower cost. Lighter computers and lighter sensors would enable more functions for a given weight, Today's computers are made of semiconductors, and the semiconductor of choice is silicon. This is not because silicon is the ideal semiconductor from which to make computers, but because we know how to make devices from it. Diamond [9] will make better computers than silicon [11]. Diamond has a wider band gap, hence electrical devices will work at higher temperatures. It has greater thermal conductivity, so devices can be more easily cooled. It has a greater breakdown field, hence devices can be smaller. It has higher electron and hole mobility, which, when combined with higher electric fields, would result in higher speed. However, there are many problems that do not make diamond a practical alternative. In fact, the use of molecular manufacturing [13] for the computer industry is quite tempting as it would allow us to build computers at a manufacturing cost of less than a dollar per pound, operating at frequencies of tens of gigahertz or more, with linear dimensions for a single device of roughly 10 nanometres, high reliability, and energy dissipation (using conventional methods) of roughly 10^{-18} joules per logic operation. A factor of crucial importance in the design of molecular-scale positional devices is the accuracy with which the tip can be positioned, particularly in the face of thermal noise. Finally, we would need a source of control signals for the molecular arm. One general approach would be to use a molecular computer and it is generally expected that some type of very small computational device will be feasible in a few decades [10]. There will be many additional advantages from the off-shoots of this technology in other application areas. The long term goal of molecular manufacturing is to build exactly what we want at low cost.

Nanomaterials and nanodevices are becoming quite useful in many areas of application. In this handbook, Chapter 57 discusses nanotechnology and its applications are provided in Chapters 58 and 59.

51.6.2 Biotechnology

Biotechnology is defined as any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use. Modern biotechnology is only 50 years old and in

the last decades it has witnessed tremendous developments. Bioengineering is a science upon which all biotechnological applications are based. Before the 1970s, the term, biotechnology, was primarily used in the food processing and agriculture industries. Since the 1970s, it has been used to refer to laboratory-based techniques being developed in biological research, such as recombinant DNA or tissue culture-based processes. It can also be defined as the application of indigenous and/or scientific knowledge to the management of (parts of) micro-organisms, or of cells and tissues of higher organisms, so that these supply goods and services of use to human beings. Biotechnology combines disciplines like genetics, molecular biology, biochemistry, embryology and cell biology, which are in turn linked to practical disciplines like chemical engineering, information technology, and robotics.

Biotechnology has applications in four major industrial areas, including health care, crop production and agriculture, non-food uses of crops (*e.g.,* biodegradable plastics, vegetable oil, biofuels), and environmental uses. For example, one application of biotechnology is the directed use of organisms for the manufacture of organic products (examples include beer and milk products). Another example is using naturally present bacteria by the mining industry in bioleaching to reclaim land spoils. Biotechnology is also used to recycle, treat waste, clean up sites contaminated by industrial activities (bioremediation), and has a military application in the production of biological weapons. *Red biotechnology* is applied to medical processes. The examples are the designing of organisms to produce antibiotics, and the engineering of genetic cures through genomic manipulation. Modern biotechnology can be used to manufacture existing drugs more easily and cheaply. The first genetically engineered products were medicines designed to combat human diseases. There are also applications to increase nutritional qualities of food crops. Proteins in foods may be modified to increase their nutritional qualities. There are very many applications of biotechnology in the medicinal use and in preparing human insulin to cure diabetes and in developing genetic engineered crops and high yielding and diseases resistant crops. However, here our main concern is with those applications that help in making sustainable products and systems (or in manufacturing) and help environmental clean up or pollution prevention.

White biotechnology, also known as *grey biotechnology*, is biotechnology applied to industrial processes. An example is the designing of an organism to produce a useful chemical. Another example is the using of enzymes as industrial catalysts to either produce valuable chemicals or to destroy hazardous/polluting chemicals [29] (using oxidoreductases). Biological leaching can be used in extracting metals from ore particularly when the grades of ore are becoming poorer and poorer day by day as we keep satisfying the need of the world for nonrenewable resources. Plastic, which has very high industrial and domestic use, was considered as the source of pollution since it was not biodegradable. Using biotechnology, we can produce biodegradable plastic. We can also use it to remove heavy metals and sulfates from water. Chlorine bleaching in pulp and paper industry is being replaced by biotechnology processes. White biotechnology tends to consume less in resources than traditional processes used to produce industrial goods.

Green biotechnology is biotechnology applied to agricultural processes. Most of the current commercial applications of modern biotechnology in agriculture are on reducing the dependence of farmers on agrochemicals. The term *blue biotechnology* has also been used to describe marine and aquatic applications of biotechnology, but its use is relatively rare.

In this handbook Chapter 56 deals with biotechnology.

Corporate Sustainability: Some Challenges for Implementing and Teaching Organizational Risk Management in a Performability Context

Rod S. Barratt

Department of Environmental and Mechanical Engineering, Faculty of Technology, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK

Abstract: This chapter discusses some pressures to ensure that 21st century products, systems and services are not only dependable but are also sustainable. Failure in any of these aspects may threaten an organization. So companies should ensure that they have a sound system of internal control and effective risk management processes. This includes measures to prevent emergencies arising or escalating, and emergency planning is essential to allow the organization to survive a crisis. Then it is essential to address the problem quickly, openly and effectively. Experience increasingly shows that risk management decisions made in collaboration with stakeholders are more effective and more durable, and so aspects of stakeholder engagement through corporate disclosure are discussed.

52.1 Introduction

Risk and hazard are commonplace words, but risk is an ambiguous word in business. To the investor, risk may be associated with the potential for financial gain, whereas an engineer may focus on the potential for loss or harm. Nevertheless, the latter has economic implications, and the trick is to manage processes to minimize their loss potential but equally to ensure that if an incident occurs, appropriate contingency measures are in place. For the educator, there are numerous incidents that may be used to illustrate a variety of technical failures which have had varying impact on investor value. There are also issues about increasing corporate disclosure to stakeholders that provide demanding educational challenges. Some of these issues are outlined and case studies explored to illustrate the failure mechanisms, the impacts and possible lessons to learn as well as opportunities to build these into educational programmes involving corporate sustainability. Examples from various industries reflect the breadth of performability considerations.

52.2 Pressure for Change

Organizations everywhere are continually changing the way they do business, their relationships between customers and suppliers, and also in the way they organize themselves through mergers, acquisitions, *etc*. There are also changes in the way organizations interface with the society

in which they operate, through growth, contraction, response to government policies, responses to new processes, new materials and so on. At the level of an organization, three areas of environmental risk may be identified:

- Risks to the environment from manufacturing processes with routine process releases into the environment. Accidents or incidents may also cause loss of containment and consequent release into the environment.
- Risks associated with purchase or inheritance of a contaminated site.
- Risks from the environment on a business arising from such problems as extreme weather conditions or long-term environmental changes, for example, through the greenhouse effect and climate change. There are also risks from other activities in the surrounding areas.

The first issue is readily apparent with clear performability linkages, while the other two may be less obvious and may be considered irrelevant. However all are important to organizations and environmental risk assessment techniques can be applied to all of them. Organizations need to look critically at all risks facing their business, and this goes wider than environmental health and safety risks. This assessment needs an understanding of the business and its processes, the market, the environment and the legislation.

Environmental risks to an organization are associated with contingent liabilities that may arise from its normal economic activity. Internationally, cost recovery legislation creates the potential for civil liability in the face of environmental damage by potentially allowing regulators and others to recover costs incurred in environmental clean-up as well as payment for natural resource damages. As corporations are increasingly responsible for the financial consequences of environmental contingencies, environmental risk assessments are a growing part of both financial and environmental management and are becoming more central to corporate governance at the board level.

So there are many pressures on organizations to address environmental issues. In the past, these pressures have all too often been considered as constraints. Organizations limited themselves to correcting negative aspects as each problem arose, and the cost of corrective action by end-of-pipe controls was emphasized. Short term remedies were favoured without consideration of the root cause of the problems. Building taller chimneys, using landfill sites further and further from cities, and installing gas cleaning plant are merely procrastination and underlying problems are not addressed. The evolution of awareness and the underpinning of legal and social pressures now present the environment as a business opportunity with the global environmental goods and services market being forecast to grow to $688 billion by 2010 and just under $800 billion by 2015 [1]. From a situation in which organizations limited themselves to correcting negative aspects of each problem with an emphasis on costs, an active environmental management phase evolved, with the environment being recognized as an area of opportunity. It is increasingly recognized that it is better not to contribute to pollution than to combat it. The next evolutionary phase integrates the behaviour of an enterprise with the environment, and the solution of environmental problems is recognized as the result of healthy management. This step by step improvement of environmental performance may be approached as suggested in Figure 52.1.

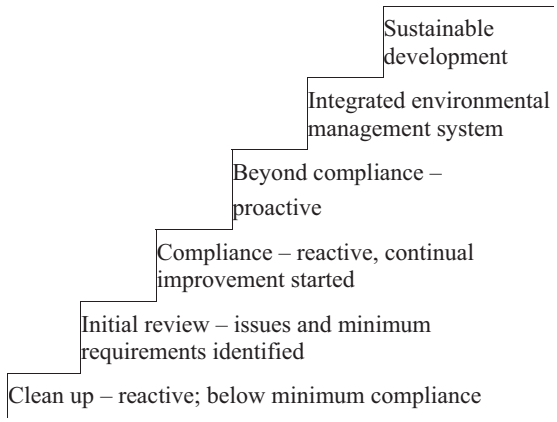

Figure 52.1. Steps of environmental management

There may be legal pressures to promote this progression, particularly through legislation. The early emphasis was on control of emissions of pollutants rather than their prevention. That idea came much later. In the UK, it was not until the Environmental Protection Act 1990 that there was an objective that processes use techniques:

> *(i) for preventing the release of substances prescribed for any environmental medium into that medium or, where that is not practicable by such means, for reducing the release of such substances to a minimum and for rendering harmless any such substances which are so released.*
>
> Section 7(2)(a) of the Environmental Protection Act 1990 in the UK (emphasis added)

This shows a clear hierarchy indicated of prevention before control that is also evident in the subsequent Integrated Pollution Prevention and Control (IPPC) Directive from the EU (Council Directive 96/61/EC). This was modeled to a large extent on the UK system, and became effective in the UK from October 1999 with subsequent UK regulations introduced in August 2000. In working to comply with this, organizations should use the best available techniques, which mean:

> *... the most effective and advanced stage in the development of activities and their methods of operation which indicate the practical suitability of particular techniques for providing in principle the basis for emission limit values designed to prevent and, where that is not practicable, generally to reduce emissions and the impact on the environment as a whole:*
>
> *– "techniques" shall include both the technology used and the way in which the installation is designed, built, maintained, operated and decommissioned,*
>
> *– "available" techniques shall mean those developed on a scale which allows implementation in the relevant industrial sector, under economically and technically viable conditions, taking into consideration the costs and advantages, whether or not the techniques are used or produced inside the Member State in question, as long as they are reasonably accessible to the operator,*
>
> *– "best" shall mean most effective in achieving a high general level of protection of the environment as a whole.*
>
> Council Directive 96/61/EC 24 September 1996

It is clear that waste minimization is a key component of the modern approach to environmental protection, and waste minimization is achieved *inter alia* by the efficient use of all resources, including energy, materials and, of course, personnel.

Good environmental management is often regarded as part of total quality management, and that an organization with effective quality systems in place should minimize problems and may not require environmental inspection as frequently as an organization without such systems. Proven good environmental management systems supported by audit data may also be demanded before an organization can secure a bank loan, by investors before they will invest in and it may be required by its customers before they will buy from it. Public liability insurance policies normally have not included pollution, and the underwriting of potential claims may present major problems in the future. Insurers are therefore likely to seek audit data before taking new risks. Few can now believe that good environmental performance is an optional extra: what was once regarded as offering a market advantage is becoming a prerequisite to entering the market-place.

Amongst the concepts and tools that help improve environmental performance is "eco-efficiency", which:

> *... is reached by the delivery of competitively priced goods and services that satisfy human needs and bring quality of life, while progressively reducing ecological impacts and resource intensity throughout the life cycle, to a level at least in line with the earth's estimated carrying capacity*. [2]

In simple terms, eco-efficiency means "doing more with less", using environmental resources more efficiently in economic processes by engineering techniques, clearly demonstrating performability principles.

One of the ways of achieving eco-efficiency is through cleaner production. This is:

> *"…the continuous application of an integrated preventative environmental strategy applied to processes, products and services. It embodies the more efficient use of natural resources and thereby minimises waste and pollution as well as risks to human health and safety. It tackles these problems at their source rather than at the end of the production process; in other words it avoids the "end-of-pipe" approach…. For processes, Cleaner Production includes conserving raw materials and energy, eliminating the use of toxic raw materials and reducing the quantity and toxicity of all emissions and wastes…For products, it involves reducing the negative effects of the product throughout its life-cycle, from the extraction of the raw materials right through to the product's ultimate disposal…. For services, the strategy focuses on incorporating environmental concerns into designing and delivering services…"* [2]

In the past, emphasis tended to be on environmental releases from the main "point" sources; nowadays the emphasis is increasingly on the control of accidental or "unauthorized releases" from industrial processes. In part this is due to increasing controls over point releases, although, ironically, this may have resulted in the environment becoming relatively more susceptible to risks from non-routine process emissions caused by equipment failure or maloperation. The public and other stakeholders are becoming less tolerant of such releases. Currently, all major companies operating within the EU must have a documented and rehearsed emergency plan. Senior management's interest in failure should not only be limited to major incidents; the treatment of smaller, less serious incidents should be of utmost concern especially in terms of the relevance or appropriateness of existing working practices.

Many improvements can be made in production processes at no or very little cost. This improves both an organization's profitability and its environmental performance, whatever the business sector. Some other "tools" for eco-efficiency and cleaner production include:

- Economic instruments such as taxes, refunds, *etc.,* that encourage optimal resource use.
- Environmental accounting to integrate environmental costs into decision making.
- Environmental audits are designed to identify an organization's environmental impacts.
- Environment management systems (EMS) offer a structured approach to measure their environmental performance, and then regularly evaluate their performance and improvement.
- Public environmental reporting is the process whereby an organization examines its environmental performance over a specified reporting period and disseminates that information to a wide audience.
- Life cycle assessment (LCA) is the collection and evaluation of quantitative data on the inputs and outputs of material, energy and waste flows associated with a product or service over its entire life cycle. This enables its environmental impacts to be determined.
- Design for the environment (DFE) or "ecodesign" examines a product's entire lifecycle and proposes changes to how the product is designed to minimize its environmental impact during its lifetime.

Several of these tools are supported by guidelines from the International Standards Organization (ISO), and some current documents are listed in Table 52.1. An integral part of an organization's environmental management system is the commitment to continual improvement and in accord with this principle, the standards are regularly reviewed.

Table 52.1. Some current standards relating to environmental management

ISO 14001:2004	Environmental management systems. Requirements with guidance for use
ISO 14015:2001	Environmental management. Environmental assessment of sites and organizations
ISO 14031:1999	Environmental management. Environmental performance evaluation – Guidelines
ISO 14040:2006	Environmental management. Life cycle assessment – Principles and framework
ISO 14044:2006	Environmental management. Life cycle assessment – Requirements and guidelines
ISO/TR 14062:2002	Environmental management. Integrating environmental aspects into product design and development
ISO 14063:2006	Environmental management. Environmental communication – Guidelines and examples
ISO 14064 -1:2006	Greenhouse gases. Part 1: Specification with guidance at the organization level for quantification and reporting of greenhouse gas emissions and removals. Parts 2 and 3 also relate.
ISO/FDIS 14065	Greenhouse gases. Requirements for greenhouse gas validation and verification bodies for use in accreditation or other forms of recognition
ISO 19011:2002	Guidelines for quality and/or environmental management systems auditing
ISO/WD 26000	Guidance on social responsibility

52.3 Internal Control

"Performability" reflects an "holistic" view of designing, producing and using a product, system or a service which will satisfy the requirements of a customer to the best possible extent without creating an adverse effect on our environment. This implies that the 21st century products, systems and services not only have to be dependable but must be sustainable [3]. Failure in any of these aspects may threaten an organization.

In September 1999 publication of "Internal Control: Guidance for Directors on the Combined Code", often called the "Turnbull report" [4], after its chairman (Nigel Turnbull, Executive Director of Reed Plc), marked a landmark in corporate governance. The guidance is based on the adoption by a company's board of a risk-based approach to internal control, and on reviewing its effectiveness. This should be incorporated by a company within its normal management and governance processes.

The span of internal control contemplated by Turnbull stretches wider than financial controls, to encompass social and environmental issues, which are often considered under the generic heading of "reputational risk". The Turnbull report [4] noted that:

> *A company's objectives, its internal organisation and the environment in which it operates are continually evolving and, as a result, the risks it faces are continually changing. A sound system of internal control therefore depends on a thorough and regular evaluation of the nature and extent of the risks to which the company is exposed. Since profits are, in part, the reward for successful risk-taking in business, the purpose of internal control is to help manage and control risk appropriately rather than to eliminate it.*

In an appendix suggesting ways for assessing the effectiveness of the company's risk and control processes, the Turnbull report posed several questions on risk assessment including:

> *Does the company have clear objectives and have they been communicated so as to provide effective direction to employees on risk assessment and control issues? For example, do objectives and related plans*

include measurable performance targets and indicators?

Are the significant internal and external operational, financial, compliance and other risks identified and assessed on an ongoing basis? (Significant risks may, for example, include those related to market, credit, liquidity, technological, legal, health, safety and environmental, reputation, and business probity issues.)

Is there a clear understanding by management and others within the company of what risks are acceptable to the board? ...

Does the company communicate to its employees what is expected of them and the scope of their freedom to act? This may apply to areas such as customer relations; service levels for both internal and outsourced activities; health, safety and environmental protection; security of tangible and intangible assets; business continuity issues; expenditure matters; accounting; and financial and other reporting.

Do people in the company (and in its providers of outsourced services) have the knowledge, skills and tools to support the achievement of the company's objectives and to manage effectively risks to their achievement?

How are processes/controls adjusted to reflect new or changing risks, or operational deficiencies?

Conventional measurement, management and quality assurance tools are not totally adequate for assessing and managing risk associated with emerging social and environmental factors that can affect financial performance. Organizations therefore seek new tools and approaches that allow them to meet the requirements set out in the Turnbull report, and that are consistent with good business practice. Tools such as those in Table 52.1 help address some of the risks.

Clearly risk is an important business issue, so it is appropriate to start by considering its meaning(s). The concepts of risk and risk management are used in many diverse fields, but their meaning differs in different disciplines. When we say we are going to take a risk we mean that we are prepared to take a chance of an adverse consequence in the expectation of a benefit. Implicit in that interpretation is that risk reflects both a likelihood of "harm" and a measure of the consequence. In everyday life, however, it is consequence that may be paramount in our mind rather than likelihood. Commonly we associate risk with some aspect of "loss", but it is important to recognize that in financial management, risk attempts to quantify the probability of loss as contrasted to the probability of gain. The emphasis is on a potential benefit.

To achieve the full benefit of embedding risk management, not only should the risks being managed be more visible, but also the resultant attention those risks receive must result in managing risks more effectively. This pressure raises the profile of risk management on the business agenda.

The Turnbull report confirms that the management of companies may be held accountable for risks beyond traditional financial threats. It establishes risk management as a "top down" process based on the management's analysis of key threats to success as diverse as consumer behaviour, supplier failure, or obsolete products as well as environmental health and safety issues. However, any review of risks should concentrate on the significant ones. These aspects of top level commitment and a focus on significant risks are similar to risk management issues from other aspects of business, particularly environmental and health and safety management.

52.4 Risk Assessment and Management

The increased complexity since the second half of the 20th century brought sources of risk with high real and perceived profiles: environmental pollution, nuclear hazards, transport accidents, financial market instabilities, toxicology and terrorism. At the business level, operational risk,

mergers, acquisitions, downsizing, technology innovations, the introduction of e-business processes, information security, market forces, economic pressures, natural disasters, competitor and business partner behaviour, regulatory and legislative changes all involve risks and the prospect and challenge of change. Organizations have always needed a philosophy and structure that not only enables them to plan for future changes but to recognize opportunities and profit from them.

We live in a period of increasing pace of change, and any organization that is unwilling or unable to adapt will lose its profitability, competitive edge, or even fail altogether. Business change alters the overall profile of risk any organization faces and the specific risks to each business process. It should also result in review and updating of business continuity plans. Unlike health and safety legislation, environmental legislation has not been so explicit in demanding risk assessments for environmental protection. However, regulatory agencies are increasingly recognising the benefits from the use of risk assessment techniques in dealing with environmental problems. Such risk assessments also serve as the basis for determining the frequency of inspections by regulators. The role of risk assessment in pollution prevention and control is also being increasingly recognized by legislators. For example, regulations on contaminated land stipulate the use of risk assessment for prioritising remediation work.

Companies themselves are also recognising the benefits of applying formal environmental risk assessment techniques to minimize their environmental liabilities and reduce the frequency of environmental incidents. These can lead to adverse publicity, and also engender significant costs from incident investigation, cleaning up the environment, prosecutions and fines. All may have an impact on the company and its "value" to stakeholders.

In general the management approach requires hazards to be identified, the risks they give rise to assessed and appropriate control measures taken to address the risks.

Risk assessment also provides a means of prioritising resources so as to ensure the most efficient use of the capital available. It can also improve the robustness of decisions on best available techniques for preventing or minimizing pollution and on the best practicable environmental option (BPEO) for minimizing the impact on the environment as a whole.

Formal risk assessment techniques offer an approach for organizations to address their risks. Many risks can be identified instinctively, or by using qualitative methods, without recourse to more detailed and time consuming quantitative risk assessment methods. However, quantitative techniques may be more appropriate when:

- there are concerns that qualitative approaches may overlook important issues;
- there are uncertainties over the likelihood or consequence (or both) of a system going wrong and where quantifying these may reduce uncertainty,
- qualitative assessments indicate a significant number of risks in a system, hence there is a need to prioritize risk reduction or mitigation work using more robust techniques. This is especially important when high levels of spending are required.

With environmental risk we have seen that the concern is with the probability of an event causing a potentially undesirable effect. It involves the separate consideration of the likelihood and the consequences of an event, for the purposes of making decisions about the nature and significance of any risks, and how best to manage any unacceptable risks. Quantitative risk assessment is thus a statistical approach, because probability is the mathematical measure of risk, but it also concerns hazard assessment that relates to the nature of the undesirable effect. Environmental agencies, use risk assessment as an objective tool to set standards, set priorities and provide assistance in decision making. It has long been applied in this way to evaluate the risks to human health arising from chemicals in the environment, for example.

Having identified the main risks to the environment it is equally important that the site environmental management systems give due recognition to them. These systems must then be audited regularly to check that they remain effective, thus ensuring a complete and up-to-date risk management system is in place, in accordance with the requirements for corporate governance.

All of these pressures lead to better environmental protection through better management of risk and planning for emergency scenarios. As noted earlier, the requirements for internal control demand that organizations address these issues.

A risk present in an organization, which has the influence to cause damage of any type, must be effectively managed to reduce it and mitigate subsequent liability and/or damage. The same applies to potential risks. Before expending valuable resources in managing the risk, senior management must first set about identifying all possible risks facing the organization and then carry out an assessment process to decide which risks are most relevant and significant to it. Once the significant risks have been identified, management systems can then be improved or established to reduce them. All areas of the business should be looked at to identify sources of risks within the company (operational). Other areas where the business impacts must also be analysed include upstream processes (supply chain), downstream processes (product end-of-life) and external areas (societal).

If significant risks to a company are managed effectively, the probability of them occurring will reduce, thus removing them from the "critical zone". Management systems such as the ISO 14000 series and OHSAS 18001, an international occupational health and safety management system specification embracing BS8800, AS/NZ 4801, NSAI SR 320 and others may mitigate many risks facing an organization [5].

Having identified risks to the environment and implemented measures to reduce or mitigate these risks it is equally important that the management systems give due recognition to them. Failure to make all relevant staff aware of these systems and the need to monitor and maintain them will give rise to more frequent incidents and greater environmental impact. In fact it defeats the objective if risk reduction or mitigation techniques are installed and the required management systems including emergency planning are not also put in to ensure they are properly operated, monitored or maintained.

Hence measures installed need to be addressed in staff training programmes, in operating instructions, in plant troubleshooting guides and in operator log sheets. They should also be given the correct priorities in any site preventative maintenance system. All of these elements form part of the management systems.

Central to approaches to understanding and managing risk more effectively is stakeholder dialog. When handled effectively, this dialog can influence views and behaviour of stakeholders and the company itself in ways that enable performance improvements in both the short and the longer term. These concerns have led to a growing number of accountability standards that provide a basis for optimising stakeholder dialog for risk assessment and management by linking it to a broad framework of measurement, accounting, auditing, verification and public disclosure. The recent standard, ISO 14063:2006, gives guidance to an organization on general principles, policy, strategy, and activities relating to both internal and external environmental communication and addresses the important "reputational risk" referred to previously.

52.5 Stakeholder Involvement

A stakeholder is anyone who has a "stake" in a risk management situation. Stakeholders typically include groups that are affected or potentially affected by the risk, the risk managers, and groups that will be affected by any efforts to manage the source of the risk. Who the stakeholders are depends entirely on the situation. The objectives, interests and responsibilities of stakeholders may be varied and contradictory.

Questions that can help identify potential stakeholders include:

- Who might be affected by the risk management decision? (They may not know it.)
- Who has information and expertise that might be helpful?
- Who has been involved in similar risk situations before?
- Who has expressed interest in being involved in similar decisions before?
- Who might be reasonably angered if not included?

Experience increasingly shows that risk management decisions made in collaboration with stakeholders are more effective and more durable. Stakeholders bring to the table important information, knowledge, expertise, and insights for developing workable solutions. They are more likely to accept and implement a risk management decision they have participated in shaping. One reason for this is differences in the perceptions of risk.

52.5.1 Perceptions of Risk

The opinions of the public have to be taken account of in the evaluation of risk. It involves interactions across many domains of the environment, and despite massive financial investment, political action and steady improvements in health, safety and the quality of life, the threats posed by technology are still perceived by many as large. Social structures and the processes of risk experience, the resulting repercussions on individual and group perceptions, and the effects of these responses on communities, societies and the economy have been termed "the social amplification of risk". This framework describes how both social and individual factors act to modify perceptions of risk and through this create secondary effects such as stigmatization of technologies, economic losses or regulatory impact as will be discussed shortly.

Sometimes, there is a discrepancy between the risks perceived by experts and the way in which risks are reported and perceived by the public. For example, studies have shown that the public often rank the risks from hazardous waste sites as most serious, whereas the experts rank the risks from these sites as medium/low on the basis of an understanding of the engineered precautions taken to manage such sites. At the other end of the scale, the public may rank the seriousness of indoor air pollution and global warming as relatively low, while experts rank them as high. In other areas there can be agreement between public and experts. Experts may use a calculation based on objective data to generate the actual risk. The perceived risk, or subjective risk, is the risk estimate obtained by surveying the public either for their estimate of the hazard involved (very safe, safe, marginal, dangerous, very dangerous) or for their estimate of the number of accidents or whatever else is the issue.

To a certain extent it is impossible to provide a truly objective measure of risk. Choosing numbers from a table of data involves a subjective decision. A combination of small probabilities and large possible outcomes are known to cause problems with perception of the risks involved, and research has shown that people tend to overestimate the risk of death from low probability causes, and underestimate the risk of death from high probability causes.

People also rank risks based on how well the process is understood, how equitably the danger is distributed, how well individuals can control their exposure and whether risk is voluntarily assumed. These items can be combined into three major factors. The first is an event's degree of dreadfulness, as determined by features such as the scale of its effects and the degree to which it affects innocent bystanders; the second is a measure of how well the risk is understood; and the third is the number of people exposed.

Dread and understanding can be used to understand perceptions. The location within a space defined by these "values" indicates a likely public response. Risks carrying a high level of dread, for example, provoke more concern than do some more familiar risks that actually cause more deaths or injuries.

The concept of risk involves interactions across many domains of the environment, and despite massive financial investment, political action and steady improvements in health, safety and the

quality of life, the threats posed by technology are still perceived by many as large. In the context of "the social amplification of risk" [6], signals about a risk may emerge from direct personal experience or through receiving information, and these signals may be processed by social and individual "amplification stations". These "amplification stations" might include:

- the scientist conducting the technical risk assessment and communicating it,
- the news media,
- pressure groups,
- opinion leaders within social groups,
- personal networks,
- public agencies.

The amplification of risks is likely to result ultimately in effects such as:

- enduring perceptions and attitudes not in favour of technology,
- impact on business sales, property values and economic activity,
- political and social pressure,
- changes in the nature of the risk through feedback,
- changes in education and training,
- social disorder such as protests or even sabotage,
- regulatory changes,
- impact on other technological advances, for example the generation of low public acceptance or trust.

The impacts may spread further to other groups, locations or generations, not unlike the ripple effect when a stone drops into a pond.

It is important to recognize that amplification and attenuation hold equal place in the framework. While instances of amplification captured the headlines in scares, addressing performability failures may involve changing behaviour, and here it is attenuation that may rule.

It is clear, then, that a growing numbers of stakeholders want to integrate environmental and social information in their decision making processes [7]. With the increased information flow across the world that increases the visibility of an organization's activities, organizations are themselves voluntarily choosing to be more transparent. The stepwise trend is suggested in Figure 52.2.

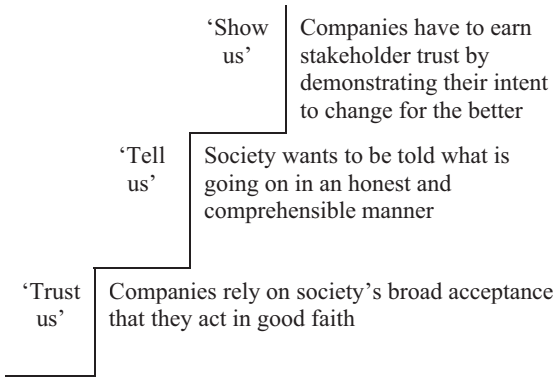

Figure 52.2. Evolution of corporate responsibility

Adverse criticism on environmental and social performance can put at risk the significant economic value of good corporate reputation and a well-regarded brand, as will be considered shortly. However, organizations that demonstrate commitment to good performance can earn the trust from society if a disaster does occur.

52.5.2 Stakeholder Dialog

Central to the approaches to understanding and managing risk more effectively is stakeholder dialog. Dialog can serve the purpose of assessing and more effectively managing aspects of risk by building trust with key stakeholders; acquiring critical information about future societal and market trends; and reaching greater consensus with stakeholders as to what they think constitutes appropriate business purpose and behaviour.

Ultimately, dialog, when handled effectively, can influence views and behaviour of stakeholders and the company itself in ways that enable performance improvements in both the short and the longer term. Poor quality dialog can reduce its value, and indeed can actually damage reputation. These concerns have led to a growing number of accountability standards and management systems developed through partnerships between business, governments and international agencies.

Public environmental reporting, sometimes referred to as "disclosure" is the communication of environmental performance information by an organization to its stakeholders. Increasingly, organizations are choosing to publish such reports, some in response to mandatory requirements, others in accordance with emerging business requirements or changing stakeholder expectations.

As an aspect of performability, pollution prevention in companies has changed from a rather narrow and technical focus on optimization of the existing production processes to a more organizational focus on environmental management. Growing emphasis on the environmental impacts from products over their life cycles, globalization with international product chains and the focus on environmental impacts from products increase the need for environmental communication in and between companies. In this regard it has been said that a preventive environmental effort in a company is a social and distributed process, where environmental communication is "the glue" keeping the process together [8]. Its importance has been recognized by ISO 14063:2006, listed in Table 52.1, which gives guidance to an organization on general principles, policy, strategy and activities relating to both internal and external environmental communication. However, as Table 52.2 indicates, there are many approaches.

While environmental and social disclosures are on the increase in annual reporting, the principal customers for the annual report package may not be directly concerned with the finer details of environmental performance, but with high-level risk, governance and assurance issues. For such users, environmental issues may be amalgamated into a general concern over so-called reputational risk. Investors require assurance that a company is meeting all necessary obligations arising from its stated environmental and social policies.

In particular, it should manage its operations in ways that meet relevant legal regulations and minimize its exposure to any potential environmental liabilities or reputational risk. These changes form part of a paradigm shift towards corporate transparency and public accountability.

Table 52.2. Approaches to environmental reporting

Compliance based	Report level of compliance against external regulations and consents. This is often a feature of heavily regulated organizations such as utilities and chemicals.
Toxic release inventory based reporting	Under US law, many companies are obliged to publish data on emissions of specific toxic substances. Such mandatory disclosure takes precedence over voluntary disclosure.
Eco-balance reporting	Some companies, especially from Europe, construct a formal eco-balance – detailed account of inputs and outputs from which performance indicators are derived.
Performance based reporting	This is probably the most common type of reporting used by most organizations. Significant areas of environmental impact are considered, performance targets set , indicators developed and progress disclosed regularly.
Product reporting	The environmental attributes of a product are evaluated, and in this case the producer responsibility goes beyond the production process itself. You see an example of this in the video case study "What's in a car?"
Environmental and social reporting	Increasing pressure to widen the scope of corporate public accountability drives many organizations to include social data such as employee statistics and working conditions in their reports.
Sustainability reporting	This stage beyond environmental and social reporting involves integrating environmental, social and economic disclosure in a single report.

Worldwide, stand-alone environmental reports or broader sustainability/social responsibility reports are becoming increasingly important as a tool in communicating with and engaging stakeholders.

The concept of public environmental reporting originated from the 1992 United Nations

Conference on Environment and Development (UNCED), the Rio Earth Summit. The Earth Summit was the first major international discussion of sustainable development as a serious global issue. Agenda 21, the "action agenda", which emerged from the Earth Summit, identified "community right-to-know" as a matter for consideration in developing environmental policy.

It recommended that organizations be transparent in their operations and report annually on their environmental performance. An organization is essentially a function of its stakeholder groups, including its employees, shareholders, the public, regulators, contractors/suppliers, customers and other interested external parties, who have varying objectives and expectations that need to be satisfied. The measurement and reporting of environmental performance is becoming increasingly important in order to satisfy the expectations of such stakeholder groups. Managers in a business activity with major incident potential have to respond to emergencies within their own organization. In effect, if an incident occurs, the organization is itself in a crisis, with functionality impaired. Corporate governance embraces all of this.

Companies should ensure that they have a sound system of internal control and effective risk management processes which are regularly reviewed by the board. The entire system, including risk management processes, must be specifically reviewed for effectiveness by the board at least on an annual basis. Time and effort spent on emergency planning may not make an immediate contribution to profits, even though in the long term it may be essential to allow the organization to survive a crisis. Planning also includes measures to prevent emergencies arising or escalating. These will certainly limit the ability of managers to take short cuts or override procedures to overcome temporary difficulties in order to maintain production. Such restrictions are often seen as unnecessary nuisances – until something goes wrong. Then it is essential to address the problem quickly, openly and effectively.

Various incidents with significant negative impact on shareholder value are indicated in Table 52.3. The Open University distance-learning course "Integrated Safety, Health and Environmental Management" includes several of these incidents as video case studies and deals extensively with emergency preparedness.

The Perrier incident is a classic example of a performability failure in which a product fails to "satisfy the requirements of a customer", and the way this failure is managed can affect company value. At the Mecklenburg County Environmental Protection Department in North Carolina, scientists used bottles of Perrier sparkling mineral water as a "pure" standard for water analysis rather than purifying water themselves. On January 19, 1990 an anomalous mass spectrometer reading indicated a corrupt sample. Perrier water had consistently been a reliable source and so faulty instrumentation was suspected, but it was found that the Perrier contained between 12.3 and 19.9 ppb of benzene. This was above the 5 ppb limit specified by America's Food and Drug Administration (FDA) but below levels that might present a health risk. Perrier were alerted to the problem, and while the concentrations of benzene did not pose "a significant short-term health risk" according to the FDA, nevertheless the company acted to protect its brand image of purity. Initially, Perrier claimed that the contamination was an isolated incident due to cleaning fluid containing benzene used on a production-line machine and only drinks in the US were affected. It recalled over 70 million bottles from US shops and restaurants. Unfortunately, the real cause was found three days later when contaminated bottles appeared in Denmark and the Netherlands, and Perrier revised its explanation, admitting that benzene was naturally present in carbon dioxide (the gas that makes Perrier effervescent) but filtered out.

The normal processing method for Perrier was to remove such impurities by passing the mineral water through carbon filters. A faulty warning light on a control panel went either undetected or unreported by employees for more than six months, allowing the filters to become blocked and no longer function. Amid growing consumer mistrust, a further 90 million bottles were withdrawn globally at an estimated loss of $263 million. Through 1991, Perrier struggled to recover. Its overall sales had declined for a second year together with the share price, around half from a high of nearly FF2000 per share prior to the benzene affair (Figure 52.3).

Table 52.3. The costs of some performability failures to businesses

Date	Company	Incident	The costs
1982	Johnson & Johnson	Product tamper and recall of 31 million bottles of Tylenol capsules (known in the UK as paracetamol) after an employee injected cyanide into some capsules, resulting in seven deaths. Advertizing and product distribution were halted. A tamper-resistant pack was designed and the product was relaunched a few months later.	In 1991, the families of the seven victims reached an out of court settlement with the company. The cost of the recall was estimated at $100 million and $50 million for business interruption losses. The company sued its insurers for $67,4 million in 1986, but lost the case.
1984	Union Carbide	Liability from the Bhopal incident.	Over $527 million
1986	Sandoz*	Fire and pollution Rhine	$85 million
1987	P&O*	Liability Zeebrugge	over $70 million
1988	Occidental*	Fire and explosions Piper Alpha	$1,400 million
1989	Exxon	On March 24, the Exxon Valdez oil tanker ran aground, spilling more than 10 million gallons, of oil into Prince William Sound, Alaska. Efforts to contain the spill were slow as was Exxon's response. The Exxon name tends to this day to be synonymous with an environmental disaster.	The cleanup cost the company $2.5 billion with $1.1 billion in various settlements. A 1994 court case also fined Exxon a further $5 billion for its recklessness, which Exxon later appealed. In addition to the direct costs of the disaster, Exxon's image was tarnished, perhaps permanently.
1990	Source Perrier	Product recall benzene carbon filters intended to remove benzene, a carcinogen, became clogged, and this went undetected for six months. No one suffered as a result of drinking the benzene-contaminated water, but Perrier was forced to recall 160 million bottles from 120 countries. There were contradictory statements from management on the extent and cause of the contamination.	Eighteen months after the incident, Perrier's share of the sparkling water market fell from 13% to 9% in the US, and from 49% to less than 30% in the UK. The cost of the recall was $263 million. The share price fell (see Figure 52.3) and the company became a takeover target. In July 1992 it was taken over by Nestle.
2001	Bridgestone/ Firestone Inc./ Ford	The recall of 16 million Firestone Wilderness AT tires in August 2000 was followed in 2001 by the US government requesting another 3.5 million Firestone tires to be recalled for safety checks by Ford, which used them on sports utility vehicles. Treads on several models were found to be separating from the tires. The tires were believed to be the cause of rollover crashes resulting in 203 deaths and over 700 injuries.	Firestone spent more than $350 million for the recall with potentially more in legal cases and a loss in public confidence of the product. The Bridgestone share price dropped from over Y2500 to below Y1000.

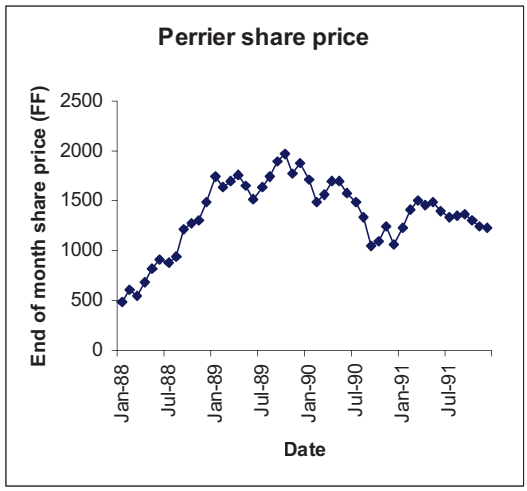

Figure 52.3. How an incident can affect share price

Another example relates to a rail incident. On 10 May, 2002 a train traveling from London Kings Cross derailed at Potters Bar when passing over points 2182A. Three of the four carriages derailed and one ploughed along the platform and struck a bridge. There were 7 deaths and over 70 people were injured. The formal inquiry report by the Rail Safety and Standards Board [9] and the Health and Safety Executive [10] concluded *inter alia* that

- Failure of points 2182A caused the derailment.
- Components in the points were in a poor condition.
- Nuts on the points were missing.
- The points had been poorly maintained and were not adjusted correctly.
- Other sets of points in the Potters Bar area were found to have similar, though less serious, maintenance deficiencies.
- Other sets of points showed evidence that attempts had been made to improve the retention of nuts, suggesting there had been difficulties in the area with such nuts loosening.
- There appears to have been no guidance or instructions for setting up, inspection or maintenance of points of the 2182A type.
- There appears to have been a failure to recognize, record or report safety-related defects in the set up and condition of points 2182A.
- There were deficiencies in response to a report of a rough ride near the points south of Potters Bar station the night before the derailment.
- Wider inspections of a sample of similar points across the rail network found conditions that were not consistent with good engineering practice. The deficiencies were less serious than those at Potters Bar.

These are clear performability failures. The Potters Bar incident had an impact on the share prices of companies involved in rail track maintenance (Figures 52.4a and b below), while companies operating in the same market sector but without rail involvement showed no comparable decline (Figures 52.4.c and d).

Studies have found that this fall often amounts to almost 8% of shareholder value and while recovery tends to occur in fifty trading days or so, the ability to recover varies considerably [11]. Some argue that if the price falls below a threshold, recovery is impossible. The impact of such incidents on companies' share prices come from the direct financial cost of the incident in terms of cash flow, with the market adjusting the stock price accordingly. Then the market adjusts the share price in accordance with its assessment of the way management handled the incident.
Important lessons come from these incidents.

First, that reputation can be harmed at an instant, but can be protected by planning for an emergency and dealing with communication issues well. Timeliness is a major factor in any emergency situation. The Johnson and Johnson incident in 1982 provided a model that a company was expected deal with the actual problem well and create a positive image of how the problem is handled. In contrast, Exxon was unsuccessful in both. While claiming that addressing the pollution was its first priority, company officials took what was regarded as too long to deploy booms to contain the spill.

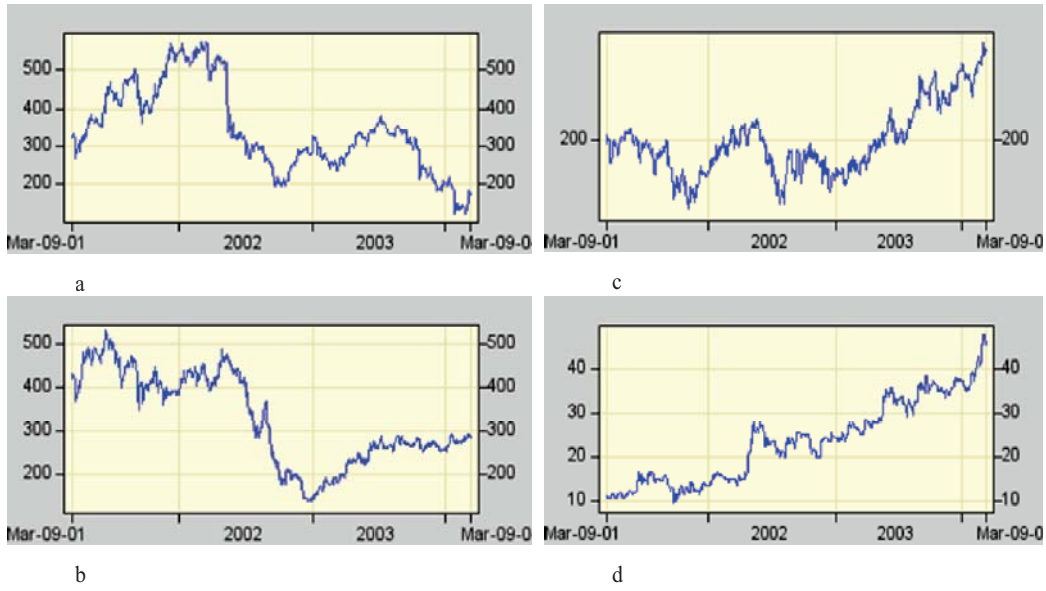

Figure 52.4. Share prices of selected companies following the Potters Bar rail crash

In addition, Exxon was criticized for refusing to acknowledge the extent of the problem, in part, due to the advice of legal counsel – a not uncommon factor in view of potential future liability claims. Company representatives also refused to comment on the incident for almost a week, while the chief executive took six days to make a statement to the media and did not visit the scene until nearly three weeks after the spill. When added together, these actions gave the public the impression that the Exxon Corporation did not take this accident seriously.

52.6 Meeting Some Educational Challenges

In the context of cleaner production referred to earlier in this chapter, a recent study [12] found that, on average, the production and provision of distance-learning courses consumed nearly 90% less energy, and produced 85% fewer climate changing carbon-dioxide emissions than conventional full-time campus based university courses. The much lower environmental impacts of distance learning compared to campus-based courses is mainly due to a major reduction in the amount of student travel, economies of scale in utilization of the campus site, and the elimination of much of the energy consumption of student housing.

The study also compared e-learning courses to print-based distance learning courses.

It showed that e-learning courses offer only a relatively small reduction in energy consumption (on average 20%) and CO_2 emissions (12%) over print based distance learning courses. This was attributed to high student use of networked computing, consumption of paper for printing of web-based material, and additional home heating for night time internet access. This study challenged claims about the "de-materialization" effects and environmental benefits of using ICT to provide services such as higher education.

Glaxo SmithKline	Pharmaceutical research	110 000	523	80	1.2	20	33	74	17	9

The environmental impacts of a service depend mainly on its requirements for travel and a dedicated infrastructure of buildings and equipment.

The use of ICT or other methods will only benefit the environment if they reduce the service's requirements for energy-intensive transport, dedicated equipment and heating and lighting of buildings. Distance education can do this and is, therefore, an approach that offers many opportunities and efficiencies [13]. It can help avoid some of the seemingly "wasteful" aspects associated with conventional approaches to education and training.

However, distance learning is not without its challenges and one of these is in relation to group activities. Nevertheless, ICT can help here through the use of course conferencing facilities. Another postgraduate course "Enterprise and the environment" seeks to develop such group activity through

the analysis of corporate reports to which students can readily gain access. Students select an organization for study, analyse corporate reports by content analysis and then compare their findings with those of their peers using the course electronic conference. This provides opportunities for different interpretations from content analysis of the same report as well as allowing comparisons in and between industry sectors.

Table 52.4 shows some findings of a student cohort examining reports for mention of specific variables linked to performability, while Table 52.5 compares various sectors. Students commented that the amount of good news reported far outweighs the bad in all sectors. In addition, food manufacturers and banks appear to write more quantitative than qualitative sentences. Perhaps companies make more environmental disclosure where they recognize the sensitivity of the business to reputation damage through the amplification of risk, and certainly this applies to food industries where there have been numerous incidents.

This assignment provides an appropriate and challenging alternative to the conventional business-based project, which in the course is available as an optional audit activity.

52.7 Conclusion

Performability is the holistic view of designing, producing and using a product, system or a service to satisfy the requirements of a customer to the best possible extent. Failures in any respect may put the organization at risk and the significance of that risk depends on the perceptions of stakeholders. Organizations are therefore under increasing pressures to identify, assess and manage their risks.

Inevitably problems occur, but by identifying potential risks, organizations can be ready to deal with the consequences to themselves and their stakeholders. If an incident does occur, appropriate dialog with stakeholders can help minimize the loss to the organization. The social amplification of risk framework relates to both potential impact and the challenges in changing behaviour.

Making engineering students aware of these issues is an important feature of modern engineering education and reflects the holistic approach inherent in the performability concept.

Towards Sustainable Operations Management
Integrating Sustainability Management into Operations Management Strategies and Practices

Alison Bettley and Stephen Burnley

Faculty of Technology, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK

Abstract: Sustainability is an increasingly relevant issue for a wide range of organizations, and therefore sustainability management strategies and practices are of growing significance. Because many sustainability impacts are strongly influenced by operations management decisions it is critical that the operations management function embraces the requirements of sustainability management. This has implications for decisions and processes associated with all aspects of operations management including strategy, design, planning and control, and improvement. For example, appropriate environmental and social performance objectives, targets and indicators need to be integrated with quality, cost and other more conventional performance measures. The closed loop supply chain perspective must be adopted and the requirements of other stakeholders in addition to the customer must drive operations decisions. The scope of any given "operation" is thereby expanded considerably and the nature of the operations management role altered, with implications both for the professional development of managers and the research needed to support the manager in this changed role.

53.1 Introduction

Over the last two decades there have been growing pressures for organizations to reduce their environmental impact and move towards "sustainability". The main driving forces for this shift [1–9] can be summarized as:

- competitive pressures, arising from:
  - recognition of the cost advantages of reducing materials and energy consumption and waste production,
  - cost benefits of taking advantage of the economic incentives of green behavior such as subsidies and reduced taxation,
  - the increasing pressures from customers (end consumers and supply chain partners) to demonstrate good environmental stewardship,
- the perceived marketing advantages from demonstration of compliance with standards and so on;
- legal obligations, in a climate of increasing regulation as scientific evidence for human influences on climate change, ozone depletion and so on hardens;

- the demands of investors for security from future liabilities consumer demands and expectations of ethical behavior and good corporate citizenship in the wake of scandals such as Enron;
- internal ethical values, reflecting changed values in society as a whole.

These pressures can and do translate into tangible benefits for the organizations that choose to respond to them – reduced costs, increased market penetration and market share, increased levels of investment, improved brand reputation, new products and markets, and enhanced customer satisfaction.

As more and more organizations recognize these opportunities, adoption of environmental management (ISO 14001 and similar) standards alongside quality management standards (ISO 9001) has become relatively commonplace. The next generation of management systems and standards will embrace sustainability more fully, by integrating social, environmental and economic objectives.

The operations function of the organization is concerned with the arrangement of resources devoted to the production and delivery of the organization's products (goods and/or services) [10]. As such, it is the "engine room" of the organization, and therefore directly responsible for a large proportion of the decisions and the activities that give rise to environmental problems. The design and management of operations strongly influence how much energy and materials resources are consumed in order to manufacture goods or deliver a service. Operations decisions are also partly responsible for how easily an item can be recycled, and the nature and extent of emissions and wastes produced during both a product's manufacture and its use. The solutions to many environmental problems, as well as the causes, therefore lie fairly and squarely in the operations management domain. Similarly operations decisions and activities have a profound impact on many of the wider concerns of sustainability such as those associated with working conditions and practices both internally and in the supply chain. Therefore, if "sustainability" is to become any type of reality, it is critically important that operations management embraces the necessary strategies and practices. This chapter explores the ways in which traditional operations management must develop in order to do just this and to play a full and effective role in progress towards sustainability, for all types of organizations.

The chapter is organized as follows. First, the nature of sustainability itself is explored. Then the scope of "operations" as it needs to be defined for the purposes of sustainability management is discussed. This then forms the basis for a discussion of the ways in which the traditional subdivisions of operations management need to be expanded to incorporate sustainability. Finally the implications for organizations, their operations and operations managers and for the research agenda are identified.

53.2 Sustainability

The conventional definition of sustainable development is "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" [11], although this tends to be interpreted differently in different contexts. Typically at present in industry it is environmental sustainability that is the focus of attention, but sustainability is actually a rather wider concept comprising a broad set of "quality of life" or "corporate social responsibility" measures embracing financial, social and environmental concerns [9, 12–14]. Corporate social responsibility (CSR) has been defined as "the continuing commitment of business to behave ethically and contribute to economic development while improving the quality of life of the workforce and their families as well as of the local community and society at large" (World Business Council for Sustainable Development, 1999, quoted in [15]). This is sometimes referred to as the "three pillars" of economic, social and environmental responsibility, the three Ps of "profit, people and planet" or as the "triple bottom line" (TBL) [16] by organizations adopting sustainability goals and seeking to report their progress to internal and external stakeholders. The very broad scope of sustainability management is illustrated by the BT case study in the box below.

The British Standard on sustainability management defines sustainable development as "an enduring, balanced approach to economic activity, environmental responsibility and social progress" [21]. An important practical implication of this is that simplistic judgments relating to one element alone cannot be made. Decisions must be taken in a way that integrates all these concerns [22], and this means taking into account the concerns of stakeholders from outside the organization as well as within it. This requires proactive steps to engage the relevant stakeholder groups to determine their interests and expectations. This is discussed in more detail in Section 53.3.

Guidance for managers wanting to adopt sustainability management exists or is emerging in the form of various voluntary management standards:

- BS 8900 Guidance for management of sustainable development [21].
- Social Accountability standard SA 8000 [23].
- ISO 26000, a forthcoming standard on sustainability management [24].
- GRI Sustainability Reporting Guidelines [25].

The British and ISO standards explicitly recognize that organizations are likely to want to integrate sustainability management with pre-existing quality and environmental management standards, and the content reflects this.

The extent to which "sustainability" can actually ever be "achieved" is a moot point, especially at the level of an individual enterprise or industry [26]. The many qualitative aspects it embraces militate against any absolute measurement, so that it is meaningless for any business, city or nation to declare itself a sustainable operation. Perhaps it is best considered as analogous to such notions as the well-known quality management "zero defects" concept, an aim around which processes are managed in order to achieve as close to a state of perfection as possible. For example, while the burning of coal to generate power is clearly unsustainable because of the depletion of finite resources and release of carbon dioxide, it is reasonable to consider a combined heat and power plant as being "more sustainable" than the less efficient power-only process.

However, there is at least one significant difference between quality and sustainability management, and that is the complexity associated with the assessment of sustainability, the number of different "measures" it embraces, the impossibility of quantification of a significant proportion of these, and the subjectivity of the judgments. Many attempts to provide the definitive set of sustainability indicators have been made [25, 27, and 28]. The GRI guidelines [25] are becoming established as a significant benchmark, see Table 53.1.

Case Study: BT's Corporate Social Responsibility Strategy

British Telecommunications Plc (BT) (a UK based telecommunications company) has a strong track record in corporate social responsibility management and reporting,it rates consistently highly in the Dow Jones Global Sustainability Index [17] and summarizes its current strategy as follows [18]:

"…to maintain our current momentum in CSR and to focus our efforts on the three biggest challenges:

The need for sustainable economic growth

The need for wider inclusion of all sections of society

The need to tackle climate change."

BT measures its performance and sets annual performance targets in all the following categories [19, 20]:

Customers

Customer satisfaction

Employees

Employee engagement

Diversity of the workforce

Health and safety: lost time injury rate; sickness absence rate

Suppliers

Supplier relationships

Ethical trading

Community

Community contribution

Environment

Global warming CO_2 emissions

Waste to landfill and recycling

Digital Inclusion

Geographical reach of broadband

Integrity

Ethical performance measure

Its annual report follows Global Reporting Initiative guidelines and provides a detailed account of its targets and progress towards them, all set out in relation to its strategic "business principles". The importance of "stakeholder dialog" and "engagement" is stressed throughout, with respect to the following six stakeholder groups: customers, employees, suppliers, shareholders, partners, community.

Whether or not any notion of absolute „sustainability" is practically attainable, it is always feasible to move nearer to it by designing and managing operations appropriately, for example, to reduce the environmental impact of an operation, or to have policies towards supply chain partners that promote good employment conditions.

This requires in the first instance appropriate definition of the scope of the operation so that all the impacts that flow from the operation are taken into account. The principles of life cycle thinking based on the technique of life cycle assessment (LCA) require that the environmental impacts of each and every stage in a product's life from materials extraction to product use and disposal are appraised (see Figure 53.1). The LCA process consists of three stages [29]:

- compiling an inventory of relevant inputs and outputs of a product or system,
- evaluating the potential environmental impacts associated with those inputs and outputs,
- interpreting the results of the inventory analysis and impact assessment phases in relation to the objectives of the study.

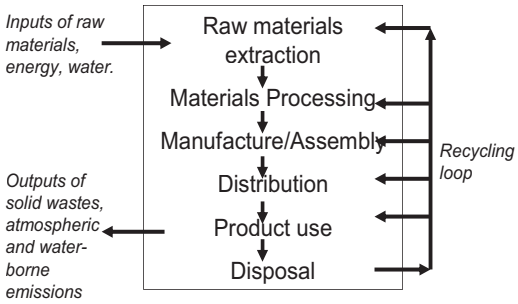

Figure 53.1. Product life cycle

The practical use by organizations of LCA's scientific principles is known as life cycle management (LCM); this is emerging as an important area of research and practice [30] in its own right [31, 32]. It demands as a first step a definition of the system under scrutiny: what should be included within its boundary and what can safely be left out? The scope of the operations system is discussed next.

53.3 Operations as a System to Deliver Stakeholder Value

An operation can be defined as a set of business processes that are directly responsible for converting a variety of resources (such as materials, money and the effort of people) into outputs (such as manufactured goods and/or delivered services) made available to customers. This classic transformation model of operations is shown in Figure 53.2.

Recent thinking in operations management has placed emphasis on taking the "supply chain perspective" so that internal processes are seen as links with external suppliers upstream and customers downstream. In this way issues such as outsourcing can be managed as part of the bigger picture to provide value for customers. Operations can then be represented as in Figure 53.3.

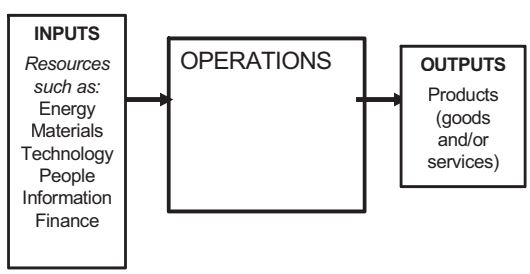

Figure 53.2. The transformation model of operations

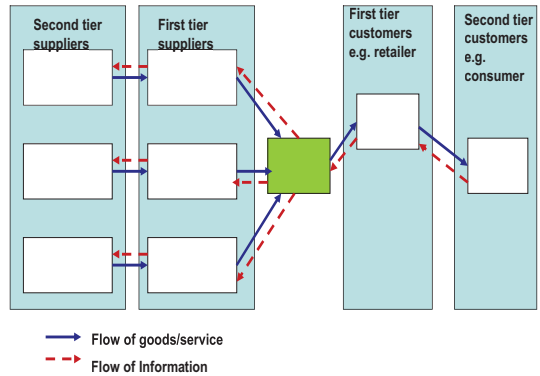

Figure 53.3. Supply network perspective of operations (adapted from [10])

Table 53.2. Stakeholders and their expectations

Stakeholder group	**Examples of expectations/interest – the value they seek from the operation**
Customers (internal or external)	Benefits from use of products/services Value for money.
Suppliers	Contracts Fair dealing
Managers/directors	Profit Fulfilment of organizational mission.
Other employees	Employment security Job satisfaction Good working conditions. Fair remuneration
Owners and other investors	Growth in value. Dividends.
Regulators	Compliance with regulation Performance improvement
Government	Taxes
Local community	Environmental stewardship Employment opportunities Community involvement
Society at large	Contribution to general economic well being Ethical behavior

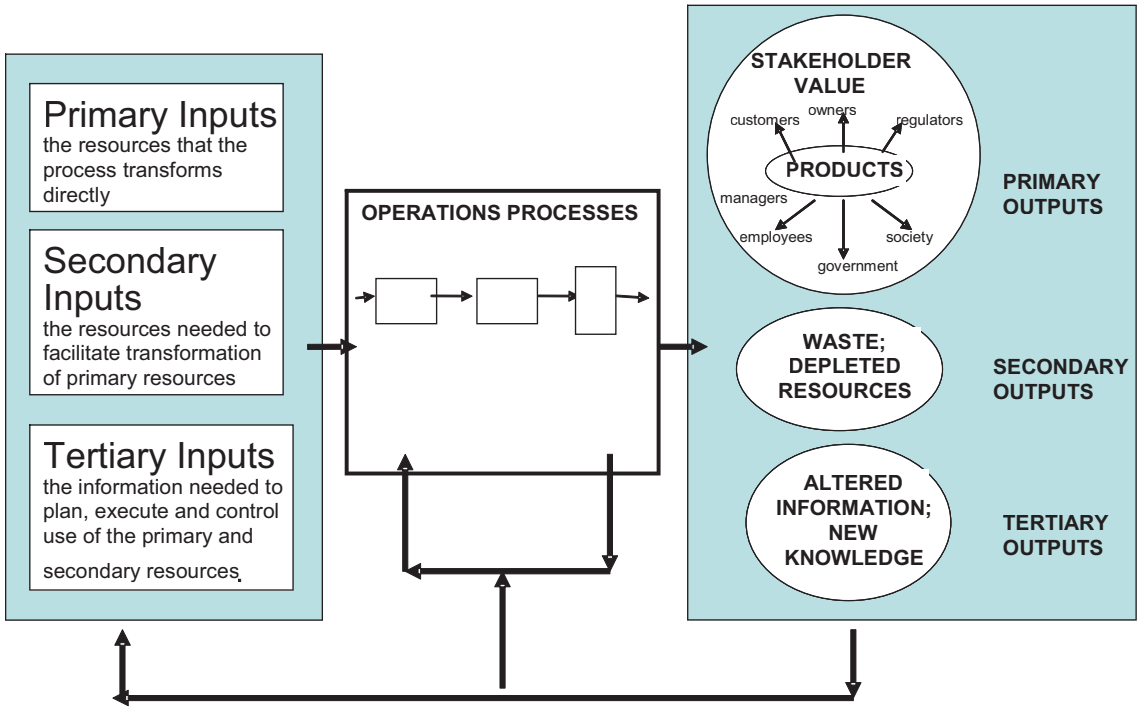

Figure 53.4. Expanded transformation model of operations

To integrate sustainability management with operations management this supply chain perspective must be extended in two linked ways.

First it is insufficient to consider the output of the operation only in terms of the value derived by the customer from the goods and services delivered by the operation. A wider set of stakeholders must be taken into account [33]. Stakeholders are individuals or groups with some sort of interest in the activity, in this case the operation. Typical stakeholders are listed in Table 53.2 along with their likely expectations of the value they seek from the operation. It is delivery of "stakeholder value", the total of the various elements of value sought by all stakeholder groups, including customers [34, 35], that might better define the overarching objective of operations management, as shown in the expanded transformation model of Figure 53.4.

To meet the needs of these various and diverse stakeholder groups, it is self-evidently necessary to understand them first, and this requires processes within the operation to engage stakeholders in an appropriate dialogue, as is specifically recommended in the British Standard on managing sustainable development [21].

Most organizations will have such processes for becoming "close to the customer" (for example, quality management tools such as QFD, or customer relationship management systems). Many may have employee consultation bodies and processes, and most will meet with and report to their shareholders. Other stakeholder groups, however, may be relatively neglected.

The "stakeholder capitalism" concept [36] builds on the stakeholder theory of the firm first developed in the 1980s and stresses the need for collaboration among supply chain partners and other interested parties. Emphasis is placed on the importance of devising and maintaining a suitable value system "architecture" to facilitate and nurture *cooperative* value creation. The entire process might be framed as stakeholder relationship management [33, 34, 37]. An important

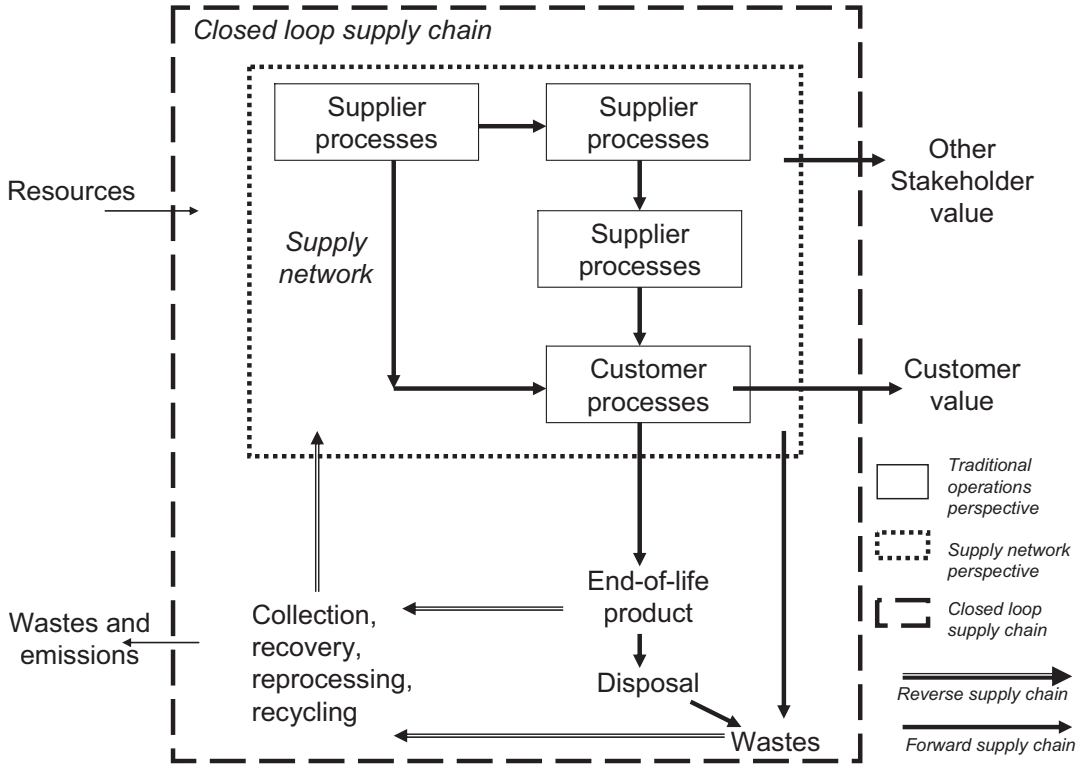

Figure 53.5. Closed loop supply chain in relation to other operations perspectives

implication of this stakeholder-focused thinking is that there is need for substantial change to traditional patterns of working across intra-organizational and inter-organizational boundaries.

The second point follows from this integrated and collaborative supply chain model, that it is necessary to consider a more complete "product system" than even the typical operations supply chain perspective embraces in order to deliver all these aspects of stakeholder value. Traditional supply chains are "forward" supply chains, ending at the point of delivery to the customer.

But if other stakeholders such as society at large are considered then this view is too restricted. The impacts arising from each and every stage in the product life cycle must be considered (see Figure 1). The "reverse supply chain" including product take-back for recycling, final disposal, waste treatment, and so on must be included in what is becoming known as the "closed-loop supply chain", for obvious reasons [38–42]. This is depicted in Figure 53.5.

An application of closed-loop supply chain thinking in the construction industry is given in the box below.

Moreover sustainability embraces more than environmental concerns so the impacts on employment, economic well-being of communities, ethical behavior and so on (as listed in Table 53.1) must also be integrated into the model. The "total product system" perspective advocated by Rhodes adopts this type of extended view, embracing after-markets, the end-of-life phase of the product life cycle and social and labor conditions associated with the various supply chain stages [43].

The "life cycle management" problem facing managers can therefore be framed as how to design and implement sustainable production systems

based on a consideration of all the various sustainability impacts of each stage in the closed loop supply chain [31, 32, 44]. The practical difficulties are manifold: vast quantities of data, different data from different sources, gaps in data, different methods of data aggregation, lack of established methods of measurement, the need for value judgments to decide which issues are priorities, the need for collaboration among all partners in the supply network, and so on. This field incorporates aspects of supply chain management and industrial ecology [31].

Industrial ecology applies the principles of natural ecology to eliminate wastes, cycle elements from end-of-life products to new products, minimize the storage of materials and intermediate products (particularly hazardous materials) and circulate energy within and between processes to minimize external energy inputs. These aims are often achieved by the co-location of processes (operated by one or more organizations) to the mutual benefit of all concerned. See [45], for examples of industrial ecology or symbiosis in practice.

The overall aim is to optimize the sustainability performance of the product system overall, but the feasibility of the business model must also be considered [42], as in the steel section case study as follows:

Case Study: Recycling and Reuse of Structural Steel Sections [38]

Steel is the most recycled material in the world – the technology to handle and return to the primary production processes many different grades of scrap (there are 29 in all) is well-developed. It is estimated that structural sections are recovered from demolition waste with 99% efficiency in the UK. 86% is "recycled" (demolition steel scrap forms the raw material for foundries and electric arc furnaces) and 13% is "reused" (reclaimed and end-of-life sections from building deconstruction which are then refabricated without the need for resmelting).

The opportunities to improve the sustainability of the construction sector through increased steel section reuse are being recognized, there are significant environmental and economic benefits of reuse. The results of a life cycle inventory (LCI) of the processes involved in each of the three main production routes can be summarized as follows [38].

Production route	Life cycle cost £/ton	Total energy requirement GJ/ton
Primary	1040	37
Recycling	950	18
Reuse	680	7

Energy consumption is used as the environmental indicator because analysis of the LCI data shows it is a good proxy for overall environmental performance. It is clear that reuse offers much higher economic and environmental benefits than recycling. However it cannot be assumed that this scale of benefits can be achieved with increased rates of reuse. Constraints on the supply loop are likely to exist, such as the following considerations.

How feasible is deconstruction rather than demolition for most end-of-life buildings?

The demolition industry is geared up for low cost rapid removal of end-of-life buildings, and buildings are not generally designed for deconstruction. Moreover deconstruction is more labor intensive with associated health and safety concerns. It seems likely that as reuse rate increases the costs will also increase, because those buildings most suitable for deconstruction will be chosen first.

How feasible is refabrication?

The work associated with preparation of reclaimed sections for refabrication will vary widely depending on the condition of the sections. The amount of preparation work will increase with reuse rate as the availability of the best quality reclaimed sections reduces.

Is there a big enough market demand for re-fabricated sections to warrant expansion in reuse?

Many of the customers for reclaimed sections expect the cost to be less than that of new parts. If they are similarly priced, customers tend to buy new to reduce perceived risk. However there is a small group of environmentally aware customers who perceive added value in the increased sustainability of reclaimed sections provided they are cost neutral.

It can be concluded that although the environmental benefits remain as indicated by the data given above, the cost savings associated with reuse are likely to fall as the reuse rate increases, making the business case for more reuse less certain.

53.4 Integration of Operations and Sustainability Management

There are several reasons why it is essential to integrate sustainability management decisions with operations management:

- Many of the decisions that affect sustainability are strategic long term ones rather than day-to-day planning and control. It is well-established, for example, that maximum environmental benefits are gained from treating the problem at source (use of an alternative less polluting material, for example) rather than at "end-of-pipe". Therefore sustainability objectives must be considered alongside other performance objectives when devising operations strategy and designing a process or product.
- In the same way that "quality" concerns must become embedded in normal working practice and organizational culture to be effective, so too must sustainability objectives and practices. All employees must be involved and have a thorough understanding of how their activities and responsibilities impact on sustainability performance.
- Operations management at all levels involves a variety of trade-off decisions requiring integration of several factors. Sustainability concerns need to sit alongside others when the relevant decisions are made.
- All aspects of operational performance should preferably be integrated into a single management system (*e.g.*, quality, sustainability, health and safety) so as to reduce the administrative overhead and potential confusion arising from multiple systems.

Many authors have considered issues of interaction and integration between especially environmental sustainability and other aspects of operations management [2, 46–50]. The wider issues raised by consideration of sustainability in the more complete and broader sense have received much less attention to date. However, this can be expected to change. Adoption of sustainable business strategies by organizations will automatically give rise to operations issues to be addressed, see, for example, The discussion by Schmidt *et al.,* of a method to measure the social aspects of sustainability to complement eco-efficiency assessments of BASF products [51].

Kleindorfer *et al*. [50] have documented the various contributions on the subject of "sustainability" to a leading OM journal and identify three groups of interventions:

- Green product and process development *i.e.* the design and development of products and processes that achieve high standards of environmental performance such as reduced energy consumption, ease of recycling and so on.
- Lean and green operations management *i.e.* the planning and control of processes to minimize materials and energy consumption, to address legal constraints and so on.
- Remanufacturing and closed loop supply chains *i.e.* the design of the complete forward and reverse supply chain to address environmental and other sustainability objectives through appropriate recycling and remanufacture.

They define sustainable operations management as "the set of skills and concepts that allow a

company to structure and manage its business processes to obtain competitive return on its capital assets without sacrificing the legitimate needs of internal and external stakeholders and with due regard for the impact of its operations on people and the environment" p. 489 of [50]. The authors note that to date the "people" part of this definition is largely absent from research and recommend that classical models of operations systems are revisited in order to integrate this element.

Sroufe *et al*., identify three sets of "environmental management practices" [52]:

- operational: day to day decisions and practices typically involving shop floor personnel,
- tactical: involving medium term deployment of resources and middle management, such as product design,
- strategic: long-term issues, involving top management decisions about how the firm creates value.

All of these are needed for successful environmental management in the firm as a whole, and many decisions, the authors note, span more than one level.

None of these frameworks sets out the full sustainability agenda for operations management, however. It is timely to identify just how current operations management theory and practice needs to change in order to embrace the full spectrum of sustainability concerns and thereby to enhance organizational performance in this respect. To this end, the requirements of "sustainable operations management" are now discussed in terms of the traditional categories of operations management activities and decision areas as shown in Figure 53.6.

Each of the four elements in Figure 53.6 is significantly implicated by the expanded scope of operations management that the "total product system" or "closed-loop supply chain" perspective demands.

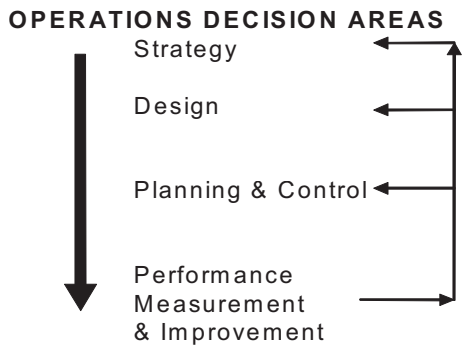

Figure 53.6. Operations management decision areas

53.4.1 Operations Strategy

Operations strategy has been defined as the "major decisions about, and strategic management of: core competencies, capabilities and processes; technologies; resources; and key tactical activities necessary in any supply network, in order to create and deliver products or services and the value demanded by a customer".

The strategic role involves blending these various "building blocks" into one or more unique, organization-specific, strategic architectures [53]. As an example, in order to deliver its overall business strategy of providing low cost stylish furniture to young people and families, furniture retailer IKEA designs and operates a "strategic architecture" consisting of, *inter alia*, the use of innovative designers, and manufacturing and retail systems that expect the customer to do a lot of the work (in-store self-service and home assembly).

Clearly an organization's uniquely designed "strategic architecture" can include provision to meet sustainability objectives. If the organization's overall business strategy includes sustainability then operations strategy, as the means by which business strategy is delivered, must reflect this. Effective sustainable operations management could become a core competence of the organization, and as such a driver of business strategy rather than merely the vehicle for its implementation [50, 54, 55].

Development of a "sustainable operations strategy" requires attention to the following:

- new business models,
- the expanded scope of the operation as a "total product system",
- the legal and regulatory regime,
- new performance objectives and indicators,
- the sustainability issues arising from each of the strategic decision areas.

Each of these is now discussed in turn.

New Business Models and Strategies

Re-appraisal of the entire value system, based on consideration of stakeholder value to be delivered, may identify new business opportunities requiring new business and operations strategies. These might include:

- The need to develop new markets for recycled material or products. This is often a very substantial practical barrier to recycling in practice [56].
- "Disintermediation": the elimination of entire processes so as to supply more directly to the end customer. This is the basis of so-called direct business models typified by the low cost airlines such as EasyJet, and insurance companies such as DirectLine.
- "Servicization": the provision of a service-based product to replace a goods-based product to fulfil a customer need, sometimes referred to as a "product-service system" [57–60]. A simple example is the leasing of fleet cars instead of their purchase. In the chemical industry a service based approach allows suppliers and customers to enter into a mutually beneficial partnership to reduce chemicals consumption [61]. In business markets there is an increasing trend towards leasing and "installed base" management [50, 62].

These models may not all have environmental protection as a key aim but potentially deliver environmental benefits, reduced costs and improved customer service simultaneously.

Geyer and Jackson [38] offer a model to aid identification and selection of new "supply loop strategies". They suggest that the priorities should be those strategies that simultaneously create both environmental and product value when compared to the primary supply chain. It is important to recognize that the results of any such analysis will change over time as a consequence of changing legislative and economic incentives and even changing perceptions of environmental hazard. What seems unattractive today may look very different tomorrow. Recognition of the dynamic nature of opportunities and strategies to address them is therefore important for managers.

The Expanded Scope of the Operation

The scope of the "operation" itself must be expanded to embrace the entire closed loop supply chain [63]. This means at the very least including additional processes, in particular:

- Processes associated with the reverse supply chain, *i.e.*, product take-back processes (including collection from the customer and distribution to waste disposal or recycling stages via appropriate "warehousing" and sorting facilities); remanufacturing and/or recycling processes; waste handling, treatment and disposal processes.
- Stakeholder engagement processes.

These are discussed in more detail under "operations design" later. Not all of these processes need necessarily be internal to the organization, but they must be considered as part of the extended supply chain. It is important that the operation is considered as an entire system so that its overall sustainability performance is optimized.

Meeting Legal Obligations

An important driving force of business and operations strategy is the political and legal environment in which the organization operates. This part of the business environment has become highly dynamic with respect to environmental and social responsibility, with ever tightening legislation to limit emissions and burgeoning initiatives to provide economic incentives for organizations (and individuals) to protect the

environment. Recent examples from the European Union include making producers responsible for the recycling of packaging, end of life vehicles and waste electronic and electrical equipment. A close watching brief is therefore required so as to be able to anticipate, and respond swiftly and appropriately to, the changing regulatory regime [3]. National regulatory regimes and infrastructures are important external drivers of operations strategy. For example, a comparison of the US and Germany found that the German provision of product take-back infrastructure reduced uncertainty and allowed firms to invest in related technology and processes, whereas in the US with no equivalent infrastructure, firms invested differently, with the objective of achieving greater manufacturing flexibility [64].

New Performance Objectives and Indicators

Conventional operations performance objectives [10] comprise cost, quality, speed, flexibility, reliability. "Sustainability" might form a sixth group, to be defined in detail to suit the needs of the individual organization but embracing environmental, and social objectives, addressing issues such as those listed earlier. Alternatively, it might be argued that at least some aspects of sustainability could be integrated into the "quality" objective, although it is harder to see how social responsibility objectives could be fitted into the existing framework. Other frameworks, such as the "balanced scorecard" approach [65] could similarly be modified to incorporate sustainability [66]. Neely's "performance prism" is unique in explicitly identifying stakeholder interests as a precursor to design of a performance measurement system [67].

Guidance on the choice of environmental performance indicators has been given in ISO 14031 [68]. Three types of indicator are likely to be needed

1) Environmental condition indicators: to reflect the state of the physical environment affected by the organization's activities.
2) Operational performance indicators: to reflect the performance of internal operations with respect to emissions and waste production, waste and energy consumed, and so on.
3) Management performance indicators: to cover aspects of environmental management such as the number of staff trained.

Hervani *et al*. [66] have interpreted this guidance for the performance measurement of "green supply chains". The GRI guidelines [25] also contain guidance on indicators to cover the various aspects of sustainability.

Sustainability Issues in the Strategic Decision Areas

The decision areas comprising "operations strategy" can be divided into two categories, structural (long-term "fixed" features) and infrastructural (more tactical in nature), each with a variety of possible sustainability implications [69] as listed in Table 53.3.

Table 53.3. Structural and infrastructural decision areas and related sustainability issues

Structural operating issues	**Examples of sustainability management issues**
Facilities	Location of facilities close to recycling plant and/or close to markets reduces the requirement for packaging and transportation [70]. Location of facilities in developing countries gives rise to ethical issues such as fairness of wage rates, child labor, and choices as to whether to comply only with local environmental regulation or the higher standards of the home country.
Process technology	Technology investment decisions can favour "sustainable" clean technologies to provide future competitive advantage [50]. Process innovation will be driven by increasingly demanding regulations requiring, for example, reduced emissions and/or more recycling.

Table 53.3 Continued

Structural operating issues	Examples of sustainability management issues
	Energy efficient technologies and those that cut down material waste have the twin benefits of saving direct operating costs as well as enhanced environmental performance.
Capacity	Environmental protection regulations may limit capacity (to limit emissions) unless additional controls are installed or process modifications made. Tradable permits may have a similar effect. Capacity to recycle is likely to become increasingly important as regulations become increasingly stringent regarding the percentage of materials to be recycled.
Vertical integration	The closed loop supply chain demands re-consideration of outsourcing or vertical integration options for supply chain configuration. Outsourcing gives rise to ethical issues in relation to treatment of supply chain partners and their employee relations. Direct business models (such as online insurance or travel booking services) cut out many of the intermediary stages between supplier and end consumer thereby saving a variety of energy and materials resources.
Infrastructural operating issues	
Suppliers	Environmental standards require "green purchasing" policies involving additional criteria to be applied in the selection of suppliers. For example car manufacturers such as Ford and Vauxhall require all their suppliers to carry ISO14001 registration and are proactive in helping suppliers achieve this. Companies are increasingly pooling resources on suppliers in order to protect themselves form poor practices further up the supply chain [71]. "Fairtrade" criteria are also relevant.

Table 53.3 Continued

Structural operating issues	Examples of sustainability management issues
New products	Life cycle thinking must be applied to product design. There may be scope for innovative "product-service systems" to reduce overall impact.
Workforce	Direct involvement of the workforce is essential for effective sustainability management. Organizational culture, and appropriate performance measurement systems play important roles.
Quality and improvement management	Environmental management systems use the same basic continuous improvement "plan, do, check, act" framework as quality management systems and many organizations seek to integrate them to reduce management system overheads. Sustainability objectives should be integrated with others in an overall performance management framework. Risk assessment techniques can play a role in deciding the priority issues for improvement. Deployment of "lean" operations strategies should lead to more resource efficiency and thereby support environmental sustainability, although research indicates that the linkage between "lean" and "green" is rather complex and a lean production strategy does not address all elements of, emissions reduction, for example [72].
Planning and control systems	Conventional planning and control techniques and systems do not embrace sustainability objectives, but in principle MRP, ERP, capacity planning tools and so on could be modified so to do.

Voluntary Standards and Integrated Performance Management Systems

Many organizations see benefits in the integration of management systems, that is incorporating the

requirements of standards such as quality management, ISO 9001 [73], health and safety management, BS8800 [74] and environmental management, ISO 14001 [75] or EMAS [76] in one overall performance management system covering all relevant performance objectives [77]. There are many common features and principles underlying these standards (such as employee involvement and continuous improvement) and the ISO standards explicitly identify particular linkages. Integration of management systems could deliver more effective implementation of individual aspects and reduce the management overhead of administering separate systems [78]. Inclusion of the requirements of sustainability management will extend such integrated systems even further, see the list of standards in Section 53.2. The case study of BMW Designworks in the following box illustrates one organization's approach.

Case Study: A New Sustainability Management System in the BMW Group [81]

BMW has a long-established tradition of environmental management. All its manufacturing facilities are certified to ISO 14001 and it has also sought to improve the environmental performance of its business partners and its non-production facilities. The company turned its attention to sustainability management in 1999 and chose Designworks/USA as a pilot site. The challenge was both to develop and to implement a sustainability management system (SMS) based on the ISO 14001 framework.

Designworks/USA, a provider of design and engineering services to the rest of the BMW group as well as to external clients in a variety of industries, was selected for the pilot because of the influence that design has over many sustainability issues and because it was perceived that designers would bring creative flair to bear on the task of developing and implementing the SMS. At the start of the initiative Dreamworks/USA had no comprehensive approach to managing its environmental and social aspects. External consultants and a member of the BMW staff familiar with their environmental management system took the lead in producing an internal standard "A Sustainability Management System Guidance" which required Dreamworks/USA to develop procedures to:

- Identify and prioritize sustainability aspects and impacts.
- Identify legal requirements related to sustainability concepts and to evaluate compliance.
- Identify legal requirements related to sustainability concepts and to evaluate compliance.
- Develop sustainability objectives and targets within each organizational function.
- Identify and deploy education and training to ensure awareness and competence.
- Regularly interact with stakeholders including regulators and the public.
- Routinely audit the organization's management system against the requirements stipulated in the SMS standard.
- Ensure that top management periodically reviews the SMS.

A form of risk assessment was used to prioritize the various sustainability aspects. This was based on seven dimensions of: probability of occurrence, intensity, duration, legal and regulatory requirements, stakeholder concerns, leadership potential, and level of control.

Benefits of the SMS have so far (only two years into the implementation process) included procedures for supplier selection and partnerships, shared commitment with some clients to sustainability, and improved internal human resource management policies and practices. A particularly notable outcome is a focus on the long term vision of the company. To date little attention has been given to results metrics, making it difficult to assess costs and benefits.

Particular challenges of implementation have included:

- Involving suppliers in the vision.
- Influencing clients to incorporate sustainability attributes into product design specifications.
- Developing the knowledge of design staff with respect to sustainability in a harsh commercial climate where all employees must account for every minute of the working day.
- The perceived conflict between the creative design culture of the organization on the one hand and the management system demands of rigorous systematic evaluation, documentation and control on the other.
- The perceived conflict between the creative design culture of the organization on the one hand and the management system demands of rigorous systematic evaluation, documentation and control on the other.
- The systematic integration of social issues into the design process.

The strategic significance of performance management systems is twofold: first, a strategic approach is needed to implement them successfully [79, 80]; and second they are the means of delivery of the competitive advantage that sustainability strategies (or indeed any other) can provide in terms of both what they achieve and what they represent in the eyes of customers and other stakeholders. The reporting requirements of standards are an important element: the transparency and credibility of good sustainability reporting is a significant public relations tool with respect to customers and regulators.

53.4.2 Operations Design

Operations design is concerned with both product and process design and their interactions. Sustainable operations design takes account of the entire product life cycle.

The sequence of design decisions needs to be as follows:

1) Analysis of the value system and determination of the *stakeholder value elements* that need to be delivered – an extension of the "product concept" idea that normally forms the basis of operations design decisions [10].
2) Design of the package of component goods and services that provides these benefits.
3) Determination and design of the *processes* needed to deliver the package, including the reverse as well as the forward supply chain.

Sustainable operations design requires particular attention to the following:

- Taking a "product-service system" perspective.
- Product and process design to optimize life cycle performance.
- Integration of the reverse supply chain.
- Development of relevant stakeholder engagement processes.
- Integration of financial and environmental costs.
- Application of risk assessment techniques.

A "Product-Service System" Perspective

The product designer must design an integrated bundle of goods and services, not just the goods element (the Volvo case study in the following box illustrates this). It is the total package that delivers the required value, the performance, to customers and all other stakeholders.

Case Study: Volvo's Alternative Fueled Vehicles [111]
As part of the Volvo Car Corporation's comprehensive approach to sustainability management, it has worked as a partner in a Swedish initiative to develop the market for alternative fueled vehicles. Such an approach recognizes that designing and producing the more sustainable product is far from enough to ensure significant market penetration, a viable business proposition and indeed significant contribution to "sustainable transport" overall. Other processes must also be put in place, such as

provision of financial incentives for consumers, fueling and service infrastructure and appropriate training for sales staff. The following extract from Volvo's Sustainability Report illustrates the wide scope of activities that are involved in ensuring that a more sustainable product is commercially successful.

1. The Offer	
Develop alternative fuel cars	*Volvo Cars has a broad offer of alternative vehicles in Sweden. in fact, of the eight car models currently in production, four of the models can be ordered with a Bi-Fuel (biomethane/natural gas engine) or FlexiFuel (powered on ethanol) engine.*
2 Government Actions and Incentives	
Swedish National Government	*No tax on renewable fuels like biogas*
	Vehicle taxation based on CO_2
	Reduction on the taxable value of alternative fuel company cars
	From 2006, major fuelling stations above a certain size must provide renewable fuel
	Governmental procurement Swedish municipal authorities
	Free parking in many towns
	No road tolls/congestion charges in Stockholm
	Preferential taxi zones
	Rebates on additional costs
	Free electricity for electric vehicles
3. Infrastructure	
Fuelling options	*Gas consists of a combination of biogas (biomethane) produced locally from organic waste and non-renewable natural gas formed in the earth's crust. E85 is produced from sugar cane or other crops. Currently, there are 62 biogas fuelling stations and approximately 350 E85 fuelling stations throughout the country*
Dealerships as fuelleling stations	*Increased availability and appeal of alternative fuel vehicles prompted some Volvo dealerships to establish CNG/biomethane fuelling stations.*
Encouraging infrastructure through partnerships	*Biogas Cities is a partnership to encourage investment in the biomethane fuel and vehicle market.*
4. Sales and Marketing	
Educating about alternative fuel cars	*Training for sales people emphasised how to sell alternative fuel cars by focusing on the customer benefits.*
Developing sales tools	*Sales tools like the web-based price comparison were developed to counteract increased competition on the environmental market. The environmental impact of different Volvo models can also be compared on our website.*

At the strategic level this might lead to entirely new business models, as discussed earlier. At the design level, the features included in the tangible part of the product offering will determine to some extent the nature of the services required. For example, maintenance intervals will be determined by technical specifications of goods and components; or the customer's need for training and service support will be determined by how user-friendly the product is perceived to be.

Marketers have long understood the need for an integrated approach, models such as the "augmented product model" [82–84] and the "augmented service offering" [85] provide guidance on the identification of all the relevant service processes that might need to be incorporated into a "product-service system".

Product and Process Design to Optimize Life Cycle Performance

Design of products to optimize the overall product performance with respect to environmental impact based on life cycle analysis and life cycle thinking

is known as "eco-design" [86–89]. The early stages of product development, where the product concept itself is devised, is recognized as particularly important for sustainability – incremental changes to existing products can only offer limited benefits. The concept of eco-design is being extended to embrace the social aspects of sustainability and the term "sustainable product design" is sometimes used to make the distinction [90].

Product and process design interact; in the case of services, of course, the process *is* the product, but in other cases too, the product specification determines the processes that must be operated. Eco-design principles might be considered to embrace process design to some extent, but the focus is almost exclusively on tangible products rather than on the manufacturing processes that produce them or on associated service processes. Eco-design of services is a relatively neglected field in the research literature.

The main elements that process designers can manipulate and some of the principal impacts on sustainability are as follows.

- *Physical layout and flow* impacts on resource efficiency; perhaps some process stages can be eliminated entirely reducing energy and materials consumption. The impact on working conditions and employee satisfaction must also be considered.
- *Supply network design:* industrial ecology principles might be applied. Socially responsible supply chain design takes account of risks that might arise from operating where human rights issues are a concern, for example [91, 92]. Design also needs to address partnership management issues because cooperation among supply chain partners is such a critical element of sustainability management [93].
- *Process technology* can impact on resource efficiency either by offering intrinsically cleaner production routes or by providing the means of better process control.
- *People:* both customers and employees may be integral elements of operations. Both need to have the motivation, knowledge and skills to make the necessary input. Education, training and communication processes are therefore of vital importance, as well as the more obvious job and service design concerns. The environmental and social impacts of different modes of working also need to be considered.

Sustainable operations design must be an integrative process, seeking to manipulate many variables and to resolve many apparent conflicts among the large number of performance criteria to be met. Proposals to simplify the approach are legion – see, for example, [94] and [95] – and in the absence of any established universal methodology many organizations devise their own, focusing on the priority issues for their particular situation. Sustainability adds in an entirely new set of difficult trade-off dilemmas (whereby achievement of one performance objective is only possible at the expense of another) that seem particularly intractable because of the impossibility in some cases of deciding which the most sustainable approach is. Subjective appraisal of the context of the decision and its consequences must be integrated with analysis of the detail of the design options. Whatever the approaches chosen, sustainable product/process design needs to manage trade-offs in a systematic way; first, to identify the trade-offs that exist and second, to support the decision in the trade-off situation [96]. Evaluation techniques based on risk assessment (discussed later) are a probable way forward.

Integration of the Reverse Supply Chain

The reverse supply chain involves the following key business processes [41]:

- Product acquisition: retrieval of the product from the market including any commercial transaction involved as well as physical collection.
- Reverse logistics: transportation to the recovery location.

- Testing and inspection: to determine the sorting and recovery options.
- Sorting and disposition: sorting is on the basis of quality and composition to determine the route of the rest of the reverse supply chain.
- Recovery: reconditioning and regaining products, components and materials.
- Re-distribution and sales of the regained products may coincide with the forward supply chain or may require new channels and markets to be developed.

The actual operating processes needed depend on the nature of the returned material, of which there are four main types [41]:

- End-of-life returns: taken back from the market to avoid environmental damage arising from waste items and materials, *e.g.*, collective recycling systems operated for batteries and tyres.
- End-of-use returns: after a period of operation; can be remanufactured or traded in second hand markets.
- Commercial returns: returned little-used or unused, *e.g.*, surplus stock; product recalls
- Re-usable items: such as pallets, refillable cartridges, bottles.

Recovery options for manufactured goods are listed in Table 53.4.

Consideration of recovery option needs to be included at the product design stage so as to maximize the opportunities for ready recovery of high value parts [98]. The economic/business aspects of the supply loop and its constituent processes must be considered as well as the technical issues, as was illustrated by the earlier steel section case study. Several different product recovery strategies have been identified in the computer industry [99]. For example, Dell uses a vertically integrated approach with its own recycling facility, while Hewlett Packard has established a joint venture to set up a recycling operation.

Table 53.4. Recovery options (adapted from [97])

Options	Operations	Output
Direct reuse	Inspection and testing to determine any damage Cleaning	As original product
Repair	Testing/inspection Restore product to working order; component replacement or repair	As original product
Refurbishing	Testing/inspection Upgrading, replacement or repair of critical modules	As original product
Remanufacturing	Manufacture new products partly from old components	New product
Cannibalization	Selective retrieval of components	Some reusable components/ parts; others to be scrapped
Scrap	Shred, sort, recycle and dispose of	Materials and residual waste

Stakeholder Engagement Processes

Sustainability management requires "engagement" or dialog with all relevant stakeholder groups. From the operations perspective, how can "stakeholder value" be delivered by an operation if there is not a clear understanding of just what aspects of value those stakeholders expect? From the stakeholders' perspective, how can they assess the operation's performance and capability to meet their needs without relevant and timely information? Not all the organization's stakeholders may be appropriate targets for dialogue with the operations function, but many will be. For example, discussion with employees about working practices, with supply chain partners about their local human rights issues, with regulators about interpretation of legal obligations,

with local communities about the local impacts of operational activities such as transportation, should or could all involve operations managers. Identification of relevant stakeholder groups is therefore an essential first step; stakeholder mapping is a useful technique to this end [36, 100].

Reporting to stakeholders is one half of the necessary dialogue. The GRI guidelines [25] identify the following characteristics of good reporting in this context:

- Materiality: covering topics that reflect the organization's significant economic, social and environmental impacts
- Inclusiveness: identifying the stakeholder groups whose interests are addressed by the report
- Completeness: presents an appropriate set of results that collectively address all the significant impacts so as to paint a complete picture of the organization's position
- Balance: includes both positive and negative aspects of performance
- Comparability: consistent reporting allowing comparisons over time and with any other appropriate reference points
- Accuracy: reporting should be accurate and detailed enough for stakeholders to assess performance
- Timeliness: reporting should be regular and at appropriate intervals for stakeholders to make informed decisions
- Clarity: information should be presented in a way that is accessible to the relevant stakeholder groups
- Reliability: information should be presented in such a way that it could be subject to examination.

The other half of the dialog, eliciting information from stakeholders, might involve surveys, panels, user groups and focus groups, for example, [101]. There has been criticism of the extent of true organizational commitment to engagement, with many of these activities viewed as little more than public relations exercises, resulting in little genuine organizational learning. The Accountability standard AA1000SES [102] seeks to counter this by providing a systematic framework for managing the engagement process so as to meet well-defined organizational objectives. This comprises a ten-stage process:

1. Identify stakeholders.
2. Initial identification of material issues.
3. Determine and define engagement objective and scope.
4. Establish engagement plan and period schedule.
5. Determine and define ways of engaging that work.
6. Build and strengthen capacity.
7. Understand material aspects, identify opportunities and risk.
8. Operationalize and internalize learning.
9. Measure, monitor and assess performance.
10. Assess, redefine and re-map.

Integration of Financial and Environmental Costs

Operations design must always take cost into account. Indeed seeking the least-cost process solution is often an objective in itself, although the interactions of cost with other factors, price and demand in particular, must be considered. "Value engineering" techniques [103] seek to link the cost of a component or feature to function so as to ensure that products are not "over-engineered" to meet specifications they do not need to fulfil. The linkage between resource use and cost means that many measures taken to reduce costs (such as eliminating a component or activity, or reducing the amount of material in the product) will also have a positive effect on sustainability. However traditional approaches to value engineering do not consider the entire product life cycle, and would require extension and adaptation to integrate sustainability concerns.

Environmental accounting forms a large field in its own right. It is in principle straightforward although effort and time consuming for an organization to assess its environmental costs. Four categories of environmental costs have been identified [104, 105]: waste and emission treatment; prevention and environmental management; material purchase value of wastes and emissions; processing costs of wastes and emissions. Few organizations use accounting systems that allow them to quantify these costs although a

comprehensive implementation of "lean thinking" should at least identify the material wastes generated. However, even if organizations did employ this type of information to identify ways to simultaneously reduce costs and improve resource efficiency, this would not necessarily lead them to address the most significant aspects from the sustainability perspective. First not all environmental costs are "internalized", they are "external costs" borne by national economies or by society at large. Examples include costs arising from the adverse health consequences of pollution, or governmental expenditure on flood prevention measures demanded by climate change. In principle there is no reason why an organization should not choose to assess the external costs arising from its activities and to use these in its internal decision making [106] in a form of "full cost accounting" [107]. In practice, determining the true costs of emissions, waste and so on is fraught with difficulty. Still more problematic would be any attempt to quantify the sustainability costs arising from adverse social consequences. For the foreseeable future, therefore, product and process designers must seek to integrate a variety of quantitative and qualitative factors to determine an overall optimum "sustainable" solution.

Application of Risk Assessment Techniques

Risk assessment techniques offer a way of prioritizing the various demands being made on the organization and its operations [108]. Risk assessment is an important generic tool that can be applied to all aspects of business management including sustainability management to determine those aspects of particular significance to the organization, and thereby requiring particular management attention. Indeed the Turnbull report of 1999 [109] specifically requires all companies quoted on the London Stock Exchange to ensure they have internal systems to control and manage *all* the business risks they face, arising from both internal and external factors.

The magnitude of a risk is the probability of occurrence of an event that could have harmful consequences multiplied by the severity of those consequences. Simple qualitative or quantitative scoring approaches can be used to rank options according to the risks they represent. More complex and detailed risk assessment systems are used routinely in operations management where there is a specific need such as when there is significant large scale hazard involved, as in the case of emergency planning. Environmental management uses risk assessment to identify *significant* environmental "aspects and impacts" [110].

An aspect or impact that could cause catastrophic damage to ecosystems or that could give rise to non-compliance with legal obligations would be deemed high risk to the organization and thereby deserving of priority attention.

Assessing risk almost inevitably involves some subjectivity, but it is nonetheless of paramount importance to use a consistent and systematic approach to provide transparent decision-making and to facilitate the revisiting of risk assessments and the decisions which follow from them as the factors involved change over time.

Risk assessment can take place at all levels of operations management, to inform decisions about business strategy, about product and process design as well as to determine the priorities for incremental improvements. For example, BT's annual CSR report contains a comparative assessment of all the various CSR risks it considers that it faces, including climate change, supply chain working conditions, diversity and outsourcing [19].

53.4.3 Planning and Control

Operations planning and control is concerned with matching supply and demand on a day to day basis. Decisions concern the loading of individual people, machines or work stations, the sequencing and scheduling of work, and monitoring and control, to check that what was planned was actually carried out, and to take remedial action as necessary. Conventionally it is quality, volume and timing that is planned and controlled, to ensure that what is produced matches what is demanded by customers, but for sustainable operations management additional objectives come into play. Decisions on loading, sequencing and scheduling should be taken with sustainability objectives in mind as well as product quality, cost and so on. Very often environmental and cost objectives will

coincide – energy efficiency leads to reduced energy costs – but this will not always be the case. Scheduling work to minimize noise pollution overnight, for example, may reduce process efficiency. The important thing is that the sustainability objectives are taken into account in making the day to day trade-off decisions. Often such trade-offs can be avoided completely by appropriate operations design, such as in this example the sound-proofing of machines, workstations or buildings.

Operations planning and control uses a variety of techniques [10], such as:

- MRP (materials requirements planning), MRPII (manufacturing resource planning), and ERP (enterprise resource planning).
- Capacity planning.
- Inventory management tools such as economic order quantity analysis and Pareto analysis.
- JIT (just in time) and lean management tools such as kanban control.

These tools have been developed to serve the traditional operations planning and control perspective and therefore do not currently explicitly provide for the management of environmental or other sustainability aspects. However, in some cases the underlying philosophy is already strongly linked to resource efficiency; the elimination of waste is a key principle of lean management techniques. In other cases environmental objectives can in principle be incorporated into the management frameworks relatively straightforwardly, although modified tool design and implementation is far from a trivial exercise [112]. The collection of a large amount of additional data is needed, requiring considerable change to established working practices and therefore posing a significant barrier to change.

The J Sainsbury case study in the following box illustrates the relevance of planning and control to sustainability objectives, and the trade-off decisions that are made in practice.

Case Study: J Sainsbury plc (UK Supermarket Chain)

J Sainsbury plc identifies transport as a significant source of environmental impact of its operations and recognizes the value of transporting its products more efficiently, both to reduce emissions and for the cost savings that result [113]. It therefore seeks not only to employ more efficient and alternative fueled vehicles but also to plan and control its logistics activities accordingly. For example, "*Our suppliers will ….take deliveries to our stores if they have empty vehicles on their way back to their sites",* p. 34 of [113]. However, some of the conflicts in objectives that businesses must manage are evident in the comment from the most recent environmental report, "*… we failed to meet our fuel consumption target due to nationwide reorganization of our transport network to increase product availability…".*

Buildings energy efficiency is also important and as well as making use of technology such as combined heat and power and solar panels, energy management is part of every store manager's annual targets and is an integral part of the formal "retail procedures" followed by all store staff. This is backed up by consumption information available in stores so that performance can be checked daily. However once again, the difficulty of combining sustainability with business objectives is highlighted: "*…in 2005/06 we experienced a large energy increase and a decrease in efficiency [measured by carbon dioxide emissions per square metre of floor space], primarily due to extended opening hours, night restocking to increase availability and the introduction of pharmacies in most of our stores",* p. 28 of [113].

With respect to wider sustainability objectives J Sainsbury plans and controls various of its store activities to provide high quality and responsive customer service such as managing performance against targets for checkout queuing times and time to answer telephone queries. It also has an active "colleague engagement" program aimed at ensuring staff are well-trained and motivated and monitors progress through a "colleague engagement index".

53.4.4 Improvement

Operations improvement is the systematic identification and evaluation of performance gaps (between the current and some desired future state) and the design and implementation of the means to close these gaps. It is typically proactively managed in the form of "continuous improvement", a concept that underpins both quality and environmental management methods as set out in the relevant standards and in performance management frameworks such as six sigma or the EFQM excellence model. This is therefore an aspect of operations management into which it ought to be relatively straightforward to integrate sustainability concerns. The common ground shared by these standards and systems can be summarized in terms of the following features:

- Continuous improvement cycle as the basis of the management framework (plan, do, check, act is a typical manifestation).
- Employee involvement and empowerment.
- Customer focus.
- Team working.
- Supportive organizational culture.
- Audit and analysis principles and techniques.

A strategic approach is needed, including top management commitment, the inclusion of sustainability at the level of corporate mission and vision level and the embedding of the principles and practices throughout all levels of the organization [52, 114].

An important part of managing improvement is determining the priorities. Typical conventional operations management approaches include importance–performance analysis [115] and the identification of core processes, critical success factors and key performance indicators [116]. The latter framework, being an all-embracing one, could incorporate sustainability performance objectives alongside others in a fully integrated model of the enterprise. In environmental management "significant" environmental aspects and impacts are usually determined via some form of risk assessment, as discussed earlier. Sustainability priorities can be determined in the same way.

A suitable set of performance indicators covering all aspects of operational performance, including sustainability, must be devised for effective audit, improvement, progress monitoring and reporting. [117–119]. Different organizations are likely to need different indicator sets and different targets, depending on the nature of their business and the context in which they operate. Environmental operational performance indicators should cover the following areas according to ISO 14031 [68]:

- Materials, *e.g.*, quantities (total or per unit output) used, recycled, disposed of.
- Energy, *e.g.*, energy use per unit of production output.
- Services supporting the organization's operations, *e.g.*, amount of cleaning agents used by contracted service providers.
- Physical facilities and equipment, *e.g.*, hours per year that a piece of equipment is in use; the amount of land used for a quantity of production.
- Supply and delivery, *e.g.*, fuel consumption of vehicle fleet.
- Products, *e.g.*, amount of energy consumed by use of a product.
- Services provided by the organization, *e.g.*, quantity of materials used during after-sales service of products.
- Wastes, *e.g.*, quantity of waste produced per year and/or per unit of production.
- Emissions, *e.g.*, quantity of air emissions with global warming potential; quantity of radiation released; noise measured at a particular location.

Guidance on indicators for the social aspects of sustainability (see Table 53.1) is provided in [14, 25, 51] and [120]. For example, employment practices might be assessed in terms of:

- Number of days lost due to job-related illnesses.
- Level of employee satisfaction.

- Participation in employee consultation mechanisms.
- Comparative wage levels.

Community relations might be assessed in terms of:

- Number of local jobs created.
- Number of employees participating in community programs.
- Participation in community liaison activities.

The implementation of sustainability management is itself an "improvement" for most organizations and progress with it will require review from time to time; the "sustainable development maturity matrix" given in BS 8900 is an appropriate tool [21].

The Marks and Spencer case study in the box below illustrates improvement in sustainability practices.

Case Study: Marks and Spencer (UK Food, Fashion and Home Retail Chain)

Marks and Spencer's Corporate Social Responsibility Report [121] stresses improvement throughout. Against each of the 17 sub-categories of product, people and places that its report considers it clearly states: what it set out to do in the previous year, how it actually performed in that year and the targets for the following year. An example covering just a single sub-category is given below. Note that the report includes comments on social as well as environmental benefits.

Reducing Waste from Packaging and Products

Since 1997, legislation has made retailers and other businesses responsible for the costs of recycling packaging.

We pay a levy (worked out on the basis of how much packaging we use), to help fund efforts to meet a UK recovery target which includes both recycling and other ways of reusing waste. For 2005, this target has increased from 63% to 65%. Over the next few years, this type of legislation will be extended to other products, starting with electrical goods in 2006.

What We Set Out to Do in 2004/05

Legislation

Monitor the planned implementation of European Union "takeback"/recycling legislation on batteries and electrical equipment.

Carrier Bags

Work with potential suppliers of sustainable plastic carrier bags to improve the version trialled.

Food Packaging

Develop an action plan to improve the environmental performance of food packaging.

Food Labelling

Phase-in new labelling policies on food products supported by training for suppliers and independent checking. Monitor customer feedback and changes to legislation.

How We Did in 2004/05

Legislation

We monitored the development of the British Retail Consortium's proposals for funding the collection and recycling of used electrical equipment for introduction in 2006. We appointed external specialists to manage our UK and Republic of Ireland packaging waste compliance.

Food Packaging

We developed a "Responsible Food Packaging" initiative which includes requirements to: reduce packaging; move towards more natural materials; use more recycled materials; and promote easy to open designs and tamper proofing. As a direct result of this we conducted trials on repackaging sandwiches in cardboard instead of plastic and using light-weight foamed

plastic trays for pre-prepared meals. We developed an easy-to-open salad bowl in consultation with "Help the Aged". We also extended the use of tamper-evident packaging wherever practical. In January 2005 we launched a sixmonth trial to use recycled plastic in the manufacture of a range of bottles and trays in partnership with the following organisations: Waste Resources Action Programme (WRAP), Closed Loop London and London Remade. In March 2005 we held a packaging workshop with our largest food supplier sponsored by WRAP which resulted in several possible projects to reduce packaging being identified.

Carrier Bags

We did not progress with the sustainable plastic carrier bag due to difficulties in making the naturally based polythene strong enough

In Addition We Have…

We continued to operate a programme that reuses or recycles around 50 million clothing hangers a year. We started a project to reduce the number of clothing hanger designs we use to reduce the costs of the hangers and improve recycling rates.

What We Aim to Do in 2005/06

Legislation

Monitor and ensure compliance with the UK implementation of legislation (Waste Electrical and Electronic Equipment Directive) covering the recycling of used electrical products in 2006.

Food Packaging

Continue to implement "Responsible Food Packaging" initiative including measures to:

- *Introduce biodegradable plastic packaging made from starch for fruit, vegetables and salads from April 2005.*
- *Replace plastic sandwich packaging with cardboard alternatives.*
- *Extend the use of light-weight foamed plastic trays to half of our pre-prepared meals saving about 50 tonnes of packaging a year.*
- *Review and improve environmental labelling of food packaging (e.g., advice on recycling).*
- *Work with Waste Resources Action Programme (WRAP) on packaging reduction initiatives.*

Clothing Packaging

Introduce a new streamlined range of clothing hangers from September 2005, supported by improved levels of reuse and recycling.

The report states "We regard CSR as a process of continuous improvement and alongside our successes we made some mistakes which we are addressing". It goes on to describe an improvement to sourcing of wood for garden furniture from sustainable sources after failing to be able to address challenges made by Greenpeace on its original claims, and improvements to waste food handling after a prosecution arising from a milk spillage incident.

53.5 Implications for Operations Management

The foregoing discussion demonstrates unequivocally that

- sustainability management needs operations management, in order for the many new and modified organizational practices essential to deliver progress towards sustainability to be appropriately designed and implemented;
- operations management needs sustainability management, in order for operations to meet the increasing demands being made by increasingly wide-ranging, vocal and influential groups of stakeholders.

There are three groups of implications arising from this.

1) The nature of the operations management discipline and function must *expand* to address the various sustainability issue adequately. This has been referred to as the "expanding horizon of operations management" [63]. While this is consistent with the importance in general of inter-functional and inter-disciplinary interfaces to the practice and theory of operations management [122], it adds considerably to the complexity of the operation.
2) The nature of the operations management function and role in organizations must not just expand to encompass the additional concerns, it must *change* in order to cope with the complexity of the expanded function. Emphasis should be placed how to design, implement and demonstrate integrative solutions that address multiple performance criteria effectively. This is likely to need confidence with the design and introduction of innovative solutions as well as competence with incremental continuous improvement approaches. Substantive development of new knowledge, skills and capabilities is required. For example, Gloet has identified the following four sets of management capabilities that must be built to support sustainability management [123].
   i. The following roles must be fulfilled: capacity to work across myriad interfaces; leadership – to articulate the vision of sustainability and social responsibility and the positive impact on the organization; change management
   ii. Effective relationship management is critical, for effective collaboration and communication across various boundaries.
   iii. Adoption of a strategic focus is necessary, for the development of sustainable business models, alignment of business and sustainability goals, and the ability to implement strategy throughout all levels of the organization.
   iv. A learning focus and systems thinking are essential to cope with the dynamic and complex nature of sustainability management.

   Professional development programs should be developed and offered accordingly.
3) There is a need for practical tools to assist the operations manager with this expanded and more complex role. Sustainability management is inherently problematic because of its large scope, the diverse nature of performance indicators, the need for value judgments and its relative newness in the business and operations management arena. Sustainable development is rooted in relatively abstract concepts requiring subjective assessment, an approach at odds with the more "scientific" analytical approach with which most operations managers are comfortable. It is therefore essential for researchers and practitioners to work in concert to develop appropriate tools to help organizations make concrete progress towards sustainability.

53.6 Conclusions

The relevance of sustainability issues to operations management is clear, yet to date, few operations managers would identify sustainability management as a key part of their remit. However, as sustainability objectives become more crucial for organizations for a whole raft of reasons, it is the operations function that must respond. Operations is, after all, the vehicle by which business strategy is implemented, and perhaps even more importantly, it is the main agent responsible for so many sustainability impacts. If the operations response is to be positive and effective then considerable change is needed on the following fronts. First, an appropriately wide systems view of the operation must be taken to allow all environmental and social impacts to be properly "managed" within the overall system. Second, it is imperative that there is integration of sustainability objectives at all levels of operations management so that the issues can be addressed at the appropriate level (strategy, design, *etc.*). Third, there is a need for appropriate professional development of operations managers to support these changes, and for additional research to

provide managers with practicable tools and techniques.

While environmental management systems are relatively well-developed and ripe for integration with operations management systems, the broader concept of sustainability management is as yet by contrast in its infancy, and its integration poses significant organizational challenges. Nevertheless it is essential that this nettle is grasped if industries and nations are to make real progress towards sustainability goals.

Indicators for Assessing Sustainability Performance

P. Zhou and B.W. Ang

Department of Industrial and Systems Engineering, National University of Singapore, Singapore

Abstract: Sustainability is a universally advocated and quoted concept. To assess the sustainability performance of an entity, *e.g,.* a company, an industry or a country, appropriate indicators are often developed for the use of analysts and decision makers. Numerous sustainability indicators can be found in the literature, which vary from a non-composite indicators to composite indicators. We first deal with non-composite indicators for sustainability. We then introduce the concept of composite indicators and discuss why they are more suitable for assessing sustainability. From the viewpoint of operations research, we describe the methods for constructing composite sustainability indicators and highlight the usefulness of multiple criteria decision analysis and data envelopment analysis. An illustrative example is presented for assessing alternative methods in constructing composite sustainability indicators.

54.1 Introduction

Sustainable development has increasingly been incorporated into different levels of society, *e.g.*, companies, industries, and countries. According to the definition given by the Brundtland Commission [57], sustainable development implies that development should "meet the needs of the present without compromising the ability of future generations to meet their own needs". The concept is easy to understand but there are many practical issues among which the assessment of sustainability is a difficult but indispensable one. Different tools have been developed for assessing sustainability. The study by Ness *et al*. [36] provides an excellent categorization of various sustainability assessment tools. According to the study, the tools can be broadly divided into three main categories, namely *indicators*, *product-related assessment*, and *integrated assessment tools*. In this chapter, we shall limit our discussion to the indicator approach to assessing sustainability.

Indicators are quantitative measures that represent the state of an individual object such as a product or a complex system. The indicator approach has been widely studied for decision and policy-making in sustainability assessment [22]. Among the numerous sustainability indicators, some are micro-level based, *e.g.*, [3, 8, 23, 29, 47, 51], while others are at the macro level, *e.g.*, [19, 21, 22, 27, 28, 39, 44, 54, 60]. In addition, the indicators for sustainability can also be classified by the theme involved, such as economic, environmental/ecological, and socio-political [21].

From the methodological viewpoint, we may also classify sustainability indicators into two groups. One could be termed *non-composite*

indicators since it involves the use of an individual or a set of individual indicators. Examples include the 58 indicators for sustainability developed by the United Nations Commission on Sustainable Development [52] and the 30 energy indicators for sustainable development proposed by the International Atomic Energy Agency [24]. The other group consists of *composite indicators,* whose development has recently gained considerable attention. Examples of composite indicators are the Human Development Index of the United Nations Development Program [45] and the Environmental Sustainability Index developed by Yale, Columbia, World Economic Forum and the Joint Research Center of European Commission [13]. We shall study these two approaches to assessing sustainability and present a survey on some methods for constructing composite sustainability indicators. This is by no means a comprehensive survey of sustainability indicators but rather an assessment on some recent methodological developments in the area.

The remainder of this chapter is organized as follows. In Section 54.2 we provide an introduction to non-composite indicators. Section 54.3 presents the concept of composite indicators and highlights their uses in assessing sustainability. In Section 54.4, we present the most popular methods for constructing composite sustainability indicators from the viewpoint of operations research. In Section 54.5, we give an example to assess the methods described in Section 54.4 in constructing composite sustainability indicators. Section 54.6 concludes the chapter.

Acronyms and Notation

CO_2	Carbon Dioxide
CSIs	Composite Sustainability Indicators
DEA	Data Envelopment Analysis
EF	Ecological Footprint
EPI	Environmental Performance Index
ESI	Environmental Sustainability Index
GDP	Gross Domestic Product
GS	Genuine Savings
HDI	Human Development Index
LPI	Living Planet Index
MCDA	Multiple Criteria Decision Analysis
OECD	Organization for Economic Co-operation and Development
SAW	Simple Additive Weighting
WDI	Weighted Displaced Ideal
WP	Weighted Product
WWF	World Wildlife Foundation
I_i	The CSI of entity i
I_{ij}	The value of entity i with respect to sub-indicator j
w_j	The standardized weight for sub-indicator j
$w_j(P_{kl})$	The weight for sub-indicator j if entity k performs better than entity l in terms of the sub-indicator; otherwise it is equal to zero
$w_j(I_{kl})$	The weight for sub-indicator j if entity k is indifferent from entity l in terms of the sub-indicator; otherwise it is equal to zero
T	Production technology
$\mathbf{x}_i = (x_{i1}, \cdots, x_{iK})$	The vector of inputs for entity i, which consists of the inputs consumed in a production process, *e.g.*, material and labor
$\mathbf{y}_i = (y_{i1}, \cdots, y_{iL})$	The vector of desirable outputs for entity i, which consists of the desirable outputs generated from a production process, *e.g.*, electricity
$\mathbf{u}_i = (u_{i1}, \cdots, u_{iS})$	The vector of undesirable outputs for entity i, which consists of the undesirable outputs generated from a production process, *e.g.*, pollutants
REI	Radial environmental performance index, *i.e.*, the optimum objective value of model (54.6)
$SBEI$	Slacks-based environmental index derived from model (54.8)
gI_i	The aggregated performance score of entity i from model (54.9)
bI_i	The aggregated performance score of entity i from model (54.10)

α A control parameter not less than 0 and not larger than 1

$I_i(\alpha)$ The CSI given by the MCDA-DEA approach with parameter α

54.2 Non-composite Indicators for Sustainability

Non-composite indicators for sustainability refer to an individual or a set of individual indicators for assessing sustainability. They can be broadly classified into two types. The first consists of a set of indicators, which are usually built upon certain important aspects of sustainable development. For example, the International Atomic Energy Agency [24] provides an excellent paradigm by carefully selecting a total of 30 energy indicators for sustainable development. These indicators are classified into social, economic and environment dimensions which are further classified into seven themes and 19 sub-themes. Among these 30 indicators, each can be used to assess a particular issue relevant to sustainable development. Since the IAEA study, the use of energy indicators for assessing sustainable development has gained much attention, *e.g.*, [27]. A set of individual indicators has the ability of covering different aspects of sustainability, and therefore provides detailed insights towards sustainable development. Nevertheless, a set of indicators is usually complex and difficult to interpret due to their large size [27]. As a result, the approach is not able to provide a concise overview of sustainability for the use of decision and policy making.

The second type of non-composite indicators consists of those which use a single measure to represent multiple aspects of sustainability. Since this type of indicators often integrates multiple aspects of sustainability by a common unit such as dollar, they may be termed an integrated index. Ang [2] recently proposed such an integrated index for monitoring energy efficiency trends. Two other well-known integrated indexes for sustainability are the genuine savings (GS) developed by World Bank [56] and the ecological footprint (EF) proposed by Wackernagel and Rees [55].

GS measures the true rate of savings in an economy after taking into account investments in human capital, depletion of natural resources and damage caused by pollution. Since GS is derived from standard national accounting measures of gross national savings by incorporating several environmental indicators, it could be treated as an effective proxy for tracking sustainable development [38]. EF is defined as "the amount of land and water area a human population would hypothetically need to provide the resources that the population consumes and to absorb the wastes that the population produces". It has been widely used as an indicator for modeling environmental sustainability, which can be used to explore the sustainability of individual lifestyles, organizations, industry sectors, regions and nations. An integrated index such as GS and EF provides an aggregated picture of the state of a system. A major feature is that it takes into account many aspects of sustainability using a common measurable unit. However, in practice it may not be easy to represent all the aspects of sustainability using the same unit. This problem, however, can be overcome by using the approach of composite indicators.

54.3 Composite Indicators for Sustainability

According to the OECD Glossary of Statistical Terms (http://stats.oecd.org/glossary), a composite indicator is formed when individual indicators are compiled into a single index on the basis of an underlying model of the multi-dimensional concept that is being measured. Technically, it is a mathematical aggregation of a set of individual indicators that measure multi-dimensional concepts but usually have no common units of measurement [35]. The approach of composite indicators has its pros and cons. Table 54.1 shows some major ones as discussed in [35] and [46].

Table 54.1. Pros and cons of composite indicators

Pros	Cons
– Can summarize complex or multi-dimensional issues for supporting decision/policy makers – Can provide a big picture which is easier to interpret than trying to find a trend in many separate indicators – Can offer a rounded assessment of countries' or regions performance – Can reduce the size of a set of indicators or include more information within the existing size limit – Can facilitate communication with general public, *e.g.* citizens and media	– May send misleading, non-robust policy messages if a composite indicator is poorly constructed – May invite politicians or stakeholders to draw simplistic policy conclusions – May involve stages where judgmental decisions have to be made – May disguise serious failings in some dimensions and increase the difficulty of identifying proper remedial action – May lead to inappropriate policies if dimensions of performance that are difficult to measure are ignored

Composite indicators have been increasingly applied for performance monitoring, benchmarking, policy analysis and public communication in wide range of sectors including economy, environment and society by many national and international organizations. Their popularity has been pointed out by Saisana *et al*. [46] as the temptation of stakeholders and practitioners to summarize complex and sometime elusive process (*e.g.*, sustainability) into a single figure to benchmark country performance for policy consumption. Three well-known composite indicators relevant to sustainable development are described below, namely the

(a) living planet index,
(b) environmental performance/sustainability indexes, and
(c) the human development index.

The living planet index (LPI) was first released in 1998 and has been updated periodically by the World Wildlife Foundation (WWF) [58] for measuring the overall state of the Earth's natural ecosystems, which includes national and global data on human pressures on natural ecosystems arising from the consumption of natural resources and the effects of pollution. It is derived from three sub-indicators that track trends in approximately 3,000 populations of more than 1,000 vertebrate species living in terrestrial, freshwater and maritime ecosystems around the world. The LPI together with EF published by the WWF provide vital information for gauging the world's progress towards sustainable development.

The environmental performance/sustainability indexes (EPI/ESI) were initiated by the World Economic Forum (WEF) in 2002 for measuring environmental protection results at the national scale. Two versions of EPI have been published so far and the latest, the 2006 EPI [14], is based on 16 sub-indicators falling into six well-established policy categories including environmental health, air quality, water resources, productive natural resources, biodiversity and habitat, and sustainable energy. The 2002 EPI includes 23 OECD countries but the 2006 EPI covers 133 countries and provides a solid foundation for assessing the progress of these countries towards sustainability. Compared to the EPI, the ESI combines more sub-indicators in a broader range and therefore provides a bigger picture for measuring long-term environmental prospects [13]. The 2005 ESI covers 146 countries and involves 76 underlying sub-indicators.

The human development index (HDI) was introduced by the United Nations Development Program in 1990, which was later published annually in the Human Development Report [45]. The HDI was constructed based on three sub-indicators that reflected three major dimensions of human development: *longevity*, *knowledge*, and *standard of living*. It offers an alternative to national income as a summary measure of human well-being. The latest version of HDI can be found in the Human Development Report 2005 [53], which covers 175 UN member countries.

Besides the above three composite indicators, there are several others which are listed in the information sever: http://farmweb.jrc.cec.eu.int/ci/ maintained by the Joint Research Center of European Commission. Considering the popularity of composite indicators and the complexity of sustainability, it is expected that composite indicators will increasingly be used to measure and evaluate sustainability. Hereafter, we call the composite indicators for sustainability as *composite sustainability indicators* (CSIs).

54.4 Recent Methodological Developments in Constructing CSIs

Many techniques have been used to construct CSIs, *e.g.*, *life cycle assessment*, *environmental accounting approach*, *production efficiency theory* as discussed in [35, 37]. From the viewpoint of operations research, the existing aggregation techniques for constructing CSIs can be divided into two categories: the *indirect approach*, which often involves the normalization of the original sub-indicators and the weighting and aggregation of the normalized data where *multiple criteria decision analysis* (MCDA) plays an important role, and the *direct approach*, in which a CSI is directly obtained from the original sub-indicators by using data envelopment analysis (DEA) type models from the point of view of productive efficiency.

54.4.1 MCDA Methods for Constructing CSIs

Consider the case where there are *m* entities whose sustainability performance is to be evaluated based on *n* sub-indicators and these sub-indicators have no common measurable units. Let I_{ij} denote the value of entity *i* with respect to sub-indicator *j* and w_j denote the standardized weight assigned to sub-indicator *j*. The weights are often interpreted as the coefficients of importance that reflect the preference information of decision makers. Without loss of generality, we further assume that all the sub-indicators are of the benefit type which satisfy the property of *the larger the better*. The problem is to aggregate $I_{ij}\,(j=1,\cdots,n)$ into a CSI I_i that can be used to assess the sustainability performance of entity *i*:

$$\begin{bmatrix} I_{11} & I_{12} & \cdots & I_{1n} \\ I_{21} & I_{22} & \cdots & I_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ I_{m1} & I_{m2} & \cdots & I_{mn} \end{bmatrix} \rightarrow \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_m \end{bmatrix}.$$

Since different sub-indicators have different measurable units, normalization procedure is often needed to give dimensionless sub-indicators. Various normalization procedures are available, *e.g.*, the *Z*-Score transformation [13] and the linear normalization [64]. Saisana *et al*. [46] have shown that the choice of normalization methods has no severe effects on the values of composite indicators derived while the choice of aggregation methods has. Hence, we shall limit our discussions to the aggregation methods for constructing CSIs in the context of MCDA. We assume that $I_{ij}\,(j=1,\cdots,n)$ are the values after normalization.

The *simple additive weighting* (SAW) method, also known as the *weighted sum* method, is a popular aggregation method for constructing CSIs. See, for examples, [13, 14, 26]. The SAW method can be formulated as

$$I_i = \sum_{j=1}^{n} w_j I_{ij} \qquad i=1,\cdots,m\,, \tag{54.1}$$

where I_i is the CSI of entity *i*. An assumption implied is that the sub-indicators are preferentially independent which may be difficult to satisfy. However, even if the assumption does not hold, the SAW method would yield extremely close approximation to the ideal value function [59]. Another problem is that the weights carry the meaning of trade-off ratios as demonstrated by Munda and Nardo [32], which is inconsistent with its meaning of importance coefficients. Despite these limitations, the SAW method has been widely applied due to its transparency and ease of understanding.

The *weighted product* (WP) method, *i.e.*, (54.2), is a MCDA method in which the system with poor performance in some attributes is penalized more

heavily [48]. It represents an in-between concept compared with the SAW method with full compensability and the non-compensatory MCDA approach [35]. Ebert and Welsch [12] have shown that the WP method would lead to a more meaningful composite indicator compared with the SAW method.

$$I_i = \prod_{j=1}^{n} (I_{ij})^{w_j} \qquad i = 1, \cdots, m \,. \tag{54.2}$$

The *weighted displaced ideal* (WDI) method is based on the concept that the best system should have the least distance from the ideal system [63]. It has been further investigated by Diaz-Balteiro and Romero [11] for constructing an appropriate sustainability index. The WDI method can be formulated as

$$I_i(p) = \left[\sum_{j=1}^{n} w_j^p I_{ij}^p \right]^{1/p} \qquad i = 1, \cdots, m \,. \tag{54.3}$$

A main advantage of the WDI method is that it allows for the nonlinearity of the aggregating function with different degree by setting $p \geq 2$. Evidently, the WDI method consists of a class of aggregating methods. If $p = 1$, the WDI method is the same as the SAW method.

In addition to the above aggregation methods, the non-compensatory MCDA approach has also been used to construct composite indicators, especially when ranking among different entities is the only consideration [32–34]. In general, two main steps are involved. In the fist step, an outranking matrix $(e_{kl})_{m \times m}$ is built based on a pair-wise comparison of different entities according to the whole set of sub-indicators using the following model:

$$e_{kl} = \sum_{j=1}^{n} (w_j(P_{kl}) + \tfrac{1}{2} w_j(I_{kl})) \quad k, l = 1, \cdots, n \,, \tag{54.4}$$

where $w_j(P_{kl})$ and $w_j(I_{kl})$ are respectively the weights of the sub-indicators presenting a preference and an indifference relation between entity *k* and entity *l*. In the second step, for each of $m!$ possible complete rankings of different entities an individual score is computed as the summation of e_{kl} over all the $\frac{m(m-1)}{2}$ pairs of entities. The ranking order with the maximum individual score is the final ranking of these entities in terms of their sustainability.

A main feature of non-compensatory MCDA approach is that it does not allow for the compensability among different sub-indicators. Therefore, it is consistent with the concept of strong sustainability [20]. The non-compensatory MCDA approach provides an explicit axiomatic system for constructing CSIs, by which the sources of technical uncertainty and imprecise assessment are reduced to the degree as small as possible [32–34]. A limitation of this approach is that it can only offer the ordinal information about the sustainability of different entities. Another limitation is that it is difficult to compute the scores for all the possible rankings when the number of entities becomes large.

As there are many MCDA aggregation methods, a problem in constructing CSIs is the choice of an appropriate method. With more emphasis given to the cardinality of composite indicators, Zhou *et al*. [64] recently developed an objective measure called the Shannon-Spearman measure for comparing alternative MCDA methods in constructing composite indicators. They found that the WP method may be the most appropriate since it could lead to the minimum information loss.

In using MCDA methods to construct CSIs, it is assumed that the weights for sub-indicators are given. In practice, it is challenging to determine such weights. A popular method for deriving the weights is the *analytical hierarchy process* (AHP), and Singh *et al*. [47] gave an illustration on how to use the AHP method to construct a CSI for the steel industry. In addition, such statistical techniques as factor analysis and principal component analysis can also offer a set of objective weights for sub-indicators for the aggregation purpose. More discussions on the comparisons of different weighting methods can be found in [35].

54.4.2 Data Envelopment Analysis Models for Constructing CSIs

Data envelopment analysis (DEA), developed by Charnes *et al*. [4], is a well established nonparametric approach used to evaluate the relative efficiency of a set of comparable entities with multiple inputs and outputs. Numerous DEA studies have so far been reported, *e.g.* [7, 15–18, 30, 40–42, 65, 67, 69]. In recent years, it has been increasingly used to construct composite indicators owing to its ability in combining multi-dimensional data into an overall index.

The use of DEA in constructing CSIs begin with the development of *environmental performance index* (EPI), which could be treated as a useful tool for assessing the environmental aspect of sustainable development. To do so, we first reconsider the relationships among various sub-indicators in a production framework. From the viewpoint of production theory, all the sub-indicators may be divided into three categories, namely *inputs, desirable outputs* and *undesirable outputs*. Their relationships can be modeled by a production technology. If we use $\mathbf{x}_i = (x_{i1}, \cdots, x_{iK})$, $\mathbf{y}_i = (y_{i1}, \cdots, y_{iL})$ and $\mathbf{u}_i = (u_{i1}, \cdots, u_{iS})$ to, respectively, denote the vectors of inputs, desirable outputs and undesirable outputs of entity i, the piecewise linear production technology given by the observed data can be modeled as:

$$\begin{aligned} T = \{(\mathbf{x},\mathbf{y},\mathbf{u}) : & \sum_{i=1}^{m} z_i x_{ik} \le x_k, k = 1, \cdots, K \\ & \sum_{i=1}^{m} z_i y_{il} \ge y_l, l = 1, \cdots, L \\ & \sum_{i=1}^{m} z_i u_{is} = u_s, s = 1, \cdots, S \\ & z_i \ge 0, i = 1, \cdots, m\} \end{aligned} \quad , \qquad (54.5)$$

In the literature, model (54.5) was coined as the environmental DEA technology which exhibits constant returns to scale [14]. More discussions on the properties and characterizations of various environmental DEA technologies can be found in [67].

Once the environmental DEA technology is specified, its incorporation with different types of efficiency measures would lead to a number of EPIs. For instance, Zaim and Taskin [62] applied the hyperbolic graph measure to construct an environmental efficiency index for comparing CO_2 emissions in OECD countries. Färe *et al*. [16] provided a formal approach to constructing an EPI by using the theory of Malmquist quantity index number. Using the idea in Färe *et al*. [16], Zaim [61] developed an aggregate pollution intensity index for measuring environmental performance of state manufacturing. More recently, Zhou *et al*. [69] proposed a non-radial DEA approach to measuring environmental performance.

Among the previous studies, the undesirable outputs orientation DEA type model (54.6) highlighted by Tyteca [49, 50], where the subscript "0" represents the entity to be evaluated, is particularly attractive. It provides an aggregated and standardized efficiency measure *REI*, *i.e.,* the optimum objective value of model (54.6), for measuring environmental performance. In addition, *REI* is the reciprocal of the Shephard input distance function used in Färe *et al*. [16] and Zaim [61]:

$$\begin{aligned} REI = \lambda^* = \min\ & \lambda \\ s.t.\ & \sum_{i=1}^{m} z_i x_{ik} \le x_{0k}, \quad k = 1, \cdots, K \\ & \sum_{i=1}^{m} z_i y_{il} \ge y_{0l}, \quad l = 1, \cdots, L \\ & \sum_{i=1}^{m} z_i u_{is} = \lambda u_{0s}, \quad s = 1, \cdots, S \\ & z_i \ge 0, \quad i = 1, \cdots, m \end{aligned} \quad , \qquad (54.6)$$

Despite its usefulness, model (54.6) has weak discriminating power in environmental performance comparisons since it use radial efficiency measure. As Zhou *et al*. [69] argued, the use of non-radial efficiency measures could improve its discriminating power by much. Nevertheless, model (54.6) as well as its extensions to non-radial cases can only model the environmental aspect of sustainability performance. This is due to the fact that these models are undesirable outputs oriented and consider only the environmental inefficiency. It is

reasonable to identify the economic inefficiencies and integrate them into *REI* to construct a CSI. Along this line, Zhou *et al*. [65] proposed the following slacks-based model for measuring economic inefficiencies after the environmental inefficiencies are eliminated:

$$\begin{aligned}\rho^* = \min\ & \frac{1-\frac{1}{K}\sum_{k=1}^{K} s_k^- / x_{0k}}{1+\frac{1}{L}\sum_{l=1}^{L} s_l^+ / x_{0l}} \\ s.t.\ & \sum_{i=1}^{m} z_i x_{ik} + s_k^- = x_{0k},\quad k=1,\cdots,K \\ & \sum_{i=1}^{m} z_i y_{il} - s_l^+ = y_{0l},\quad l=1,\cdots,L \\ & \sum_{i=1}^{m} z_i u_{is} = \lambda^* u_{0s},\quad s=1,\cdots,S \\ & z_i \geq 0,\quad i=1,\cdots,m; s_k^-, s_l^+ \geq 0\end{aligned} \tag{54.7}$$

The set of constraints on undesirable outputs in model (54.7) can guarantee that the entity evaluated has now been an efficient practitioner in the environmental aspect of sustainability. Therefore, model (54.7) can be used to evaluate the economic inefficiency of the entity evaluated by a slacks-based efficiency measure ρ^* after its pollutants are adjusted to their minimum levels. By integrating the pure environmental inefficiency and the economic inefficiency, Zhou *et al*. [65] proposed the following slacks-based environmental index:

$$SBEI = \lambda^* \times \rho^* . \tag{54.8}$$

Since *SBEI* combines environmental and economic inefficiencies, it could be treated as a composite indicator for modeling sustainability performance. A major feature of this index is that it puts environmental protection in the first position and economic development second. In addition, *SBEI* is also a standardized index because it lies in the interval (0,1] and satisfies the property "the larger the better".

Previous studies have shown that DEA models could offer an appealing framework to construct a CSI without the predetermination of weights for sub-indicators. However, since the approach is built on the production theory in economics, it requires the categorization of sub-indicators into inputs, desirable outputs and undesirable outputs. Considering the diversity of sub-indicators related to sustainable development, in some cases it may not be appropriate to treat them as inputs, desirable outputs and undesirable outputs in a unifying production framework.

54.4.3 An MCDA-DEA Approach to Constructing CSIs

As mentioned earlier, a critical issue in using MCDA aggregation methods to construct CSIs is the subjectivity in assigning weights for sub-indicators. Different weight combinations may lead to different ranking results and it is unlikely that all the entities would easily reach a consensus in determining an appropriate set of weights. In addition, it may not be easy to obtain the expert information for deriving the weights. Although previous DEA models could offer a framework for constructing a CSI without assigning the weights for sub-indicators, it still requires us to categorize sub-indicators into inputs, desirable outputs and undesirable outputs. To avoid these issues, the following model [43, 68], which combines the idea of DEA and the SAW method, can be used:

$$\begin{aligned}gI_i = \max\ & \sum_{j=1}^{n} w_{ij}^g I_{ij} \\ s.t.\ & \sum_{j=1}^{n} w_{ij}^g I_{kj} \leq 1,\quad k=1,\cdots,m . \\ & w_{ij}^g \geq 0,\ j=1,\cdots,n\end{aligned} \tag{54.9}$$

Model (54.9) provides an aggregated performance score for entity i in terms of its sustainability performance. By solving model (54.9) repeatedly for each entity, we will obtain a set of indexes $gI_1, gI_2, \cdots, gI_m$ for these entities. Note that the objective function in model (54.9) is externally similar to the SAW method. The main difference is that in model (54.9) the weights for sub-indicators are endogenous and changeable while in the SAW method they are exogenous and fixed. In essence, model (54.9) is an output maximizing multiplier DEA model with multiple outputs and constant

inputs. It should be pointed out that the approach proposed by Despotis [9, 10] to reassessing the *human development index* can be considered as an extension to model (54.9). More recently, Ramanathan [43] applied the same model to study a multi-criteria inventory classification problem.

In virtue of its DEA feature, model (54.9) can help each entity select the "best" set of weights for use. It avoids the subjectivity in determining weights and therefore provides each entity a relatively objective index for measuring sustainability. Nevertheless, if an entity has a value dominating other entities in terms of a certain sub-indicator, this entity would always obtain a score of 1 even if it has severely bad values in other more important sub-indicators. Furthermore, only model (54.9) may lead to the situation that a large number of entities have a performance score of 1 and further ranking among them becomes difficult. To address these issues, Zhou *et al*. [66] recently developed a model as follows:

$$\begin{aligned} bI_i = \min & \sum_{j=1}^{n} w_{ij}^b I_{ij} \\ s.t. & \sum_{j=1}^{n} w_{ij}^b I_{kj} \geq 1, \quad k = 1, \cdots, m . \\ & w_{ij}^b \geq 0, j = 1, \cdots, n \end{aligned} \tag{54.10}$$

Model (54.10) seeks the "worst" set of weights for each entity which are used to aggregate the sub-indicators into a performance score. Externally, model (54.10) is very similar to an input minimizing multiplier DEA model with multiple inputs and constant outputs. However, in model (54.10) all the sub-indicators are of the benefit-type and it is not appropriate to consider them as "inputs". It provides a way for further performance comparison among those incomparable entities only based on model (54.9).

The two indexes provided by models (54.9) and (54.10) are based on the weights that are most favourable and least favourable for each entity, which could only reflect partial aspects of an entity in terms of its sustainability performance. It is therefore logical and reasonable to combine them into an overall index by the following way:

$$I_i(\alpha) = \alpha \cdot \frac{gI_i - gI^-}{gI^* - gI^-} + (1-\alpha) \cdot \frac{bI_i - bI^-}{bI^* - bI^-}, \tag{54.11}$$

where $gI^* = \max\{gI_i, i = 1, \cdots, m\}$, $gI^- = \min\{gI_i, i = 1, \cdots, m\}$, $bI^* = \max\{bI_i, i = 1, \cdots, m\}$, $bI^- = \min\{bI_i, i = 1, \cdots, m\}$, and $0 \leq \alpha \leq 1$ is a control parameter. If $\alpha = 1$, $I_i(\alpha)$ is a normalized version of gI_i. If $\alpha = 0$, $I_i(\alpha)$ is a normalized version of bI_i. For other cases, $I_i(\alpha)$ is a compromise between the two indexes. If decision makers have no strong preference, $\alpha = 0.5$ would be a fairly neutral and reasonable choice.

Compared with models (54.9) and (54.10), model (54.11) provides a more encompassing CSI since it takes into account two extreme cases. It has been used to address a multi-criteria inventory classification problem in a recent study [68]. According to Zhou *et al*. [66], $I_i(\alpha)$ satisfies a number of desirable properties including the units invariant property. The units invariant property implies that it is not necessary to normalize the sub-indicators into dimensionless before aggregation.

Another desirable feature of the above procedure, *i.e.* models (54.9) –(54.11), is that they can easily incorporate some additional information about the weights for sub-indicators when they become available. In principle, this can be done by a number of methods as reviewed in [1]. Cherchye *et al*. [5, 6] and Mahlberg and Obersteiner [31] have given a few demonstrations on how to restrict the flexibility of weights. Zhou *et al*. [66] pointed out that the use of "proportion constraints" is more suitable for the current scenario because it is not difficult to have a consensus among decision makers or domain experts as to the relative importance of each sub-indicator. In addition, the "proportion constraints" type of weight restrictions has the desirable units invariant property [6].

From the above discussions we can find that models (54.9)–(54.11) offer a flexible and systematic procedure to constructing CSIs. Since the computation of $I_i(\alpha)$ integrates the ideas of MCDA and DEA, we may call the procedure

MCDA-DEA approach. The approach uses some DEA concepts while retaining the simplicity and ease of understanding of the SAW method. It simultaneously considers data weighting and aggregation in the process of constructing CSIs and avoids the procedure of data normalization.

54.5 An Illustrative Example

Consider then example where the sustainability performance of 30 OECD countries in 2002 are to be assessed based on the four sub-indicators namely, total primary energy supply, population, GDP and CO_2 emissions. Since the four sub-indicators could only reflect partial aspects of sustainability, the example is mainly used for illustration purposes rather than to provide any policy implications. The data were collected from the International Energy Agency [25] and their summary statistics can be found in [65].

We apply the group of MCDA methods (exclusive of the non-compensatory MCDA approach), the DEA models and the MCDA-DEA approach as described in Section 54.4 to compute the CSIs of the countries, respectively. The non-compensatory MCDA approach is not included because it can only give the rank indexes of the countries but will involve the computation and comparisons of scores for 30! rankings. For MCDA methods, the linear normalization procedure highlighted in [64] and equal weights ($w_1 = w_2 = w_3 = w_4 = 0.25$) setting are adopted. In the DEA models, total primary energy supply and population are taken as input, GDP as desirable output and CO2 as undesirable output. In terms of the MCDA-DAE approach, $\alpha = 0.5$ is used as the control parameter.

Table 54.2 shows the CSIs as well as the ranks of the 30 countries in the sequence of their CSI averages. It can be seen that the CSIs derived from MCDA methods are closely related, and so do those derived from DEA models. On the other hand, the CSIs based on the MCDA methods have no strong correlation with the CSIs based on the DEA models. These could be explained by the diverse intrinsic natures of MCDA and DEA. Interestingly, the CSIs from the MCDA-DEA approach have the relatively consistent correlation with the CSIs from other methods. It is likely due to the fact that the MCDA-DEA approach integrates the ideas of MCDA and DEA.

Not surprisingly, various aggregation methods could lead to different CSIs and even different rankings, which demonstrate the importance of selecting an appropriate aggregation method. In general, if it is appropriate to model sub-indicators in a production framework, DEA type models (54.6) to (54.8) are recommended since they have good theoretical foundation and can provide a CSI with higher discriminating power, *i.e.*, *SBEI*. In addition, their uses will not involve the determination of the weights for sub-indicators. Otherwise, the MCDA-DEA approach seems to be more suitable since the weights need not be predetermined. Besides, the MCDA-DEA approach can provide a flexible and encompassing index by the use of control parameter α. However, if the emphasis is on simplicity and ease of understanding, the WP method is recommended since it is simple and has some good theoretical properties compared with other MCDA methods [12, 64].

Table 54.2. CSIs of 30 OECD countries by alternative aggregation methods

Country	MCDA			DEA		MCDA-DEA

54.6 Conclusion

Indicators have been widely used to assess sustainability performance. Many indicators for sustainability have been developed, among which some are non-composite while others are composite indicators. We give an overview on indicators for sustainability. From the viewpoint of operations research, we describe the methods for constructing composite sustainability indicators (CSIs) and highlight the usefulness of MCDA and DEA. We introduce the so-called MCDA-DEA approach as a suitable method for constructing CSIs since it incorporates the good features of the DEA approach and the SAW method. We then present an illustrative example for assessing alternative aggregation methods in constructing CSIs. Some general guidelines on the selection of an appropriate aggregation method are also presented.

Sustainable Technology

Ronald Wennersten

Royal Institute of Technology, School of Energy and Environmental Technology
Department of Industrial Ecology, Sweden

Abstract: Technology has increased the capabilities of mankind during the last 100 years in a revolutionary way. We are now, however, facing a totally new situation where we can see obvious signs of dysfunctions in planetary processes like climate change, globally spread synthetic chemicals, *etc.* At the same time, as we have realized that "the sky is the limit", there is an even more vigorous reliance on technology. Many researchers, politicians and company leaders have strong faith in that new technologies will solve the problems. Sustainable technology cannot exist as such. Technological change as well as societal change is needed in order to steer technology towards sustainability. These changes can only be achieved through a combination of top-down and bottom-up processes. Top-down processes will have to engage co operation between governments, business NGOs as well as other powerful institutions. Bottom-up movements will be built on small-scale socio-technical experiments by local authorities and citizens groups, innovative professionals and entrepreneurs, artists and other out-of-the-box thinkers. Technological change is a path-dependent process which can cause severe lock-in effects. The choices made in the past will restrict our possibilities today. In a similar way, our choices today have consequences for the range of options left open to future generations. It is important for society to try to foresee the impact of technological change, so that the merits of such change can be discussed in a democratic process. Against this background tomorrow's technicians need to have a comprehensive view based on studies of economy, sociology and ecology where the consequences of the technology and driving forces for sustainable development are central. In such a process, visions based on scenario techniques, will be important tools for creating visible pathways to a more sustainable future.

55.1 Introduction

Technology has increased the capabilities of mankind during the last 100 years in a revolutionary way. At the same time this development has lead to large negative effects on the global environment as well as major changes in social behaviour of people. More than 50% of the population on earth is now living in cities with new consumption behaviours. We are facing a serious situation where we can see obvious signs of dysfunctions in planetary processes like climate change, globally spread synthetic chemicals *etc.*

At the same time, as we have realized that "the sky is the limit", there is an even more vigorous reliance on technology. Many researchers,

politicians and company leaders have strong faith in that new technologies will solve the problems. It is like an ever ongoing process that new technology should solve the problems that technology has created. This reversed way of handling the situation has turned out to be increasingly costly, but we just do not seem have the knowledge and tools to control the development.

This paper will address the role of technology in directing our societies towards more sustainable pathways. One of the key questions to discuss is if there are such thing as sustainable technologies and how we can distinguish these technologies from non sustainable technologies.

The success of technology is partly based on the success of natural science with its ability to quantify natural phenomena and in using mathematical models for creating possibilities to make predictions. At the top of this hierarchy are the basic sciences like physics and chemistry where a very limited system can be modeled with great "exactness". The natural sciences have formed a penetrating norm for "good science" also influencing social sciences. It is important to realize that the success story of science and technology is precisely based on specialization and strict limitation of the system borders. The tackling of problems concerning sustainable development, however, imply the opposite, generality and wide system boundaries. Another important conception is that science is objective and free of value judgments. Scientists and engineers are expected to deliver an objective expert judgment allowing politicians to make the most rational decisions. This conception has to be questioned at many levels.

55.2 What Is Technology for?

It should be clear that the intention here is not to appraise what is good or bad in these perceptions, but rather to conduct an unbiased discussion of the role of technology and the engineer in the development of a sustainable society. A rather broad definition of the concept technology will be adopted namely:

- Science of industrial arts and manufactures
- Applied science
- All means employed by a social group to provide material comforts

Technology defined in this way includes:

- New materials as nano materials, polymers
- Products as mobile phones, cars, medicines
- Processes as environmental technologies
- Production technologies as biotechnology

There is an on going discussion about the hen and the egg whether technology is pushed into the society or dragged by consumer demand. Most people, however, agree upon the statement that technology is one of the most important factors for economic development and also the main factor for the progress in many sectors like in construction, agriculture, transport, and energy.

There are, however, a lot of signs that technology in itself is not the sole solution for many of the real underlying problems of human beings and below are a few examples of this:

- In spite of the fact that the market is full of technology intended to save time, many people feel that they have less and less time for themselves.
- The IT-industry provides us with technology to improve the communication between people and still, more and more people experience isolation and lack of close human contact.
- Increasingly efficient technologies in the fishery industry have resulted in rapid fish depletion in the seas.
- The car industry provides proof of impressive development of car performance. Cars are, however, still one of the major threats to sustainability in cities and for the emission of green house gases.
- Combating poverty – a central subject for discussion in the Johannesburg conference – has not demonstrated success through the development of science and technology.

Many more examples could be listed, but these demonstrate anyway how the development of technology takes place as a partly aimless stroll in

a maze due to the knowledge fragmentation, that is precisely the basis for its success. It is obvious that many people have experienced a better life through technology development, but the question is more how we proceed further on. There might be so that the level where more products are not raising the quality of life for people has been reached in many developed countries. New lifestyles and values have to be found.

The development of technology is more and more controlled by relatively short-term micro-economical goals. This results in an appearance of technical and economical rationality on the micro level. However it appears technically and economically irrational on the macro level when it comes to damages to and depletion of ecological systems and natural resources, and difficulties in satisfying the basic human needs on a global scale. This situation is very much conserved through a one-sided focus on the micro-economical level in education and research at the technical universities, stressing the possibilities for patenting and commercial exploitation of results.

What should be counted at the end, *i.e.*, the real effects on people, needs and values, cannot be understood and described on the micro level with its strict system boundaries. Individual human behavior is too complex and we have to adapt constantly to new knowledge and experience, making the use of historical data uncertain. Human values also have a cultural basis depending on the social environment, which is also an important part of sustainable development. The main question to discuss here is if technological change has an important role in sustainable development or if sustainable development belongs to a class of human problems which has been classified as "no technical solution problems" [1].

55.3 The Linear Production System

The industrialized society is built upon a more or less linear transformation of natural resources into different goods and at the end waste, as shown in Figure 55.1, utilizing more and more sophisticated technologies. This transformation has been possible only through the use of cheap "unlimited" resources of fossil fuels. It is important to understand that the cornerstones of this system were starting to shake only 50 years ago with the signs of serious global environmental effects and the oil crisis. We now have the technological tools to affect the carrying capacity of the global eco systems. We can no longer move the problems to other areas on earth as we have constantly done in the past. However it seems that we are more and more locked in concerning technological systems depending on fossil fuels. This dependence is both structural and institutional. There is an immense infrastructure that supports the existing technological systems. The ways we develop technologies are hidden in our research, educational and funding institutions. It is also more or less hidden from public control in the democratic process.

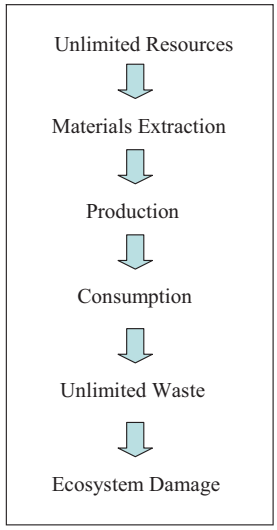

Figure 55.1. The linear production system

55.4 Is Globalization a Solution?

Today we are facing a situation where cheap material and fossil fuel resources are becoming scarcer. Globalization has stimulated the use of energy even more. Oil and gas demand is high and growing, so much that the world today consumes twice as much oil as is found. Countries like China and India, who cannot escape the technological lock-in, have ever growing energy needs. The

world does and will continue to depend primarily on oil coal, and gas for our energy requirements now and into the foreseeable future. The cost for developing new fossil resources also seems to increase exponential in spite of technological development.

Liberal economists argue that the raising demand for resources will create markets for the development of new technologies both for renewable energy sources but also in exploiting new reservoirs for fossil fuels. This development is, however, highly dependent on a stable political situation which can favor a continuous growth of the global market.

The situation is now that the places with the greatest demand for fossil fuels cannot supply their own needs. Over the next few decades, oil and gas production in the North Sea, North America and China are expected to fall, or rise too little to keep pace with demand. Only a few places have surplus reserves—chiefly the Middle East, Africa and Russia. Decision-makers in the energy industry, government, and international agencies thus face difficult decisions. How will the supply-demand problem be resolved? One possibility is a continuation of globalization. According to this vision, free markets will ensure that investment capital and fossil fuels are distributed efficiently [2]. At the other extreme is a future that involves more regulation and confrontation. Rather than free markets, anxious governments will decide how capital and energy supplies are apportioned. Rather than globalization, this would be "deglobalization" with a continuation of the "old ways" of bi-lateral political agreements securing point to point long term supply lines and markets. We can see many signs of such a development today. China is very active in developing bi-lateral cooperation in Africa to secure supplies of energy and mineral resources as well as gaining control of transport routes, *e.g.*, directly pipe crude from the Middle East to Xingjian. United States has a global strategy for securing energy supplies where the Middle East has a central role as well as controlling transport routes, *e.g.*, the Strait of Malacca. Lately they have announced a more active strategy for controlling resources also in Africa.

Russian energy group Gazprom has recently stated in a press release [3] that they will develop the Shtokman field without foreign partners. The Shtokman gas condensate deposit lies in the Barents Sea, in the north of Russia. The Shtokman gas will instead be piped to European markets. The Gazprom change in policy came as a total surprise for large multinational oil companies who had expected to get possibilities to take part in the exploration of the vast gas field. The dependence on fossil fuels of our industrial system is thus more and more becoming a security problem threatening the globalization process.

55.5 Technology Lock-in

Technology-lock in has been discussed from the point of view that mature technologies have developed comparative advantages over a long time with the effect that new technologies have difficulties for break through. One example of this is the gasoline car, which have been developed for more than 100 years, and where we now have an established infrastructure with gas stations, reparation facilities, *etc.* [4]. This situation will effectively hinder the development of alternative technologies for cars.

This lock-in effect is even more serious if we look at higher system levels. Incremental innovations in existing technology chains and even replacement of single technologies with new technologies within the existing framework can usually be favoured by research and development effects, legislation, subsidiaries, *etc.* The industrial system, based on the principles discussed earlier, has, however, created a lock-in effect which is deeply rooted at many levels, structural and institutional. For many reasons the focus on technological development is on a low system level while the problems often arise on a higher system level incorporating many types of technologies. An "environmentally friendly" bulldozer running on hydrogen that it is used to destroy rain forest cannot be classified as sustainable technology.

The development of new technologies is not a straight forward process following the development of science. Many important inventions like

the steam engine was invented before the basic principles of thermodynamics were evolving. However it is obvious in many ways that technology development is becoming more and more controlled by scientific development.

The knowledge of the processes for technological change among developers is limited. Engineers often know as little of technological change as a fish knows about hydrodynamics. The innovation process is also complex and it can be difficult to foresee the end products. As technological tools increase in complexity, so does the type of knowledge needed to support them. Complex modern machines require libraries of written technical manuals of collected information that has continually increased and improved. Their designers, builders, maintainers, and users often require the mastery of decades of sophisticated general and specific training given at our engineering faculties. Moreover, these tools have become so complex that a comprehensive infrastructure of technical knowledge-based tools, processes and practices exist to support them. Complex manufacturing and construction techniques and organizations are needed to construct and maintain them. Entire industries have arisen to support and develop succeeding generations of increasingly more complex tools.

This situation has created an extremely complicated lock-in situation which will hinder radical changes in technological systems to evolve, systems based on more sustainable solutions. The existing ways of technology transfer to developing countries also favors the development of similar lock-in effects in these countries.

It is thus obvious that the evolution of sustainable technology systems will call for major changes in innovation processes, public participation, education, *etc.*

55.6 From Techno-centric Concerns to Socio-centric Concerns

55.6.1 Changing the Focus

In order to achieve a major change in the development of sustainable technologies, it is of great importance to understand the driving forces and institutional infrastructures for technology development. If we are going to develop really sustainable technologies, we have to understand these driving forces and let this knowledge affect areas like innovation processes, education, *etc.*, in a more fundamental way than today.

The development of technologies has had different driving forces and concerns through history. In the early civilizations the driving force for technology development has been necessity in the struggle for survival which has been formulated in the phrase “necessity is the mother of invention”. To support a growing population new technologies in, *e.g.*, agriculture developed. In this phase we can say that the development was both techno-centric and socio-centric, but less eco-centric. The technology had to extend the ability to perform different tasks but it had also an important cultural role. The environmental issues were of less importance simply because the effects were minor and people could move around if negative effects occurred.

Starting from the industrial revolution the development of technologies was very much techno-centric. The focus for technology development was mainly on technical and economical viability. People had to adapt to the mayor changes in culture when they moved from rural areas into the growing cities. This situation is obvious today in many developing countries. The large improvements of the abilities of technologies, which was made possibly through machineries and cheap fossil fuels created a new situation. When serious environmental effect reached a level that it threatened economic growth, end of pipe technology solutions were gradually developed. From the beginning there was a resistance from industry towards increasing costs connected to environmental concern, but today this is accepted in the developed economies and there is even a large and viable market for products in this area. The change in concerns has evolved gradually through the process shown in Figure 55.2.

Today it is hard to see that the development of technology is really that of necessity. Flat screen TVs have hardly been produced as a result of necessity. The development today is more a result

of temporary resource abundance. In this situation the globalization with new growing markets is of central importance for the world economy.

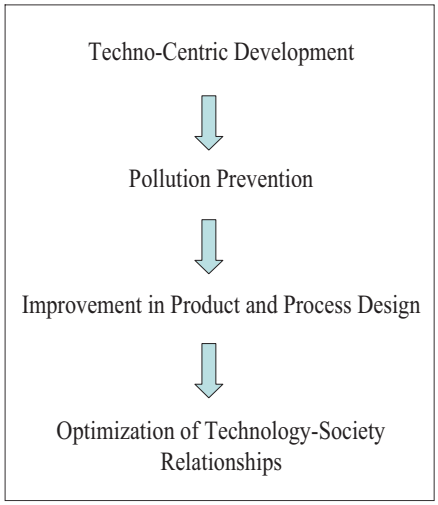

Figure 55.2. Evolution of technology in relation to environment and society

Following this development concepts like cleaner production and Design for Environment (DSE) have developed towards eco-centric concerns. Environmental concerns have been gradually more integrated in the company activities through different management system like ISO 14001.

However the existing paradigm is still that technology is considered largely in isolation from the environmental, social, political, and economic processes that shape it – processes that are themselves shaped, altered and adapted by technology. Optimization of technology–society relationships is still hardly developed. An approach like DSE aims to minimize the environmental consequences of human activities through modification of technological artefacts. An important tool for this is life cycle analysis. At the company level, this translates into the application of environmental constraints to traditional business beliefs and behaviours. The goal is one of optimization through the development of existing relationships and marginal modifications of industrial systems. This is one important effect of lock-in on the existing system level. Radical changes are very difficult to achieve.

55.6.2 Towards a More Holistic View

A more holistic conceptualization of technology, however, directs attention away from the technological artefacts toward the knowledge, relationships, values and assumptions that underpin technological choices. Greener, cleaner, more environmentally friendly technology is no longer the means to more sustainable paths. Rather the goal should be design for society (DFS). technology from this perspective is the product of a complex set of relationships internal and external to the company, many beyond its direct control.

Designing for and within society extends research and practice of technology management and development beyond the traditional frameworks of engineering and management decision making and asks fundamental questions about the nature and the role of companies and technologies in their social and environmental contexts. DFS would include a more holistic view of techno-centric, eco-centric, and socio-centric concerns as shown in Figure 55.3.

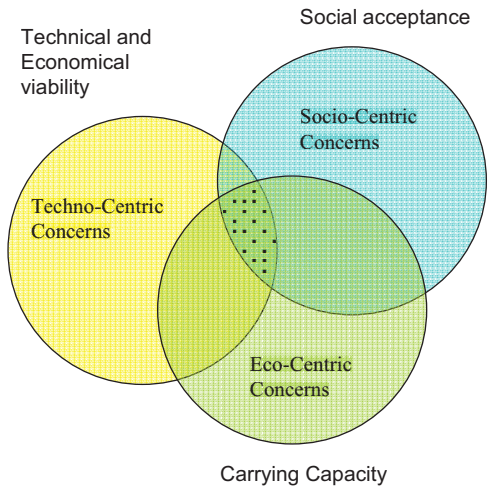

Figure 55.3. The relation between eco-centric, techno-centric, and socio-centric concerns

DFS would include important moral aspects like equity and justice concerning existing and future generations. A conclusion from this is that a radical change in this process cannot be achieved by multi national companies or institutions.

It can only be changed through a democratic process involving broad participation from society. The social question is probably the key issue to solve for stopping rebound effects with the development of technology. It is human behaviour and the resulting social dynamics that lie at the heart of today's social and ecological problems.

Social sustainability is dependent on ecological sustainability for maintaining the carrying capacity of the living systems. On the other hand ecological sustainability has become dependent on social sustainability. With a growing population, constrained in their abilities to meet their needs, it becomes increasingly difficult to protect the environment and even more to save resources for future generations.

If one today should try to sum up the misery of the world, the reason for this misery would in a very limited extension be due to the fact that the industrialized countries have invented too few technical products that can be sold. In this context it is also interesting to look at "Millennium Development Goals" formulated by UN. In the beginning of the new millennium there was an important worldwide, international consensus decision about development goals and actions: The eight goals that were established were:

- Eradicate extreme poverty and hunger,
- Achieve universal primary education,
- Promote gender equality and empower women,
- Reduce child mortality,
- Improve maternal health,
- Combat HIV/AIDS, malaria and other diseases,
- Ensure environmental sustainability,
- Develop a global partnership for development.

This is a clear example of the necessity to include the socio-centric concern in formulating sustainability targets and objectives. A changing view towards design for society will have a profound effect on the way technology is developed. In order for this more holistic approach to evolve, we will need fundamental changes in the society initiated by a broad discussion among all stakeholders. Key issues will be the change in how we educate engineers and the development of a technological culture in society with a broad public participation.

55.7 Technology and Culture

The evolution of science and technology has formed a strong belief in the concept of progress in society. The idea was conceived and developed mainly by science and is based on a new picture of the world and the premise that science views itself as an infinitely developing system of knowledge and a way of remaking the world. Therefore progress became one of the industrial-society ideology's pillars and the idea of progress might be one of the most important corner stones in the western society. It might also be natural that in a world of change, time is perceived as some linear property while in a old nomad culture with very little change, time is a more circular property.

We have now reached a state where we slowly are coming to realize that this line of progress is by no way guaranteed in the evolutionary process. If we do not change our paths to become more sustainable for all life forms, then we will go the same way as every other life form that failed to adapt to the carrying capacities of the eco systems.

Changes in production systems and cultural changes go hand in hand. The gradual process of industrialization imposed one of the most radical shifts in living conditions and culture in human history. Technical innovations not only changed working conditions, but forced profound social change on the whole fabric of society, upon human relations and the individual's perception of time and space. This rapid change at all levels in our society and the dependence on technology has also created a fundamental criticism towards science and technology as the fundaments for the industrial development and globalization.

The author Paul Virilio has focused on speed as one of the most important factors and threats in our society where the fast development of technology is seen as one of the main threats to human beings. In an interview he says [5]:

> *"This means that history is now rushing headlong into the wall of time. As I have*

> *said many times before, the speed of light does not merely transform the world. It becomes the world. Globalization is the speed of light. And it is nothing else! Globalization cannot take shape without the speed of light. In this way, history now inscribes itself in real time, in the 'live', in the realm of interactivity." "But we must engage in resistance first of all by developing the idea of a technological culture." "For example, we have developed an artistic and a literary culture. Nevertheless, the ideals of technological culture remain underdeveloped and therefore outside of popular culture and the practical ideals of democracy. This is also why society as a whole has no control over technological developments. And this is one of the gravest threats to democracy in the near future. It is, then, imperative to develop a democratic technological culture."*

In the Western societies, with an increasingly faster metabolism, people often experience a gap between their human ambitions and real life. They have less time to fulfil their ambitions which are steadily growing. There is also a growing skepticism towards politicians and experts which creates fundamental difficulties when new technologies are introduced. If we want to rely on democratic processes we have to accept that technology development is a part of society and should be discussed more broadly in. Civil society will have a fundamental role in a transition to a more sustainable society. A system where people are involved in democratic processes is the best organization for a fair distribution of goods and power, and for minimizing the perils of life.

55.8 Technology and Risk

An important and complex issue is the relation between technology and risk. What kind of new risks will be introduced with new technologies and how can we assess them from a sustainability point of view? Each wave of technology trend to create a set of waste previously unknown by humans, *e.g.*, toxic waste, radioactive waste, electronic waste.

There are numerous of examples when new technologies have created new risks which were revealed many years after their introduction. One of the more well known is the introduction of the chemical DDT. In 1948 the Swiss chemist Paul Hermann Müller won the Nobel Prize for his discovery of DDT, an insecticide useful in the control of malaria, yellow fever and many other insect-vector diseases. The substance was regarded as a miracle agent to control insects and it was used widely and in large amounts. About 40 ears later signs of serious effects on the environment showed up. DDT accumulated in the food chain and affected reproduction of animals high up in this chain, *e.g.*, seals. The first debate about this was created in the 1960s by Rachel Carson with her book "Silent Spring".

The effects of technology on the environment are both obvious and subtle. The more obvious effects include the depletion of non renewable natural resources (such as petroleum, coal, ores), and the added pollution of air, water, and land. The more subtle effects include long-term effects like global warming, deforestation, natural habitat destruction, and coastal wetland loss.

The history shows us that the delay of revealing risks with new technologies could be as long as 50 years and then the damage to environment could be severe. At the same time there is a constant stream of unsystematic alarms from media around new technologies, alarms which are very difficult to handle for politicians and the public. Are we introducing new "DDTs" today? Chemicals like Perfluorinated chemicals (PFCs) and their precursors is a group of chemicals widely used in a range of consumer, *e.g.*, non-stick coatings on items such as cooking pans, and stain repellent coatings on everything from carpets and furniture to microwave popcorn bags and fast-food packaging. Although more research is needed, existing studies have shown that perfluorinated chemicals are extremely persistent and bio accumulative, as well as probably cancer-causing and hormone disrupting. Recent research has indicated that a major source of PFCs in the environment is the migration of PFC precursors from consumer products; in other words, PFCs are leaking from our products into the environment.

Examples of new technologies being introduced without comprehensive risk assessment are:

- Nano materials,
- Genetically modified crops and food,
- Gene therapy,
- Energy technologies, *e.g.*, fusion.

There are three important questions to rise in accordance to this:

1. How can we assess the long term effects of new technologies and new materials including effects on environment, human health, culture, human behaviour, criminal use, *etc.*?
2. How can the risk perspective be assessed and communicated to other stakeholders in the democratic process?
3. Who should decide what is an acceptable risk is and if new technologies should be accepted?

It is often considered that the development of science and technology have created a more secure environment for mankind. Paradoxically, however, it seems as if technological development has increased rather than decreased people's worries over various risks. People are afraid of BSE, radiation from mobile phones, toxins in food, terrorism *etc.* Furthermore, there is no indication that the confidence people place in experts has increased. On the contrary there are clear tendencies that people increasingly look for answers outside science. One of the precise reasons for this situation is the fragmentation of research and education and the fact that the results produced are difficult to communicate to a broader public. The basic difficulty for communication is perhaps not the knowledge base of the receivers, but rather the perception by the scientific community that research results are always objective and free from value judgments. This is a very serious problem that is undermining confidence in science and technology and in the long term the democratic foundations of society. From the very beginning engineers must anchor their solutions more carefully in terms of society, which requires a change in education. Openness about values in development of technology is a basis for re-creating the confidence in the engineer in the society.

Risk is thus an important parameter in many decision processes in our society. There are several problems with existing methods for risk assessment. One is that there are large uncertainties in the results. Another problem is that there are no well defined methods for describing what often is called "worst case" scenarios. The public has a strong tendency to focus on the worst possible consequences while experts tend to weight in uncertainties and probabilities, which will lower the risk. Worst Case will just not happen! The results from existing methods for risk assessment are also very difficult to communicate to the different stakeholders involved in the decision process.

In a democratic society it is important that the methods for risk assessment are transparent and the results from risk assessment should be possible to communicate in participatory decision processes involving many stakeholders, *e.g.*, politicians, NGOs, public. Concerning risk it is important to discuss how the precautionary principle can be applied. That is if we do not know the risks we should be precautious. We cannot rely on calculated low probabilities for events to happen any more. Accident likes that in Chernobyl and effects like that from DDT shows that skepticism towards these calculations is highly justified. Technological risks have an essential role in a broad public discussion. This will be an important part of a more developed technology culture.

55.9 Innovation and Funding of R&D

In the last few years sustainable development has been recognized as a serious challenge and major strategic issue by managers in many companies. Although pressures for this vary across industrial and national contexts, they are increasingly changing the rules of competition, making extant competencies obsolete, creating winners, losers and opportunities for niche players. Traditional risk management techniques and innovation strategies are insufficient to deal with these added difficulties. Effective sustainable development

innovation involves embedded organizational capabilities and the ability recognizes and responds to often context specific, conflicting and sometimes ambiguous pressures. Yet it is precisely because sustainable development innovation is hard, and important, that such capabilities can be the grounds for competitive advantage. The development of environmental protection technologies opened new markets for business. The same situation will now occur for sustainable development, but it will require totally new and more complex strategies.

Innovations, like in environmental technologies, are often focused on products or product chains. More seldom higher system levels are taken into account. The reason for this is that innovations in systems, like transportation systems, in a city is hard to finance because there will be many actors taking part and delivering products to the system. There is thus a need for new funding mechanisms supporting the development of technology from socio-centric concerns that is on a higher system level. This will need a closer co operation between several stakeholders like companies, public sector, and universities.

Many researcher put hope on new technologies for radical dematerialism as the new innovation strategy. This could be achieved through production of goods using less material and energy. However this race is becoming more and more like that of the hare and the tortoise. Using less material and energy in products will not keep up with the increase in consumption. Dematerialism could also be achieved through substitution of human labor. The hope is than that the sustainability of economies of the future will be based almost entirely on services; leasing will become the norm for products, and firms must learn to sell services, not products [6].

On the other hand, the one-sided concentration on the invention of marketable products which we have today is problematic. Much evidence is there to show that more focus should be on more qualitative research in social science and the humanities and especially on trans-disciplinary research.

55.10 Engineering Education for Sustainable Development

Technology has the potential to play a vital role in the development of sustainable societies and new concepts and tools for a deeper understanding of the evolution of technology are being developed in research. There are, however, large barriers for more holistic and socio-centric concepts to be practically realized in the industrial society. There are two important explanations for this. One is that these new concepts have not on a deep level influenced the education programs at the technical universities [7]. Still the engineering education is very much taught as if technological change was independent of the societal context. The other explanation is that there is still not an effective triple helix working in practice with a close co operation between universities, industry, and the public sector. This cooperation will be essential for a more radical change in the industrial systems and consumer behaviours.

The traditional view with a knowledge split where engineers possess the expert knowledge and politicians make decisions about the direction has proved unsustainable. We must create an educational system where the engineering students themselves develop values and understanding of all parts of a sustainable development, and use this as a part of their engineering knowledge. Perhaps a central part of the new role for engineers is precisely to list scientific criteria for a technological development that supports sustainable development on local and global scale. This change will increasingly be required by the industry through their changing strategies towards sustainable development.

When the environmental education at our technical universities started in the beginning of the 1970s its emphasis was on environmental protection. Central issues were basic ecology, the effects of point discharges and environmental protection techniques with regard to cleaning of water and air in particular. This was a clear reflection of the environmental work that took place in many western countries from the end of the 1950s up to the mid 1980es. During this period there was an intense expansion of water and air

cleaning technology, focusing on point discharges, a type of activity where the role of the engineer was evident. In other parts of the industry the environmental issues were still not relevant.

In connection to regional problems, such as acidification and eutrophication gaining importance, an increasingly larger portion of system analyses were added to the syllabus during the 1980s. Cause and effect, measures and effects, more system based analysis, formulated a number of new problems. The environment issue became more complex.

In the beginning of the 1990s, a change took place in the western world. The focus was shifted from point discharges to products and services**.** The environmental work in a company became more focused on studies of the total life cycle of a product" from cradle to grave", *e.g.*, from raw material withdrawal via production and product to mass disposal at the end. In the environmental syllabus basic environment management was introduced.

At the same time, global environmental issues came into focus. Large scale environmental problems such as the carbon dioxide problem and discharge of different compounds affecting the ozone layer were now discussed. The problems here are concerned with the impact on the most basic of the eco-system's functions, and the consequences of environmental destruction are considerably more serious than the local problems discussed during the early environmental work. We have now begun to realize that we have started closing in on the outer boundaries of the global system.

From this threat, the concept of sustainable development developed during the 1980s where ecological carrying capacity and the relationship between environment and growth became increasingly important, as well as the relationship between South and North. The Rio Conference 1992 formulated this change in a number of documents.

This change of the environmental work that has taken place during the last ten years has also changed the impact and content of the environmental issues for the engineer. During the 1970s environmental work in the society was concentrated to very few technicians within communal and private business with the aim to develop and handle environmental protection technology in large installations with point discharges. Laws and discharge approvals from local and regional authorities controlled their activities. Other engineers rarely reflected on the environmental work.

Focus on products and services during the 1990s have resulted in a demand in the market for the company's environmental work. The need for environmental management was strengthened and a large number of tools were developed, such as environmental labeling, ISO-certification, LCA, *etc.* This created a need for environment management skills for all engineers independent of where in the production line he/she was placed. This change of the need for knowledge for all technicians also shows the importance of having a general and compulsory environmental syllabus as important as other parts of the engineering curriculum.

We can thus see that the active role for the engineer in sustainable development has slowly changed from the 1960s and 1970s, where technology for environmental protection was the focus to the 1980s and 1990s when the environmental work on the company level started to become integrated and environmental aspects of technological development becoming increasingly proactive. Knowledge of environmental management becomes important for the engineer. The technical development is, however, still not conditioned upon what is sustainable from a global perspective. Knowledge of environmental management will hardly suffice for the role of the engineer in sustainable development and therefore it just remains necessary to discuss and formulate the need for knowledge required to carry out a sustainable development.

Technology and the engineer will play a very important role in the development towards sustainable societies. The education for sustainable development, however, has a long way to go before it has any effect on this process. The difficulties to overcome are of different powers.

One task is to clearer formulate the role of the engineer and thus the role of the technical universities in sustainable development. What is

science and what are values in sustainable development? This also includes a discussion about the views on natural science and its relation to economy and social issues in a broader society perspective. The engineer must already in his education be taught to understand and take part in public debates about the role of technology to satisfy human needs.

It took 25 years in many technical universities to get a compulsory and general environmental education for all students. There are many lessons from this development and below are some of these briefly highlighted:

- The management of the technical university must take a stance and clearer position regarding sustainable development and the need for the student to have general knowledge in the form of compulsory courses in addition to the engineering subjects.
- There must be an open debate at the university and in society about the role of the engineer and technology in sustainable development. Is it possible to develop the technology on a scientific ground without values? How and when will these values come in and how shall this be made clear in the public debate? The confidence in the engineer must be re-established.
- The discussion about education and sustainable development must be broadened between teachers and researchers to make it possible for everybody to participate.
- Continuing education of teachers must be given priority for education of students to achieve high quality. For this to happen, the basic forms of education must be changed towards further use of case studies and less lecturing. The Internet will also play an important role in freeing the teachers from administration and tied lectures.
- Research and research methods connecting to issues about the role of technology and sustainable development must be given priority. Education must gather nutrition from research in the form of questions and concrete case studies.

The concept of sustainable development includes the creation of possibilities for welfare today without preventing possibilities for welfare tomorrow. This perspective must be a guiding principle for the engineers of tomorrow. This is easy to say, but it is difficult to apply in practice. In today's globalized world technical innovations and technical progress have such a large impact on habits and behavior, on the economy and thus the flow of energy and material. The use of technology and development is controlled by a number of economical and social factors that must be recognized. Against this background tomorrow's technicians need to have a comprehensive view based on studies of economy, sociology and ecology where the consequences of the technology and driving forces for sustainable development are central.

55.11 Industrial Ecology – The Science of Sustainability

There is an existing industrial paradigm in our society, which is still mainly based on the idea of the linear production system with "minor" changes. The tendency in developing technologies is still mainly to first create the problems and then to mitigate them. There are, however, signs of a developing paradigm on a totally different system level. This can clearly be seen in the evolution of industrial ecology as a research field. Industrial ecology is an emerging field which might turn out to be a suitable platform for a more practical approach to sustainable technologies.

From being very much focused on industrial metabolism, industrial ecology has gone further to incorporate a more comprehensive, integrated view of all the components of the industrial economy and their relations with the bio sphere and the society. Industrial ecology has very much followed the evolutionary process shown in Figure 55.2. In one of the first textbooks [8] in the following description is given:

> *"Industrial ecology is the means by which humanity can deliberately and rationally approach and maintain a desirable carrying capacity, given continued economic, cultural and technological evolution. The concept requires that an industrial system be viewed nor in isolation from its surrounding systems, but in concert with them. It is a systems view in which one seeks to optimize the total materials cycle from virgin material, to finished material, to component, to product, to obsolete product, and to ultimate disposal. Factors to be optimized include resources, energy, and capital."*

The concept of industrial ecology is developing rapidly and important new considerations are how the north–south dimensions and how different concepts like justice and equity should be tackled. This evolution is a natural process in developing industrial ecology towards a more socio-centric perspective.

55.12 Conclusions

Technology can and will have a major role to play in developing more sustainable paths for our societies. Sustainable technology cannot, however, exist as such. Technological change as well as societal changes is needed in order to steer technology towards sustainability. These changes can only be achieved through a combination of top-down and bottom-up processes. Top-down processes will have to engage governments, business NGOs as well as other powerful institutions. Bottom-up movements will be built on small-scale socio-technical experiments by local authorities and citizens groups, innovative professionals and entrepreneurs, artists and other out-of-the-box thinkers.

Technological change is a path-dependent process which can cause severe lock-in effects. The choices made in the past will restrict our possibilities today. In a similar way, our choices today have consequences for the range of options left open to future generations. It is important for society to try to foresee the impact of technological change, so that the merits of such change can be discussed in a democratic process. In such a process visions based on scenario techniques will be important tools for creating visible pathways to the future.

Biotechnology: Molecular Design in a Globalizing World

M.C.E. van Dam-Mieras

Open Universiteit Nederland, Heerlen, The Netherlands

Abstract: Presently we are living in a society that could be described to some extent as a global networked society. Differences in welfare between the different parts of that society are enormous. However, in that global networked society the need for a development that is more sustainable than the present one is becoming more and more obvious. The chapter deals with the question "What does the process of co-development of modern biotechnology and society look like in a globalizing world?"

56.1 Introduction

Biotechnology can be described as the use of biological systems for the production of goods and the provision of services at an economically relevant scale. Described in this way it is a technology that has a very long tradition already. Since the development of genetic modification in the second half of the previous century biotechnology has led to violent debates in society. But also modern biotechnology is broader than genetic modification. It may be seen as a result of developments in molecular sciences that enable analysis, modeling, simulation and modification of biological systems at a molecular scale in the context of research and the development of products and services.

The societal debates referred to above are a normal phenomenon in the process of co-development of technology and society. Technology development is a complex process that can not be managed in a "top-down" way, it also asks for "bottom up activities" that cannot really be planned. This process of co-development is complex and rather unpredictable.

56.2 What is Biotechnology?

A description of biotechnology could be "biotechnology is the use of biological systems for the production of goods and the provision of services at an economically relevant scale". Such a broad description would also include agriculture and the food and feed industry of course, which is not what comes to ones mind first in relation to modern biotechnology. A characteristic that jumps to the fore in modern biotechnology is that this technology is based upon developments in molecular sciences applied to biological systems. Modern molecular sciences make it possible to analyze, model, simulate, design and modify biological systems at a molecular level. From that perspective the distinction between, for instance, biotechnology and nanotechnology is rather inspired by the sector in which the knowledge is

applied and in practice the boundaries between the domains are fading. Within biotechnology itself molecular sciences also blur the boundaries between different sub-sectors such as health, agriculture, and industrial production. It may be expected that biotechnology through its (potential) applications in many fields will influence most sectors of the economy. Therefore, reflection on its potential impact on ecological systems and on the sustainability of production systems deserves attention [10].

Modern biotechnology is not only characterized by the application of molecular knowledge to biological systems, but further, a second characteristic is the combination of molecular sciences and ICT. Without ICT instruments it would not be possible to store, process, and manage the huge amounts of data generated in (bio)molecular research and to model, simulate, design, and modify biological systems and processes.

56.3 The Importance of (Bio)Molecular Sciences

Modern biotechnology and genetic modification are often mentioned in one breath and the societal debate mainly focuses on the latter. Changes in DNA, the natural storage medium for genetic information, are not only produced in the biotechnology laboratory, however, they also occur in nature. Exchange of DNA during crossing over is a part of the process of meiosis during the formation of gametes, bacteria can exchange DNA via plasmids, a viral infection can result in small changes in host DNA, and so-called mutagenic chemical compounds and radiation can lead to DNA mutations. These naturally occurring processes have inspired the development of the technique of DNA recombination. What is characteristic for recombinant DNA technology is that the modifications are deliberately brought about in the laboratory and that the exchange of DNA is more targeted, as far as possible, than in natural processes of DNA exchange. Recombinant DNA technology makes possible an exchange of DNA between unrelated species and this cannot be brought about by natural crossings. Furthermore, the modern techniques for analysis and separation make the selection process of modified cells easier. The resulting genetic modifications should be placed in the context of processes relevant to man in domains such as health, agriculture, and industrial production [11].

In addition to recombinant DNA techniques and techniques for analysis and separation of molecules and cells, also the possibility to isolate and culture cells from different origin is crucial. In microbiology there is, of course, a rather long experience with the cultivation of bacteria, yeasts, and viruses, but the culture of isolated cells from different organisms like plants, animals, and humans is more recent. During research on recombinant DNA technology and cell culture work is done on a very small scale in the laboratory, but in the development of production processes and services scaling up to larger volumes has to take place. The latter belongs to the domain of bioprocess technology

56.3.1 The “Omics” Research Domains

The extensive international co-opration in the human genome project [18] has contributed to the emergence of a whole range of “omics” research domains. Examples are genomics, proteomics, metabolomics, pharmacogenomics, and nutri-genomics.

Genomics research deals with the way genetic information is stored in the genome of cells. Genetic information is codified in the sequence of four DNA building blocks. Which of the codified information will be expressed at a certain moment is determined by, among others, the external conditions and the development stage of the cells. The field of research dealing with the expression of genetic information is also called functional genomics.

Proteogenomics deals with the translation of genetic information into protein structures within cells. Before the genetic information stored in DNA can become physiologically effective DNA structures have to be translated into protein structures. Proteins are crucial for all processes taking place in living cells. The old idea of one

gene code for one protein has been abandoned. Apparently, the genetic information on a gene can be read in different ways. The huge amounts of proteins and the complexity of their interactions make proteomics another interesting field of research.

Metabolomics concentrates on the study of metabolic processes within cells. The metabolic household within cells is a highly co-ordinated interaction between very large amounts of bio-molecules. It is effective, efficient and flexible and is continuously adapted to external conditions.

In pharmacogenomics the genetic information on human DNA is taken as a point of departure in the development of new drugs.

Nutrigenomics places genetic information in the context of food and nutrition.

56.3.2 Techniques for Analysis and Separation of (Bio)Molecules

The developments described above also influence developments in other domains, for instance, in the domain of techniques for the analysis, and separation of (bio)molecules and cells. The analysis and separation technologies in the bio-molecular research domain make it possible to identify very small amounts of bio-molecules in highly complex samples. In research this opens the way to a study of biological processes at a cellular and molecular level. The technologies can also be used for optimization of monitoring, control and management of production processes and production chains. An important characteristic of this new generation of techniques for analysis and separation is that, thanks to the combination of (bio)molecular knowledge, information technology, and automation very small amounts of biological compounds in very large amounts of samples can be analyzed at a high speed.

56.3.3 Bio-informatics

Moreover, the contribution of bio-informatics, the integration between bio-molecular sciences and information technology, is of great importance. On the one hand, bio-informatics produces databanks with data on structure of DNA and proteins. On the other, the development of computer software that makes possible processing, storage, and search of these huge amounts of data is part of the field of bio-informatics. Bio-informatics makes it possible to model, simulate, and design at a molecular scale. Of course, the enhancement of communication and co-operation between the highly international community of peers cannot be overestimated either.

56.3.4 Biotechnology and Nanotechnology

In biotechnology and in research in the “omics” domains the emphasis is on the application of molecular knowledge in the context of biological systems. The demarcation from nanotechnology is not very sharp, however. Nanotechnology focuses on the development of functional devices at a molecular scale. One can think of applications in the field of micro-electronics (miniaturization), energy (solar cells), and medical practice (diagnosis and drugs delivery). These developments will most probably result in the design of new classes of micro- and nano-produced devices in which biological and non-biological components can be combined. The integration of expertise from electronics, silicium technology, chemistry, and bio-moleular sciences opens many new perspectives.

56.4 Application of Biotechnology in Different Sectors of the Economy

Modern biotechnology can be seen as a key technology that will not only lead to innovations is many sectors, but will also result in many new interactions between different sectors of the economy. The technology also has great potential for making large scale production processes more sustainable. However, sustainable development is a complex process and the availability of technology per se will not lead to a more sustainable development that the present one. Changes in behavior, organization, institutions, and power relations are needed as well.

56.4.1 Biotechnology and Healthcare

In the healthcare sector development in bio-molecular sciences and technology can result in completely new products or ways of diagnosis, treatment, and prevention, or in new production methods for existing products. The use of recombinant DNA technology in health care will result in new drugs, DNA vaccines, constructs for gene therapy, and therapeutic stem cells.

Biotechnology can also contribute to the development of cleaner production processes in the pharmaceutical industry. In the pharmaceutical sector, just as in the sector of fine chemicals, relatively small amounts of high prize products are developed. The waste streams from the production process may be rather large, however. The replacement of chemical conversion steps by biotechnological conversion steps can make the production process more efficient and can result in a reduction of waste streams, which will lead to a reduction of costs. The investments that have to be made to replace conventional process steps by biotechnological process steps are high, however.

Another point of attention in the pharmaceutical sector is the protection of intellectual property rights (IPR). The production costs in the sector may not be so high, but the initial R and D costs and the costs of assessing effectiveness and safety of products are very high. This makes the protection of property rights an important issue in this sector. These very high developments costs in the pre-market development stage also explain why in the present global economy many of newly developed products will not be available for people in developing countries [3],[23],[21], and [32].

56.4.2 Biotechnology and Agriculture

Within the agricultural sector the objective is often a higher yield by adaptation to unfavouable culture conditions and the incorporation of resistance against diseases, pests, and herbicides. Such applications in the domain of plant breeding do not result in completely new products, but rather in the (man-desired) improvement of existing crops. Recombinant DNA technology enables the introduction of genetic information from unrelated organisms and that can not be realized with conventional breeding techniques. Furthermore, the application of bio-molecular knowledge has also greatly increased possibilities for selection. Therefore, modern biotechnology brings more characteristics within reach and reduces the development time of crops. A relatively new development is the use of genetically modified plants in the production of pharmaceutical products (biopharming).

Also in this sector there are important points of discussion in the context of sustainable development. The protection of intellectual property rights and access to knowledge and technology for people in economies in transition is such a very important point of discussion. In relation to the availability of food for developing countries one could argue that reflection on the impediments for agricultural production and trade in the context of WTO agreements could be more important that modern biotechnology. Furthermore, as in large scale agricultural production processes physical or biological containment is impossible, the environmental risks are another point of discussion.

Modern biotechnology can also be used to increase productivity in cattle-breeding and dairy-farming. It offers new tools for the toolbox that is used in the industrialization of the sector for almost a century already. Animal productivity is supported by animal health care, drugs, artificial insemination, manipulation of reproduction processes, embryo transplantation, mathematical processing of data on production and descent, the feed industry, mechanization, and automation. A relatively new possibility of the application of biotechnology in this sector is the production of drugs and xeno-transplants in transgenic animals. The ethical aspects of the latter applications have led to intensive debates.

56.4.3 Biotechnology and the Food Industry

Most agricultural products are processed before they are consumed. Processing can take place in the kitchen at home, but very often a number of process steps is carried out in the food industry. This sector has much experience with classical biotechnology (conservation, dairy products,

alcoholic beverages, meat-products, soy products). Many processes can be optimized using modern biotechnology and in addition to that new products are developed and waste streams are reduced or applied in other production processes. Also the newly developed analytical techniques are of great importance to this sector for the assessment and control of quality.

By applying good manufacturing practices (GMP) the environmental risks in the food industry generally can be managed and there is not much debate in society on that, but there is debate on health risks and on the right of consumers to buy biotech-free products. As nutrition has a high emotional value, and the availability of food is not a point of concern in industrialized societies, the acceptance of perceived potential health risks by consumers is low. This leads to the paradox that carefully controlled large scale production is perceived as less safe than artisan production, in spite of the fact that in the latter the number of mistakes per kilo will be greater. It must be remarked, however, that according to the Human Development Report 2001 [27] the aversion against genetically modified food is greater in Europe and the United States that in developing countries. An important reason may be that in developing countries food availability cannot be taken for granted.

56.4.4 Biotechnology and Industrial Production

In industrial production in general modern biotechnology creates new opportunities for new products, new production processes and process optimization. In, for instance, the chemical industry the use of biological raw materials to replace fossil raw materials and the replacement of chemical conversions by bio-conversions can greatly contribute to the improvement of both ecological and economic performance. There is not much debate in society on the application of modern biotechnology in industrial production in general. When appropriate GMP procedures are used the environmental risks can be managed, and furthermore in this sector there often is no direct contact with consumers. The risk of this "invisibility" is that the opportunities from the perspective of sustainable development are not discussed either. Reasoning from an ecological perspective the potential risks and benefits of modern biotechnology in large scale production processes should not only be considered at the level of specific production processes and products chains, but also at a systems level [29].

56.5 Biotechnology and Sustainable Development

It was described above that biotechnology can contribute to an optimization of production processes. As the products and production processes used in biotechnology are very similar to those in living nature there is certainly potential for an increase in sustainability of large scale production systems [10],[29]. But a more sustainable development is not only a matter of technology. Sustainable development is a complex process requiring co-operation between different players with differing and sometimes (at least on the short term) conflicting interests [12]. In the context of sustainable development it can be expected that future shortages and social and managerial risks will in the end result in radical changes in the nature and the sectoral and regional structure of economic activities. Before continuing the reflections of biotechnology developments in society a short historical introduction on the globalization of the economy and some of its consequences will be given.

56.5.1 Sustainable Development and Globalization

A reflection on sustainable development cannot be separated from a reflection on the processes of industrialization and globalization. In a historical perspective these developments cannot be detached from the developments that took place in Europe in the 17th century.

The "knowledge revolution" that took place in Europe in the 17th century [13] induced the Industrial Revolution because innovations based on fundamental knowledge developed in an enabling social environment made a different organization

of production processes and society possible. It resulted in drastic changes in technology, economy, and society and created welfare, at least in the industrialized societies. It also contributed to the development of nation states responsible for public interest, for a proper functioning of economic markets, for safety, and for the development of social institutions that constitute a safety net for their citizens. Welfare in these nations was to some extend shared among citizens and resulted over time in increased possibilities for individual development. These developments were also connected to the process of colonialism and globalization of the economy. In the second part of the 20th century the process of globalization has been boosted by developments in the field ICT and by a worldwide liberalization of trade. The liberal market paradigm since the end of the cold war contributed to ending colonialism and developments in ICT made it possible to organize human activities in a geographically spread way.

Also today technological innovations based on fundamental insights, like those in molecular sciences, taking place in an enabling social environment, constitute conditions for economic and social developments. However, they no longer take place mainly on a national level. The possibilities for transportation of persons, goods, and information leads to a world in which human activities are geographically spread, production chains cross national borders, and virtual space is increasingly becoming a space for activities complementary to physical space [2],[4],[5] and [7]. People and organizations will have to learn how to be part of a global society while remaining bound for most of their time to their physical environment. The emerging global space connects all places on earth and relates the human activities in different societies. The reach of choices made has consequences for others in other societies, which should be taken into account as well. Governments, organizations operating in the private domain, NGOs, and world citizens have a joint responsibility for the developments in the global space.

56.5.2 Sustainable Development, Policy, and Responsibility

Working on sustainable development implies dealing with dilemmas in complex societal environments and taking decisions under uncertainty. For many citizens it may be difficult to understand such complex problems, which makes it difficult for governments to get acceptance for drastic policy measures needed [33]. The legitimacy of policy measures also is a difficult question because the expected problems:

- may only become evident in the future ,
- will become manifest at remote places and thus ask for international solidarity,
- may not happen at all.

Policy development in such complex situations asks for weighting in which the use of the precautionary principle can be helpful [14]. In practice it will never be possible to exclude all risks and therefore the question is which level of knowledge is needed to take a responsible decision. This challenge for government policy has resulted in the development of innovative methods for policy making at the national level; open policy processes and stakeholder participation are examples of those developments [26],[33]. Because the sovereignty and power of nation states is bound to their territory a most urgent question is how, and via which actors, this responsibility can be “scaled up” to the global level. How can an “incubator” be created in which the different actors involved can develop in mutual interactions good practices fitting in the global reality?

For companies responsibility is expressed in concepts such as corporate social responsibility, which deals with concepts such as integrity, good governance, and a series of objectives desirable from the societal perspective [22].

NGO plays an important role in the globalization of civil society. The effectiveness of socially active NGOs lies in their flexibility and the dynamics of the network structures in which they operate. [1],[28] and [31].

World citizens can influence developments in the global space in at least three ways: as a citizen, as a consumer and as a producer. In practice the behavior of individuals in these different roles is not always consistent and sometimes even conflicting. In addition, choices on how to apply knowledge and capital are of great importance.

56.6 Innovations, Civil Society, and Global Space

Technologies based on knowledge of structures and systems at the molecular level (modern biotechnology, the "omics" domains, nanotechnology) can be seen as key technologies but they will not result in innovations if there is no interaction between technology and society. Society and technology are related via a process of co-evolution in which society influences innovations and innovations affect the societal context. The civil society therefore is an important "incubator" for innovation. New societal practices related to the innovations that develop in civil society will finally "coagulate" in laws and regulations. As long as developments take place at a national level, laws and regulations will co-develop with innovations and therefore will match, at least to a large extent, with norms and values broadly accepted in society. But what happens when technology is developing in a global networked society? There is no parallel to the process of co-evolution of technology and society at a global level.

56.6.1 Biotechnology and Governmental Policy

One could state that it is the task of governments to provide safety to their citizens their citizens and to contribute to (the generation of) welfare. The instruments for fulfilling those tasks are laws and regulations on the one hand and the creation of incentives on the other. In relation to biotechnology nations will thus try to develop regulation that will control the possible risks associated with genetic engineering and to create conditions for economic development.

Regulations in relation to a new technology like biotechnology have to deal with many values: sustainability, freedom of choice, biodiversity, the integrity of organisms, the dignity of human life, the protection of intellectual property rights, justice, and solidarity are all involved [9]. At a national or a community scale one could say that the formulation of regulations could be seen as the articulation of societal rules that have developed with time in a continuously evolving "civil society". Developed according to such a process laws and regulations will fit in with the economic, socio-cultural and political climate prevalent in society. But as technologies based on bio-molecular knowledge are developing in a globalize economy the developments may be less smooth.

Of course for every emerging technology the application of knowledge will display region-specific characteristics but the strong international dimension in economy, technology development, and trade ask for a supra-national dimension in the development of adequate regulation as well. This is true for the application of biotechnology in all sectors of the economy but at the moment it is perhaps most evident in relation to the use of modern biotechnology in agriculture and the food industry. The effects of the introduction of genetically modified organisms (GMOs) in these large scale production systems will not be held within national borders. The "co-development" of technology, "civil society", and regulations can no longer be taken for granted because there are a number of societies involved. We have to find out by and while doing this how this process can be orchestrated.

In the recent report "Genetic Engineering and Globalization" the COGEM, the advisory committee on genetic engineering to the Ministry of Housing, Spatial Planning and Environment in The Netherlands, reflected on the (often unintended) worldwide effects of national and European regulation with regard to genetic engineering. In the report they focused on the regulation of the cultivation of genetically modified (GM) crops and the resultant GM products.

56.7 Biotechnology, Agriculture, and Regulations

The cultivation of GM crops and the worldwide trade in the resultant GM products has increased from 1.7 million hectares in 1996 to 80.7 million hectares in 2004 and there appears to be no end yet to this tremendous rate of growth [6],[19]. At the moment GM agriculture is, for different reasons, being carried out on only a very small scale in Europe and Africa, while GM crops are being grown on a large scale in both North and Latin America, and GM agriculture is burgeoning in Asian countries. Of course these crops and their products are traded internationally as well.

At present, the cultivation of GM crops is mainly limited to herbicide-tolerant and insect-resistant maize, soy, cotton, and rape, but the cultivation of other crops with these and other properties can be anticipated. At the moment thousands of trials under field conditions are being carried out worldwide on tens of different crops with innumerable different properties. Examples are petunias with a modified bloom color, frost-tolerant potatoes, vaccine-producing alfalfa, and coffee with reduced caffeine content.

With regard to GM agriculture, the governmental tasks indicated above are translated in the Netherlands in particular and in Europe as a whole into a policy in which, in addition to the safety of food and the environment, the coexistence of different types of agriculture is taken care of and the freedom of choice of consumers and growers is guaranteed. But of course the cross-border nature of (the trade in) GM agricultural products means that national and European regulations can have (unwanted) effects in other parts of the world. On the other hand, practices and policies developed in other parts of the world will have consequences for Europe as well

For instance, strict regulatory requirements emanating from a European concern for mankind and the environment, societal resistance, and nationally shared ethical principles and norms can constitute a barrier to commercial development of GM crops for other countries. The European consumer's resistance to GM food products is for some producers in other parts of the world a major barrier to cultivating GM crops. The very limited extent of consumers' acceptance in Europe has resulted in regulations that are far more restrictive than those in other parts of the world. European regulations can lead to the adoption of western assessment regimes in other countries. This is not of necessity an intended effect but it can be a consequence of the standards set on imports which affect the country's trading position. It can also be a psychological effect: if they are so cautious in countries where the technology was developed then maybe their example should be followed. For instance, in Africa genetic engineering is applied to agriculture at only a minor scale. There are social, cultural and geographic reasons for that, but also European regulation with regard to GM crops may contribute.

The opinions on the usefulness of GM agriculture for developing countries differ. Some stakeholders state that GM agriculture has much to offer to developing countries such as resistance to plagues and insects, reductions in the use of pesticides (if these are used), harvest increase and drought tolerance. Others believe that GM agriculture has very little to offer to developing countries and will only increase their degree of dependence as GM agriculture is a form of industrialized farming that for the greater part is not attuned with the economic balances and socio-cultural beliefs in these countries. Industrialized agriculture produces for the world market and focuses on bulk crops and uniformity. Is countries where small-scale agriculture is predominant were to adopt the industrialized production model the loss of local agrarian know-how and the disappearance of locally adapted varieties could be a consequence. From the perspective of sustainable development a different approach to the development of agriculture, supported by a different form of biotechnology might be more attractive. Of course producers and citizens in developing countries should have both the right and the opportunity to make their own assessments and choices [9],[20],[24],[25],[30].

In Latin America the influence of opinions from within the EU is much smaller as there the US rather forms the frame of reference. GM crops are cultivated on a large scale in Latin America on the

basis of technology principally developed in the US. In Asian countries such as China and India the dependence on other countries is much less because of their own large markets and because of the fact that major developments of the own knowledge and technology have been set in motion by recent political developments. As a consequence these countries will develop their own GM crops and the accompanying regulatory regimes. In some aspects they are ahead of developments in Europe.

As to regulations relevant to GM agriculture with a supra-national dimension the following can be mentioned: the Carthagena Protocol on Biosafety (CPB, a supplementary agreement to the UN Biodiversity convention), the Codex Alimentarius (dealing with food safety) and the conventions within the framework of the World Trade Organization (WTO).

The CPB makes provisions for procedures for the supply of information of an exporting party to an importing party, in order that the latter can make a well-considered decision about the possible import of GMOs. It is the intention to promote the exchange of information about GMOs and regulations via a so-called Biosafety Clearing House and to help countries in the implementation of regulatory systems that contribute to the objectives of the CPB. Also the United Nations Environment Programme (UNEP) and the Global Environment Facility (GEF) offer help, such as the so-called UNEP-GEF Toolkit, to countries in their design of a National Biosafety Framework (NBF). However, this type of help has its drawbacks. It may lead to the institution of a complex and extensive system of regulation that does not tie in with the local needs and capacity. Also many countries involved have nothing to do with the cross-border movement of GMOs, or do not have at their disposal the means to maintain an administrative system such as NBF. Instead capacity-building should be adapted to suit regional resources and needs and should also take into account the local parties involved. In its report the COGEM states that technology and society shape each other in a process of co-evolution and when that is not taken into account during the transfer of regulatory concepts inefficient solutions will be the result. An approach in which the context of local policy is furthered in the development of regulatory structures could be far more promising.

56.8 Conclusions

The author wants to state that she sees the process of sustainable development as a race against time during which mankind will have to learn by and while doing to organize society and its processes and institutions in a way that is more sustainable than it is now. Individuals and organizations will have to develop the ability to think, communicate, learn and collaborate across the boundaries that divide different disciplinary, social and cultural perspectives. Some key notions in this respect are dialogue, mutual respect, creativity and willingness to change.It would be a shame not to use the potential of biotechnology in this context.

Nanotechnology: A New Technological Revolution in the 21st Century

Ronald Wennersten, Jan Fidler and Anna Spitsyna

Royal Institute of Technology, School of Energy and Environmental Technology,
Department of Industrial Ecology, Sweden

Abstract: Nanotechnology is going to be a major driving force behind the impending technological revolution in the 21st century. Both private and public sector spendings are constantly increasing. The size of the market for nanotechnology products is already comparable to the biotechnology sector, while the expected growth rates over the next few years are far higher. Nanotechnology manufacturing is a fundamentally new process in which structures are built from the bottom up, one atom at a time. Nanotechnology has the potential of producing new materials and products that may revolutionize all areas of life. Nanotechnology protagonists believe that nanotechnology will provide unsurpassed benefits for the society. Meanwhile, its antagonists believe that nanotechnology may pose serious health and environmental risks and advocate that the precautionary principle should govern the development and deployment of such products. Although it is difficult to predict precisely how nanotechnology will impact society, current understanding, under either the spectacular benefit or the serious risk scenarios, presages a huge impact on society in areas that include the environment, healthcare, energy, and electronics.

57.1 Introduction

The term “nanotechnology” describes a range of technologies performed on a nanometer scale with widespread applications across all sectors, from textiles to biosciences and consumer preparations such as cosmetics. Nanotechnology refers to several technologies of the very small, with dimensions in the range of nanometers and exploits specific properties that arise from structuring matter at a length scale characterized by the interplay of classical physics and quantum mechanics. Nanotechnology is an underlying technology ennabling other technologies.

Nanotechnology has been around for two decades, but the first wave of applications is only now beginning to break. It will affect everything from the batteries we use to the pants we wear to the way we treat cancer. The term “nannos” is a prefix that means “little old man”, “dwarf” in Greek. One nanometer (nm) is one thousand millionth of a meter. This comma, for instance, spans about half a million nanometers, a dollar bill is 100,000 nanometers thick, a human hair is about 80,000 nanometers wide, and a water molecule almost 0.3 nm.

The vision and inspiration for nanotechnology came from Nobel laureate Richard Feynman in a 1959 speech entitled “There's Plenty of Room at

the Bottom". His vision was that there are enough places on the molecular level that we could in future use a focused electron beam to write "the entire 24 volumes of the Encyclopedia Britannica on the head of the pin". He also saw the possibility to arrange the atoms one by one; in other words "bottom-up" manufacturing on the molecular level [1].

Nanotechnology starts at the bottom and builds up one atom at a time. Apart from making things that are very small, nanotechnology promises "absolutely perfect copies" of a device. Broadly speaking, nanotechnology may be divided into two areas: *nanomaterials*, and *nanodevices*. Norio Taniguchi of Tokyo University created the term "nanotechnology" in 1974 to describe the precision manufacture of materials with nanometer tolerances [2].

At the nano size familiar materials begin to develop odd properties when they are of nano size. If a piece of aluminium foil is torn into tiny strips, it will still behave like aluminium, even after the strips become so small that a microscope is needed to see them. But if one keeps chopping them smaller and smaller, at some point, 20 to 30 nm, the pieces can explode. Nano aluminium could be an additive to rocket fuel [3].

Not all materials change properties, but the fact that some do is an advantage; new materials can be engineered, such as plastic that conducts electricity and coating that prevents iron from rusting. The reason why substances behave differently at the nanoscale is because that is where the essential properties of matter are determined. If we arrange calcium carbonate molecules in a saw tooth pattern, for instance, we will get a fragile chalk. If the same molecules are stacked like bricks, they help form the layers of the tough shell of an abalone.

There is a growing interest in nanoscience and nanotechnology because they are seen as having the potential to bring changes in many fields of research and application. These emerging technologies meet with both optimism and pessimism among experts. Nanotechnology has the potential of producing new materials and products that may revolutionize all areas of life. Meanwhile, its critics believe that nanotechnology may pose serious health and environmental risks, and advocate that the precautionary principle should govern the development and deployment of such products. Although it is difficult to predict precisely how nanotechnology will impact society, current understanding, under either the spectacular benefit or the serious risk scenarios, presages a huge impact on society in areas that include the environment, healthcare, energy, and electronics.

Nanoscale materials have been used for decades in a range of applications. Modern industrial nanotechnology had its origins in the 1930s, in processes used to create silver coatings for photographic film; and chemists have been making polymers, which are large molecules made up of nanoscale subunits [3].

Today's nanotechnology, for example the planned manipulation of materials and properties on a nanoscale, exploits the interaction of three technological streams [3]:

- the control of the size and manipulation of nanoscale building blocks,
- the characterization of materials on a nanoscale (for example, spatial resolution, chemical sensitivity), and
- the understanding of the relationships between nanostructure and properties and how these can be engineered.

The properties of materials can be different on a nanoscale for two main reasons:

First, nanomaterials have, a relatively larger surface area than the same mass of material produced in a larger form. This can make materials more chemically reactive (in some cases, materials that are inert in their larger form are reactive when produced in their nanoscale form), and affect their strength or electrical properties.

Second, below 50 nm, the laws of classical physics give way to quantum effects, provoking optical, electrical, and magnetic behaviors different from those of the same material at a larger scale. These effects can give materials very useful physical properties such as exceptional electrical conduction or resistance, or a high capacity for storing or transferring heat, and can even modify biological properties, with silver for example becoming a bactericide on a nanoscale. These

properties, however, can be very difficult to control. For example, if nanoparticles touch each other, they can fuse, losing both their shape and those special properties—such as magnetism—that scientists hope to exploit for a new generation of microelectronic devices and sensors.

57.2 Top-down and Bottom-up Design

For assembling nanoscale materials and devices two approaches can be used: top-down and bottom-up. Bottom-up approaches means that smaller components arrange themselves into more complex assemblies, while top-down approaches means to create nanoscale devices by using larger, externally-controlled ones to direct their assembly.

The top-down approach often uses the traditional workshop or microfabrication methods where externally-controlled tools are used to cut, mill and shape materials into the desired shape and order.

Bottom-up approaches, in contrast, use the chemical properties of single molecules to cause single-molecule components to automatically arrange themselves into some useful conformation.

The current state-of-the-art in nanotechnology uses micro-electro-mechanical Systems (MEMS) processes to produce nanoparticles such as carbon nanotubes and buckyballs. MEMS manufacturing is a top-down method that starts by gathering the materials needed to manufacture the product, but many of the parts that make up the product are formed by chemical reactions, photolithography, and other lithographic techniques.

MEMS manufacturing is capable of producing features that are not visible to the human eye without the assistance of a microscope and may be capable of producing some of the same products that will be produced by nanotechnology in the future.

One eventual goal of nanotechnology is to use molecular manufacturing to individually place each atom. Although MEMS technology already produces objects in the range of 1–100 nanometers, molecular manufacturing will provide advantages over MEMS. Molecular manufacturing will produce nanomaterials with no impurities because atom placement is individually controlled. Molecular manufacturing requires nanodevices, as will be discussed below. Nanomaterials may also serve as the raw material for products manufactured using traditional or MEMS techniques.

Although nanomaterials hold great potential, nanodevices are where the true potential of nanotechnology lies. Currently, nanotechnology uses tools, such as scanning tunneling microscopes or atomic force microscopes, to arrange atoms one at a time. The process is slow, expensive, and limited in its potential to build from the bottom.

However, nanotechnology visionary, Eric Drexler [4], contemplating the marvels of the ribosome, foresees a vastly different method of building at the bottom. Drexler proposed an atomic assembler, similar to a robotic arm, capable of grasping a single atom and bonding it to other atoms. A microscopic robot arm receiving instructions, possibly from a computer, is the basis of molecular manufacturing.

Drexler [4] refers to a device capable of molecular manufacturing as a nanofactory. The first nanofactories are likely to be about the size of a desktop printer, requiring specialized feedstock, an external energy source, and an external computer. Inside the robot factory, the robot arm will arrange the feedstock into nanodevices. The devices produced by a nanofactory will be microscopic because a molecular fabricator, even with an assembler that works at a million cycles per second, produces only about a nanogram of product per year. Drexler proposes that a nanofactory should be capable of building the parts for additional nanofactories, so that multiple nanofactories can operate simultaneously to produce related parts that may be assembled into macroscopic objects [3].

However, the concept of assemblers and molecular manufacturing is not without its detractors. In a 2001 issue of Scientific America, Richard E. Smalley, 1996 Nobel Laureate in chemistry (co-discoverer of buckminsterfullerene), maintained that the atomic forces between atoms make it impossible for an assembler to precisely position atoms. He contends that putting “every atom in its place ... would require magic fingers” [4]. Smalley concedes that the ribosome does

precise and reliable chemistry, but that it "can occur only under water" and that "molecular manufacturing will forever be severely limited." To be sure, eminent scientists have aligned themselves on both sides of the debate and except for their rhetoric and the ribosome; there is no evidence that assemblers will ever be a reality.

57.3 Applications of Nanotechnology

An enormous improvement for a variety of product properties due to nanoscale effects has been achieved over the past few years; although a distinct onset of nanotechnology in the past cannot be defined. This apparent contradiction is based on the fact that today's common definitions of nanotechnology enclose long existing products, which are based, for example, on thin layers or small particles. Therefore, products that are either based on nanosized features or on nanoscale properties might just match the current "nano" requirements by chance. Wide-spread products like computer hard drives are indeed based on nanotechnology, but were not associated with the term "nano" when they were launched. Modern hard disk drives, with their enormous capacity of up to several 100 Gb would not be possible without the so called GMR effect (giant magneto resistance), which is based on the coupling of magnetic layers, separated by an ultra thin "nano"-spacer and was discovered in the late 1980s. Therefore, it is clear that the boundary between products related to the prominent term "nanotechnology" and others is fuzzy.

Besides the traditional fields of high technology, life sciences are expected to undergo a vivid change due to the impact of "nanobiotechnology". In biology the word "nanotechnology" is of particular importance; it is nature's intrinsic way to build on the nanometer scale molecule by molecule through self-organization. This "assembling" method is extremely efficient and may be helpful for the conservation of nature and natural resources. It is expected that the concept of "self-assembly" will be an approach for a sustainable development in the future. However, such futuristic concepts are far from being realized at present or in a medium term view.

The increasing need for energy in the world is accompanied by a surge in air and water pollution. Nanotechnology may provide solutions for improving renewable energy systems, such as fuel cells, solar cells or hydrogen storage, and help to foster their implementation in the future. Below the potential applications of nanotechnology for some sectors are given more in detail.

57.4 Applications in the Energy Sector

Breakthroughs in nanotechnology may provide technologies that will contribute to worldwide energy security and supply. A report published by Rice University (Texas) in February 2005 [4] identified numerous areas in which nano-technology may contribute to more efficient, inexpensive, and environmentally sound tech-nologies than are readily available. Although the most significant contributions may be to unglamorous applications such as better materials for exploration equipment used in the oil and gas industry or improved catalysis, nanotechnology is being proposed in numerous energy domains, including solar power; wind; clean coal; fusion reactors; new generation fission reactors; fuel cells; batteries; hydrogen production, storage and transportation; and a new electrical grid that ties all the power sources together.

The possible main contributions of nano-technology may be to:

- lower the costs of photovoltaic solar energy tenfold,
- achieve commercial photocatalytic reduction of CO_2 to methanol,
- create a commercial process for direct photoconversion of light and water to produce hydrogen,
- lower the costs of fuel cells between tenfold and a hundredfold and create new, sturdier materials,
- improve the efficiency and storage capacity of batteries and supercapacitors between tenfold and a hundredfold for automotive and distributed generation applications,

- create new lightweight materials for hydrogen storage for pressure tanks, liquid hydrogen vessels, and an easily reversible hydrogen chemisorptions system,
- develop power cables, superconductors or quantum conductors made of new nano-materials to rewire the electricity grid and enable long-distance, continental and even international electrical energy transport,
- reduce or eliminate thermal sag failures, eddy current losses and resistive losses by replacing copper and aluminium wires,
- develop thermochemical processes with catalysts to generate hydrogen from water at temperatures lower than 900 C° at commercial costs,
- create super strong, lightweight materials that can be used to improve energy efficiency in cars, planes and in space travel; the latter, if combined with nanoelectronics based robotics, possibly enabling space solar structures on the moon or in space,
- create efficient lighting to replace incandescent and fluorescent lights,
- develop nanomaterials and coatings that will enable deep drilling at lower costs to tap energy resources, including geo-thermal heat, in deep strata, and
- create CO_2 mineralization methods that can work on a vast scale without waste streams.

57.5 Environmental Applications

As applications of nanotechnology develop over time, they have the potential to help shrink the human footprint on the environment. This is important, because over the next 50 years, according to according to World Resources 2000 and United Nations press releases, the world's population is expected to grow by 50%, global economic activity is expected to grow by 500%, and global energy and materials use is expected to grow by 300%. So far, increased levels of production and consumption have offset our gains in cleaner and more-efficient technologies. This has been true for municipal waste generation, as well as for environmental impacts associated with vehicle travel, groundwater pollution, and agricultural runoff. Below is a short summary of how nanotechnology can create materials and products that will not only directly advance our ability to detect, monitor, and clean up environmental contaminants, but also help us avoid creating pollution in the first place. By more effectively using materials and energy throughout a product lifecycle, nanotechnology may contribute to reducing pollution or energy intensity per unit of economic output.

Examples of where nanotechnology can be used for environmental prevention are:

- synthetic or manufacturing processes that can occur at ambient temperature and pressure,
- the use of non-toxic catalysts with mini-mal production of resultant pollutants,
- the use of aqueous-based reactions thus avoiding organic solvent,
- building of molecules as needed –"just in time", and
- nanoscale information technologies for product identification and tracking to manage recycling, remanufacture, and end of life disposal of solvents.

Many promising features of nanoscaled objects have been identified, leading to superior product functionality and thus providing means for a better life. In general, nanotechnologically improved products rely on a change in the physical properties when the feature sizes are shrunk. Nanoparticles, for example, take advantage of their dramatically increased surface area to volume ratio. Their optical properties, for example fluorescence, become a function of the particle diameter. When brought into a bulk material, nanoparticles can strongly influence the mechanical properties, such as the stiffness or elasticity. Such "nanomaterials" will enable a weight reduction accompanied by an increase in stability and an improved functionality, such as "easy-to-clean", "anti-fog", "anti-finger-print" or "scratch-resistance", to name a few.

Other environmental contributions from nanotechnology can be selective membranes that can filter decontaminants or even salt from water, nanostructured traps for removing pollutants from industrial effluents, characterization of the effects of nanostructures in the environment, maintenance of industrial sustainability by significant reductions in materials and energy use, reduced sources of pollution, increased opportunities for recycling.

57.6 Other Areas of Applications

In the OECD report an overview is given [3] of the many domains where nanotechnology is expected to fundamentally change products and how they are produced over the next two decades.

Nanoscale materials, as mentioned above, have been used for a long time in several applications and are already present in a wide range of products, including mass-market consumer products. Among the most well known is a type of glass for windows which is coated with titanium oxide nanoparticles that react to sunlight to break down dirt. When water hits the glass, it spreads evenly over the surface, instead of forming droplets, and runs off rapidly, taking the dirt with it. Nanotechnologies are used by the car industry to reinforce certain properties of car bumpers and to improve the adhesive properties of paints.

Examples of fields from the above report which are expected to develop are given below.

Semiconductors and Computing

The computer industry is already working on a nanoscale. Although the current production range is at 90 nm, 5 nm gates have been proven in labs, although they cannot be manufactured yet. By 2015, semiconductor development priorities will have changed, as the focus shifts from scaling and speed to system architecture and integration, with user specific applications for bio-nanodevices, the food industry and construction applications. Another trend is the convergence between IT, nanotechnology, biotechnology, and cognitive sciences. The higher speeds at which information will be disseminated will change how we work with computers, and also perhaps how we deal with things like damaged nerves, possibly by developing direct interfaces with the nervous system and electronic circuits, so-called neuromorphic engineering, where signals are directly transmitted from a human organism to a machine.

Electronics and Communications

Recording using nanolayers and dots, flat-panel displays, wireless technology, new devices and processes across the entire range of communication and information technologies, factors of thousands to millions improvements in both data storage capacity and processing speeds and at lower cost and improved power efficiency compared to present electronic circuits are available today.

Chemicals and Materials

Catalysts that increase the energy efficiency of chemical plants and improve the combustion efficiency (thus lowering pollution emission) of motor vehicles, super-hard and tough (in other words not brittle) drill bits and cutting tools, “"smart” magnetic fluids for vacuum seals and lubricants are the examples.

Pharmaceuticals, Healthcare, and Life Sciences

Because of their small size, nanoscale devices can readily interact with biomolecules on both the surface of cells and inside of cells. By gaining access to so many areas of the body, they have the potential to detect disease and deliver treatment in new ways. Nanotechnology offers the opportunity to study and interact with cells at the molecular and cellular scales in real time, and during the earliest stages of the development of a disease. Since nanocomponents can be made to share some of the same properties as natural nanoscale structures, it is hoped that it will be possible to develop artificial nanostructures that sense and repair damage to the organism, just as naturally occurring biological nanostructures such as white blood cells do. Examples of potential applications are: drugs, gene and drug delivery systems targeted to specific sites in the body, bio-compatible replacements for body parts and fluids, self-diagnostics for use in the home, sensors for labs-on-a-chip, and material for bone and tissue regeneration.

Food and Agriculture

Nanotechnology is rapidly converging with biotech and information technology to radically change food and agricultural systems. Over the next two decades, the impacts of nano-scale convergence on farmers and food may even exceed that of farm mechanization or of the Green Revolution. Food and nutrition products containing nano-scale additives are already commercially available. Likewise, a number of pesticides formulated at the nanoscale are on the market and have been released in the environment.

Textiles

The textile industry may be affected quite heavily by nanotechnology, with some estimates market impact of hundreds of billions the next decade. Nanoscience already has stain-resistant and wrinkle-resistant clothing, and developments will focus on upgrading existing and performances of textile materials; "smart" textiles with unprecedented functions such as:

- sensors and information acquisition,
- multiple and sophisticated protection,
- health-care and wound-healing functions, and
- self-cleaning and repair functions.

Manufacturing

Precision engineering based on new generations of microscopes and measuring techniques, new processes and tools to manipulate matter at an atomic level, nanopowders that are sintered into bulk materials with special properties that may include sensors to detect incipient failures and actuators to repair problems, chemical-mechanical polishing with nanoparticles, self-assembling of structures from molecules, bio-inspired materials and biostructures.

Space Exploration

In this sphere, we may see developments of lightweight space vehicles, economic energy generation and management, and ultra small and capable robotic systems.

57.7 Market Prospects

The first winners in the nanotechnology industry are likely to be the manufacturers of instruments allowing work on a nanoscale. According to market researchers, the nanotechnology tools industry ($245 million in the US alone) will grow by 30% annually over the next few years. The following projected three-phase growth path seems credible [4]:

- In the present phase, nanotechnology is incorporated selectively into high-end products, especially in automotive and aerospace applications.
- By 2009, commercial breakthroughs will unlock markets for nanotechnology innovations. Electronics and IT applications will dominate as microprocessors and memory chips built using new nanoscale processes come on to the market.
- From 2010 onwards, nanotechnology will be commonplace in manufactured goods. Health care and life sciences applications will finally be significant as nano-enabled pharmaceuticals and medical devices emerge from lengthy human trials.

As the OECD survey emphasizes, most statistical offices do not collect data on nanotechnology R&D, human resources or industrial development, in part because nanotechnology remains a relatively new field of science and technology, and also because of its interdisciplinary and cross-sectorial character. Given this, estimates of potential nanotech markets tend to come from private sources such as specialized consultancy firms that survey a wide number of actors in the field. Lux Research, for example, states that:

"Sales of products incorporating emerging nanotechnology will rise from less than 0.1% of global manufacturing output today to 15% in 2014, totalling $2.6 trillion. This value will approach the size of the information technology and telecom industries combined and will be ten times larger than biotechnology revenues". Insurers SwissRe echo this: "Sales revenues from products manufactured using nanotechnology have already reached 11-digit figures and are projected to

generate 12-digit sums by 2010, even 13-digit sums by 2015."

57.8 Nanotechnology for Sustainability

Nanotechnology offers the potential, as many other technologies, to be used for the benefit of human beeing or for destructive means. We can only speculate what the actual future of nanotechnology will be.

The term "sustainability" can be described as the ability to achieve economic growth with protection of natural systems and provision of a high quality of life for people in the long run. As was mentioned above, technology plays an important role in the transition towards sustainable development, as it is one of the most significant ways in which we interact with our environment. We use technologies to extract natural resources, to modify them for human purposes. We need to develop and use technologies with sustainability in mind.

To be able to assess and understand whether a technology is sustainable or not it is important to provide an assessment against a number of different criteria, which are not actually developed yet.

To create such criteria, firstly we need to define, what sustainable technology is. By technologies we understand not just individual technologies, but total systems, which include processes goods and services, equipment, and organizational and managerial procedures. The technology that fits well with the goal of sustainable development and has the potential to protect or pollute the environment less, use resources in sustainable manner, recycle more wastes and products, and promotes a societal move towards sustainability; this is sustainable technology.

The evaluation criteria for sustainable technologies require different indicators that cover all sustainability aspects:

1. Social and economic conditions.
2. Productive capacity and production organization.
3. Ecosystem health.

One way of identifying the potential of nanotechnology, regarding sustainability effects is to use the criteria developed by the UN called the millennium development goals (MDG):

1. Eradicate extreme poverty and huger.
2. Achieve universal primary education.
3. Promote gender equality and empower women, which means to eliminate gender disparities in primary and secondary education.
4. Reduce child mortality, *i.e.*, reduce the number of children who die from water-borne diseases.
5. Improve maternal health, *i.e.*, reduce the ratio of maternal mortality.
6. Combat HIV/AIDS, malaria, and other diseases, *i.e.*, to stop the spread of major diseases.
7. Ensure environmental sustainability, *i.e.*, integrate the sustainable development principles into country programs and policies, stop the loss of environmental resources. Archive the improvement in lives by reducing the proportion of people without access to safe drinking water.
8. Develop a global partnership for development, *i.e.*, develop open and rule-based trading.

Following the described potentials of nanotechnology the impacts from nanotechnology could be on goals 1, 4, 6 and 7:

1. Nanotechnology has the potential to bring major improvements in the living standards of people in the developing world through the development of technologies within the agriculture and food sector. As with GMO this is, of course, dependent on who will control the technology, if it will be available for poor countries without too high costs.

4. Two million children die each year from water-related diseases, such as diarrhea, cholera, typhoid, and schistosomiasis, which result from a lack of adequate water sources and sanitation. Nanotechnology offers the potential of developing new and cheap water treatment technologies.

6. New methods for prevention, diagnosis and treatment of diseases. The Australian company,

Starpharma™ is developing a HIV microbicide gel, based on dendrimer nanotechnology, that will remain effective when applied by women up to four hours in advance of sexual intercourse, and the Austin Research Institute has conducted successful trials into nano-vaccines for malaria. Nanotechnologies include the "lab-on-a-chip", which offers all the diagnostic functions of a medical laboratory, and other biosensors based on nanosized tubes, wires, magnetic particles and semiconductor crystals. These inexpensive, hand-held diagnostic kits detect the presence of several pathogens at once and may be used for wide-range screening in small peripheral clinics.

7. Air pollution remediation: including nanotech-based innovations that destroy air pollutants with light; make catalytic converters more efficient, cheaper and better controlled; detect toxic materials and leaks; reduce fossil fuel emissions; and separate gases.

57.9 Risks to the Environment and Human Health

The potential risk with nanomaterials concerning negative effects on the environment and human health is another aspect of trying to assess it from a perspective of sustainable development. Here we can draw many conclusions from the experiences around genetically modified organisms (GMO). We also all have in mind the story of DDT where the initial positive effects ended in an environmental disaster.

Nanotechnology, is now maturing rapidly with more than 300 claimed nano-technology products already on the market [4]. Yet concerns have been raised that the very properties of nanostructured materials that make them so attractive could potentially lead to unforeseen health or environmental hazards. Along with the discussion of their enormous technological and economic potential, a debate about new and specific risks related to nanotechnologies has started. The catch-all term "nanotechnology" is so broad as to be ineffective as a guide to tackling issues of risk management, risk governance and insurance. A more differentiated approach is needed regarding all the relevant risk management aspects.

As it is stated in the OECD report [4] the spectre of possible harm—whether real or imagined—is threatening to slow the development of nano-technology unless sound, independent, and authoritative information is developed on what the risks are, and how to avoid them. In what may be unprecedented pre-emptive action in the face of a new technology, governments, industries, and research organizations around the world are beginning to address how the benefits of emerging nanotechnologies may be realized while minimizing potential risks.

In particular the health, environmental, and safety risks related to free rather than fixed manufactured nanoparticles have been identified. There is already a recognized health risk. Epidemiological studies on ambient fine and ultrafine particles incidentally produced in industrial processes and from traffic show a correlation between ambient air concentration and mortality rates. The health effects of ultrafine particles on respiratory and cardiovascular endpoints highlight the need for research also on manufacture nanoparticles that are intentionally produced.

The implications of the special properties of nanoparticles with respect to health and safety have not yet been taken into account by regulators. Size effects are not addressed in the framework of the new European chemicals policy REACH. Nanoparticles raise a number of safety and regulatory issues that governments are now starting to tackle. A review of current legislation and continuous monitoring by the authorities is needed.

At present, the exposure of the general population to nanoparticles originating from the dedicated industrial processes is marginal in relation to those produced and released unintentionally such as through combustion processes. The exposure to manufactured nanoparticles is mainly concentrated on workers in nanotechnology research and nanotechnology companies. Over the next few years, more and more consumers will be exposed to manufactured nanoparticles. Labeling requirements for nano-particles do not exist. It is inevitable that in future

manufactured nanoparticles will be released gradually and accidentally into the environment. Studies on biopersistence, bioaccumulation and ecotoxicity have only just started.

With respect to health, environmental and safety risks, almost all concerns that have been raised are related to free, rather than fixed manufactured nanoparticles. The risk and safety discussion related to free nanoparticles will be relevant only for a certain portion of the widespread applications of nanotechnologies. In initial studies, manufactured nanoparticles have shown toxic properties. These can enter the human body in various ways, reach vital organs via the blood stream, and possibly damage tissue. Due to their small size, the properties of nanoparticles not only differ from bulk material of the same composition but also show different interaction patterns with the human body. A risk assessment for bulk materials is, therefore, not sufficient to characterize the same material in nanoparticulate form.

57.10 Conclusions

According to its advocates nanotechnology offers an immense potential in many industrial sectors, *e.g.*, in energy and environmental areas. Following these positive evaluations of the potentials of nanotechnology it should lead to major contributions to a more sustainable development of our industrialized societies. The prospects for controversies over nanotechnology are very dependent on the uses to which it is put. Addressing the underlying governance issues will be the key issues. One of the most intelligent ways to address this is to dedicate further research to widely shared goals that are amenable to technological innovation like climate change and to take on board the lessons from a real engagement with public concerns. The risk is that large multinational companies will control nanotechnology and that the public influence will be very limited. For those involved in scientific policy making and funding this may be uncomfortable, but as recently pointed out "we cannot carry on ignorantly lurching from one mess to the next".

Many experiences show that the most fruitful way of handling potential conflicts is to use upstream conflict resolution that is to handle potential conflicts before they become intractable. This will demand more research on the environmental, health, social, and economic impacts of nanotechnology. The problem, however, is that the ratio of research money going into these areas compared to into the pure technological sector is very low. Today there is a positive attitude to nanotechnology and we can see products marketed as "contains nanoparticles". We only need some products showing toxic properties to drastically change such a positive attitude among the public. At the end of the 19th century there were found labels on spring water bottles saying "contains natural radioactivity". Who would use this today?

An Overview of Reliability and Failure Mode Analysis of Microelectromechanical Systems (MEMS)

Yuanbo Li and Zhibin Jiang

Department of Industrial Engineering and Management
School of Mechanical Engineering, Shanghai Jiao Tong University
800 Dong Chuan Road, Min Hang District, 200240 Shanghai China

Abstract: The reliability issues concerning on microelectromechanical systems (MEMS) have steadily developed in recent years. One of the processes to understand MEMS reliability is to know the failure modes of these microdevices. In this chapter, we seek to report on both well known and unknown failure modes of MEMS. Most of the failure patterns are the same in nanoelectromechanical systems (NEMS), because NEMS followed a developmental path similar to that of MEMS in functional design, materials, and fabrication. Therefore, the existing results of MEMS failure modes can be used as a reference to nano-scale system reliability research. The failure modes discussed in this chapter contain stiction, wear, fracture, crystallographic defect, creep, degradation of dielectrics, environmentally induced failure, electric related failure, parasitic capacitance, dampening effects, delamination, and packaging.

58.1 Introduction

Reliability is the characteristic of a device concerning its ability to achieve specified requirements under well-defined conditions over a given period of time [1]. The goal of the reliability process is to understand the effect of design, processing, and post-processing on the device lifetime. Thus, issues on MEMS reliability are seeking to discover numerous methods and new technologies to increase the lifetime of MEMS.

In this chapter, we first provide a brief overview of MEMS and its reliability research methodologies, and itemize a list of MEMS failure modes that are commonly encountered.

Then we particularly discuss stiction, wear, fracture, crystallographic defect, creep, degradation of dielectrics, environmentally induced failure, electric related failure, parasitic capacitance, dampening effects, delamination, and packaging.

58.2 MEMS and Reliability

A variety of MEMS devices have been produced and some are commercially used in biomedical, aerospace, IT, industrial, defense, and automobile applications, such as accelerometers and digital micromirror devices, which were sold in 85 million units and $400 million from 2001 to 2002. These technologies allow numerous novel designs to be

Table 58.1. MEMS component categories based on their applications

Name	Definition
Micro sensors	Devices designed to detect physical or environmental changes
Infrared sensors; pressure sensors, inertial sensors, accelerometers, gyroscopes, chemical sensors, gas sensors, motion, thermal, and optical sensors.	
Micro actuators	Devices designed to activate or stimulate other MEMS component devices
Electrostatic actuators, thermal stimulus actuators	
Radio frequency (RF) MEMS	Devices used to switch, transmit, filter, and manipulate radio frequency (RF) signals
Metal contact switches, tunable capacitors, tunable filters, micro-resonators, RF switches	
Optical MEMS	Devices designed to direct, reflect, filter, or amplify light
Optical reflectors, micro-mirrors, optical switches, attenuators	
Micro-fluidic MEMS	Devices designed to interact with fluid-based systems
Pumps; Valves; Channels.	
Bio MEMS	Devices designed to interact with biological samples such as proteins, biological cells, medical reagents, *etc*.
DNA chips, microsurgical instruments, intra-vascular devices, laprascopic procedures, microfluidic chips	
Power MEMS	Devices designed to generate and store on-chip power or energy for portable systems
Microscale turbochargers, power generators, micro thrusters	
MEMS-based data storage systems	Small storage systems with large capacity
Micro-positioning and tracking devices, optical, thermal, or atomic force data tracks	

developed, and these new products will probably have serious economic, social, environmental, and military implications. Their names and applications are showed in Table 58.1 [2],[3].

Reliability issues are becoming increasingly important as MEMS devices shrink in size and become more complex, because failures are discovered at a late phase of fabrication, which causes high costs and waste of manufacturing resources. It is essential to reconsider reliability aspects from the traditional reactive way to the proactive way. In this chapter, we pay more attention to the failure physics approach. This is due to the fact that failure modes are governed by mechanical, electrical, thermal, and chemical processes or a combination of them all. Reliability of microsystems is dependent on their structure, material properties, fabrication process, and the life cycle environment. By understanding these possible failure modes, potential reliability problems can be identified and solved. Material design, characterization, and process evaluation therefore play an important role in assuring product reliability. A general scheme of the methodology is presented in Figure 58.1 for the study of micro-system reliability issues.

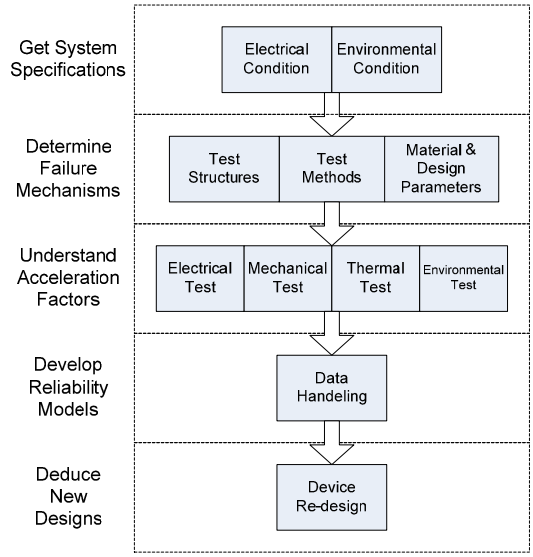

Figure 58.1. Scheme of microsystem reliability issues analysis methodology

58.3 MEMS Failures Mode and Mechanism Analysis

As mentioned above, a critical part of under-standing the reliability of any system comes from

Table 58.2. MEMS component categories based on their application

Failure modes	Failure mechanisms
Stiction	•Capillary forces •Van der Waals molecular forces •Casimir forces •Hydrogen bridging (H-bridging) • Electrostatic forces
Wear	•Adhesion •Abrasion •Corrosion •Friction
Fracture	•Stress induced bending, shearing, torsional •Shock induced •Fatigue
Crystallographic defect	•Point defects •Dislocations •Planar defects •Bulk defects
Creep	•Applied stress •Intrinsic stress •Stray stresses (thermal, residual)
Degradation of dielectrics	•Leakage •Charging •Breakdown
Environmentally induced failure	•Vibration •Shock •Humidity effects •Radiation effects •Contamination •Temperature changes
Electric-related failures	•Electrostatic discharge (ESD) •Electrical overstress (EOS) •Electromigration •Electrical breakdown •Electromagnetic pulses (EMP)
Packaging reliability	•Hermeticity and vacuum maintenance •Thermal issues
Other failure modes	•Parasitic capacitance •Dampening effects •Delamination

understanding the possible ways in which the system may fail. In MEMS, there are several failure modes that have been found to be the primary sources of failure within devices. In this section, we will give a short overview of the most common encountered failure modes and their modes.

Most MEMS are designed with some basic parts, such as cantilever beams (single side clamped, double side clamped), membranes (either closed at the sides to another structural member, or as a free floating plate), springs (often doubling as cantilever beams), hinges, *etc*. Unassailably, these elements often suffer from the same degradation or failure modes, regardless of their application. A list of common degradation or failure modes of MEMS is given in Table 58.2.

58.3.1 Stiction

One of the most important and almost unavoidable problems in MEMS is stiction, which was first reported in 1950 by Bowden and Tabor. Stiction is the adhesion of contacting surfaces due to surface forces, which mainly contain capillary forces, van der Waals molecular forces, Casimir forces, hydrogen bridging, and electrostatic forces [4].

The sticion problem of MEMS can be divided into two categories, one is release-related stiction and the other is in-use stiction [5]. Release-related stiction occurs during the process of the sacrificial layer removal in fabrication of microstructures, and such stiction is caused primarily by capillary forces.

In-use stiction usually occurs when micro-structures are exposed to a humid environment [6]. The relation between the capillary stiction force and the relative humidity is given in Figure 58.2. The model of single side clamped cantilever beams sticking to the substrate over a certain length at the

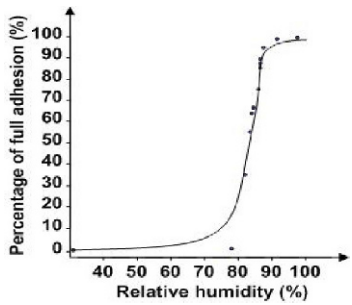

Figure 58.2. Function between adhesion and relative humidity [11]

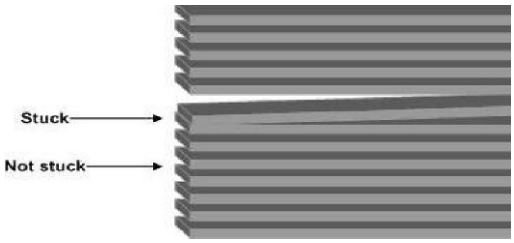

Figure 58.3. Cantilever beams stuck at the free end [12]

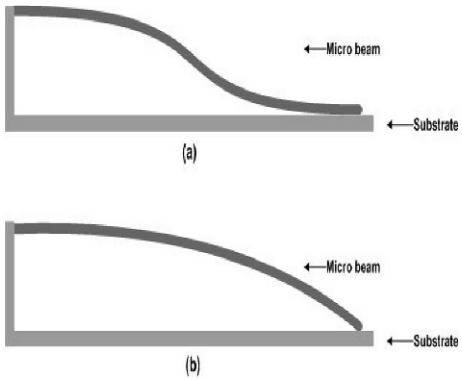

Figure 58.4. (a) S-shaped beam and (b) arc-shaped beam [8]

tip was used to calculate the adhesive forces (Figure 58.3). Yee *et al*. [7] later modifications to the model to include residual stress gradients in the free-standing thin film beams. De Boer [8],[9] and [10] first distinguished two kinds of adhered beams (Figures 58.4(a) and (b)): the deflected beam can be S-shaped or arc-shaped.

Van der Waals forces will become important for the adhesion behavior when the surfaces of the MEMS device are in a completely waterless environment, or when hydrophobic surfaces are used. If there is water between the surfaces, capillary forces will completely dominate the van der Waals forces, unless the surfaces are exceptionally smooth.

The Casimir force is the attractive pressure between two flat, parallel metal plates placed very near to each other in a vacuum. The Casimir force is reduced to the so-called nonretarded van der Waals force when the separation between the metallic surfaces is small compared to the characteristic wavelength of their absorption spectra [13]. Svetovoy *et al.* [14], Pinto [15] and Lamoreaux [16] reported calculations of the Casimir force. Sernelius *et al*. [17] complemented some flaws in Lamoreaux' findings.

H-bridging may increase the surface interaction energy, when MEMS surfaces are covered with OH bonds. When the ambient temperature is below 200°C, a surface with molecules of H-bridging will certainly be a hydrophilic surface, which will intrigue significant capillary condensation, unless the relative humidity is extremely low [18]. From wafer bonding experiments, Spierings *et al*. [19] and Backlund *et al*. [20] calculated that the adhesion energy was between 0.6 Jm^{-2} and 0.27 Jm^{-2} based on this bonding model. Legtenberg *et al*. calculated, for Si MEMS, that adhesion energies for flat surfaces are between 0.1 Jm^{-2} and 0.3 Jm^{-2}. Due to the surface roughness, the real interaction energy is much lower and H-bridging may only be observable for hydrophilic, OH terminated surfaces in a waterless environment [18].

Theoretically, stiction due to electrostatic forces can be categorized as temporary electrostatic charging and permanent charge accumulation. Temporary charging can occur during processing or operation as a result of differences in contact potential, tribocharging of rubbing surfaces, and ion trapping in oxide layers [21]. Permanent charging is not expected due to these effects because the non-equilibrium charging will relax in time [22].

58.3.2 Wear

Wear occurs when the material is removed from a solid surface as the result of mechanical action [23]. Wear involves not only the mechanical properties and chemistry of the objects in contact, but also the pressure, the adhered lengths, and the interfacial velocity, as well as the lubrication condition under which these objects make contact [24]. Wear can be categorized into three broad branches: adhesive wear, abrasive wear, and corrosive wear.

Adhesive wear occurs when one surface pulling fragments off of another surface while they are sliding. The surface forces finally resulting adhesion originate from a number of attractive or repulsive forces, including capillary, van der Waals, electrostatic forces and so on. When studying the adhesion forces and contact types, the sub-

boundary lubrication (SBL) adhesion model, the sidewall adhesion model [25], the elastic-plastic model [26], adhesive contact model, and the three-dimensional fractal surface geometry model [27] are usually used. Experiments show that the adhered length, rest time, relative humidity, temperature, and sliding velocity of a micro-cantilever can affect the adhesion forces between two contacting surfaces [28],[29]. Ali and Phinney [28] indicated that only beams that have adhered lengths during actuation smaller than 0.4–0.5 of their length are able to free themselves after the actuating voltage is removed. A study at Sandia National Laboratories found that wear related failure rates can be described by the lognormal and the Weibull models.

Abrasive wear occurs when a hard, rough surface slides on top of a softer surface and strips away underlying material. While less prevalent in MEMS than adhesive wear, it can occur if particulates are caught in microgears and this can tear a surface apart. Abrasive wear was calculated on the basis of statistical data and elaborated formulas have been given [30],[31] and [32].

Corrosive wear occurs when two surfaces chemicall Corrosive wear occurs when two surfaces chemically interact with one another, and the sliding process strips away one of the reaction products. This type of wear may cause failure in chemically active MEMS. Certain types of microfluidic systems and biological MEMS are susceptible to corrosive wear. Ovchinnikov and Pochtman [33] specifically reviewed this field. Zwierzycki and Stachowiak [34] discussed some mathematical models describing corrosive and mechanical wear, and compared their model with others.

Friction becomes dominant over the inertial and gravitational forces when the device size shrinks. The important investigated tribological properties of MEMS include the adhesive force and friction force dependence on operating parameters such as rest time and sliding velocity, and environmental conditions such as relative humidity and temperature [29].

58.3.3 Fracture

One of the most important and almost unavoidable problems in MEMS is fracture. Fracture is most likely to occur in structural beams with long thin pieces of material that often serves as the supporting basis for a structure, which are a basic building block of most MEMS devices. Stress and shock are recognized as the two factors that induce fracture. It has been investigated that stress induced fracture is due to three ways things: bending stress [35],[36], shearing stress [37],[38] and torsional stress [39].

When analyzing bending stress on a structural beam (with one or two sides clamped), the critical issue is to understand how the beams bend under different loadings. The most common method to determine this involves the Euler–Bernoulli equation. When calculating the shearing stress, the average shearing stress and the vertical shear in a section of a beam should be calculated. When calculating torsional stress, it is useful to relate a torque to the angle of twist, also the length of the beam, the modulus of rigidity, the longer side of the surface and the shorter side of the surface. When analyzing shock induced fracture, we can refer to shock impact as an environmentally induced failure.

Fatigue is caused by the cyclic loading of a structure below the yield or fracture stress of a material, which is shown to be a major failure mechanism in polysilicon MEMS structures [40]. This loading leads to the formation of surface microcracks that cause the slow weakening of the material over time and create localized plastic deformations. Doubly clamped silicon micro-components models are used in the research. Recent research reported that water and water vapor can also accelerate fatigue processes in Si MEMS structures, ultimately leading to premature fracture of polysilicon components under cyclic loading conditions [41]. Stress cycles, local micro-cracking originating on the surface of silicon films create tensile residual stress, which strongly influence the fatigue strength [42]. Another fatigue mechanism termed reaction-layer fatigue suggests that fatigue of silicon-based microfilms occurs through a process of sequential, mechanically

induced oxidation and environmentally assisted cracking of the surface layer of the material. This progressive accumulation of fatigue damage is accompanied with a decrease in the stiffness of microfilms of silicon materials.

58.3.4 Crystallographic Defects

Many materials used for MEMS are produced by means of crystalline methods, which may induce many kinds of defects, which are recognized as crystallographic defects. Crystallographic defects may be classified as point defects, dislocations, planar defects, and bulk defects.

Point defects are departures from symmetry in the alignment of atoms in a crystal that affects only one or two lattice sites. These defects are created in semiconductors during growth, where their formation is governed by thermodynamics and growth kinetics [43],[44]and [45]. Point defects are categorized into the following groups: vacancies, interstitial, point replacement, impurities, anti-site defects, and complexes [45],[46]. A dislocation is a one-dimensional array of point defects in an otherwise perfect crystal and can be observed using transmission electron microscopy, field ion microscopy, and atom probe techniques. They occur when a crystal is subjected to stresses that exceed the elastic limits of materials. The two basic types of dislocations are screw dislocation and the edge dislocation caused by the termination of a plane of atoms in the middle of a crystal. Planar defects have three types of defects called grain boundaries occurring where the crystallographic direction of the lattice abruptly changes, anti-phase boundaries occurring in ordered alloys, and stacking faults occurring in a number of crystal structures. Bulk defects contain voids and impurities.

58.3.5 Creep

Creep, the slow movement of atoms under mechanical stress, is expected to be one of the major reliability problems for certain types of MEMS, such as RF MEMS switches, especially at high RF powers.

Recent research reported that both increases in temperature and stress are shown to increase the creep rate. According to Tregilgas' report, the creep effect in Al thin films is so large that other materials should be found to replace it. In order to achieve a high melting point where the probability of creep is low, a number of Al compounds have been developed, such as Al_3Ti, AlTi, AlN and a mixture of Al_3Ti and AlN [47]. Modlinski *et al*. used substrate curvature measurements to study the creep properties of Al, $Al_{98.3}Cu_{1.7}$, $Al_{99.7}V_{0.2}Pd_{0.1}$ and $Al_{93.5}Cu_{4.4}Mg_{1.5}Mn_{0.6}$ films using isothermal tensile stress relaxation [48],[49], and [50]. They found that $Al_{93.5}Cu_{4.4}Mg_{1.5}Mn_{0.6}$ is the alloy that is most resistive to creep. Tuck *et al*. [51] investigated creep in polysilicon at high temperatures under stress. They showed that with the appropriate temperature and stress levels, the material begins to creep and the data follow a typical curve as shown in Figure 58.5. The strain *versus* time curve illustrates three stages of creep in polysilicon, the transient creep region, the steady state strain region, and the strain acceleration region. The first stage is identified by a continuously decreasing strain rate. The second stage has a constant strain rate due to the two competing processes of strain hardening and recovery. The third stage ultimately leads to failure, which is characterized by grain boundary separation, internal crack, cavities, and possibly necking in the deformation region.

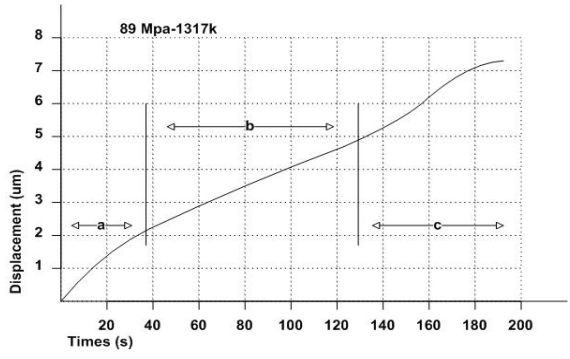

Figure 58.5. A typical creep curve illustrating three stages of creep in polysilicon [51]

Stray stresses are a failure mechanism that is endemic to thin film structures. In MEMS, small

stresses will cause noise in sensor outputs and large stresses will lead to mechanical deformation. Thermal and residual stresses are the two sources of stray stress in MEMS.

Thermal stress is a process-induced factor caused by bimetallic warping. Residual stresses are a result of the energy configuration of thin films. If these films are not in their lowest energy state, residual stress can either shrink or expand the substrate. While there are high-temperature techniques for annealing out residual stress, these methods are not always compatible with MEMS processing.

58.3.6 Degradation of Dielectrics

A well-known problem with MEMS containing dielectric layers is the charging that may occur in the dielectric layer. Silicon dioxide and silicon nitride coatings are commonly used as dielectric layers for short-circuit protection in capacitive silicon microsensors and microactuators, as well as RF MEMS [52].

The most obvious source of dielectric charging is ionizing (nuclear) radiation, the effect of which has been tested on electrostatic, electrothermal and bimorph actuators. The two types of radiation used in experiment are low-energy X-ray and Co-60 gamma. For electrostatic actuators, they exhibited a decrease in capacitance and thereby an increase in voltage per deflection when subjected to the low-energy X-ray radiation environment but no changes in Co-60 gamma environment. For the electrothermal actuators, neither X-ray nor gamma irradiation affected their operation [53].

In order to prevent degradation of the dielectrics phenomenon, new coating materials, the high-k gate dielectric materials are used. They are dielectric materials with a dielectric constant greater than the dielectric constant of silicon dioxide, normally k > 4. A review of high-k dielectrics reliability issues has been made by Ribes *et al*. [54].

The separate consideration of soft gate oxide breakdown (SBD), progressive (PBD), and hard (HBD) breakdown events is necessary to set up an adequate application specific reliability assessment methodology. SBD and the HBD are localized and randomly distributed all over the device area [55]. SBD and the HBD both coexist, soft and hard breakdowns being spatially uncorrelated. The PBD is the initiator of SBD or HBD. Various breakdown occurrences are shown in Figure 58.6. The first stack wear-out is the interfacial layer breakdown. It is characterized by a progressive breakdown (PBD). The charge to breakdown of this event is dependent on the gate current and thuso to the high-k layer thickness. The gate current increases until second breakdown, which can be soft (SBD) or hard (HBD) depending on the spot size. Both breakdowns have been identified as the breakdown of the high- layer [54].

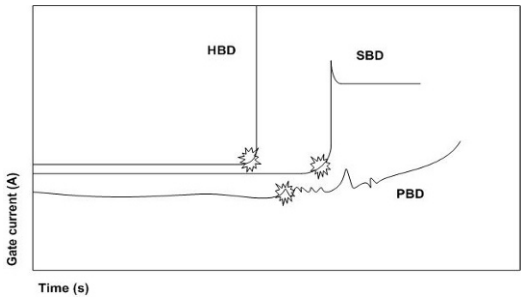

Figure 58.6. The three different occurrences of breakdown (HBD, SBD, PBD) [54]

Wen Luo, Yue Kuo and Way Kuo [56] investigated the intrinsic reliability of some promising high-k gate dielectric candidates, TaO_x, HfO_x, ZrO_x, Hf-doped TaO_x, and Zr-doped TaO_x thin films. The result of their research indicated that high-*k* thin films showed a lower leakage current than SiO_2, but they had the disadvantage of a higher relaxation current. Additionally, measurements of PZT/HfO_2 multi-layered dielectrics showed the expected high dielectric constant for high switching isolation and low leakage current for very low operating power consumption. From bias-stressing tests, PZT/HfO_2 was verified as having significantly better dielectric characteristics in very low charging effects and a long lifetime in comparison to Si_3N_4 [57].

58.3.7 Environmentally Induced Failure

Environmentally induced failure mechanisms are external effects that can also cause failure in

MEMS. The most important failures induced by environment are vibration, shock, humidity, and radiation.

For micromirror clamped situation, when the vibration frequencies are between 200 Hz and 10 kHz, it works properly [58],[59]. When the actuator is not clamped, vibration causes motion in the actuator promoting the surfaces to rub, and this generates wear debris leading to failure [60]. To ensure accurate detection and measurement of MEMS vibration, many vehicles and testing methods have been invented and fabricated, for example, the piezoelectric actuator (PZT) method [61], optical microscopy combined with image processing [62], laser TV holography [63], and spin-valve sensors [64].

Shock differs from vibration in that it is a single mechanical impact instead of a rhythmic event. Exposure of MEMS to shock environments can occur during fabrication, deployment, or operation. These may lead to failures in different modes, inducing fracture, delamination, and stiction, especially in microactuators [65]. When analyzing the failure modes of shock loaded MEMS, a single clamped beam model (microstructures attached to elastic substrates) [66], clamped-clamped beam model (microstructures attached to solid surface) [67], and dynamic finite element analysis (FEA) method [68],[69] are used.

Humidity can induce brittle fatigue, adhesion, and wear. As mentioned before, adhesion increases exponentially with relative humidity [70]; and wear debris decreases as the humidity increases, because when the humidity level is high, the formation of surface hydroxides may act as a lubricant [71].

The knowledge of radiation effects on MEMS is still limited. Many researchers have studied the radiation effect on thermal actuators [72], accelerometer [73],[74], actuators [53]. Recent work indicates that because dielectric layers trap charged particles, creating a permanent electric field under radiation environment, radiation-tolerant designs must limit the use of dielectrics, which could be a challenging design problem [73],[74].

Contamination due to inappropriate packaging may interfere with the operation of moving MEMS structures [75]. The effects of random contamination have been modeled in the CAD program CARAMEL (contamination and reliability analysis of microelectromechanical layout) [76]. The results of CARMEL simulations indicate that a wide range of defective structures are due to the presence of particulate contaminations [76],[77]. These particles have been known to electrically short out MEMS and can also induce stiction and adhesion. Defects induced by particulates are classified into three categories: surface, anchor, and broken structures [78]. Other forms of contamination include ionic contamination [79] and lead contamination [80].

Temperature changes have serious effects on MEMS. High temperatures may cause buckling of the switch structure, which may lead to device failure. By contrast, low temperatures may result in an undesirably high pull-in voltage, which can compromise the device life by charge build-up or lead to other failure modes [81],[82], and [83].

58.3.8 Electric-related Failures

Another failure mechanism is electric charge induced failure. It includes four failure models: electrostatic discharge (ESD), electrical overstress (EOS), electromigration, electrical breakdown, and electromagnetic pulses (EMP).

ESD is the transfer of electrical charge between two bodies at different potentials, either through direct contact or through an induced electrical field. Such an event accounts for more than 25% of failures in microelectronic devices, including gate oxide breakdown, junction spiking, and latch-up [84]. In general, ESD can be characterized by the different origins of the charges generated and thus by three different models: the human body model (HBM), the charge device model (CDM), and the machine model (MM) [85]. Preventing ESD damage to components involves two approaches: (1) control of the manufacturing environment to suppress electrostatic charge generation and damaging discharge events, and (2) modification of the component design to increase the ability to withstand an ESD event [86].

EOS is caused by thermal overstress to a component's circuitry. The amount of damage caused by EOS depends on the magnitude and

duration of electrical transient pulse widths, which can be broadly classified into long (>100 ms) and short (<100 ms) types. For short pulse widths, the most common failure mode is junction spiking; for long electrical pulse widths, the most common failure modes are melted metallization and open bond wires [87]. Preventing EOS damage involves three approaches: (1) ensure proper testing of components and boards; (2) use quality power supplies with the following features: over voltage protection, proper heat dissipation, use of fuses at critical locations; (3) adhere to a strict equipment maintenance program to ensure that equipment is properly grounded and there are no loose connections.

Electromigration is mass transport due to momentum exchange between conducting electrons and diffusing metal atoms. Eelectromigration-induced failure involves flux divergence, vacancy, and atom accumulation with or without compositional variations, void and hillock nucleation, and growth and shape changes [88],[89]. Ambient temperature, current density, and the direction of electron flow are three important factors leading to electromigration of MEMS [90],[91], and [92].

Electrical breakdown leads to disruption in a polymer and occurs when an applied voltage can no longer be maintained across material without excessive flow of current and physical disruption. EMP induces a broadband, high-intensity, short-duration burst of electromagnetic energy, which leads to disruption in a polymer [93],[94],[95],[96], and [97].

58.3.9 Packaging Reliability

The two key issues related to MEMS packaging reliability are hermeticity and vacuum maintenance, and thermal issues. We discuss them separately.

Vacuum packaging is important because several MEMS devices such as resonators, gyroscope sensors, and pressure sensors need to maintain the frequency response and quality factor (Q-factor). Degradation of the vacuum and hermetic condition may induce internal friction, charge separation in capacitive devices, and moisture corrosion in metallization, or electrolytic conduction [98],[99]. Currently, vacuum packaging can be accomplished on the wafer level by the glass-silicon anodic bonding technique [100],[101]. However, few methods exist to ensure the reliability of anodically bonded vacuum packaging. Sung-Hoon Choa [102] found that leakage and outgassing are the two dominant failure mechanisms of anodic vacuum packaging.

Two key thermal issues related to MEMS packaging are: heat dissipation from actuators and integrated circuitry components; and thermal stress generated during the packaging process. When the size of transistor on a chip shrinks, heat dissipation becomes a serious problem. Inefficient power dissipation may raise the working temperature and affect device performance. Moreover, thermal stress may cause deformation of the MEMS structure, resulting in frequency change, or even breakage of the structure [103]. Because most MEMS packages still follow the typical IC packaging architecture, a thermal management device called a heat pipe is used in MEMS fabrication.

58.3.10 Other Failure Mechanisms

Many other factors, such as parasitic capacitance, dampening effects, and delamination, may also induce MEMS failure. Parasitic capacitance does not cause failure in and of itself, but it can cause unexpected electrical and mechanical behavior in devices. MEMS damping is usually caused by the presence of gaseous molecules. There are multiple kinds of damping caused by the atmosphere, and the type of damping depends largely upon the device geometry. For closely packed parallel surfaces, squeeze film dampening will be predominant; for a device moving in plane, there will be structural dampening. The way to prevent damping is to utilize vacuum packaging. Delamination can be induced by a number of means, from mask misalignments to particulates on the wafer during processing. It can also arise as the result of fatigue induced by the long term cycling of structures with mismatched coefficients of thermal expansion. Acoustic microimaging (AMI) and the scanning acoustic microscope (SAM) are

commonly used to assess the delamination in plastic encapsulated microcircuits [104],[105].

58.4 Conclusions

Although reliability issues of MEMS have been researched in recent years, they are still in the initial stage and are not yet mature. The knowledge of failure modes and failure mechanisms of MEMS is still limited and much work is urgently needed. One possible way to study reliability issues of MEMS would be to identify the failure phenomenon with different patterns, because many failure modes are not seen in the IC industry. In this case, the expectations and perceptions of MEMS failure issues have become important in industrial manufacturing and laboratory researching scopes, which requires carefully identification experiments on MEMS devices to gain insightful knowledge of different failure modes and mechanisms.

In addition, researchers must take into account MEMS failure issues such as stiction, wear, fracture, crystallographic defect, creep, degradation of dielectrics, environmentally induced failure, electric related failure, parasitic capacitance, dampening effects, and delamination and packaing. To gain a better understanding of these failures, many observation and testing instruments should be used in the semiconductor industry to study MEMS, such as scanning electron microscopy (SEM), focused ion beams (FIB), atomic force microscopy (AFM) [106], and ballistic-electron-emission microscopy (BEEM) [107]. Simulation, modeling methods, and an interrelated mathematical approach, such as the neural-network method [108], and the unified quantum correction model [109], should be used to study MEMS failure modes and improve MEMS performance. MEMS device failure mechanism research should stress the characteristics of the basic materials, and the physical disciplines behind them before this industry can become a successful commercialization.

Moreover, MEMS reliability does not merely contain failure mechanism analysis. As we mentioned in Section 58.2, it is just part of the MEMS reliability process. Traditionally “input” reliability research should be changed to an “output” research method, which requires researchers to consider reliability aspects in all phases of the product development.

Amorphous Hydrogenated Carbon Nanofilm

Dechun Ba and Zeng Lin

Northeastern University, Shenyang, P.R. China

Abstract: Amorphous hydrogenated carbon (a-C:H) nanofilm is a metastable form of amorphous carbon with significant sp3 bonding. a-C:H is a semiconductor with a high mechanical hardness, chemical inertness, and optical transparency. This chapter will describe the deposition methods, deposition mechanisms, characterization methods, electronic structure, gap states, defects, doping, luminescence, field emission, mechanical properties, and some applications of a-C:H. The films have widespread applications as protective coatings in areas such as magnetic storage disks, optical windows, and micro-electromechanical devices (MEMs).

59.1 Introduction

Amorphous hydrogenated carbon (a-C:H) nanofilm is a metastable form of amorphous carbon containing a significant fraction of sp^3 bonds. It can have a high hardness, wearability, thermal conductivity, chemical inertness, optical transparency, and a low friction coefficient, and it is a wide band gap semiconductor. A-C:H films have widespread applications as protective coatings in areas such as car parts, biomedical coatings, and micro-electromechanical devices (MEMS), and have practical applications in optical windows and magnetic disks [1].

There have been great developments in the field of disordered carbons. New ways have been developed to synthesize a-C:H nanofilms, while a range of disordered carbons with local fullerene-like order on a nanometer length scale have been discovered. a-C:H nanofilms have now been characterized in great detail. The ways to grow the most diamond-like nanofilms are now understood. Their growth mechanism is broadly understood in terms of the subplantation of incident ions.

A-C:H nanofilm has some extreme properties similar to diamonds, such as hardness, elastic modulus, and chemical inertness; however, these are achieved in an isotropic disordered thin film with no grain boundaries. It is much cheaper to produce than diamond itself. This has great advantages for many applications.

It is convenient to display the compositions of the various forms of amorphous C-H alloys on a ternary phase diagram as in Figure 59.1 [1],[2]. A range of deposition methods, such as plasma enhanced chemical vapor deposition (PECVD), is able to reach into the interior of the triangle. This produces a-C:H nanofilm. Although it is diamond-like, as is seen from Figure 59.1 the content of sp^3 bonding is actually not so large, and its hydrogen content is rather large. Thus, a more sp^3 bonded material with less hydrogen, which can be

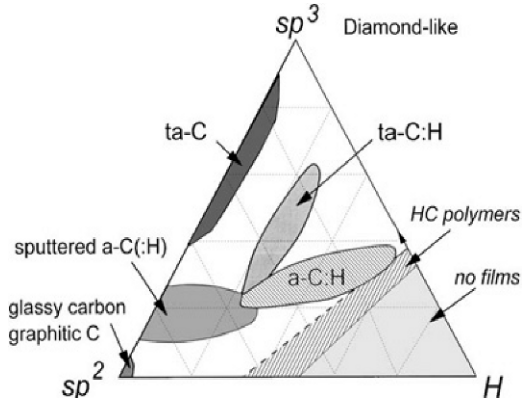

Figure 59.1. Ternary phase diagram of bonding in amorphous carbon-hydrogen alloys

produced by high plasma density PECVD reactors, is called hydrogenated tetrahedral amorphous carbon (ta-C:H) [3].

59.2 Deposition Methods

59.2.1 Ion Beams

The first a-C:H nanofilms were prepared as thin films using ion beam deposition [4]. It is possible to produce a-C:H nanofilms by a wide range of deposition methods. The methods can be categorized according to whether they are most suitable for laboratory studies or industrial production. The common feature of these methods is that the a-C:H nanofilm is condensed from a beam containing medium energy (~100 eV) carbon or hydrocarbon ions. It is the impact of these ions on the growing film that induces the sp^3 bonding. The best deposition process for a-C:H nanofilms will provide a carbon ion flux at about 100 eV *per* carbon atom., with a narrow energy distribution, a single energetic species, and a minimum number of non-energetic (generally neutral) species [3].

In a typical ion beam deposition system, carbon ions are produced by the plasma sputtering of a graphite cathode in an ion source. Alternatively, as in the Kaufman source, a hydrocarbon gas such as methane is ionized in a plasma [5],[6]. An ion beam is then extracted through a grid from the plasma source by a bias voltage. The carbon ions or hydrocarbon ions are then accelerated to form the ion beam in the high vacuum deposition chamber. In both cases, the ion source runs at a finite pressure, so that the beam also contains a large flux of unionized neutral species. This can reduce the flux ratio of ions to neutrals to as low as 2–10%. Ion beam sources tend to run best at higher ion energies of 100–1000 eV.

A variant of ion beam deposition is the cascade arc source [7]. Here, a high-pressure source produces intense plasma, which then expands supersonically into a high vacuum, giving rise to large fluxes of ions and radicals.

59.2.2 Sputtering

The most common industrial process for the deposition of carbon nanofilm is sputtering. The most common form uses the dc or rf sputtering of a graphite electrode by an Ar plasma. Because of the low sputter yield of graphite, magnetron sputtering is often used to increase the deposition rate. Magnets are placed behind the target to cause the electrons to spiral and increase their path length, and thus to increase the degree of ionization of the plasma. As ion bombardment helps the formation of sp^3 bonding, the magnetic field can be configured to pass across to the substrate, which causes the Ar ions to also bombard the substrate, to give an “unbalanced magnetron”. A dc bias can be applied to the substrate to vary the ion energy. A-C:H nanofilm can be produced by reactive sputtering, by using a plasma of Ar and hydrogen or methane, and a-CNx can be produced using an argon-nitrogen plasma.

Alternatively, in ion beam sputtering, a beam of Ar ions can be used to sputter from the graphite target to create the carbon flux. A second Ar ion beam can be used to bombard the growing film, to densify the film or encourage sp^3 bonding. This is called ion beam assisted deposition (IBAD) or ion plating.

Sputtering is preferred in industrial applications because of its versatility, its widespread use to sputter many materials, and its ease of scale up. Also, the deposition conditions can be controlled by the plasma power and gas pressure but they are

reasonably independent of the substrate geometry or condition. A disadvantage of sputtering is, like ion beam deposition, that it can have a relatively low ratio of energetic ions to neutral species, so that it does not produce the hardest DLC films. However, sputtering methods with a very high fraction of ions have been developed by Schwan *et al*. [8] and Cuomo *et al*. [9] to produce a-C with a relatively large sp^3 fraction, but this is at the expense of a low growth rate.

59.2.3 PECVD

The most popular laboratory deposition method is RFPECVD (radio frequency plasma enhanced chemical vapor deposition) [10]–[19]. The reactor consists of two electrodes of different areas. The rf power is usually capacitively coupled to the smaller electrodes on which the substrate is mounted, and the other electrode (often including the reactor walls) is earthed. The rf power produces a plasma between the electrodes. The higher mobility of electrons compared to the ions in the plasma creates a sheath next to the electrodes with an excess of ions. This has a positive space charge, so the plasma develops a positive voltage with respect to the electrodes, which equalizes the mean electron and ion current to the wall [1], as shown in Figure 59.2.

The sheaths act as diodes, so that the electrodes acquire dc self-bias voltage equal to their peak rf voltage. The rf voltage is divided between the sheaths of the two electrodes as in a capacitive divider, according to their inverse capacitance. Thus, the dc self bias voltage varies inversely with the electrodes areas [1],

$$\frac{V_1}{V_2} = \left(\frac{A_2}{A_1}\right)^2 \tag{59.1}$$

The smaller electrode with smaller capacitance acquires the larger bias voltage and becomes negative with respect to the larger electrode. This makes the substrate electrode. The negative sheath voltage accelerates the positive ions to give the bombardment needed to create the sp^3 bonding.

The gas used in PECVD has a significant effect on the a-C:H properties. In the early days, precursors with low ionization potentials such as benzene were chosen, as this gave a much higher growth rate. The deposition rate increases roughly exponentially with decreasing ionization energy as shown in Figure 59.3. For mechanical applications, it is desirable to maximize the hardness, which we shall see means minimizing the incorporation of hydrogen. This requires using a precursor with small H/C ratio such as acetylene, as this strongly affects the H/C ratio of the resulting film.

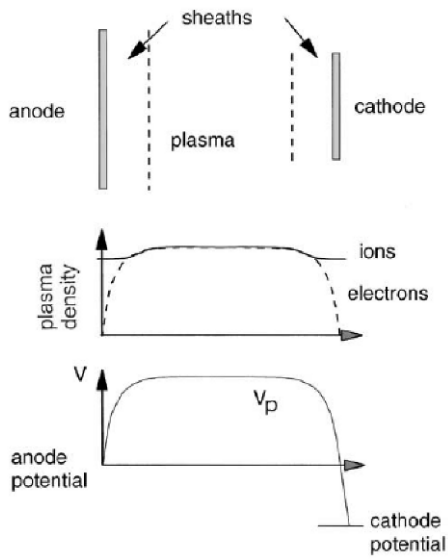

Figure 59.2. Electron and ion distributions that create sheaths between the neutral plasma and the walls

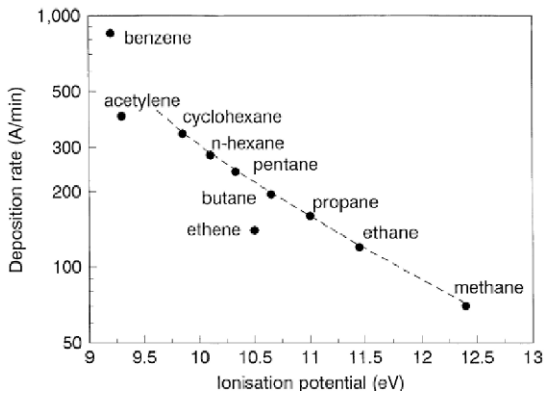

Figure 59.3. Growth rate of a-C:H by PECVD *vs.* ionization potential of the precursor gas

It is now known that a-C:H properties depend on the ion energy *per* C atom. Thus, a benzene ion $C_6H_n^+$ with six carbons requires high bias voltages to reach the desired 100 V *per* atom. Acetylene is more acceptable because 200 V is easier to handle. Acetylene is in fact a very useful source gas for low pressure deposition, because its strong C≡C bond means it has a simple dissociation pattern, giving mainly $C_2H_n^+$ ions [3]. There is also less plasma polymerization than as occurs with methane. Acetylene is the preferred source gas for mechanical applications. However, acetylene is unsatisfactory for electronic applications because it is not available in a high purity form and possesses a substantial nitrogen impurity [20], which can cause a doping effect particularly if used in high-density plasmas. Methane remains a popular choice for electronic applications because it is available in high purity.

59.3 Deposition Mechanism of a-C:H

The key property of a-C:H nanofilm is its sp^3 bonding. The deposition process that promotes sp^3 bonding is a physical process, ion bombardment. The highest sp^3 fractions are formed by C+ ions with ion energy around 100 eV.

There are many processes in the deposition of a-C:H, as shown in Figure 59.4. The strong dependence of the properties of plasma deposited a-C:H on the bias voltage and hence on the ion energy indicates that ions play a critical role in the deposition of a-C:H. The ion flux fraction is much less than 100% and may be typically 10%. The a-C:H can be deposited from different source gases such as CH_4, C_2H_2, C_2H_4, and C_6H_6. The variation of the film density with bias voltage for each source gas can be redrawn on a scale of bias voltage *per* C atom in the molecule. When this is done, the maxima in density lie at a similar energy. This indicates that the action of ions is still *via* subplantation. This can be understood as follows. An energetic molecular ion incident at the film surface will break up into atomic ions and the energy will be distributed evenly. Thus, each atomic ion will subplant independently with that energy.

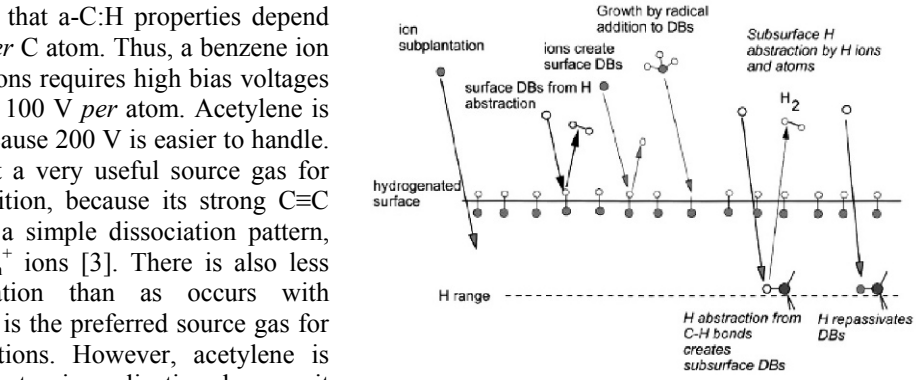

Figure 59.4. Component processes in the growth mechanism of a-C:H

A complete model of the growth of a-C:H requires us to also describe the chemical processes of neutral species and of dehydrogenation [21]−[29], as well as the physical process of subplantation. There are three general stages of the plasma deposition; the reactions in the plasma (dissociation, ionization, *etc*.), the plasma-surface interaction and the subsurface reactions in the film. The plasma reactions are driven by the energetic electrons, as defined by the electron energy distribution (EED). There will be other species formed in secondary reactions such as polymerization. These tend to be less important at the lower pressures used for a-C:H deposition. Except in the case of high-density plasmas, the mass spectrometer analyses show that undissociated source gas molecules are still the dominant species in the plasma.

The plasma species incident on the growing film will consist of ions and neutrals. The neutrals will be closed shell molecules such as undissociated precursor gas, monoradicals such as CH_3, di-radicals, and other unsaturated species such as C_2H_4 or C_2H_2. The plasma also contains significant amounts of atomic hydrogen.

It is known that neutral species contribute to growth because the mass deposition rate exceeds the rate due to ions alone. The first effect of note is that the growth rate decreases with increasing temperature. This was first thought to be because the neutrals were weakly adsorbed on the surface, which would desorb at higher temperatures. It is now known that this temperature dependence is

due to the etching of the film by atomic hydrogen [23]−[25]. Growth itself is independent of temperature. The etching rate increases with temperature, so the net growth rate decreases with temperature.

The contribution of each neutral species to the growth rate depends on their sticking coefficient. The a-C:H surface is essentially fully covered with C-H bonds, so it is chemically passive. Di-radicals and other unsaturated species can insert directly into surface C-C or C-H bonds, so these species react strongly with the film and their sticking coefficients approach 1. On the other hand, closed shell neutrals like CH_4 have very low sticking coefficients of under 10^{-4} and their effect is negligible. The monoradicals have a moderate effect. They cannot insert directly into a bond, they can only react with the film if there is an existing dangling bond on the surface. They will add to this bond to form a C–C bond. The dangling bond must be created by removal of an H from a surface C–H bond. This can occur by an ion displacing an H from the bond, or by an H atom abstracting H from the bond,

$$\equiv C - + H^{'} \rightarrow \equiv C^{'} - + H_2 \qquad (59.2)$$

or by another radical like CH_3 abstracting H from the C–H bond. Measurements have found that atomic H′ is the most efficient species for abstraction (30 times faster than CH_3) [28]. CH_3 then adds to this dangling bond. Thus, the effective sticking coefficient of CH_3 is small, but it is high in the presence of atomic hydrogen [27],[28]. This leads to a synergistic effect of H′ on the sticking probability of CH_3 [28].

Neutral hydrocarbon species can only react at the surface, they cannot penetrate the film. Hydrogen atom and ions are different. H atoms being so small, they can penetrate about 2 nm into the film. There, they can again abstract H from C–H bonds and create subsurface dangling bonds and H_2 molecules. Some of these dangling bonds will be re-saturated by incoming atomic H [1].

Ions can also penetrate the film. Carbon and hydrocarbon ions can cause subplantation. A more typical role of ions in a-C:H is to displace H from C-H bonds. This H can then recombines with other H′ to form H_2 molecules, and desorbs from the film. This is the main process, which causes the H content of PECVD a-C:H to decrease with increasing bias voltage. Some of the atomic H′ does not recombine, but finds dangling bonds to re-saturate.

Because of their low mass, hydrogen ions interact weakly with C atoms. Thus, H+ ions have the longest range and penetrate deepest into the film. They undergo the same reactions as atomic H′, but to a greater depth. Thus, it was noted that a-C:H films have three characteristic depths; the surface itself is controlled by reactions of hydrocarbon and hydrogen species; the upper 2 nm in which chemistry is controlled by reactions of atomic H`, and a larger depth depending on ion energy in which reactions are controlled by H^+ ions [1].

59.4 Bulk Properties of a-C:H

The properties of a-C:H have been studied by many researchers [15],[16],[30]–[67]. Figure 59.5 shows the variation of the main properties, the sp^3 fraction, hydrogen content, mass density, and optical gap with the bias voltage V_b for a-C:H films deposited from different source gases: methane, acetylene and benzene [15],[34], and [45]. Most properties of a-C:H depend on the incident ion energy *per* C atom. For conventional PECVD, the incident ion energy is about 0.4 times the bias voltage V_b [13],[14].

The bonding configurations in a-C:H deposited from methane have been studied in detail by Tamor *et al*. [34] using NMR to derive the fractions of the various C:H configurations as a function of V_b. The result shows how the total sp^3 fraction and hydrogen content both decrease continuously with increasing V_b, and also how the hydrogen is preferentially bonded to the sp^3 sites.

The bonding and properties of a-C:H films fall into three regimes defined by the ion energy or bias voltage V_b used in deposition. The actual value of V_b for these regimes depends on the precursor gas and the deposition pressure. At low bias voltages, the films have a large hydrogen content, a large sp^3 content and a low density. The films are called polymeric a-C:H or soft a-C:H.

The optical gap is over 1.8 eV and it can even extend up to 3.5 or 4 eV [58]. This is a very wide gap. At intermediate bias voltages, the H content has fallen, the sp^3 content is less and the films have a maximum in density. In this regime, the amount of C–C sp^3 bonding reaches its maximum and the films have their highest diamond-like character. The optical gap lies in the range 1.2–1.7 eV. At high bias voltages, the H content has fallen further and the bonding has become increasingly sp^2-like. The Raman spectra now possess a D peak, and this shows that some sp^2 sites are aromatic [40]. The films can be called graphitic.

The bonding in a-C:H can be described as follows. The C sp^3 sites form a continuous network of C−C bonds. Most sp^3 sites are bonded to one or more hydrogens. A large part of the sp^3 bonding in a-C:H is due to the saturation of bonding by hydrogen. The sp^2 sites in a-C:H form small clusters in this matrix. The cluster sizes or sp^2 site distortions increase with increasing V_b, which causes the band gap to decrease. In soft a-C:H, the clusters tend to be olefinic and do not give a Raman D peak [38]. In a-C:H deposited at high bias, the sp^2 clusters become larger and increasingly aromatic, and so give rise to the observed D peak. The dispersive Raman spectra confirm this. The G peak position saturates at 1600 cm^{-1} at high photon energies for high bias samples, while it continues above1 1600 cm^{-1} for polymeric a-C:H.

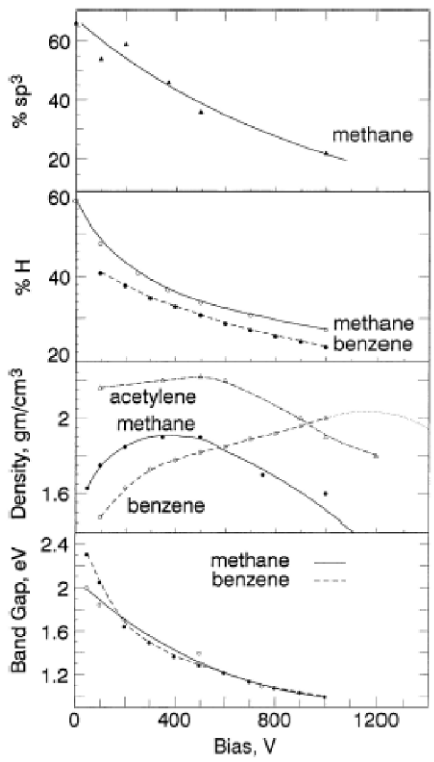

Figure 59.5. Variation of sp^3 fraction, hydrogen content, density, and optical gap with deposition bias voltage

The properties of a-C:H depend on the ion energy *per* C atom, E. Often the depositing species is a molecular ion $C_mH_n^+$. When the molecular ion hits the film surface, it breaks up and shares their kinetic energy between the individual daughter carbon atoms. The effective energy *per* C atom is then

$$E = \frac{E_i}{m}. \tag{59.3}$$

This means that the properties of a-C:H will depend on the precursor molecule, when scaled according to this reduced ion energy *per* C atom. Thus the maximum in density for a-C:H prepared from acetylene will occur at about twice the bias voltage of that from methane, and that from benzene at about six times it. The hydrogen content of the a-C:H film is always slightly lower than that of the precursor molecules. Hydrogen is lost during growth by chemical sputtering-the displacement of H from C-H bonds by incoming ions. This process is roughly proportional to the molecular ion energy. The H content of a-C:H prepared from methane is larger than that prepared from other precursors, largely because the H/C ratio of methane is so large.

59.5 Electronic Applications

In silicon complementary metal-oxide-semiconductor (CMOS) device technology, the device dimensions are continually shrinking, in a process known as Moore's Law. At present, the insulator used between data lines is silicon dioxide. However, RD associated with the capacitance of these lines is becoming too significant. It is necessary to replace SiO_2 with an insulator with a

lower dielectric constant (k) to reduce this capacitance. The (low frequency) k of SiO_2 is 3.9. Various carbon-based films are candidate dielectrics [68][69]. These materials must satisfy other criteria as well as low k. They must be thermally stable to 400°C, have adequate rigidity, low mechanical stress, low dissipation, low leakage, good adhesion, and be processable using acceptable means. The industry first used fluorinated SiO_2 but there is a lower limit to its k. Various carbon-based materials have been tried, such as a-C:H, fluorinated amorphous carbon (a-C:F). The aim is to find materials to reach k values of 1.5–2.1.

There are two components to k, the electronic part and the lattice part. The lattice part is minimized by avoiding ionic bonds. The electronic part is minimized by using low atom densities and strong, less polarizable bonds. A-C:H can reach k values down to 2.6 by deposition at low bias voltages and higher pressures. The main problem with these polymeric a-C:H is that they have low thermal stability and evolve hydrogen and hydrocarbons at below 400°C. The k of a-C:H follows the same trend as the loss of thermal stability, and only films with k above 3.3 are sufficiently stable [69].

59.6 Mechanical and Other Properties

The mechanical properties of a-C:H nanofilms are of great importance because of the use of a-C:H as a protective coating[70]−[77]. A great advantage of a-C:H compared to CVD polycrystalline diamond is that it is amorphous with no grain boundaries. This means the films are extremely smooth. A-C:H is also deposited at room temperature, which is an advantage for temperature sensitive substrate such as plastic. A-C:H nanofilms also have extremely good coverage, so they act as good corrosion barrier. This is particularly useful in a major application, which is to coat disks and recording heads in the magnetic storage technology [75]–[77]. The disadvantages of a-C:H nanofilms are their intrinsic stress and thermal stability. These problems are now being circumvented.

59.6.1 Elastic Properties

Many of the mechanical properties of a-C:H nanofilms are measured by a nanoindenter [78],[79]. In this experiment, a small diamond tip is progressively forced into the film, and the force–displacement curve is measured. Figure 59.6, shows a typical curve for a-C:H. The curve is also measured for the unloaded cycle. The hardness is defined as the pressure under the tip, given by the ratio of force to the projected area of plastic deformation. It is well known that for accuracy, the indentation depth must be limited to a fraction of order 10% of the total film thickness. This is particularly important for the case of hard on soft films, such as a-C:H. The hardness is found with reasonable accuracy by this procedure.

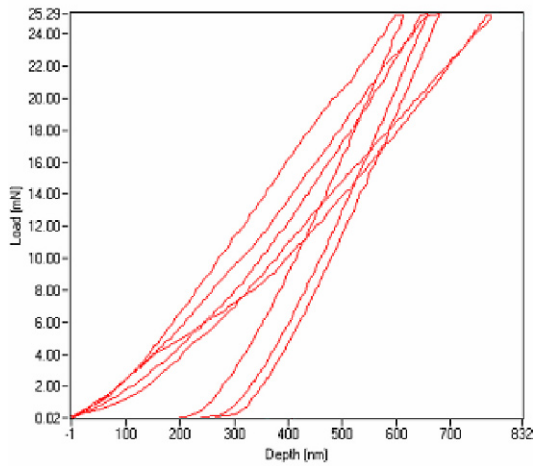

Figure 59.6. Load-unloading curve for a nano-indentation measurement of a-C:H

59.6.2 Hardness

The hardness is a measure of the yield stress of a material. Figure 59.7 shows the hardness of a-C:H deposited by PECVD from methane and benzene precursors. The hardness is low at low bias voltage, for the polymeric a-C:H films [1]. The hardness then rises to a maximum corresponding to the maximum diamond-like character, and then it decreases as the films acquire a more graphitic bonding. The hardness reaches a maximum at low

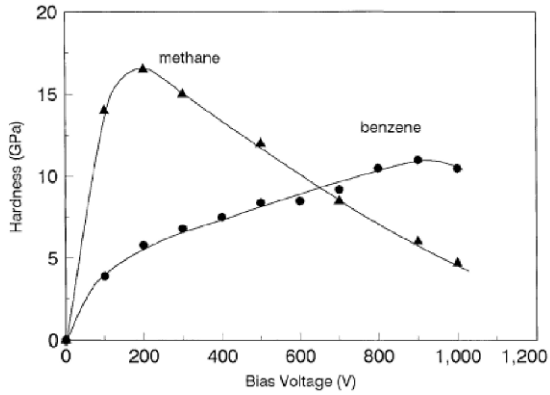

Figure 59.7. Variation of nanohardness of a-C:H with deposition bias voltage

bias voltages for methane a-C:H, while the hardness for the benzene-derived film reaches a maximum around 1000 V.

Note that the maximum nanohardness of the a-C:H in Figure 59.5 is 17 GPa. The importance of using a nanoindenter and small indent depth is well known. If conventional microindenters are used on a-C:H, these give hardness values of typically three times higher than the nanoindenter. Thus, hardness values for a-C:H nanofilms over 20 GPa should be viewed as exaggeration unless there is some reason in terms of improved bonding or low hydrogen content to account for them.

59.6.3 Adhesion

The major use of a-C:H is for protective coatings. Thick films are preferred for this, to maximize the wear life. The compressive stress limits the maximum thickness of adhesive films. A film of thickness h will delaminate when the elastic energy *per* unit volume due to the stress σ exceeds the surface fracture energy γ *per* surface, so for adhesion

$$2\gamma > \frac{\sigma^2 h}{2E}, \tag{59.4}$$

or

$$h < \frac{4\gamma E}{\sigma^2}. \tag{59.5}$$

This sets an upper limit of film thickness. Now, it is known that the stress, Young's modulus and hardness all tend to be proportional to each other. Maximizing the hardness means that the stress is a maximum. Thus, maximizing the hardness will minimize the thickness of an adherent layer, so that little is gained.

Various strategies are used to maximize the film thickness. First, it is essential to ensure there is good adhesion between the film and the substrate. The film should fail by fracture within the substrate. This can be achieved by cleaning the surface by Ar ion bombardment before deposition. Another method is to use a high ion energy for the first stage of deposition, to cause ion beam mixing between film and substrate in order to ensure a mixed interface.

Second, a carbide-forming adhesion layer such as Si, Cr or W can be deposited first before the carbon [70]–[80]. Silicon works well for glass substrates used in sunglasses and bar-code scanners, on which a wider gap a-C:H may not adhere. Films can be made that are inhomogeneous or graded, so that they have internal stress relief mechanisms.

Third, it is possible to use multi-layers to provide internal stress relief. This has been used by Lin Zeng [81] *et al*., for a-C:H films and by Meneve *et al.* [82] for a-CSi_x:H.

A major effort has been made to reduce stress by alloying with, for example, Si[83] or metals[84]. Si has three beneficial effects. It can promote sp^3 bonding by chemical means, as it does not exert sp^2 hybridization, so it is not necessary to use as much ion bombardment to get sp^3 bonding. It increases the thermal stability of the hydrogen. It also improves the friction performance, as discussed shortly, by maintaining a low friction to higher humidity.

59.6.4 Friction

A-C:H nanofilms are notable for their low friction coefficients[70],[71],[85]–[95]. It has been found that a-C:H in a vacuum can have a friction coefficient μ as low as 0.01 [94]. For a-C:H, μ depends strongly on the relative humidity. Values of μ below 0.05 are found in a vacuum and at low humidity and μ increases strongly at high humidity. It is found that the friction coefficient in

low humidity regime depends on the precursor used to make the a-C:H [94]. It varies with the ratio of H/C in the precursor, with a-C:H from CH_4 having the lowest μ and a-C:H from C_2H_2 having the largest μ. The a-C:H prepared from hydrogen-diluted methane has the lowest friction coefficient. μ increases to 0.1–0.15 when the humidity rises to normal atmospheric values of 30% and above. *In situ* studies have shown that the higher μ arises from the water, not oxygen, in the atmosphere.

59.6.5 Wear

It is found a-C:H has a low wear rate of order 10^{-7} mm^3N^{-1} [96]. The wear mechanism of a-C:H is the friction mechanism, adhesive wear *via* transfer layer. The sp^3 bonding transforms by stress-induced transformation to a graphite overlayer, which acts as a lubricant, and then a-C:H forms a C:H transfer on the counter surface [90].

59.6.6 Surface Properties

A-C:H is also notable for its small surface energy [84]. The surface energy is usually measured using the contact angle. Low surface energies give large contact angles. Surface energies are typically 40-44 mNm^{-1}. a-C:H generally has a contact angle with water of 55–70°. Unusually, this is found to be independent of deposition bias voltage [97],[98].

Dimigen and coworkers [98] tested the effects of alloying elements on the surface energy of a-C:H. They found the surface energy of a-C:H increased from 41 mNm^{-1} for pure a-C:H to 52 mNm^{-1} with oxygen addition, but decreased to 19–24 mNm^{-1} with the addition of Si or F.

59.6.7 Biocompatible Coatings

There is considerable interest in using various forms of a-C:H as biocompatible coatings, on parts such as replacement hip joints, heart valves, and so on [99]–[102]. This arises from the low friction coefficient of a-C:H and the belief that a carbon material must be biologically compatible. In many coatings, the main requirement is that a-C:H has good adhesion to the underlying unit and does not produce metallic wear debris. Deeper investigations have studied the attachment of blood cells, proteins, *etc*.

59.6.8 Coatings of Magnetic Hard Disks

One of the most important uses of a-C:H nanofilms is as protective coating on magnetic storage disks [75]–[77]. A-C:H is used because it makes extremely smooth, continuous, and chemically inert films, with a surface roughness below 1 nm. A-C:H nanofilms have no competitors as a coating material for this application.

The first role of a-C:H film was to provide protection against corrosion. Simple a-C was used, deposited by magnetron sputtering. Later, a-C:H was used, produced by the reactive sputtering in an Ar/hydrogen atmosphere. Its role was to provide also protection against mechanical wear and damage during head crashes. The best performing a-C:H contained more hydrogen than needed to maximize its hardness. This indicated that the role is not simple protection against dry wear, but that the interaction with the lubricant is critical. The surface termination of a-C:H immediately after deposition is important for its surface properties and the interaction with the lubricant.

59.6.9 Surface Property Modification of Steel

A-C:H films have practical applications in optical windows and magnetic disks [103],[104]. In this respect, the process of a-C:H film deposition on steel substrate has actual and potential importance in that it can be applied further to drills, gears, bearings, moulds/dies, punches, and medical devices. Thus, a systematic study on the process applied to depositing a-C:H film on steel substrates is indispensable, along with relevant mechanical properties and frictional characteristics involved.

When depositing a-C:H film on steel substrate, an interdiffusion effect of carbon atoms takes place on the interface to adversely affect the film adhesion strength because of the reaction in contact with Fe. On investigation it was found that introducing a transition interlayer between a-C:H film and substrate is an effective way to prevent

the interdiffusion so as to increase adhesion strength, and many kinds of interlayers have all been proved feasible, such as Si, Al, Cr, Mo, Ti, TiN, TiC, CrN, Si_3N_4 and SiC layers [105],[106]. Lately, the composite interlayers with functional gradient predeposited on substrates, such as Ti/Ti_xC_y and Ti/TiN/TiCN/TiC films, have been developed to increase the film adhesion strength, especially to enhance the bearing capacity of the top layer (a-C:H film) [107]. The change in the gradient and hierarchical structure of the transition interlayer will optimize the distribution of internal stresses to allow the film to work under severe rubbing/scratching conditions.

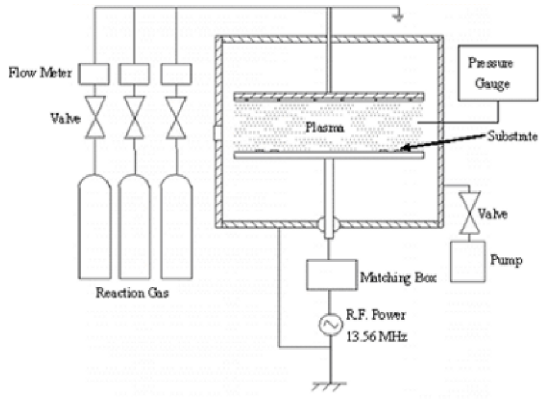

Figure 59.8. Schematic of RFPECVD setup for a-C:H film deposition

In the PECVD deposition process, a gas mixture of butane with argon was used to deposit a-C:H film on stainless steel substrate in an experimental setup as shown in Figure 59.8. The size of substrate was 10 mm *10mm *3 mm, and the surface had been polished. To improve the adhesion strength between the a-C:H film and substrate, an ion beam assisted deposition technique was used to predeposit Ti/TiN/TiC film with a functional gradient on the substrate, of which the thickness of the Ti, TiN, and TiC film was 100 nm, 100 nm, and 200 nm, respectively. Then, a-C:H film with a certain thickness was deposited on the transition interlayer by the rf PECVD process; the deposition parameters are shown in Table 59.1.

Table 59.1. Deposition parameters of a-C:H film on an underlayer film

Step No.	Operation	Condition
1	Prepumping	P～2Pa
2	Plasma cleaning	Ar U=1500V P～4Pa
3	Filling in reaction gas	Ar/C_4H_{10}
4	a-C:H grain growth	Ar/C_4H_{10} U=2000V-2800V
5	a-C:H film deposition	Ar/C_4H_{10} U=1000V

The properties of a-C:H films were measured or characterized at room temperature by various apparatus, such as Raman spectra by with Labram HR800 laser Raman spectrometer supplied by Jobin Yvon in France. The adhesion strength was tested by UMT-2M sliding tribometer supplied by CETR in the USA. The film surface morphology was observed using the Nanoscope III atomic force microscope (AFM) supplied by DI, USA. The tribological properties of a-C:H films were tested by the SurfTest SJ-201 ball-on-disc tribometer on which the diamond probe or hardened stainless steel ball may be taken as the counterpart. The testing was carried out in dry conditions at room temperature in such a way that a dry sliding motion was done repeatedly between the counterpart and the disk specimen. It was thus possible to measure the friction coefficient continuously *via* on-line monitoring, with different friction loads chosen as 1, 2, 5 and 10 N, and different rotating speeds as 30, 60, 120, 180, 240 and 300 rpm in testing. After the testing, the surface morphology in the worn area was observed by the SSX-500 SEM supplied by Shimatsu in Japan, and the structural change in the same area was analyzed by laser Raman spectroscopy, as well as the wear-out condition of steel balls taken as the counterpart.

In the test, we tried to polish the substrate thoroughly and changed the deposition parameters to a great extent, but the results showed that it was impossible to deposit directly a-C:H film on the

steel substrate bythe rf PECVD process. The films deposited in such conditions were presented in powder form and were rubbed off very easily. The cause was possibly that the carbon atoms had a strong diffusion effect on the steel substrate. For this reason, a predeposition technique was used in the experiment, *i.e.*, a Ti/TiN/TiC film with a functional gradient by which both the structure and composition of the film will change gradually, was predeposited on substrate as a transition interlayer of a-C:H film. The hardness and Young's modules of such a transition interlayer were 20 and 220 GPa, respectively. As a result, a-C:H films were successfully deposited on the stainless steel substrates. The adhesion strength of such a-C:H film was 6.0 N by the sliding test.

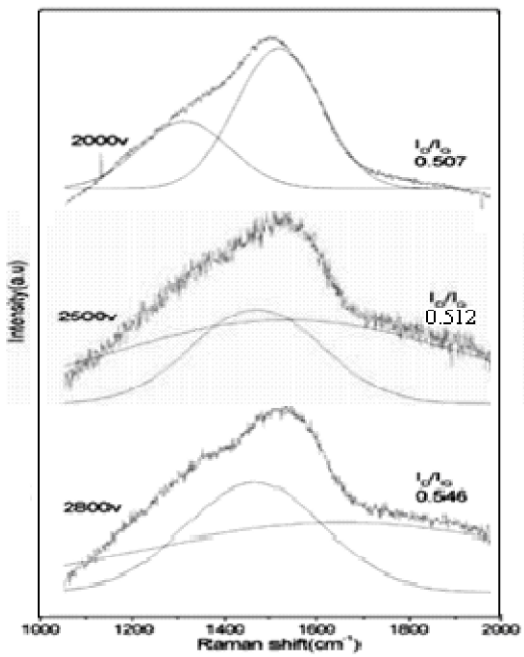

Figure 59.9. Raman spectra of a-C:H films deposited on stainless steel substrates with transition layers at different voltages

Figure 59.9 shows the laser Raman spectra of a-C:H film deposited on stainless steel substrates under different voltages. It can be seen that there is a broad peak with its center at about 1560 cm^{-1} along the abscissa.

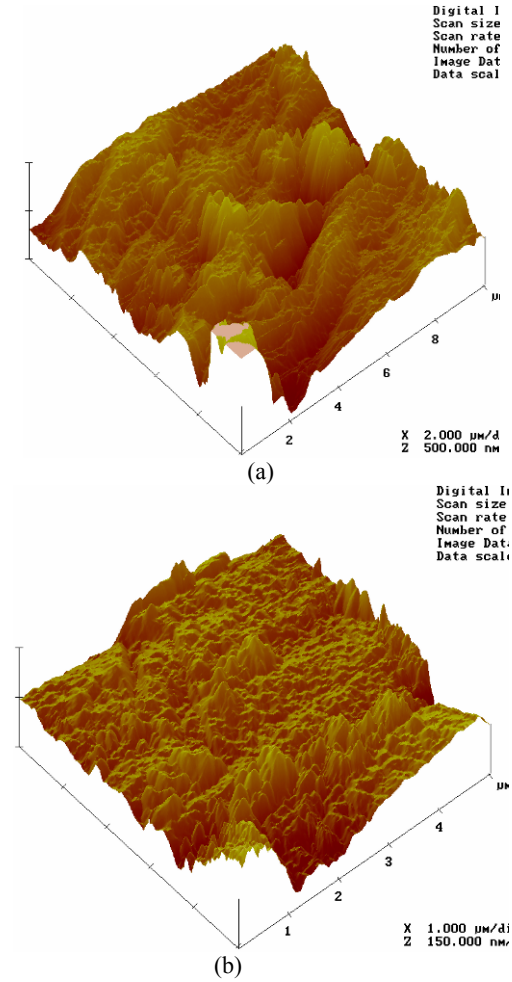

Figure 59.10. AFM images of the transition interlayer and a-C:H film: **(a)** surface of TiN transition interlayer, **(b)** surface of a-C:H film

This provides a typical Raman spectrum for a-C:H film, which can be decomposed into two Gaussian curves, *i.e.*, a G-peak with its center at 1580 cm^{-1} and a D-peak with its center at 1330 cm^{-1}. Comparing the three spectral lines with each other, we can see that the D-peak increases to 1430 cm^{-1} from 1315 cm^{-1} and the G-peak increases to 1735 cm^{-1} from 1520 cm^{-1}, accompanied with a voltage increase to 2800 V from 2000 V. In addition, the area ratio of D-peak to G-peak, I_D/I_G, increases with the increasing deposition voltage.

Figure 59.10 shows the difference between the transition interlayer and a-C:H film by means of an AFM image. Figure 59.10(a) shows the image of the transition interlayer, of which the scanned area is 10 μm*10 μm. As shown, the surface is rather rough mainly because in ion deposition process the sputtering action is so strong that a lot of pores and cracks formed there. Figure 59.10(b) shows the image of a a-C:H film deposited under 2500 V by the rf PECVD process, of which the scanned area is 5 μm*5 μm which means a double magnification in comparison with that shown in Figure 59.10(a). As shown, the surface of the ra-C:H film is comparatively flat, and the compactness of the film is improved as a whole except the area with one or two big island-like points.

Table 59.2. Tribological properties of stainless steel with different top layers

No.	Material	Friction coefficient	Wear rate (mm^3/Nm)
1	steel	0.9	7.67×10^{-6}
2	Steel/TiN	0.7	2.11×10^{-9}
4	Steel/TiN/a-C:H	0.5	1.03×10^{-10}

From the friction test, it was found that the friction coefficient of a-C:H film is relatively stable within 600 cycles, which shows the good quality of a-C:H film. Table 59.2 shows the tribological properties of stainless steel with different top layers. From the friction test, it was found that the hard layer TiN and a-C:H can both decrease the friction coefficient and wear rate, while a-C:H top layer has a better performance. In addition, from Table 59.2, it is clear that the a-C:H layer with TiN/TiC as the interlayer has the best tribological properties.

To reveal further the surface morphology of scratched areas, SEM was used to observe it on both film and ball surfaces, and the results are shown in Figure 59.11. In Figures 59.11(a) and (b) the SEM images of a-C:H film sample before and after wear-off, respectively, are shown. It can be seen that the sample surface before wear-off is smooth with even grain distribution, but cracks and scraps are found in scratched area after wear-off. This fact reveals that there is a strong plastic deformation of the film sample after the frictional sliding process [108]. The SEM images in Figures 59.11(c) and (d) are the ball as counterpart before and after wear-off, respectively, from which it can be seen that, similar to the film sample, cracks and scraps are found on surface after wear-off. This shows that there is also a plastic deformation of the ball after the frictional sliding process. According to the Hertz theory, the local contact stress between the two counterfaces can exceed the compressive strengths of both materials at some contact points [109]. Therefore, surface damage of both the film and the counterpart during the dry sliding test can be expected.

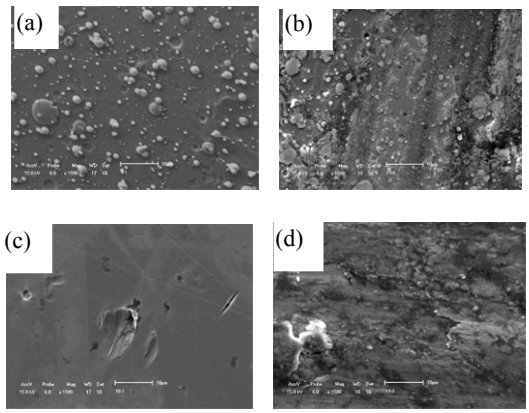

Figure 59.11. SEM images of the surface morphologies of a-C:H film and TiC ball coated with a-C:H before and after the wear-off testing: **(a)** Surface of a-C:H film before testing; **(b)** surface of wear track after the testing; **(c)** surface of the ball before testing; **(d)** surface of the ball after testing

On the other hand, from the Raman spectra of a-C:H film before and after wear-off in the dry sliding test, as shown in Figure 59.12, it can be seen that the Raman spectra of all wear tracks display a distinctly double peaked structure, with the D peak located at ~1400 cm^{-1} and the G peak at ~1580 cm^{-1}. The spectrum from the wear debris has a similar structure. Furthermore, the ratio of I_D/I_G has a much higher value compared to the data before the sliding test. Such a variation tendency in the Raman spectrum is similar to the case that a-C:H film is annealed at higher temperatures [110]. It was observed that upon annealing the trans-

formation of sp^3 bonded carbon to sp^2 bonded carbon occurred, and a more conspicuous D peak appeared simultaneously. Therefore, it is proposed that the sliding-induced heat accumulation on local contact areas between the two counterfaces can probably cause a gradual destabilization of the sp^3 C-H bonds, and thus promote the transformation of the sp3 bonded structure to the graphite-like sp^2 structure [111]. The tribological behavior of a-C:H film appears to be controlled by the graphite transfer layer formed by the thermal and strain effects during the sliding wear test, and a self-lubricating effect on sliding friction can be achieved [112]. The low friction and low wear rate of a-C:H film and the counterpart may be explained by the formation of this transfer layer with low shear strength.

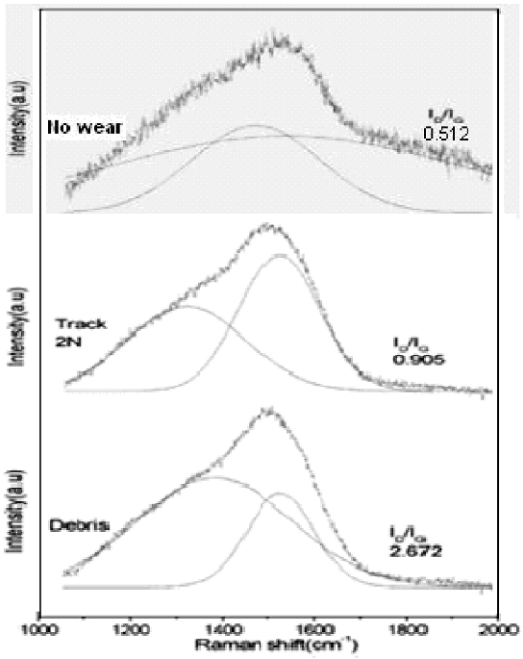

Figure: 59.12. Raman spectra of a-C:H film before and after wear-off

In summary, the rf PECVD process was used in a C_4H_{10}/Ar plasma atmosphere for a-C:H film deposition on stainless steel substrate. The adhesion strength between the film and substrate was improved effectively by resorting to a Ti/TiN/TiC transition interlayer with a functional gradient. By properly choosing the different deposition parameters, *e.g.*, voltage, we can change the tribological properties of a-C:H film, and by optimizing the technological parameters we can lower the friction coefficient and the wear rate of a-C:H film to be less than 0.2 and 1.07×10^{-12} mm^3/Nm, respectively. In particular the friction coefficient of a-C:H film can be kept stable for 600 cycles in a rotary sliding test without lubrication. Moreover, the friction and wear behavior of the a-C:H film was dependent on its friction-induced graphite transfer film formed on the worn surface of the counterpart parts during the sliding wear test. In the end, a-C:H film and the counterpart are both deformed plastically after wear-off.

Applications of Performability Engineering Concepts

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: This chapter is intended to introduce some of the areas of applications of performability engineering that have been presented in this handbook. Only the areas of current interest and importance have been included. It is expected that the chapters will accelerate the process of bringing about synergetic interaction between the practioners of performability engineering in several other relevant areas of applications.

60.1 Introduction

Performability engineering is a composite index to reflect the holistic aspect of performance of any product, system, or services. The objective of initiating such a discussion is to make designers, producers, and users aware of various aspects of performability [1] including survivability and security, so that these aspects are not overlooked while planning any new product, or system.

In fact, there are a number of possible areas of applications and various models [2–9] are available, and it is no the intention to cover them all. Instead, we have selected only those areas that are considered important currently and where the area of application seems to be most appropriate. It is also not possible due to space limitations and the objective of the handbook to include all aspects of the problems in the chosen areas of applications. However, we have attempted to present at least one relevant application in the context of the present scenario from each of the selected constituent areas of performability engineering.

60.2 Areas of Application

For the sake of this handbook, we have chosen the following areas of applications:

60.2.1 Healthcare Sector

The health care industry is one of the world's largest and fastest-growing industries. It consumes over 10% of gross domestic product of most the developed nations. Healthcare can form an enormous part of a country's economy. In fact, in 2003, healthcare costs paid to hospitals, physicians, nursing homes, diagnostic laboratories, pharmacies, medical device manufacturers, and other components of the healthcare system, consumed 15.3% of the GDP of the United States (higher than in any other country) and is expected to rise to 19.6% of GDP by 2016. In fact, the medical industry is one of the fastest growing segments of US economy.

Another reason for higher spending in this sector all over the world is due to the increased life

expectancy and reduction in mortality during the 20th century, which have resulted in an increased aging population. This has snowballed in an increased demand for medical equipment and electronic gadgets for monitoring and diagnostic purposes. In fact, the number of old people will increase further as healthcare programs improve. It is estimated that by 2030, one in every five Americans will be an old person.

In this area of application, we have two chapters, *viz.,* Chapters 61 and 62, included in this handbook. The application has been chosen in view of the growth of this sector and its current importance.

60.2.1.1 Performance of Medical Devices

The first chapter deals with the high performance requirement of medical devices, which is becoming higher ever. Naturally, the quality, reliability, and maintainability of medical equipment and instruments are of great concern to performability engineers. The Chapter 61, from Respironics Inc. looks into all these aspects in detail.

60.2.1.2 Improvement of the Health Delivery System

The second area of application under this sector is on the use of Six Sigma in improving the performance of healthcare delivery system. Developed nations are working to improve these systems as their numbers keep growing. There are some 850 integrated healthcare delivery systems (IDSs) in the United States today. Currently, most systems are considered to be in an evolving state of integration as they attempt to provide a user-friendly service, a one-stop-shopping environment that eliminates costly intermediaries, promotes well-being and improves general health conditions.

It seems appropriate since the management of healthcare delivery systems has always been embroiled in several legal-politico and socio-economic influences and further requires new and innovative improvements due to spectacular advancements in healthcare technologies. Because it is customer-centric, Six Sigma seems the most appropriate methodology for application in suggesting improvements in activities involved in the case under examination. The authors have suggested new systems engineering tools such as CSQFD, VSM, LP, and queuing analysis for the Six Sigma framework and a case study demonstrating the application of this roadmap to improve the waiting times in a retail pharmacy has been presented. The authors claim that the proposed Six Sigma framework is expected to prove highly suitable in healthcare delivery systems, particularly for drug dispensing, radio-logical, admission, and laboratory services.

60.2.2 Structural Engineering

Techniques for the analysis of structures in mechanical engineering or civil engineering are very similar. This is another area of application that has lagged behind the electrical and electronic sector in the application of performability concepts. These applications have not yet fully matured and there is lot to do in this area.

Chapter 63 of this handbook deals with the reliability methodology as is applicable to civil engineering structures, which is equally applicable to mechanical members. The author, who has written a couple of books on the subject, presents in detail the theory and methodology used in probabilistic designs of structural members, which is different from the methodology used in the case of electronic and electrical systems. Probabilistic analysis and design using FORM, SORM, and Monte Carlo simulation is often used with mechanical and civil engineering structures in order to provide economical structures, which otherwise have often been over-designed using high safety factors at high cost with no surety of not failing under actual conditions of use.

60.2.3 Communications

Communication [10, 11] has become a very important technological area in the 21st century. The convenience advanced by wireless communication devices (*e.g*., cellular phones), and the technological advances in portable-lightweight computers (*e.g.*, laptops and PDAs), among others, have triggered the proliferations and set the upward

trends of the uses of WCN around the world. Perhaps the most common use is to connect laptop users who travel from location to location. Another common use is for mobile networks that connect *via* satellite. Wireless networking is used to meet a variety of needs. A wireless transmission method is a logical choice to network a LAN segment that must frequently change locations.

WCN introduces several communication network-related challenges that are different from those considered in traditionally wired CN. This chapter reviews the differences between their communication system performability issues.

A lot of research has been done in the performability analysis of wired CN, but not much is available related to WCN, possibly because the area is new, and the issues in WCN performability are application specific. The performability issues in a non-*ad hoc* and non-mobile WCN can be solved directly using the existing techniques for wired CN because nodes in both networks are stationary. However, the *ad hoc* nature and/or node mobility and the node's limited resources (*e.g.*, battery lifetime), which are typical characteristics of the other WCN models, require different treatments. Chapter 64 of this handbook describes the performability analysis of both the static topology WCN and MANET. It also surveys recent approaches to improving the path reliability in MANET.

60.2.4 Computing Systems

Grid computing is gaining a lot of attention and importance within the IT industry. Standards, enabling technologies, toolkits, and products are now becoming available that allow businesses to use and benefit from grid computing. The most common description of *grid computing* includes an analogy to a power grid where a utility company provides the interface to a complex network of generators and power sources. The vision of grid computing is similar. Once the proper kind of infrastructure is in place, a user will have access to a virtual computer that is reliable and adaptable to his needs. This virtual computer will consist of many diverse computing resources. But these individual resources will not be visible to the user. Grid computing is a newly developed technology for complex systems with large-scale resource sharing, wide-area communication, and multi-institutional collaboration. Many experts believe that grid technologies will offer a second chance to fulfil the promises of the Internet.

The real and specific problem that underlies the grid concept is coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations. Sharing that is not confined to file exchanges but rather direct access to computers, software, data, and other resources. This is required by a range of collaborative problem-solving and resource-brokering strategies emerging in industry, science, and engineering. This sharing is highly controlled by the resource management system, with resource providers and a consumer defining what is shared, who is allowed to share, and the conditions under which the sharing occurs.

The advantages of grid computing are that we can solve large, more complex problems in much shorter times, and collaboration with other organizations becomes easier and allows us to make better use of existing hardware. However, there are disadvantages as well, for example, the still evolving grid software and standards, the learning curve to get started, and non-interactive job submission. Generally there are three kinds of grids, *viz.*, the computational grid, specifically for computing power, the data grid, for housing and providing access to data across organizations, and the scavenging grid, which is the most commonly used. This has a large number of desktop machines and the owners of these machines are usually given control over when their resources are available to participate in the grid.

Chapter 65 in the handbook discusses all the associated problems, particularly as related to their performance.

60.2.5 Fault Tolerant Systems

Fault-tolerance is the property that enables a system to continue operating properly in the event of the failure of some of its components. Fault-tolerance [12] is particularly desired in high-availability or life-critical systems, or in essential

public concerns such as air, rail, and automobile traffic control, emergency response systems, airline flight controls, nuclear power plant safety systems, and most of all, our rapidly growing dependence on healthcare delivery *via* high-performance computing and communications. When these systems fail, lives and money may be lost. Sometimes, undiscovered design faults (such as software bugs and glitches) can cause system crashes during peak demand, resulting in service disruptions and financial losses. Complex systems may suffer stability problems due to unforeseen interactions of overlapping fault events and mismatched defense mechanisms. New threats from hackers and criminally minded individuals invade systems, causing disruptions, misuse, and damage. Accidents result in severed communication links, affecting entire regions. Finally, we face the possibility of system damage by these "info-terrorists." Fault tolerance is our best guarantee that high confidence systems will not betray the intentions of their designers and the trust of their users by succumbing to physical, design, or human-machine interaction faults.

The growing need for networked environments is setting new challenges to the designers of fault tolerance in systems. Fault tolerance covers areas like system architecture, hardware and software design, operating systems, Internet protocol (IP) network communications, parallel and grid processing, and verification and testing. Since fault tolerant systems are designed to perform even in the presence of faults, errors or attacks, their performance is evaluated by taking into account the consequences of the embedded fault handling actions.

A considerable amount of research is needed to tackle the problem of network performability in the networking environment. As new technologies are developed and new applications are discovered, new approaches in fault tolerance are also required. In a multi-technology, multi-network environment, in each of the networking layers, different types of failures/attacks and responses are possible. Research is needed to exploit the impact of the failure propagation from one network to another as layer restoration processes may affect each other.

As hardware and software systems are increasingly becoming large and complex, the concern for performance becomes more serious, particularly in many technological areas, such as space reconfigurable VLSI technology, cluster based FPGA architectures, and computing platforms with numerous processors. It is expected that the concern for performability in the research and application of fault tolerant systems will become more pronounced in future.

Chapter 66 discusses in great detail all aspects of this subject of current interest.

60.2.6 Prognostics and Health Monitoring

Equipment prognostics and health management as part of operations and maintenance can be used in accurately predicting impending failures and providing a mechanism for remedial measures such as replacing parts safely before failure. An ideal general purpose prognostic system would use data driven prognostics approaches that do not require *a priori* knowledge of the system. The prognostic system would learn the characteristics of the monitored system with use, so that anomalies could be detected quickly as it learned and remaining life estimates could be given with smaller associated uncertainty.

The fact that a fault has been declared, however, does not necessarily mean that immediate maintenance action is needed. That is where prognostics come in. Prognostic software will use inputs from multiple sensors, operating data, and failure histories in order to predict the life of a component, and to determine when and what type of maintenance is required.

A blade slightly damaged by some foreign object entering the engine may be deformed, but if it is not affecting performance to any great degree and if a crack is not growing, replacement might be safely postponed to a regularly scheduled maintenance shutdown. Many existing health monitoring systems use fault detection and diagnostic techniques, but are not focused on automating prediction of future machine conditions. To prevent dangerous situations from occurring, and to help lower the operating and maintenance costs, designers and planners have

begun to look into key enabling technologies that provide not only early warning of potential disasters, but are also substantive indicators of the real-time health of engine components and the overall system. Blade tip sensors embedded in the engine case have been used for decades to measure blade tip clearance and blade vibration. Many sensing technologies have been used: capacitive, inductive, optical, microwave, infrared, eddy-current, pressure, and acoustic.

The prognostic approach is based on the current state of the component or machine, and on the available operating and failure history data. The ability to monitor and predict failures, detect and classify anomalous events, and assess remaining useful life [13] in electronic systems can provide significant cost benefits, enhanced mission readiness and condition based maintenance. These approaches have been very much in use for mechanical equipment, propulsion engines, turbines, and other rotating machines, pressure vessels, *etc*., but have not been popular with electronic equipment.

Prognostics and health monitoring (PHM) techniques make use of sensing, recording, and interpretation of environmental, operational, and performance-related parameters indicative of a system's health. Product health monitoring can be implemented through the use of various techniques to sense and interpret parameters that are indicative of:

- performance degradation, by knowing the deviation of operating parameters from their expected values;
- physical or electrical degradation, by observing material cracking, corrosion, inter-facial delamination, or increases in electrical resistance or threshold voltage;
- changes in a life-cycle environment, by noticing the usage duration and frequency, ambient temperature and humidity, vibration, and shock.

By observing the equipment's health, based on its monitored life-cycle conditions, maintenance procedures can be developed. The objective is to predict the advent of failure in terms of a distribution of remaining life, level of degradation, or probability of mission survival. PHM has become a requirement for any system sold to the DoD.

Chapter 67 of this handbook is from CALCE, which has been doing a poineering work in this area and it is amply made clear by this chapter that if we can assess the extent of deviation or degradation from an expected normal operating condition for electronics, information can be derived on advanced warning of failures, minimizing unscheduled maintenance, extending maintenance cycles, and improving availability by timely repairs, reducing the life-cycle cost of equipment by decreasing inspection costs, downtime, and inventory; and for improving qualification and assisting in the design and logistical support of fielded and future systems.

In other words, prognostics and health monitoring should help improve electronic system performance and reduce its life cycle costs, just as it does in mechanical equipment. The application to electronic equipment is a recent occurrence.

60.2.7 Maintenance of Infrastructures

Maintenance of infrastructure is vital in the economic well-being of a country. There are several aspects that can be discussed under this title, but we will discuss here only two important infrastructures of public interest, *viz*, rail and civil structures that include machanical structures as well.

60.2.7.1 Railway Tracks

Maintenance [14, 15] is a critical function for ensuring performance of a system. More so if it concerns railways. It is of great concern for those nations where rail transportation constitutes a major infrastructure like highways. In countries like India with a total track length of about 64,000 kilometres, and 13 million passengers and 1.3 million tonnes of freight carried by 14300 trains every day, it constitutes an important infrastructure and the lifeline of economy, resulting in an annual revenue of about US$ 18 billion. To maintain such a large length of track (which is fifth largest after USA, Russia, Canada, and China) under single

management is by no means is an easy task. Moreover, as railways are associated with passengers and freight, it always has the risk of loss of lives and loss of assets. New technologies and better safety standards are constantly introduced but still accidents occur all over the world. Of course risk of train collisions and derailments can be reduced by better safety measures and elimination of root causes. These causes will require an effective maintenance strategy to govern optimization of inspection frequency and/or improvement in skill and efficiency. A detailed and careful study of the defects that emerge both on the rolling stock and rail infrastructure is essential to frame out the correct maintenance strategy.

Detection and rectification of rail defects are major issues for all rail players around the world. Some of the defects include worn out rails, welding problems, internal defects, corrugations, and rolling contact fatigue (RCF) initiated problems such as surface cracks, head checks, squats, spilling, and shelling. If undetected and/or untreated these defects can lead to rail breaks and derailments. There is also a need for better prediction of rail defects over a period of time based on operating conditions and maintenance strategies. Trains subject the track structure to repeated loading and unloading as they pass. Each loading–unloading cycle causes deformation of the track, part of which is elastic and recovers; while other parts suffer permanent deformation. Track settlement is an integrated process in which the settlement of one component affects that of another. As soon as the track geometry starts to deteriorate, the variations of the train/track interaction forces increase, and this speeds up the track deterioration process. Measurement of track geometry irregularities is the most used automated condition monitoring technique in railway infrastructure maintenance.

Rail degradation is basically due to wear and fatigue. Track curvature has a major influence on degradation. A narrow curve implies wear, whereas tangent track implies fatigue. Fatigue is a major future concern as business demands for higher speed, higher axle loads, higher traffic density, and higher tractive forces increase. The presence of manufacturing defects in the rail subsurface and the direction of the crack mouth on the rail surface are both responsible for guiding crack development direction The presence of water or snow on the rails may also increase the crack propagation rate.

We have included Chapter 68 in this handbook, which looks into all these aspect in more detail, including the maintenance optimization of rail tracks. The basic idea is to reduce the operation and maintenance costs while still maintaining high safety standards and minimizing accidents [16–21].

60.2.7.2 Civil Structures

The performance of civil engineering systems over time is subject to a number of uncertainties [22, 23]. These include operational conditions, material characteristics, and environmental exposure. Usually, civil engineering structures age due to wear, corrosion, fatigue, and other phenomena. At some point of time they must be inspected and either repaired or replaced just as any deteriorating equipment. For concrete structures the most important aging phenomena in temperate climates are corrosion due to carbonation and/or chloride attack, for steel structures it is rust and fatigue. In general, aging phenomena are uncertain. A failure is defined when a more or less complicated function of those variables reaches a limiting state for the first time. Failure time distributions are determined numerically. This makes analyses rather complex and rather different from analyses where analytical failure time models based on rich data can be used.

60.2.8 Restructured Power Systems

This is a new development that originated towards the end of the last century and will become relevant in the 21st century. Restructuring started in 1980 in Chile and the UK and spread to Latin America (Argentina) and in diverse form to USA, Australia, and number of Asian Countries in the 1990s. Since then the US electric industry, a $220 billion industry, is undergoing a tough change in the way it delivers electricity to millions of households and industries through out the country. It was the last great government-sanctioned

monopoly and is now being deregulated slowly and opened to competition, giving consumers the power to choose their electricity provider in much the same way as they choose telephone companies today.

Restructuring or deregulating the power supply industry is a very complex exercise and depends on national strategies and policies, macroeconomic developments and existing conditions, and its application is therefore likely to be different in different countries. Liberalization, deregulation, and privatization all are part of market reforms. It was believed that privatization in the power industry would eliminate power thefts, subsidy, and bring in a higher operating efficiency, and reduce labor and workplace inefficiencies.

It is true that several factors such as technological advances, changes in political and ideological conditions, regulatory failures, high tariffs, managerial inadequacies, global financial drives, environmental activism, and shortage of public resources for development in developing countries have been accelerating the worldwide advent of restructuring of the energy supply industry although the main drive for restructuring, particularly in the UK, came from the government's belief that competition among energy suppliers would offer a wide choice for electricity consumers giving them a say in who supplies the power to them while lowering prices and expanding services. It was thought that reducing government control of the industry would benefit consumers, which would outweigh the benefits of long-established practices followed earlier.

However, the success story is different in California, which in 1996 became one of the first states to enact an electricity restructuring plan. Not long after the plan was introduced, price increases began to erode the public support for deregulation and just two years after the deregulation was enacted, California consumer groups succeeded in putting on the ballot an initiative that would have thrown out the state's deregulation plan.

In fact, the situation during the 1980s was quite conducive to the deregulation regime and provided stimulus for implementation. The advances in gas turbine technology led to more efficient small turbines and generation, which matched the efficiency of large units, particularly when run on natural gas. The price of natural gas also declined, and the restrictions on the use of natural gas were eased in that period.

Restructuring and deregulation has brought in the notions of competition and marketing strategies in addition to introducing new technical considerations in the operation of these independently owned but operationally interconnected parts of the system under the control of another independent authority with the generic name of independent system operator (ISO). ISO holds the unique position of having the responsibility and authority for secure operation of the system without owning it. The traditional vertically integrated utility is now split into several companies such as generation companies (gencos), transmission companies (transcos) and distribution companies (discos), and retail companies. Also due to different market structures in the existing restructured power systems, the reliability and price problems for various market models are different. Generally speaking, the market models can be classified into PoolCo, bilateral contracts and hybrid models.

We have included Chapter 70 to discuss all these new developments and present the new regime that will govern the restructuring of the energy system in the 21st century.

60.2.9 PRA for Nuclear Power Plants

Generally, a nuclear power plant is significantly more expensive to build than the equivalent coal-fueled or gas-fueled plant. However, coal is significantly more expensive than nuclear fuel, and natural gas is significantly more expensive than coal. Thus, capital cost aside, natural gas-generated power is the most expensive. Most forms of electricity generation produce some form of negative externality, costs imposed on third parties that are not directly paid by the producer, such as pollution which negatively affects the health of those near and downwind of the power plant, and generation costs often do not reflect these external costs. A UK Royal Academy of Engineering report in 2004 was conducted with the aim to develop "a

robust approach to compare directly the costs of intermittent generation with more dependable sources of generation". Wind power was found to be more than twice as expensive as nuclear power. Also an OECD/IEA study from 2005 estimated nuclear power total-lifetime costs *per* kWh electric *versus* coal and natural gas for 12 nations and nuclear power generally superseded coal (even without a carbon tax), even though the study unrealistically assumed 40-year plant lifetimes (new plants are designed to operate for 60 or more years). The World Nuclear Association states that "Sun, wind, tides and waves cannot be controlled to provide directly either continuous base-load power or peak-load power when it is needed. In practical terms they are therefore limited to some 10–20% of the capacity of an electricity grid, and cannot directly be applied as economic substitutes for coal or nuclear power, however important they may become in particular areas with favourable conditions."

Thus nuclear power will continue to be produced since:

- it costs about the same as coal, so it is not expensive to make;
- it does not produce smoke or carbon dioxide, so it does not contribute to the greenhouse effect or global warming;
- it produces huge amounts of energy from small amounts of fuel;
- it produces small amounts of waste; and
- it is reliable.

However it has disadvantages as well:

- Although the amount of waste produced is not much, it is highly dangerous and must be disposed of by sealing up and buried for many years to allow the radioactivity to die away.
- A substantial amount of money has to be spent on safety, since a nuclear accident can be a major disaster.

People are increasingly becoming concerned about the safety of nuclear plants and it is reflected from the fact that in the 1990s nuclear power was the fastest-growing source of power in much of the world. In 2005 it was the second slowest-growing. Notwithstanding the foregoing statement, the safety record of nuclear plants has been quite exemplary. Yet the people must be convinced by objective assessment of risk [24–30] associated with any technology they use.

The World Nuclear Association (WNA accredited to the United Nations, is an independent, non-profit organization, funded primarily by membership subscriptions) provides a comparison of deaths due to accidents among different forms of energy production. In their comparison, deaths *per* TWy of electricity produced are 885 for hydropower, 342 for coal, 85 for natural gas, and 8 for nuclear power. Moreover, there have been only two major reactor accidents in the history of civil nuclear power, *viz.,* Three Mile Island and Chernobyl. The first was contained without harm to anyone and the other involved an intense fire without the provision for containment (serious design defect). These are the only major accidents to have occurred in more than 12,700 cumulative reactor-years of commercial operation in 32 countries. The risks from western nuclear power plants, in terms of the consequences of an accident or terrorist attack, are minimal compared with other commonly accepted risks.

However, to address the safety concern the goal is to protect man and his environment by limiting the release, under any circumstances, from the radioactive materials that the facility contains; in other words, ensuring the containment of radio-active materials. This is achieved by providing three-layer barriers between the radioactive source and the public, *viz.,* the fuel cladding, the primary reactor coolant system, and the containment building. It is further ensured in the event of an accident, that its consequences must be limited to a level that is acceptable for both the public and the environment.

Probabilistic risk assessment (PRA) or *probabilistic safety analysis* (PSA) can be conducted to calculate the probability of damage to the core as a result of sequences of accidents identified by the study. PSA [31–38] can now help assess the size of radioactive releases from the reactor building in the event of an accident, as well as the impact of such releases on the public and the environment. These studies are referred to as levels

1, 2, and 3 PSAs respectively. Level 1 study is corresponding to the assessment of the risk of a core melt accident. Level 2 analyses are performed, or are planned, in most NEA countries in view of their importance in determining accident management strategies and identifying potential design weaknesses in reactor containment building. Level 3 analyses are used for emergency planning, since it assesses the amount of release of radioactivity in the environment if containment fails to contain the accident.

The results of these analyses can, therefore, identify not only the weaknesses but also the strengths with regard to the plant's safety, and thus assist in setting priorities and focusing efforts on the points identified as the most sensitive in terms of the contribution they can make to improve the safety of facilities.

We have included Chapter 71 on probabilistic risk assessment for nuclear power plants from an experienced author who has spent a great deal of time in a German nuclear reactor establishment.

60.2.10 Problems in Software Engineering

The last four chapters, *viz.*, Chapters 72, 73, 74, and 75 are related to software reliability or quality problems. Software reliability is a growing field and much research is being done in this area to develop models for prediction and growth. In fact, computers and intelligent parts are quickly pushing their mechanical counterparts out of the market. Appliances such as washing machines, telephones, TVs, and watches, are having their analog and mechanical parts replaced by CPUs and software. It is the predominance of software driven devices and equipment that has brought software to forefront of current revolution. Software can make decisions, but can be just as unreliable as human beings. Software can also have small unnoticeable errors or drifts that can culminate into a disaster. Fixing problems may not necessarily make the software more reliable. On the contrary, new serious problems may arise. In 1991, after changing three lines of code in a signaling program containing millions of lines of code, the local telephone systems in California and along the Eastern seaboard came to a stop. Software reliability [39] is an important attribute together with functionality, usability, performance, serviceability, capability, installability, maintainability, and documentation. Sometimes, software reliability may be hard to achieve, because the complexity of software tends to be high. While the complexity of software is inversely related to software reliability, it is directly related to other important factors in software quality, especially functionality, capability, *etc*. Emphasizing these features will tend to add more complexity to software.

There are two major differences between hardware and software failure rate curves [40]. One difference is that in the last phase, software does not have an increasing failure rate but hardware does. In this phase, software approaches obsolescence; there is no motivation for any upgrades or changes to the software. Therefore, the failure rate will not change. The second difference is that in the useful-life phase, software will experience a drastic increase in failure rate each time an upgrade is made. The failure rate levels off gradually, partly because of the defects found and fixed after the upgrades.

Too much proliferation of software reliability models [3] has taken place as people try to understand the characteristics of how and why software fails, and try to quantify software reliability. Over 200 models have been developed since the early 1970s, but how to quantify software reliability still remains largely unresolved.

Software modeling techniques [39] can be divided into two subcategories: prediction modeling and estimation modeling. Using prediction models, software reliability can be predicted early in the development phase and enhancements can be initiated to improve the reliability. Prediction models include Musa's execution time model [41], Putnam's model, and Rome Laboratory models, whereas estimation models include exponential distribution models, the Weibull distribution model, and the Thompson and Chelson model, *etc*. Current interest in software quality and reliability are indicated from the papers published recently [42–50].

Measuring software reliability is a difficult problem even today, because we do not have a

good understanding of the nature of software. There is no clear definition to what aspects are related to software reliability. Even the most obvious product metrics such as software size do not have a uniform definition. It is better to measure something related to reliability to reflect the characteristics, if we cannot measure reliability directly. The current practices of software reliability measurement can be divided into four categories, *viz.*, product metrics, project management metrics, process metrics, and fault and failure metrics.

Chapter 72 outlines the basic software development process. Some of the existing NHPP software reliability models and their applications are presented along with a generalized software reliability model, considering environmental factors. The concepts of software fault tolerant and software cost models are briefly discussed.

Chapter 73 explores the utility of lognormal distribution in software reliability growth modeling. The authors demonstrate that several observable properties of software systems are in fact related, being grounded in the conditional nature of software execution. This leads to the emergence of a lognormal distribution of rates of events in software systems. These include failure rates of defects and execution rates of code elements. They further discuss how the lognormal growth model can be obtained from the distribution of the first occurrence times of defects and apply it to reliability growth.

Chapter 74 indicates how within the short delivery times that are now becoming very common these days, the software product quality can be improved and in fact be controlled in the early stages of software development. The author employs multivariate linear analysis by making use of process measurement data, derives effective process factors improves product quality, and obtains quantitative relationships between quality assurance/management activity and final product quality.

In Chapter 75, the authors, present software reliability growth models (SRGMs) that describe the relationship between the number of faults removed and the number of test cases used. They also discuss flexible discrete SRGM, which can depict either exponential or S-shaped growth curves, depending upon the parameter values estimated from the past failure data.

Sustainability

Application of sustainability concept can be seen from a few representative examples like [51–53].

60.2.11 Concluding Comments

We have attempted to present very few applications that are of current interest and have relevance in the present context. It was neither our intention, nor it was physically possible to discuss all areas of applications but to present a set of 15 chapters presented here that provides an indication of a set of representative problems in the vast area of applications of performability engineering. Also since there can be thousands of references on applications and it is not possible to include all of them here, we have included mainly those representative references which have been published in the International Journal of Performability Engineering and it is hoped that with the publication of this handbook, further interest will be generated through the cross fertilization of ideas and many more new areas for applications will be opened up.

Reliability in the Medical Device Industry

Vaishali Hegde

Respironics Inc. Sleep and Home Respiratory Central Facility
Monroeville, Pennsylvania, 15146, USA

Abstract: The medical industry is one of the fastest growing segments of the US economy. Increasingly, medical equipment is being used outside a controlled hospital environment. The complexity and increased use of medical equipment in non-hospital environments has made the need for safe, reliable products imperative. Although reliability engineering tools are well established, their application to the medical industry is fairly new. This chapter discusses the reliability tools and standards applicable to the medical equipment industry.

61.1 Introduction

The medical industry is one of the fastest growing segments of the US economy. In 2004, healthcare spending in the US reached $1.9 trillion, and was projected to reach $2.9 trillion in 2009 [1]. In 2004, the US spent 16% of its gross domestic product (GDP) on healthcare. It is projected to rise to 20% in the next decade. The United States is not the only country in the world spending large sums of money on healthcare. Countries all over the world are spending more and more on healthcare every year. According to the Organization for Economic Cooperation and Development, healthcare spending accounted for 10.9% of the GDP in Switzerland, 10.7% in Germany, 9.7% in Canada, and 9.5% in France [2].

Healthcare spending is increasing all over the world due to increased life expectancy and consequently the increased aging population. Reduction in mortality during the 20th century led to large increases in life expectancy. By 2000, life expectancy in the US was approximately 76.9 years. According to the US Census Bureau's projections, by 2030, the older population in the US is projected to be double that of 2000, growing from 35 million to 72 million. By 2050, they project the older population to be around 86.7 million. In other words, nearly one in five Americans will be age 65 and over in 2030 [3].

In 2000, about 92% of people aged 65 and over had made at least one healthcare visit to a doctor's office, an emergency room, or a hospital during the past year (NCHS, 2003a). Among people 65 and older, the number of healthcare visits increased with age.

Chronic diseases have caused most elderly deaths throughout the last 50 years. Diseases of the heart, malignant neoplasms (cancer), cerebro-vascular diseases (stroke), chronic obstructive pulmonary diseases/chronic lower respiratory diseases, and pneumonia and influenza were the top five causes of death for people aged 65 and

over, in year 2000 [3]. Treatment of these chronic diseases requires several different types of medical devices. All data mentioned above points to an explosive growth in the medical device and medical services market in the world.

When it comes to medical equipment, failure is not an option. From critical devices such as oxygen concentrators, lasers, ventilators, MRI scanners, insulin pumps, implantable pacemakers to instruments as straightforward as stethoscopes, injections, and thermometers, medical equipment must be reliable. The medical industry must have higher reliability standards than other fields. However, a high reliability standard is hard to maintain in today's environment of intense global competition, pressure for shorter product-cycle times, stringent cost constraints, higher customer expectations for quality and reliability, and complex global and heterogeneous markets.

Medical electronic products are increasingly being used in non-hospital environments by non-clinical personnel. This is because sophisticated medical products are becoming more compact and portable. For example, a few years ago, an oxygen concentrator weighed 75 pounds, had to be plugged into the wall for power, and had to be used in a controlled clinical environment. Today, a portable oxygen concentrator weighs only 8 pounds, can operate on batteries and can be used in a home environment. Developing and producing a medical electronic product reliable enough to continuously repeat certain key functions over and over again like clockwork and alarming appropriately in case of a fault condition, is now more important than ever before.

Today, reliability takes on even greater significance since medical devices designed for specific applications are becoming more expensive. It is not uncommon for cancer treatment or surgery equipment to cost a few million dollars. While hospitals may be relatively profitable, they cannot afford to have too many of these expensive products. If one such medical system incurs downtime due to failure, it can adversely affect the hospital's bottom line, its reputation, and the well-being of its patients [4]. In some cases, medical electronics products in use for several years require updating to increase their reliability as greater healthcare demands are placed on them.

The financial impact of having an unreliable or unsafe medical product in the market can be devastating for a medical device manufacturer. Since December 13, 1984, the FDA Medical Device Reporting (MDR) regulations have required firms who have received complaints of device malfunctions, serious injuries or deaths associated with medical devices to notify FDA of the incident. The MDR regulation provides a mechanism for FDA, manufacturers, importers and user facilities to identify and monitor significant adverse events involving medical devices. The goals of the regulation are to detect and correct problems in a timely manner. MedWatch, the FDA's safety information and adverse event reporting program is set up for health professionals and consumers to report serious adverse reactions and problems related to drugs, medical devices, cosmetics, *etc*. MedWatch plays a critical role in FDA's post marketing surveillance – the process of following the safety profile of medical products after they've begun to be used by consumers. The FDA publishes a weekly FDA Enforcement Report that contains all enforcement actions including recalls, field corrections, seizures, and injunctions. This report is published on the internet at http://www.fda.gov/opacom/Enforce.html. It also maintains MAUDE (manufacturer and user facility device experience database), which contains reports of adverse events involving medical devices.

Depending on the severity of MDR or MedWatch report filed, a defective medical device may have to be recalled. A recall is a method of removing or correcting products that are in violation of laws administered by the Food and Drug Administration (FDA). Filing an MDR or recalling a medical device takes a significant amount of time, effort, and resources on the part of the manufacturer. It can have a negative impact on a device manufacturers' reputation in the marketplace. It may lead to product liability lawsuits, particularly in the US. All this could consequently lead to an adverse impact on sales and profits.

Low reliability can have a significant impact on service, repair, and warranty costs as well. In fact, warranty cost is inversely proportional to the reliability of a medical device. Hence, more and more manufacturers are willing to invest in reliability related tasks to try and reap the benefits in terms of warranty costs. A 5% increase in reliability focused development costs will return a 10% reduction in warranty costs. A 20% increase in reliability focused development costs will typically reduce warranty costs by half and a 50% increase in reliability focused development costs will reduce warranty cost by a factor of 5 [5].

61.2 Government (FDA) Control

As the use of medical devices for critical life supporting functions increases, governments around the world are regulating their design, manufacture, quality, reliability, proper use and disposal. The Food and Drug Administration (FDA) is the US Government agency that oversees most medical products, foods and cosmetics. Within FDA, the Center for Devices and Radiological Health (CDRH) oversees the safety and effectiveness of medical devices and radiation-emitting products.

The FDA is responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, the nation's food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing the public health by helping to speed innovations that make medicines and foods safer, and more affordable, and helping the public get the accurate, science based information they need to use medicines and foods to improve their health.

Products regulated by FDA include all foods except meat and poultry, prescription and non-prescription drugs, blood products, vaccines and tissue transplantation, medical devices and radiological products, including cellular phones, animal drug and feed, and cosmetics. In addition to setting product standards, FDA regulates the labeling of products under its jurisdiction. This information must be valid, well documented, and not misleading. FDA plays a major role in protecting consumers and the public health.

The Federal Food, Drug, and Cosmetic Act of 1938 authorized the FDA to take formal or informal regulatory measures against the mis-branding or adulteration of medical devices. Amendments to this act in 1976 empowered the FDA to regulate medical devices during their design and development phases. The Safe Medical Device Act passed in 1990, authorized the FDA to implement the Preproduction Quality Assurance Program. This program requires medical device manufacturers to address deficiencies that lead to failure during design. Nowadays, similar types of regulations concerning medical devices are being followed in other countries. For example, the Medical Device Directive (MDD) of the European Union (EU) outlines the requirements for medical devices in the EU countries.

61.3 Medical Device Classification

The FDA has established three regulatory classes for medical equipment based on the level of control necessary to assure the safety and effectiveness of the device. The class to which a device is assigned determines, among other things, the type of premarketing submission/application required for FDA clearance to market.

Device classification is risk based, that is, the risk the device poses to the patient and/or the user is a major factor in the class it is assigned. All classes of devices are subject to General Controls which are the baseline requirements of the Food, Drug and Cosmetic (FD&C) Act.

The three classes and the requirements that apply to them are:

- Class I: General Controls

Class I devices are subject to the least regulatory control. They present minimal potential for harm to the user and are often simpler in design than Class II or Class III devices. Class I devices are subject to "General Controls" as are Class II and Class III devices. Examples of Class I devices include elastic bandages, examination gloves, and hand-held surgical instruments.

- Class II: General Controls and Special Controls

Class II devices are those for which general controls alone are insufficient to assure safety and effectiveness, and existing methods are available to provide such assurances. In addition to complying with general controls, Class II devices are also subject to special controls. Special controls may include special labeling requirements, mandatory performance standards and postmarket surveillance. Examples of Class II devices include powered wheelchairs, infusion pumps, and surgical drapes.

- Class III: General Controls and Premarket Approval

Class III is the most stringent regulatory category for devices. Class III devices are those for which insufficient information exists to assure safety and effectiveness solely through general or special controls. Premarket approval by FDA, is required for this class of devices. Premarket approval is the required process of scientific review to ensure the safety and effectiveness of Class III devices.

Class III devices are usually those that support or sustain human life, are of substantial importance in preventing impairment of human health, or which present a potential, unreasonable risk of illness or injury.

The reliability activities that need to be performed during the life cycle of a product, depends to some degree on the classification of the product. Class III devices need maximum analyses and testing because they support or sustain human life.

61.4 Reliability Programs

Reliability engineering tools are well established, however, their application to the medical industry is fairly new. The first step in launching a safe and reliable medical product is a good reliability program. What are the hallmarks of a good reliability program? Developing realistic reliability goals early, planning an implementation strategy and then executing the strategy are all key features of a good reliability program.

The four phases of a reliability program are [6].

- The concept phase,
- the design phase,
- the prototype phase, and
- the manufacturing phase.

Several different reliability tools are available for use in the four phases of a reliability program. In the concept phase, one can use benchmarking and gap analyses to develop a reliability program and integration plan.

In the design phase, one can use reliability modeling and predictions, derating analysis/ component selection, worst case circuit analysis, thermal analysis, electromagnetic analysis, design of experiments, risk management/FMECAs, fault tree analysis, human factors analysis and software reliability analysis to increase reliability of a product.

In the prototype phase, one can perform highly accelerated life testing (HALT), design verification testing (DVT), and reliability demonstration testing (RDT).

In the manufacturing phase, the reliability tools that can be used are highly accelerated stress screening (HASS), on-going reliability testing, FRACAS/CAPA system setup, and end-of-life assessment.

61.4.1 The Concept Phase

61.4.1.1 Benchmarking

Benchmarking is the process of comparing the current project, methods, or processes with the best practices in the industry. Benchmarking is crucial to both a startup company as well as an established company that is coming out with a new product to assure the new product is competitive based on reliability and cost. For example, company A, a new entrant into the medical manufacturing market, wants to start selling a new type of dialysis pump. Company A should check the warranty information, annual service plan and recommended maintenance schedule of leading competitor products to try and benchmark their dialysis pump with respect to MTBF, failure rate, service interval, *etc*., against competitor pumps.

61.4.1.2 Gap Analysis

Gap analysis compares your current capabilities with what is expected of your product in the industry. Before performing a gap analysis you have to set a reliability goal and perform a review of your current capabilities. Gap = goals − current capabilities. For example, a ventilator manufacturer currently has a ventilator on the market that has a field reliability of 0.988. It is now planning to add an oxygen blending feature to this ventilator. They would like the new ventilator to have a reliability goal of 0.9999 to meet customer expectation. The process of determining the current capability (0.988), the goal (0.9999), and the gap (0.9999 − 0.988 = 0.0119) is called gap analysis.

The output of this phase is the reliability program. The program generally quantifies out of box failure rate, reliability within warranty period, and reliability throughout life of the product. It also defines a schedule of the different activities that will be performed to achieve your reliability goal.

61.4.2 The Design Phase

61.4.2.1 Reliability Modeling and Predictions

A reliability prediction is a method of calculating the reliability of a product by assigning a failure rate to each individual component and then summing all of the failure rates. Standards such as MIL-HDBK-217, Bellcore, PRISM, CNET, HRD5, *etc*., can be used for reliability predictions. A reliability model presents a clear picture of functional interdependencies and provides the framework for developing quantitative product level reliability estimates to guide design trade-off process. Models are helpful for identification of single points of failure, making numerical allocations, evaluating complex redundant configurations, and showing all series-parallel relationships.

61.4.2.2 Derating Analysis/Component Selection

In MIL-STD-721 derating is defined as using an item in such a way that applied stresses are below rated values. Limitation of electrical, mechanical and environmental stresses is critical to high reliability. One common rule of thumb used in electronics is that 50% derating can decrease the failure rate by 30%. The Telcordia SR332 (reliability prediction procedure for electronic equipment) standard gives derating information. Component selection must be based on the basis of derating analysis. Design engineers should select appropriate component ratings to avoid over-stressing them. In the case of implantable medical devices, biocompatibility and reliability of the material and components should be considered as well, while making component selections.

61.4.2.3 Worst Case Circuit Analysis

Worst case circuit analysis (WCCA) is an analysis technique which, by accounting for component variability, determines circuit performance under a worst case scenario, *i.e.*, under extreme environmental or operating conditions. The output of a WCCA allows an assessment of actual applied part stresses against rated part parameters, which can help ensure the application of sufficient part stress derating to meet design requirements. One of the most critical steps involved in completing a meaningful WCCA is the development of a part characteristic database. This database should contain a composite of information necessary for quantifying sources of component parameter variation. Once these sources have been identified, the database can be used to calculate worst case component drift for critical parameters.

61.4.2.4 Thermal Analysis

Temperature is one of the important variables that impacts system reliability. Therefore, the thermal design of a system must be planned and evaluated carefully. Thermal analysis techniques can be used to evaluate the circuit board, casing, and junction temperatures and check for components that exceed their temperature limits. The analysis can also be used to identify the hot spots and components on the board that designers may modify by various means to eliminate thermal problems. Typical solutions are adding heat sinks, thermal pads, and thermal vias, using thicker ground or power planes, local conduction pads, thermal screws, changing of radiation emissivity by coatings, or relocating components.

61.4.2.5 Electromagnetic Analysis

Electromagnetic compatibility, or EMC means that a device is compatible with (*i.e.*, no interference is caused by) its electromagnetic (EM) environment and it does not emit levels of EM energy that cause electromagnetic interference (EMI) in other devices in the vicinity. A medical device can be vulnerable to EMI if the levels of EM energy in its environment exceed the EM immunity (resistance) to which the device was designed and tested. The different forms of EM energy that can cause EMI are conducted, radiated, and electrostatic discharge (ESD). EMI problems with medical devices can be very complex, not only from the technical standpoint but also from the view of public health issues and solutions. The Center for Devices and Radiological Health (CDRH) encourages manufacturers of electro-medical equipment to use the IEC 60601-1-2 standard, a widely recognized standard issued by the International Electrotechnical Commission, Geneva, Switzerland. The standard provides various limits on emissions and immunity.

61.4.2.6 FMECA

Failure modes, effects and criticality analysis (FMECA) is a reliability evaluation and design review technique that examines the potential failure modes within a system or lower indenture level, in order to determine the effects of failures on equipment or system performance. FMECA uses a "bottom up" approach. This approach begins at the lowest level of the system hierarchy and traces up through the system hierarchy to determine the end effect on system performance. The criticality portion of this method allows us to place a numerical value or rating on the criticality of the failure effect on the entire system or user. After the initial analysis, one can prioritize the failure modes, provide mitigations, reanalyze, rescore and confirm that risks are at an acceptable level. There are several different types of FMEAs. For example, design FMEAs, process FMEAs, functional FMEAs, system FMEAs, *etc*. The basic approach for all the FMEAs is the same. A sample section of a FMEA worksheet is given in Figure 61.1.

61.4.2.7 Fault Tree Analysis

A fault tree analysis is a systematic, deductive methodology for defining a single specific undesirable event and determining all possible reasons or failures that could cause that undesirable event to occur. The undesired event is the top event in the fault tree and is generally a catastrophic or complete failure of the product. Fault trees use concepts of logic gates to determine the overall reliability. In medical devices, patient harm is the most common undesired top event. The results of FTA can be used as a troubleshooting tool during service calls, after the product is available in the market. A sample section of a fault tree is given in Figure 61.2.

System				Potential						FMEA Number					
Subsystem				Failure Mode and Effects Analysis						Prepared By					
Component				(Design FMEA)						FMEA Date					
Design Lead										Revision Date					
Core Team										Page					
											Action Results				
Item / Function	Potential Failure Mode(s)	Potential Effect(s) of Failure	Sev	Potential Cause(s)/ Mechanism(s) of Failure	Prob	Current Design Controls	Det	RPN	Recommended Action(s)	Responsibility & Target Completion Date	Actions Taken	New Sev	New Occ	New Det	New RPN
EEPROM / Store therapy settings	Data Bit Loss	No therapy due to loss of therapy parameter setting	10	Corruption	4	NV RAM BIST	1	40	Store therapy setting in a backup location						

Figure 61.1. Sample Section of a FMEA Worksheet

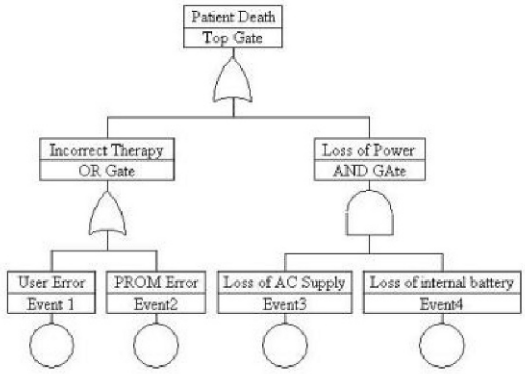

Figure 61.2. Sample section of a fault tree

61.4.2.8 Human Factors Analysis

Human factors analysis should be performed with safety, manufacturing, and maintainability in mind. Human beings are famous for not reading and following instructions. Surrounding distractions is a major concern in the hospital environment. Medical device manufacturers have to make sure that hospital staff is able to use the medical equipment correctly and efficiently in spite of all the other surrounding hospital distractions. They also have to make sure that symbols used on their medical devices meet standards approved by the FDA. AAMI (Association for the Advancement of Medical Instrumentation) has published a technical information report on graphical symbols for electrical equipment in medical practice.

61.4.2.9 Software Reliability Analysis

Software is an important component of medical devices. A software life cycle can be divided into design, coding, and testing. If good practices are followed in all stages of the software life cycle a reliable software product will be ensured. The USAF model and the Mills model are two software reliability models that are generally considered useful for medical devices. The USAF model was developed by the US Air Force Laboratory in Rome, NY. to predict software reliability during the initial phases of the software life cycle. The model begins by developing the predictions of fault density and then transforming them into other reliability measures such as failure rates [7]. The Mills model was developed by H.D. Mills [8] by reasoning that an estimation of faults remaining in software could be made through a seeding process that assumes a homogeneous distribution of a representative class of faults. Before starting the seeding process, fault analysis is performed to determine the expected types of faults in the code and their relative frequency of occurrence [7].

61.4.3 The Prototype Phase

Testing is an important part of any product development cycle. It is performed to verify performance, understand failure modes and weaknesses of the product, benchmark your product against competitor products, determine reliability and safety of the product, and study the impact of stress on performance of the product. Reliability and safety testing is crucial in medical devices.

Testing can be performed in two different modes: standard or accelerated. In standard mode, tests are performed in ambient temperature, at typical operating stress conditions. In accelerated mode, parameters such as temperature, voltage, current, and cycling, are increased well above their normal levels to reduce test times.

In the prototype phase, one can perform highly accelerated life testing (HALT), design verification testing (DVT), and reliability demonstration testing (RDT).

61.4.3.1 HALT

Highly accelerated life testing is a quick and cost effective tool used for discovering design issues and improving design margins. Thermal stress and vibration stress are the two main stresses applied during HALT. Generally a product is subjected to a cold thermal cycle, a hot thermal cycle, a fast thermal transition cycle, a vibration cycle, and a combined thermal-vibration cycle. A root cause analysis is performed at the end of the test to determine the cause of failures. Design and processing changes can be made based on HALT findings. A verification HALT can be performed to ensure that problems are fixed and new problems have not been introduced. For example, during a HALT test, a ventilator with an operating range of 5 C to 40 C, provided incorrect therapy above 35 C and shut down at 65 C. The root cause of failure

was determined to be the temperature rating of a proximal pressure flow sensor. The standard sensor was changed to an extended temperature range sensor to solve the problem. On the same ventilator, the internal battery was disconnecting at very low vibration levels. The battery connector was changed to a positive latch, mini lock type connector to prevent disengagement of the battery. Both the sensor issue and the battery connector issue would not have been discovered before product release if HALT had not been performed.

61.4.3.2 DVT

Design verification testing is performed to verify product functionality. Generally, this testing is performed under normal operating conditions; no external stresses are applied. The results of design verification testing are generally required during pre-market notification 510(k) submittal to the FDA.

61.4.3.3 RDT

Reliability demonstration testing is used to validate reliability prediction analyses and gather a measure of confidence that the released product will achieve a certain reliability target. In this test, a sample of units is tested at slightly accelerated stresses for several months. The stresses are higher than normal operating stress conditions but lower than HALT stress conditions. The stresses are held constant thus enabling you to calculate the acceleration factor for the test. MTBF (mean time between failures) can be obtained from test results. This test is generally performed once before product release.

61.4.4 The Manufacturing Phase

In the manufacturing phase, the reliability tools that can be used are highly accelerated stress screening (HASS), on-going reliability testing, FRACAS/CAPA system setup, and end-of-life assessment.

61.4.4.1 HASS

Highly accelerated stress screening is used to reduce out of box quality returns, decrease field service and warranty costs, and detect and correct process defects. Typical failures that HASS will find are soldering defects, bent IC leads, socket failures, incorrect components or component placement and programming errors. It is recommended that a HALT be performed prior to performing a HASS. HALT will help to identify the operating and destructive limits of a product. This information is essential while developing a HASS process.

61.4.4.2 ORT

On going reliability testing is performed to get an indication of the reliability of the product before it is shipped to customers. In this test, a sample of product is taken off a production line and tested for a period of time, adding the cumulative test time to ensure that the reliability target will be met. The samples are rotated on a periodic basis to get an on-going reliability. One must take care not to wear out any components because these units are shippable units and you cannot risk taking significant life out.

61.4.4.3 FRACAS/CAPA System Setup

Failure reporting and corrective action systems (FRACAS) or corrective and preventive action systems (CAPA) provide a framework for controlling corrective action processes. At its core, FRACAS is a closed loop corrective action system which enables you to collect failure data, analyze data and determine root cause, document the corrective action and implement controls to prevent the reoccurrence of the failure. An integral part of CAPA is a failure review board (FRB). The board is typically a cross-functional group representing quality, reliability, engineering, manufacturing, and regulatory and other departments depending on the nature of the business. The board is responsible for reviewing and approving recommended corrective actions and evaluating effectiveness of corrective actions after implementation. A FRACAS system is essential for medical device manufacturers because of the FDA Medical Device Reporting (MDR) regulations.

61.4.4.4 EOL Assessment

End of life assessment is performed to determine when a product is starting to wear out, whether the

preventive maintenance strategy is effective and whether the predictions performed during design phase were accurate. EOL assessment uses the Weibull plotting technique to figure out where the product is on the bathtub curve. Field failure data is used to determine the number of days before failure.

61.5 Reliability Testing

There are many different reasons for performing reliability testing. The main reasons are to induce failure modes as well as detect unanticipated failure modes so corrective actions can be implemented, to determine if items or system meet reliability requirements, to compare estimated failure rates to actual failure rates, to monitor reliability growth over time, to determine the safety margin in a design, to estimate MTBF or MTTF values, and to identify weaknesses in the design or parts [9].

O'Connor states that reliability testing is a part of an integrated test program involving statistical testing, to optimize the design of the product and the production processes; functional testing, to confirm the design; environmental testing, to ensure that the product can operate under the projected environments; reliability testing, to ensure that the product will operate for its expected life; and safety testing, to ensure safety of the product for use by humans, animals or property [10].

Developing a test plan is the first step of an integrated test program. The Reliability Toolkit provides a test plan outline which includes the following steps: define purpose and scope, list reference documents, and define test item facilities, test requirements, test schedule, test conditions, test monitoring, test participation, failure definitions, test ground rules, and test documentation [11].

Test procedures are required for the proper execution of the test plan. Test procedures must address calibration and proofing the test equipment. They must have a detailed description of the tools, parts, adjustments, hook ups, datasheets, tools, and materials required for the test. The Reliability Toolkit provides a reliability test procedure checklist that includes equipment operation, on/off cycles, operation modes, exercising methods, performance verification procedure, failure event procedure, and adjustments and preventive maintenance schedule [11].

There are several different types of reliability tests that can be performed over the life of the product cycle. Reliability development/growth tests (RD/GT), reliability qualification tests (RQT), performance tests, screening tests, and probability ratio sequential tests (PRST).

61.5.1 The Development/Growth Test

This type of test is run to determine if there is a need to change the design to achieve reliability specification, or to verify improvements occurring in design reliability after changes have been made. These tests are generally run in the prototype or development phase. Estimates of MTTF or MTBF can be obtained from these tests.

61.5.2 The Qualification Test

The objective of this type of test is to determine if a design is acceptable for the intended function. Qualification tests in many cases include aspects of vibration, shock, temperature cycling and other environmental considerations the product will see in use.

61.5.3 The Acceptance Test

Acceptance testing is statistically derived to determine if an item is to be accepted or rejected for use, either individually or on a lot basis. This method of testing does not provide MTBF, MTTF or any other quantifiable measure.

61.5.4 The Performance Test

Performance testing is conducted on completed designs and normally manufactured items to verify the reliability predictions and test results in the preproduction phase. This testing provides a benchmark for comparison of previous activities to see if they are effective in delivering a design that meets reliability requirements.

61.5.5 Screening

Screening tests are performed with the intent of eliminating the infant mortality period. By eliminating infant mortality period, the yield of finished product is improved, and a higher reliability is achieved out in the field.

61.5.6 Sequential Testing

Sequential testing for products designed to operate for some period of time is outlined in MIL-STD-781. These tests called Probability Ratio Sequential Tests (PRST) are based on the ratio of an acceptable MTBF, which should have a high probability of acceptance to an unacceptable MTBF, which should have a low probability of acceptance. Items are placed on test, and failures that occur are plotted against test time. A decision is made based on the plotted point. The decision is one of three, accept the items as meeting the required MTBF, reject the items as not meeting acceptable MTBF, or continue testing.

Sequential test plans provide the least amount of time to make a decision when product is either very good or very bad as compared to reliability requirements. When the product is borderline, testing can be continued for an indeterminate period of time, which is an unacceptable situation. To prevent the tests from continuing indefinitely there are specific truncation points designed in these tests. The test will terminate at either a given amount of failures or a predetermined test time, if a decision has not been made.

61.6 MTBF Calculation Methods in Reliability Testing

MTBF (mean time between failures) is used frequently to assess reliability of a medical product. There are five methods to estimate MTBF in reliability testing [7].

- Time terminated, failed items replaced.
- Time terminated, failed items not replaced.
- Failure terminated, failed items replaced.
- Failure terminated, failed items not replaced.
- No failures.

All the methods assume exponential distribution (constant failure rate). Each method is described below.

61.6.1 Time Terminated, Failed Items Replaced

In this method, testing is terminated at a preassigned time, and all failed items are replaced immediately after their individual failures. MTBF can be calculated using

$$MTBF = MT_d / n, \tag{61.1}$$

where T_d is the test duration time, M is the number of items placed on test and n is the total number of failures. One does not need to record the time to failure of each individual unit on test. For example, a medical device manufacturer places fifteen identical handheld oximeters on test, for 2400 hours. 6 of the 15 oximeters failed in the 2400 hour time period. All failed oximeters are replaced as soon as they fail. An estimate of the MTBF of the tested oximeters can be given by:

$$\begin{aligned} MTBF &= (15)(2400)/6 \\ &\equiv 6000 hours . \end{aligned}$$

Therefore, the MTBF of the oximeters is 6000 hours.

61.6.2 Time Terminated, Failed Items Not Replaced

In this method, testing is terminated at a preassigned time, and the failed items are not replaced. MTBF can be calculated using

$$MTBF = \left\{ \sum_{i=1}^{n} T_i + (M-n)T_d \right\} \Big/ n, \tag{61.2}$$

where T_i is the time to failure, M is the number of items placed on test; T_d is the test duration time and n is the total number of failures. One needs to

record the time to failure of each individual unit on test.

For example, a manufacturer started a test with five identical defibrillators. Two of the five defibrillators failed after 75 and 110 hours. The failed defibrillators were not replaced. The test was terminated at a predetermined time of 500 hours. What is the MTBF of the tested defibrillators?

$$MTBF = \{(75+110)+(5-2)(500)\}/2$$
$$\equiv 842.5 hours .$$

Therefore, the MTBF of the defibrillators is 842.5 hours.

61.6.3 Failure Terminated, Failed Items Replaced

In this method, testing is stopped at a predetermined number of failures, and each failed item is replaced. MTBF can be calculated using

$$MTBF = MT_d / n , \quad (61.3)$$

where T_d is the test duration time, M is the number of items placed on test, and n is the total number of failures. The equations for time terminated and failure terminated are equivalent when failed items are replaced.

61.6.4 Failure Terminated, Failed Items Not Replaced

In this method, testing is terminated at a predetermined number of failures, and the failed items are not replaced. MTBF can be calculated using

$$MTBF = \left\{ \sum_{i=1}^{n} T_i + (M-n)T_d \right\} \Big/ n , \quad (61.4)$$

where T_i is the time to failure, M is the number of items placed on test; T_d is the test duration time and n is the total number of failures.

61.6.5 No Failures Observed

In this method, MTBF cannot be calculated because no failures are observed. However, a lower one-sided confidence limit can be calculated to state the minimum limit of the MTBF for a specified confidence level.

$$LOCL = (2T_t) / \chi^2_{\alpha,m} . \quad (61.5)$$

61.7 Reliability Related Standards and Good Practices for Medical Devices

Nowadays, compliance to certain safety, quality, and usability standards is a pre-requisite to gaining approval from FDA to market a medical device in the USA. There are over 700 medical standards available on different topics for different types of devices. Some standards directly or indirectly related to medical device quality, reliability, safety, and usability are given in Table 61.1.

Table 61.1. Reliability standards

Standard Reference No.	Standard Title/Description
ANSI/AAMI/ISO 14971:2000 and 14971:2000/A1:2003	Medical devices – Application of risk management to medical devices
ANSI/AAMI ES1-1985	Safe current limits for electro medical apparatus
ASTM F1100 – 90	Standard Specification for Ventilators Intended for Use in Critical Care
ASTM F1246 – 91	Standard Specifications for Electrically Powered Home Care Ventilators, Part 1 – Positive Pressure Ventilators and Ventilator Circuits
ASTM F1463	Specification for alarm signals in medical equipment used in anesthesia and respiratory care
ASTM F0792	Guide for computer automation in the clinical laboratory
AAMI EOTP-2/85	Performance evaluation of ethylene oxide sterilizers – EO test packs, good hospital practice
AAMI TIR 12:2004	Designing, testing, and labeling reusable medical devices for reprocessing in healthcare facilities: A guide for medical device manufacturers
AAMI TIR 32:2004	Medical device software risk management
AAMI HE-1988	Human factors engineering guidelines and preferred practices for the design of medical devices
	Guidance for the content of Pre-market Submissions for Software Contained in Medical Devices Issued May 11, 2005 by CDRH
ISO 10651-6	Lung ventilators for medical use – Particular requirements for basic safety and essential performance
ISO 10993-1	Biological evaluation of medical devices – Part 1: Evaluation and testing
ISO 15001	Anesthetic and respiratory equipment – Compatibility with oxygen
ISO 8185:1997	Humidifiers for medical use – General requirements for humidification systems
ISO 9000 series	ISO 9000 series of quality standards
ISO 1348	Quality systems – medical devices – particular requirements for the application of ISO9002
IEC 60601-1-1	Medical Electrical Equipment Part 1: General requirements for safety – Collateral Standard: safety requirements for medical electrical systems
IEC 60601-1-2	Medical Electrical Equipment Part 1: General requirements for safety – Collateral Standard: electromagnetic compatibility.

Table 61.1. Continued

Standard Reference No.	Standard Title/Description
IEC 60601-1-6	General requirements for safety – Collateral Standard: Usability
IEC 60601-1-8	General requirements for safety – Collateral Standard: General requirements, tests and guidance for alarm systems in medical electrical equipment and medical electrical systems
IEC 68-2-64	Environmental Testing Part 2: Test methods Test Fh: Vibration, broad-band random (digital control) and guidance
IEC 1123	Reliability testing compliance test plans for success ratio
IEC 605	Equipment reliability testing
UL544	Standard for safety of medical and dental equipment
UL 2601-1	Medical Electrical Equipment, Part 1: General Requirements for Safety
MIL HDBK-338	Electronic reliability design handbook
MIL HDBK 217F	Reliability prediction of electronic equipment
MIL-STD-1629A	Procedures for performing a failure mode, effects and criticality analysis
MIL HDBK-781	Reliability test methods, plans, and environments for engineering development, qualification and production
MIL-STD-2155	Failure reporting, analysis and corrective action system (FRACAS)

A Tasks-based Six Sigma Roadmap for Healthcare Services

Loon-Ching Tang, Shao-Wei Lam and Thong-Ngee Goh

Department of Industrial and Systems Engineering, National University of Singapore, 1 Engineering Drive 2, Singapore 117576, Singapore

Abstract: Due to the numerous success stories of the Six Sigma quality initiative, it has become a subject of intense study and discussion in both the industry and academia over the past fifteen years. A fundamental tenet behind the success of Six Sigma is the use of structured strategies to achieve well-defined business goals. An enhanced Six Sigma framework, which takes into account the distinctly transactional nature of processes found in an extended healthcare delivery system is proposed here. Critical differences in the key elements of a Six Sigma program between manufacturing and transactional environments are first identified to motivate the proposed framework. The new framework includes some new systems engineering tools that are deemed more effective than the traditional set of Six Sigma tools. A case study is presented to demonstrate the suitability of these tools within the proposed Six Sigma framework.

62.1 Introduction

The management of extended healthcare delivery systems[1] has always been complicated by a variety of systems complexities. These may be a result of numerous external legal-politico and socio-economic influences, and internal interactions arising from a closely knitted, interdependent web of operational activities and human interactions. Dramatic advancements in healthcare technologies in recent years have further introduced un-precedented challenges in the management of such organizations.

Given the complex nature of any extended healthcare delivery system, a recent report by the Institute of Medicine (IOM) [1] recognized that *systems engineering* tools developed for the design, analysis and control of complex systems may possibly help to achieve a high quality healthcare delivery system. The Six Sigma quality initiative appears to be a viable, organizationally effective, and sustainable platform for the introduction of these tools for the improvement of the quality of healthcare processes. Six Sigma programs are designed to adopt a comprehensive systems perspective to achieve breakthrough quality improvements in complex products and processes. Traditional Six Sigma programs already

[1] Extended healthcare delivery system in this article is defined as any medium to large scale healthcare organization, such as hospitals and polyclinics, that offers a comprehensive range of healthcare services.

encompass a compact, yet highly effective set of systems engineering tools ranging from project management and process mapping to statistical quality engineering techniques such as design of experiments (DOE) and Monte Carlo simulation. In order to address various quality issues peculiar to extended healthcare delivery systems, the current Six Sigma framework will need to evolve into one that further underscores the importance of systems modeling and optimization.

A fundamental tenet behind the success of Six Sigma is the use of s*tructured task oriented strategies* to achieve *well-defined goals* [2, 3]. The generic structure of these strategies (or frameworks) is similar in nature. One of the most well-known frameworks is the define-measure-analyze-improve-control (or DMAIC) framework with its unique set of *tasks* to be accomplished within each well-defined execution phase. The DMAIC framework was essentially developed from the manufacturing environment. Within such frameworks, statistical techniques and lean management tools have, in turn, been identified to accomplish the key tasks at each stage of a Six Sigma project.

Other well-known frameworks include the Design for Six Sigma frameworks of identify-design-optimize-validate (IDOV) and define-measure-analyze-design-validate (DMADV). These have been developed for product design and development industry. Although the generic structures of Six Sigma frameworks appear similar in nature as they broadly contain phases that deal with the problem definition, analysis, improvement, and solution implementation, the definition of key tasks within these structured strategies generally has to be translated from the characteristics of different environments. As an example, robust design and reliability engineering are typically more applicable for a product design environment than a manufacturing process. The unique requirements of different industries mandate different definition of key tasks within generic Six Sigma frameworks. The definition of key tasks naturally translates to different toolsets that are deemed most effective for different industrial environment.

The traditional Six Sigma framework was essentially developed from a manufacturing environment. As healthcare delivery systems comprise processes that are typically transactional in nature, an enhanced framework is proposed that can more effectively bridge the gap between the definition and achievement of Six Sigma goals. As a motivation for this framework, critical differences in the key elements of a Six Sigma program between manufacturing and transactional environments are first identified and discussed in the next section. A case study is then presented to demonstrate the effective integration of some new tools within the proposed Six Sigma framework.

62.2 Task Oriented Strategies of Six Sigma

Six Sigma programs are designed with an emphasis on the identification, measurement, reduction, and control of variations found in a realistic environment. The origin of Six Sigma can be attributed to the development of quality programs in Motorola in the 1980s [2]. By clearly specifying a set of proven task-oriented and well-structured strategies built upon sound systems engineering principles and statistical foundations, Six Sigma is seen to be able to effectively enhance profitability by reducing cycle time, defect rate and rework through project-by-project quality improvement efforts.

The potential of Six Sigma in healthcare has been acknowledged by many healthcare researchers and practitioners. A search in scientific healthcare literature through the PubMed database using the keyword “Six Sigma” revealed more than 79 relevant publications since 1995 (see Figure 62.1). There is a growing number of case studies that report successful Six Sigma implementations in the healthcare industry (see, for example, [4]) and consider a wide variety of customer-centric improvement activities directed at operational processes such as in the reduction of medication errors, patient waiting times in radiology department, billing errors, inventory levels, *etc*.

Given the phenomenal success behind Six Sigma, there has been some research that attempts to understand the success factors that drive it. The power behind this program has been attributed to

several critical characteristics [2]. Some theoretical underpinnings based on a goal theoretic perspective that underlie the success behind Six Sigma have also been proposed and investigated by Linderman *et al.* [5, 3]. One of the key propositions behind the goal theoretic framework [3] is the use of well-structured methods to tackle complex process improvement tasks in Six Sigma. The use of such structured methods has always been one of trademarks of Six Sigma and recognized as a key success factor [2].

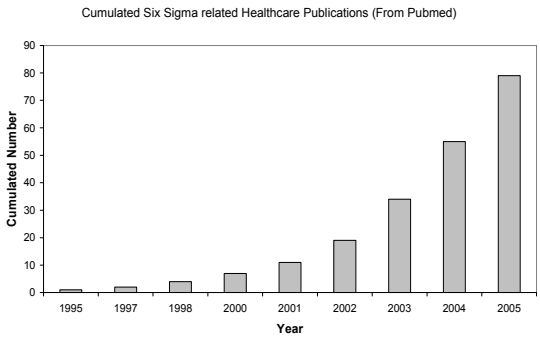

Figure 62.1. Exponential growth of Six Sigma related healthcare publications

There are differently structured Six Sigma methods that comprise generic lists of essential tasks to be fulfilled. A master task list typically found in structured Six Sigma problem solving strategies is given in Table 62.1. The most widely adopted framework is the DMAIC framework. Broadly, the DMAIC framework is a systematic project-based improvement process that essentially contains a project definition phase, process measurement and analysis phases, a process improvement phase, and a process stabilization and control phase executed in a sequential and iterative manner [2]. A classification of tasks in the master task list is given within this framework in Table 62.1.

Apart from the DMAIC framework, there are also other Six Sigma frameworks that have been developed as a result of peculiar characteristics within generic processes (examples include DMADV and IDOV frameworks for product development processes). Regardless of whatever framework Six Sigma is manifested in, a fundamental tenet behind the goal theoretic explanation underlying Six Sigma frameworks is that well-defined goals are supplemented with suitable tasks and tools within well-structured methods that enable the resolution of complex problems existing in the gulf between goal setting and goal achievement [3]. To a reasonable extent, this hypothesis has been empirically verified by Linderman *et al*. [5].

As the DMAIC framework was originally developed for a mass-manufacturing environment, a number of attempts have been made in recent years to adapt this framework to a predominantly service-oriented healthcare delivery environment. In these attempts, a myriad of practical issues

Table 62.1. Master task list in Six Sigma (task classification for DMAIC framework)

Master task list classification for: Define → Measure → Analyze → Improve → Control (DMAIC)				
Define	**Measure**	**Analyze**	**Improve**	**Control**
Understand customer needs	Translate CTQs to KPOVs	Identify KPIVs	Identify possible solutions	Establish control plan
Develop project charter and scope	Collect data on KPOVs	Quantify and analyze KPIVs	Select solution	Implement large-scale solution
Systems identification	Establish baseline		Pilot and optimize solution	Close project

ranging from cultural inertia to human resource capabilities and data generation problems have been identified and dealt with [6, 4, 7]. Such adaptations are in line with the goal theoretic perspective, which advocates the importance for an effective task oriented and structured problem solving methodology to bridge the gulf between goal setting and goal achievement. The need for more effective frameworks adapted to the peculiar needs of different industry sectors is further highlighted and dealt with for the healthcare delivery environment in this paper.

Inadequacies of the traditional DMAIC framework have motivated the authors to re-examine this Six Sigma framework for its suitability in the healthcare delivery environment. To that end, differences in several key elements of Six Sigma programs that are generic for manufacturing and transactional environments are first identified (see Table 62.2). As a consequence of these differences, a new Six Sigma roadmap, fortified with new systems engineering tools and lean concepts underscoring a team based execution strategy, is proposed for the healthcare delivery environment. A case study demonstrating the effectiveness of such a framework is then described.

62.3 Six Sigma Roadmap for Healthcare

A new Six Sigma framework for operational quality and efficiency improvements in healthcare delivery systems is proposed. It consists of five phases, namely, "define", "visualize", "analyze", "optimize" and "verify" (**DVAOV**). A comparison of the key phases and objectives of this framework with the traditional DMAIC framework [2] is shown in Table 62.3. Key systems engineering tools recommended for each of these phases together with key activities and outputs are shown in Table 62.4. In the following sections, the integration of new systems engineering tools into the proposed roadmap would be discussed in detail.

Table 62.2. Differences in key features of traditional and transactional Six Sigma

Key features	Manufacturing Six Sigma	Transactional Six Sigma
CTQs	Clearly defined within a market segment	Difficult to define (presence of substantial ambiguities even within market segments)
Systems Identification	System boundary is easier to define	System boundary difficult to establish (more significant interactions amongst processes and customers)
	Processes are easily identifiable and stable over units produced	Processes are more obscure and sensitive to customer encounters
	Clearly defined downstream customers	Involves multiple internal and external customers or stakeholders
KPIV	Little variability	Substantial variability (Customers interactions are not identical)
	Little human judgment	Usually involves significant human judgment
	Usually controllable	Difficult to control
KPOV	Measurable and quantifiable	May not always be quantifiable
	Usually obtainable from DOE	Can only be obtained from observational data
	Data can usually be modeled by normal distribution	Data is seldom normally distributed
Rework and wastes	Easily measurable	Difficult to quantify
	More obvious attributable causes	Causes are usually not obvious

Table 62.3. Comparison of manufacturing DMAIC with healthcare DVAOV

Manufacturing DMAIC		Healthcare DVAOV	
Phase	**Objective**	**Phase**	**Objective**
Define	Define the problem (including customer impact and potential benefits)	Define	Define the problem and system boundary (including customer impact and potential benefits)
Measure	Identify the CTQs of the product or service. Verify measurement system capability, assess baseline and set improvement targets	Visualize	Achieve a shared vision of the current process; identify CTQs, KPOVs; verify data collection schemes; assess baselines and identify wastes in current process; set improvement targets
Analyze	Understand root causes of defects; identify key process input variable(KPIVs)	Analyze	Understand resource constraints and root causes of defects; identify KPIVs
Improve	Quantify influences of KPIVs on the CTQs; identify acceptable limits of these variables; modify the process to stay within these limits	Optimize	Quantify influences of KPIVs on the CTQs; identify robust solutions that is expected to stay within acceptable target limits
Control	Ensure that the modified process now keeps the key process output variables (KPOVs) within acceptable limits and maintain gains in the long term	Verify	Obtain buying-in and validate recommendation via simulation and pilot run; implement solution and validate results by monitoring performance; replicate improvements to other similar processes

62.3.1 The "Define" Phase

The effective execution of the "define" phase can be considered one of the key success factors of Six Sigma projects. In many instances, the root cause of Six Sigma project failures could be traced back to this important phase. Reasons such as insufficient consultation with stakeholders, lack of commitment amongst stakeholders, vague definitions of requirements, project scope and objectives, mismanaged expectations, poor cost and budget allocations, inappropriate schedule planning, *etc.*, have often been quoted as the reason behind the failure of Six Sigma projects. The key levers for the effective resolution of these problems essentially reside in the "define" phase.

There are typically three key deliverables in the "define" phase (see Table 62.4). They are the business case, project charter, and a detailed project plan. The business case essentially sets down the "WHY's" of the project (reasons or motivations) and is derived in consideration of the key financial, marketing and strategic objectives of the enterprise. The project charter sets out the detailed scope, goals and roadmap ("HOW's") and includes a detailed breakdown of stakeholders involved, budget, schedule and plan.

One of the key complexities peculiar to transactional processes in the "define" phase is the increased difficulty of defining appropriate critical-to-quality characteristics (CTQs), especially as perceived by customers. This arose partly because of the difficulty in defining market segments due to the heterogeneity of customers' expectations of service products. Furthermore, service processes frequently do not have well-defined stakeholders. In order to clarify vague customers' requirements and maintain a system-wide perspective in quality improvement, there is a need to introduce more powerful tools such as the comprehensive service

quality function deployment (CSQFD) described by Dube [8].

The CSQFD proposed by Mazur [9] following Akao [10] and adapted by Dube [8] is more suitable for transactional processes such as healthcare delivery systems than the traditional QFD. There are more widely varying customers' requirements with multiple tangible and intangible quality attributes in transactional environments. The inclusion of the customer deployment (CD) and voice of the customer (VOC) matrices prior to the house-of-quality (HOQ) matrix in CSQFD enables a more systematic means to segment customers with differing expectations, structure customer characteristics and thereby, derive customers' requirements at the HOQ level. The CSQFD approach further emphasizes the need to take into account these customer characteristics and requirements when generating the "HOW's" for subsequent matrices. Such an approach would enable the unique co-production and interpersonal nature of service processes to be addressed more effectively in comparison to traditional QFD approaches.

Table 62.4. Proposed DVAOV framework for healthcare delivery processes

Phase	Key Tasks	Key Tools	Key Outputs
DEFINE	Understand customer's needs Estimate cost savings Selection of projects Planning and scheduling of projects	CSQFD Project management tools Cost analysis Linear Programming	Business Case Project charter Detailed project schedule and plan
VISUALIZE	Understand the current process Benchmark and identify competitive gaps Identify root causes Conduct qualitative risk analysis Design of data collection system and collection of data	Process maps Value stream analysis Gap analysis Cause and effectmMatrix FMEA Statistical sampling techniques, experimental design (DOE)	AS-IS process map VSM Maps CE Diagrams Risk charts Quantitative process data
ANALYZE	Establish and validate statistical assumptions for data collected Evaluate key statistics More detailed estimation of cost savings	Exploratory data analysis (EDA) Statistical hypothesis tests Multi-vari studies Cost analysis Linear models Queuing methodologies Linear programming	Summary of key statistics Detailed cost estimates
OPTIMIZE	Develop key input-output transfer function Evaluate options and propose most effective course of action Performing scenario/ what-if or sensitivity analysis on proposed course of action and alternatives	Response surface methodology Linear programming Queuing methodologies Simulation	Tradeoff analysis charts Preliminary action plans for alternative courses of action
VERIFY	Conduct process simulation Implement pilot process and collect data Validate improvement plans Establish SOPs and process control plans Communicate SOPs to other similar processes	Statistical process control Process capability analysis Simulation	Control plans Actual implementation plan New process SOPs Replication plans

Apart from the comprehensive CSQFD approach suitable for transactional processes, powerful mathematical programming techniques such as linear programming (LP) can be applied for tasks of project selection and management in the "define" phase. The LP modeling structure is general enough that many real-world problems of varying degrees of complexity, particularly in the domain of resource allocation problems, can be easily modeled and optimized. The use of LP for project selection with an integrated consideration of project costs and budget through an improved quality function deployment (QFD) based framework is discussed by Tang and Paoli [11].

62.3.2 The "Visualize" Phase

In view of the fact that transactional environments are characterized by processes that often involve many stakeholders participating in the service delivery process at close proximity to the customers, a new "visualize" phase is proposed. In this phase, critical elements of the original "measure" phase are retained with an additional emphasis on achieving a common vision of current processes. A shared vision is particularly important as it facilitates the inclusion of important stakeholders through a team-based approach to problem-solving. A common understanding of the current processes will help to mitigate some difficulties faced in a transactional environment, such as the identification of systems boundary and task elements. It will also facilitate consensus building and critical stakeholders' buy-in on new process standards and targets and in replicating improvements to other processes.

In order to achieve the goals of the new "visualize" phase, various visual tools such as mindmaps [12] or the current and future reality trees (CRT and FRT) from the theory of constraints advocated by Goldratt [13, 14] can be used to complement existing tools in the original "measure" phase. Here, a powerful visualizing technique that has its roots in lean thinking is proposed. This is the value stream mapping (VSM) approach. Such an approach not only serves as an effective tool to satisfy the key goals of the "visualize" phase, it also contains information essential for the downstream analyze and optimize phases. An updated VSM further allows the effective dissemination of process goals and replication of the improvements to other similar processes.

The VSM approach is well-documented in [15–17] and has been used in a variety of industries [18–21] including the healthcare industry [19]. A VSM process is usually carried out in a cross-functional team-based environment that synthesizes the perspectives and needs of relevant stakeholders representing different organizational elements [17]. One of the key strengths of VSM lies in its ability to provide a clear visual examination of an entire system, which facilitates the consideration of different stakeholders' perspectives. The characteristics of customer demands would translate to the products or service processes that should be mapped. Issues related to processes which do not contribute to the value of a final manufactured product or service process (known as "wastes" or "muda" [22, 16]) can then be identified and considered in a team-based environment. System boundaries defining the scope of each Six Sigma project and clarifying improvement objectives can also be clearly identified as VSM essentially involves an external to internal mapping process. The external value stream maps are living documents updated from feedback gained from each individual Six Sigma project. The construction of value steam maps is typically modular in nature. If the external value stream maps of an enterprise have been created and updated, it will only be necessary to focus on the detailed internal value stream maps within a particular Six Sigma project. This would enable Six Sigma project teams to maintain focus on the key processes at hand, whilst not losing sight of the big picture. VSM is a key enabler for effective root-cause and risk analysis using tools such as cause and effect diagrams and FMEA.

62.3.3 The "Analyze" and "Optimize" Phases

The objectives of the "analyze" and "optimize" phases are essentially similar to the original "analyze" and "improve" phases in traditional manufacturing Six Sigma. New systems engin-

eering tools are added to these two phases to effectuate optimization of processes unique to transactional environments. These new tools are queuing methodologies and linear programming (LP). The integration of these tools into the new DVAOV Six Sigma framework is shown in Table 62.4.

Queuing analysis directly deals with the quality of the service process in terms of servers' efficiency and effectiveness and has been effectively applied in a wide variety of service industries such as banking, healthcare, telecommunications, *etc*. Such analyses are well-suited for the analysis of various healthcare delivery processes as its very concern is in the study and improvements of systems which are subject to uncertain occurrence of demands and duration for the satisfaction of these demands. Service quality in healthcare delivery systems is often related to the length of delay before receiving the service which is directly influenced by the uncertainty in demand occurrence and duration of service performance. Queuing methodologies have been widely employed to solve a large variety of resource management problems such as those related to drug dispensing, admission management, specialist clinic scheduling (see, for example, [23, 24]). Given the stochastic considerations of queuing methodologies, it can also be effectively coupled with statistical theory in survival analysis for longer term management of clinical resources.

Linear programming (LP) was introduced in the preceding discussion of the "define" phase for the selection of projects and allocation of resources for project execution. In practical applications, LP is commonly related to the optimal allocation of limited resources or optimal asset management. Given such general applicability, LP can thus be deployed in various phases of the Six Sigma process. It can also be deployed in the "improve" phase for selecting the best options for quality or productivity improvements. Sensitivity analysis associated with LP further allows the evaluation of different improvement alternatives.

In typical real-world scenarios, Six Sigma project teams usually have to deal with the optimization of multiple conflicting objectives, such as in minimizing costs or resource usage and maximizing quality (or minimizing the number of defects or delays), the ability to meet a target response whilst maintaining an acceptable level of process variations, *etc*. Such multiple objectives optimization problems under the RSM framework has been effectively dealt with using various different multiple objective programming techniques, such as goal programming techniques [25]. Under a linear programming formulation, multiple objective linear programming frameworks (MOLP) provides a particularly favorable alternative for the generation of multiple Pareto optimal choices for deliberations by Six Sigma teams [26].

62.3.4 The "Verify" Phase

The "control" phase is replaced by a "verify" phase. Essentially, the elements of the design and implementation of control measures are retained. The *validation* and *replication* of new improved processes are highlighted in this framework. Due to the strong interpersonal nature of service processes and close interactions between producers and consumers of services, there is an added emphasis on a comprehensive validation scheme, which typically requires some form of process simulation prior to pilot implementation. The VSM output from the "visualize" phase coupled with properly validated results are expected to ease this process. The replication of validated improvements to other similar processes within the healthcare organization has also been instituted. Usually processes of similar nature can be found within an extended healthcare organization (*e.g*., multiple pharmacies (central and satellite pharmacies) existing within a single hospital). The effective deployment of improved processes will allow maximal benefits to be harvested from a single Six Sigma project.

One of the key success factors in this phase for the new framework is still a successful application of *statistical process control* (SPC). The ultimate goal of SPC is for continual improvement of processes (whether transactional or manufacturing). SPC has reportedly been used in the healthcare industry since the 1950s [27] and is equally applicable to both clinical and non-clinical healthcare processes [28–31]. Many recent innovations in

SPC charting tools have been found to be useful in healthcare processes. Some prominent examples are the *g* and *h*-type control charts for monitoring the number of cases between hospital acquired infections or other adverse healthcare events [32–34]. As many additional complexities encountered in SPC data in healthcare processes (cyclic/ trending behaviors, autocorrelation, correlated processes, *etc.*) are also typical of other industries, some recent innovations in SPC chart technology for other industries (such as for high yield manufacturing processes [35, 36]) would be useful.

62.4 Case Study of the Dispensing Process in a Pharmacy

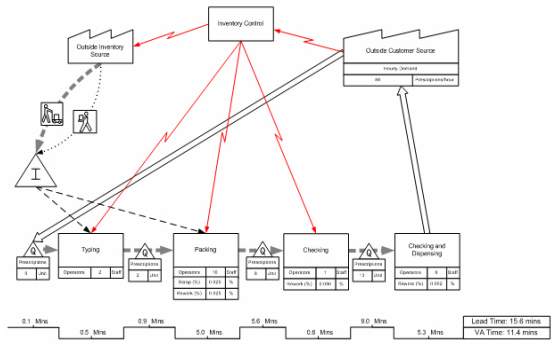
The objective of the project in this case study is to investigate the waiting times in an outpatient pharmacy of a large hospital. The investigation was prompted by complaints about the long waiting times required before drug prescriptions were dispensed. As there are multiple satellite pharmacies with similar processes to the outpatient pharmacy, the project will be able to reap benefits beyond this particular department. The success of this project would enable the Six Sigma team to garner more extensive buy-in and support from the management and other hospital staff. This is essential for sustainable implementation and successful execution of future Six Sigma projects.

A present value stream map depicting the existing situation was generated in the "visualize" phase using VSM tools. The team members provided initial estimates of the arrival rates of patients, service and rework rates. These were updated after they identified the data requirements and designed appropriate data collection strategies to obtain more accurate estimates. A simple example of such a value stream map is shown in Figure 62.2. Queuing analysis was used estimate the expected queue lengths and waiting times. The entire process can be represented by the open queuing network shown in Figure 62.3. Steady state queuing analysis is adequate here as the arrival and service rates are fast enough to ensure the system reaches its steady state in a short time. Some useful queuing results used are shown in Table 62.5. Mean waiting times of each service station can be computed from Little's theorem [37].

Table 62.5. Simple queuing results for Markovian arrival and service processes

Type of service station*	Mean queue length of service station *i*	Utilization, ρ_i	Nomenclature
M/M/1	$\frac{\rho_i^2}{1-\rho_i^2}$	$\rho_i = \frac{\lambda_i}{s_i \mu_i}$	λ_i : Mean arrival rate to the queuing system μ_i: Mean service rate by the server s_i: Number of servers
M/M/s	$\frac{(s_i\rho_i)^{s_i}\rho_i P_{i,0}}{s_i!(1-\rho_i)^2}$ where, $P_{i,0} = \left[\sum_{n=0}^{s_i-1}\frac{(s_i\rho_i)^n}{n!} + \frac{(s_i\rho_i)^{s_i}}{s_i!(1-\rho_i)}\right]$		

* *M/M/1* and *M/M/s* are standard abbreviations to characterize service stations in queuing methodologies. Both of these two types of stations experience Markovian arrival and service processes with infinite queuing capacity and FCFS service discipline. *M/M/s* system has s independently and identically distributed servers.



Rework Proportions		
	Typing	Packing
Packing	0.025	
Checking	0.025	0.025
Dispensing	0.001	0.001

Figure 62.2. Value stream map and rework proportions for a drug dispensing process

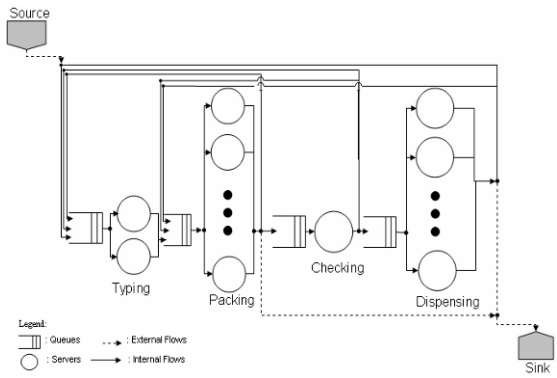


Figure 62.3. Queuing network representation of a drug dispensing process

The mean total waiting times for the entire drug dispensing process in the pharmacy can be computed by summing up the mean waiting and service times at each service station. The mean total waiting time for the entire process did not include the mean service time of the final dispensing and checking process. For the computations of mean total waiting times, the arrival rate at each queuing station, i, at statistical equilibrium can be derived from:

$$\lambda_i = \lambda_{i,0} + \sum_{j=1}^{N} \lambda_j p_{ji} , \qquad (62.1)$$

where

N : The number of queuing stations in the network.

$\lambda_{i,0}$: The arrival rate to station i from external sources.

p_{ji} : The probability a job is transferred to the jth node after service is completed at the ith node. p_{ji} hence represents the rework proportion after each process.

Due to concerns regarding the exponential assumption on service time distribution, an additional analysis was conducted with the assumption of service processes following any general distributions (*M/G/1* and *M/G/S* queuing systems). This serves to demonstrate that the assumption of exponentially distributed service times would result in more conservative system design choices. Each service station i, was assumed to experience a Poisson arrival process in the preceding analysis. Service stations with single and multiple servers were assumed to experience service processes that follow any general distributions, which are independently and identically distributed. The mean waiting queue lengths of each station can be computed using results shown in Table 62.6 [38, 39].

The mean waiting times for these stations can again be computed using Little's theorem [37]. The mean total waiting time for the entire process can be computed by summing up mean waiting and mean service times at each service station. Figure 62.4 shows the difference in mean waiting times computed with and without exponential service time assumptions across different number of packers. The mean total waiting times were observed to be higher with exponential distributional assumptions. In general, the exponential assumption usually results in more conservative system designs. Decisions based on mean waiting times and queue lengths predicted from such models would thus err on the safe side.

Table 62.6. Queuing results for *M/G/1* and *M/G/S* queuing stations

Type of service station	Mean queue length of service station *i*	Nomenclature
M/G/1	$\frac{\rho_i^2}{1-\rho_i}\cdot\frac{\left(1+\psi_i^2\right)}{2}$	ρ_i : Utilization factor ($\rho_i = \frac{\lambda_i}{s_i\mu_i}$)
M/G/s *	$\frac{1}{\lambda_i}\left(\psi_i^2\overline{W}_i^{M/M/s} + \left(1-\psi_i^2\right)\overline{W}_i^{M/D/s}\right)$	λ_i : Mean arrival rate to the queuing system
	where	μ_i: Mean service rate by the server
	$\overline{W}_i^{M/D/s} = \frac{1}{2}\cdot\frac{1}{K_i}\cdot\overline{W}_i^{M/M/s}$	s_i: Number of servers
		ψ_i^2: Squared coefficient of variation of service times, T_i.
	$K_i = \left(1+(1-\rho_i)(s_i-1)\frac{\sqrt{4+5s_i}-2}{16\rho_i s_i}\right)$	

* $\overline{W}_i^{M/M/s}$ is the mean waiting time of an *M/M/s* queuing system and $\overline{W}_i^{M/D/s}$ is the mean waiting time of an *M/D/s* queuing system with Markovian arrival and deterministic service processes.

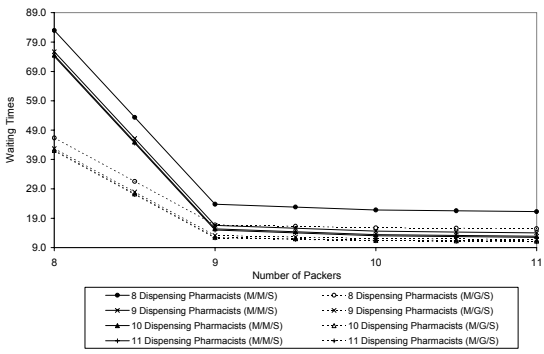

Figure 62.4. Comparisons of mean total waiting times computed with and without exponential service time assumptions

62.4.1 Sensitivity Analysis

In the "optimize" phase, the impact of different systems configurations on the overall waiting times can be assessed by varying the number of packers and dispensing pharmacists through a sensitivity analysis. It was observed that the waiting times are observed to be relatively stable with number of packers above 8. Figure 62.5 shows this result over the different numbers of dispensing pharmacists.

Root cause analysis (RCA) was also performed with the value stream maps to elicit more improvement opportunities. From the RCA (see for Ishikawa diagram in Figure 62.6), it was suggested that a new screening process be implemented at the point when the pharmacy receives prescriptions from patients as this would help to alleviate problems associated with errors in prescriptions and medicine shortages.

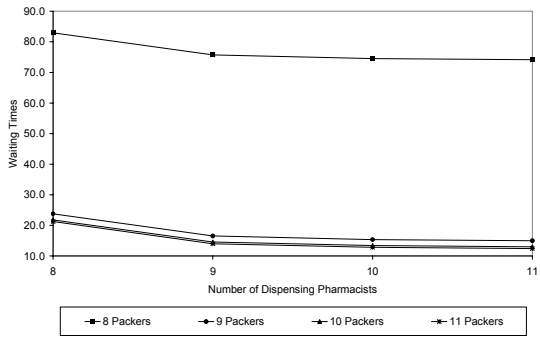

Figure 62.5. Sensitivity of total waiting times to different system configurations

Table 62.7. Comparisons of sojourn times for each process and mean total waiting times

Type of job	W/o screening	With screening
Screening	0	2.6 (1 pharmacist)
Typing	0.6 (2 typists)	0.6 (2 typists)
Packing	5.9 (10 packers)	5.6 (10 packers)
Checking	6.2 (1 pharmacist)	5.0 (1 pharmacist)
Dispensing and checking	9.0 (8 pharmacists)	2.0 (7 pharmacists)
Mean total waiting time	21.7	15.8

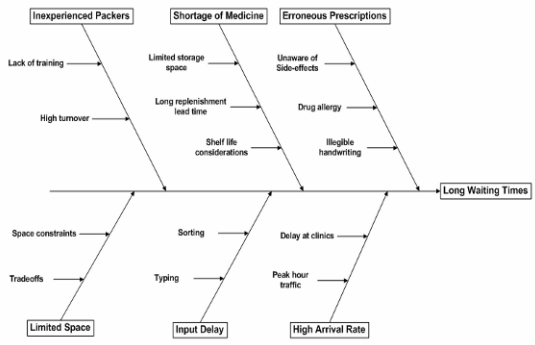

Figure 62.6. Root cause analysis of long waiting times with fish-bone diagram

A pilot run was implemented on the existing process with one dispensing pharmacist moved to the newly implemented screening process. Table 62.7 shows the improvements in the average sojourn times (sum of waiting and service times) of each process and the mean total waiting time computed. Improvements can be observed in the new process because many interruptions that occurred during the dispensing process were effectively reduced by an additional screening process upfront. As a result, the productive time of

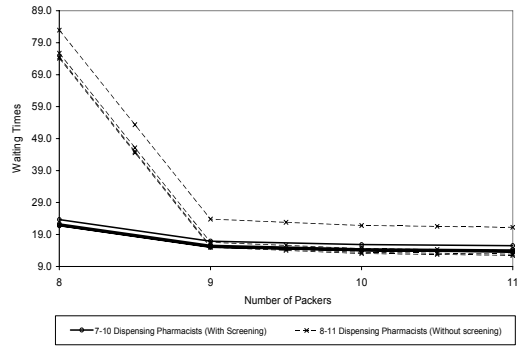

Figure 62.7. Sensitivity of total waiting times for the process with screening

pharmacists increased and the mean queue length in front of the dispensing process shortened from 13 to 3.

Various possible system configurations were experimented with a different number of packers and dispensing pharmacists with the additional screening process. From the analysis, the proposed new configuration was found to be more robust to changes in manpower deployment over the packing and dispensing sub-processes (see Figure 62.7). Eventually, this new robust design was adopted to ensure waiting time stability over possible variations in manpower deployment.

Process validations on results generated have been dealt with throughout the "analyze" and "optimize" phases in the preceding discussions. At the final "verify" phase, standard operating procedures (SOPs) were put in place in order to ensure stability of new processes. Several new control measures were proposed by the team and implemented with the understanding and inputs from the relevant stakeholders.

62.5 Conclusions

A new Six Sigma framework for extended healthcare delivery systems is proposed in this article. Several new systems engineering tools such as CSQFD, VSM, LP, and queuing analysis are proposed within this framework. A case study demonstrating the application of this roadmap for improving the waiting times in a retail pharmacy is

also presented. The proposed Six Sigma framework and its accompanying tools are expected to be more suitable for the myriad of transactional processes (*e.g.*, drug dispensing, radiological, admission, and laboratory services) found in healthcare delivery systems.

Status and Recent Trends in Reliability for Civil Engineering Problems

Achintya Haldar

University of Arizona, Tucson, AZ, USA

Abstract: Civil engineering is one of the oldest engineering disciplines and has over 5000 years of glorious history. However, only recently, in the mid 1960s, have attempts been made to consider the presence of uncertainty in civil engineering problems. Structural engineering has provided leadership in developing the necessary mathematics and the related design guidelines. Several reliability evaluation methods, including the Monte Carlo simulation technique, are discussed in this chapter and elaborated with the help of examples. A stochastic finite element approach is presented to estimate reliability, particularly when the limit state or performance function is implicit. Finally, recent trends in the the use of reliability techniques in civil engineering problems are discussed. It is necessary to have readily available sophisticated computer programs for reliability analysis. Cognitive sources of uncertainty also need to be incorporated. Developments of meshless methods, robust and stochastic optimization techniques, structural health assessment, monitoring, and maintenance programs, better prediction of future extreme events like earthquake, wind, draught, tornado and tsunami, and system reliability procedures are advocated.

63.1 Introduction

Civil engineering profession has a well documented 5000 years of glorious history. It is one of the oldest engineering disciplines. Our forefathers built civil engineering systems, including shelters, water distribution systems, *etc*., based on intuition. Structures made with stone and mud or with other available materials from nature were built, say, around 3000 BC, before the construction of pyramids. The first structure where technology was used may be the pyramids. The Step Pyramid at Saqqara was built by Imhotep in 2750 BC.

Experience, intuition, and empirical rules might have played very crucial role at this early stage of development. Stone and masonry were primary materials used for construction. The Parthenon was built in 438 BC and is an outstanding example of earlier development. Then Aristotle (384–322 BC) and Archimedes (287–212 BC) helped to formulate the mathematics behind our wonderful history.

The success also demonstrated some weaknesses in our understanding. Observing hazards or failures, Hammurabi, the king of Babylonia, who died in about 1750 BC, issued building code provisions. They were carved in stones and can be seen in the Louvre in Paris. They addressed many different issues including economic provisions (prices, tariffs, trade, and commerce), family law (marriage and divorce), criminal law (assault,

theft), and civil law (slavery, debt). Penalties varied according to the status of the offenders and the circumstances of the offenses. Interpreting the laws in the context of civil engineering, it can be concluded that the responsibilities of the builders were defined depending on the consequences of failure. We cannot afford to have similar codes at present.

In the last 500 years, the mathematical aspects of civil engineering have improved significantly due to the contributions of many scholars including Leonardo da Vinci (1452–1519), Galileo (1564–1642), Andrea Palladio (1518–1580), Robert Hooke (1635–1703), Johann Bernoulli (1667-1748), Daniel Bernoulli (1700–1782), Leonard Euler (1707–1783), Charles Augustine de Coulomb (1736–1806), Louis Navier (1785–1836), Squire Whipple (1804–1888), Karl Culmann (1821–1881), J.W. Schwedler (1823–1894), Benoit-Paul-Emile Clapeyron (1799–1864), James Clerk Maxwell (1831–1879), Otto Mohr (1835–1918), Alberto Castigliano (1847–1884), Charles E. Greene (1842–1903), H. Muller-Breslau (1851–1925), August Foppl (1854–1924), G. Maney (1888–1947), Hardy Cross (1885–1959), R. Southwell (1888–1970), and others. Haldar [1] and West [2] discussed the subject in more detail elsewhere. There is no doubt that civil engineering has a long, proud history. Where do we go from here?

63.2 The Need for Reliability-based Design in Civil Engineering

In spite of our best efforts; we cannot build a failure-proof structure. Our inability to predict the future loading conditions and structural strength are some of the major reasons. Freudenthal [3] is considered to be one of first scholars who advocated for the incorporation of the reliability-based design concept in civil engineering practices. The area has expanded tremendously since then. Benjamin and Cornell [4], and Ang and Tang [5, 6] discussed the chronological developments in the related areas. An extensive list of related publications is given by Haldar and Mahadevan [7, 8].

In civil engineering, the structures group provided leadership in the recent past in developing the risk-based design concept. In structural engineering, there are many design codes based on the material to be used (concrete, steel, wood, masonry, *etc*.), types of structures (buildings, bridges, on-shore, off-shore, *etc*.), and types of loading (earthquake, wind, flood, underground, on ground, *etc*.). Almost all of these codes were modified based on the current design philosophy, *i.e.*, risk-based design concept [9–13]. In the following sections, the development of the risk-based design concept in civil engineering in the context of structural engineering is emphasized.

63.3 Changes in Design Philosophies – Design Requirements

In all engineering designs, the basic concept is that the capacity, resistance or supply should at least satisfy the demand. The demand is defined depending on the area of application. It may be the load effect on a structure, the completion time for a construction project, the traffic on a highway, recommended air or water qualities by a regulatory agency, *etc*. However, since most of the parameters in supply and demand are full of uncertainties, they cannot be predicted with certainty, and thus satisfactory performance cannot be assured. Instead, assurance can only be given in terms of the probability of success in satisfying some performance criterion. In engineering terminology, the probabilistic assurance of performance is referred to as *reliability*.

The presence of uncertainty is always considered in civil engineering design in the form of a safety factor applied to the load, resistance, or both. Before the introduction of the load and resistance factor design (LRFD) concept by the American Institute of Steel Construction (AISC) in 1986 [14], the allowable stress design (ASD) was used by the profession [15]. In ASD, the allowable stresses were calculated using a safety factor. It considered the unfactored nominal loads or load combination, producing the nominal load effect S_n. The allowable resistance R_a was calculated by dividing the nominal resistance R_n by a safety

factor. The acceptable design required that S_n be less than R_a. Then, the profession realized that the loads are more unpredictable than the resistance. This led to the use of the ultimate strength design (USD) concept [9]. In USD, the loads are multiplied by load factors representing the uncertainty in them, producing the ultimate load effect. The safe design required that R_n is greater than the ultimate load effect. However, uncertainty is expected in both the load and resistance parameters. This led to the development of the LRFD concept. The LRFD design guidelines developed by the AISC are based on numerous fundamental assumptions and the load and resistance factors are selected in such a way that would satisfy an underlying risk, although unknown to most design engineers [7, 14, 16, 17]. The basic drawback of the LRFD approach is that it fails to give options to engineers to design for other underlying risks that are not considered in the development of the design guidelines. For example, the underlying risk for a nuclear power plant, a multi-story building, or a temporary structure, does need to be the same, and the corresponding load and resistance factors should be adjusted to reflect this. However, it cannot be done at present.

A more advanced form of risk-consistent design known as the performance based design (PBD) is now being advocated. Engineering designs must satisfy numerous strength and serviceability-related performance criteria. A strength failure may lead to failure. However, serviceability failure (excessive lateral, interstory, or vertical deflection, unwanted vibration, *etc*.) may not lead to failure and thus may not need to satisfy the more demanding strength criteria. In PBD, design engineers will have options to consider numerous performance criteria satisfying the corresponding specified acceptable risks. This may produce more economical design than LRFD and other deterministic approaches. However, the PBD concept is now in the elementary stage of its development.

63.4 Available Analytical Methods – FORM/SORM, Simulation

If a design needs to satisfy specific risks, procedures must be available to estimate them and they should be acceptable to all concerned parties. The risk-based design concept has been under development since the 1960s, as briefly discussed next.

Without losing any generality, let us assume that R represents the resistance and S represents the load effect on a structural element to be designed. R and S cannot be predicted with certainty and should be considered as random variables. They can be represented by their corresponding probability density functions (PDFs), denoted by $f_R(r)$ and $f_S(s)$, respectively. They are shown in Figure 63.1. A PDF is completely defined in terms of its underlying distribution and the parameters of the distribution. In most cases, the parameters of the distribution can be evaluated from the information on the mean, standard deviation, and coefficient of variation (COV) of the underlying random variable. Since absolute safety cannot be assured, a safe design requires that R is greater than S with some pre-selected safety level. This concept can be mathematically expressed as [7]:

$$\begin{aligned} P(\text{failure}) &= P(R < S) \\ &= \int_0^\infty \left[\int_0^s f_R(r)\, dr \right] f_S(s)\, ds \\ &= \int_0^\infty F_R(s)\, f_S(s)\, ds \end{aligned} \tag{63.1}$$

where $F_R(s)$ is the cumulative distribution function (CDF) of R evaluated at s. This is considered to be the fundamental equation of the reliability-based design concept. The shaded area in Figure 63.1 qualitatively represents the probability of failure and gives the physical interpretation of (63.1). Haldar and Mahadevan [7] discussed in detail that by shifting the locations of the two PDFs (locations of the mean values of R and S, *i.e.*, μ_R and μ_S, considering the dispersions of the two PDFs (in terms of standard deviation of R and S, *i.e.*, σ_R and σ_S), and the PDFs themselves [$f_R(r)$ and $f_S(s)$], the shaded

area can be manipulated and the corresponding risk can be estimated. Obviously, a smaller area will represent safer design, and the area cannot be zero, at least conceptually.

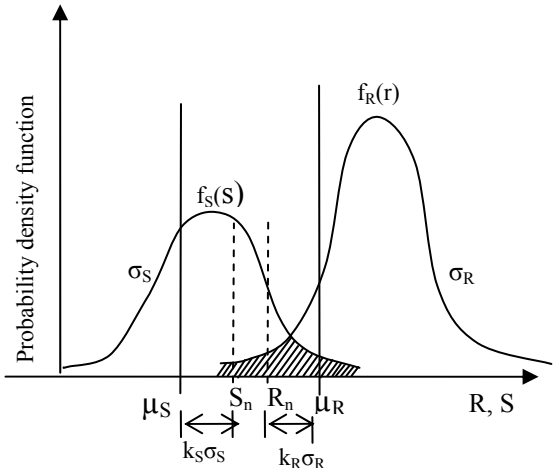

Figure 63.1. Reliability based design concept (from [7])

In general, (63.1) cannot be evaluated in close form for multiple random variables, except for some special cases [7]. Several methods of various degrees of sophistication were developed to address this fundamental problem. To make the discussion more general, *R* and *S* need to be represented by numerous basic random variables; essentially the resistance and load-related random variables present in a particular problem. Reliability or probability of failure is always estimated with respect to a performance criterion or limit state. Thus, besides the basic random variables, the demand or the performance requirement, generally given in design guidelines, should also be a component of a limit state. Generally, a limit state function is represented as:

$$Z = g(\mathbf{X}) = g(X_1, X_2, \cdots, X_n) \qquad (63.2)$$

where X_i's are the *i*th random variable in the limit state. When $Z = 0$, it represents the failure surface; when $Z < 0$, it represents the unsafe region; and when $Z > 0$, it represents the safe region.

Using (63.2), the probability of failure, p_f, *i.e.*, $P(Z < 0)$ can be represented by a multi-dimensional integral as:

$$p_f = \int \cdots \int_{g(\,)\langle 0} f_X(x_1, x_2, \cdots, x_n)\, dx_1 dx_2, \cdots, dx_n \qquad (63.3)$$

where $f_X(x_1, x_2, \cdots, x_n)$ is the joint PDF of all the basic random variables and the integration is carried out in the failure region, *i.e.*, $g(\,)\langle 0$. If the basic random variables are assumed to be statistically independent, the joint PDF can be replaced by the individual PDF. Equation (63.3) is another representation of (63.1) and is known as the *full distributional approach*. Again, information on the multidimensional integral is generally not available. Even when the information is available, the integration of the joint PDF is expected to be difficult; an analytical approximation is a practical necessity. The first level of approximation can be grouped into two types; namely, the first-order reliability method (FORM) and the second-order reliability method (SORM). In FORM, the limit state equation is represented by a linear function of the basic random variables, and in SORM, the limit state is represented by a second-order approximation. Only the commonly used different versions of FORM available in the literature will be emphasized here. Further information on SORM can be found in Haldar and Mahadevan [7].

63.4.1 First-order Reliability Methods

Historically, the first-order reliability methods (FORMs) were developed using the information on the first two moments (mean, and variance or standard deviation, or COV) only. The earlier version of FORM is known as the first-order second-moment (FOSM) or the mean value first-order second-moment (MVFOSM) method. The original formulation of this approach was suggested by Cornell [18] for only two variables, *R* and *S*. The limit state function was defined as $Z = R - S$, and both *R* and *S* were assumed to be statistically independent normal variables. For this

case, the safety index or reliability index β can be shown to be:

$$\beta = \frac{\mu_Z}{\sigma_Z} = \frac{\mu_R - \mu_S}{\sqrt{\sigma_R^2 + \sigma_S^2}} \tag{63.4}$$

The corresponding probability of failure, p_f can be shown to be:

$$p_f = \Phi(-\beta) = 1 - \Phi(\beta) \tag{63.5}$$

where Φ( ) is the CDF of the standard normal distribution.

An alternative formulation was proposed by Rosenbleuth and Esteva [19] for when *R* and *S* are statistically independent lognormal random variables. However, considering realistic practical problems, it is too idealistic to assume that a limit state function can be expressed in terms of only two statistically independent either normal or lognormal random variables. The discussion needs to be extended to consider limit state functions of the general form represented by (63.2). To use (63.4), the mean and variance of the limit state function represented by (63.2) must be evaluated; in some cases even approximately.

To generate the necessary information, the limit state function can be expanded in a Taylor series about the mean values of the basic variables as:

$$Z = g(\mu_{\mathbf{X}}) + \sum_{i=1}^{n} \frac{\partial g}{\partial X_i}\left(X_i - \mu_{\mathbf{X}_i}\right) + \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} \frac{\partial^2 g}{\partial X_i \partial X_j}\left(X_i - \mu_{X_i}\right)\left(X_i - \mu_{X_i}\right) + \cdots \tag{63.6}$$

where the partial derivatives are evaluated at the mean values of the random variables and μ_{X_i} is the mean value of X_i. Considering only the linear terms, *i.e.*, the first two terms in (63.6), the first-order approximate mean and variance of *Z* can be shown to be:

$$\mu_Z' \approx g\left(\mu_{X_1}, \mu_{X_2}, \cdots, \mu_{X_n}\right) \tag{63.7}$$

and

$$\sigma_Z^2 \approx \sum_{i=1}^{n}\sum_{j=1}^{n} \frac{\partial g}{\partial X_i}\frac{\partial g}{\partial X_j} Cov\left(X_i, X_j\right) \tag{63.8}$$

where $Cov\left(X_i, X_j\right)$ is the covariance of X_i and X_j. If the variables are statistically independent, the variance (63.8) becomes:

$$\sigma_Z^2 \approx \sum_{i=1}^{n}\left(\frac{\partial g}{\partial X_i}\right)^2 \sigma_{X_i}^2 \tag{63.9}$$

The first-order approximation of the mean and variance can be improved by including the second-order term in the Taylor series expansion. If only information on the mean and variance is available of all the random variables, the second-order variance cannot be calculated since it requires information on the third and fourth moments. However, the second-order mean can be shown to be:

$$\mu_Z'' \approx \mu_Z' + \frac{1}{2}\sum_{i=1}^{2}\left(\frac{\partial^2 g}{\partial X_i^2}\right)\mathrm{Var}\left(X_i\right) \tag{63.10}$$

In the context of FOSM, the use of second-order mean and first-order variance was advocated by Ayyub and Haldar [20]. Assuming that *Z* is normal with the mean calculated by (63.7) or (63.10) and the variance calculated by (63.8) or (63.9), the reliability index and the corresponding probability of failure can be calculated by (63.4) and (63.5), respectively.

FOSM has many deficiencies. The method does not use the information on distribution even when it is available. When *g* ( ) is highly nonlinear, the Taylor series approximation may introduce a significant amount of error in the estimation of the mean and variance. More importantly, the safety index defined by (63.4) does not give the same result for different but mechanically equivalent formulations of the same limit state function. It can be shown easily that the limit state functions defined as ($R - S < 0$) and ($R/S < 1$) are mechanically equivalent; however, using FOSM the reliability index calculated using (63.4) would be different for the two cases. Ayyub and Haldar [20] also showed that if the limit state functions are formulated in terms of stress and strength (they are essentially the same), the reliability index according to FOSM will be different.

The lack of invariance in the reliability index evaluation prompted Hasofer and Lind [21] to propose the advanced first-order second moment

(AFOSM) method; essentially for only normal random variables. In this formulation, random variables are defined in the reduced coordinate as:

$$X_i' = \frac{X_i - \mu_{X_i}}{\sigma_{X_i}}; i = 1, 2, \cdots, n \qquad (63.11)$$

where X_i' is a random variable with zero mean and unit standard deviation. In the context of AFOSM, X_i' is a standard normal variable. With this transformation, the original limit state equation g(**X**) = 0 becomes g(**X'**) = 0 in the transformed or reduced coordinates. The Hasofer–Lind safety index, denoted as β_{HL}, is the minimum distance from the origin to the limit state surface in the reduced coordinates. It can be defined as:

$$\beta_{HL} = \sqrt{(\mathbf{x}'^*)^t (\mathbf{x}'^*)} \qquad (63.12)$$

where **x**'* is the coordinates of the checking point in the reduced coordinates.

The concept is shown in Figure 63.2 for a linear limit state equation. The minimum distance point on the limit state surface is known as the design point or the most probable failure point. The reliability index according to AFOSM will give an identical reliability index to that calculated by using FOSM when the limit state equation is linear and all the variables are normal. However, the reliability indexes are calculated in completely different ways in these two approaches. The AFOSM method gives a geometric interpretation of the reliability index. As can be observed from Figure 63.2, if the reliability index is large, the safe region increases and the corresponding probability of failure becomes smaller.

When the limit state equation is nonlinear, the AFOSM method can be used, however, an iterative optimization procedure needs to be used to evaluate the reliability index, as shown in Figure 63.3. The Hasofer–Lind reliability index can be exactly related to the failure probability using (63.5) if all the variables are statistically independent and normally distributed. For any other situations, it will not give the correct reliability information. To incorporate information on distribution for linear and nonlinear limit states,

(b) Reduced coordinates

Figure 63.2. Reliability evaluation for linear performance function (from [7], with permission from John Wiley & Sons, Inc.)

Rackwitz and Fiessler [22] proposed improvements of the AFOSM method. At present, the more general and improved version of the Hasofer–Lind AFOSM method is known as the first-order reliability method (FORM). For the nonlinear limit state function, when it is represented by the second-order approximation at the checking point, it is known as the second-order reliability method (SORM). FORM is routinely used in many

engineering disciplines. Haldar and Mahadevan [7] suggested an alternative version of FORM that is particularly applicable when the limit states are not explicit functions of the basic random variables or when they are complicated nonlinear functions.

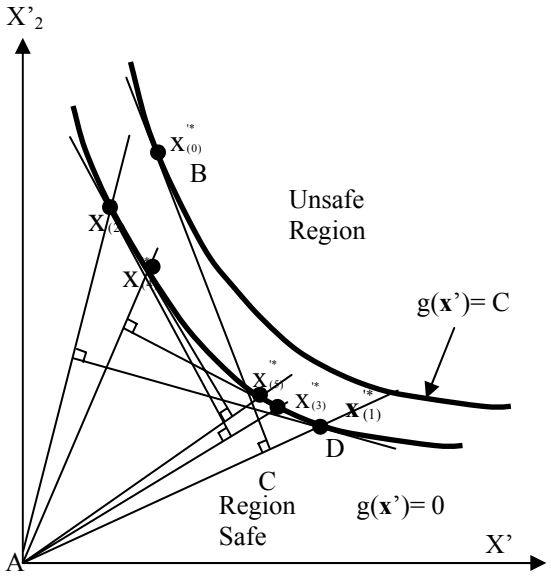

Figure 63.3. Reliability evaluation for linear performance function (from [7], with permission from John Wiley & Sons, Inc.)

63.4.2 An Iterative Procedure for FORM

The most commonly used FORM algorithm, with some improvements as suggested in [20], for nonlinear explicit limit state functions consisting of correlated nonnormal variables are briefly discussed next. In most engineering problems, the basic variables are generally assumed to be statistically independent since dependency significantly increases the difficulty in the reliability evaluation. An iterative solution strategy is required. The following brief discussions are expected to clarify the procedure for the reliability evaluation for this difficult case.

Step 1: Define the appropriate limit state function in terms of the basic random variables as in (63.2).

Step 2: Assume an initial value of the reliability index β. An initial β value of 3 is reasonable to start the iteration process.

Iteration 1

Step 3: Assume the coordinates of the initial checking point x_i^*, $i = 1, 2, \ldots, n$. The initial values are generally assumed to be the mean values of the random variables.

Step 4: Compute the equivalent normal mean and standard deviation of all the nonnormal random variables at the checking point. Denoting the equivalent normal mean and standard deviation of the ith random variable as $\mu_{X_i}^N$ and $\sigma_{X_i}^N$, respectively, It can be shown [7] that they can be estimated as:

$$\mu_{X_i}^N = x_i^* - \Phi^{-1}\left[F_{X_i}\left(x_i^*\right)\right]\sigma_{X_i}^N \tag{63.13}$$

and

$$\sigma_{X_1}^N = \frac{\phi\left\{\Phi^{-1}\left[F_{X_i}\left(x_i^*\right)\right]\right\}}{f_{X_i}\left(x_i^*\right)} \tag{63.14}$$

where $F_{X_i}\left(x_i^*\right)$ and $f_{X_i}\left(x_i^*\right)$ are the CDF and the PDF of the nonnormal random variable evaluated at the checking point, respectively, and $\Phi^{-1}(\,)$ and $\phi\,(\,)$ are the inverse of the CDF and the PDF of the standard normal distribution, respectively.

For a lognormal random variable X with parameters λ_X and ζ_X, the equivalent normal mean and standard deviation at the checking point x^* can be simplified to be [7]:

$$\sigma_X^N = \xi_X\, x^* \tag{63.15}$$

and

$$\mu_X^N = x^*\left(1 - \ln x^* + \lambda_X\right) \tag{63.16}$$

Step 5: If the variables X_i's are correlated, they need to be transformed into uncorrelated reduced normal **Y** variables. The original limit state equation needs to be expressed in terms of **Y** variables. The following steps can be followed.

The correlation matrix of the X_i variables can be expressed as:

$$\left[\mathbf{C}\right] = \begin{bmatrix} 1 & \rho_{X_1,X_2} & \cdots & \rho_{X_1,X_n} \\ \rho_{X_2,X_1} & 1 & \cdots & \rho_{X_2,X_n} \\ \vdots & \vdots & & \vdots \\ \rho_{X_n,X_1} & \rho_{X_n,X_2} & \cdots & 1 \end{bmatrix} \tag{63.17}$$

where ρ_{X_i,X_j} is the correlation coefficient of the X_i and X_j variables.

The relationship between **X** and **Y** can be shown [7] as:

$$[\mathbf{X}] = \left[\sigma_{\mathbf{X}}^{N}\right][\mathbf{T}][\mathbf{Y}] + \left\{\mu_{\mathbf{X}}^{N}\right\} \tag{63.18}$$

where $\mu_{X_i}^{N}$ and $\sigma_{X_i}^{N}$ are the equivalent normal mean and standard deviation of X_i, respectively, evaluated at the checking point using (63.13) and (63.14), and **T** is a transformation matrix. Note that the matrix containing the equivalent normal standard deviation in (63.18) is a diagonal matrix. The transformation matrix **T** can be shown to be:

$$[\mathbf{T}] = \begin{bmatrix} \theta_1^{(1)} & \theta_1^{(2)} & \cdots & \theta_1^{(n)} \\ \theta_2^{(1)} & \theta_2^{(2)} & \cdots & \theta_2^{(n)} \\ \vdots & \vdots & & \vdots \\ \theta_n^{(1)} & \theta_n^{(2)} & \cdots & \theta_n^{(n)} \end{bmatrix} \tag{63.19}$$

where $\left\{\theta^{(i)}\right\}$ is the normalized eigenvector of the ith mode of the correlation matrix $[\mathbf{C}]$ and $\theta_1^{(i)}, \theta_2^{(i)}, \cdots, \theta_n^{(i)}$ are the components of the ith eigenvector. Eigenvalues are the variance of **Y** and **Y** will have zero mean.

Using (63.18), all the basic random variables **X**'s can be transformed to statistically independent standard normal variables **Y**'s. The limit state equation defined in Step 1 now can be rewritten in terms of **Y**'s.

Step 6: Transform the initial checking point of X_i's to Y_i's, using :

$$\mathbf{Y} = \mathbf{T}^{t}\ \mathbf{X}' \tag{63.20}$$

where matrix **T** is defined by (63.19) and the vector **X**' contains all the random variables X_i's in the reduced coordinates evaluated at the checking point. For X_i, it can be expressed as:

$$X_i = \frac{x_i^{*} - \mu_{X_i}^{N}}{\sigma_{X_i}^{N}} \tag{63.21}$$

Step 7: Compute partial derivatives $\left(\frac{\partial g(\ )}{\partial Y_i}\right)^{*}$ of the transformed limit state function obtained in Step 5 evaluated at the checking point $\mathbf{y}^{*}$ defined in Step 6.

Step 8: Compute the direction cosines α_i at the checking point as:

$$\alpha_{Y_i} = \frac{\left(\frac{\partial g}{\partial Y_i}\right)^{*} \sigma_{Y_i}^{N}}{\sqrt{\sum_{i=1}^{n}\left(\frac{\partial g}{\partial Y_i}\,\sigma_{Y_i}^{N}\right)^{*2}}} \tag{63.22}$$

Iteration 2

Repeat Steps 3 to 8 until the estimate of the direction cosines converge with a predetermined tolerance. A tolerance level of 0.005 is common. Obviously, just after one iteration, no conversion decision of the direction cosines can be made. This will necessitate the execution of Steps 9 and 10.

Step 9: Compute the new checking point in the Y coordinates as:

$$y_i^{*} = -\alpha_{Y_i}\ \beta\ \sigma_{Y_i}^{N} \tag{63.23}$$

Step 10: Transform the coordinates of the new checking point in Step 9 to original coordinates using (63.20). When the coordinates of the new checking point are available, it is essentially Step 3 discussed earlier.

After repeating Steps 3 to 8 several times (three or four in most cases), the direction cosines will converge. Then, the new checking point can be evaluated using Steps 9 and 10, keeping β as the unknown parameter. This additional computation suggested by Ayyub and Haldar [20] may improve the robustness of the algorithm. The assumption of an initial value for β in Step 2 is necessary only for the sake of this additional computation.

Step 11: Compute an updated value for β satisfying the limit state equation at the new checking point.

Step 12: Repeat Steps 3 to 11 until β converges to a predetermined tolerance level. A tolerance level of 0.001 can be used, particularly if a computer is used to carry out the calculations.

63.4.3 Example

All 12 steps discussed earlier can be better explained with the following example.

A simply supported beam of span L = 9.144 m is loaded by a uniformly distributed load w in kN/m and a concentrated load P in kN applied at the midspan. The maximum deflection of the beam at the midspan can be calculated as

$$\delta_{\max} = \frac{5}{384}\frac{w L^4}{EI} + \frac{1}{48}\frac{P L^3}{EI} \tag{63.24}$$

where E is Young's modulus and I is the moment of inertia of the cross-section of the beam. A beam with EI = 182,262 kN m^2 is selected to carry the load. Suppose w and P are correlated lognormal variables with a mean of 35.03 kN/m and 111.2 kN, respectively. The corresponding standard deviations are 5.25 kN/m and 11.12 kN, respectively. The correlation between w and P is 0.7. Consider the allowable deflection at midspan as 38.1 mm. The task is to estimate the reliability index and the corresponding probability of failure of the beam using FORM.

Solution

It is not possible to show all the hand calculations here, but the results are summarized in Table 63.1. Calculations for the first and the final iterations are shown in the following sections.

Step 1: The limit state function for the problem can be shown to be

$$g(\,) = 0.0381 - \left(4.99444 \times 10^{-4}\, w + 8.73919 \times 10^{-5}\, P\right) \tag{63.25}$$

w and P are lognormal random variables. They can be expressed as $w \sim Ln(\lambda_w, \zeta_w)$ and $P \sim Ln(\lambda_P, \zeta_P)$, respectively. The parameters of w and P can be calculated as:

$$\zeta_w = \sqrt{\ln\left[1 + \left(\frac{5.25}{35.03}\right)^2\right]} = 0.149$$

and

$$\lambda_w = \ln 35.03 - \frac{1}{2} \times 0.149^2 = 3.545$$

$$\delta_P = \frac{11.12}{111.2} = 0.1 \cong \zeta_P$$

and

$$\lambda_P = \ln 111.2 - \frac{1}{2} \times 0.1^2 = 4.706$$

Since w and P are correlated, they need to be transformed in to uncorrelated $\mathbf{Y}$ variables.

However, since the equivalent normal mean and standard deviation of both of them need to be evaluated at the checking point and the coordinates of the checking point are expected to be different at each iteration, the limit state function will change for each iteration. Hand calculations are not suggested for this type of problem. However, for the sake of clarity, some of the important steps are presented below in terms of different steps discussed earlier.

Step 2: Assume β = 3 to start the iteration.

Iteration 1

Step 3:

The coordinates of the initial checking point are w^* = 35.03 and P^* = 111.20.

Step 4:

The corresponding equivalent normal mean and standard deviation of w and P are:

$$\sigma_w^N = 0.149 \times 35.03 = 5.22$$

$$\mu_w^N = 35.03 \times (1 - \ln 35.03 + 3.545) = 34.64$$

$$\sigma_P^N = 0.1 \times 111.2 = 11.12$$

$$\mu_P^N = 111.2 \times (1 - \ln 111.2 + 4.706) = 110.61$$

Step 5:

The correlation matrix [**C**] given by (63.17) for the problem is

$$[\mathbf{C}] = \begin{bmatrix} 1 & 0.7 \\ 0.7 & 1 \end{bmatrix}$$

The two eigenvalues for the correlation matrix can be shown to be 0.3 and 1.7 [23]. The corresponding normalized eigenvectors can be evaluated and the tranformation matrix [**T**] given by (63.19) can be shown to be

$$[\mathbf{T}] = \begin{bmatrix} 0.707 & 0.707 \\ -0.707 & 0.707 \end{bmatrix}$$

Using (63.18), it can be shown that

$$\begin{Bmatrix} w \\ P \end{Bmatrix} = \begin{bmatrix} 5.22 & 0 \\ 0 & 11.12 \end{bmatrix} \begin{bmatrix} 0.707 & 0.707 \\ -0.707 & 0.707 \end{bmatrix} \begin{Bmatrix} Y_1 \\ Y_2 \end{Bmatrix} + \begin{Bmatrix} 34.64 \\ 110.61 \end{Bmatrix}$$

Or,

$$w^* = 3.69 \times (Y_1 + Y_2) + 34.64$$

$$P^* = 7.86 \times (Y_2 - Y_1) + 110.61$$

Step 6:

Using (63.20), it can be shown that

$$\begin{Bmatrix} y_1^* \\ y_2^* \end{Bmatrix} = \begin{bmatrix} 0.707 & -0.707 \\ 0.707 & 0.707 \end{bmatrix} \begin{Bmatrix} 0.0747 \\ 0.0531 \end{Bmatrix} = \begin{Bmatrix} 0.0153 \\ 0.0904 \end{Bmatrix}$$

Step 7:

$$\left(\frac{\partial g}{\partial Y_1} \right)^* = -1.1560 \times 10^{-3}$$

$$\left(\frac{\partial g}{\partial Y_2} \right)^* = -2.5298 \times 10^{-3}$$

Step 8:

$$\alpha_{Y_1} = \frac{-1.156 \times 10^{-3} \times \sqrt{0.3}}{\sqrt{\left(-1.156 \times 10^{-3}\right)^2 \times 0.3 + \left(-2.5298 \times 10^{-3}\right)^2 \times 1.7}}$$

$$= \frac{-0.63317 \times 10^{-3}}{3.358675 \times 10^{-3}} = -0.1885$$

$$\alpha_{Y_2} = \frac{-2.5298 \times \times 10^{-3} \times \sqrt{1.7}}{3.358675 \times \times 10^{-3}} = -0.9821$$

As summarized in Table 63.1, it took four iterations before the direction cosines converged with an accuracy of 0.005. At this stage, the updated reliability index was estimated to be 2.789. The reliability index was assumed to be 3.0 to start the iteration. Obviously, the reliability index did not converge with an accuracy level of 0.001 and further calculations are necessary. In the next iteration, the direction cosines converged with an accuracy of 0.005. Again, the reliability index was calculated and found to be 2.778. It is an improvement but not within the accuracy level of 0.001. The final iteration was then initiated as presented next.

Final Iteration

Step 2:

From previous iteration $\beta = 2.778$

Step 3:

$$w^* = 5.486(0.3267 + 3.5377) + 30.83 = 52.03$$

$$p^* = 9.820(3.5377 - 0.3267) + 107.28 = 138.81$$

Step 4:

$$\sigma_w^N = 0.149 \times 52.03 = 7.75$$

$$\mu_w^N = 52.03 \times (1 - \ln 52.03 + 3.545) = 30.86$$

$$\sigma_P^N = 0.1 \times 138.81 = 13.89$$

$$\mu_P^N = 138.81 \times (1 - \ln 138.81 + 4.706) = 107.29$$

Step 5:

$$\begin{Bmatrix} w \\ P \end{Bmatrix} = \begin{bmatrix} 7.75 & 0 \\ 0 & 13.89 \end{bmatrix} \begin{bmatrix} 0.707 & 0.707 \\ -0.707 & 0.707 \end{bmatrix} \begin{Bmatrix} Y_1 \\ Y_2 \end{Bmatrix} + \begin{Bmatrix} 30.86 \\ 107.29 \end{Bmatrix}$$

Or,

$$w^* = 5.479 \times (Y_1 + Y_2) + 30.86$$

$$P^* = 9.82 \times (Y_2 - Y_1) + 107.29$$

$$g(\,) = 0.0381 - 4.9944 \times 10^{-4} [5.479 \times (Y_1 + Y_2) + 30.86]$$

$$- 8.73919 \times 10^{-5} [9.82 \times (Y_2 - Y_1) + 107.29]$$

$$= 0.013324 - 1.8782 \times 10^{-3} Y_1 - 3.5946 \times 10^{-3} Y_2$$

Step 6:

$$\begin{Bmatrix} y_1^* \\ y_2^* \end{Bmatrix} = \begin{bmatrix} 0.707 & -0.707 \\ 0.707 & 0.707 \end{bmatrix} \begin{Bmatrix} 2.732 \\ 2.269 \end{Bmatrix} = \begin{Bmatrix} 0.3273 \\ 3.5357 \end{Bmatrix}$$

$$\alpha_{Y_1} = \frac{-1.8782 \times 10^{-3} \times \sqrt{0.3}}{\sqrt{\left(-1.8782 \times 10^{-3}\right)^2 \times 0.3 + \left(-3.5946 \times 10^{-3}\right)^2 \times 1.7}}$$

$$= \frac{-1.02873 \times 10^{-3}}{4.79836 \times 10^{-3}} = -0.2144$$

$$\alpha_{Y_2} = \frac{-3.5946 \times 10^{-3} \times \sqrt{1.7}}{4.79836 \times 10^{-3}} = -0.9767$$

Step 8:

$$Y_1^* = 0.2144 \times \beta \times \sqrt{0.3} = 0.1174\beta$$

$$Y_2^* = 0.9767 \times \beta \times \sqrt{1.7} = 1.27346\beta$$

$$0.013324 - 1.8782 \times 10^{-3} \times 0.11743\beta - 3.5946 \times 10^{-3} \times 1.27346\beta = 0$$

Or, $\beta = 2.777$

Table 63.1. Reliability evaluation using FORM for correlated nonnormal variables

Steps 1 and 5	$g( ) = 0.0381 - (4.99444 \times 10^{-4} w + 8.73919 \times 10^{-5} P)$ (original with correlated variables) $g( ) = 0.0111 - 1.1560 \times 10^{-3} Y_1 - 2.5298 \times 10^{-3} Y_2$ (first iteration) $g( ) = 0.013324 - 1.8782 \times 10^{-3} Y_1 - 3.5946 \times 10^{-3} Y_2$ (final iteration)						
Step 2	β	3.0				2.789	2.778
Steps 3 and 10	w^*	35.03	49.96	53.59	53.85	52.10	52.03
	p^*	111.20	138.37	141.43	141.31	138.85	138.81
Step 4	μ_W^N	34.64	31.66	30.21	30.09	30.83	30.86
	σ_W^N	5.22	7.44	7.98	8.02	7.76	7.75
	μ_P^N	110.61	107.38	106.67	106.70	107.28	107.29
	σ_P^N	11.12	13.84	14.14	14.13	13.89	13.89
Step 6	y_1^*	0.0153	0.1562	0.3337	0.3634	0.3309	0.3273
	y_2^*	0.0904	3.3222	3.8093	3.8263	3.5449	3.5357
Step 7	$\left(\frac{\partial g}{\partial Y_1}\right)^*$	-1.1560×10^{-3}	-1.7724×10^{-3}	-1.9429×10^{-3}	-1.9588×10^{-3}	-1.8837×10^{-3}	-1.8782×10^{-3}
	$\left(\frac{\partial g}{\partial Y_2}\right)^*$	-2.5298×10^{-3}	-3.4818×10^{-3}	-3.6907×10^{-3}	-3.7048×10^{-3}	-3.6001×10^{-3}	-3.5946×10^{-3}
Step 8	α_{Y_1}	–0.1885	–0.2091	–0.2159	–0.2168	–0.2147	–0.2144
	α_{Y_2}	–0.9821	–0.9779	–0.9764	–0.9762	–0.9767	–0.9767
Step 11					2.789	2.778	2.777
Step 12	β						2.777

The reliability index has converged. The corresponding probability of failure of the beam in deflection is about 2.7×10^{-3}.

63.5 Probabilistic Sensitivity Indexes

In a real practical problem, the number of random variables present in the formulation can be numerous. However, not all of them have equal influence on the reliability evaluation. Their relative influence can be established by using a *sensitivity index*. The information on the gradient vector of the performance function in the standard normal variable space, already evaluated using FORM, can be used for this purpose. A sensitivity vector can be defined as [7]:

$$\gamma = \frac{\mathbf{SB}^t \alpha}{\left|\mathbf{SB}^t \alpha\right|} \tag{63.26}$$

where **S** is the diagonal matrix of standard deviations of the variables (equivalent normal standard deviations for the nonnormal random variables), **B** is a diagonal matrix required to transform the original **X** variables to equivalent uncorrelated standard normal variables **Y,** and α is the unit vector in the direction of the gradient vector.

The elements of the vector γ can be referred to as sensitivity indexes of the individual variables. Variables with low sensitivity indexes calculated at the end of the first few iterations can be treated as deterministic at their mean values in the subsequent iterations in the search for the β value. This may significantly reduce the computational effort required to obtain the underlying reliability.

63.6 Reliability Evaluation Using Simulation

With the advancement in computational power, simulation is becoming very attractive to estimate the underlying reliability [24, 25]. It does not require the sophisticated mathematical background necessary to implement FORM/SORM type reliability evaluation methods. With only a little background in probability and statistics, one can use simulation to estimate the reliability. Lewis and Orav [26] wrote "Simulation is essentially a controlled statistical sampling technique that, with a model, is used to obtain approximate answer for questions about complex, multi-factor probabilistic problems." They added "It is this interaction of experience, applied mathematics, statistics, and computing science that makes simulation such a stimulating subject, but at the same time a subject that is difficult to teach and write about." It provides a cheaper alternative to evaluate risk or the effect of uncertainty in the computer environment than the expensive physical experiments in the laboratory or in the field.

The method commonly used for this purpose is the Monte Carlo simulation technique. In the simplest form, each random variable is sampled several times satisfying the underlying probabilistic characteristics. Considering each realization of all the random variables produces a set of numbers that indicates one realization of the problem itself. Solving the problem for each realization deterministically is known as a simulation cycle, trial, or run. Using many simulation cycles gives the overall probabilistic characteristics of the problem, particularly when the number of cycles tends to infinity.

Monte Carlo simulation can be carried out with the help of following steps; (1) define the problem to be simulated in terms of all the random variables, (2) quantify the probabilistic characteristics of all the random variables in terms of their probability density or mass functions, (3) generate random numbers for these random variables satisfying their probabilistic characteristics, (4) solve the problem deterministically numerous times for each set of realizations of all the random variables, (5) extract the necessary probabilistic information from N such realization, and (6) determine the efficiency and accuracy of the simulation.

The first two steps are similar to the FORM/SORM approaches. Generating random numbers satisfying the underlying probabilistic characteristics is the essence of simulation. Most modern computers have the capability of generating uniformly distributed random numbers between 0 and 1. For an arbitrary seed value, the generator will produce the required number of uniformly distributed random numbers between 0 and 1. Depending on the size of the computer, the random numbers can be repeated. However, for engineering problems, this situation is rarely encountered. Random numbers generated this way are called *pseudo random numbers*. These uniform random numbers are then transformed into other random numbers satisfying the probabilistic characteristic of the basic random variable of interest. The *inverse transformation technique* is generally used for this purpose [7]. Some computers can directly generate random numbers for commonly used distributions.

Once the random numbers are generated for all the random variables present in the problem providing N sets of random numbers, the problem

defined in Step 1 then can be deterministically solved producing N sample points. The statistical information on these N sample points can be extracted in numerous ways. In most formulations, the function g ( ) in Step 1 will produce negative result if the system fails. Let N_f be the number of simulation cycles when g( ) is negative out of a total of N simulation cycles. Then the probability of failure can be expressed as:

$$p_f = \frac{N_f}{N} \tag{63.27}$$

The accuracy of (63.27) in predicting the probability of failure is a major concern. For a small probability of failure and/or small N, a considerable amount of error is expected in estimating p_f. For many engineering problems, the probability of failure may be smaller than 10^{-5}. Therefore, on an average, only 1 out of 100,000 trials would show a failure. For a reasonable estimate, at least 10 times this minimum, that is 1 million simulation cycles, is usually recommended to estimate the probability of failure of the order of 10^{-5}.

The previous discussions clearly indicate the basic simplicity in the simulation approach. They also point out its drawback, *i.e.*, it could be tedious or cumbersome for reliability evaluation of large systems with low probability of failure. The efficiency of simulation can be improved by using *variance reduction techniques* (VRTs). VRTs are expected to estimate the probability of failure with a reduced number of simulation cycles. The efficiency can be improved by altering the input scheme, by altering the model, or by special analysis of the output. The VRTs can also be grouped according to the purpose, *i.e.*, sampling methods, correlation methods, and special methods.

The sampling methods either constrain the sample to be representative or distort the sample to emphasize the important aspects of the function being estimated. Some of the sampling methods are systematic sampling, importance sampling, stratified sampling, Latin hypercube sampling, adaptive sampling, randomization sampling, and conditional expectation. The correlation methods employ strategies to achieve correlation between functions or different simulations to improve the efficiency. Some VRTs in correlation methods are common random numbers, antithetic variates, and control variates. Other special VTRs include partition of the region, random quadratic method, biased estimator, and indirect estimator. VRTs can also be combined to further increase the efficiency of the simulation [7].

It is usually impossible to know beforehand how much efficiency can be improved by using a specific technique. It should be noted that VRTs significantly increase the computational difficulty and a considerable amount of expertise may be necessary to implement them. The most desirable feature of simulation, its basic simplicity, is thus lost.

63.7 Reliability Evaluation Using FOSM, FORM, and Simulation

As mentioned earlier, any one of the methods discussed in the previous sections can be used to estimate reliability or probability of failure. An example is given here to demonstrate their advantages and disadvantages.

63.7.1 Example

Suppose a very tall chimney of height 36.58 m and diameter 2.53 m is made with steel plates of thickness 6.35 mm. The probability of failure of the chimney needs to be estimated when subjected to the wind load. Suppose the limit state function for the problem, as suggested by Haldar and Ayyub [27] is:

$$Z = \pi X_1 F_y - 0.04136 C_f X_2 V_{10}^2 \tag{63.28}$$

where X_1 is a function of thickness and outer radius of the chimney, C_f is a pressure coefficient, X_2 is a function of velocity pressure coefficient, gust factor, and the diameter of the chimney, and V_{10} is the wind velocity 10 m above the ground surface. They are all considered to be random variables and their probabilistic characteristics are summarized in Table 63.2.

Table 63.2. Probabilistic characteristics of random variables

Random variables	Mean	COV	Prob. distri-bution
X_1 (m^3)	5.6×10^{-3}	0.08666	Log normal
X_2 (m)	3.246	0.18652	Log normal
F_y (kPa)	262.0×10^3	0.10	Normal
C_f	0.672	0.10	Normal
V_{10}^2 (km/hour)	101.49	0.16	(Type II, u = 0)

The probability of failure of the chimney is calculated in several ways, including using FOSM (i) with first-order mean and first-order variance, (ii) second-order mean and first-order variance, (iii) FORM, (iv) basic Monte Carlo simulation, (v) Monte Carlo simulation with conditional expectation VRT, and (vi) Monte Carlo simulation with conditional expectation plus antithetic variates VRT. The results are summarized in Table 63.3.

Several important observations can be made from this example. As the example points out, the FOSM method with first-order mean or second-order mean may not improve the estimation of the probability of failure significantly. It will depend on the nonlinearity in the limit state function. However, these means may not give a realistic measure of safety. The limit state function represented by (63.28) is nonlinear and contains a random variable with extreme value distribution [7]. The probabilities of failure obtained by FOSM (two alternatives) and FORM are found to be 6.2×10^{-7} or 6.9×10^{-7} and $7.1 \times 10^{-4,}$ respectively. The results are about three orders of magnitude different, and FOSM gives very non-conservative result giving a false sense of reliability or safety. The results clearly indicate that FOSM should not be used in the reliability estimation.

Eliminating FOSM, it is important now to validate the FORM result. The validation can be achieved by comparing the RORM result with the simulation results. If one follows the suggestion made earlier, the appropriate number of simulation cycles will be at least $\approx \left(1 \big/ p_f \right) \times 10 = 13{,}500$. The results shown in Table 63.3 indicate that the basic Monte Carlo simulation even with 5,000 simulation cycles will not produce one failure, and 20,000 cycles will not give a result similar to FORM. At this stage, one may erroneously conclude that the FORM result is not correct. The example clearly indicates that definitive conclusion about any simulation scheme may not be meaningful and should be avoided as much as possible. If one stops after 20,000 simulation cycles, the probability of failure estimation will be somewhat inaccurate and the simulation will not validate the FORM result.

To demonstrate the desirable features of VRTs, the basic Monte Carlo simulation scheme is then integrated with VRTs. In one scheme (option v) only one VRT (conditional expectation VRT) is used, and in the other scheme (option vi); two VRTs are combined (conditional expectation and antithetic variates). The first scheme with one VRT gives a result similar to FORM only after 5,000 cycles. However, the second scheme with two VRTs, confirms the FORM result even with 500 cycles. The accuracy of prediction of both schemes improves as the total number of simulation cycles increases. This is generally described in terms of COV of the prediction. The results in Table 63.3 indicate that the COV of the mean probability of failure went down as N increases. In any case, both simulation schemes confirm the FORM result. One major conclusion of this exercise is to suggest that FORM should be used for reliability estimation whenever possible. A considerable amount of research is now being carried out on various aspects of simulation with VRTs. However, it is difficult to predict which VRT scheme will be appropriate for a particular problem.

Table 63.3. Reliability evaluation using different techniques

FOSM				FORM		Monte Carlo simulation					
First-order mean, first-order variance		First-order mean, first-order variance				Simulation cycles	Direct	Conditional expectation VRT		Conditional expectation plus antithetic variates VRT	
β	p_f	β	p_f	β	p_f	N	$p_f = N_f/N$	Mean	COV	Mean	COV
4.85	6.173×10^{-7}	4.83	6.877×10^{-7}	3.19	7.11×10^{-4}	500	0.000	8.44×10^{-4}	0.0642	7.427×10^{-4}	0.0370
						1,000	0.000	8.029×10^{-4}	0.0508	7.472×10^{-4}	0.0288
						5,000	0.000	7.415×10^{-4}	0.0208	7.362×10^{-4}	0.0118
						20,000	4.5×10^{-4}	7.451×10^{-4}	0.0107	7.389×10^{-4}	0.0063

63.8 FORM for Implicit Limit State Functions – The Stochastic Finite Element Method

The discussions so far assume that the limit state functions are available in explicit forms, *i.e.*, they are available in terms of random variables present in the formulation. They can be differentiated with respect to the random variables to estimate the direction cosines and the gradient vector to locate the most probable failure point. However, for most problems of practical interest, limit state functions are not available in the explicit form. This is particularly true for nonlinear problems. The probability of failure implies that it should be estimated just before failure considering all major sources of nonlinearity and uncertainty. However, commonly used FORM/SORM-based evaluation methods cannot be used to predict realistic failure probability.

Several computational schemes can be pursued for the reliability analysis for implicit limit state functions. These can be broadly divided into three categories, based on their essential philosophy, as (1) Monte Carlo simulation with VRTs, (2) response surface approach, and (3) sensitivity-based analysis. As mentioned earlier, the efficiency and accuracy of Monte Carlo simulation with or without VRTs are always open to questions. The response surface approach approximately constructs a polynomial approximation of the implicit limit state function. Its efficiency depends on the form of the polynomial and it needs to be generated in the failure region which will be unknown in most cases. The sensitivity-based approaches can be defined in three ways: (1) the finite difference approach, (2) classical perturbation, and (3) iterative perturbation. The author and his team used the iterative perturbation technique to evaluate the reliability of systems considering all major sources of nonlinearity and uncertainty. They called it the stochastic finite element method (SFEM) [8].

With the advances in computational power, it is quite appropriate to develop a finite element method- (FEM) based reliability analysis technique parallel to the deterministic analysis procedure. In this way, complicated structural arrangements and different sources of nonlinearity can be modeled in efficient ways. However, the basic drawback of the FEM is that it cannot incorporate information on uncertainties in the variables even when it is available. As mentioned earlier, in the available FORM/SORM approaches, the structural behavior needs to be considerably idealized to estimate the

reliability. The desirable features of the two approaches can be combined leading to the SFEM approach.

The SFEM-based approach is very difficult, however, the concept is briefly discussed below for the sake of completeness. Without losing any generality, the limit state function can be expressed in terms of the set of basic random variables **x**, the set of displacements **u** and the set of load effects **s** (except the displacements, such as internal forces). The displacement vector can be expressed as **u** = **QD**, where **D** is the global displacement vector and **Q** is a transformation matrix. The limit state function can be expressed as $g(\mathbf{x},\mathbf{u},\mathbf{s})=0$. In general, **x**, **u**, and **s** are related in an algorithmic sense, for example, a finite element code. For reliability computation, it is convenient to transform **x** into the standard normal space **y** = y**(x)** such that the elements of **y** are statistically independent and have a standard normal distribution. An iteration algorithm can be used to locate the design point on the limit state function using the first-order approximation. During each iteration, the structural response and the response gradient vectors are calculated using finite element models. The following iteration scheme can be used for finding the coordinates of the design point:

$$\mathbf{y}_{i+1}=\left[\mathbf{y}_i^t\alpha_i+\frac{g(\mathbf{y}_i)}{\left|\nabla g(\mathbf{y}_i)\right|}\right]\alpha_i \tag{63.29}$$

where

$$\nabla g(\mathbf{y})=\left[\frac{\partial g(\mathbf{y})}{\partial y_1},\ldots,\frac{\partial g(\mathbf{y})}{\partial y_n}\right]^t \tag{63.30}$$

and

$$\alpha_i=-\frac{\nabla g(\mathbf{y}_i)}{\left|\nabla g(\mathbf{y}_i)\right|} \tag{63.31}$$

To implement the algorithm, the gradient $\nabla g(\mathbf{y})$ of the limit state function in the standard normal space can be derived as [8]:

$$\nabla g(\mathbf{y})=\left[\frac{\partial g(\mathbf{y})}{\partial \mathbf{s}}\mathbf{J}_{s,x}+\left(\mathbf{Q}\frac{\partial g(\mathbf{y})}{\partial \mathbf{u}}+\frac{\partial g(\mathbf{y})}{\partial \mathbf{s}}\mathbf{J}_{s,D}\right)\mathbf{J}_{D,x}+\frac{\partial g(\mathbf{y})}{\partial \mathbf{x}}\right]\mathbf{J}_{y,x}^{-1} \tag{63.32}$$

where $J_{i,j}$'s are the Jacobians of transformation (*e.g.*, $J_{s,x}=\partial s/\partial x$) and y_i's are statistically independent random variables in the standard normal space. The evaluation of the quantities in (63.32) will depend on the problem under consideration (linear or nonlinear, two-dimensional or three-dimensional, *etc*.) and the performance functions used. The essential numerical aspect of SFEM is the evaluation of three partial derivatives, $\partial g/\partial s$, $\partial g/\partial u$, and $\partial g/\partial x$, and four Jacobians, $J_{s,x}$, $J_{s,D}$, $J_{D,x}$, and $J_{y,x}$. They can be evaluated by the procedures provided in [8]. Once the coordinates of the design point y* are evaluated with a preselected convergence criterion, the reliability index β can be evaluated as:

$$\beta=\sqrt{(\mathbf{y}^*)^t(\mathbf{y}^*)} \tag{63.33}$$

The corresponding probability of failure can be estimated using (63.5). A more recent discussion on SFEM can be found in Huh and Haldar [28, 29].

63.9 Recent Trends in Reliability for Civil Engineering Problems

One of the interesting questions at this stage would be where to go from here in the use of reliability for civil engineering problems. The question can be answered in terms of analytical developments and potential application areas. It is believed that the analytical development in the relaibility evaluation area is now mature enough to address all major issues. However, there is considerable room for improvement in the simulation area. Furthermore, in spite of its maturity, the reliability area is not popular among practising engineers and with the deterministic community. In the past, the reliability community overlooked the education component in developing the area. Moreover, the lack of user-friendly computer programs is another obstacle in spreading the word. The challenge can be addressed on two fronts. Reliability-based computer programs can be developed for direct applications or should be made a part of the commercially available deterministic software. There are some movements on both fronts. Several commercially available reliability-based computer programs are now available. NESSUS [30, 31],

PROBAN [32], CALREL [33], and OPENSEES [34] are examples of such software. Proppe *et al*. [35] discussed in detail the necessity of adding probabilistic features in existing deterministic finite element programs. For proper interface with the deterministic software, they advocated a graphical user interface. The COSSAN [36] software attempted to implement the concept.

Applications of the reliability methods in civil engineering problems are fertile areas, and the interest is expected to remain high in the near future. All major design guidelines have either already been revised or are in the process of being revised in reflecting the risk-based design guidelines. However, at present, some problems that cannot be addressed using codified approaches need our attention. Some future analytical and application-oriented topics are briefly discussed below.

Cognitive Sources of Uncertainty

Most of the work on reliability-based engineering incorporates noncognitive (quantitative) sources of uncertainty using crisp set theory. Cognitive or qualitative sources of uncertainty are also important. They come from the vagueness of the problem arising from the intellectual abstractions of reality. According to Ayyub and Klir [37], Albert Einstein stated, "*The mere formulation of a problem is often far more essential than its solution*." They also stated that according to Werner Karl Heisenberg "*What we observe is not nature itself, but nature exposed to our method of questioning*." To incorporate cognitive sources of uncertainty, fuzzy set theory is being developed. This area is expected to grow in the near future.

The crisp set and fuzzy set theories follow different axioms. Most problems with practical significance contain both random and fuzzy variables. Combining different types of uncertainties is a major challenge. This author attempted to initiate related work in the past with limited success [38]. Incorporation of cognitive sources of uncertainty has made significant progress in economics, *e.g.*, in buying and selling stocks. Economists have received the Nobel Prize for this type of activity in the recent past. However, a considerable amount of work still needs to be conducted for engineering applications by combining different sources on uncertainty.

For the sake of completeness, it is important to point out that the applications of artificial neural networks (ANN), the more generic term used by the research community being soft computing, in civil engineering have been noteworthy in the recent past [39]. In addition to ANN, other soft computing techniques include genetic algorithms, evolutionary computation, machine learning, organic computing, probabilistic reasoning, *etc*. The applicability of these techniques may be problem specific, some of them can be combined, or one technique can be used when another has failed to meet the objectives of the study. Soft computing differs from conventional hard computing. Unlike hard computing, soft computing is tolerant of imprecision, uncertainty, partial truth, and approximation. To some extent, it essentially plays a role similar to human mind.

Meshless or Meshfree Methods

As mentioned earlier, the introduction of the FEM-based analysis concept significantly helped the growth of structural engineering. The SFEM method developed by the author is the stochastic part of it. However, it is an approximate technique. The generation of a finite element mesh may be tedious and the solution will depend on the expertise of the analyst. This brings in a nonunique solution to a specific problem. The solution of a problem without using a structured grid is expected to be very appealing. This is known as meshless or meshfree methods. This area is expected to grow in the near future [40, 41].

Robust and Stochastic Optimization

Available optimization techniques enable us to design efficient and economical structures, in most cases. However, a major limitation of deterministic optimization techniques is that they are unable to incorporate uncertainties in the design variables even when the information is available. It is now well-established in the profession that engineering analysis and design cannot be completed without considering the presence of uncertainty. Conceptually, the development of optimum design procedures for structures under uncertainty can be

broadly divided in to three categories: (i) performance-based optimization where the objective is to minimize the expected value of the performance function, (ii) robust optimization where the design is the least sensitive to the changes in input uncertain parameters, and (iii) reliability-based optimization by incorporating statistical information of all the decision variables in the objective function and by minimizing the probability of failure. Robust optimization, as a measure of the performance, can be considered as a design procedure that is insensitive (or less sensitive) to the changes in the input decision variables within a range of interest while satisfying the safety requirements [42]. Moreover, when statistical information on the decision variables is not sufficient or complete, robust optimization is also an attractive alternative. The progress in the area of robust design optimization method has been taken place in various forms through nonlinear programming-based optimization procedures. These are primarily based on probabilistic and sensitivity-based approaches.

Reliability-based optimization of the cost function brings specified reliability for a particular limit state. But it may be sensitive to variations of specific design variables. Comprehensive reliability-based optimization techniques, including genetic algorithms, are being developed by incorporating statistical information of all the decision variables in the objective function and by minimizing the probability of failure [43]. Two most commonly used measures in probabilistic approaches are the mean and variance of the performance function. Generally, the variance is minimized with respect to the original performance requirements. A more balanced approach consisting of cost minimization and satisfying the performance requirements at the same time is expected to be very desirable. The various approaches that utilize probabilistic information reported in the literature are the weighted-sum method [44, 45], the compromise programming approach [46], and the physical programming method [47]. If cost is a decision variable, the optimization problem may not be unique world-wide. Cost depends on many factors including the locations and the standard of living of the people being affected. Rackwitz [48] introduced the life quality index factor to address the problem.

Health Assessment and Monitoring

In-service structural health assessment is also an upcoming research item. Developments of sophisticated new sensors, wireless data transmission, and the power of computers have contributed to progress in this area [49]. The structural behavior or the signature of the structure are expected to change as defects developed in them. Not all defects affect the structural behavior in a similar way. They can be tracked without compromising the underlying reliability of the structure. The structural elements need to be repaired or replaced when they become a cause for concern. After the necessary repair or replacement, it is also necessary to determine if all the defects are identified and repaired properly.

In-service health assessment requires that necessary information be generated with a minimum amount of uncertainty-filled information and without causing major disruption to the normal operation of the structure. The author and his associates are in the process of developing such a method. They are using the system identification (SI)-based defect assessment technique at the local element level. The classical SI approaches have three essential components: input excitation, the system to be identified generally represented in an algorithmic form such as finite elements, and the output response information. Knowing the input and output response time histories, the third component, *i.e.*, the system can be identified. For a finite element representation, it is equivalent to identifying the stiffness parameters of all the elements. However, in most cases of practical importance, input excitation information is not available. Also, for a large structural system, measuring responses at all dynamic degrees of freedom may not be practical or economical. Furthermore, all measured responses are expected to contain numerous sources of error, noise, or uncertainty. These observations require a system to be identified using only noise-contaminated limited response information and without using any input excitation information. However, the task is extremely complicated and mathematically challenging [50–54].

The research team at the University of Arizona is in the process of developing such a method. They have called it the generalized iterative least square extended Kalman filter with unknown input (GILS-EKF-UI) method [55]. Students from many different engineering disciplines, including aerospace, mechanical, and structural engineering, have been involved in developing the method. It is also a good example of advantages of multi-disciplinary collaboration. In the context of the use of reliability methods for civil engineering problems, methods developed in other disciplines need to be utilized and integrated in intelligent ways.

Structural Maintenance

Historically, building new structures has been a source of pride to all structural engineers. Unfortunately, all structures age with time. Several thousand bridges in the US are over their design life. Ideally, they should be replaced when they have out-lived their design life. The situation clearly indicates that structural engineers are doing their job properly, as expected. However, the resources required to build new structures are decreasing.Extension of the life of existing structures has become a necessity and is now a new research topic. The life of a structure can be extended by inspection and with proper maintenance. Inspection outcomes are full of errors or uncertainty-filled, and the maintenance strategies may be numerous. New inspection methods and tests need to be developed or available techniques need to be improved. Inspectors capable of carrying out the inspections need to be trained. Appropriate retrofitting strategies or options need to be developed. Ultimately, incorporating all available information including the cost of repair or replacement, a decision analysis framework needs to be developed for use by practising engineers. A considerable amount of work has yet to be completed. Zhao *et al.* [56] proposed such an approach for further consideration.

Methods are now also available for structural maintenance considering the degradation of the structures as they age, the cost of inspections, and cost of repairs or replacements as they become necessary [57] by incorporating information on uncertainty in the problem. The design and construction of structures considering their long-term behavior (aging, corrosion, fatigue, *etc*.) in the presence of uncertainty are expected to grow in the near future. A structural performance/health assessment method denoted as GILS-EKF-UI is being developed at University of Arizona [58]. The unique feature of this algorithm is that it can identify members' properties and in the process access the performance/health of a structural system using only noise-contaminated dynamic response information measured at few locations, completely ignoring the excitation information.

Prediction of Future Events Like Earthquake, Wind, Draught, Tornado, and Tsunami

As mentioned earlier, we have significant limitations in predicting natural phenomena like earthquake, wind, drought, tornado, tsunami, *etc*. Obviously, the success of civil engineering will depend on how accurately we predict these events. We currently have the mathematical sophistication to design structures if we can predict future events in the presence of uncertainty. A considerable amount of work, both theoretical and experimental, is needed to improve our understanding in predicting these events.

System Reliability

In general, engineering systems need to satisfy more than one limit state function. The limit state functions are generally of two types: (i) strength and (ii) serviceability. The strength limit state function is generally related to the behavior of a member (beam, column, *etc*.) at the element level. However, more than one member needs to fail to cause structural failure for statically indeterminate structures. The serviceability limits states (defection, interstory drift, lateral drift, *etc*.) are generally applicable at the structural or system level. The concept used to consider multiple failure modes and/or multiple component failures is known as system reliability evaluation.

In general, system reliability evaluation is complicated and depends on many factors including (1) the contribution of the component failure events to the system's failure, (2) the redundancy in the system, (3) the post-failure behavior of a component and the rest of the

system, (4) the statistical correlation between failure events, and (5) the progressive failure of components.

The application of the system reliability concept in various engineering disciplines can be described, at best, as non-uniform. In the context of civil/structural engineering, two basic approaches are (1) the cut-set or failure mode approach (FMA) or performance mode approach (PMA) and (2) the tie-set or stable configuration approach (SCA). In FMA, all possible ways in which a structure can fail are identified. A fault tree diagram, which decomposes the main failure event into unions and intersections, can be used for this purpose. FMA is very effective for systems with ductile components (components continue to carry loads after reaching their capacity), particularly when the dominant failure mechanisms of the system can be easily identified. SCA considers how a system or its damaged state can carry loads without failure. SCA is effective for highly redundant systems with brittle components (components that fail to carry loads after reaching their capacity) or with ductile and brittle components.

Once the failure modes or stable configurations of a system are identified, system reliability evaluation involves evaluating the probability of union and intersection of events considering their statistical correlation. In many cases, the statistical correlation may be difficult to estimate. Also, it is difficult to estimate the joint probabilities of more than two failure events. These difficulties result in estimations of upper and lower bounds for the system reliability evaluation. A more complete discussion on the topic can be found in Haldar and Mahadevan [7] and Chowdhury and Haldar [59].

63.10 Concluding Remarks

Civil engineering is the oldest engineering profession and has had over 5000 years of glorious history. The profession has accepted all challenges and provided services at the highest level to society worldwide. It is a profession whose main purpose is to improve the quality of life. However, due to the presence of a considerable amount of uncertainty, it is not possible to design totally safe structures. Based on the available information, the design philosophies have changed over the years. In the last three decades, risk-based design has become an integral part. Several methods with various degrees of sophistication are now available. They are presented in this chapter. Some of the future trends in the reliability-based design in civil engineering are also presented. Considering some emerging areas, multidisciplinary efforts are encouraged.

Abstract: This chapter discusses the performability models for WCN. The reliability issues, such as component failure models and evaluations that are relevant to WCN are described. System communication models for WCN, including the many-sources-to-terminal model widely used in WSN, are described. The performability evaluations of two typical WCN environments: static topology and the *ad hoc* network are described in detail. This chapter also discusses recent techniques to improve the end-to-end routing reliability in MANET.

64.1 Introduction

Performability analysis of a communication network (CN) is very important as it helps gauge the resiliency of the network in meeting some user quality of service requirement. Techniques to analyze and to improve the performability of the wired CN are extensively described in the literature. A wireless CN (WCN), in many ways, is different from the traditional CN and, consequently, its performability issues are also different in several ways. The proliferations of WCN, such as mobile *ad hoc* networks (MANET), and wireless sensor networks (WSN), make their performability issues equally important, if not even more important, because a WCN is more complex in nature than the wired CN, its components are less resourceful, and the components are more susceptible to failures. Limited resources (*e.g.*, battery, memory, and bandwidth) reduce the intrinsic performance and reliability of WCN, and thus methods to improve the metrics in WCN are imperative. The node mobility in WCN makes network links have higher unavailability rates and makes the performability analysis of a WCN even more difficult.

The performability issues of a *wired* or *wireless* CN, through which data are expected to traverse from one or many sources to one or many destinations, are increasingly becoming more critical with increasing user dependency on the network services. In general, the performability analysis of a CN starts with its communication performance model, which is defined by the user *quality–of–service* (QoS) requirements, and its reliability model. The performability metric of a CN, thus, indicates the reliability of the system in meeting the user QoS requirement. Refer to [1] and [2] for QoS and reliability models, respectively.

The conveniences advanced by wireless communication devices (*e.g.*, cellular phones), and

the technological advances in portable–lightweight computers (*e.g.*, laptops and PDAs), among others, have triggered the proliferations and set the *future trends* of the uses of WCN around the world [3].

A WCN comprises a set of nodes each of which is capable of transmitting to or receiving from other nodes. The nodes in the network, among others, can be a computer, concentrator, end user terminal, mobile station, repeater acting as a transmitter/receiver, or a sensor node. Two nodes in a WCN, in contrast to a *wired* CN, are connected by wireless communication links either directly (without infrastructure – the *ad hoc* mode) or through a base station (the infrastructure mode). In an *ad hoc* WCN, the wireless nodes communicate with each other without using a fixed infrastructure, and when two nodes are not within their transmission range, the intermediate nodes relay the messages between nodes. In some networking environments, such as wireless home or office with stationary workstations, the network nodes are wireless but non–mobile (*stationary*). In others, the network nodes are both wireless and *mobile* [3]. The stationary nodes form a fix topology or a random topology (*ad hoc*), if deployed randomly. An *ad hoc* network with mobile nodes is a *mobile wireless ad hoc network* (MANET). MANET is a new frontier for WCN and is different from a traditional WCN in many ways. One major difference is that a routing path in MANET uses a sequence of *mobile* nodes, a wireless link connecting each pair of the nodes. The *wireless sensor network* (WSN) is another class of WCN. Nodes in WSN, forming a certain topology, can be mobile or stationary and deployed randomly (*ad hoc*). Typically, a WSN comprises more but less resourceful nodes than those in the other types of WCN.

The WCN introduces many communication/network–related challenges that, in many ways, differ from those considered in the traditional wired CN [3]. This chapter typically views the differences from their communication system performability issues.

While there has been much effort directed towards performability analysis in wired CN [2], there has been less treatment of WCN, partially because (i) some WCN performability issues are application specific and (ii) it is relatively new. The performability issues in a non-*ad hoc* and non-mobile WCN can be solved directly using the existing techniques for wired CN because nodes in both networks are stationary. However, the *ad hoc* nature and/or nodes mobility and the node's limited resources (*e.g.*, battery lifetime), which are typical characteristics of the other WCN models, require different treatments. For example, one of the main causes to node failures in WCN is due to limited battery lifetime. Thus, techniques (*e.g.*, routing) put more emphasis on reducing battery consumption and sacrifice performances typical to wired CN. Performability evaluation of a fixed topology WCN, with operational links, emphasizes node stability. Alternatively, with node mobility, link unavailability is more critical in the performability evaluation of MANET. Further, the many-to-one-terminal communication model (Section 64.2.2.2), used for data acquisition analysis of WSN applications, should also be taken into account.

The lay out of the chapter is as follows. In Section 64.2, we present various system models, including the reliability models, assumptions, and communication and component failure models of WCN. Section 64.3 presents three examples of performability analysis and improvement methods used in WCN. It describes the performability analysis of the static topology of WCN and MANET. It also surveys recent approaches to improve the end-to-end path reliability in MANET. Finally, we conclude this chapter in Section 64.4.

64.2 System Models

64.2.1 Reliability Models and Assumptions

Due to the nature of the problem, this chapter does not describe the stochastic models based on the Markov or semi-Markov models. This, however, presents a combinatorial (non-state-space) model. Examples for this model include the reliability block diagram (RBD), fault trees (FT without or with repeated events), and probabilistic graphs (PG). The RBD shows the functional relationships among resources and indicates which system elements must operate to accomplish the intended

function successfully. An FT maps the operational dependency of a system on its components. However, unlike an RBD, the FT represents a probability of failure approach to system modeling. The phrase *without repeated events* means that inputs to all the gates are distinct, while *with repeated events* assumes non-distinct inputs. The PG models the system as a graph, wherein each node is a computing unit (or processing entity) and links denote communication lines between them. In this chapter, the PG model describes the various WCN reliability issues.

The following assumptions, made for the WCN performability analysis, are helpful in making the reliability computation tractable: (i) All elements (nodes and links) of the network are always in active mode (no standby or switched redundancy); (ii) The state of each element i of the network is either *operating* with a probability p_i or *failed* with probability q_i; $p_i + q_i = 1$. Thus, the probability is $p_i = 1 - \frac{MTTR_i}{MTBF_i}$, where $MTTR_i$ ($MTBF_i$) refers to the mean time to repair (mean time between failures) of a component i. Section 64.2.3 describes other WCN component failure models; (iii) The states of all elements are statistically independent; and (iv) Graph model of WCN is free from directed cycles and self-loops.

64.2.2 System Communication Models and Reliability Measures

64.2.2.1 Overview

Refer to [36] for a number of reliability measures. We use one or more of the following categories:

- *two-terminal* or (s,t) reliability is the probability that a source node s communicates with a terminal node t.
- *All-terminal* reliability is the probability that all operative nodes communicate.
- *K-terminal* or source-to-many terminals (SMT) reliability is the probability of a source node s communicating with some K ($K \geq 1$) operative terminal nodes.
- *Many-sources-to-terminal* (MST) reliability is the probability that some K ($K \geq 1$) nodes communicate with a terminal node t.

The network (modeled as $G(V,E)$) reliability $R_K(G)$, for a set of specified nodes $K \subseteq V$, is the probability that all elements of at least one minpath are working. Here $V(E)$ is the set of nodes (links) in G. Note, the minpath depends on the specified set K as well as the reliability measure and system QoS under consideration. For $K = 2$, $R_K(G)$ is the *two-terminal* reliability and a minpath is a simple path between an (s,t)-node pair. Reference [2] provides the definitions of a simple path, and algorithms to enumerate them. For $K=V$, $R_K(G)$ is *all-terminal* reliability, an important measure for reliable broad-casting in a CN. SMT reliability is applicable for the resiliency issue of network multi-casting. The MST reliability, on the other hand, analyzes the reliability of a WSN. Table 64.1 lists models and their applications. This chapter uses the s-t model.

Table 64.1. Various WCN communication models

Models		Example applications
1	Unicast (s,t)	Event transmission from the sensor to the user.
2	Multi-cast (s,T_i)	User tasking/query dissemination to several target sensors.
3	Broadcast (s,T)	user tasking/ query dissemination to all target sensors.
4	Many-to-one (S,t)	Sensor data aggregation to a user.
4.1	(1-of-S, t)	Bush-fire and intrusion detection in one sensor field.
4.2	(k-of-S, t)	GPS that uses k=3 satellites to determine locations.
4.3	(k_i-of-S_i, t)	Climate data acquisition (multi-modal – temperature, pressure, humidity).

From the performance aspect, *delay* guarantee, among others, is widely used QoS metric in CN. Several path routing algorithms consider that a transmitted message can reach its destination within the required delay constraint [4]. The routing problem in the most general form is NP-complete, and to make the problem tractable the routing path delay measure allows only the total number of links or nodes (hop count) that a message needs to traverse to reach its destination. Nevertheless, hop count measure arguably captures network cost and, thus, minimizing path length

(hop count) becomes one of the criteria for computing efficient routing paths [5]. This chapter uses the hop count QoS in WCN.

64.2.2.2 MST Reliability

A WSN consists of a large number of sensor nodes. Here each node has some means of communication and sensor mechanisms. The sensor nodes, deployed randomly, form some regular geometric topology over a wide area sensor field [6], and send data (event) to a sink. In a multi--hop WSN, the sensor nodes are located beyond the distance range of the communication media from the sink; thus, the data pass through intermediate nodes.

WSN has been proposed for various critical monitoring systems such as battlefield surveillance, nuclear, biological and chemical attack detection, forest fire detection, flood detection, and precision agriculture using various communication models. Data dissemination in WSN is categorized into *tasks* (sink to sensors, Models 1 to 3 in Table 64.1) and *events* (sensors to sink, Models 1 and 4 in Table 64.1). Regardless of the application, data dissemination is often event driven and reliable. Its timely event detection is critical [6] because it starts appropriate actions as quickly as possible. For applications requiring uni-modal information, the group of sensor nodes may send redundant information, and the sink requires only one or several of them to arrive (Models 1, 4.1 and 4.2) before it can start reacting to the occurring event. For example, consider a WSN with many redundant target sensors to monitor a remote bush fire, and each target sensor is expected to send an alarm signal to the sink as soon as it detects fire. Model 4.3 groups the sensors. Each group monitors a different class of phenomena. (It is a multi--modal data acquisition.] This model also applies to climate monitoring and various surveillance systems.

The widely adopted *directed diffusion* paradigm [7] for WSN includes an event acquisition mechanism that is robust to node failures, where the transmitted signals may still reach the sink through alternative paths. However, alternative paths may increase the number of hops that messages have to traverse (before reaching the sink). Thus, the overall *expected hop count* (EHC) goes up. Most WSN applications (*e.g.*, battlefield surveillance, nuclear, and biological and chemical attack detection) require end-to-end delay-constraints. In addition, given the resource-limited nature of WSN and the delay-sensitive nature of their applications, evaluating and improving the performability of WCN become critical, leading to a *new trend* in the research area.

64.2.2.3 (s,t) Reliability

The (*s*,*t*) reliability measure or its variance (like average terminal reliability, node-to-node grade of service, end-to-end blocking, functional reliability, *etc*.) is widely known in the literature.

The (*s*,*t*) reliability depends on the availability of each link and/or node in the path. Section 64.2.3 discusses the causes of link and node failures in WCN and the typical methods used to measure the link/node reliability metric. Section 64.3.1 extends the (*s*,*t*) reliability measure for a WCN with fixed topology that uses average hop count and node availability parameters, while considering perfect links. In contrast, Section 64.3.2, considers a random graph model [8] used to analyze the connectivity of mobile ad hoc WCN with link failures and perfect nodes. Topological changes in MANET make (*s*,*t*) paths frequently broken [9] that negatively affect the efficiency (since each path failure recovery is costly [10]) and the per-formability of the network. Therefore improving the end-to-end path reliability in the network is critical, and is arguably more important in MANET's path selection than other QoS metrics commonly used in the traditional wired CNs [10]. Multi-path routing improves the end-to-end performability in WCN [11, 12]. In Section 64.3.3, we present a survey on recent techniques to enhance the end-to-end performability in MANET.

64.2.3 Component Failure Models

In the wired CN, the network system components (nodes and links) fail randomly due to component wear out, natural catastrophes, software bugs, or deliberate acts (*e.g.*, terrorist attacks). On top of these sources of failure, the use of wireless links, nodes mobility, and limited battery lifetime in a

WCN provide other reasons for component unavailability. Thus, the performability issue in a WCN is more challenging than that in wired CN. This chapter uses availability (unavailability) and reliability (failures) interchangeably.

Reference [13] considers node unavailability in analyzing the reliability and EHC of a fixed topology WSN. The harsh nature of WSN deployment environment makes the sensor nodes subject to random failures. The reliability of a sensor node, $p(t)=e^{-\lambda t}$, is modeled using the Poisson distribution to capture the probability of operational within a time interval $(0,t)$, where λ is the failure rate of the node. Researchers have considered robust sensor systems using evolvable hardware [14] that emphasizes on the robustness of a system with respect to sensor failures.

Alternatively, sensor nodes are unavailable due to power failures. Brooks *et al.* [15] considered node failure only when the battery power is exhausted. They [15] used three methods: data agreement, communication range managements, and node positioning to extend the effective lifetime of the WSN. To achieve better performability, applications (*e.g.*, routing methods) are designed emphasizing on conserving node battery lifetime, and a better understanding on the power consumptions of operations (*e.g.*, communication, program computation) in sensor nodes. Section 64.2.3.1 describes the various energy consumptions in several typical node operations.

In MANET, node mobility is the main source of link failures. Some links break when nodes move out of range of each other. Interferences on the wireless medium may also cause the link failures. Section 64.2.3.2 presents a typical approach to compute the link availability in MANET.

64.2.3.1 Energy Consumption in WSN

Sensor networks rely on battery power. Reference [16] considers the use of ambient energy sources for sensor networks and concludes this is not currently feasible. Reliance on limited, non-renewable battery energy resources means that all aspects of sensor networks need to be as energy efficient as possible. Refer to [6] and [17] for a discussion on energy model for sensor networks, which must consider all aspects of node behavior.

From the empirical analysis of the sensor node, power consumption in [18] suggests the following: (i) For most commercial ARM8 processor instructions, the energy required is 4.3×10^{-9} joules per bit. Multiplication requires 31.9×10^{-9} joules per bit; (ii) The Berkeley smart dust prototypes consume ~ 0.05×10^{-9} joules per bit for most instructions (multiplication is not supported); (iii) Radio frequency ground communications require 10^{-7} joules per bit for 0–50 meters, and 50×10^{-6} joules per bit for 1–10 kilometers.

These figures are lower bounds, based on ongoing research programs. Commercial products are unlikely to reach these levels of efficiency in the near future: (i) Per bit energy consumption for multiply instructions on commercial processors is in the range 48 to 0.84×10^{-9} joules per bit [19]; (ii) Communications require from 40 to 0.1×10^{-6} joules per bit [18]; (iii) Reception energy needs are 2×10^{-6} (GSM) and 10^{-7} (Bluetooth) joules per bit for. [18].

Energy requirements for communications are proportional to $r^{-\alpha}$ where r is communication range in meters. The α exponent is between 2 and 5. A value of 3 is reasonable for many applications [20]. For commercial and prototype systems, transmitting one bit for one hop is on the order 10^2 times more expensive than computing one instruction on one bit.

References [18] and [21] claim transmission energy is the dominant drain on sensor networks when per hop communication is over 10 meters. This claim is based on three applications that have minimal on-board computation. Two examples in [18] only sample data, do an analog-to-digital conversion, execute a filter and transmit data. The other example does a least squares estimate of vehicle velocity from five data samples. This amounts to executing one very small matrix multiplication. For nodes that perform minimal to no local data processing, communications energy consumption is certain to be greater than the computation energy requirements.

Empirical tests [15] show that, for many sensor network applications, computation dominates energy consumption. Consider the two tracking approaches: beamforming and closest point of approach (CPA). Beamforming [22–25] is a form

of spatial filter that aggregates output from a group of sensor nodes placed locally. CPA [26–29] techniques involve using the output from a single sensor node, usually the node closest to the event. The beamforming approach is more accurate, while requiring $\sim 10^3$ times more energy. Beamforming is computation intensive, performing cross-correlation over multiple time series to estimate signal direction of arrival. The CPA based approach requires minimal computation. Energy need for communications uses the Bluetooth energy per bit. Communication was responsible for less than 20% of the total energy drain.

In the security domain, both [19] and [30] show that encryption, decryption, and secure hashing are computation intensive, with a large energy overhead. References [19] and [31] measure the energy drain of key initialization communications.

64.2.3.2 Computing Link Availability in MANET

In MANET nodes mobility is the main source of link unavailability, and due to high cost in recovering from a routing path failure, path reliability is of utmost important [10]. The most direct technique to compute the link availability in MANET is by taking a snapshot of the network topology, assuming the positions of the nodes are likely to be fixed for a period of time. However, such assumption may not be justifiable considering the dynamic nature of MANET.

Recently Jiang, *et al.* [10] proposed a prediction-based link availability estimation; they used a pair $(T_p, L(T_p)]$ to quantify link availability in MANET. For a link that is available at time t_0, $T_p > 0$ is the predicted maximum time period that the link will be continuously available until $t_0 + T_p$. Assuming both nodes associated with the link keep their current velocities (*i.e.*, speed and direction) between time t_0 and $t_0 + T_p$, the parameter T_p can be predicted accurately [10]. Then, relaxing the assumption (*i.e.*, allowing possible changes in the node velocities) and using T_p, they [10] show how to compute the link availability estimation $L(T_p)$, which is defined as the probability that the link will be available continuously during time period T_p. Then, the link reliability metric is computed as $r_l = T_p \times L(T_p)$, which is then used in [10] to develop a routing algorithm to maximize end-to-end path reliability. Note that T_p by itself is not sufficient to gauge the availability of a link. For example [10], the reliability metrics of links l_1 (T_p=10 s, $L(T_p)$=0.001) and l_2 (T_p=5 s, $L(T_p)$=0.1) are 0.01 and 0.5, respectively, and thus link l_2 is more reliable. Reference [32] shows an enhanced $L(T_p)$ estimation which gives a better accuracy than that obtained in [10], and reference [33] proposes a technique to predict link availability $L(T)$, for any time duration T. This later technique is more suitable for multi-media streaming application. Other link availability predictors for MANET are discussed in [10] and [33].

Brooks, *et al.* [8] used a random graph to model an *ad hoc* WCN. The *ad hoc* network is represented by its graph connectivity matrix, where each matrix element is the Bernoulli probability giving the link availability between two corresponding nodes. Section 64.3.2 describes the details of the random graph approach.

64.3 Performability Analysis and Improvement of WCN

64.3.1 Example I: Computing Reliability and Expected Hop Count of WCN

Reference [34] uses a probabilistic graph G to represent a static topology WCN, and describes two algorithms: Alg1 and Alg2, to compute the (s,t) reliability $TR(G)$ and the EHC of the network with probabilistic node failures. Alg1 is based on complete-state enumeration, while Alg2 avoids generating all network states by utilizing breadth-first-search to recursively obtain all (s,t) shortest paths and the factoring theorem [2] to make each newly generated state disjoint from the previous states. The technique is recursively expressed as

$$TR(G) = p_i\, TR(G|\text{ node } i \text{ is functional}) + (1-p_i)\, TR(G|\text{ node } i \text{ is not operational}), \quad (64.1)$$

where p_i is the probability that node i in G is functional. Note that (64.1) uses the concept of Shannon's expansion principle in Boolean logic for reliability modeling. Several researchers have developed factoring algorithms that implement the

series-parallel probability reductions and polygon reductions and use optimal link-selection strategies. It is important to note that this method can be employed using the graph representation, without knowing the connectivity information (*i.e.*, minpath, mincut, or spanning tree). Note that the factoring approach represents each disjoint term in single-variable inversion (SVI) notation [36], and the approach performs worst on a WCN whose (*s*,*t*) simple paths are disjoint paths. The SVI-based technique requires $1+\sum_{j=2}^{m}\prod_{i=1}^{j-1}|P_i|$ disjoint terms to represent *m* disjoint paths $P_1, P_2, \ldots, P_m$, where $|P_i|$ represents the number of nodes in path *i*. For this case, [34] provides a polynomial time approach (Alg3) to compute the reliability and EHC of the network. Another polynomial time algorithm (Alg4) in [34] is also proposed for computing the reliability measures of a WCN that can be represented as an interval-graph [35]. However, when the WCN has all but one or a few disjoint paths, we cannot use Alg3 to compute its reliability measure, and Alg2 performs worst for this case. Similarly, when the network forms an "almost interval-graph" Alg4 is inappropriate to use [37].

This section proposes a two-step approach to compute *TR*(*G*) and EHC that was first presented in [37]. First, all (*s*,*t*) simple paths (considering only the nodes) of the WCN are generated and sorted in increasing cardinality (hence shortest path first) order. Reference [37] describes two algorithms that enumerates the (*s*,*t*) paths of WCN: one for general networks, and the other for interval graphs (described in Section 64.3.1.2). In the second step, the approach uses a multi-variable inversion (MVI)-based sum-of-disjoint-products (SDP) [38] technique to generate the mutually disjoint terms (*mdt*) for the paths. Simulations on general networks reported in the literature [37] showed that the SDP-based technique is several orders of magnitude faster than the factoring technique. In addition, the technique solves the reliability metrics of WCN that contains all (*s*,*t*) disjoint-paths in time polynomial in the order of the number of its nodes. From the sorted paths in each of randomly generated interval graphs, an SDP technique [38] generates one *mdt* for each path, and it was conjectured in [37] that the two-step approach solves the *TR*(*G*) and EHC of an interval-graph in time polynomial in the order of simple paths. Reference [37] also presents the applications of the technique in WCN topology designs and their performability improvements.

64.3.1.1 Concepts

A. System Model and Representation

In the undirected graph model *G*(*V*,*E*) of a WCN, each node in *V* represents a site or a repeater in the network, and each link in *E* denotes a communication service. Two nodes are connected if the nodes are within the communication range of each other. A node is said to be *up* (*down*) if it is operational (failed). Links (*E*) are assumed to be always *operational*. An *up* (*down*) node is denoted by a Boolean expression v_j ($\overline{v_j}$). A Boolean expression $\overline{v_1}v_4 + \overline{v_3}v_4$, for example, represents an operational condition when nodes v_1 and/or v_3 fail, as long as node v_4 is operational. Note, it is *single-variable inversion* (SVI) representation [36]. The expression can also be represented concisely as $\overline{v_1 v_3} v_4$, where the inversion of multiple variables is allowed. This latter representation is *multi-variable inversion* (MVI) [36]. Let p_j (resp. q_j=1–p_j) be the operational (resp. failure) probability of a node v_j, and assume node failures are statistically independent. An (*s*,*t*) *simple* (node) path *i*, P_i, from a source node *s* to a terminal node *t* is formed by the set of *up* nodes such that no nodes are traversed more than once. In other words, $P_i = (v_0, v_1, \ldots, v_{k-1}, v_k)$, where v_0=*s*, v_k=*t*, and each 2 sequenced nodes in the path are connected by a link $e \in E$. An (*s*,*t*) path P_i is redundant with respect to an (*s*,*t*) *simple* path P_j if P_i contains all nodes in P_j. The WCN (Figure 64.1) has $P_{s,t}$={(*s*,*a*,*b*,*d*,*t*), (*s*,*a*,*c*,*e*,*d*,*t*), (*s*,*a*,*c*,*e*,*j*,*t*), (*s*,*f*,*c*,*e*,*d*,*t*), (*s*,*f*,*c*,*e*,*j*,*t*), (*s*,*f*,*g*,*h*,*i*,*j*,*t*)}.

B. The SDP Technique

Consider an (*s*,*t*) pathset $P_{s,t}=\{P_1, P_2, \ldots, P_{m-1}, P_m\}$ of a network *G*, and let E_i represent an event that all nodes in a simple path P_i operate. These events are not mutually disjoint. Making the events mutually disjoint is necessary to help generate an equivalent probability expression. This is a complex problem in the field of system reliability

as the reliability problem is NP-hard [2]. Reference [36] provides a survey of efficient SDP techniques.

64.3.1.2 (s,t) Simple-path Generators

A. General Networks

Path generators in the literature [2] consider an (*s*,*t*) simple path as a sequence of links that connect the node pair. We can use any existing link-based path generator [2] to obtain an (*s*,*t*) simple (link) pathset, which can be converted into its equivalent (*s*,*t*) simple (node) pathset. However, the approach incurs path redundancy tests. Consider the network in Figure 64.1 and its two non-redundant simple (link) paths ((*s*,*a*),(*a*,*b*),(*b*,*d*),(*d*,*t*)) and ((*s*,*a*),(*a*,*b*),(*b*,*d*), (*d*,*e*),(*e*,*j*),(*j*,*t*)). Converting the paths considering nodes, we obtain paths (*s*,*a*,*b*,*d*,*t*), and (*s*,*a*,*b*,*d*,*e*,*j*,*t*), respectively, where the second path is redundant. Reference [37] describes an efficient recursive function that enumerates all non-redundant simple (node) paths of an undirected graph *G*(*V*,*E*). The path generator [37] does not generate any redundant simple (node) paths, and therefore no path redundancy checks are required.

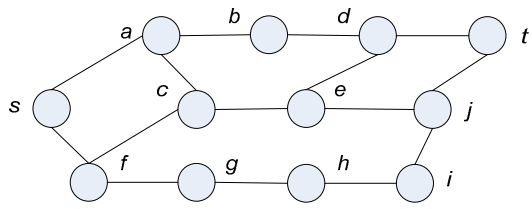

Figure 64.1. A 12-node, 15 links WCN

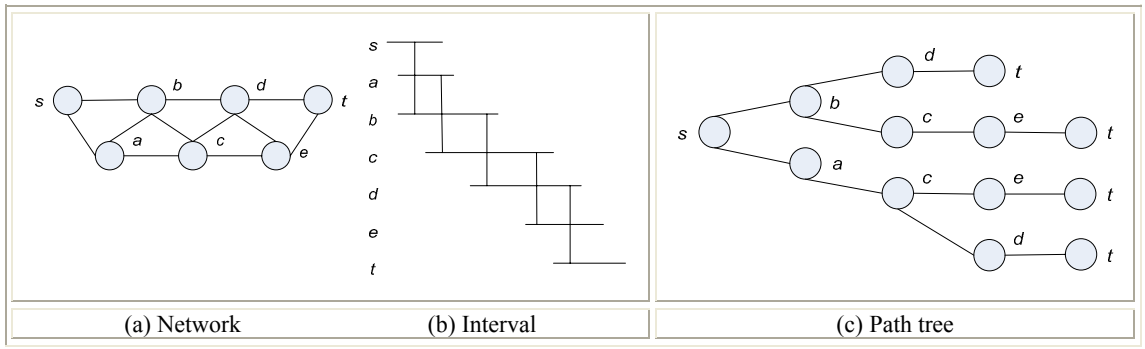
B. Interval Graph

An undirected graph *G* is an interval-graph if its nodes can be put into one-to-one correspondence with a set of intervals of a linearly ordered set such that two nodes are connected by a link in *G* if and only if their corresponding intervals have nonempty intersections [35]. An interval-graph has been proposed in the literature to model a WCN where the intersection of the range of transmission can be represented by its intersecting intervals [34]. Figure 64.2 shows an interval-graph and its interval representation. An interval-graph $G(V,E,C,\sigma)$ has a *perfect elimination sequence* $\sigma=(v_1,v_2, \ldots,v_n)$ of nodes in V and a sequence of maximal cliques $C=(C_1,C_2, \ldots,C_\kappa)$ of G such that maximal cliques containing one node occur consecutively [34]. For a WCN, $s= v_1$, and $t = v_n$, and the interval-graph in Figure 64.2 has σ = (*s*,*a*,*b*,*c*,*d*,*e*,*t*), and C = ({*s*,*a*,*b*}, {*a*,*b*,*c*}, {*b*,*c*,*d*}, {*c*,*d*,*e*}, {*d*,*e*,*t*}); both σ and C can be generated in linear time [35]. Notice that the cliques that contain node *c* are listed in consecutive order in C. Let us define $\tau=(\hat{v}_1, \hat{v}_2, \ldots, \hat{v}_n)$, where $\hat{v}_i \in \{1,2, \ldots,\kappa\}$ denotes the largest clique number in C for v_i such that $v_i \in C_{\hat{v}_i}$. Node *c* in Figure 64.2(a) appears in cliques C_2, C_3, and C_4, and therefore $\hat{v}_4=\hat{c}=$ max{2,3,4}=4. Similarly, the largest clique numbers for nodes *s*, *a*, *b*, *d*, *e*, and *t* are 1, 2, 3, 5, 5, and 5, and τ=(1,2,3,4,5,5,5).

Soh, *et al*. [37] proposed a function *NPG_IG*() that utilizes the preprocessed cliques in an interval graph to generate the (*s*,*t*) simple pathset.



(a) Network (b) Interval (c) Path tree

Figure 64.2. A 7-node, 11 link interval-graph

The function generates the path tree in Figure 64.2(c) for the interval graph of Figure 64.2(a). The tree represents $P_{s,t}$={(*s*,*b*,*d*,*t*), (*s*,*b*,*c*,*e*,*t*), (*s*,*a*,*c*,*e*,*t*), (*s*,*a*,*c*,*d*,*t*)}.

64.3.1.3 SDP Technique to Computing the Reliability and EHC of Static Topology WCN

Let $P(l)$ be the probability that the source node *s* is connected to the terminal node *t* with a *shortest* path of length $1 \le l \le n-1$. Without loss of generality, we assume that the source node *s* is always *up*, while the terminal node *t* may fail with certain probability. The expected hop count (EHC) between a source node *s* and a terminal node *t* in a WCN is computed as [34]:

$$EHC = \left(\sum_{l=1}^{l=k-1} lP(l) \Big/ \sum_{l=1}^{l=k-1} P(l) \right). \qquad (64.2)$$

Equation (64.2) assumes that the routing protocol in the network always finds the available (*s*,*t*) shortest path. When path is unavailable (*e.g.*, because of failure node) the router finds the next possible shortest path with the same or longer hop count. The problem of computing EHC has been shown #P-hard [34]. Figure 64.3 shows an efficient SDP approach to compute the reliability measures. The algorithm utilizes a path generator [37] to generate the (*s*,*t)* simple (node)-pathset of a WCN. Step 2 of the algorithm sorts the paths in the increasing cardinality order. This step is required to model the aforementioned routing protocol (*i.e.*, shortest path first). It is also suited well for an SDP technique because the algorithm runs more efficiently when the input paths are sorted in increasing cardinality order [39]. In Step 3, an MVI-based SDP technique computes $P(l)$ from each path in $P_{s,t}$ that has cardinality *l*, for $1 \le l \le k-1$. Finally, Step 4 uses (64.2) to compute the *EHC* of the network.

To illustrate EHC_SDP, consider the WCN in Figure 64.1. Steps 1 and 2 generate an increasing cardinality ordered simple pathset $P_{s,t}$={(*s*,*a*,*b*,*d*,*t*), (*s*,*a*,*c*,*e*,*d*,*t*), (*s*,*a*,*c*,*e*,*j*,*t*), (*s*,*f*,*c*,*e*,*d*,*t*), (*s*,*f*,*c*,*e*,*j*,*t*), (*s*,*f*,*g*,*h*,*i*,*j*,*t*)}. This, in turn, is used by an MVI-based SDP technique [10] in Step 3 to generate six *mdt*: $P(4)=sabdt$, $P(5)=sacedt\ \bar{b} + sacejt\ \bar{d} + sfcedt\ \bar{a} + sfcejt\ \bar{a}\ \bar{d}$, and $P(6)=sfghi\,jt\ \overline{abd}\ \overline{ce}$. Notice that the factoring algorithm in [7] produces 12 *mdt*. Converting the six *mdt* into its reliability expression and considering p_s=1, $P(4)=p_a\ p_b\ p_d\ p_t$, $P(5)=p_a\ p_c\ p_e\ p_d\ p_t\ q_b + p_a\ p_c\ p_e\ p_j\ p_t\ q_d + p_f\ p_c\ p_e\ p_d\ p_t\ q_a + p_f\ p_c\ p_e\ p_j\ p_t\ q_a\ q_d$, and $P(6)=p_f\ p_g\ p_h\ p_i\ p_j\ p_t\ (1-p_a\ p_b\ p_d)\ (1-p_c\ p_e)$. Assuming equal operational node reliability of 0.9, $TR(G) = P(4)+P(5)+P(6) = 0.65610+0.18305+0.02736 = 0.86651$. Using (64.2), $EHC=(4P(4)+5P(5)+6P(6))/TR(G) = 4.2744$ hops. Notice that the minimum (maximum) hop count is 4 (6), and $4 \le EHC \le 6$.

Simulations in [37] shows the SDP technique better than the factoring approach in [34], because: (i) it produces less number of *mdt*, (ii) it generates the *mdt* faster, and (iii) it computes the $TR(G)$ and EHC of WCN with all disjoint paths (WCN that forms an interval-graph) in polynomial time in the order of its nodes (simple paths). The method produces less *mdt* as it uses MVI notation [2], in contrast to the SVI in Alg2 [34].

Algorithm EHC_SDP
Step 1: Generate (*s*,*t*) simple (node)-pathset $P_{s,t} = \{P_1, P_2, \ldots, P_m\}$
Step 2: Sort paths in $P_{s,t}$ in increasing cardinality order
Step 3: Use an SDP technique to compute $P(l)$ from $P_{s,t}$ for $1 \le l \le k-1$, and

$$TR(G) = \sum_{l=1}^{l=k-1} P(l)$$

Step 4: Compute expected hop count //(64.2).

Figure 64.3. Algorithm *EHC_SDP*

64.3.1.4 Computing the reliability and EHC for special structure WCN

A. WCN with Multiple Disjoint Paths

Consider a WCN where the source node *s* is connected to the destination node *t* through multiple disjoint paths. Note that [11] proposes the use of multiple disjoint paths to provide high network resistance to link/node failures in MANET. The SDP approach computes the performability of the WCN in $O(|V|^2)$ [37].

B. Interval-graph WCN

The SDP technique in [38] generates the *mdt* from $P_{s,t}$ of the interval graph in Figure 64.2(a) as: $s\ b\ d\ t$, $s\ b\ c\ e\ t\ \bar{d}$, $s\ a\ c\ e\ t\ \bar{b}$, $s\ a\ c\ d\ t\ \bar{e}\ \bar{b}$. Notice that each of the simple paths is converted into exactly one *mdt*. In a simulation of 1000 randomly generated interval-graphs [37] (70 nodes network with node degree between 2 to 5), the SDP approach generates one equivalent *mdt* for each simple path, when the paths are sorted in increasing cardinality order. The simulation results lead to a conjecture that the performability of interval-graph $G(V,E,C,\sigma)$ is computable in polynomial time in the order of its simple paths [37].

64.3.2 Example II: Mobile Network Analysis Using Probabilistic Connectivity Matrices

An increasing number of networks are constructed without central planning or organization. Examples include the Internet, *ad hoc* wireless networks, and peer-to-peer (P2P) systems like Napster and Gnutella. Mobile computing implementations often fit this category, since user positions vary unpredictably. On the other hand, it is often quite easy to determine the aggregate statistics for the user classes.

Traditional methods of analysis are often inappropriate for these systems, since the exact topology of the system at any point in time is unknowable. For these reasons, researchers turn to statistical or probabilistic models to describe and analyze these network classes [40–42]. Random graph and percolation theories allow us to use statistical descriptions of component behaviors to determine many useful characteristics of the global system. This section presents a network analysis technique that combines random graph theory, percolation theory, and linear algebra for analyzing statistically defined networks.

Random graph theory originated with the seminal works of Erdös and Rényi in the 1950s. Until then, graph theory considered either specific graph instances or deterministically defined graph classes. Erdös and Rényi considered graph classes with a uniform probability for edges existing between any two nodes. Their results were mathematically interesting and found applications in a number of practical domains [40].

Another random network model, given in [41], is used to study *ad hoc* wireless networks like those used in many mobile networks. A set of nodes is randomly distributed in a two-dimensional region. Each node has a radio with a given range *r*. A uniform probability exists (in [41] the probability is 1) for edges being formed between nodes as long as they are within range of each other. This network model has obvious practical applications. Many of its properties resemble those of Erdös–Rényi graphs, yet it also has significant clustering like the small-world model [42].

This section presents a technique for analyzing random and pseudo-random graph models, first presented in [8]. It constructs connectivity matrices for random graph classes, where every matrix element is the probability an edge exists between two given nodes. This contains elements of discrete mathematics, linear algebra, and percolation theory. It is useful for a number of applications. Applications already documented include system reliability [43] and QoS [44] estimation.

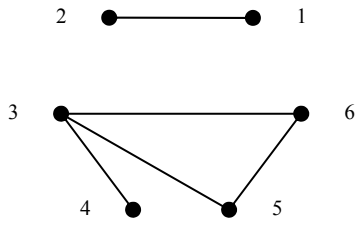
64.3.2.1 Preliminaries

A graph is defined as the tuple $[V, E]$. V is a set of vertices, and E is a set of edges. Each edge e is defined as (i,j) where i and j designate the two vertices connected by e. In this section, we consider only undirected graphs where $(i,j)=(j,i)$. An edge (i,j) is incident on vertices i and j. We do not consider multi-graphs where multiple edges can connect the same end-points.

Many data structures are used as practical representations of graphs. Refer to [45] for common representations and their usage. For example, a graph where each node has at least one incident edge can be fully represented by the list of edges. Another common representation of a graph, which we explore in more depth, is the connectivity matrix. The connectivity matrix M is a square matrix where each element $m(i,j)$ is 1 (0) if there is (not) an edge connecting vertices i and j. For undirected graphs, this matrix is symmetric.

Figure 64.4 shows a simple graph and its associated connectivity matrix.

As a matter of convention, the diagonal of the matrix can consist of either zeros or ones. Ones are frequently used, based on the simple assertion that each vertex is connected to itself. We use the convention where the diagonal is filled with zeros. A *walk* of length z is an ordered list of z edges $((i_0,j_0),(i_1,j_1),\ldots,(i_z,j_z))$, where each vertex j_a is the same as vertex i_{a+1}. A *path* of length z is a walk where all i_a are unique. If j_z is the same as i_0, the path is a *cycle.* A connected component is a set of vertices where there is a path between any two vertices in the component. (In the case of di-graphs, this is a fully connected component.) A complete graph has an edge directly connecting any two vertices in the graph. A complete subgraph is a subset of vertices in the graph with edges directly connecting any two members of the set.



(a) Graph

$$\begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 \end{bmatrix}$$

(b) Connectivity matrix

Figure 64.4. A six-node graph

A useful property of connectivity matrices is the fact that element $m^z(i,j)$ of the power z of graph G's connectivity matrix M (*i.e.*, M^z) is the number of walks of length z from vertex i to vertex j that exist on G [46]. This can be verified using the definition of matrix multiplication and the definition of the connectivity matrix. It is possible to find the connected components in a graph using iterative computation of M^z. After each exponentiation: (i) Set all non-zero elements of the M to one, giving C^1, (ii) Set C^{i+1} to C^i C^1, (iii) Set all non-zero elements of C^{i+1} to 1, (iv) Set C^{i+1} to the inclusive or of $C^{i+1}$and C^i, (v) Stop when C^{i+1} is equal to C^i.

Each row of C^i has a one in the element corresponding to each node in the same connected component. The number of distinct rows is the number of connected components.

64.3.2.2 Matrix Construction

We now show how to construct connectivity matrices for analyzing classes of random and pseudo-random graphs. The first model we discuss is the Erdös–Rényi random graph [47]; we then consider a graph model of an *ad hoc* wireless network.

The number of nodes n, and a uniform probability, p, of an edge existing between any two nodes, define Erdös–Rényi graphs. We use E for $|E|$ (*i.e.*, the number of edges in the graph). Since the degree of a node is essentially the result of multiple Bernoulli trials, the degree of an Erdös–Rényi random graph follows a Bernoulli distribution. Therefore, as n approaches infinity, the degree distribution follows a Poisson distribution.

It has been shown that the expected number of hops between nodes in these graphs grows proportionally to the log of the number of nodes [48]. Note that Erdös–Rényi graphs do not necessarily form a single connected component. When $E–n/2 << -n^{2/3}$ the graph is in a sub-critical phase and almost certainly not connected. A phase change occurs in the critical phase where $E= n/2 +O(n^{2/3})$ and in the supercritical phase where $E–n/2 >> - n^{2/3}$ a single giant component becomes almost certain. When $E= n \log n/2+ O(n)$ the graph is fully connected [49]. (Note that the expected number of edges for an Erdös–Rényi graph is $n(n–1)p/2$.)

Definition: The *probabilistic connectivity matrix M* of an n node random graph is an n-by-n matrix where each element (j,k) is the Bernoulli probability an edge exists between nodes j and k. By convention we set elements where $j=k$ to zero. The probabilistic connectivity matrix construct

translates random graph classes into an equivalent set of probabilities for the existence of edges between two given nodes. Note that, in contrast to many matrix representations of stochastic systems, the rows and columns of M do not necessarily sum to 1.

As an example, for an Erdös–Rényi graph with n set to 3 and p set to 0.25, the probabilistic connectivity matrix is:

$$\begin{bmatrix} 0 & 0.25 & 0.25 \\ 0.25 & 0 & 0.25 \\ 0.25 & 0.25 & 0 \end{bmatrix}. \quad (64.3)$$

Mobile wireless networks, in particular *ad hoc* wireless networks, with no fixed infrastructure, are suited to analysis using random graphs. A fixed radius model for random graphs is used in [41] to analyze phase change problems in *ad hoc* network design. In Section 64.3.2.3, we study phase changes in an *ad hoc* sensor network to determine whether or not a given system will produce a viable sensor network. After the phase change, a system can almost certainly self-organize into a viable network. Before the phase change, self-organization is virtually impossible. The approach presented in this section is used to predict where the phase change occurs.

The model in [41] places nodes at random in a limited two-dimensional region. Two uniform random variables provide a node's x and y coordinates. Since nodes in proximity with each other have a high probability of being able to communicate, the distance r between pairs of nodes is used as a threshold. If r is less than a given value, then an edge exists between the pair of nodes. Otherwise, no edge exists. Many similarities exist between this graph class and the graphs studied by Erdös and Rényi.

The analysis in [41] looks at finding phase transitions for constraint satisfaction problems. Range-limited graphs differ from Erdös–Rényi graphs in that they have significant clustering. We use the model from [41], except, where they create an edge with probability one when the distance between two nodes is less than the threshold; we allow the probability to be any value in the range [0,1].

The range-limited graph class differs from Erdös–Rényi and other random graph classes in that, while a random process defines it, the random process determines edge creation only indirectly. This makes it difficult, if not impossible, to undertake formal analysis. Instead of formally decomposing the graph definition into a set of Bernoulli probabilities, we are forced to derive a model that approximates system behavior. We provide results in Sections 64.3.2.3 and 64.3.2.4 showing that this model, while not perfect, is a useful tool for predicting system behavior.

We construct range-limited graphs using the following parameters:

- n – the number of nodes
- max_x (max_y) – the size of the region in the x (y) direction
- r – the maximum distance between nodes where connections are possible
- p – probability that an edge exists connecting two nodes within range of each other.

*Range-limited graph model definition***:** For range limited graphs, element (j,k) of the probabilistic connectivity matrix has value:

$$p\,(2c - c^2) \quad (64.4)$$

where c is a constant defined by:

$$c = r^2 - \left(\frac{j}{n+1} - \frac{k}{n+1}\right)^2 \quad (64.5)$$

when $r^2 \geq \left(\frac{j}{n+1} - \frac{k}{n+1}\right)^2$ and otherwise zero.

*Range-limited graph model derivation***:** Each element (j,k) of the probabilistic connectivity matrix is defined by the probability an edge exists between the pair of nodes j and k that is given by (64.4) and (64.5). Derivation of (64.4) and (64.5) proceeds in two steps. Step (i) Sort nodes by the x coordinate value (y could be used as well; the choice is arbitrary) and use order statistics to find the expected value of the x coordinate for each node; Step (ii) Determine the probabilities that an edge existing between two nodes using the expected values from Step (i).

By definition, each node is located at a point defined by two random variables: the x and y coordinates. Without loss of generality, max_x and max_y are used to normalize the values of x, y, and r to the range [0,1]. Constant scaling factors are needed to compensate for lack of symmetry when max_$x \neq$ max_y.

Rank statistics estimate the probability that two given nodes k and j are within communications range. To do this, sort each point by its x (or y) coordinate. For n samples from a uniform distribution of range [0,1], the rank statistics give expected value of the jth largest as $j/(n+1)$ with variance $\frac{1}{n+2}\left(\frac{j}{n+1}\right)\left(1-\frac{j}{n+1}\right)$. Node position j in the sorted list therefore has expected value $j/(n+1)$. Since our *ad hoc* network model uses the Euclidean distance metric, an edge exists between two nodes j and k with probability p when:

$$\left(x_j - x_k\right)^2 + \left(y_j - y_k\right)^2 \leq r^2 \ . \qquad (64.6)$$

Entering the expected values for the x ordinate of the nodes of rank j and k, it is:

$$\left(y_j - y_k\right)^2 \leq r^2 - \left(\frac{j}{n+1} - \frac{k}{n+1}\right)^2 \ . \qquad (64.7)$$

By definition, the random variables giving the x and y positions of the nodes are uniformly distributed and uncorrelated.

The probability that relation (64.7) holds is the probability that the square of the difference of two normalized uniform random variables is less than the constant value c that we define as the right hand side of (64.7). Figure 64.5 presents this as a geometry problem. The values of the two uniform random variables with range [0,1] describe a square region where every point is equally likely. The white region in the lower right hand corner of Figure 64.5 is the area that does not satisfy (64.7) because $y_j - y_k$ is greater than c. It is a right triangle, whose hypotenuse has these end points:

- When y_k is zero, y_j cannot be greater than c. The triangle base has length $1-c$.
- When y_j is one, y_k cannot be less than $1-c$. The triangle height is $1-c$.

The area of this triangle is therefore $(1-c)^2/2$.

The region that does not satisfy Equation 64.7 because $y_j - y_k$ is less than $-c$, is contained in the triangle in the upper left hand corner of Figure 64.5. The area of that region is also $(1-c)^2/2$, which can be demonstrated either by using symmetry or by repeating the logic in the previous paragraph and switching the variable names.

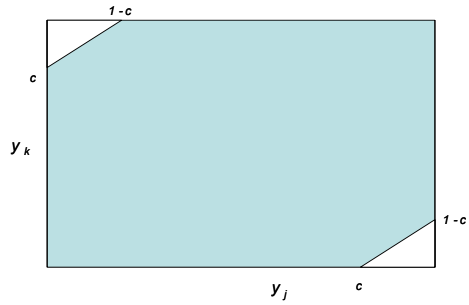


Figure 64.5. Geometric representation of (64.7)

Summing the areas of the two white triangles in Figure 64.5 gives:

$$(1-c)^2 \ . \qquad (64.8)$$

Since the area satisfying (64.7) is not contained in the two white triangles, the likelihood that nodes j and k are within communications range is:

$$1-(1-c)^2 = 1-(1-2c+c^2) = 2c-c^2 \ . \qquad (64.9)$$

Multiplying (64.9) by the probability p that two nodes within range can communicate ends the derivation of (64.4) and (64.5).

An example matrix for six nodes in a unit square with r=0.3 and p=1.0 is:

$$\begin{bmatrix} 0 & 0.134 & 0.0167 & 0 & 0 & 0 \\ 0.134 & 0 & 0.134 & 0.0167 & 0 & 0 \\ 0.0167 & 0.134 & 0 & 0.134 & 0.0167 & 0 \\ 0 & 0.0167 & 0.134 & 0 & 0.134 & 0.0167 \\ 0 & 0 & 0.0167 & 0.134 & 0 & 0.134 \\ 0 & 0 & 0 & 0.0167 & 0.134 & 0 \end{bmatrix} \qquad (64.10)$$

Figure 64.6 shows a three-dimensional plot of an example matrix. When we compare the number of edges for range-limited graphs constructed directly versus those constructed using the probabilistic connectivity matrices as a function of n and r. The approximation achieved by this model is good, but

not perfect. One reason for the deviation is the use of expected values in the derivation. For graph instances with a small number of nodes the variance of the node positions is greater. Second order effects are possible. Using expected values also assumes independence between random variables. Independence may not strictly hold throughout the range limited graph construction process. As we discuss in Sections 64.3.2.3 and 64.3.2.4, in spite of under-counting the number of edges, this model is very useful for predicting many aspects of network behavior. In particular, we have found it very useful for predicting where phase changes occur in the system.

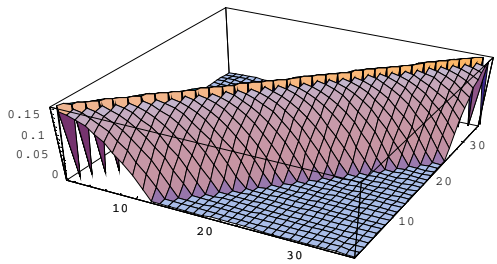

Figure 64.6. Three-dimensional plot of the connectivity matrix for a range limited graph of 35 nodes with r=0.3

64.3.2.3 Matrix Characteristics

By definition, connectivity matrices are square with the numbers of rows and columns both equal to the number of vertices in the graph (n). Each element (j,k) is the probability an edge exists between nodes j and k. Since we consider only non-directed graphs, (j,k) must equal (k,j) and therefore care needs to be taken to guarantee that algorithms for constructing matrices provide symmetric results.

An instance of a graph class can be produced by using the probabilistic connectivity matrix and performing $n(n-1)$ Bernoulli trials. One trial is made for each element (j,k) where $k>j$. If it is successful edge (j,k) exists. This produces an instance of the graph with the caveat that the range limited connectivity matrix is based on a model that approximates the statistics of the actual process. The graph constructed has slightly different statistics than actual range-limited graphs.

Theorem 1: The sum of each row (column) of the probabilistic connectivity matrix provides the expected degree of the corresponding node in G.

Proof: The expected value of a single trial of a Bernoulli distribution is the probability of success. The expected value of a sum of random variables is the sum of the expected values. Therefore the expected number of edges incident on node j is $\sum_{k=0}^{n-1}(j,k)$. QED.

A. Probability of Walks of z Hops between Nodes

Consider the usage of probabilistic connectivity matrixes. First application calculates the likelihood of connections of multiple hops between nodes. To do so, we define an analog to matrix multiplication.

Theorem 2: The probability a path of two hops exists between nodes j and k ($j \neq k$) in a random graph is:

$$1-\prod_{l\neq j,k}(1-(j,l)(l,k)) \ , \qquad (64.11)$$

where (j,l) and (l,k) are elements of the probabilistic connectivity matrix.

Proof: Each element (j,k) of the probabilistic connectivity matrix is the probability an edge exists between nodes j and k. Since self-loops are not considered, a path of length two between nodes j and k must pass through an intermediate node l that is neither j nor k. This value is the probability of the union of a set of events defined by the likelihoods of paths through all intermediate nodes.

The product of two probabilities is the likelihood of the intersection of their events when they are independent. Since the existence of each edge in the graph is determined by an independent Bernoulli trial, the likelihood edges exist simultaneously from node j to node l and node l to node k, is the product of elements (j,l) and (l,k).

The probability that either of two independent events j and k occurs is: $p_j+p_k-p_jp_k$. The probability three events j, k, and l occur can be computed recursively as $p_l + (p_j+ p_k - p_jp_k) - p_l(p_j + p_k - p_jp_k)$. This is commonly referred to as inclusion-exclusion. As the number of events increases the

number of factors involved increases, making this computation awkward for large numbers of events. An equivalent computation is:

$$1-\prod_{l\neq j,k}(1-p_{jl}p_{lk}) \quad . \tag{64.12}$$

Equation (64.12) is more efficient to compute. It computes the complement of the intersection of all the complements of the atomic events, which is equivalent to the union of the set of events. Since the matrix elements represent probabilities, (64.11) is the probability a path of two hops exists between nodes j and k. QED.

Definition: The probabilistic-matrix multiplication is defined for probabilistic connectivity matrixes using (64.11). Since all connectivity matrixes are square, probabilistic matrix multiplication is defined only for matrixes of the same dimension (n by n). The product of matrix A with matrix B is a new matrix AB where each element $ab(j,k)$ ($j\neq k$) of matrix AB is:

$$ab(j,k)=1-\prod_{l\neq j,k}(1-a(j,l)b(l,k)), \tag{64.13}$$

where $a(j,l)$ and $b(l,k)$ are elements of matrixes A and B respectively. Element $ab(j,j)$ is by convention always zero.

The similarity between this definition and standard matrix multiplication should be obvious. Equation (64.13) is needed to maintain independence when summing probabilities. As a matter of convention, we set the diagonal elements (j,j) of probabilistic connectivity matrixes to zero. Our applications typically concern the likelihood paths exist between nodes by computing the likelihoods of paths passing through any intermediate node. The value (j,j) is the probability a path connects node j with itself. The existence of loops in the graph does not increase the likelihood other nodes are connected. Constraining diagonal values to zero automatically removes loops from our calculations.

Theorem 3: For a graph class represented by a probabilistic connectivity matrix M, element (j,k) of M^z is the probability that a walk of length z exists between nodes j and k. Here, M^z is the product of M with itself z times using our conventions.

Proof: The proof is by induction. By definition, each element (j,k) is the probability an edge exists between nodes j and k. M^2 is the result of multiplying matrix M with itself. Using Theorem 2 each element (j,k) of M^2, except the diagonals, is the probability a path of length two exists between nodes j and k. Using the same logic, M^z is calculated from M^{z-1}using matrix multiplication to consider all possible intermediate nodes l between nodes j and k. Where M^{z-1} has the probabilities of a walk of length $z-1$ between j and l, and M has the values defined previously. QED

Example 1: Probabilities of walks of length three in an Erdös–Rényi graph of four nodes for p=0.65 and 0.6 are shown in (64.14) and (64.15), respectively.

B. Critical Values and Phase Changes

This section describes critical values and phase changes phenomenon in *ad hoc* networks modeled by random graphs. For Erdös–Rényi [47] and range-limited [50] graphs, first order monotone increasing graph properties follow 0-1 laws. These properties appear with probability asymptotically approaching either 0 or 1, as the parameters defining the random graph class decrease/increase.

$$M=\begin{bmatrix}0&0.65&0.65&0.65\\0.65&0&0.65&0.65\\0.65&0.65&0&0.65\\0.65&0.65&0.65&0\end{bmatrix}\ M^2=\begin{bmatrix}0&0.666&0.666&0.666\\0.666&0&0.666&0.666\\0.666&0.666&0&0.666\\0.666&0.666&0.666&0\end{bmatrix}\ M^3=\begin{bmatrix}0&0.679&0.679&0.679\\0.679&0&0.679&0.679\\0.679&0.679&0&0.679\\0.679&0.679&0.679&0\end{bmatrix}, \tag{64.14}$$

$$M=\begin{bmatrix}0&0.6&0.6&0.6\\0.6&0&0.6&0.6\\0.6&0.6&0&0.6\\0.6&0.6&0.6&0\end{bmatrix}\ M^2=\begin{bmatrix}0&0.59&0.59&0.59\\0.59&0&0.59&0.59\\0.59&0.59&0&0.59\\0.59&0.59&0.59&0\end{bmatrix}\ M^3=\begin{bmatrix}0&0.583&0.583&0.583\\0.583&0&0.583&0.583\\0.583&0.583&0&0.583\\0.583&0.583&0.583&0\end{bmatrix}. \tag{64.15}$$

A plot of property probability versus parameter value forms an S-shaped curve with an abrupt phase transition between the 0 and 1 phases [47], [41]. The parameter value where the phase transition occurs is referred to as the critical point. The connectivity matrices defined in this section can identify critical points and phase transitions in graph classes.

As an example, consider graph connectivity in Erdös–Rényi graphs. As mentioned in Section 64.3.2.2, this property has three phases determined by the number of edges in the graph: sub-critical (graph almost certainly not connected), critical, and supercritical (graph almost certainly connected). The distribution of the number of edges E in an Erdös–Rényi graph has a binomial distribution defined by taking $n(n-1)/2$ trials taken with probability p. In the sub-critical phase, the size of the largest graph component is O(log n); making the graph almost certainly disjoint. In the supercritical phase, the largest graph component size is $O(n)$. A single giant component dominates the graph. In the supercritical phase, the probability that the graph is fully connected converges to $e^{-e^{-c}}$ where $p = \{\log n + c + O(1)\}/n$ [47]

Theorem.4: For Erdös–Rényi graphs of n nodes with $0<p<1$ the probability of an edge existing between any two nodes in a probabilistic connectivity matrix M, the critical point for the property of graph connectivity occurs when $M=M^2$ [*i.e.*, $p = 1-(1-p^2)^{n-2}$]. When $M>>M^2$ [*i.e.*, $p >> 1-(1-p^2)^{n-2}$], the graph is in its sub-critical phase. When $M<<M^2$ [*i.e.*, $p << 1-(1-p^2)^{n-2}$], the graph is in its supercritical phase. (Note probability p is real valued).

Proof: By definition, all non-diagonal elements of the Erdös–Rényi graph matrix have the same value p and diagonal elements have value zero. By symmetry, all non-diagonal elements of M^n for any n will have the same value (diagonal elements are constrained to remain zero). We use the symbols <, >, <<, and >> to compare these matrices by referring to the value of the non-diagonal elements.

Non-diagonal elements of M^2 have value $1-(1-p^2)^{n-2}$ from (64.12). From Theorem 3, this is the likelihood a path of two hops exists between any two nodes in the graph. Let $p^{(2)}$ represent non-diagonal elements of M^2 [*i.e.*, $1-(1-p^2)^{n-2}$]. $p^{(2)}$ is monotone increasing with respect to p. Both p and $p^{(2)}$ are constrained to range [0,1]. The minimum (maximum) value 0 (1) of both occurs when p is 0 (1), at which point any value of n will satisfy the equation and no phase change occurs.

If $p^{(2)} > p$, the probability a path of three hops exists between any two nodes ($p^{(3)}$) is greater than the probability a path of two hops exists ($p^{(2)}$). $p^{(3)}$ has value $1-(1-p^{(2)}\ p)^{n-2}$, which is monotone increasing with respect to both p and $p^{(2)}$. By recursion, the probability any two nodes are connected increases with the path length as long as $p^{(2)} > p$. As $p^{(n-1)}$ approaches 1, a single giant component exists almost certainly. Although, there remains a finite shrinking probability that isolated nodes exist. By definition, the graph is in its supercritical phase.

By symmetry, when $p^{(2)} < p$ the likelihood a path of j hops connects any two nodes decreases monotonically with j. As $p^{(n-1)}$ approaches 0, the giant component almost certainly does not exist and the graph becomes increasingly disjoint. By definition [47], the graph is in its subcritical phase.

When $M << M^2$ the graph has been shown to be in its supercritical phase and when $M >> M^2$ the graph has been shown to be in its subcritical phase. This leaves $M \approx M^2$ as the critical phase. By definition, the critical phase is the neighborhood of the critical point so the critical point can be calculated as the point where $M = M^2$. QED

Reference [8] has empirically verified Theorem 4. Without rigor, we apply Theorem 4 to non-Erdös–Rényi graph classes to find estimate where phase changes occur. The application (Section 64.3.2.4) shows this to be a pragmatic solution.

64.3.2.4 Application of Example II

We present a security application from [51], where *ad hoc* sensor network security is enforced by a set of k keyservers chosen at random from a total of n nodes. Each keyserver serves all nodes within h hops. Keyservers can collaborate to identify and remove malicious nodes, such as clones. Here we show how to determine the number of keyservers needed. The phase change for the secure communications network occurs when:

$$k = 2 + \frac{\log(1 - p_{ij}^{(2h-1)})}{\log(1 - (p_{ij}^{(2h-2)})^2)}, \quad (64.16)$$

where k is the number of keyservers, the keyserver serves all nodes with h hops, and p_h is the probability of a walk of h or fewer hops existing between nodes with the labels $i=\left\lfloor \frac{n}{2} \right\rfloor$ and $j=\left\lfloor \frac{n}{2} \right\rfloor + 1$ from the *ad hoc* network model.

As shown in the model derivation, the phase change occurs when $p_{h+1}=p_h$. By applying (64.12) recursively, we find the likelihood of a walk of $2h-1$ hops between nodes i and j:

$$p_{ij}^{(2h-1)} = 1 - \prod_{l=1, l\neq i, l\neq j}^{n} (1 - p_{il}^{(2h-2)} * p_{lj}^{(1)}) \ . \quad (64.17)$$

Two keyservers can communicate if there is a walk of length $2h-1$ or less between them. Since keyservers are placed at random on the *ad hoc* network, we have an Erdös–Rényi graph where any two keyservers can communicate with the probability defined in (64.17). The probability that any two multi-cast regions with keyservers k_1 and k_2 can communicate using an intermediary is therefore:

$$p_{k_1k_2}^{(2)} = 1 - \prod_{i,j=1; i,j\neq k_1; i,j\neq k_2}^{k} (1 - p_{ij}^{(2h-1)} \times p_{ij}^{(2h-1)}), \quad (64.18)$$

which simplifies to:

$$p_{k_1k_2}^{(2)} = 1 - (1 - (p_{ij}^{(2h-1)})^2)^{k-2} \quad (64.19)$$

so that the phase change occurs when:

$$p_{ij}^{(2h-1)} = p_{k_1k_2}^{(2)} = 1 - (1 - (p_{ij}^{(2h-1)})^2)^{k-2} \quad (64.20)$$

Taking the log of both sides and rearranging terms yields (64.16).

Simulations of our *ad hoc* model were run using MATLAB to verify these analytical predictions. Refer to [8] for details. For Erdös–Rényi graphs, it is determined that the phase change occurs when the number of edges is $E = n/2 + O(n^{2/3})$ [49]. Note that these results are asymptotes as graph size approaches infinity and do not consider constant offsets in the O notation. Results from our approach are therefore consistent with the analysis in [47] and [49].

64.3.3 Example III: Improving End-to-end Performability in *Ad Hoc* Networks

64.3.3.1 (s,t) Routing in Ad Hoc Network

Two of the most widely used MANET routing protocols are dynamic source routing (DSR) [52] and the *ad hoc* on-demand distance vector (AODV) [53]. Both are *on-demand* or *reactive* protocols, where (*s*,*t*) paths discovery is initiated only when they are needed, in contrast to the *proactive* protocol, where each node maintains a routing table even when there is no network routing activity. The path discovery step in a reactive protocol requires route request (RREQ) message flooding to the entire network to reach the destination [52], and hence is expensive while generating only a single (*s*,*t*) path.

The node mobility in MANET makes frequent network topology changes which, in addition to nodes/links failures, may disconnect the existing (*s*,*t*) path that forces the source node to re-run the costly discovery step that also leads to a long path recovery delay. Multi-path routing protocol can be used to improve the end-to-end reliability and to reduce the frequency of using the discovery step. Most of the proposed multi-path routings are either an extension of the DSR or AODV to generate multiple (*s*,*t*) paths in one discovery step [12]. Among others, the multiple paths are used for load balancing, higher bandwidth aggregation, and performability improvement. Multi-path has also been proposed to improve the performability of WSN [54] and internetwork [55]. This section provides a survey of recent multi-path protocols for improving MANET performability.

64.3.3.2 Improving End-to-end Performability in MANET

Typically, a multi-path routing protocol attempts to find a set of node disjoint, link disjoint or non-disjoint paths [12]. Note that paths with disjoint node (*i.e.*, no node overlap) also imply disjoint links (*i.e.*, no link overlap).

Split multipath routing (SMR) [56] generates two maximally disjoint node paths: a primary path,

and a backup path. When the destination receives RREQs, it composes a primary path from the information in the first arriving RREQ (thus an (s,t) shortest delay path), and selects the backup path from the following RREQs it receives such that the path is maximally disjoint from the primary path. Then, the destination sends a route reply (RREP) for each of two paths to the source. To reduce the frequency of using route discovery, the source reinitiates the step when both the primary and backup paths are broken. When the primary path fails, the source will receive a route error (RERR) message, and it needs to resend the lost packet through the alternative path. It is shown in [56] that SMR performs better than DSR in terms of robustness to node mobility as well as end-to-end packet delay.

The back up source routing (BSR) [57] establishes and maintains a backup route that comprises a primary path having the minimal end-to-end delay and a backup path having shared nodes with the primary path, in contrast to the disjoint paths in SMR [56]. Note, the overlapping nodes in the primary and backup reduces the recovery time and overhead when the primary path fails because the packet can be resend from a shared node closest to the failure spot, and the RERR message reaches only up to the shared node, respectively. The backup route is used to prolong the lifetime of the path-pair, which obviously reduces the frequency of using the route discovery step. The reference defines the reliability of a backup route as the mean value of the lifetime of the route. Given a primary path the scheme [57] selects a backup path to maximize the reliability. With node mobility, BSR will also dynamically update backup routes to keep the routes optimal.

In MP-DSR [58], a user is allowed to set a path reliability requirement as its QoS, and the protocol uses a distributed routing algorithm to generate a set of (s,t) node-disjoint paths to meet the reliability constraint. For any time instant t_0, an end-to-end reliability is defined as the probability of successful (s,t) data transmission until time $t_0 + T_p$. The reliability is computed from the node-disjoint pathset, where each path reliability is computed from the link availabilities, which can be obtained using Jiang's prediction approach [10] discussed in Section 64.2.3.2. Given the user path reliability requirement, MP-DSR calculates the number of paths required and the lowest path reliability for each path to meet the user constraint. The two parameters are used in intermediate nodes to decide if a RREQ message be discarded or forwarded towards the destination. Upon receiving the RREQs (*i.e.*, pathset), the destination sorts the paths in the order of their reliabilities, composes a set of disjoint paths from the pathset that together meets the user requirement, and sends RREP that includes the disjoint pathset to the source.

The DPSP in [11] selects a set of disjoint paths to maximize end-to-end reliability. Essentially, DPSP solves the problem of maximizing a parallel-series system graph [11]. Note that the problem of finding the most reliable pathset has been shown to be computationally hard [11], and the maximum number of link disjoint paths equals the smallest cardinality of the minimal (s,t)-cut. DPSP assumes that the underlying routing protocol (reactive or proactive) has completed its path discovery step, and from the generated alternative paths DPSP constructs a communication graph G_p which gives a partial view of the network. Then, G_p is used to compose a directed probabilistic graph D_p that includes the link reliability information generated by each node incident to the links. Given a D_p, DPSP first finds the most reliable path, and stores it in the set of disjoint path DP. Then, iteratively it selects the next most reliable path B, which is included directly into DP if B is disjoint to all paths in DP. If B is not disjoint with any of the path in DP (the non-disjoint paths are called interlacing paths), DPSP transforms the interlacing paths into a set of disjoint paths to be added in DP. However, if the new set of disjoint paths does not produce better pathset reliability, DPSP cancels the transformation. Note, the cumulative reliability of the set of disjoint paths found by DPSP is the lower bound of the terminal reliability of the network.

Reference [59] uses M-for-N *diversity coding* and a set of disjoint paths to improve the performability of end-to-end data transmission. The scheme divides an X bits packet into N equal sized blocks, and adds M blocks of the same size (generated from X) for redundancy. Then, it

transmits an equal number of blocks (*e.g.*, one block) through each of the disjoint paths. The *M*-for-*N diversity coding* guarantees that the original packet (*i.e.*, *X*) can be reconstructed in the destination provided it receives at least *N* (out of *N*+*M*) blocks. Therefore, the problem solved in the scheme [59] reduces into allocating the *N*+*M* blocks among all disjoint paths to maximize the probability for the destination to receive at least *N* blocks.

64.4 Conclusions

We have discussed several issues related to computing and improving the performability of WCNs. In addition to the random failures that make components in a wired-non-mobile CN fail, a node in a WSN may be non-operational due to non-renewable power failures, and therefore better understanding of energy consumption in WSN is important to improve network performability. We have shown that for many classes of WSN applications, computation, in addition to the wireless communication, may dominate energy consumption. Due to mobility a wireless link between two nodes may be unavailable when the nodes are not within communication range from each other. We have discussed recent techniques to estimate the link reliability in mobile WCN. Finally three examples of performability issues of WCN have been presented. First, we discuss an efficient technique to compute the reliability and expected hop count of a static topology (non-mobile) WCN. Second, we describe a method to statistically analyse the performability of a mobile ad hoc WCN. The method utilizes random graph theory, percolation theory, and linear algebra. Finally, a survey of recent techniques to improve the end-to-end path reliability in MANET has been presented.

Abstract: Grid computing is a newly developed technology for complex systems with large-scale resource sharing, wide-area communication, and multi-institutional collaboration. Although the developmental tools and infrastructures for the grid have been widely studied, grid reliability analysis and modeling are not easy because of its largeness, complexity and stiffness. This chapter introduces the grid computing technology, analyzes different types of failures in grid system and their influence on its reliability and performance. The chapter then presents models for star-topology grid considering data dependence and tree-structure grid considering failure correlation. Evaluation tools and algorithms are developed, based on the universal generating function, graph theory, and the Bayesian approach. Illustrative numerical examples are presented to show the grid modeling and reliability/performance evaluation.

65.1 Introduction

Grid computing [1] is a newly developed technology for complex systems with large-scale resource sharing, wide-area communication, and multi-institutional collaboration [2–6]. Many experts believe that the grid technologies will offer a second chance to fulfill the promises of the Internet.

The real and specific problem that underlies the grid concept is coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations [4]. The sharing that we are concerned with is not primarily file exchange but rather direct access to computers, software, data, and other resources. This is required by a range of collaborative problem-solving and resource-brokering strategies emerging in industry, science, and engineering. This sharing is highly controlled by the resource management system [7], with resource providers and consumers defining what is shared, who is allowed to share, and the conditions under which the sharing occurs.

Recently, the open grid service architecture [5] has enabled the integration of services and resources across distributed, heterogeneous, dynamic, virtual organizations. A grid service is desired to complete a set of programs under the circumstances of grid computing. The programs may require using remote resources that are distributed. However, the programs initially do not know the site information of those remote resources in such a large-scale computing

environment, so the resource management system (the brain of the grid) plays an important role in managing the pool of shared resources, in matching the programs to their requested resources, and in controlling them to reach and use the resources through wide-area networks.

The structure and functions of the resource management system (RMS) in the grid have been introduced in details by [7–10]. Briefly stated, the programs in a grid service send their requests for resources to the RMS. The RMS adds these requests into the request queue [7]. Then, the requests are waiting in the queue for the matching service of the RMS for a period of time (called waiting time) [11]. In the matching service, the RMS matches the requests to the shared resources in the grid [12], and then builds the connection between the programs and their required resources. Thereafter, the programs can obtain access to the remote resources and exchange information with them through the channels. The grid security mechanism then operates to control the resource access through the certification, authorization, and authentication, which constitute various logical connections that causes dynamicity in the network topology.

Although the developmental tools and infrastructures for the grid have been widely studied [1], grid reliability analysis and evaluation are not easy because of its complexity, largeness, and stiffness. The gird computing contains different types of failures that can make a service unreliable, such as blocking failures, time-out failures, matching failures, network failures, program failures, and resource failures. This chapter thoroughly analyzes these failures.

Usually the grid performance measure is defined as the task execution time (service time). This index can be significantly improved by using the RMS that divides a task into a set of subtasks which can be executed in parallel by multiple online resources. Many complicated and time-consuming tasks that could not be implemented before are now working well under the grid environment.

It is observed in many grid projects that the service time experienced by the users is a random variable. Finding the distribution of this variable is important for evaluating the grid performance and improving the RMS functioning. The service time is affected by many factors. First, various available resources usually have different task processing speeds online. Thus, the task execution time can vary depending on which resource is assigned to execute the task/subtasks. Second, some resources can fail when running the subtasks, so the execution time is also affected by the resource reliability. Similarly, the communication links in grid service can be disconnected during the data transmission. Thus, the communication reliability influences the service time as well as data transmission speed through the communication channels. Moreover, the service requested by a user may be delayed due to the queue of earlier requests submitted from others. Finally, the data dependence imposes constraints on the sequence of the subtasks' execution, which has a significant influence on the service time.

This chapter first introduces the grid computing system and service, and analyzes various failures in grid system. Both reliability and performance are analyzed in accordance with the performability concept. Then the chapter presents models for star- and tree-topology grids respectively. The reliability and performance evaluation tools and algorithms are developed based on the universal generating function, graph theory, and the Bayesian approach. Both failure correlation and data dependence are considered in the models.

65.2 Grid Service Reliability and Performance

65.2.1 Description of Grid Computing

Today, the grid computing systems are large and complex, such as the IP-Grid (Indiana-Purdue Grid), which is a state wide grid (http://www.ip-grid.org/). IP-Grid is also a part of the TeraGrid that is a nationwide grid in the USA (http://www.teragrid.org/). The largeness and complexity of the grid challenge the existing models and tools to analyze, evaluate, predict, and optimize the reliability and performance of grid systems. The global grid system is depicted in the Figure 65.1. Various organizations [4], integrate/

share their resources on the global grid. Any program running on the grid can use those resources if it can be successfully connected to them and is authorized to access them. The sites that contain the resources or run the programs are linked by the global network as shown in the left part of Figure 65.1.

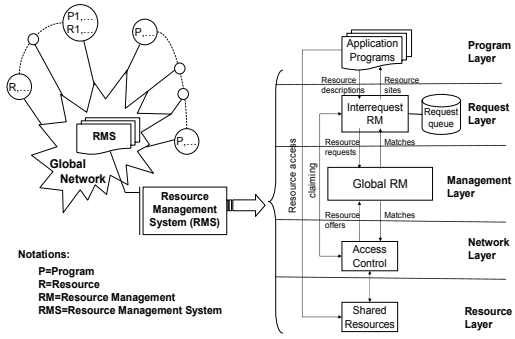

Figure 65.1. A grid computing system

The distribution of the service tasks/subtasks among the remote resources is controlled by the resource management system (RMS), which is the "brain" of grid computing [7]. RMS has five layers in general, as shown in Figure 65.1: the program layer, the request layer, the management layer, the network layer, and the resource layer.

1) *Program layer*: The program layer represents the programs of the customer's applications. The programs describe their required resources and constraint requirements (such as deadline, budget, function, *etc.*). These resource descriptions are translated to the resource requests and sent to the next request layer.
2) *Request layer*: The request layer provides the abstraction of "program requirements" as a queue of resource requests. The primary goals of this layer are to maintain this queue in a persistent and fault-tolerant manner and to interact with the next management layer by injecting resource requests for matching, claiming matched resources of the requests.
3) *Management layer*: The management layer may be thought of as the global resource allocation layer. It has the function of automatically detecting new resources, monitoring the resource pool, removing failed/unavailable resources, and most importantly matching the resource requests of a service to the registered/detected resources. If resource requests are matched with the registered resources in the grid, this layer sends the matched tags to the next network layer.
4) *Network layer*: The network layer dynamically builds connection between the programs and resources when receiving the matched tags and controls them to exchange information through communication channels in a secure way.
5) *Resource layer*: The resource layer represents the shared resources from different resource providers including the usage policies (such as service charge, reliability, serving time, *etc*.).

65.2.2 Failure Analysis of Grid Service

Even though all online nodes or resources are linked through the Internet with one another, not all resources or communication channels are actually used for a specific service. Therefore, according to this observation, we can make tractable models and analyses of grid computing *via* a virtual structure for a certain service. The grid service is defined as follows:

> *Grid service is a service offered under the grid computing environment, which can be requested by different users through the RMS, which includes a set of subtasks that are allocated to specific resources via the RMS for execution, and which returns the result to the user after the RMS integrates the outputs from different subtasks.*

The above five layers coordinate together to achieve a grid service. At the "program layer", the subtasks (programs) composing the entire grid service task initially send their requests for remote resources to the RMS. The "request layer" adds these requests in the request queue. Then, the "management layer" tries to find the sites of the resources that match the requests. After all the requests of those programs in the grid service are matched, the "network layer" builds the connections among those programs and the matched resources.

It is possible to identify various types of failures on respective layers:

- *Program layer*: Software failures can occur during the subtask (program) execution; see, *e.g.*, [13, 14].
- *Request layer*: When the programs' requests reach the request layer, two types of failures may occur: "blocking failure" and "time-out failure". Usually, the request queue has a limitation on the maximal number of waiting requests [7]. If the queue is full when a new request arrives, the request blocking failure occurs. The grid service usually has its due time set by customers or service monitors. If the waiting time for the requests in the queue exceeds the due time, the time-out failure occurs [11].
- *Management layer*: At this layer, "matching failure" may occur if the requests fail to match with the correct resources, [15, pp. 185–186]. Errors, such as incorrectly translating the requests, registering a wrong resource, ignoring resource disconnection, misunderstanding the users' requirements, can cause these matching failures.
- *Network layer*: When the subtasks (programs) are executed on remote resources, the communication channels may be disconnected either physically or logically, which causes the "network failure", especially for those long time transmissions of large dataset [16].
- *Resource layer*: The resources shared on the grid can be of software, hardware or firmware type. The corresponding software, hardware or combined faults can cause resource unavailability.

65.2.3 Grid Service Reliability and Performance

Most previous research on distributed computing studied performance and reliability separately. However, performance and reliability are closely related and affect each other, in particular under the grid computing environment. For example, while a task is fully parallelized into m subtasks executed by m resources, the performance is high but the reliability might be low because the failure of any resource prevents the entire task from completion. This causes the RMS to restart the task, which reversely increases its execution time (*i.e.*, reduces performance). Therefore, it is worth assigning some subtasks to several resources to provide execution redundancy. However, excessive redundancy, even though improving the reliability, can decrease the performance by not fully parallelizing the task. Thus, the performance and reliability affect each other and should be considered together in the grid service modeling and analysis.

In order to study performance and reliability interactions, one also has to take into account the effect of service performance (execution time) upon the reliability of the grid elements. The conventional models [17–20] are based on the assumption that the operational probabilities of nodes or links are constant, which ignores the links' bandwidth, communication time and resource processing time. Such models are not suitable for precisely modeling the grid service performance and reliability.

Another important issue that has much influence the performance and reliability is data dependence, which exists when some subtasks use the results from some other subtasks. The service performance and reliability is affected by data dependence because the subtasks cannot be executed totally in parallel. For instance, the resources that are idle in waiting for the input to run the assigned subtasks are usually hot-standby because cold-start is time consuming. As a result, these resources can fail in waiting mode.

The considerations presented above lead the following assumptions that lay in the base of grid service reliability and performance model.

Assumptions:

1) The service request reaches the RMS and is being served immediately. The RMS divides the entire service task into a set of subtasks. The data dependence may exist among the subtasks. The order is determined by precedence constraints and is controlled by the RMS.
2) Different grid resources are registered or automatically detected by the RMS. In a grid service, the structure of virtual network (consisting of the RMS and resources

involved in performing the service) can form star topology with the RMS in the center or, tree topology with the RMS in the root node.

3) The resources are specialized. Each resource can process one or multiple subtask(s) when it is available.
4) Each resource has a given constant processing speed when it is available and has a given constant failure rate. Each communication channel has constant failure rate and a constant bandwidth (data transmission speed).
5) The failure rates of the communication channels or resources are the same when they are idle or loaded (hot standby model). The failures of different resources and communication links are independent.
6) If the failure of a resource or a communication channel occurs before the end of output data transmission from the resource to the RMS, the subtask fails.
7) Different resources start performing their tasks immediately after they get the input data from the RMS through communication channels. If same subtask is processed by several resources (providing execution redundancy), it is completed when the first result is returned to the RMS. The entire task is completed when all of the subtasks are completed and their results are returned to the RMS from the resources.
8) The data transmission speed in any multi-channel link does not depend on the number of different packages (corresponding to different subtasks) sent in parallel. The data transmission time of each package depends on the amount of data in the package. If the data package is transmitted through several communication links, the link with the lowest bandwidth limits the data transmission speed.
9) The RMS is fully reliable, which can be justified to consider a relatively short interval of running a specific service. The imperfect RMS can also be easily included as a module connected in series to the whole grid service system.

65.2.4 Grid Service Time Distribution and Reliability/Performance Measures

The data dependence on task execution can be represented by $m \times m$ matrix H such that $h_{ki} = 1$ if subtask i needs for its execution output data from subtask k and $h_{ki} = 0$ otherwise (the subtasks can always be numbered such that $k<i$ for any $h_{ki} = 1$). Therefore, if $h_{ki} = 1$ execution of subtask i cannot begin before completion of subtask k. For any subtask i one can define a set ϕ_i of its immediate predecessors: $k \in \phi_i$ if $h_{ki} = 1$.

The data dependence can always be presented in such a manner that the last subtask m corresponds to final task processed by the RMS when it receives output data of all the subtasks completed by the grid resources.

The task execution time is defined as time from the beginning of input data transmission from the RMS to a resource to the end of output data transmission from the resource to the RMS.

The amount of data that should be transmitted between the RMS and resource j that executes subtask i is denoted by a_i. If data transmission between the RMS and the resource j is accomplished through links belonging to a set γ_j, the data transmission speed is

$$s_j = \min_{L_x \in \gamma_j} (b_x), \qquad (65.1)$$

where b_x is the bandwidth of the link L_x. Therefore, the random time t_{ij} of subtask i execution by resource j can take two possible values

$$t_{ij} = \hat{t}_{ij} = \tau_j + \frac{a_i}{s_j} \qquad (65.2)$$

if the resource j and the communication path γ_j do not fail until the subtask completion and $t_{ij} = \infty$ otherwise. Here, τ_j is the processing time of the *j-th* resource.

Subtask i can be successfully completed by resource j if this resource and communication path γ_j do not fail before the end of subtask execution. Given constant failure rates of resource j and links,

one can obtain the conditional probability of subtask success as

$$p_j(\hat{t}_{ij}) = e^{-(\lambda_j+\pi_j)\hat{t}_{ij}}, \quad (65.3)$$

where π_j is the failure rate of the communication path between the RMS and the resource j, which can be calculated as $\pi_j = \sum_{x\in\gamma_j}\lambda_x$, λ_x is the failure rate of the link L_x. The exponential distribution (65.3) is common in software or hardware components' reliability that had been justified in both theory and practice [15].

These give the conditional distribution of the random subtask execution time t_{ij}:

$\Pr(t_{ij} = \hat{t}_{ij}) = p_j(t_{ij})$ and

$\Pr(t_{ij} = \infty) = 1 - p_j(t_{ij})$.

Assume that each subtask i is assigned by the RMS to resources composing set ω_i. The RMS can initiate execution of any subtask j (send the data to all the resources from ω_i) only after the completion of every subtask $k \in \phi_i$. Therefore the random time of the start of subtask i execution T_i can be determined as

$$T_i = \max_{k\in\phi_i}(\tilde{T}_k), \quad (65.4)$$

where $\tilde{T}_k$ is random completion time for subtask k. If $\phi_i = \varnothing$, *i.e.* subtask i does not need data produced by any other subtask, the subtask execution starts without delay: $T_i = 0$. If $\phi_i \neq \varnothing$, T_i can have different realizations $\hat{T}_{il}$ ($1 \le l \le N_i$).

Having the time T_i when the execution of subtask i starts and the time t_{ij} of subtask i executed by resource j, one obtains the completion time for subtask i on resource j as

$$\tilde{t}_{ij} = T_i + t_{ij}. \quad (65.5)$$

In order to obtain the distribution of random time $\tilde{t}_{ij}$ one has to take into account that probability of any realization of $\tilde{t}_{ij} = \hat{T}_{il} + \hat{t}_{ij}$ is equal to the product of probabilities of three events:

- execution of subtask i starts at time $\hat{T}_{il}$: $q_{il}=\Pr(T_i = \hat{T}_{il})$;
- resource j does not fail before start of execution of subtask i: $p_j(\hat{T}_{il})$;
- resource j does not fail during the execution of subtask i: $p_j(\hat{t}_{ij})$.

Therefore, the conditional distribution of the random time $\tilde{t}_{ij}$ given execution of subtask i starting at time $\hat{T}_{il}$ ($T_i = \hat{T}_{il}$) takes the form

$$\Pr(\tilde{t}_{ij} = \hat{T}_{il} + \hat{t}_{ij}) = p_j(\hat{T}_{il})p_j(\hat{t}_{ij}) = p_j(\hat{T}_{il} + \hat{t}_{ij}) = e^{-(\lambda_j+\pi_j)(\hat{T}_{il}+\hat{t}_{ij})}, \quad (65.6)$$

$$\Pr(\tilde{t}_{ij} = \infty) = 1 - p_j(\hat{T}_{il} + \hat{t}_{ij}) = 1 - e^{-(\lambda_j+\pi_j)(\hat{T}_{il}+\hat{t}_{ij})}.$$

The random time of subtask i completion $\tilde{T}_i$ is equal to the shortest time when one of the resources from ω_i completes the subtask execution:

$$\tilde{T}_i = \min_{j\in\omega_i}(\tilde{t}_{ij}). \quad (65.7)$$

According to the definition of the last subtask m, the time of its beginning corresponds to the service completion time, because the time of the task proceeds with RMS is neglected. Thus, the random service time Θ is equal to T_m. Having the distribution (pmf) of the random value $\Theta \equiv T_m$ in the form $q_{ml} = \Pr(T_m = \hat{T}_{ml})$ for $1 \le l \le N_m$, one can evaluate the reliability and performance indices of the grid service.

In order to estimate both the service reliability and its performance, different measures can be used depending on the application. In applications where the execution time of each task (service

time) is of critical importance, the system reliability $R(\Theta^*)$ is defined (according to performability concept in [21–23] as a probability that the correct output is produced in time less than Θ^*.

This index can be obtained as

$$R(\Theta^*) = \sum_{l=1}^{N_m} q_{ml} \cdot 1(\hat{T}_{ml} < \Theta^*). \quad (65.8)$$

When no limitations are imposed on the service time, the service reliability is defined as the probability that it produces correct outputs without respect to the service time, which can be referred to as $R(\infty)$. The conditional expected service time W is considered to be a measure of its performance, which determines the expected service time given that the service does not fail, *i.e.*,

$$W = \sum_{l=1}^{N_m} \hat{T}_{ml} q_{ml} / R(\infty). \quad (65.9)$$

65.3 Star Topology Grid Architecture

A grid service is desired to execute a certain task under the control of the RMS. When the RMS receives a service request from a user, the task can be divided into a set of subtasks that are executed in parallel. The RMS assigns those subtasks to available resources for execution. After the resources complete the assigned subtasks, they return the results back to the RMS and then the RMS integrates the received results into entire task output which is requested by the user.

The above grid service process can be approximated by a structure with star topology, as depicted by Figure 65.2, where the RMS is directly connected with any resource through respective communication channels. The star topology is feasible when the resources are totally separated so that their communication channels are independent. Under this assumption the grid service reliability and performance can be derived by using the universal generating function technique.

65.3.1 Universal Generating Function

The universal generating function (u-function) technique was introduced and proved to be very effective for the reliability evaluation of different types of multi-state systems [24].

The u-function representing the pmf of a discrete random variable Y is defined as a polynomial

$$u(z) = \sum_{k=1}^{K} \alpha_k z^{y_k}, \quad (65.10)$$

where the variable Y has K possible values and α_k is the probability that Y is equal to y_k.

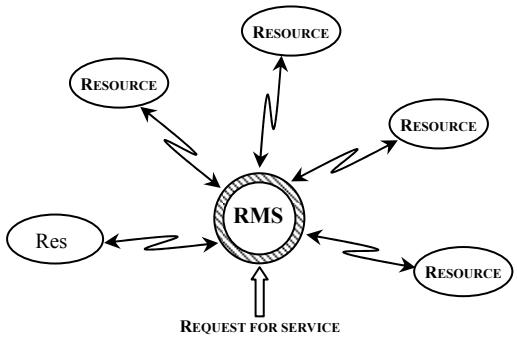

Figure 65.2. Grid system with star architecture

To obtain the u-function representing the pmf of a function of two independent random variables $\varphi(Y_i, Y_j)$, composition operators are introduced. These operators determine the u-function for $\varphi(Y_i, Y_j)$ using simple algebraic operations on the individual u-functions of the variables. All of the composition operators take the form

$$U(z) = u_i(z) \otimes_{\varphi} u_j(z) = \sum_{k=1}^{K_i} \alpha_{ik} z^{y_{ik}} \otimes_{\varphi} \sum_{h=1}^{K_j} \alpha_{jh} z^{y_{jh}} = \sum_{k=1}^{K_i} \sum_{h=1}^{K_j} \alpha_{ik} \alpha_{jh} z^{\varphi(y_{ik}, y_{jh})} \quad (65.11)$$

The u-function U(z) represents all of the possible mutually exclusive combinations of realizations of the variables by relating the probabilities of each

combination to the value of function $\varphi(Y_i, Y_j)$ for this combination.

In the case of grid system, the u-function $u_{ij}(z)$ can define pmf of execution time for subtask *i* assigned to resource *j*. This u-function takes the form

$$u_{ij}(z) = p_j(\hat{t}_{ij}) z^{\hat{t}_{ij}} + (1 - p_j(\hat{t}_{ij})) z^{\infty}, \quad (65.12)$$

where $\hat{t}_{ij}$ and $p_j(\hat{t}_{ij})$ are determined according to (65.2) and (65.3), respectively.

The pmf of the random start time T_i for subtask *i* can be represented by u-function $U_i(z)$ taking the form

$$U_i(z) = \sum_{l=1}^{L_i} q_{il} z^{\hat{T}_{il}}, \quad (65.13)$$

where

$$q_{il} = \Pr(T_i = \hat{T}_{il}). \quad (65.14)$$

For any realization $\hat{T}_{il}$ of T_i the conditional distribution of completion time $\tilde{t}_{ij}$ for subtask *i* executed by resource *j* given $T_i = \hat{T}_{il}$ according to (65.6) can be represented by the u-function

$$\tilde{u}_{ij}(z, \hat{T}_{il}) = p_j(\hat{T}_{il} + \hat{t}_{ij}) z^{\hat{T}_{il} + \hat{t}_{ij}} + (1 - p_j(\hat{T}_{il} + \hat{t}_{ij})) z^{\infty}.$$

The total completion time of subtask *i* assigned to a pair of resources *j* and *d* is equal to the minimum of completion times for these resources according to (65.7). To obtain the u-function representing the pmf of this time, given $T_i = \hat{T}_{il}$, composition operator with $\varphi(Y_j, Y_d) = \min(Y_j, Y_d)$ should be used:

$$\begin{aligned}
\tilde{u}_i(z, \hat{T}_{il}) &= \tilde{u}_{ij}(z, \hat{T}_{il}) \otimes_{\min} \tilde{u}_{id}(z, \hat{T}_{il}) \\
&= [p_j(\hat{T}_{il} + \hat{t}_{ij}) z^{\hat{T}_{il} + \hat{t}_{ij}} + (1 - p_j(\hat{T}_{il} + \hat{t}_{ij})) z^{\infty}] \\
&\otimes_{\min} [p_d(\hat{T}_{il} + \hat{t}_{id}) z^{\hat{T}_{il} + \hat{t}_{id}} + (1 - p_d(\hat{T}_{il} + \hat{t}_{id})) z^{\infty}] \\
&= p_j(\hat{T}_{il} + \hat{t}_{ij}) p_d(\hat{T}_{il} + \hat{t}_{id}) z^{\hat{T}_{il} + \min(\hat{t}_{ij}, \hat{t}_{id})} \\
&+ p_d(\hat{T}_{il} + \hat{t}_{id})(1 - p_j(\hat{T}_{il} + \hat{t}_{ij})) z^{\hat{T}_{il} + \hat{t}_{id}} \\
&+ p_j(\hat{T}_{il} + \hat{t}_{ij})(1 - p_d(\hat{T}_{il} + \hat{t}_{id})) z^{\hat{T}_{il} + \hat{t}_{ij}} \\
&+ (1 - p_j(\hat{T}_{il} + \hat{t}_{ij}))(1 - p_d(\hat{T}_{il} + \hat{t}_{id})) z^{\infty}.
\end{aligned} \quad (65.15)$$

The u-function $\tilde{u}_i(z, \hat{T}_{il})$ representing the conditional pmf of completion time $\tilde{T}_i$ for subtask *i* assigned to all of the resources from set $\omega_i = \{j_1, \ldots, j_i\}$ can be obtained as

$$\tilde{u}_i(z, \hat{T}_{il}) = \tilde{u}_{ij_1}(z, \hat{T}_{il}) \otimes_{\min} \ldots \otimes_{\min} \tilde{u}_{ij_i}(z, \hat{T}_{il}), \quad (65.16)$$

$\tilde{u}_i(z, \hat{T}_{il})$ can be obtained recursively:

$$\begin{aligned}
&\tilde{u}_i(z, \hat{T}_{il}) = \tilde{u}_{ij_1}(z, \hat{T}_{il}), \\
&\tilde{u}_i(z, \hat{T}_{il}) = \tilde{u}_i(z, \hat{T}_{il}) \otimes_{\min} \tilde{u}_{ie}(z, \hat{T}_{il})
\end{aligned}$$

for $e = j_2, \ldots, j_i$. (65.17)

Having the probabilities of the mutually exclusive realizations of start time T_i, $q_{il} = \Pr(T_i = \hat{T}_{il})$ and u-functions $\tilde{u}_i(z, \hat{T}_{il})$ representing corresponding conditional distributions of task *i* completion time, we can now obtain the u-function representing the unconditional pmf of completion time $\tilde{T}_i$ as

$$\tilde{U}_i(z) = \sum_{l=1}^{N_i} q_{il} \tilde{u}_i(z, \hat{T}_{il}). \quad (65.18)$$

Having u-functions $\widetilde{U}_k(z)$ representing pmf of the completion time $\widetilde{T}_k$ for any subtask $k \in \phi_i = \{k_1,...,k_i\}$, one can obtain the u-functions $U_i(z)$ representing pmf of subtask i start time T_i according to (65.4) as

$$U_i(z) = \widetilde{U}_{k_1}(z) \underset{\max}{\otimes} \widetilde{U}_{k_2}(z) ... \underset{\max}{\otimes} \widetilde{U}_{k_i}(z) = \sum_{l=1}^{N_i} q_{il} z^{\hat{T}_{il}}. \quad (65.19)$$

$U_i(z)$ can be obtained recursively:

$$U_i(z) = z^0,$$
$$U_i(z) = U_i(z) \underset{\max}{\otimes} \widetilde{U}_e(z)$$
for $e = k_1, \ldots, k_i$. (65.20)

It can be seen that if $\phi_i = \varnothing$ then $U_i(z) = z^0$.

The final u-function $U_m(z)$ represents the pmf of random task completion time T_m in the form

$$U_m(z) = \sum_{l=1}^{N_m} q_{ml} z^{\hat{T}_{ml}}. \quad (65.21)$$

Using the operators defined above one can obtain the service reliability and performance indices by implementing the following algorithm:

1. Determine $\hat{t}_{ij}$ for each subtask i and resource $j \in \omega_i$ using (65.2);
   Define for each subtask i ($1 \le i \le m$) $\widetilde{U}_i(z) = U_i(z) = z^0$.
2. For all i:
   If $\phi_i = 0$ or if for any $k \in \phi_i$ $\widetilde{U}_k(z) \neq z^0$ (u-functions representing the completion times of all of the predecessors of subtask i are obtained)
   2.1. Obtain $U_i(z) = \sum_{l=1}^{N_i} q_{il} z^{\hat{T}_{il}}$ using recursive procedure (65.20);
   2.2. For $l = 1, \ldots, N_i$:
   2.2.1. For each $j \in \omega_i$ obtain $\widetilde{u}_{ij}(z, \hat{T}_{il})$ using (65.14);
   2.2.2. Obtain $\widetilde{u}_i(z)$ using recursive procedure (65.17);
   2.3. Obtain $\widetilde{U}_i(z)$ using (65.18).
3. If $U_m(z) = z^0$ return to step 2.
4. Obtain reliability and performance indices $R(\Theta^*)$ and W using (65.8) and (65.9).

65.3.2 Illustrative Example

This example presents analytical derivation of the indices $R(\Theta^*)$ and W for simple grid service that uses six resources. Assume that the RMS divides the service task into three subtasks. The first subtask is assigned to resources 1 and 2, the second subtask is assigned to resources 3 and 4, the third subtask is assigned to resources 5 and 6:
$\omega_1 = \{1,2\}$, $\omega_2 = \{3,4\}$, $\omega_3 = \{5,6\}$.
The failure rates of the resources and communication channels and subtask execution times are presented in Table 65.1.

Table 65.1. Parameters of grid system for the analytical example

No. of sub i	No. of res j	$\lambda_j+\pi_j$ (sec^{-1})	$\hat{t}_{ij}$ (sec)	$p_j(\hat{t}_{ij})$
1	1	0.0025	100	0.779
	2	0.00018	180	0.968
2	3	0.0003	250	-
	4	0.0008	300	-
3	5	0.0005	300	0.861
	6	0.0002	430	0.918

Subtasks 1 and 3 get the input data directly from the RMS, subtask 2 needs the output of subtask 1, the service task is completed when the RMS gets the outputs of both subtasks 2 and 3: $\phi_1 = \phi_3 = \varnothing$, $\phi_2 = \{1\}$, $\phi_4 = \{2,3\}$. These subtask precedence constraints can be represented by the directed graph in Figure 65.3.

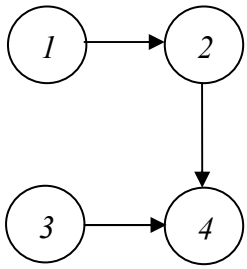

Figure 65.3. Subtask execution precedence constraints for the analytical example

Since $\phi_1 = \phi_3 = \varnothing$, the only realization of start times T_1 and T_3 is 0 and therefore, $U_1(z)=U_2(z)=z^0$. According to step 2 of the algorithm we can obtain the u-functions representing pmf of completion times $\tilde{t}_{11}$, $\tilde{t}_{12}$, $\tilde{t}_{35}$ and $\tilde{t}_{36}$. In order to determine the subtask execution time distributions for the individual resources, define the u-functions $u_{ij}(z)$ according to Table 65.1 and (65.9):

$$\tilde{u}_{11}(z,0) = \exp(-0.0025\times 100)z^{100} + [1-\exp(-0.0025\times 100)]z^{\infty} = 0.779z^{100} + 0.221z^{\infty}$$

In a similar way we obtain

$$\tilde{u}_{12}(z,0) = 0.968z^{180} + 0.032z^{\infty};$$

$$\tilde{u}_{35}(z,0) = 0.861z^{300} + 0.139z^{\infty};$$

$$\tilde{u}_{36}(z,0) = 0.918z^{430} + 0.082z^{\infty}.$$

The u-function representing the pmf of the completion time for subtask 1 executed by both resources 1 and 2 is

$$\tilde{U}_1(z) = \tilde{u}_1(z,0) = \tilde{u}_{11}(z,0) \underset{\min}{\otimes} \tilde{u}_{12}(z,0) =$$

$$(0.779z^{100} + 0.221z^{\infty}) \underset{\min}{\otimes} (0.968z^{180} + 0.032z^{\infty})$$

$$=0.779z^{100} + 0.214z^{180} + 0.007z^{\infty}.$$

The u-function representing the pmf of the completion time for subtask 3 executed by both resources 5 and 6 is

$$\tilde{U}_3(z) = \tilde{u}_3(z,0) = \tilde{u}_{35}(z) \underset{\min}{\otimes} \tilde{u}_{36}(z) =$$

$$(0.861z^{300} + 0.139z^{\infty}) \underset{\min}{\otimes} (0.918z^{430} + 0.082z^{\infty})$$

$$=0.861z^{300} + 0.128z^{430} + 0.011z^{\infty}.$$

Execution of subtask 2 begins immediately after completion of subtask 1. Therefore,

$$U_2(z) = \tilde{U}_1(z) = 0.779z^{100} + 0.214z^{180} + 0.007z^{\infty}$$

(T_2 has three realizations 100, 180 and ∞).

The u-functions representing the conditional pmf of the completion times for the subtask 2 executed by individual resources are obtained as follows.

$$\tilde{u}_{23}(z,100) = e^{-0.0003\times(100+250)}z^{100+250} + [1-e^{-0.0003\times(100+250)}]z^{\infty} = 0.9z^{350} + 0.1z^{\infty};$$

$$\tilde{u}_{23}(z,180) = e^{-0.0003\times(180+250)}z^{180+250} + [1-e^{-0.0003\times(180+250)}]z^{\infty} = 0.879z^{430} + 0.121z^{\infty};$$

$$\tilde{u}_{23}(z,\infty) = z^{\infty};$$

$$\tilde{u}_{24}(z,100) = e^{-0.0008\times(100+300)}z^{100+300} + [1-e^{-0.0008\times(100+300)}]z^{\infty} = 0.726z^{400} + 0.274z^{\infty};$$

$$\tilde{u}_{24}(z,180) = e^{-0.0008\times(180+300)}z^{180+300} + [1-e^{-0.0008\times(180+300)}]z^{\infty} = 0.681z^{480} + 0.319z^{\infty};$$

$$\tilde{u}_{24}(z,\infty) = z^{\infty}.$$

The u-functions representing the conditional pmf of subtask 2 completion time are:

$$\tilde{u}_2(z,100) = \tilde{u}_{23}(z,100) \underset{\min}{\otimes} \tilde{u}_{24}(z,100) =$$

$$(0.9z^{350} + 0.1z^{\infty}) \underset{\min}{\otimes} (0.726z^{400} + 0.274z^{\infty})$$

$$=0.9z^{350} + 0.073z^{400} + 0.027z^{\infty};$$

$$\tilde{u}_2(z,180) = \tilde{u}_{23}(z,180) \underset{\min}{\otimes} \tilde{u}_{24}(z,180) =$$

$$(0.879z^{430} + 0.121z^{\infty}) \underset{\min}{\otimes} (0.681z^{480} + 0.319z^{\infty})$$

$$=0.879z^{430} + 0.082z^{480} + 0.039z^{\infty};$$

$$\tilde{u}_2(z,\infty) = \tilde{u}_{23}(z,\infty) \underset{\min}{\otimes} \tilde{u}_{24}(z,\infty) = z^{\infty}.$$

According to (65.18) the unconditional pmf of subtask 2 completion time is represented by the following u-function

$$\tilde{U}_2(z) = 0.779\tilde{u}_2(z,100) + 0.214\tilde{u}_2(z,180) + 0.007z^{\infty}$$

$=0.779(0.9z^{350}+0.073z^{400}+0.027z^{\infty})+0.214(0.879z^{430}+0.082z^{480}+0.039z^{\infty})+0.007z^{\infty}$

$=0.701z^{350}+0.056z^{400}+0.188z^{430}+0.018z^{480}+0.037z^{\infty}$

The service task is completed when subtasks 2 and 3 return their outputs to the RMS (which corresponds to the beginning of subtask 4). Therefore, the u-function representing the pmf of the entire service time is obtained as

$$U_4(z) = \tilde{U}_2(z) \underset{\max}{\otimes} \tilde{U}_3(z)$$

$=(0.701z^{350}+0.056z^{400}+0.188z^{430}+0.018z^{480}+0.037z^{\infty}) \underset{\max}{\otimes} (0.861z^{300}+0.128z^{430}+0.011z^{\infty})=0.603z^{350}+0.049z^{400}+0.283z^{430}+0.017z^{480}+0.048z^{\infty}.$

The pmf of the service time is:

$\Pr(T_4 = 350) = 0.603$; $\Pr(T_4 = 400) = 0.049$;

$\Pr(T_4 = 430) = 0.283$; $\Pr(T_4 = 480) = 0.017$;

$\Pr(T_4 = \infty) = 0.048$.

From the obtained pmf we can calculate the service reliability using (65.8):

$R(\Theta^*) = 0.603$ for $350 < \Theta^* \le 400$;

$R(\Theta^*) = 0.652$ for $400 < \Theta^* \le 430$;

$R(\Theta^*) = 0.935$ for $430 < \Theta^* \le 480$;

$R(\infty) = 0.952$

and the conditional expected service time according to (65.9):

$W = (0.603\times350 + 0.049\times400 + 0.283\times430 + 0.017\times480) / 0.952 = 378.69$ sec.

65.4 Tree Topology Grid Architecture

In the star grid, the RMS is connected with each resource by one direct communication channel (link). However, such approximation is not accurate enough even though it simplifies the analysis and computation. For example, several resources located in a same local area network (LAN) can use the same gateway to communicate outside the network. Therefore, all these resources are not connected with the RMS through independent links. The resources are connected to the gateway, which communicates with the RMS through one common communication channel. Another example is a server that contains several resources (has several processors that can run different applications simultaneously, or contains different databases). Such a server communicates with the RMS through the same links. These situations cannot be modeled using only the star topology grid architecture.

In this section, we present a more reasonable virtual structure which has a tree topology. The root of the tree virtual structure is the RMS, and the leaves are resources, while the branches of the tree represent the communication channels linking the leaves and the root. Some channels are commonly used by multiple resources. An example of the tree topology is given in Figure 65.3 in which four resources (R1, R2, R3, R4) are available for a service.

The tree structure models the common cause failures in shared communication channels. For example, in Figure 65.4, the failure in channel L6 makes resources R1, R2, and R3 unavailable. This type of common cause failure was ignored by the conventional parallel computing models, and the above star-topology models. For small-area communication, such as a LAN or a cluster, such an assumption that ignores the common cause failures on communications is acceptable because the communication time is negligible compared to the processing time. However, for wide-area communication, such as the grid system, it is more likely to have failure on communication channels. Therefore, the communication time cannot be neglected. In many cases, the communication time may dominate the processing time due to the large amount of data transmitted. Therefore, the virtual tree structure is an adequate model representing the functioning of grid services.

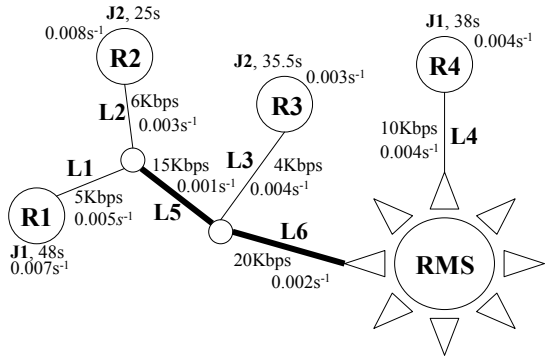

Figure 65.4. Virtual tree structure of a grid service

65.4.1 Algorithms for Determining the pmf of the Task Execution Time

With the tree structure, the simple u-function technique is not applicable because it does not consider the failure correlations. Thus, new algorithms are required. This section presents a novel algorithm to evaluate the performance and reliability for the tree-structured grid service based on graph theory and the Bayesian approach.

65.4.1.1 Minimal Task Spanning Tree (MTST)

The set of all nodes and links involved in performing a given task form a task spanning tree. This task spanning tree can be considered to be a combination of minimal task spanning trees (MTST), where each MTST represents a minimal possible combination of available elements (resources and links) that guarantees the successful completion of the entire task. The failure of any element in a MTST leads to the entire task failure.

For solving the graph traversal problem, several classical algorithms have been suggested, such as depth-first search, breadth-first search, *etc*. These algorithms can find all MTST in an arbitrary graph [16]. However, MTST in graphs with a tree topology can be found in a much simpler way because each resource has a single path to the RMS, and the tree structure is acyclic.

After the subtasks have been assigned to corresponding resources, it is easy to find all combinations of resources such that each combination contains exactly m resources executing m different subtasks that compose the entire task. Each combination determines exactly one MTST consisting of links that belong to paths from the m resources to the RMS. The total number of MTST is equal to the total number of such combinations N, where

$$N = \prod_{j=1}^{m} |\omega_j| \qquad (65.22)$$

(see Section 65.4.2.1).

Along with the procedures of searching all the MTST, one has to determine the corresponding running time and communication time for all the resources and links.

For any subtask j, and any resource k assigned to execute this subtask, one has the amount of input and output data, the bandwidths of links, belonging to the corresponding paths γ_k, and the resource processing time. With these data, one can obtain the time of subtask completion (see Section 65.4.2.2).

Some elements of the same MTST can belong to several paths if they are involved in data transmission to several resources. To track the element involvement in performing different subtasks and to record the corresponding times in which the element failure causes the failure of a subtask, we create the lists of two-field records for each subtask in each MTST. For any MTST S_i ($1 \le i \le N$), and any subtask j ($1 \le j \le m$), this list contains the names of the elements involved in performing the subtask j, and the corresponding time of subtask completion y_{ij} (see Sections 65.4.2.3 and 65.4.2.4). Note that y_{ij} is the conditional time of subtask j completion given only MTST i is available.

Note that a MTST completes the entire task if all of its elements do not fail by the maximal time needed to complete subtasks in performing which they are involved. Therefore, when calculating the element reliability in a given MTST, one has to use the corresponding record with maximal time.

65.4.1.2 pmf of the Task Execution Time

Having the MTST, and the times of their elements involvement in performing different subtasks, one can determine the pmf of the entire service time.

First, we can obtain the conditional time of the entire task completion given only MTST S_i is available as

$$Y_{\{i\}} = \max_{1\le j\le m}(y_{ij}) \text{ for any } 1\le i\le N. \quad (65.23)$$

For a set ψ of available MTST, the task completion time is equal to the minimal task completion times among the MTST.

$$Y_{\psi} = \min_{i\in\psi}(Y_{\{i\}}) = \min_{i\in\psi}\left[\max_{1\le j\le m}(y_{ij})\right]. \quad (65.24)$$

Now, we can sort the MTST in an increasing order of their conditional task completion times $Y_{\{i\}}$, and divide them into different groups containing MTST with identical conditional completion time. Suppose there are K such groups denoted by $G_1, G_2, ..., G_K$ where $1 \le K \le N$, and any group G_i contains MTST with identical conditional task completion times Θ_i ($0 \le \Theta_1 < \Theta_2 < ... < \Theta_K$). Then, it can be seen that the probability $Q_i = \Pr(\Theta = \Theta_i)$ can be obtained as

$$Q_i = \Pr(E_i, \overline{E}_{i-1}, \overline{E}_{i-2}, ..., \overline{E}_1) \quad (65.25)$$

where E_i is the event when at least one of MTST from the group G_i is available, and $\overline{E}_i$ is the event when none of MTST from the group G_i is available.

Suppose the MTST in a group G_i are arbitrarily ordered, and F_{ij} (j=1,2,…, N_i) represents an event when the j-th MTST in the group is available. Then, the event E_i can be expressed by

$$E_i = \bigcup_{j=1}^{N_i} F_{ij}, \quad (65.26)$$

and (65.25) takes the form

$$\Pr(E_i, \overline{E}_{i-1}, \overline{E}_{i-2}, ..., \overline{E}_1) = \Pr(\bigcup_{j=1}^{N_i} F_{ij}, \overline{E}_{i-1}, \overline{E}_{i-2}, ..., \overline{E}_1). \quad (65.27)$$

Using the Bayesian theorem on conditional probability, we obtain from (65.27) that

$$Q_i = \sum_{j=1}^{N_i} \Pr(F_{ij}) \cdot \Pr(\overline{F}_{i(j-1)}, \overline{F}_{i(j-2)}, ..., \overline{F}_{i1}, \overline{E}_1, \overline{E}_2, \cdots, \overline{E}_{i-1} \mid F_{ij}) \quad (65.28)$$

The probability $\Pr(F_{ij})$ can be calculated as a product of the reliabilities of all the elements belonging to the jth MTST from group G_i.

The probability $\Pr(\overline{F}_{i(j-1)}, \overline{F}_{i(j-2)}, ..., \overline{F}_{i1}, \overline{E}_1, \overline{E}_2, \cdots, \overline{E}_{i-1} \mid F_{ij})$ can be computed by the following two-step algorithm (see Example 4.2.4).

Step 1: Identify failures of all the critical elements' in a period of time (defined by the start and end time), during which they lead to the failures of any MTST from groups G_m for m=1,2,…i-1 (events $\overline{E}_m$), and any MTST S_k from group G_i for k=1,2,…, $j-1$ (events $\overline{F}_{ik}$), but do not affect the MTST S_j from group G_i.

Step 2: Generate all the possible combinations of the identified critical elements that lead to the event $\overline{F}_{i(j-1)}, \overline{F}_{i(j-2)}, ..., \overline{F}_{i1}, \overline{E}_1, \overline{E}_2, \cdots, \overline{E}_{i-1} \mid F_{ij}$ using a binary search, and compute the probabilities of those combinations. The sum of the probabilities obtained is equal to $\Pr(\overline{F}_{i(j-1)}, \overline{F}_{i(j-2)}, ..., \overline{F}_{i1}, \overline{E}_1, \overline{E}_2, \cdots, \overline{E}_{i-1} \mid F_{ij})$. When calculating the failure probabilities of MTSTs' elements, the maximal time from the corresponding records in a list for the given MTST should be used. The algorithm for obtaining the probabilities $\Pr\{\overline{E}_1, \overline{E}_2, \cdots \overline{E}_{i-1} \mid E_i\}$ can be found in Dai *et al.* [16].

Having the conditional task completion times $Y_{\{i\}}$ for different MTST, and the corresponding probabilities Q_i, one obtains the task completion time distribution (Θ_i, Q_i), $1\le i\le K$, and can easily calculate the indices (65.8) and (65.9) (see Section 65.4.2.5).

65.4.2 Illustrative Example

Consider the virtual grid presented in Figure 65.4, and assume that the service task is divided into two subtasks J1 assigned to resources R1 and R4, and J2 assigned to resources R2 and R3. J1, and J2 require 50 Kbits, and 30 Kbits of input data, respectively, to be sent from the RMS to the corresponding resource; and 100 Kbits, and 60 Kbits of output data respectively to be sent from the resource back to the RMS.

The subtask processing times for resources, bandwidth of links, and failure rates are presented in Figure 65.4 next to the corresponding elements.

65.4.2.1 The Service MTST

The entire graph constitutes the task spanning tree. There exist four possible combinations of two resources executing both subtasks: {R1, R2}, {R1, R3}, {R4, R2}, {R4, R3}. The four MTST corresponding to these combinations are: S_1: {R1, R2, L1, L2, L5, L6}; S_2: {R1, R3, L1, L3, L5, L6}; S_3: {R2, R4, L2, L5, L4, L6}; S_4: {R3, R4, L3, L4, L6}.

65.4.2.2 Parameters of MTSTs' Paths

Having the MTST, one can obtain the data transmission speed for each path between the resource, and the RMS (as minimal bandwidth of links belonging to the path); and calculate the data transmission times, and the times of subtasks' completion. These parameters are presented in Table 65.2. For example, resource R1 (belonging to two MTST S_1 & S_2) processes subtask J1 in 48 seconds. To complete the subtask, it should receive 50 Kbits, and return to the RMS 100 Kbits of data. The speed of data transmission between the RMS and R1 is limited by the bandwidth of link L1, and is equal to 5 Kbps. Therefore, the data transmission time is 150/5=30 seconds, and the total time of task completion by R1 is 30+48=78 s.

Table 65.2. Parameters of the MTSTs' paths

Elements	R1	R2	R3	R4
Subtasks	J1	J2	J2	J1
Transmission speed (Kbps)	5	6	4	10
Data transmission time (s)	30	15	22.5	15
Processing time (s)	48	25	35.5	38
Subtask complete time (s)	78	40	58	53

65.4.2.3 List of MTST Elements

Now one can obtain the lists of two-field records for components of the MTST.

S_1: path for J1:(R1,78); (L1,78); (L5,78); (L6,78); path for J2: (R2,40); (L2,40); (L5,40); (L6,40).

S_2: path for J1: (R1,78), (L1,78), (L5,78), (L6,78); path for J2: (R3,58), (L3,58), (L6,58).

S_3: path for J1: (R4,53), (L4,53); path for J2: (R2,40), (L2,40), (L5,40), (L6,40).

S_4: path for J1: (R4,53), (L4,53); path for J2: (R3,58), (L3,58), (L6,58).

65.4.2.4 pmf of Task Completion Time

The conditional times of the entire task completion by different MTST are

Y_1=78; Y_2=78; Y_3=53; Y_4=58.

Therefore, the MTST compose three groups:

$G_1 = \{S_3\}$ with $\Theta_1 = 53$; $G_2 = \{S_4\}$ with $\Theta_2 = 58$; and $G_3 = \{S_1, S_2\}$ with $\Theta_3 = 78$.

According to (65.25), we have for group G_1: $Q_1=\Pr(E_1)=\Pr(S_3)$. The probability that the MTST S_3 completes the entire task is equal to the product of the probabilities that R4, and L4 do not fail by 53 seconds; and R2, L2, L5, and L6 do not fail by 40 seconds.

$\Pr(\Theta=53)=Q_1=\exp(-0.004\times53)\exp(-0.004\times53)\exp(-0.008\times40)$
$\times\exp(-0.003\times40)\exp(-0.001\times40)\exp(-0.002\times40) = 0.3738.$

Now we can calculate Q_2 as

$$Q_2=\Pr(E_2,\overline{E}_1)=\Pr(F_{21})\Pr(\overline{E}_1|F_{21})=\Pr(F_{21})\Pr(\overline{F}_{11}|F_{21})=\Pr(S_4)\Pr(\overline{S}_3|S_4)$$

because G_2, and G_1 have only one MTST each. The probability that the MTST S_4 completes the entire task $\Pr(S_4)$ is equal to the product of probabilities that R3, L3, and L6 do not fail by 58 seconds; and R4, and L4 do not fail by 53 seconds.

$$\Pr(S_4) = \exp(-0.004\times53)\exp(-0.003\times58)\exp(-0.004\times53)\exp(-0.004\times58)\exp(-0.002\times58)$$

= 0.3883

To obtain $\Pr(\overline{S}_3|S_4)$, one first should identify the critical elements according to the algorithm presented in the Dai *et al.* [16]. These elements are R2, L2, and L5. Any failure occurring in one of these elements by 40 seconds causes failure of S_3, but does not affect S_4. The probability that at least one failure occurs in the set of critical elements is

$$\Pr(\overline{S}_3|S_4) = 1-\exp(-0.08\times4)\exp(-0.03\times4)\exp(-0.01\times4) = 0.3812.$$

Then,

$$\Pr(\Theta=58) = \Pr(E_2, \overline{E}_1) = \Pr(S_4)\Pr(\overline{S}_3|S_4) = 0.3883\times0.3812 = 0.1480.$$

Now one can calculate Q_3 for the last group $G_3 = \{S_1, S_2\}$ corresponding to $\Theta_3 = 78$ as

$$Q_3 = \Pr(E_3, \overline{E}_2, \overline{E}_1) = \Pr(F_{31})\Pr(\overline{E}_1, \overline{E}_2|F_{31}) + \Pr(F_{32})\Pr(\overline{F}_{31}, \overline{E}_1, \overline{E}_2|F_{32}) = \Pr(S_1)\Pr(\overline{S}_3, \overline{S}_4|S_1) + \Pr(S_2)\Pr(\overline{S}_1, \overline{S}_3, \overline{S}_4|S_2)$$

The probability that the MTST S_1 completes the entire task is equal to the product of the probabilities that R1, L1, L5, and L6 do not fail by 78 seconds; and R2, and L2 do not fail by 40 seconds.

$$\Pr(S_1) = \exp(-0.007\times78)\exp(-0.008\times40)\exp(-0.005\times78)\exp(-0.003\times40)\times\exp(-0.001\times78)\exp(-0.002\times78) = 0.1999.$$

The probability that the MTST S_2 completes the entire task is equal to the product of the probabilities that R1, L1, L5, and L6 do not fail by 78 seconds; and R3, and L3 do not fail by 58 seconds.

$$\Pr(S_2) = \exp(-0.007\times78)\exp(-0.003\times58)\exp(-0.005\times78)\exp(-0.004\times58)\times\exp(-0.001\times78)\exp(-0.002\times78) = 0.2068.$$

To obtain $\Pr(\overline{S}_3, \overline{S}_4|S_1)$, one first should identify the critical elements. Any failure of either R4 or L4 in the time interval from 0 to 53 seconds causes failures of both S_3, and S_4; but does not affect S_1. Therefore,

$$\Pr(\overline{S}_3, \overline{S}_4|S_1) = 1-\exp(-0.004\times53)\exp(-0.004\times53) = 0.3456.$$

The critical elements for calculating $\Pr(\overline{S}_1, \overline{S}_3, \overline{S}_4|S_2)$ are R2, and L2 in the interval from 0 to 40 seconds; and R4, and L4 in the interval from 0 to 53 seconds. The failure of both elements in any one of the following four combinations causes failures of S_3, S_4, and S_1, but does not affect S_2:

1. R2 during the first 40 seconds, and R4 during the first 53 seconds;
2. R2 during the first 40 seconds, and L4 during the first 53 seconds;
3. L2 during the first 40 seconds, and R4 during the first 53 seconds; and
4. L2 during the first 40 seconds, and L4 during the first 53 seconds.

Therefore,

$$\Pr(\overline{S}_1, \overline{S}_3, \overline{S}_4|S_2) = 1-\prod_{i=1}^{4}\left[1-\prod_{j=1}^{2}[1-\exp(\lambda_{ij}\cdot t_{ij})]\right] = 0.1230,$$

where λ_{ij} is the failure rate of the jth critical element in the ith combination (j=1,2), (i=1,2,3,4); and t_{ij} is the duration of the time interval for the corresponding critical element.

Having the values of $\Pr(S_1), \Pr(S_2), \Pr(\overline{S}_3, \overline{S}_4|S_1)$, and $\Pr(\overline{S}_1, \overline{S}_3, \overline{S}_4|S_2)$, one can calculate

$$\Pr(\Theta=78) = Q_3 = 0.1999\times0.3456+0.2068\times0.1230=0.0945.$$

After obtaining Q_1, Q_2, and Q_3, one can evaluate the total task failure probability as
$\Pr(\Theta=\infty)=1-Q_1-Q_2-Q_3$
$=1-0.3738-0.1480-0.0945=0.3837$,
and obtain the pmf of service time presented in Table 65.3.

Table 65.3. pmf of service time

Θ_i	Q_i	$\Theta_i Q_i$
53	0.3738	19.8114
58	0.1480	8.584
78	0.0945	7.371
∞	0.3837	∞

65.4.2.5 Calculating the Reliability Indices

From Table 65.3, one obtains the probability that the service does not fail as

$$R(\infty) = Q_1 + Q_2 + Q_3 = 0.6164,$$

the probability that the service time is not greater than a pre-specified value of θ^*=60 seconds as

$$R(\theta^*) = \sum_{i=1}^{3} Q_i \cdot 1(\Theta_i < \theta^*) = 0.3738 + 0.1480 = 0.5218,$$

and the expected service execution time given that the system does not fail as

$$W = \sum_{i=1}^{3} \Theta_i Q_i / R(\infty) = 35.7664 / 0.6164 = 58.025$$

seconds.

65.4.3 Parameterization and Monitoring

In order to obtain the reliability and performance indices of the grid service one has to know such model parameters as the failure rates of the virtual links and the virtual nodes, and bandwidth of the links. It is easy to estimate those parameters by implementing the monitoring technology.

A monitoring system (the *Alertmon NetworkMonitor,* http://www.abilene.iu.edu/noc.html) is being applied in the IP-grid (Indiana Purdue Grid) project (www.ip-grid.org), to detect the component failures, to record service behavior, to monitor the network traffics, and to control the system configurations.

With this monitoring system, one can easily obtain the parameters required by the grid service reliability model by adding the following functions in the monitoring system:

1) Monitoring the failures of the components (virtual links and nodes) in the grid service, and recording the total execution time s of those components. The failure rates of the components can be simply estimated by the number of failures over the total execution time.
2) Monitoring the real time network traffic of the involved channels (virtual links) in order to obtain the bandwidth of the links.

To achieve the above monitoring functions, network sensors are required. We presented a type of sensor attaching to the components, acting as neurons attaching to the skins. This means the components themselves or adjacent components play the roles of sensors at the same time when they are working. Only a little computational resource in the components is used for accumulating failures/time and for dividing operations, and only a little memory is required for saving the data (accumulated number of failures, accumulated time, and current bandwidth). The virtual nodes that have memory and computational function can play the sensing role themselves; if some links have no CPU or memory, then the adjacent processors or routers can perform this data collecting operations. Using such a self-sensing technique avoids overloading of the monitoring center even in the grid system containing numerous components. Again, it does not affect the service performance considerably since only small part of computation and storage resources is used for the monitoring. In addition, such a self-sensing technique can also be applied in monitoring other measures.

When evaluating the grid service reliability, the RMS automatically loads the required parameters from corresponding sensors and calculates the service reliability and performance according to the approaches presented in the previous sections. This strategy can also be used for implementing the autonomic computing concept.

65.5 Conclusions

Grid computing is a newly developed technology for complex systems with large-scale resource sharing, wide-area communication, and multi-institutional collaboration. Although the developmental tools and techniques for the grid have been widely studied, grid reliability analysis and modeling are not easy because of their complexity of combining various failures.

This chapter introduced the grid computing technology and analyzed the grid service reliability and performance under the context of performability. The chapter then presented models for star-topology grid with data dependence and tree-structure grid with failure correlation. Evaluation tools and algorithms were presented based on the universal generating function, graph theory, and the Bayesian approach. Numerical examples were presented to illustrate the grid modeling and reliability/performance evaluation procedures and approaches.

Future research can extend the models for grid computing to other large-scale distributed computing systems. After analyzing the details and specificity of corresponding systems (*e.g.*, NASA ANTS missions), the approaches and models can be adapted to real conditions.

The models are also applicable to the wireless network that is more failure prone. Hierarchical models can also be analyzed in which output of lower level models can be considered as the input of the higher level models. Each level can make use of the proposed models and evaluation tools.

Status and Trends in the Performance Assessment of Fault Tolerant Systems

John Kontoleon

Dept. of Electrical and Computer Engineering
Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract: Fault tolerance (FT) covers a wide spectrum of application areas and includes numerous considerations, such as, to refer to a few, system architecture, hardware and software design, operating systems, Internet protocol (IP) network communications, parallel and grid processing, and verification and testing. As fault tolerant systems are designed to perform even in the presence of faults, errors or attacks, their performance can be evaluated by taking into account the consequences of the embedded fault handling actions. After a brief description of the basic concepts, this chapter presents the general aspects of fault handling techniques in both hardware and software. Global FT issues, such as those encountered in modern computer networks are also presented. A discussion on the expected future trends points out the challenges in this critical area.

66.1 Introduction

The evolution in computer technology and architecture, with an increased VLSI replication, massive parallel and grid processing, and large-scale distributed systems, has been accompanied by advances in fault tolerant design [1]–[6]. Fault tolerance aims at preserving the delivery of correct service in the presence of faults. The design of fault tolerance into a system must be faced at the early stages of its conceptualization. Performance of fault tolerant systems is a measure of their ability to deliver efficiently the required service. The price of building fault tolerant systems in terms of performance depends on the requirements of their delivered service and can be justified after the systematic investigation of different ways for improving fault tolerance in the same application. The fundamental idea behind building in a fault tolerance capability is to provide the system with redundant resources in order to overcome the effects of faults. So far, there have been numerous research contributions, covering various aspects of fault tolerance and fault tolerant design related techniques, both in hardware and software. Broadly speaking, in recent years, much research in this area has been motivated by technological advances, micro-architectural innovations, high levels of VLSI integration, and internetworking [7],[8]. A fault tolerant system may be able to tolerate a set of single or multiple faults. System faults can be either fail-silent or Byzantine faults [9].

These faults are handled according to their nature, extent, and duration. Hardware may fail in a non-

predictable way causing arbitrary behavior before the system is halted. Software is hardly ever free of bugs and may also exhibit an unpredictable behavior. Last but not least, attacks are so widespread that they are a significant source of malicious corruption of nodes in distributed applications [10],[11]. The effectiveness of fault handling techniques, referred to as coverage, can be accomplished through modeling or fault injection. A system usually delivers more than one levels of service quality. Faults may cause the reduction of the quality of service even though that service remains satisfactory. Such degradation may also be due to additional computation demands associated with error processing or may be the consequence of fault related actions, as for example reconfiguration. An example could be the failure of a node in a computer cluster, causing the performance drop or even the temporal interruption of the service.

Over the last decade there has been a tremendous growth in the market of computer networks having varying capabilities both in hardware and software [12]. While in the past the network performance issues were approached by providing sufficient bandwidth, in recent years it has been recognized that this alone is not sufficient for managing complex heterogeneous networks. Network fault management has become more sophisticated by moving the intelligent code to the nodes where data is resident or through the application of artificial intelligence and expert systems methods. For instance, network reconfiguration is an intelligent activity that changes service requirements on the basis of the system's change. Fault management, proactive or reactive, centralized or not, enhances network's fault tolerance by handling problems that could otherwise cause the performance drop or even the interruption of the provided services.

This chapter serves three purposes. Firstly, to define the relevant kinds of redundancy, together with the implications, for approaching the wide area of hardware faults tolerance. Some system models are briefly revisited to sketch fault tolerant computing. Next to address the software fault tolerance, by briefly touching traditional and more novel techniques. Software fault tolerance is not as mature as hardware and its application relies mostly on the development of diverse software. Finally, to focus on global fault tolerant issues encountered in large computer architectures and in an internetworking environment. A section with a case study of a RAM system fault tolerant architecture and its performance evaluation is also included.

66.2 Hardware Fault Tolerant Architectures and Techniques

The common approach to fault tolerant design is redundancy. Hardware redundancy may be passive, active or a combination of both, so called, hybrid redundancy [13]. The choice for the most appropriate form of redundancy is usually dictated by the complexity of the functions of the particular system as well as that of the additional hardware for implementing and managing fault tolerance.

66.2.1 Passive Redundancy

Passive redundancy, assumes a number of replicas for the purpose of masking single or multiple failures. Fault detection and notification of the malfunction of a replica are often based on the assumption that only one replica can fail at a time. A good example of this type of redundancy is TMR (see Figure 66.1), in which three independent modules are used together with a voter. The voter provides the output on the basis of the majority of votes of the individual modules. This architecture can tolerate a single failure, failing silently, and at the same time provides an early warning on the "health" of the participating modules.

One basic prerequisite for TMR is that the module and voter reliabilities must be at least 0.75 and 0.889, respectively. NMR, an extension of this approach, can tolerate multiple failures. Obviously, TMR and NMR are quite costly, but more importantly, they rely on the proper function of the voter, which in the "chain" example, possibly adds a weak link in the chain. In general, depending on the particular functions of the modules, the voter can be a very simple or a very complex system. In applying TMR, NMR or any other passive redundancy technique (*e.g.*, quadded logic, *etc.*)

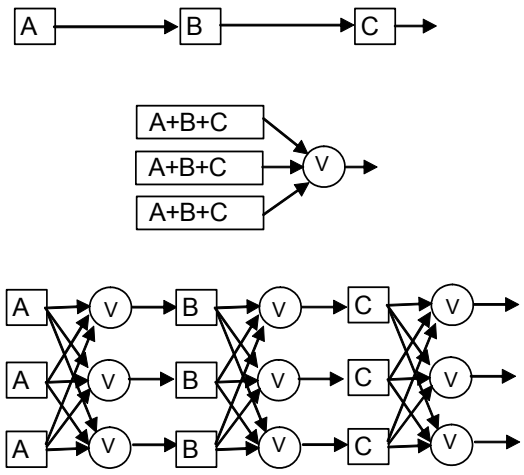

Figure 66.1. Application of triple modular redundancy at the system and subsystem levels

one has to consider very carefully factors such as the level of system modularization, the module complexity, and the voter complexity at the specific module level.

66.2.2 Dynamic and Hybrid Techniques

While in passive redundancy any failed modules still participate in the decision making of system's output, in active or dynamic redundancy, fault tolerance is achieved by having one main module providing the required service and a number of spares, which may be online or offline (dynamic sparing). Upon the main module failure, the first standby undertakes its duties becoming the main and so on. Failed modules no longer play any role in the system. In general, to implement this fault tolerant strategy the basic steps involve fault detection, reconfiguration, and recovery. In computing systems fault detection can be carried out, to some extent, by running diagnostics (see Figure 66.2), but the usual approach is by duplication and comparison (see Figure 66.3). Reconfiguration aims at isolating or replacing a failed unit and recovery, when needed, *i.e.*, at eliminating the effects of errors. In general, dynamic redundancy can be applied at various system levels, but one major consideration on making such a decision is

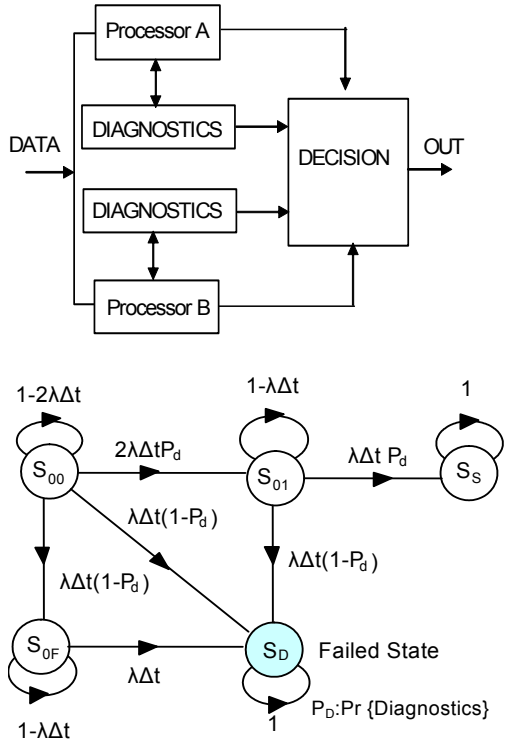

Figure 66.2. Processor duplication with independent self-diagnostics

the complexity of the fault detection and reconfiguration circuitry.

A more fault tolerant distributed approach in computing systems is to provide full reconfiguration at the processor level as well as at the memory module level (Figure 66.4); the system is configured with two CPUs, one active and one backup, and two parity based memory modules.

Each memory "write" by the active CPU is made to both memory modules and on every memory "read" the output of both memory modules is compared. If a mismatch is detected, the processor believes the memory module with the correct parity. The other memory module is marked and a fault trigger is generated. The backup processor monitors the health of the active, so that if a fault is detected in the active processor, the standby takes over both memory modules.

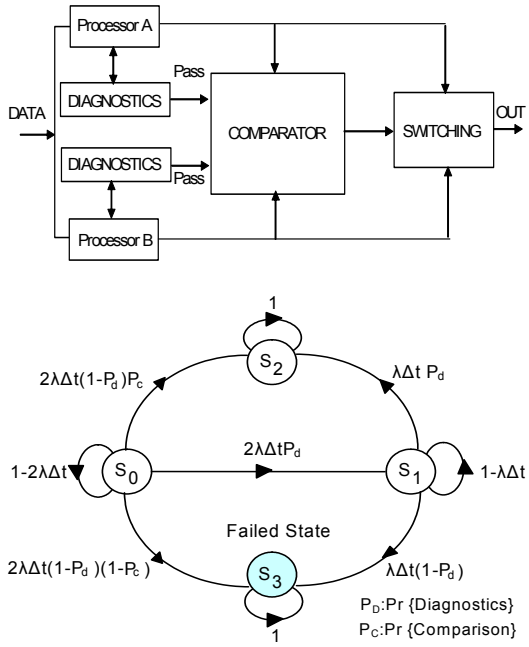

Figure 66.3. Processor duplication with self-diagnostics followed by comparison

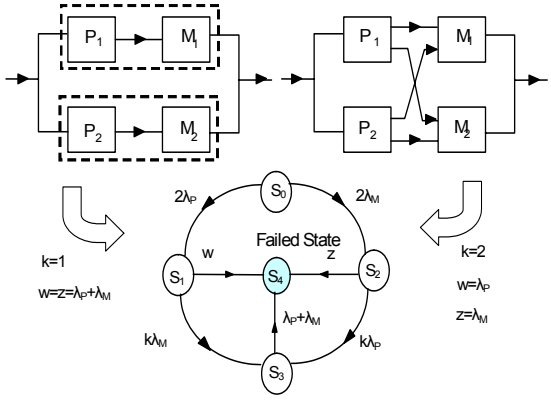

Figure 66.4. A duplex processor-memory system with reconfiguration at the memory module level

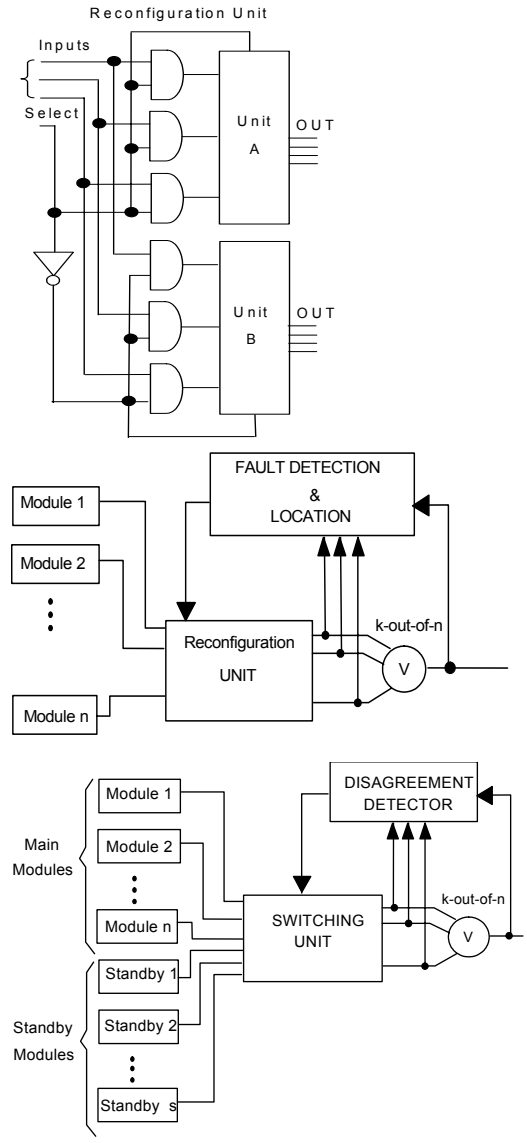

Figure 66.5. Fault tolerant implementations by hybrid redundancy

Hybrid redundancy (Figure 66.5) combines fault masking and dynamic redundancy to provide a high fault tolerant configuration, usually at much higher cost; fault masking prevents the system from delivering an incorrect service and dynamic redundancy restores its capability for fault masking by replacing any faulty units.

66.2.3 Information Redundancy

Information redundancy provides fault tolerance by replicating or coding data. Both approaches require large amounts of extra hardware resources and most often, in critical applications, a combination of both is used. Encoding/decoding [14] allows the detection or correction of information that is retrieved from storage or transmitted *via* communication links. Both processes use the rules of a code to convert data words to codewords and *vice versa*. Some examples of data coding are the parity codes, the linear codes, the cyclic codes, and the arithmetic codes. In general, three techniques are usually employed to provide error detection/ correction in memories:

Coding: Parity codes are widely used in large memory systems to provide error detection since they are fast and inexpensive. SEC-DED (single error correction/double error detection) Hamming codes, however, have become more popular because of their error correcting capabilities. Other codes have also been proposed, most of which are designed to handle specific types of multiple errors.

Replication: The use of multiple memory copies results in highly reliable systems, but significantly increases the hardware overhead. While duplication provides fast on-line error detection, triplication (with voting) provides efficient multiple error correction. This may become more popular if memory prices continue to decrease.

Re-addressing: This technique is based on permuting the memory addresses and/or data lines between the memory arrays and the CPU to eliminate errors. Spare memory units may be used to replace defective elements. Complex control circuits are usually needed to accomplish reconfiguration. Error detection and fault diagnosis circuits, to distinguish hard and soft errors, are also required. In order to eliminate soft errors some degree of redundancy must be introduced either in hardware or software or both. Some work in recent years has addressed this subject to some extent. In high-speed memories the most commonly used codes are the Hamming SEC and SEC-DED codes. In addition to SEC-DED, high data integrity implementations can also afford memory duplication, as the one shown in Figure 66.6.

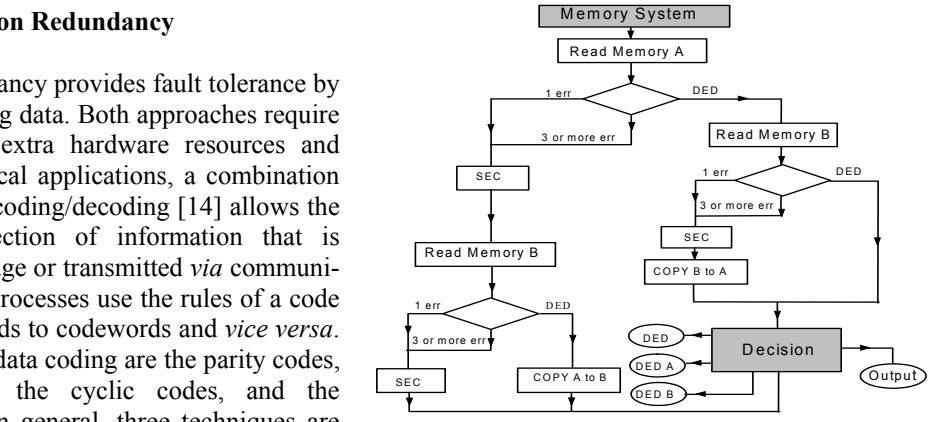

Figure 66.6. Duplex RAM with SEC-DED encoding/decoding

66.3 Software FT: Learning from Hardware

Despite the fact that most real time systems focus on hardware fault tolerance, the contribution of software errors (bugs) to system outages remains great. Software failures, as they are not due to wearing out processes but to design or data errors, are receiving increased attention [15]. Such failures occur when software is called to work in an environment for which it was not designed or tested. Software fault tolerance, as it happens in hardware, is achieved by the introduction of some kind of software redundancy. This redundancy covers errors occurring during software development, in improperly translating or implementing the algorithm into a programming language. As in hardware, software structuring is a prerequisite for effectively handling the software complexity. For instance, N-tier systems use hardware and software resources dynamically to allow each layer of a component part to be developed and managed independently. Thus, a computer application can be divided into logical layers (tiers) with embedded fault tolerance mechanisms to give the ability to recover from an error. Considerations, such as the extent of system decomposition and the layers to be diversified must be carefully examined. It can

be stated, but it is not always true, that smaller components facilitate the fault handling actions, such as confinement, and the larger components facilitate the diversity. As a single fault may affect many redundant functions or even the selection mechanism of these functions, making impossible for the system to recover, it is imperative to secure independence at all levels of software development. Currently, various fault injection techniques and tools are used to evaluate software performance, by simulating faults during the execution of the code under test.

66.3.1 Basic Issues: Diversity and Redundancy

Computer software is one example where design and specification errors are particularly relevant. Traditional fault tolerant hardware techniques, dealing mainly with permanent or transient hard failures, have inspired many existing software strategies. However, unless diversity is used, redundancy alone is not enough for tolerating software design faults [16],[17]. For a redundant configuration with two computer systems with identical software, there will not be any tolerance to single points of failure since the software will have common mode failures. Diverse software involves separate software implementations with the aim of achieving independence at the level of software faults. Assuming that this requirement is fulfilled, it will be most unlikely to have the simultaneous failure of two or more software versions for all sets of input data.

Many software faults are also data-dependent, in the sense that they will never occur unless a specific sequence of data inputs is encountered. This has led to the development of data diverse fault tolerant techniques for complementing the design diverse techniques [18]. In overall, fault tolerant software must cope with both design and data-dependent faults. Fault tolerant software implies redundant diverse software mechanisms for detecting errors and limiting their propagation. It also requires a means of rolling back the system to such a point in time before the fault was encountered and restoring all parts of the system that have been affected. As in hardware there exist numerous possibilities for the amount and level of software redundancy allocation. In hardware, redundancy is allocated at the component, subsystem and the system level. In analogy, redundancy in software is usually applied to the procedure, the process or to the complete software level. This, in the "chain of links" analogy, is a strengthening an individual link or an ensample of adjacent links or as introducing an additional chain. Deciding on the level of redundancy allocation has much to do with the difficulty of introducing redundancy at a specific level. For instance, it is much more complex to make a logic circuit fault tolerant by allocating redundancy at the gate or chip level than by replicating it. In analogy to this, one has to consider the amount of additional software complexity required by the various redundancy allocation levels.

66.3.2 Space and Time Redundancy

Unlike hardware, in order for the software to perform the required functions it must always be accompanied by hardware. Digital hardware, such as that of a computing system, is the underline framework of software and it plays a very important role in the development of fault tolerant software mechanisms. Upon program execution the computer can be instructed to hold results that are more likely to be incorrect. Assuming that the cause of the incorrect results is a transient error, it is expected that a second trial, *i.e.*, the use of time redundancy, can render the correct results. Time redundancy is fairly common in software and usually is accompanied by space redundancy, *i.e.*, diverse versions of software. Space redundancy provides separate diverse copies of software or data and time redundancy allows the recomputation by shifting the information in time.

Fault detection is a very basic consideration in providing fault tolerance. Neither space nor time redundancy can be introduced in software without having first detected that an error has occurred. Software failure is detected by watchdog and/or health messages. As a consequence, processor automatically reboots from a ROM resident image or restarts the offending tasks without needing an operating system reboot. A watchdog timer [19], implemented in hardware or software, is a widely

used means for checking proper system function. A timeout signals that some time constrain has been violated and a corrective action is required. This corrective action can take the form of retry or abort. The choice between these two depends on the criticality of the encountered function, but most often abort follows the unsuccessful repetition of retry, a number of times. Fault detection in many software techniques is accomplished by some type of an acceptance test.

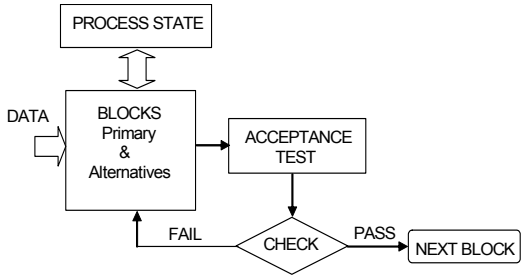

Figure 66.7. Backward error recovery

In general, software fault tolerance is based on dynamic and masking redundancy. In dynamic redundancy, several components are used, but only one is active at any time. In the case of an error, the active component is replaced by a spare component. In masking redundancy, all components are active but the effects of single or multiple errors are masked. Traditional techniques, such as the recovery block (RB) and the N-version programming (NVP), for tolerating software design faults relate to passive and active dynamic redundancy. One difference is that the first of these is usually applied at the subsystem (software module) level while the other at the software system level. In RB there exist many software implementations, each decomposed into a number of blocks. As in standby sparing, only one implementation, starting with the first block of the primary, is used at a time. This technique (Figure 66.7), uses acceptance tests and checkpointing for accomplishing backward recovery; upon the detection of a fault in a block the state of the process is restored to its previous state and an alternative is executed. Checkpointing, at the cost of system performance, can be introduced not only at the initial process state, but also in other intermediate states. Again, the implementation of RB rises the question of redundancy allocation and the extent of software modularization. One possibility for increasing the effectiveness of RB is to employ, instead of cold, "hot" alternatives, or in terms of hardware terminology, a modular hot standby system. This, in digital system terms, leads to the parallel execution of the alternative versions.

Data diversity techniques, such as retry blocks and N-copy programming, can also be used to improve the efficiency of check pointing. NVP (Figure 66.8), in analogy to static NMR redundancy in hardware, employs a number of diverse versions of software and a selection mechanism (voter). These versions are executed in parallel and the selection mechanism decides for the output. The effectiveness of NVP greatly depends on the degree of independence of the software versions. An improvement of NVP that allows voting on a subset of versions is the $t/(n-1)$-variant programming. Adaptive NVP introduces weighting factors in the versions for the purpose of adaptively influencing the voting.

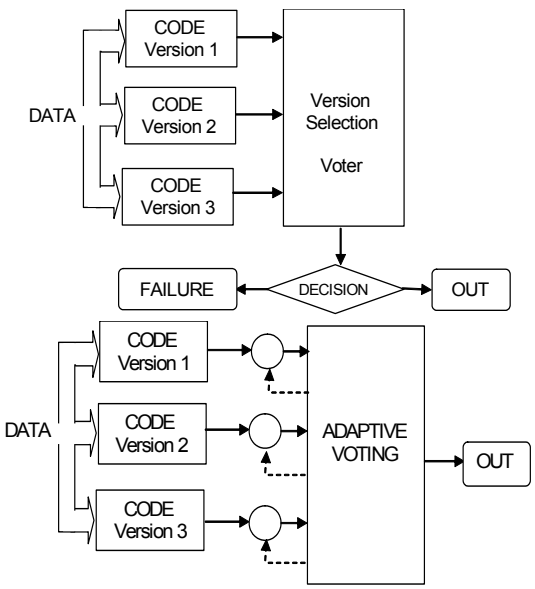

Figure 66.8. N-version programming (three levels) and adaptive NVP

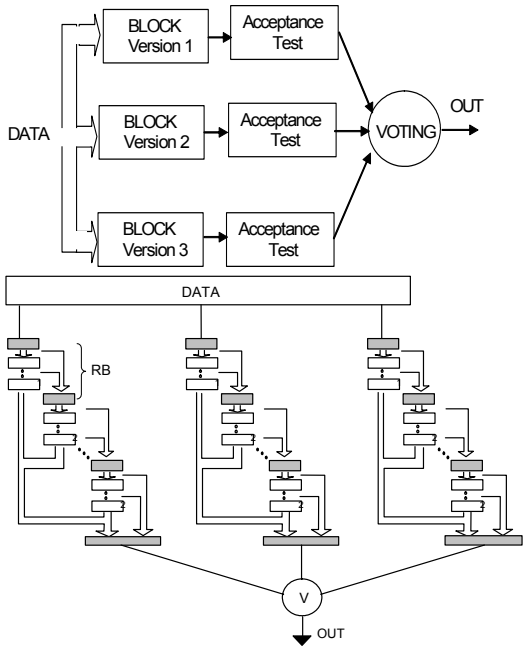

Figure 66.9. N-self-checking programming

Numerous voting techniques, such as majority voting, fuzzy voting, median and average voting, and so on, are used for selecting the correct output from the different software versions. It must be pointed out that the voter complexity may have a severe impact on performance and reliability. The combination of RB and NVP into the N-self-checking programming technique (Figure 66.9), though more complicated, provides a means for achieving fault tolerance in critical applications. A cost effective technique capable of tolerating arbitrary replica behavior is the Byzantine fault tolerance (BFT) in which replicas can be repaired periodically, on the basis of an abstract view of the states of correct replicas. Byzantine fault tolerance requires a minimum of $3f+1$ replicas to tolerate f Byzantine faults and is designed to protect against arbitrary behavior including software bugs and security violations. It can function correctly even if a number of its replicas act arbitrarily and not according to specification.

Software fault tolerance techniques based on RB and NVP are not cost effective compared to algorithmic-based techniques (ABFT) and assertion and sanity-based techniques (ASBT) [20]. In ABFT, fault tolerance is achieved by embedding tailored software for checking and possibly correcting the computations. The technique is not applicable to arbitrary programs, but it is very effective in regular data structures. Assertions provide an error detection mechanism by introducing logical statements or by specifying few sanity checks within a program. A prerequisite for its application is the specific knowledge of the algorithm and program. This technique is very simple, does not require any hardware and does not degrade performance. To deal with software "aging" a technique known as rejuvenation [21] is often used. Software rejuvenation is a proactive fault management technique aimed at cleaning up the system internal state to prevent the occurrence of more severe crash failures in the future.

66.4 Global Fault Tolerance Issues

Today, various services are developed over multiple interconnected networks with different technologies and infrastructures. The great interest in the use of the Internet platform for providing business-to-business (B2B) services, has been followed by a similar interest in the area of global computing with particular emphasis in security and fault tolerance. As local and global environment characteristics are different, there is a variety of approaches for developing fault tolerant applications [22],[23]. Generally, in such a complex multinetwork environment, there are too many opportunities for failures. Traditionally, such failures were mainly due to hardware malfunctions in a node, ranging from processor or memory failures to network interface or switch and router failures. Today, other types of possible failures/attacks exist, which could remove a large number of nodes from the system or could affect severely its performance. Also, fault tolerance becomes much more difficult in multilayered architectures where software/protocol errors and attacks can propagate from one network to another.

There are numerous failure modes in computing systems and applications, giving rise to a number of various complexity faulty models for

the assessment of their fault tolerance attributes. A fault is a deviation from the expected behavior and may be due, among other things, to hardware, software and communication errors. A fairly general classification for faults in computer networks can be based on the output or response received by a faulty node. Assuming that some output must be received, the lack of such an output may be due to a crash failure or to a communication link failure or to the combination of both. This fault may further be classified in more detail, as transient, intermittent, timing, omission and so on. Assuming, however, that upon its failure a processor continues to run exhibiting arbitrary behavior, a more serious fault condition, known as the Byzantine failure, occurs. That is, fault free computing nodes cannot detect any failed nodes.

66.4.1 Fault Tolerant Computer Networks

Many high availability implementations in the computer internetworking are based on active replication solutions. A secondary idle node (stanby) is used for the purpose of monitoring a primary node (active). It undertakes its duties in the case of primary node failure. Since standby has to take over under fault conditions, it must be synchronized with the active node. This synchronization can be achieved in various ways, each having different hardware and performance costs. For instance, in bus cycle level synchronization the active and the standby nodes are locked at processor bus cycle level. The standby watches each processor instruction that is performed by the active and it performs the same instruction in the next bus cycle in order to compare its output with that of the active unit. Clearly, this approach introduces wait states in bus cycle execution and lowers the overall performance. Active replication can also be applied for multiple backup nodes for the primary. All nodes process the same inputs generating results that are compared using a Byzantine algorithm. Nodes producing incorrect output beyond a threshold number of times, are declared as faulty and ignored. Back up servers work poorly with Byzantine faults since the backup will be receiving erroneous data without being able to recognize them as wrong.

The standby solution does not take advantage of the processing power of the standby nodes and offers no scalability. To increase reliability and performance, the process of computer clustering is widely used; this additionally allows expandability, which leads to computer power upgrade and the preservation of the existing computer system investment. While many implementations use clustering to build a more powerful virtual server, at the same time they provide a higher level of fault tolerance. Resources are shared among multiple systems by running some requests on one physical server and other requests on another server. The decision on which server handles the requests is taken by appropriate management software. In the case of a server failure, a request is rerouted to the next available server (Figure 66.10). This, in the "chain of links" analogy is as strengthening an individual link without the need of introducing additional links. In some critical cases, it may even be necessary to allow several such links to be consolidated into one. Clustering is also used in Web services to maintain continuous access and provide multiple connections. Clusters, as they have redundant nodes, can tolerate single and multiple failures and at the same time provide high performance by splitting a computational task across many different nodes. Nodes, in computer clusters are centrally managed and usually communicate through fast LANs. Memory storage is shared among all nodes. Grid clusters, are closely related to cluster computing but the workstations involved operate more like a computing utility rather than like a single computer; grids manage the allocation of jobs that are performed independently.

66.4.2 Network Protocol-based Fault Tolerance

The basic functionality of a network is to allow communication among its members by the use of certain rules, the protocols [24],[25]. In recent years, extensive studies have been carried out on unicast and multicast routing protocols. Interconnected networks are made up of numerous components such as fiber cables, interfaces, hubs, switches, routers, transceivers, and so on. The

design of network fault tolerance has to take into account many considerations, among which network performance is of paramount importance.

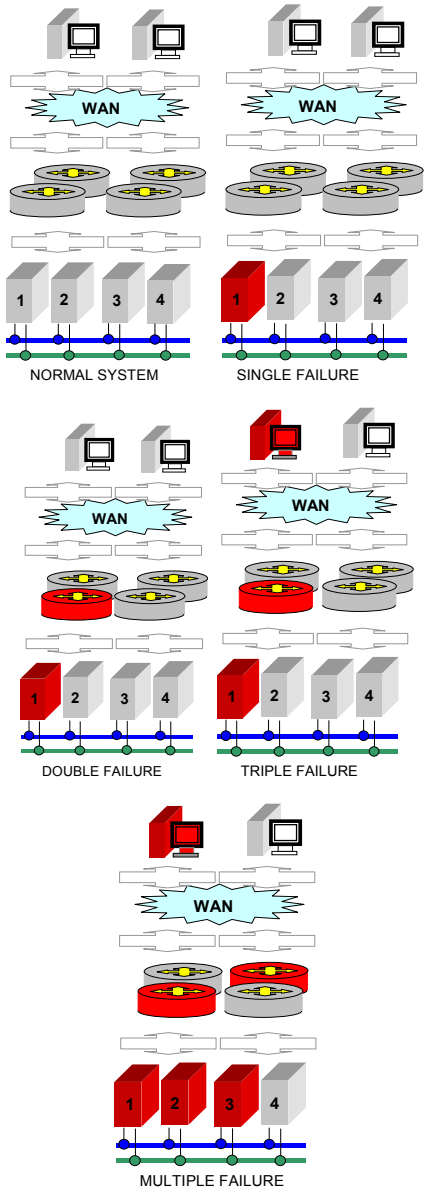

Figure 66.10. Fault tolerant system with active replication at the subsystem level

Failures in networks, usually cause the interruption of the communication within or between sub networks or lead to a degraded performance. The communication path between a client and a server contains networking devices that can be viewed as links in a chain. The longer the chain, the higher the probability of path failure. In the Internet infrastructure the weak links are single points of failure and performance bottlenecks. The latter are due to network elements that do not have enough resources to handle the amount of traffic they receive. Deciding on the network infrastructure and the amount and the level of redundancy allocation is becoming a major consideration for achieving fault tolerance. Within this context, different routing and router protocols are used.

Unicast link state routing protocols are used to calculate the best working route to destination, by acquiring knowledge on any faulty links. One example is the Spanning Tree Protocol (STP), widely used in Ethernet LANs, working in a switched/bridged environment; bridges send periodically a “hello” packet and listen from others. If a bridge has not heard any packets, and the timeout has been reached, the bridge calculates a new route. Virtual LAN's can have multiple STP processes running, providing fault tolerance to link failures and traffic load balancing. With links in their intact state, different routes can be assigned to the same destination. If one link fails, the traffic in that link is moved to some other link. The Open Shortest Path First (OSPF) protocol, very popular in Internet, provides fault tolerance in network backbone. Similarly, Cisco’s Enhanced Interior Gateway Protocol (EIGRP), determines link distances on the basis of available bandwidth, delay, load utilization, and link status. Unicast protocols can be used to implement multicast communications, but they consume much bandwidth and cause longer delays. So far many multicast communications routing protocols have been developed that are based on source tree and shared tree routing.

Data packets travel between two hosts through a number of routers, located at gateways. Their role is to find the best path to route packets. Routers, apart from dedicated hardware, contain various software components to implement a variety of functions such as, virtual private networks (VPN), routing protocols, network address translations, dynamic address

allocation and firewalls. Router protocols [26],[27] do not participate in routing but they provide fault tolerant router interface to clients by the collection of the network's topological data through the exchange of adjacent link information and the use of this information for deciding on the shortest path from source to destination or the (re)construction of its routing table. The concept of virtual routers assumes a group of routers with a virtual IP address for the group apart from the IP addresses of its group members. The highest priority member in a group is the active router, the others being acting as standby routers. Each router monitors the other router's health by transmitting "hello" packets (advertisements). Switchover is automatic and rapid and takes place upon the failure of a router, which is revealed by the absence of its packet transmissions. In the case of an active router failure the high priority standby member assumes its duties. In Cisco's Hot Standby Router Protocol (HSRP), the network load is shared among all the group routers, until a failure occurs. HSRP, supported on Ethernet, Fast Ethernet, Token Ring, FDDI, and ATM, is a solution that allows network topology changes to be transparent to the host. This is based on the exchange of multicast messages that advertise priority among similarly configured routers and typically host rerouting takes approximately 10 seconds. Similar to this is the Virtual Router Redundancy Protocol (VRRP) in which only the standby routers monitor the health of the active router. Multigroup HSRP (MHSRP) equipped with adequate hardware, allows a single router interface to participate to more than one hot standby group.

By considering the contribution of link failures to network low performance and unavailability it can be stated that this of WAN links is critical because they form the backbone network connecting diverse sites. Routers can automatically compensate for failed WAN links through routing algorithms. By supporting load balancing, duplication of a WAN link (Figure 66.11(1)) not only provides a backup link but also leads to a better performance as a result of the increased link bandwidth. Network load balancing is a different flavor of load sharing. However, other alternatives have to be considered as for example, to add a link between the front routers (Figure 66.11 (2)). This offsets the effect of a failure in any single link and improves performance due to the distributed functionality. In general, meshed networks provide alternative paths, allowing the router to compensate for link failures. Whereas, in either case, the additional link improves fault tolerance and performance this cannot be generalized. Other possibilities for improving fault tolerance at the subnetwok level are also possible. One of these is at the level of an Ethernet LAN by adding another active

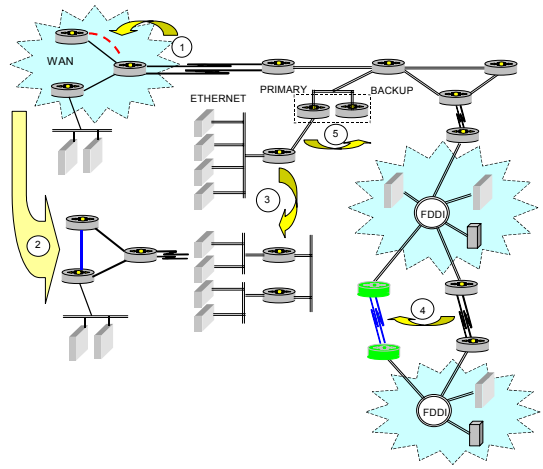

Figure 66.11. Internetworking fault tolerance

router (Figure 66.11(3)). This, doubles the cost of network connectivity for each end station, and it is only practical when full redundancy is required. Typically, when dual routers are used (Figure 66.11 (4, 5)), the backup routers are not used unless the primary router fails.

Typical fault tolerant internetworking configurations contain multiple routers connecting LANs. As mentioned above, after a link failure, routing protocols undertake the task to find new paths for maintaining network connectivity and/or an acceptable performance. However, the LANs performance characteristics are limited by the speed at which their hosts can detect a topology update. Also, routers add new vulnerable "links" in the chain of paths, which finally may cause adverse effects on performance and reliability. As fault tolerant networks are designed to perform even in the presence of failures, their performance can be evaluated by taking into account the consequences

of fault handling protocols and actions. In some cases the fault handling actions can result in a degraded performance but in others they may be inefficient for handling severe faults or too slow for meeting performance requirements. Algorithms in routing protocols have to support routes of arbitrary length, from source to destination, and to this end, they require different convergence time. IP routing protocols, as they are often based on distance vector strategies, have the drawback that often the required convergence time is too long. Overlay networks (Figure 66.12), with virtual links connecting two edge nodes of the physical network, can alleviate this problem by making many nodes that are many hops apart to appear as if they are directly connected.

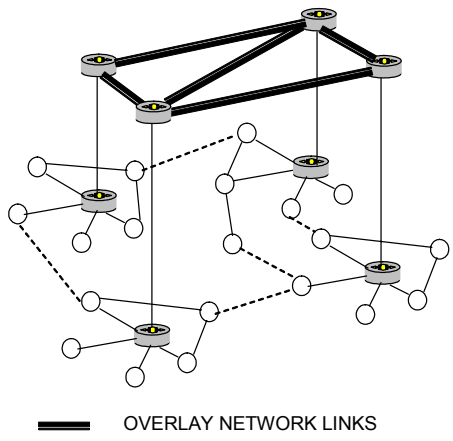

Figure 66.12. Virtual overlay network links with application level routers on top of the physical network

66.4.3 Fault Tolerance Management

There are many opportunities for hardware/software failures in a network node, starting from the failure of a simple network interface up to the failure of a processor or the hang of software. Fault tolerance problems arise because application components may eventually fail due to hardware failures, operator mistakes or design faults. Traditionally, fault tolerance was introduced by adding extra hardware resources. The most common means of providing fault tolerance is by passive and active replication. Hardware fault tolerance includes redundant communications, replicated processors, additional memory, and redundant power supplies. The hang of software can result from a bug in the application running at the node or even a hardware fault. The usual approach for handling application failures is to periodically checkpoint the computational state of the application so that it can be restored in the event of a system failure. In many situations, common cause failures can remove a large number of nodes causing the applications running on the affected nodes to crash or produce incorrect results. By managing the hardware resources, the computer increases its ability to continue its operation. High availability computing cluster implementations attempt to manage the redundancy inherent in a cluster, by eliminating single points of failure. Clustering also provides load balancing by distributing the load to a number of identical back end servers, so that the overall throughput is multiplied. To fail over, the healthy nodes take over the traffic from any failed node without interrupting the traffic flow. The management of the available resources in the cluster's nodes is a critical responsibility and is carried out in the centralized management nodes. Centralized management nodes handle all node monitoring responsibilities and job allocation by identifying faults and initiating the necessary fault handing actions, depending on the cluster configuration.

A computer cluster can be configured to be symmetrical or asymmetrical, on the basis of the roles of the individual servers. In the symmetrical type, as in the three-server cluster of Figure 66.13, all servers have the same role and the only difference is in the sequence with which each server undertakes the role of another. That is, in the case of the active server failure, the first backup server undertakes its duties and in the case of a backup server failure the next priority backup assumes its duties. Such clusters are not used in critical applications and, therefore, no real time synchronization among their members is required. In the asymmetrical cluster type, all servers are active and their roles are different. In order for a server to be able to undertake the role of another server, full synchronization is required. Such clusters have a common memory, accessed from all

active servers, so that the memory content of each server is synchronized with that in the common memory. Node management tools facilitate the processes of role allocation to the servers and distinguish on a logical layer the role of each server in a cluster. These roles can change automatically according to the system requirements and the predefined processes:

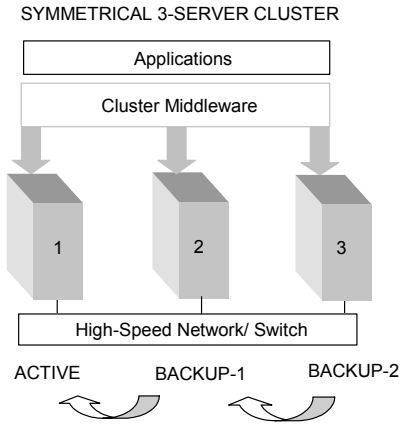

Figure 66.13. Symmetrical three-server cluster

Normal: A normal server can support an active application and also act as "live" for another application. In a data base management system, a normal server can manage actively the database of a particular service and can also have the role of "live" for other services. Short "alive" messages monitor its health by other servers.

Live: A live server is in a state to undertake the duties of the normal server, as soon as a problem with the normal server is revealed. It can also act as the normal server in another application. Within its duties are the synchronization with the normal server, the monitoring of the health of the normal server, the changeover to normal, and the reporting to other nodes about its new role.

Stand-by: A stand-by server is synchronized with the live server and monitors its health. It can also act as backup for another application. Among its duties is the synchronization with the backup so that the backup can undertake its duties. In this case it reports to all other nodes about its new duties.

Backup: A backup server for an application can replace a stand-by server and can also act as stand-by for another application. In the case of its promotion to standby, it reports about its new role to all other nodes.

Many present day powerful servers have many processors supporting micropartitioning and dynamic logical partitioning with complete independence among partitions. By proper monitoring, a faulty processor is automatically disabled and replaced with the backup without any interruption of the system operation (Figure 66.14).

Managing the fault tolerance in distributed computing systems [28] is a major issue, presenting a challenge to system designers. A

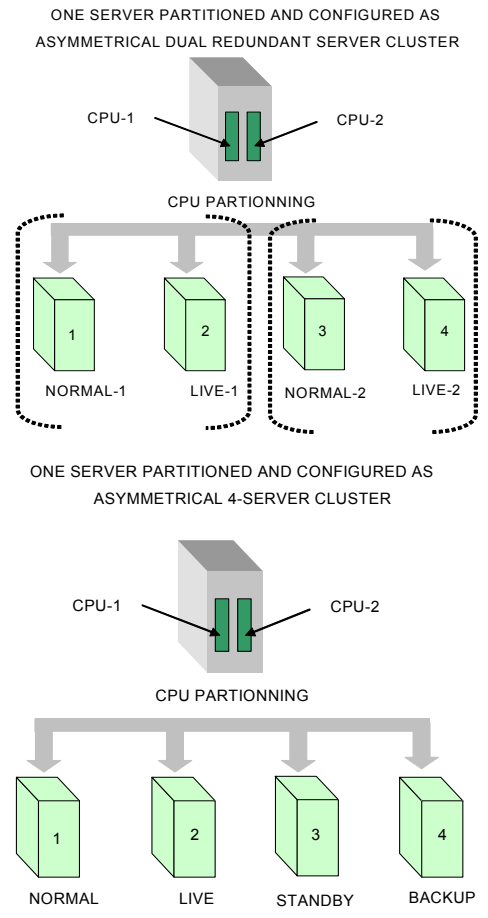

Figure 66.14. Multiprocessor server partitioned and configured as a dual redundant server and as an asymmetrical four-server cluster

failure of a component in the system may result from a fault in the component itself or from the propagation of a fault in another part in the system. Thus, failures in the system depend on the global execution state of the system, *i.e.*, the combined states of all the components in the system. A fault tolerant distributed system employs a distributed collection of processes such that a corruption of one process is not affecting the functionality of the whole system. In distributed systems fault tolerance is also achieved by replicating critical components. Replicas handle faults as well as the system workload. While in a local system synchronization is not a problem, a distributed system comprises a set of autonomous machines (see Figure 66.15), each with its own clock. Computing nodes exchange messages *via* communication links. The synchronization primitives, which are easily implemented in a local system, are much more complicated. Algorithms for asynchronous systems are prone to malfunction if the imposed timing bounds, on message transmission and response times, are violated. In a local system, a critical region is used to control access to a shared resource, so that only one thread can access that resource concurrently.

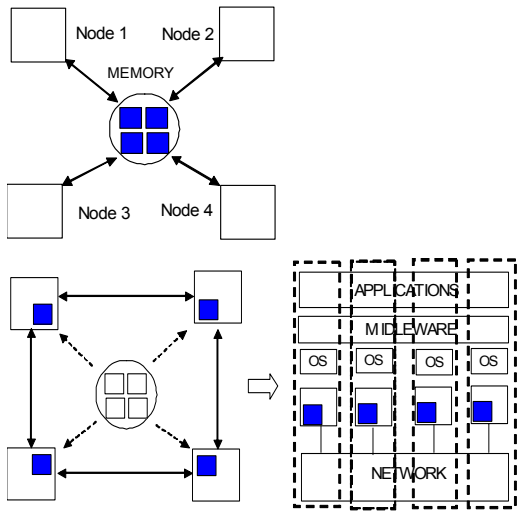

Figure 66.15. Migration of shared memory: local system *vs*. distributed system

Implementing a distributed system requires that all nodes need to have consensus on their exact state and make collective decisions without conflicts. As long as the state between the nodes is consistent, the system can successfully handle a failure. Each node can establish a checkpoint, but it is not possible to establish a checkpoint of all the nodes simultaneously. Thus, synchronization between group members is essential in order to detect a faulty process and to reach a consistent state. In distributed checkpointing [29] all processes cooperate to establish their local checkpoints, so that their ensemble represents a consistent global state. A lack of synchronization can lead to an uncontrolled rollback to the state at the start of execution, known as domino effect. Consistency is often achieved by group membership negotiated protocols, which ensure that all nodes share a common view of the system configuration. Achieving agreement on group membership is an essential prerequisite for reliable group communication. Despite the numerous algorithms and techniques developed to confront failures, the area of fault tolerant distributed computing presents many challenging problems. Byzantine fault tolerance has recently been shown to be practical for the development of certain classes of client-server, distributed applications; however, more research is needed for incorporating it into multitier distributed applications. Centralized applications are generally perceived to be more reliable than distributed applications.

Most real time systems comprise software running in parallel across multiple processors, implying that data is also distributed. Due to a number of reasons, such as software bugs and processor reboot, data may become inconsistent. The RAID technology improves performance and provides a fault tolerant solution of storing data by the use of two or more disks. This solution is based on redundancy management of disk space and can be implemented by hardware or software. The hardware solution has advantages over the software as it does not occupy host's system memory, it is not dependent on server CPU performance and load, and it does not consume CPU cycles. Also, hardware arrays have more fault tolerance, as they are not dependent on software that can potentially be unavailable due to a faulty disk. RAID systems appear as one drive and can be configured in

different ways each with different performance and fault tolerant attributes. Disk mirroring, used in RAID level 1 (Figure 66.16), writes simultaneously all data to two hard disks, in order to provide protection against the failure of either of the disks. In the event of a drive failure, a copy of the data is taken from the other. The controller must be able to perform two concurrent separate reads *per* mirrored pair.

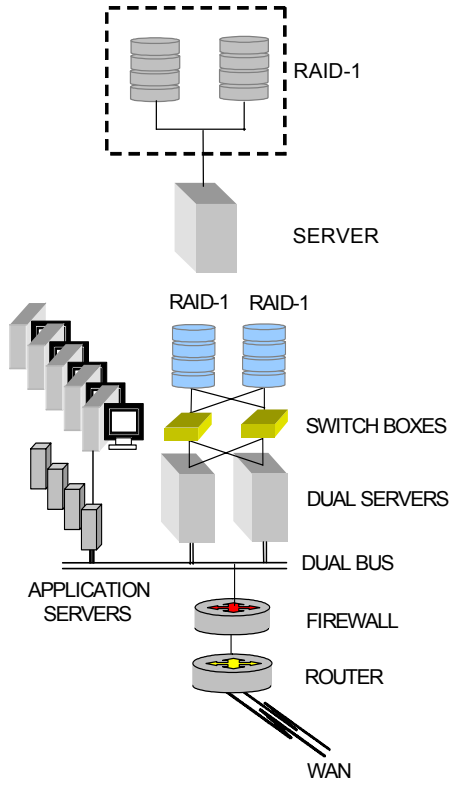

Figure 66.16. Server and fault tolerant dual central system supported with RAID-1

Disk duplexing improves fault tolerance, by the use of more than one controller to control the mirrored hard drives. To maximize throughput of the storage system the I/O load is balanced across all drives, so that drives can be, as much as possible, equally busy. A very good load balancing is achieved by striping, *i.e.*, by partitioning the disk space into stripes that are written alternatively into different disks. Stripes can be as small as one sector and as large as several megabytes; to optimize performance the size of stripes should be large enough to accommodate the size of records. In such a case, I/O operations can be performed on different drives and the data will be evenly distributed.

In RAID-2 all stripes are stored in different disk drives with each data word having its ECC word (Hamming) on separate disks. On read operation, the ECC code can correct "on the fly" single bit errors. RAID-3, 4, and 5 employ disk stripping with EEC parity information stored on one or more drives. RAID 0+1 (or RAID 10), implemented as a striped array whose segments are RAID-1 arrays, has the same fault tolerance as RAID-1 and it is recommended for its high performance and fault tolerance.

66.5 Performance Evaluation: A RAM Case Study

In recent years, there has been a noticeable activity in relation to performability and performance analyses in specific applications [30]–[32]. These applications mainly refer to the computer-based technology such as microprocessors, random access memories, multiprocessor systems, and mass storage systems. Evaluating or predicting performance overheads due to the fault tolerance mechanisms is not an easy task, particularly if performance in the presence of faults is degradable.

Assessing the performance of fault tolerance mechanisms can be accomplished by developing system models that adequately describe their complete fault handling functionality and by fault injection. System modeling relies on the development of a formal mathematical representation of the complete system and its functionality. Fault injection is used for fault removal during the system building and aims to remove design and implementation deficiencies, and fault forecasting, after the system's complete implementation, to assess the performance of the system's fault tolerant mechanism. Figure 66.17 shows the hardware architecture and modeling of a duplex RAM memory system with SEC and memory scrubbing for eliminating soft errors [33]. Soft errors are due

to external events, such as noise and alpha particles that do not cause permanent memory damage, but may cause incorrect data or code execution. Scrubbing [34],[35] offers an effective method to recover from soft errors, by reading and rewriting the memory content at regular time intervals. In general MTTF is accepted as an appropriate metric for system reliability. The proper selection of the scrubbing interval T_S has a key role in achieving an acceptable MTTF (see Figure 66.18).

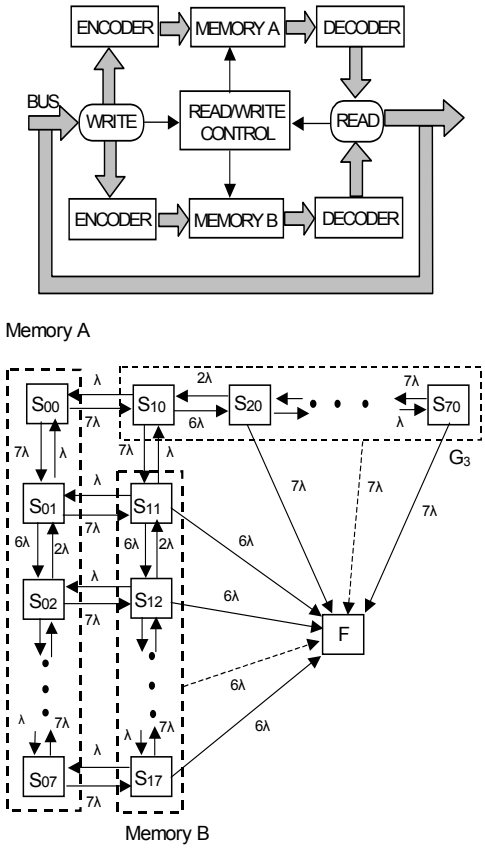

Figure 66.17. Duplex memory system modeling with SEC and memory scrubbing

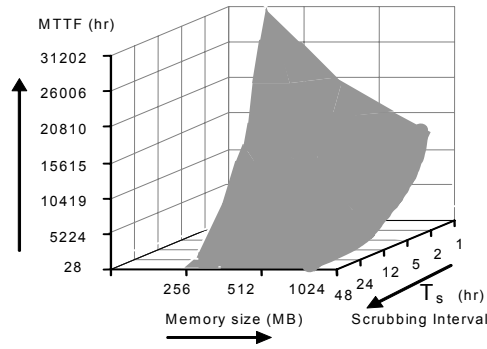

Figure 66.18. Performance of a duplex memory system with SEC and memory scrubbing

In a large memory system an enormous number of complex fault patterns can developed during normal system operation, making the performance analysis very time consuming. A performance assessment of the general architecture of SEC-DED self testing and repairing (STAR)-RAM [36]–[38] (Figure 66.19) is facilitated using the state-merging and assorted random testing (SMART) approach [36], which is a Monte Carlo-based simulation that deals with groups of elements involving huge number of components. The system is modeled in terms of a collection of group state vectors, where each group vector represents a series of group states in the presence of consecutive fault hits, and contains one or more dummy states to trap a group and/or system failure

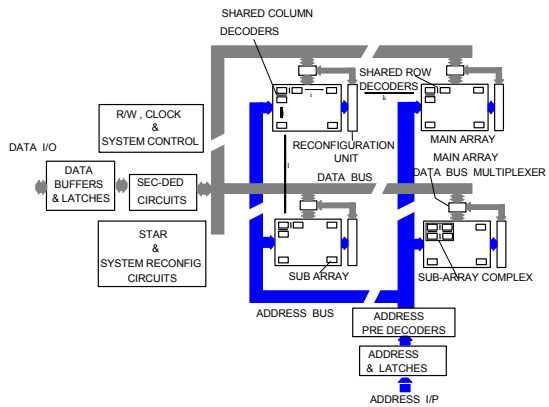

Figure 66.19. Architecture of STAR-RAM

state. A single group vector is generated for one of all identical system groups and is then linked to all these groups resulting in a substantial reduction in the total number of generated system vectors. A random fault pattern is then generated in each experiment and is mapped to the currently simulated group vector. The vector is examined to determine the group condition and its impact on the subsequent system state to decide whether it is correctable or not.

The discrimination between soft and hard faults is based on the fact that memory locations containing hardware faults cannot correctly store the applied test patterns, in opposition to those locations containing soft faults. Upon error detection during a normal memory read cycle, BIST circuits are triggered for repairing the currently accessed memory location. The algorithm first copies the contents of the tested location to the scratch memory so that data can later be restored, it then applies four subsequent test patterns with interchanged adjacent bit values for detecting all cell stuck-at faults and word single coupling faults. Finally, the repair of hard-failed locations is carried out. When a memory byte is verified to have a hard fault, the first available spare is assigned the address of this byte. Any attempt to access this location is then sent to the allocated spare by redirecting the memory data-bus. If, however, the fault is determined to be a soft error, the data is corrected, rewritten to the suspected location, and is sent to the host. This prevents the build up of soft errors in the memory, providing highest data reliability and error free operation of the system. The STAR engine can be configured so that BIST is triggered upon either single or double error detection. Single error triggering offers better data reliability by preventing accumulation of soft and hard errors, but it results in a degraded performance (slower memory access) because each time an error is detected a full test cycle is executed. In contrast, double error BIST triggering yields faster access when single errors are detected but reduces data reliability as double errors cannot be recovered. In both cases however, the memory system hardware reliability is not affected.

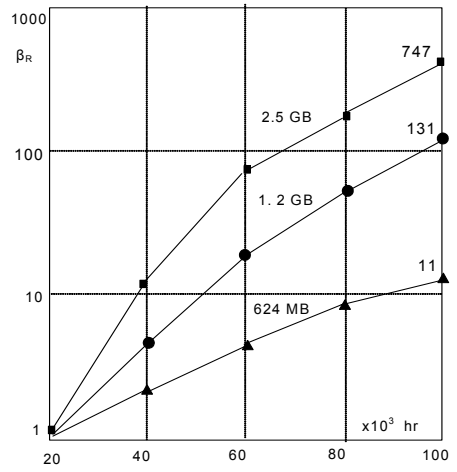

Figure 66.20. STAR-RAM performance enhancement

Based on the approximate device count of SEC-DED RAM, the additional hardware overhead required by the STAR circuits is less than 1% of the total chip area. This is due to the very small number of spares in the main array reconfiguration unit required to yield a high level of memory reliability. In comparison with conventional memory systems without error detection/ correction, the SEC-DED memory introduces hardware overhead in the range 10–40% of the total chip area. Compared to the simple SEC-DED system, the STAR memory system performance is affected by the frequency of error occurrence and on the error weight triggering of the BIST circuits. Performance, as assessed by the reliability enhancement factor β_R, (ratio of reliabilities of the STAR over the non-STAR system), for up to 100000 hours of operation, is shown in Figure 66.20.

66.6 Conclusions and Future Trends

Fault tolerance has matured into a very broad discipline encompassing many aspects of hardware and software system design. Recent rapid changes in computer architectures, with increased integration in VLSI devices, new parallel processing capabilities, and widely distributed networks have been accompanied by further advances in fault tolerant design. The development

of submicron fabrication technologies, with ever-smaller devices, promises further improvements in the performance of VLSI circuits, yet it also leads to several new technical challenges, due to increased design complexity. The declining device dimensions and voltages have caused an increased rate of soft errors due to noise and alpha particle radiation. The usual approach for developing fault tolerant architectures, which include both defects in the chip and soft errors during operation, is to provide spatial and temporal redundancy. As new technologies are developed and new applications arise, new fault tolerance approaches are also needed. In this regard, mention is made of the widespread use of field programmable gate array (FPGA) technology that has caused the migration of many software-based applications to hardware. However, as this technology proliferates in high performance systems the impact of path delay faults becomes more pronounced.

In software, many techniques have been developed for implementing fault tolerance. A lot of these are variations of old traditional techniques or have a philosophy that originates from hardware-based techniques. Software systems are characterized by a very large number of states without the regularity that would allow their merging into a relatively small number of equivalent state groups. Therefore, software correctness can only be verified to some extent, thus, leaving the possibility for the manifestation of any design faults. More research is needed on developing methods capable of handling the present day computational complexity with sufficient verification and coverage. Yet, newer reported techniques have to prove their effectiveness in real systems and applications. Currently, a broad based comparison of the performance of newer methods does not exist.

Computer clusters, massively parallel architectures, and other large-scale distributed systems with complex interconnection networks present new challenges in system control performance and fault tolerance. Despite the flexibility in system composition provided by such systems, improving fault tolerance of services collaborating in multiple application scenarios remains a challenging task. Although today's architectures are usually robust enough to survive node failures without suffering complete system failure, many high performance computing applications have to restart from the beginning whenever a node fails. The large number of computing nodes incorporated within a cluster dramatically increases the likelihood of node failures during program executions. Therefore, ongoing research focuses on graceful degradation and the continuation of program execution despite individual node failures.

The growing need for networked environments is posing new challenges to the fault tolerant design. Much research remains to be done to face network reliability in today's complex networking environment. As new technologies are developed and new applications arise, new fault tolerance approaches are also needed. In a multitechnology multinetwork environment, in each of the networking layers, different types of failures/attacks and responses are possible. Further research is needed to exploit the impact of the failure propagation from one network to another as layer restoration processes may affect each other. Also, the efficiency and performance of the network management coordination, at each of the interacting layers, needs to be addressed. Network architecture and management should be also revisited to examine optimal network reconfiguration after an attack. Software protocols, operations errors, and software attacks define a broad area where more sophisticated mechanisms and algorithms are needed for providing high fault tolerant services and avoid bottlenecks and congestion. Research on intrusion detection mechanisms has to demonstrate how severely the network's performance can be affected if protocol failure or a software attack occurs.

Both hardware and software systems have seen a large increase in their complexity. Concerns for reliability grow in many technological areas, including space reconfigurable VLSI technology, cluster based FPGA architectures and computing platforms with numerous processors. As the requirement for high performability is a major factor, driving the interest in fault tolerance, it is expected that the movement in the research and application fields toward more sophisticated error handling mechanisms and algorithms will be more pronounced.

Prognostics and Health Monitoring of Electronics

Nikhil Vichare, Brian Tuchband, and Michael Pecht

Center for Advanced Life Cycle Engineering (CALCE), University of Maryland, College Park, USA

Abstract: This chapter provides a basic understanding of prognostics and health monitoring of products and systems, and the techniques being developed at CALCE to enable prognostics for electronic systems.

67.1 Introduction

As a result of intense global competition, companies are considering novel approaches to enhance the operational efficiency of their products. For many products and systems, especially those with long life-cycle reliability requirements, high in-service reliability can be a means to ensure customer satisfaction. In addition, competitive market requirements, as well as demands for increased warranties and the severe liability of product failures, have forced manufacturers to improve the reliability of their products. Higher field reliability and operational availability[1] requires knowledge of in-service use and life-cycle operational and environmental conditions.

In particular, many data collection and reliability prediction schemes are designed before in-service operational and environmental aspects of the system are entirely understood. As a result, outputs from these schemes may not satisfy all the user requirements. In addition, with reductions in product development cycle times, there is limited time to carry out extensive reliability trials.

Interest has been growing in monitoring the ongoing health of products and systems in order to predict failures and provide warnings in advance of catastrophic failure. Here, relative health is defined as the extent of degradation or deviation from an expected normal condition. Prognostic is the prediction of the future state of health based on current and historical health conditions [1].

While the application of health monitoring is well established for the assessment of mechanical systems, this is not the case for electronic systems. However, electronics are integral to the functionality of most systems today, and their reliability is often critical for system reliability [2]. This chapter provides a basic understanding of prognostics and health monitoring of products and systems and the techniques being developed to enable prognostics for electronic systems.

[1] Operational Availability: The degree (expressed as a decimal between 0 and 1, or the percentage equivalent) to which a piece of equipment or system can be expected to work properly when required. Operational availability is often calculated by dividing uptime by the sum of uptime and downtime

67.2 Reliability and Prognostics

Reliability is the ability of a product or system to perform as intended (*i.e.*, without failure and within specified performance limits) for a specified time, in its life-cycle environment. Commonly used electronics reliability prediction methods generally do not accurately account for the life-cycle environment of electronic equipment. This arises from fundamental flaws in the reliability assessment methodologies used [3], and uncertainties about the product life-cycle loads [4]. In fact, traditional reliability prediction methods based on the use of handbooks have been shown to be misleading and to provide erroneous life predictions [3], a fact that led the U.S. military to abandon their electronics reliability prediction methods [4]. Although the use of stress and damage models permits a more accurate account of the physics-of-failure [5], their application to long-term reliability predictions based on extrapolated short-term life testing data or field data is typically constrained by insufficient knowledge of the actual operating and environmental application conditions of the product.

Prognostics and health monitoring (PHM) techniques combine sensing, recording, and interpretation of environmental, operational, and performance-related parameters indicative of a system's health. Product health monitoring can be implemented through the use of various techniques to sense and interpret the parameters indicative of (i) performance degradation, such as deviation of operating parameters from their expected values; (ii) physical or electrical degradation, such as material cracking, corrosion, interfacial delamination, or increases in electrical resistance or threshold voltage; or (iii) changes in a life-cycle environment, such as usage duration and frequency, ambient temperature and humidity, vibration, and shock. Based on the product's health, determined by its monitored life-cycle conditions, maintenance procedures can be developed. Health monitoring therefore permits new products to be concurrently designed for a life-cycle environment known through monitoring [1].

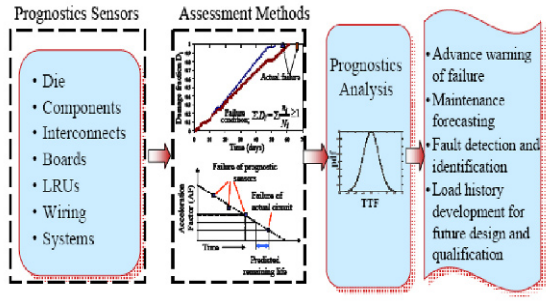

Figure 67.1. Framework for prognostics and health monitoring

The framework for prognostics is shown in Figure 67.1. Sensor data from various levels of an electronic product or system will be monitored *in situ* and analyzed using prognostic algorithms. Different implementation approaches can be adopted individually or in combination. These approaches will be discussed in detail in the next section. Ultimately, the objective is to predict the advent of failure in terms of a distribution of remaining life, level of degradation, or probability of mission survival.

67.3 PHM for Electronics

PHM has emerged as one of the key enablers for achieving efficient system-level maintenance and lowering life-cycle costs. In November 2002, the U.S. Deputy under Secretary of Defense for Logistics and Materiel Readiness released a policy called condition-based maintenance plus (CBM+) [6].

CBM+ represents an effort to shift unscheduled corrective equipment maintenance of new and legacy systems to preventive and predictive approaches that schedule maintenance based upon the evidence of need. The importance of PHM implementation was explicitly stated in the DoD 5000.2 policy document on defense acquisition [7], which states that "program managers shall optimize operational readiness through affordable, integrated, embedded diagnostics and prognostics, and embedded training and testing, serialized item management, automatic identification technology (AIT), and iterative technology refreshment." Thus, PHM has become a requirement for any

system sold to the DoD. A 2005 survey of eleven CBM programs highlighted "electronics prognostics" as one of the most needed maintenance-related features or applications, without regard for cost [8], a view also shared by the avionics industry [9].

Safety-critical mechanical systems and structures, such as propulsion engines, aircraft structures, bridges, buildings, roads, pressure vessels, rotary equipment, and gears, have been known to benefit from advanced sensor systems and models, developed specifically for *in situ* fault diagnosis and prognosis (often called health and usage monitoring or condition monitoring) [10]–[14]. Thus, for mechanical systems, there is a considerable body of knowledge on health monitoring.

Today, most products and systems contain significant electronics content to provide needed functionality and performance. However, the application of PHM concepts to electronics is rare. If one can assess the extent of deviation or degradation from an expected normal operating condition for electronics, this information can be used to meet several powerful goals, which include (1) advanced warning of failures; (2) minimizing unscheduled maintenance, extending maintenance cycles, and maintaining effectiveness through timely repair actions; (3) reducing the life-cycle cost of equipment by decreasing inspection costs, downtime, and inventory; and (4) improving qualification and assisting in the design and logistical support of fielded and future systems. In other words, since electronics are playing an increasingly large role in providing operational capabilities for today's systems, prognostic techniques have become highly desirable.

67.4 PHM Concepts and Methods

The first efforts in diagnostic health monitoring of electronics involved the use of built-in test (BIT), defined as an on-board hardware-software diagnostic means to identify and locate faults. A BIT can consist of error detection and correction circuits, totally self-checking circuits, and self-verification circuits [1].

Two types of BIT concepts are employed in electronic systems: interruptive BIT (I-BIT) and continuous BIT (C-BIT). The concept behind I-BIT is that normal equipment operation is suspended during BIT operation. The concept behind C-BIT is that equipment is monitored continuously and automatically without affecting normal operation. BIT concepts are still being developed to reduce the occurrence of spurious failure indications.

Several studies [15],[16] conducted on the use of BIT for fault identification and diagnostics showed that BIT can be prone to false alarms and can result in unnecessary costly replacement, re-qualification, delayed shipping, and loss of system availability. However, there is also reason to believe that many of the failures were "real" but intermittent in nature [17]. The persistence of such issues over the years is perhaps because the use of BIT has been restricted to low-volume systems. Thus, BIT has generally not been designed to provide prognostics or remaining useful life due to accumulated damage or progression of faults. Rather, it has served primarily as a diagnostic tool.

The different approaches to prognostics and the state of research in electronics PHM are presented here. Three current approaches include (1) the use of fuses and canary devices; (2) monitoring and reasoning of failure precursors; and (3) monitoring environmental and usage loads for damage modeling.

67.4.1 Fuses and Canaries

Expendable devices, such as fuses and canaries, have been a traditional method of protection for structures and electrical power systems. Fuses and circuit breakers are examples of elements used in electronic products to sense excessive current drain and to disconnect power from the concerned part. Fuses within circuits safeguard parts against voltage transients or excessive power dissipation, and protect power supplies from shorted parts. For example, thermostats can be used to sense critical temperature limiting conditions, and to shut down the product, or a part of the system, until the temperature returns to normal. In some products, self-checking circuitry can also be incorporated to

sense abnormal conditions and to make adjustments to restore normal conditions, or to activate switching means to compensate for the malfunction [18].

The word "canary" is derived from one of coal mining's earliest systems for warning of the presence of hazardous gas using the canary bird. Because the canary is more sensitive to hazardous gases than humans, the death or sickening of the canary was an indication to the miners to get out of the shaft. The canary thus provided an effective early warning of catastrophic failure that was easy to interpret. The same approach has been employed in prognostic health monitoring. Canary devices mounted on the actual product can also be used to provide advance warning of failure due to specific wearout failure mechanisms. Mishra *et al*. [19] studied the applicability of semiconductor-level health monitors by using pre-calibrated cells (circuits) located on the same chip with the actual circuitry. The prognostics cell approach, known as Sentinel Semiconductor™ technology, has been commercialized by Ridgetop Group to provide an early warning sentinel for upcoming device failures [20]. The prognostic cells are available for 0.35, 0.25, and 0.18 micron CMOS processes; the power consumption is approximately 600 microwatts. The cell size is typically 800 μm^2 at the 0.25 micron process size. Currently, prognostic cells are available for semiconductor failure mechanisms such as electrostatic discharge (ESD), hot carrier, metal migration, dielectric breakdown, and radiation effects.

The time to failure of these prognostic cells can be pre-calibrated with respect to the time to failure of the actual product. Because of their location, these cells contain and experience substantially similar dependencies as does the actual product. The stresses that contribute to degradation of the circuit include voltage, current, temperature, humidity, and radiation. Since the operational stresses are the same, the damage rate is expected to be the same for both the circuits. However, the prognostic cell is designed to fail faster through increased stress on the cell structure by means of scaling.

Scaling can be achieved by controlled increase of the current density inside the cells. With the same amount of current passing through both circuits, if the cross-sectional area of the current-carrying paths in the cells is decreased, a higher current density is achieved. Further control in current density can be achieved by increasing the voltage level applied to the cells. A combination of both of these techniques can also be used. Higher current density leads to higher internal (joule) heating, causing greater stress on the cells. When a current of higher density passes through the cells, they are expected to fail faster than the actual circuit [19].

Figure 67.2 shows the failure distribution of the actual product and the canary health monitors. Under the same environmental and operational loading conditions, the canary health monitors wear out faster to indicate the impending failure of the actual product. Canaries can be calibrated to provide sufficient advance warning of failure (prognostic distance) to enable appropriate maintenance and replacement activities. This point can be adjusted to some other early indication level. Multiple trigger points can also be provided, using multiple cells evenly spaced over the bathtub curve.

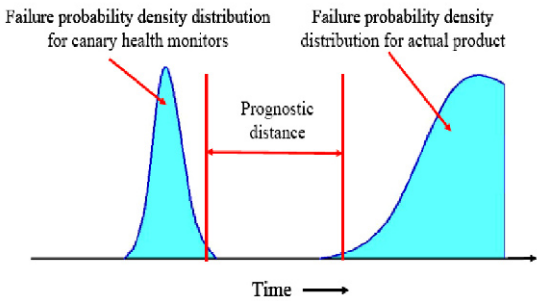

Figure 67.2. Advanced warning of failure using canary structures

The extension of this approach to board-level failures was proposed by Anderson *et al*. [21], who created canary components (located on the same printed circuit board) that include the same mechanisms that lead to failure in actual components. Anderson *et al*., identified two prospective failure mechanisms: (1) low cycle fatigue of solder joints, assessed by monitoring solder joints on and within the canary package; and (2) corrosion monitoring, using circuits that are

susceptible to corrosion. The environmental degradation of these canaries was assessed using accelerated testing, and degradation levels were calibrated and correlated to actual failure levels of the main system. The corrosion test device included an electrical circuitry susceptible to various corrosion-induced mechanisms. Impedance spectroscopy was proposed for identifying changes in the circuits by measuring the magnitude and phase angle of impedance as a function of frequency. The change in impedance characteristics can be correlated to indicate specific degradation mechanisms.

Still, there remain unanswered questions with the use of fuses and canaries for PHM. For example, if a canary monitoring a circuit is replaced, what is the impact when the product is re-energized? What protective architectures are appropriate for post-repair operations? What maintenance guidance must be documented and followed when fail-safe protective architectures have or have not been included? This approach is difficult to implement in legacy systems, because it may require re-qualification of the entire system with the canary module. Also, the integration of fuses and canaries with the host electronic system could be an issue with respect to real estate on semiconductors and boards. Finally, the company must ensure that the additional cost of implementing PHM can be recovered through increased operational and maintenance efficiencies.

67.4.2 Monitoring and Reasoning of Failure Precursors

A failure precursor is an event that signifies impending failure. A precursor indication is usually a change in a measurable variable that can be associated with subsequent failure. For example, a shift in the output voltage of a power supply would suggest impending failure due to a damaged feedback regulator and opto-isolator circuitry. Failures can then be predicted by using a causal relationship between a measured variable that can be correlated with subsequent failure.

A first step in PHM is to select the life-cycle parameters to be monitored. Parameters can be identified based on factors that are crucial for safety, that are likely to cause catastrophic failures, that are essential for mission completeness, or that can result in long downtimes. Selection can also be based on knowledge of the critical parameters established by past experience and field failure data on similar products and on qualification testing. More systematic methods, such as failure mode mechanisms and effects analysis (FMMEA) [22], can be used to determine parameters that need to be monitored.

Pecht *et al*. [23] proposed several measurable parameters that can be used as failure precursors for electronic components including switching power supplies, cables and connectors, CMOS integrated circuits, and voltage-controlled high-frequency oscillators (see Table 67.1).

Testing was conducted to demonstrate the potential of select parameters for viably detecting incipient failures in electronic systems. Supply current monitoring is routinely performed for testing of CMOS ICs. This method is based upon the notion that defective circuits produce an abnormal or at least significantly different amount of current than the current produced by fault-free circuits. This excess current can be sensed to detect faults. The power supply current (Idd) can be defined by two elements: the Iddq-quiescent current and the Iddt-transient or dynamic current. Iddq is the leakage current drawn by the CMOS circuit when it is in a stable (quiescent) state. Iddt is the supply current produced by circuits under test during a transition period after the input has been applied. Iddq has been reported to have the potential for detecting defects such as bridging, opens, and parasitic transistor defects. Operational and environmental stresses, such as temperature, voltage, and radiation, can quickly degrade previously undetected faults and increase the leakage current (Iddq). There is extensive literature on Iddq testing, but little has been done on using Iddq for *in situ* PHM. Monitoring Iddq has been more popular than monitoring Iddt [24]–[26].

Smith and Campbell [27] developed a quiescent current monitor (QCM) that can detect elevated Iddq current in real time during operation. The QCM performed leakage current measurements on every transition of the system clock to get maximum coverage of the IC in real time. Pecuh *et*

al. [25] and Xue and Walker [26] proposed a low-power built-in current monitor for CMOS devices. In the Pecuh *et al*., study, the current monitor was developed and tested on a series of inverters for simulating open and short faults. Both fault types were successfully detected and operational speeds of up to 100 MHz were achieved with negligible effect on the performance of the circuit under test. The current sensor developed by Xue and Walker enabled Iddq monitoring at a resolution level of 10 pA. The system translated the current level into a digital signal with scan chain readout. This concept was verified by fabrication on a test chip.

GMA Industries [28]–[30] proposed embedding molecular test equipment (MTE) within ICs to enable them to continuously test themselves during normal operation and to provide a visual indication that they have failed. The molecular test equipment could be fabricated and embedded within the individual integrated circuit in the chip substrate. The molecular-sized sensor "sea of needles" could be used to measure voltage, current, and other electrical parameters, as well as sense changes in the chemical structure of integrated circuits that are indicative of pending or actual circuit failure. This research focuses on the development of specialized doping techniques for carbon nanotubes to form the basic structure comprising the sensors. The integration of these sensors within conventional IC circuit devices, as well as the use of molecular wires for the interconnection of sensor networks, is an important factor in this research. However, no product or prototype has been developed to date.

Kanniche and Mamat-Ibrahim [31] developed an algorithm for health monitoring of voltage source inverters with pulse width modulation. The algorithm was designed to detect and identify transistor open circuit faults and intermittent misfiring faults occurring in electronic drives. The mathematical foundations of the algorithm were based on discrete wavelet transform (DWT) and fuzzy logic (FL). Current waveforms were monitored and continuously analyzed using DWT to identify faults that may occur due to constant stress, voltage swings, rapid speed variations, frequent stop/start-ups, and constant overloads. After fault detection, "if-then" fuzzy rules were used for VLSI fault diagnosis to pinpoint the fault device. The algorithm was demonstrated to detect certain intermittent faults under laboratory experimental conditions.

Table 67.1. Potential failure precursors for electronics

Electronic subsystem	Failure precursor
Switching power supply	• DC output (voltage and current levels) • Ripple • Pulse width duty cycle • Efficiency • Feedback (voltage and current levels) • Leakage current • RF noise
Cables and connectors	• Impedance changes • Physical damage • High-energy dielectric breakdown
CMOS IC	• Supply leakage current • Supply current variation • Operating signature • Current noise • Logic level variations
Voltage-controlled oscillator	• Output frequency • Power loss • Efficiency • Phase distortion • Noise
Field effect transistor	• Gate leakage current/resistance • Drain-source leakage current/resistance
Ceramic chip capacitor	• Leakage current/resistance • Dissipation factor • RF noise
General purpose diode	• Reverse leakage current • Forward voltage drop • Thermal resistance • Power dissipation • RF noise
Electrolytic capacitor	• Leakage current/resistance • Dissipation factor • RF noise
RF power amplifier	• Voltage standing wave ratio (VSWR) • Power dissipation • Leakage current

Lall *et al*. [32],[33] have developed a damage precursor-based residual life computation approach for various package elements to prognosticate electronic systems prior to the appearance of any

macro-indicators of damage. In order to implement the system-health monitoring, precursor variables have been identified for various package elements and failure mechanisms. Model algorithms have been developed to correlate precursors with impending failure for computation of residual life. Package elements investigated include first-level interconnects, dielectrics, chip interconnects, underfills, and semiconductors. Examples of damage proxies include the phase growth rate of solder interconnects, intermetallics, normal stress at chip interface, and interfacial shear stress. Lall *et al*., suggest that the precursor-based damage computation approach eliminates the need for knowledge of prior or posterior operational stresses and enables the management of system reliability of deployed non-pristine materials under unknown loading conditions. The approach can be used on redeployed parts, sub-systems, and systems, since it does not depend on the availability of prior stress histories.

Self-monitoring analysis and reporting technology (SMART), currently employed in select computing equipment for hard disk drives (HDD), is another example of precursor monitoring [34],[35]. HDD operating parameters, including the flying height of the head, error counts, variations in spin time, temperature, and data transfer rates, are monitored to provide advance warning of failures (see Table 67.2). This is achieved through an interface between the computer's start-up program (BIOS) and the hard disk drive.

Systems for early fault detection and failure prediction are being developed using variables such as current, voltage, and temperature, continuously monitored at various locations inside the system. Sun Microsystems refers to this approach as continuous system telemetry harnesses [36]. Along with sensor information, soft performance parameters such as loads, throughputs, queue lengths, and bit error rates are tracked. Prior to PHM implementation, characterization is conducted by monitoring the signals of different variables to learn a multivariate state estimation technique (MSET) model. Once the model is established using this data, it is used to predict the signal of a particular variable based on learned correlations among all variables [37]. Based on the expected variability in the value of a particular variable during application, a sequential probability ratio test (SPRT) is constructed. During actual monitoring the SPRT will be used to detect the deviations of the actual signal from the expected signal based on distributions (and not on single threshold value) [38],[39].

During implementation, the performance variables are continuously monitored using sensors already existing in Sun Microsystems' servers and recorded in a circular file structure. The file retains data collected at high sampling rates for seventy-two hours and data collected at a lower sampling rate for thirty days. For each signal being monitored, an expected signal is generated using the MSET model.

Table 67.2. Monitoring parameters based on reliability concerns in hard drives

Reliability issues	Parameters monitored
• Head assembly - crack on head - head contamination or resonance - bad connection to electronics module • Motors/bearings - motor failure - worn bearing - excessive run-out - no spin • Electronic module - circuit/chip failure - interconnection/solder joint failure - bad connection to drive or bus • Media - scratch/defects - retries - bad servo - ECC corrections	• Head flying height: A downward trend in flying height will often precede a head crash. • Error checking and correction (ECC) use and error counts: The number of errors encountered by the drive, even if corrected internally, often signals problems developing with the drive. • Spin-up time: Changes in spin-up time can reflect problems with the spindle motor. • Temperature: Increases in drive temperature often signal spindle motor problems. • Data throughput: Reduction in the transfer rate of data can signal various internal problems.

This signal is generated in real time based on learned correlations during characterization (see Figure 67.3). A new signal of residuals is generated, which is the arithmetic difference of the actual and expected time-series signal values. These differences are used as input to the SPRT model, which continuously analyzes the deviations and provides an alarm if the deviations are of concern [37]. The monitored data is analyzed to (1) provide alarms based on leading indicators of failure, and (2) enable use of monitored signals for fault diagnosis, root-cause analysis of no-fault-founds (NFF), and analysis of faults due to software aging [40].

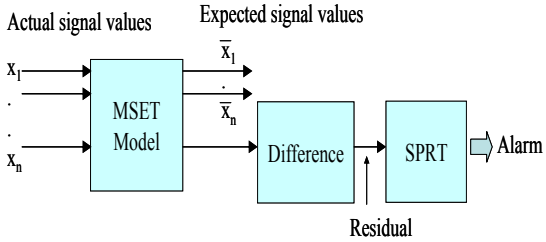

Figure 67.3. Sun Microsystems' approach to PHM

Brown *et al*. [41] demonstrated that the remaining useful life of a commercial global positioning system (GPS) can be predicted by using a precursor-to-failure approach. The failure modes for GPS included precision failure, due to an increase in position error, and solution failure, due to increased outage probability. These failure progressions were monitored *in situ* by recording system-level features reported using the national marine electronics association (NMEA) protocol 0183. The GPS was characterized to collect the principal feature value for a range of operating conditions. The approach was validated by conducting accelerated thermal cycling of the GPS with the offset of the principal feature value measured *in situ*. Based on experimental results, parametric models were developed to correlate the offset in the principal feature value with solution failure. During the experiment, the BIT provided no indication of an impending solution failure [41].

In general, to implement a precursor reasoning-based PHM system, it is necessary to identify the precursor variables for monitoring, and then develop a reasoning algorithm to correlate the change in the precursor variable with the impending failure. This characterization is typically performed by measuring the precursor variable under an expected or accelerated usage profile. Based on the characterization, a model is developed--typically a parametric curve-fit, neural-network, Bayesian network, or a time-series trending of a precursor signal. This approach assumes that there is one or more expected usage profiles that are predictable and can be simulated in a laboratory setup. In some products the usage profiles are predictable, but this is not always true.

For a fielded product with highly varying usage profiles, an unexpected change in the usage profile could result in a different (non-characterized) change in the precursor signal. If the precursor reasoning model is not characterized to factor in the uncertainty in life-cycle usage and environmental profiles, it may provide false alarms. Additionally, it may not always be possible to characterize the precursor signals under all possible usage scenarios (assuming they are known and can be simulated). Thus, the characterization and model development process can often be time-consuming and costly and may not always work.

67.4.3 Monitoring Environmental and Usage Loads for Damage Modeling

The life-cycle environment of a product consists of manufacturing, storage, handling, operating and non-operating conditions. The life-cycle loads (Table 67.3), either individually or in various combinations, may lead to performance or physical degradation of the product and reduce its service life [42]. The extent and rate of product degradation depends upon the magnitude and duration of exposure (usage rate, frequency, and severity) to such loads. If one can measure these loads *in situ*, the load profiles can be used in conjunction with damage models to assess the degradation due to cumulative load exposures.

The assessment of the impact of life-cycle usage and environmental loads on electronic structures and components was studied by Ramakrishnan and Pecht [42]. This study introduced the life-consumption monitoring (LCM) methodology

Table 67.3. Examples of life-cycle loads

Load	Load conditions
Thermal	Steady-state temperature, temperature ranges, temperature cycles, temperature gradients, ramp rates, heat dissipation
Mechanical	Pressure magnitude, pressure gradient, vibration, shock load, acoustic level, strain, stress
Chemical	Aggressive versus inert environment, humidity level, contamination, ozone, pollution, fuel spills
Physical	Radiation, electromagnetic interference, altitude
Electrical	Current, voltage, power, resistance

(Figure 67.4), which combined *in situ* measured loads with physics-based stress and damage models for assessing the life consumed.

The application of the LCM methodology to electronics PHM was illustrated with two case studies [42],[43]. The test vehicle consisted of an electronic component-board assembly placed under the hood of an automobile and subjected to normal driving conditions in the Washington, DC, area. The test board incorporated eight surface-mount leadless inductors soldered onto an FR-4 substrate using eutectic tin-lead solder. Solder joint fatigue was identified as the dominant failure mechanism. Temperature and vibrations were measured *in situ* on the board in the application environment. Using the monitored environmental data, stress and damage models were developed and used to estimate consumed life.

The remaining life of the test board, estimated by LCM, is compared in Figure 67.5 with estimates obtained using similarity analysis, SAE handbook data, and the actual measured life. As shown in Figure 67.5, the remaining life estimated by either similarity analysis or using data from SAE handbook differs significantly from the actual life of the board, whereas the remaining life estimated by LCM is in excellent agreement with actual life. The discrepancies between either similarity analysis or SAE estimates and actual life are attributed to the fact that neither approach accounts for the accident that the car experienced on day 22 [42]. Only LCM accounted for this unforeseen event because the operating environment was being monitored *in situ*.

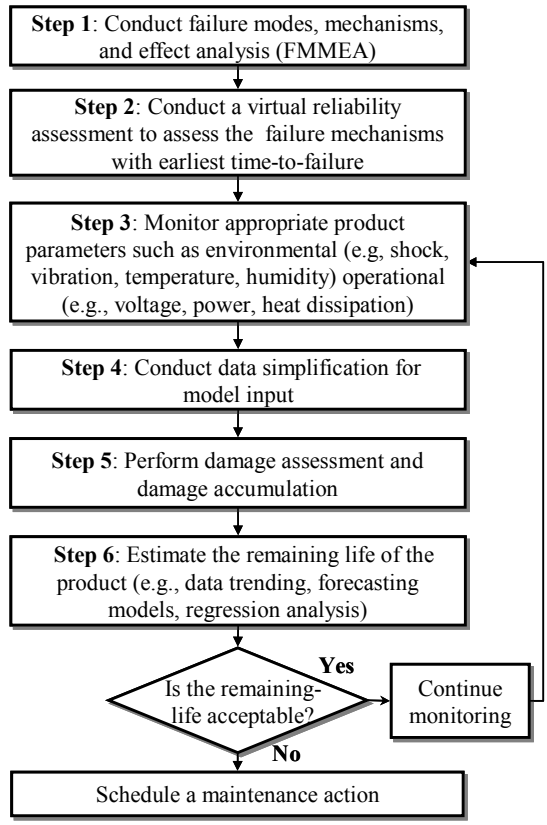

Figure 67.4. CALCE life-consumption monitoring methodology

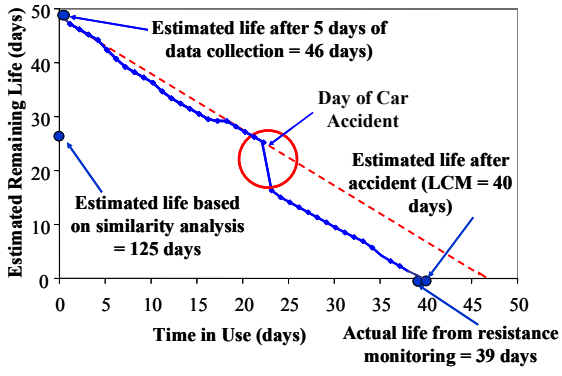

Figure 67.5. Remaining-life estimation of test board

Mathew *et al*. [44] applied the LCM methodology in conducting a prognostic remaining-life assessment of circuit cards inside a space shuttle solid rocket booster (SRB). Vibration-time history, recorded on the SRB from the pre-launch stage to splashdown, was used in conjunction with physics-based models to assess the damage caused due to vibration and shock loads. Using the entire life-cycle loading profile of the SRBs, the remaining life of the components and structures on the circuit cards were predicted. It was determined that an electrical failure was not expected within another forty missions. However, vibration and shock analysis exposed an unexpected failure of the circuit card due to a broken aluminum bracket mounted on the circuit card. Damage accumulation analysis determined that the aluminum brackets had lost significant life due to shock loading.

Shetty *et al*. [45] applied the LCM methodology for conducting a prognostic remaining-life assessment of the end effector electronics unit (EEEU) inside the robotic arm of the space shuttle remote manipulator system (SMRS). A life-cycle loading profile for thermal and vibrational loads was developed for the EEEU boards. Damage assessment was conducted using physics-based mechanical and thermomechanical damage models. A prognostic estimate using a combination of damage models, inspection, and accelerated testing showed that there was little degradation in the electronics and they could be expected to last another twenty years.

Vichare *et al*. [2] outlined generic strategies for *in situ* load monitoring, including selecting appropriate parameters to monitor and designing an effective monitoring plan. Methods for processing the raw sensor data during *in situ* monitoring to reduce the memory requirements and power consumption of the monitoring device were presented. Approaches were also presented for embedding intelligent front-end data processing capabilities in monitoring systems to enable data reduction and simplification (without sacrificing relevant load information) prior to input in damage models for health assessment and prognostics.

Embedding the data reduction and load parameter extraction algorithms into the sensor modules as suggested by Vichare *et al*. [46] can lead to reduction in on-board storage space, low power consumption, and uninterrupted data collection over longer durations. A time-load signal can be monitored *in situ* using sensors, and further processed to extract cyclic range (Δs), cyclic mean load (Smean), and rate of change of load (ds/dt), using embedded load extraction algorithms. The extracted load parameters can be stored in appropriately binned histograms to achieve further data reduction. After the binned data is downloaded, it can be used to estimate the distributions of the load parameters. The usage history is used for damage accumulation and remaining life prediction.

Efforts to monitor life-cycle load data on avionics modules can be found in time-stress measurement device (TSMD) studies. Over the years TSMD designs have been upgraded using advanced sensors, and miniaturized TSMDs are being developed due to advances in microprocessor and non-volatile memory technologies [47].

Searls *et al*. [48] undertook *in situ* temperature measurements in both notebook and desktop computers used in different parts of the world. In terms of the commercial applications of this approach, IBM has installed temperature sensors on hard drives (Drive-TIP) [49] to mitigate risks due to severe temperature conditions, such as thermal tilt of the disk stack and actuator arm, off-track writing, data corruptions on adjacent cylinders, and outgassing of lubricants on the spindle motor. The sensor is controlled using a dedicated algorithm to generate errors and control fan speeds.

Strategies for efficient *in situ* health monitoring of notebook computers were provided by Vichare *et al*. [50]. In this study, the authors monitored and statistically analyzed the temperatures inside a notebook computer, including those experienced during usage, storage, and transportation, and discussed the need to collect such data both to improve the thermal design of the product and to monitor prognostic health. The temperature data was processed using two algorithms: (1) ordered overall range (OOR) to convert an irregular time-temperature history into peaks and valleys and also to remove noise due to small cycles and sensor variations, and (2) a three-parameter Rainflow

algorithm to process the OOR results to extract full and half cycles with cyclic range, mean, and ramp rates. The effects of power cycles, usage history, CPU computing resources usage, and external thermal environment on peak transient thermal loads were characterized.

The European Union funded a project from September 2001 through February 2005, named environmental life-cycle information management and acquisition for consumer products (ELIMA), which aimed to develop ways of better managing the life cycles of products using technology to collect vital information during a product's life to lead to better and more sustainable products [51]. Though the focus of this work was not on prognostics, the project demonstrated the monitoring of the life-cycle conditions of electronic products by field trials. ELIMA partners built and tested two special prototype consumer products with data collection features, and investigated the implications for producers, users, and recyclers. The ELIMA technology included sensors and memory built into the product to record dynamic data such as operation time, temperature, and power consumption. This was added to static data about materials and manufacture. Both a direct communication (*via* GSM module) as well as a two-step communication with the database (RFID data retrieval followed by an Internet data transfer) was applied. As a case study, the member companies monitored the application conditions of a game console and a household refrigerator-freezer.

Skormin *et al*. [52] developed a data-mining model for failure prognostics of avionics units. The model provides a means of efficiently clustering data on parameters measured during operation, such as vibration, temperature, power supply, functional overload, and air pressure. These parameters are monitored *in situ* on the flight using time-stress measurement devices. The objectives of the model are (1) to investigate the role of measured environmental factors in the development of particular failure; (2) to investigate the role of combined effects of several factors; and (3) to re-evaluate the probability of failure on the basis of known exposure to particular adverse conditions. Unlike the physics-based assessments made by Ramakrishnan and Pecht [42], the data-mining model relies on the statistical data available from the records of a time-stress measurement device (TSMD) on cumulative exposure to environmental factors and operational conditions. The TSMD records, along with calculations of probability of failure of avionics units, are used for developing the prognostic model. The data mining enables an understanding of the usage history and allows tracing the cause of failure to individual operational and environmental conditions.

67.5 Implementation of PHM in a System

Implementing an effective PHM strategy for a complete product or system may require integrating different prognostic health monitoring approaches. The first step is an analysis to determine the weak link(s) in the system based on the potential failure modes and mechanisms to enable a more focused monitoring process. Once the potential failure modes, mechanisms, and effects (FMMEA) have been identified, a combination of canaries, precursor reasoning, and life-cycle damage modeling may be necessary, depending on the failure attributes. In fact, different approaches can be implemented based on the same sensor data.

For example, operational loads of computer system electronics such as temperature, voltage, current, and acceleration, can be used with damage models to calculate the susceptibility to electromigration between metallizations and thermal fatigue of interconnects, plated-through holes, and die attach. Also, the processor usage, current, and CPU temperature data can be used to build a statistical model that is based on the correlations between these parameters. This model can be appropriately trained to detect thermal anomalies and identify signs for certain transistor degradation.

Future electronic system designs will integrate sensing and processing modules that will enable *in situ* PHM. Advances in sensors, microprocessors, compact non-volatile memory, battery technologies, and wireless telemetry have already

enabled the implementation of sensor modules and autonomous data loggers. Integrated, miniaturized, low-power, reliable sensor systems operated using portable power supplies (such as batteries) are being developed. These sensor systems have a self-contained architecture requiring minimum or no intrusion into the host product, in addition to specialized sensors for monitoring localized parameters. Sensors with embedded algorithms will enable fault detection, diagnostics, and remaining life prognostics, which will ultimately drive the supply chain. The prognostic information will be linked *via* wireless communications to relay needs to maintenance officers. Automatic identification techniques such as radio frequency identification (RFID) will be used to locate parts in the supply chain, all integrated through a secure web portal to acquire and deliver replacement parts quickly on an as-needed basis.

67.6 Health Monitoring for Product Take-back and End-of-life Decisions

In addition to in-service reliability assessment and maintenance, health monitoring could also be effectively used for supporting product take-back and end-of-life decisions. Product take-back indicates the responsibility of manufacturers for their products over the entire life cycle, including disposal. The motivation driving product take-back is the concept of extended producer responsibility (EPR) for post-consumer electronic waste [53]. The objective of EPR is to make manufacturers and distributors financially responsible for their products when they are no longer needed.

End-of-life product recovery strategies include repair, refurbishing, remanufacturing, reuse of components, material recycling, and disposal. One of the challenges in end-of-life decision making is to determine on an application-specific basis whether any components could be reused and what subset should be disposed of in order to minimize system costs [54]. Several interdependent issues must be considered concurrently to properly determine the optimum component re-use ratio, including assembly/disassembly costs and any defects introduced by either process, product degradation incurred in the original life cycle, and the waste stream associated with the life cycle. Among these factors, the estimate of the degradation of the product in its original life cycle could be the most uncertain input to end-of-life decisions. This task requires knowledge of the entire history of the product's life cycle. This could be effectively carried out using health monitoring.

The methods of assessing product degradation for recovery reported in the literature have focused on the use of non-destructive testing. For example, the Applied Research Lab at Penn State University [55] developed a low-cost assessment approach for the usability of paints beyond their expiration dates, based upon monitoring the paint conductivity and polarization as a function of frequency to extend the shelf life of stock.

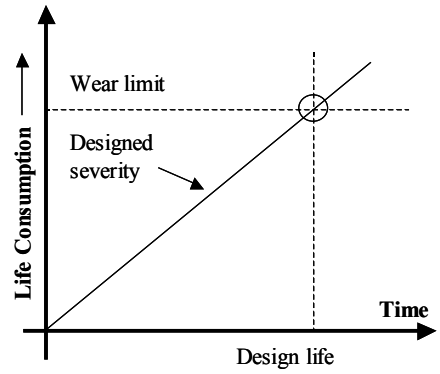
While these approaches are based upon tests conducted after the product is returned or considered expired, efforts to develop *in situ* monitoring techniques enabling product recovery have also been reported. Scheidt *et al*. [56] proposed the development of special electrical ports, referred to as green ports, to retrieve product usage data that could assist in the recycling and reuse of electronic products. Klausner *et al*. [57],[58] proposed the use of an integrated electronic data log (EDL) for recording parameters indicative of product degradation. EDL was implemented on electric motors to increase the reuse of motors. In another study, [59] domestic appliances were monitored for collecting usage data by means of electronic units fitted on the appliances. This work introduced the life-cycle data acquisition unit, which can be used for data collection and also for diagnostics and servicing. Middendorf *et al*. [60] suggested developing life-information modules to record the cycle conditions of products for reliability assessment, product refurbishing, and reuse.

Designers often establish the usable life of products and warranties based on extrapolating the accelerated test results to assumed usage rates and life-cycle conditions. These assumptions may be based on worst-case scenarios of various parameters composing the end user environment. Thus if the assumed conditions and actual use

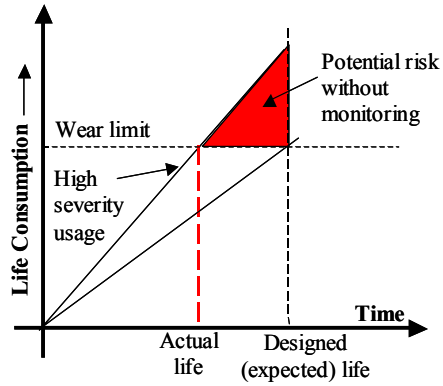
conditions are the same, the product would last for the designed time, as shown in Figure 67.6(a). However, this is rarely true, and usage and environmental conditions could vary significantly from those assumed. For example, consider products equipped with life-consumption monitoring systems for providing *in situ* assessment of remaining life. In this situation, even if the product is used at a higher usage rate and in harsh conditions, it can still avoid unscheduled maintenance and catastrophic failure, maintain safety, and ultimately save cost. These are typically the motivational factors for use of health monitoring or life consumption monitoring, as shown in Figure 67.6(b).

One of the vital inputs in making end-of-life decisions is the estimate of degradation and the remaining life of the product. Figure 67.6(c) illustrates a scenario in which a working product is returned at the end of its designed life. Using the health monitors installed within the product, the reusable life can be assessed. Unlike testing conducted after the product is returned, this estimate can be made without having to disassemble the product.

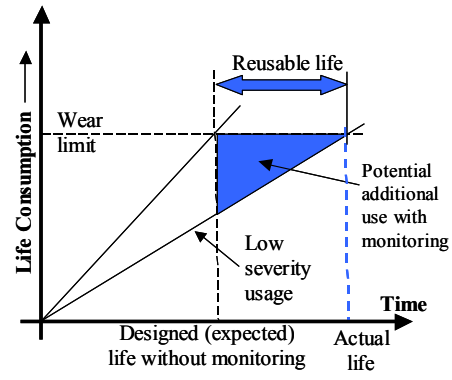
Ultimately, depending on other factors such as cost of the product, demand for spares, cost, and yield in assembly and disassembly, the manufacturer can choose to reuse or dispose. For example, in the case study of LCM, assuming that the car is deemed unusable and is returned by the customer after the accident on day 22, the manufacturer could use the collected data to estimate the remaining life of the board and decide on its reuse or disposal.



(a) Usage as *per* design



(b) More severe usage than intended design



(c) Less severe usage than intended design

Figure 67.6. Application of health monitoring for product reuse

67.7 Conclusions

Prognostics and health monitoring is emerging as a popular alternative over traditional reliability assessment methods. The applicability of PHM to electronic products and systems has been presented. The current approaches for implementing prognostics and health monitoring in products and systems are (1) installing built-in structures that will fail faster than the actual product when subjected to application conditions; (2) monitoring and reasoning of parameters (*e.g.*, system characteristics, defects, performance) that are indicative of an impending failure; and (3) monitoring and modeling environmental and usage data that influence the system's health and converting the measured data into life consumed. A combination of these approaches may be necessary to successfully assess the degradation of the product in real time and subsequently provide the estimate of useful life before the need for maintenance or replacement. Finally, the use of health monitoring in accurately estimating product degradation to assist end-of-life decisions has been presented.

RAMS Management of Railway Tracks

Narve Lyngby, Per Hokstad, and Jørn Vatn

Department of Production and Quality Engineering
The Norwegian University of Science and Technology
N-7491 Trondheim, Norway

Abstract: This chapter provides a review of ageing/degradation models relevant for railway tracks. Recent models for maintenance/renewal optimization used in railways will also be presented. Further, some of the methods/techniques are applied in a few case studies, using actual data. Finally some future trends are outlined.

68.1 Introduction

In the past, railway maintenance procedures were traditionally planned based on the knowledge and experience of each company, accumulated over many decades of operation, but without any kind of reliability-based or risk-based approaches. With the major goal of providing a high level of safety to the infrastructures there was not much concern over economical issues [29].

However, nowadays, limitations in budget are forcing railway infrastructure managers to reduce operational expenditure. Therefore, efforts are being made to apply reliability-based and risk-informed approaches for the maintenance optimization of railway infrastructures. The underlying idea is to reduce the operation and maintenance expenditures while still assuring high safety standards [29].

Optimizing maintenance involves an estimation of the degradation of an object or a system and the consequence of this degradation, often in form of cost.

Having knowledge about the degradation, we can estimate when measures are necessary, when a life span reaches its technical and/or economic end, *etc*. Only by estimating these figures correctly, can accurate life cycles, including all maintenance work to be carried out throughout the useful life, be drawn. Especially the possibility of predicting the residual lifetime of any asset is of high importance.

The consequence of degradation affects safety and operational expenditures as well as speed limitations and corrective maintenance actions.

68.2 Railway Tracks

After the Second World War, the national railway companies used designs of their own. Later, international standards were adopted that often implied heavier rails: UIC54 rails and in many countries today, UIC 60 rails [25]. Instead of

jointed rails, continuous welded rails (CWR) became the new standard, which resulted in greater passenger comfort and less maintenance. Improvements to the rails were complemented with innovations in the design of sleepers, fastening sections, and ballast beds.

In addition to these gradual improvements, completely modified track types have also been developed. Firstly, new ballast track sections have recently become available; these have a different sleeper design than conventional ballasted tracks. In Germany a wide-sleeper track has been developed, where the weight of the sleepers themselves has doubled, but the pressure on the ballast bed has been almost halved as a result of the new shape, resulting in considerably less (geometric) maintenance [30]. In Austria a frame sleeper track has been developed, where a longitudinal beam has been added to the traditional sleeper concept. Subsidence has been reduced by two-thirds, thanks to the more continuous support of the rails [31]. In addition, considerable technological progress has also been made in the development of ballast-less track sections that replace ballast by concrete or asphalt beds (slab-tracks).

However, the most common type of railway track is the ballasted railway track. Figure 68.1 shows a ballasted railway track consisting of rails and sleepers, laid in and fixed by ballast on an existing sub-grade. This economic design, which was chosen on the basis of experience, has remained virtually unchanged despite technological developments in the components. Tracks are long, large structures stretching hundreds or thousands of kilometers. In addition to its economical benefits, the design is a rational structure for supporting heavy fast trains on soft ground.

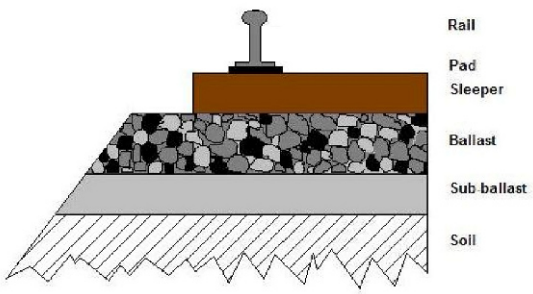

Figure 68.1. Configuration of a railway track

Rails are longitudinal steel members that guide and support the train wheels, and transfer concentrated wheel loads to the supporting sleepers spaced evenly along its length. The rails are held to the sleepers with steel fasteners that ensure that they do not move vertically, longitudinally, or laterally. Tracks with concrete sleepers have a rubber pad placed between the rail and the sleeper in order to reduce the peak forces from the rails onto the sleepers [6]. The sleepers provide a solid, even and flat platform for the rails, and form the basis of a rail fastening section. They hold the rails in position and maintain the designed rail gauge. Sleepers are laid on top of compacted ballast layer at a distance of typically 60–70 cm. Sleepers receive concentrated vertical, lateral, and longitudinal loads from the wheels and rails, and distribute them over a wider ballast area to decrease the stress to an acceptable level [6]. The ballast transmits these vertical forces into the sub-grade [7]. The secondary function of the ballast is to give the track a good lateral stability. The lateral strength of a railway track is to a large extent defined by ballast lateral resistance. After maintenance and renewal actions of the ballast layer, the ballast particles are not consolidated well enough, and lateral resistance is low. This means that the geometrical settlement of the track is quite fast in the first period before the track settles.

Sub-ballast is a layer of aggregates between the ballast layer and the sub-grade, and is usually comprised of well-graded crushed rock or sand/gravel mixtures. It prevents penetration of ballast grains into the sub-grade, and also prevents upward migration of fines into the ballast layer. Sub-ballast, therefore, acts as a filter and separating layer in the track sub-structure, transmits and distributes stress from the ballast layer down to the sub-grade over a wider area, and acts as a limited drainage medium.

Sub-grade is the ground where rail track structure is constructed. It may be naturally deposited sub-grade or specially placed fill material. The sub-grade must be stiff and have a sufficient bearing capacity to resist traffic induced stresses at the sub-ballast/sub-grade interface.

Instability or failure of the sub-grade will result in an unacceptable distortion of the track geometry and alignment, even with excellent ballast and sub-ballast layers.

In addition, the track consists of a drainage section (sub-drain, trench, *etc*.) to avoid moisture problems in the track. Moisture in the track is by many regarded as the main parameter affecting the degradation progression, and is therefore a very important asset to consider in the optimization of maintenance.

68.2.1 Railway Track Degradation

A railway track degrades even if it is not in use or maintained [24]. This is visible on disused railway tracks where the vegetation has taken over. The vegetation is forcing its way from the side of the track to finally cover the track completely. This natural degradation is slower on tracks with traffic, but will still make a contribution to the overall degradation. Vegetation and remnants of vegetation bind up moisture, which can lead to freezing and worsen the stability of the track.

Together with this natural degradation, the traffic contributes to the degradation of the track. Forces from trains passing put stress on the railway track components. The whole track degrades at the same time, but the different maintenance points degrade at different rates [24].

It would be too great of a task to describe the degradation of all railway track components and their interaction in this chapter. Instead, a description of the settlement of tracks and the degradation of rails is given in a few words. These degradation processes will later be used as examples in some case studies on RAMS.

68.2.1.1 Track Settlement

Trains subject the track structure to repeated loading and unloading as they pass. Each load–unload cycle causes deformation of the track, part of which is elastic and recovers; while part suffers permanent deformation.

Track settlement is an integrated process in which settlement of one component affects that of another. As soon as the track geometry starts to deteriorate, the variations of the train/track interaction forces increase, and this speeds up the track deterioration process. According to Dahlberg [2] track settlement occurs in two major phases. Directly after a major maintenance action of the ballast the settlement is relatively fast until the gaps between the ballast particles have been reduced and the ballast is consolidated. The second phase of settlement is slower and is caused by several basic mechanisms of ballast and sub-grade behavior, for example, continued volume reduction, *i.e.*, densification caused by particle rearrangement, sub-ballast and/or sub-grade penetration into ballast voids, volume reduction caused by particle breakdown, volume reduction caused by abrasive wear, inelastic recovery on unloading due to micro-slip between ballast particles, movement of ballast and sub-grade particles, and so on.

Measurement of track geometry irregularities is the most used automated condition monitoring technique in railway infrastructure maintenance. Most problems with tracks (at least the ones concerning the ballast and sub-structure) are revealed as track geometry irregularities [1].

68.2.1.2 Rail Degradation

Rail degradation is basically due to wear and fatigue [12]. These mechanisms vary in strength depending on the track load. In this respect, the track curvature has a major influence on the following relationships of degradation:

- narrow curves implies wear,
- tangent track implies fatigue.

This is shown as a plot in Figure 68.2.

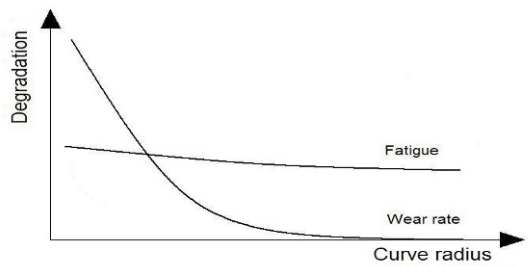

Figure 68.2. Wear and fatigue mechanisms as a function of curve radii. The degradation index corresponds to a relative degradation rate [12]

Wear occurs due to interaction of rail and wheel. It includes abrasive wear and adhesive wear. Adhesive wear is predominant in curves and dry conditions [14]. Abrasive wear is observed at the wheel tread and rail crown, and adhesive wear is observed at the wheel flange and gauge face.

In order to reduce the rate of wear, wheels and rail are lubricated. Lubrication helps to reduce rail gauge face wear and reduces energy or fuel consumption along with noise reduction [13]. In other words; lubrication is good economy.

Rail fatigue accounted for about 60% of defects found by East Japan Railways in the late 1990s, while in France (SNCF) and UK (Railtrack) the figures were about 25% and 15%, respectively. Fatigue is a major future concern as business demands for higher speed; higher axle loads, higher traffic density, and higher tractive forces increase [13].

Effective ways to reduce the initiation and propagation of fatigue failures is an important field of research, see [15][16][17][18][20]. Lubrication reduces the wear rate and damage to the rails but on the other hand, it also causes fluid entrapment in cracks, which leads to crack pressurization and reduces the crack face friction that allows relative shear of the crack faces. This accelerates crack propagation. The presence of manufacturing defects in the rail sub-surface and the direction of the crack mouth on the rail surface are both responsible for guiding the direction of crack development [32][33]. The presence of water or snow on the rails may also increase the crack propagation rate. When these minute head checks are filled with water or lubricants they do not dry up easily. During wheel rail contact, these liquids become trapped in the crack cavities and build up very high localized pressure, which may even be greater than the compressive stress. If head checks are in the direction of train traffic, crack growth takes place due to liquid entrapment, but when head checks are in the opposite direction to train traffic, the liquid is forced out before it is entrapped..

68.2.2 Inspections and Interventions

Maintenance of railway tracks includes inspections and interventions. With the inspections, infra-structure managers employ various methods to obtain information about the tracks. These methods are complementary and provide a wealth of information for maintenance planning, as well as ensuring track safety.

68.2.2.1 Inspections

The inspection methods used on railway tracks include both manual and automated methods. Visual inspection is a much used method. To accomplish this, a trained inspector walks the track or rides on a slow moving track vehicle and looks for track problems. However, many rail defects cannot be seen with the naked eye, hence other methods must be utilized to supplement the visual process. Special equipment travelling over the rails that incorporates ultrasonic or inductive methods for detecting those internal, small, and otherwise not visible defects is then used. Track geometry problems such as variations in track gage, cross level, twist, profile, and alignment can be measured manually with the use of hand devices, but it is a time consuming process. More efficient is a vehicle that continuously measures the track geometry as it travels along the track. Most of these vehicles use laser measurements or accelerometers. Laser measurement can also generate transverse rail profiles. These profiles can be used to measure wear or identify areas of plastic flow.

68.2.2.2 Interventions

Intervention is here used as actions carried out to improve the quality of an asset, including both maintenance (preventive and corrective) and renewal actions. There are different types of interventions ordered by data from inspections or at fixed intervals, such as; tamping, grinding, track lifting, ballast cleaning, rail renewal, sleeper renewal, *etc*. Some of the interventions that are more important for permanent railway track are described below.

Tamping is the common term for the operation of lining, leveling, and tamping, since it is performed by the same machine. The maintenance action is performed by lifting the track and literally squeezing the ballast beneath the sleeper to fill the void spaces generated by the lifting operation.

Tamping is an effective process for re-adjusting the track geometry [10]. However, some detrimental effects, such as ballast damage, loosening of the ballast bed, and reduced track resistance accompany it. Loosening of ballast by the tamping process causes high settlement in the track. Tamping is eventually needed again over a shorter period of time, and in the long run, ballast gradually becomes contaminated by fines, which impairs drainage and its ability to hold the track geometry. Eventually fouled ballast will need to be replaced, or cleaned and re-used in the track [10].

The ballast layer can be fouled due to ballast breakdown, infiltration from the ballast surface, sleeper wear, infiltration from the underlying granular layers, and sub-grade infiltration. This will affect the bearing capacity of the ballast bed and the drainage function, which in turn will cause the ballast to function less effectively. A ballast cleaner removes the fouled ballast and put the cleaned ballast back in the track.

Grinding has been undertaken for many years to maintain rail to increase rail life. Rail grinding objectives have included the removal of corrugation (undulations on the rail surface that increase dynamic forces), the removal of rail surface damage (which also improves ultrasonic inspection), and rail re-profiling to improve vehicle steering. In the last two decades increasing emphasis has been given to grinding to remove cracks produced by rolling contact fatigue (RCF). Such cracks form on almost all railways, from transit sections to high-speed passenger railway s and heavy-haul freight railways. While much theoretical and experimental work is in progress to understand RCF; most railways see grinding as the only tool that is currently available to control the development of small cracks into significant defects.

68.3 Degradation Modeling

So far, we have described the railway track and its, degradation briefly. However, moving on to the realm of modeling, it may be helpful to start looking at the railway track from the point of view of reliability. This stochastic point of view will also form the basis in the maintenance optimization described later.

68.3.1 Stochastic Modeling

The track is considered to be reliable when it performs its intended function under operating conditions for a specified period of time. When this is not the case, the track "fails". The probability that the track will fail in a small time interval from time t to $t + \Delta t$, given that the item has survived up to time t, is called the hazard rate. The concept of the hazard rate is involved in most methods and approaches to maintenance analysis [34]. The hazard rate function can have several behaviors. As far as the railway is concerned, the most likely character is the so-called bath tub curve, as shown in Figure 68.3.

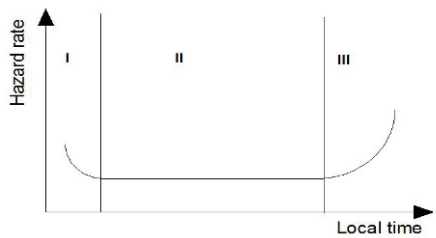

Figure 68.3. Bathtub curve with a local time-dependent hazard rate

As illustrated in Figure 68.3, the bathtub curve may be divided into three phases:

I. Infant mortality (infancy) period.
II. Useful life period.
III. Wear-out period.

During the early life of an item (I), there are early failures caused by initial weakness or defects in material, poor quality control, inadequate manufacturing methods, human error, initial settlement, *etc*. Early failures show up early in the life of an item and are characterized by a high failure rate in the beginning, which keeps decreasing as time elapses. Other terms for this decreasing failure rate period are the burn-in period, the break-in period, the early failure period, the wear-in period, and the debugging period.

During the second part of the bathtub curve (II), the hazard rate is approximately constant. This period of life is known as the useful life during which only random failures occur. There are various reasons for the occurrence of failures in this period, for example, power surges, temperature fluctuations, human errors, overloading, earthquakes, *etc*. Screening techniques or maintenance practices cannot eliminate these failures, but by making the design of the item more robust with respect to the environments, the effects can be reduced.

After the useful life the wear-out period starts (III), when the failure rate increases. The causes for these "wear-out" failures include wear due to aging, fatigue cracking, corrosion and creep, short designed-in life of the maintenance point under consideration, poor maintenance, wear due to friction, and incorrect overhaul practices.

In Figure 68.3, the word "local time" is used to emphasize the fact that time is relative to the last failure. The bathtub curve indicates that the number of failures will be reduced if an item is maintained before it reaches the right extreme of the curve.

There is also another bathtub curve related to the global section time, as shown in Figure 68.4, where the local bathtub curves are also illustrated.

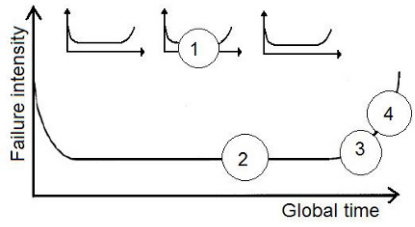

Figure 68.4. Bathtub curve with a global time-dependent failure intensity [34]

Note that on the *y*-axis the dimension is *failure intensity, or performance loss.* This reflects that the important issue now is the number of failures (overall degradation) *per* time unit, or generally loss of performance, independent of what has happened up to time *t*.

In Figure 68.4 the numbers 1, 2, 3, and 4 are identified, where the following maintenance situations apply:

1. Point maintenance, related to the explicit failure modes of a maintenance point.
2. Life extension maintenance. The idea here is to carry out maintenance that prolongs the life length of the section. A typical example is rail grinding to extend the life length of rails.
3. Maintenance carried out in order to improve performance, but not renewal. A typical example is adding ballast to pumping sections to improve track quality and reduce the need for track adjustment
4. Complete renewal of major railway maintenance points or sections.

Transferring this theory to railway track maintenance, the following distinguish between local curves as failures within maintenance points and global curves as failures in sections. Here maintenance points are defined as points along the track susceptible to inspection and/or interventions, whereas sections are longer parts of track, often with defined parameter values.

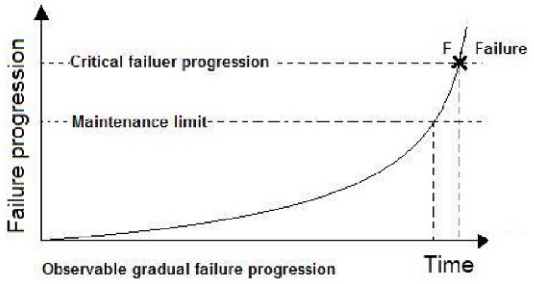
68.3.2 Degradation in Local Time

As mentioned; the bathtub curve indicates a wear-out zone. However, the shapes of the degradation in this wear-out zone differ depending on which maintenance point that is observed.

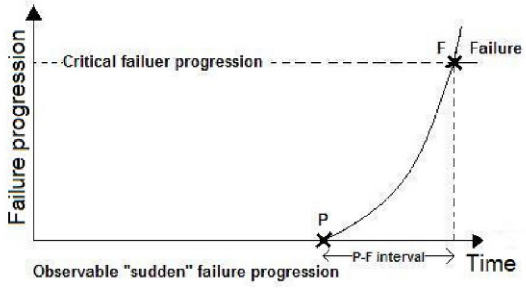
Vatn [34] has classified different failure classes related to the characteristics of maintenance point degradation:

a. gradual failure progression, and
b. "sudden" failure progression.

In addition to these failure models, Vatn described two models where the failure progression is not observable for some reason. These models are not included here, as it is expected that it will be possible to observe the failure progression for all maintenance points of the railway track.



(a)



(b)

Figure 68.5. Two different failure models

The two different classes of failures are illustrated in Figure 68.5.

a. Observable Gradual Failure Progression

With gradual failure progression, it is assumed that the progression of failure can be observed. The geometrical degradation of a railway track is a typical example. In order to ensure full capacity of the track, the geometrical deviations must be below a certain limit. If we exceed this limit, action must be taken in the form of speed restrictions or a full stopping of the line. A failure occurs when the geometrical deviation exceeds a specified limit.

b. Observable "Sudden" Failure Progression (PF Interval)

Now assume that the track section can operate for a very long time without any sign of potential failure, but at some point of time a potential failure would be evident. In Figure 68.5(a) "P" indicates potential failure, *i.e.*, the time where an impending failure is observable. The time interval before the failure is first observable, and the time until a failure occurs is very often denoted the PF interval. In practical terms, then, the PF interval is the grace time available to detect the presence of a defect before it causes the actual failure.

An example of this is a rail that is exposed to a combination of fatigue and a flat wheel that initiates a crack (potential failure, P). However, such cracks can be detected by ultrasonic inspection, and hopefully so before the crack propagates to a failure.

68.3.3 Degradation of Sections

When we look at the sections, the life spans changes along with the consideration of the degraded state. From a life span of one to five years for maintenance points, we now consider the whole section implying a life span of 30 to 60 years. While considering a section, the overall degradation must be considered. This implies a change from following the degradation of one maintenance point until failure to a number of failures, *e.g.,* loss of performance or quality.

The challenge in looking at sections lies in the consideration of many factors that eventually lead to the degradation. Underlying degradation processes of maintenance points together with changing effect of maintenance carried out within the life span are considered. Zoeteman [35] refers to a figure by Ebershon and Ruppert [22] (Figure 68.6), visualizing the problem and showing a theoretical degradation for the geometry of a railway track. The track roughness increases with the amount of time/tonnage carried. At some point, intervention is needed. The broken lines show that replacing the track can be postponed through tamping. After some time the effectiveness of this maintenance may become inadequate, which is reflected in a decreased interval. Replacement becomes necessary before the track condition passes the "operational limit" when the safety of traffic may be at stake. Figure 68.6 also shows an entirely different option, which is to upgrade the section, *e.g.,* with an improved ballast bed; the reduced amount of maintenance and extended life should be traded off against this investment.

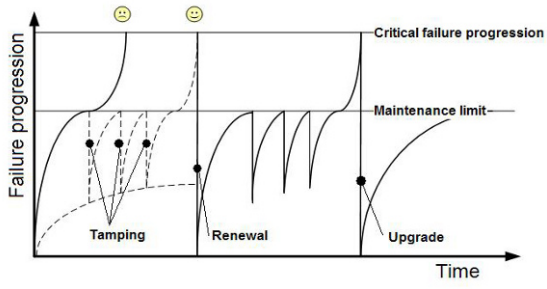


Figure 68.6. Degradation of track geometry [22]

Degradation is a complicated process. The rate at which the degradation occurs is a function of time and/or usage intensity. If all railway track sections were identical, operated under exactly the same conditions and in exactly the same environment, then, all sections would degrade in the exact same manner. However, usage intensity or operating conditions together with environmental conditions, and material varies between sections.

Several attempts have been made to make empirical models based on records or measurements made on tracks to explain the complicated degradation process.

Four models explaining track settlement are presented as examples:

1. An empirical track settlement model based on Japanese experience [11].
2. A statistical deterioration model made by the Office for Research and Experiments of the International Union of Railways (ORE).
3. A series of equations predicting settlement rate from ballast pressure based on experiments at the Technical University of Munich [3].
4. An Austrian model looking at development of track quality from a passenger's point of view.

The degradation process is explained in these models through a set of variables, which more or less remain the same for various models. The most important variables according to the Japanese model [11] are traffic, time, track condition, and humidity. This choice of variables is supported by the German and the Austrian models with some deviations; the German and Austrian models do not consider humidity, however both models regard vehicle characteristics as an important variable. The UIC model [2] contains no track parameters but only loading parameters such as traffic volume, dynamic axle load, and speed.

As can be seen from these models, the settlement is modeled quite differently, even though the variables used are more or less the same. In the models from Japan and ORE, the settlement grows linearly with respect to the loading, whereas in the German model the settlement grows only logarithmically with respect to loading [the term containing log (N)]. The discrepancy between the two models might be large, especially if the parameters in the equations are determined for a relatively small number of loading cycles and the equations are thereafter used to determine the settlement after a large number of loading cycles. The difference is even larger comparing the German model to the Austrian one, which is proclaims an exponential development of the settlement. Instead of saying that the sub-grade and ballast are more compact over time (that it settles), which in turn slows the settlement, the Austrian model says that the rougher the track becomes the more dynamic forces are created when trains pass, which in turn increases the settlement.

68.3.3.1 The Japanese Study

In early 1960, the Japanese railway companies published a relationship that enables an estimation of the settlement of railway ballast when subjected to cyclic loading. Originally developed from laboratory results, the following equation is currently used to estimate the deformation, y, of both the heavy haul narrow gauge and the high standard gauge:

$$y = \gamma\left(1 - e^{-\alpha x}\right) + \beta x\,, \qquad (68.1)$$

where x is the repeated number of loadings or tonnage carried by the track, α is the vertical acceleration required to initiate slip and can be measured using spring loaded plates of the ballast material on a vibrating table, β is a coefficient proportional to the sleeper pressure and peak acceleration experienced by the ballast particles

and is affected by the type and condition of the ballast material and the presence of water, and γ is a constant dependent on the initial packing of the ballast material.

68.3.3.2 The Heavy Axle Load Study (ORE)

ORE has suggested a model to estimate track deterioration, e [8]. The deterioration is divided into two parts: the first part describes the deterioration directly after tamping, e_0, and the second part describes the deterioration depending on traffic volume T, dynamic axle load $2Q$ and speed v. The relationship reads

$$e = e_0 + hT^{\alpha}(2Q)^{\beta}v^{\gamma}, \qquad (68.2)$$

where h is a constant and the parameters α, β, and γ have to be estimated from experimental data. Due to a lack of data, UIC suggests α=1 and β=3. Further, it is assumed that the influence of the speed can be neglected, implying that v^{γ} need not be treated separately, but may be included in the proportionality factor h.

68.3.3.3 The German Study

Experiments under well controlled laboratory conditions at the Technical University of Munich representative of vehicles passing a dipped joint have been used to establish equations to calculate rate of settlement (S) [3]. The ballast pressure is multiplied by the log of the number of axle passes as follows:

$$S = a \times p \times \ln \Delta N + b \times p^{1.21} \times \ln N \quad , (68.3)$$

As can be seen from the equation a logarithmic settlement law has been used. The first term represents the fast settlement just after a maintenance action. ΔN expresses a pre-loading period comprising the first passing axles. ΔN should be ≤ 10000 and N in the second part should express the total number of passing axles. The ballast pressure p should be calculated with the Zimmermann method [3]. The parameters a and b are constants suggested to be in the value range; 1.57–2.33 (a) and 3.04–15.2 (b).

68.3.3.4 The Austrian Study

TU Graz has examined settlement developments in Austria by the quality figure MDZ, which represents accelerations in the vehicle caused by track imperfections [9]. The MDZ figure comprises of both horizontal and vertical deviations in tracks together with a lack of super elevation and speed [5]. An exponential development of the MDZ figure over time was found giving the following expression for track quality:

$$Q = Q_0 \times e^{-b \times t}, \qquad (68.4)$$

where Q is the track quality represented by the MDZ number and Q_0 the initial track quality. TU Graz has also examined the assets management problem [4].

68.4 Methods for Optimizing Maintenance and Renewal

Using the models of degradation as the basis, the maintenance in form of inspection and intervention intervals can be optimized with respect to the total cost of maintenance and risk.

68.4.1 Optimizing Point Maintenance

In the degradation models, a limit called “critical failure progression” is defined. This is a limit saying that degradation passing this limit is assumed to be critical. However, in real life there often exists more than just one level. In the Norwegian rail administration there are three limits. A maintenance limit (ML) indicates further investigation, an action limit (AL) says that maintenance is required, and finally operational restriction and maintenance is mandatory when passing a safety limit (SL).

The failure progression is a random variable. When the failure progression exceeds the maintenance limit a corrective maintenance action is performed, which resets the section. If the failure progression exceeds the failure limit a failure occurs. The failure progress can be specified in various ways. Two common used models for the failure progression are the Wiener process and the

Gamma process. Both processes are continuous-time stochastic processes.

A limitation of these processes is that the degradation is assumed to be linear with time. This is problematic when, *e.g.*, cracks are modeled, since the failure progression is believed to go faster and faster as the crack size increases.

Yet another limitation is the assumption of independence, which is often used in reliability analysis. It means that if one maintenance point in a section fails and is repaired, all the other maintenance points in the section will function as normal without regard to the repair going on. For many sections this assumption will be unrealistic, and other approaches have to be used to determine the section availability. An alternative approach is to base the analysis on Markov models. By using Markov models a wide range of dependencies can be taken into account. [21].

Another important method used within the railway industry is Monte Carlo simulation. The simulation is carried out by generating certain random and discrete events in a computer model in order to create a realistic or "typical lifetime scenario of the section. In the Monte Carlo approach a realization of the life process is simulated on the computer and, after having observed the simulated process for some time, estimates are made of the desired measures of performance, thus the simulation is treated as a series of real experiments. Simulation is an attractive alternative because it allows the modeling of virtually any time to failure distribution, as well as allowing behaviors that preclude analytic solution. Further, simulation may be a more efficient approach in complex sections where it would be to time consuming to develop analytical models. The major disadvantage of simulation is the long simulation times needed to achieve high accuracy. In addition, in many situations, a sort of "black box" with little insight in the processes going on will be created.

68.4.1.1 Barrier Modeling

A risk model with a format that allows the prediction the risk level as a function of the maintenance level is a useful tool when calculating costs. An example of such a model is the barrier model, which looks at the outcome in term of cost if barriers in connection with the maintenance point should fail. A barrier is defined as that part of a section that prevents the occurrence, or at least lowers the occurrence probability to a minimum, of the so called "top-event", if a maintenance point fails. A "top-event" describes the worst direct consequence of any failure. Normally there is more than one barrier preventing the occurrence of the 'top-event'. The idea of barrier thinking is illustrated in Figure 68.7, where the case of crack growth in rails is illustrated:

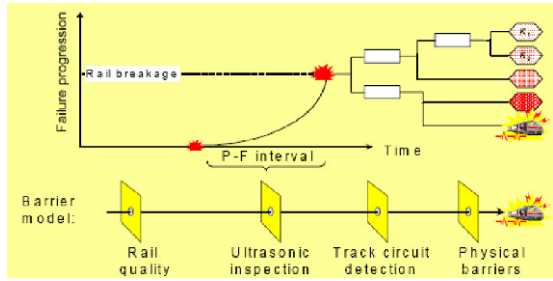

Figure 68.7. Barrier modeling, printout from [34]

It is only because of the existence of these barriers, that railways can be run in the way they are. Up to now for most maintenance points the existing barriers have been defined, but their influence is only estimated. It will take a lot of further work to calculate their true factors explicitly. Still, it is regarded as most important to integrate those barriers in the calculations, because it is always better to take facts that obviously exist into account even if the exact figures are not known, than not to include any value.

68.4.1.2 Cost Analysis

In order to optimize the maintenance effort, the maintenance point performance measures and the cost model must be combined, and then balance with the maintenance cost. The maintenance cost is specified by:

PM_{Cost}	Cost *per* preventive maintenance (PM) activity (intervention).
I_{Cost}	Cost per inspection.
CM_{Cost}	Cost per corrective maintenance

(CM) action.

The cost *per* unit time is now given by:

$$C(\tau) = C_R(\tau) + [1/\tau_{Int} + rr(\tau)]PM_{Cost}, \\ + I_{Cost}/\tau_{Insp} + \lambda(\tau)CM_{Cost}, \quad (68.5)$$

where $C_R(\tau)$ are costs calculated from risk model. $\lambda(\tau)$ and $rr(\tau)$ are the effective failure rate and the renewal rate, respectively. In the equation τ_{Int} is used to denote the maintenance interval in case of interventions, whereas τ_{Insp} denotes the maintenance interval in the case of periodic inspections. Further τ is used without any index when the interval must be found from the type of maintenance activity. To find the optimum maintenance interval $C(\tau)$ from the equation for various values of the maintenance interval, τ, can be calculated and then the value for τ that minimizes $C(\tau)$ can be chosen. The output of such an optimization task can also be plotted in a diagram as illustrated by Figure 68.8.

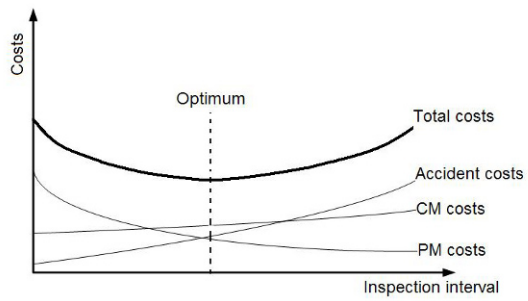

Figure 68.8. Optimization of maintenance intervals

Here the cost of corrective maintenance as a consequence of failures is measured upon the cost of preventive maintenance.

68.4.2 Optimizing Section Maintenance and Renewal

Here the objective is to establish a sound basis for the optimization of maintenance and renewal. The idea is to choose maintenance activities in time and space such that costs are minimized in the long run. Different "headings" are used for such an analysis, *e.g.*, LCC analysis, cost/benefit analysis and NPV (net present value) analysis.

As in the latter approaches, the degradation as a function of time is the background of this approach as well. This degradation can be transformed into cost functions, and when the cost becomes very large it might be beneficial to perform maintenance or renewal activities on the infrastructure. In the following, the notation $c(t)$ is introduced for the costs as a function of time. The costs included in this function mainly include

- punctuality loss,
- accident cost, and
- extra operational and maintenance costs due to reduced track quality.

By a maintenance or renewal action the function *c(t)* is typically reset, either to zero, or at least a level significantly below the current value. Thus, the operating costs will be reduced in the future if investments in a maintenance or renewal project are made.

Figure 68.9 shows the savings in operational costs, $c(t) - c^*(t)$, if maintenance or renewal at time T is performed. In addition to the savings in operational costs, savings due to an increased "residual life time" will also often be achieved.

Special attention will be paid to projects that aim at extending the life length of a railway section. A typical example is rail grinding to extend the life length of the rail, but also for the fastenings, sleepers, and ballast. Figure 68.10 shows how a smart activity ( ) may suppress the increase in *c(t)* and thereby extend the point of time before the cost explodes and a renewal is necessary.

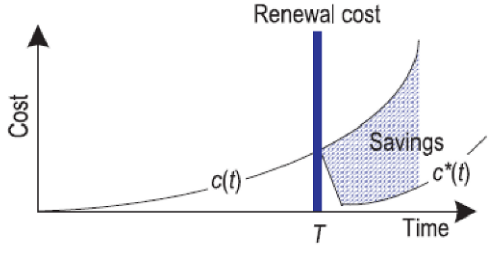

Figure 68.9. Cost savings [34]

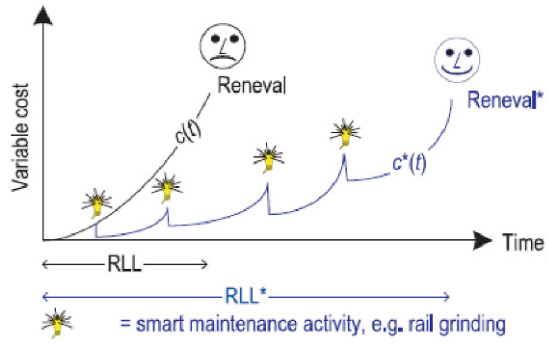

Figure 68.10. Life length extension [34]

Following this line of argument, from a cost-benefit point of view, all projects with a cost–benefit ratio higher than or equal to one should be carried out. The challenge lies in finding the optimal time to carry out the project. However, due to a lack of financial resources and insufficient work capacity, the infrastructure managers might have to drop some of the projects. A tool design to help prioritizing projects, *i.e*, the Norwegian PRIFO tool has been conceived. Figure 68.11 illustrates the output of the PRIFO tool.

Project Nr.	Rating	Cost/Benefit Ratio	
Project 5	1	6,4	
Project 3	2	6,2	
Project 12	3	5,4	Projects are supposed to be run
Project 11	4	5,1	
Project 1	5	4,3	
Project 7	6	3,4	
Project 2	7	3,2	limit line due to financial restrictions
Project 13	8	2,8	
Project 4	9	1,5	Economic, but not executed projects
Project 9	10	1,2	
Project 7	11	1	economic limit line
Project 10	12	0,8	Projects should never be run
Project 8	13	0,5	

Figure 68.11. Ranking of projects, printout of the PRIFO tool

The results of the PRIFO tool are supposed to be listed and rated according to their cost–benefit ratio. The higher this figure is, the more economically beneficial is the assessed project.

68.5 Case Studies on RAMS

Examples of optimization of inspection intervals for the ultrasonic inspection car and the geometrical inspection car are presented in two cases.

68.5.1 Optimizing Ultrasonic Inspection Intervals

68.5.1.1 Introduction

Failure and inspection data from *Dovrebanen* (a part of the Norwegian railway line from Trondheim to Oslo) are analyzed. The degradation/repair process within the fixed inspection interval is modeled as a time continuous Markov chain. Also the change of state implemented at the end of an inspection interval is modeled as a (time discrete) Markov chain.

The model will demonstrate how reliability depends on the inspection interval, and will thus support identification of the most cost effective preventive maintenance strategy for the railway line in question.

The critical failures (*i.e.*, the broken rail) can either be seen as shocks (*i.e.*, with no "warning"), or as a gradual degradation, where the line goes through various degraded states (with cracks) until it gets a critical failure. When a degraded failure occurs, the railway line is still functioning, and the crack can only be revealed by inspections of the line. Those inspections are performed at regular intervals by ultrasonic inspection cars (UIC). However, at each inspection there is only a probability q of detecting a degraded failure. A piece of rail that is degraded is more prone to suffer a critical failure than a piece of rail that is not degraded (*i.e.*, in the OK state). When a critical failure occurs, the failure has to be repaired in order to maintain regular traffic. More details are given in [26], and we note that the same data has also been analyzed in [27].

68.5.1.2 A General Markov Failure Model

A phase type distribution is used for time to failure. The failure model includes two different states for degraded failures and two different states for critical failures. In addition we have an OK state (see Figure 68.12).

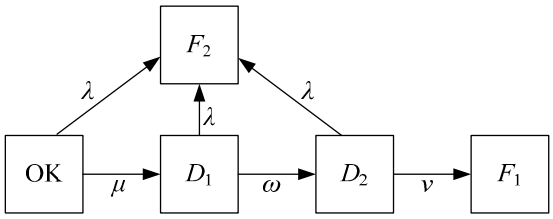

Figure 68.12. A general Markov failure model

The critical failures can be divided into two categories: failures due to degradation, denoted F_1 and "shock" failures, denoted F_2. The latter failures happen when the rail is exposed to large external forces like rolling stock. Those failures cannot be avoided by inspection. The critical failures due to degradation, however, can be avoided by preventive repair if they are discovered at inspections.

The first degraded state, denoted D_1, is for minor degraded failures (cracks). If a rail is detected to be in this state, the observations are made more frequently so that a critical failure due to degradation should not be possible. When the degraded state D_2 is detected (larger cracks) the failure is repaired immediately.

The development of degraded and critical failures is modeled by a time continuous Markov chain, see Figure 68.12. If the railway line does not have a critical failure, there is a constant rate λ for getting a shock failure F_2. In order to reach the critical failure state F_1 the rail has to go through the degraded states D_1 and D_2.

We partition the rail into small pieces of rail so that one piece is in only one of the states OK, D_1, D_2, F_1, or F_2, (and the above rates refer to these small pieces with the length of 1 m).

68.5.1.3 A Specific Failure Model for the Railway Case

In the following illustrations, for simplicity we ignore the state F_2 (see Figure 68.13) . The effect of this failure category can afterwards be incorporated by just adding an additional failure rate, λ (see Figure 68.12).

However, in order to later also model the maintenance of the degradation failures, we split the degradation states, according to whether these are detected or not. A subscript *u* on the degraded states indicates that a degraded failure is undetected (by UIC). Likewise, a subscript *d* indicates a degraded failure that is detected. Thus, at the beginning of an inspection interval, we can start in one of the states OK, D_{1u}, or D_{2u} D_{1d}. The Markov diagram is presented in Figure 68.13, which is valid for the complete inspection interval of length *T*. Note that if we during the inspection detect that the line is in the state D_1, then the next inspection interval will start in state D_{1d}. Here ρ refers to the transition rate caused by additional inspection in a detected state D_1 as explained above.

D_{1u} = Minor degraded failure (crack) being undetected.

D_{1d} = Minor degraded failure detected by UIC; then the observations are made more intensive (frequent) so that a critical failure due to degradation is not possible.

D_{2u} = Major degraded failure (crack) being undetected; (state believed to be OK).

D_{2d} = Undetected major degraded failure when the piece of line earlier has been detected to be in state D_1; and is therefore it is closely monitored, but it is *not* known that the state D_2 is reached. As soon as the state D_2 is detected the failure is repaired immediately and the piece of rail goes to OK.

The direct rate to OK follows by the assumption of immediate repair. For simplicity, we introduce an absorbing state OK*, and transfer to OK is carried out at the start of the next inspection interval. Thus both the states F_1 and OK* are made absorbing states in the time continuous chain, meaning that a fresh start in OK always takes place at the beginning of an interval. This means that the same piece of rail can never have two failures or visits to D_{2u} within the same interval, and we do not *start* in OK in the middle of an interval. This is a computationally simplifying assumption that will not affect our results to a great extent.

Further, note that the modeling allows transitions from D_1 to D_2 to have different rates, depending on whether the degradation to D_1 is detected or not. The rate of failures (to F_1) is, however, assumed to be the same for both D_{2u} and D_{2d}.

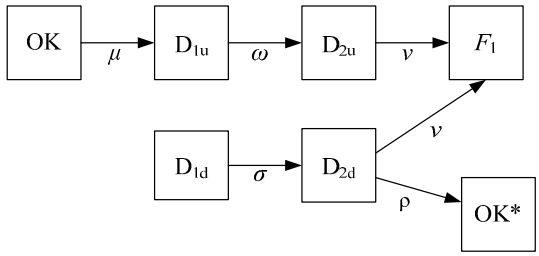

Figure 68.13. Markov model adapted to the railway case (now ignoring state F_2)

Using transition rates as in Figure 68.3, we can now easily write the intensity matrix, Q, of this time continuous Markov chain, now numbering the states as OK = 1, D_{1u} = 2, D_{1d} = 3, D_{2u} = 4, D_{2d} =5, F_1 = 6, OK* = 7. This 7x7 matrix is of the form

$$Q = \begin{bmatrix} A & K \\ 0 & 0 \end{bmatrix} \tag{68.6}$$

where A is a 5x5 matrix and the "0"s here are matrices consisting of zeros only.

Then using a suitable method for solving Markov chains, for example, the computer package Maple, we can easily find the transition probabilities of the process. Let $X_n(t)$, n=1, 2, ….., be the state of the time continuous Markov chain at time t in the nth inspection interval, and let

$$p_{jk}(t) = \mathrm{P}(X_n(t) = k \mid X_n(0) = j) \tag{68.7}$$

We denote this matrix of transition probabilities by $P(t)$ and get

$$P(t) = \begin{bmatrix} e^{tA} & A^{-1}(e^{tA} - I)K \\ 0 & I \end{bmatrix}, \tag{68.8}$$

where I is the identity matrix of appropriate dimension.

68.5.1.4 The Maintenance Model

Next we introduce the Markov chain for transitions at the inspection. The states $X_n(0)$ and $X_n(T)$ are of particular interest, where T is the length of the interval. Now consider the transitions of state that may occur as the result of the inspection (occurring at times T, $2T$, ….). In order to be able to fit the model to the failure/inspection data, we now introduce the variables U_n and V_n. U_n tells the true state for a small piece of rail immediately before inspection, and V_n tells the true state immediately after inspection, *i.e.*, at the start of the next inspection interval. Thus actually

$$U_n = X_n(T), \quad n = 1, 2, \ldots \tag{68.9}$$

$$V_n = X_{n+1}(0), \quad n = 1, 2, \ldots \tag{68.10}$$

These have the asymptotic distributions

$$\pi_k = \mathrm{P}(U_n = k); \quad k = 1, \ldots.., 7 \tag{68.11}$$

$$\psi_k = \mathrm{P}(V_n = k); \quad k = 1, \ldots, 7, \tag{68.12}$$

and the corresponding row vectors (vectors in bold) are:

$$\boldsymbol{\pi} = (\pi_1, \pi_2, \ldots\ldots.., \pi_7), \tag{68.13}$$

$$\boldsymbol{\psi} = (\psi_1, \psi_2, \ldots\ldots, \psi_7). \tag{68.14}$$

Further, we introduce probabilities that degraded failures are detected by inspection:

q_1 = Probability that state D_1 of a line segment is detected.

q_2 = Probability that a degraded failure, D_2 is detected by the inspection; not knowing in advance that the state D_1 was reached.

q_3 = Probability that a degraded failure, D_2 is detected by the inspection; knowing in advance that the state D_1 was reached.

We can then introduce the matrix, R, for the transitions at the inspections, *i.e.*, transitions from U_n to V_n.

$$R = \begin{array}{c} \begin{matrix} \text{OK} & \text{D}_{1u} & \text{D}_{1d} & \text{D}_{2u} & \text{D}_{2d} & \text{F}_1 & \text{OK*} \end{matrix} \\ \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1-q_1 & q_1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ q_2 & 0 & 0 & 1-q_2 & 0 & 0 & 0 \\ q_3 & 0 & 0 & 0 & 1-q_3 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \end{array} \tag{68.15}$$

Now the transition matrix for U_n equals R · P(T), and similarly the transition matrix for V_n equals

P(T) · R. Now the asymptotic distributions of U_n and V_n , are determined from the relations

$$\psi = \pi \cdot R, \quad (68.16)$$

$$\pi = \psi \cdot P(T). \quad (68.17)$$

Thus, the vector $\boldsymbol{\pi}$ is found from

$$\boldsymbol{\pi} = \boldsymbol{\pi} \cdot R \cdot P(T). \quad (68.18)$$

68.5.1.5 Overall Model and Assumptions

As indicated above the two Markov chains can be combined into one total model, see Figure 68.14. Here we give the state numbers 1, …., 7 in addition to the notation OK. *etc*., and again for simplicity we ignore the state F_2. The solid lines represent the possible transitions within an inspection interval T, (*cf.* matrix P(T)). Recall that we make the simplifying assumption that one small piece of rail can only have one visit to OK* and F_1 (and F_2) within one inspection interval. Therefore we actually treat these as absorbing states in the time continuous Markov chain, and the process always start in state OK at the beginning of the next interval.

The dotted lines of Figure 68.14 indicate transitions at the end of the test interval (*cf.* matrix R). With probability q_1 we leave D_{1u} and with probability q_2 we leave D_{2u} (thus observing state D_2 but then going directly to OK, which is the starting state at the beginning of next interval). Further, with probability q_3 we leave D_{2d} (thus actually observing D_2), and there will also be transitions from the "absorbing states" OK* and F_1 to OK.

Thus, in the total the model we have a time-continuous Markov chain in the time spans between inspections, while at the inspections we have transitions following a time discrete Markov chain.

The model and the estimation are based on some assumptions:

- The processes U_n and V_n, are assumed to be stationary processes (the actual railway line is quite old so this is a rather realistic assumption).
- The probability distributions of the time continuous processes are identical for all inspection intervals (*i.e.,* stationarity is assumed also in this respect).

Failures are equally distributed over the railway line (homogeneity). However, the estimated rates can be seen as averages for the line in question.

We treat the critically failed states as absorbing states that are also repaired at the inspections. This implies that one small piece of rail cannot fail critically twice within one inspection interval. The mean time to repair (MTTR) = 0.

68.5.1.6 Input Data

The input parameters for the estimation of model parameters are listed in Table 68.1. Degraded failures have been recorded since 1 January 1991 and had been exposed to eight tests by October 2002. Critical failures have been recorded since 1 January 1989, and assuming the same length of the test interval (T=4299/8=537 days) also for these, this implies that these have been exposed to 9.4 tests. In total 800 degraded failures were observed. For 22 of these the severity was not recorded (*i.e.* not categorized as D_1 or D_2), and these 22 failures were just distributed proportionally amongst the two categories, giving in total 331 failures of type D_1 and 469 of type D_2.

Further, 20 of the D_2 failures had already been observed in state D_1 (*i.e.* coming from state D_{1d} and are actually monitored closely). It is then assumed that the test detects the transition to D_2, and so these failures are corrected, and there is a transition back to state OK. The 449 detected failures of type D_{2u} represent transitions from D_{1u}, *i.e.*, the degradations are observed for the first time. These are a fraction q_2 of the actual number of rail

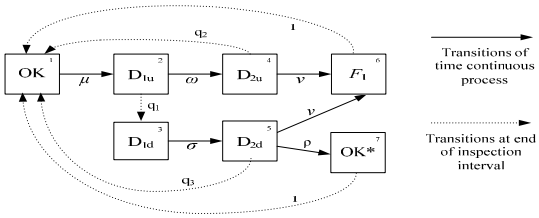

Figure 68.14. Overall failure/maintenance model, (state F_2 not included)

Table 68.1. Input data to analysis

Parameter definition	Parameter	Value
Length of rail	L	365 km = 365 000 m
Number of tests/inspections 1989–2002	n_{TF}	9.4
Number of tests/inspections 1991–2002	n_{TD}	8
Number of days, 1989–2002	N_1	5027
Number of days, 1991–2002	N_2	4299
Length of test/inspection interval	T	537 days
Number of observations in state D_1, (*i.e.*, transitions from D_{1u} to D_{1d})	N_{D1}	331
Number of observations in D_2 when it was not known that state was degraded, (*i.e.*, transitions from D_{2u})	N_{D2a}	449
Number of observations in D_2 when it was known that state was degraded, (*i.e.*, transitions from D_{1d})	N_{D2b}	20
Number of observations in F_1	N_{F1}	249
Number of observations in F_2	N_{F2}	81
Probability of detecting D_1 failure at test	q_1	0.4 (expert judgment)
Probability of detecting D_2 failure at test (state D_1 not detected previously)	q_2	0.7 (expert judgment)
Probability of detecting D_2 failure at test (state D_1 already detected)	q_3	0.9 (expert judgment)
Rate of detecting D_2 in additional inspections; (assuming on the average two additional inspections within each interval T)	ρ	$(2/T)q_3$ (exp. judgm.)

pieces in state D_{2u}, and will by the test be brought back to the state OK. The other will remain in state D_{2u}. Finally, the number of critical failures of type F_1 and F_2 are given as 249 and 81, respectively.

In order to carry out the estimation of the unknown rates some parameters must be estimated by expert judgments (operational experience). These are the probabilities q_1, q_2 and q_3, and the rate (ρ) of reaching state D_2 under additional inspections when state D_1 is detected.

68.5.1.7 Estimation

It is now quite easy to estimate the distribution of U_n under stationarity. For instance, the estimate of π_6 is given by the number of observations in F_1. The equations for π_4 and π_2 are obtained similarly. Finally, the estimated π_5 and π_7 are found from the number of detections of state D_2 given that degradation D_1 is already known. One third of these observations are assumed to be carried out at the ordinary inspections (see bottom of Table 68.1), and two thirds at the additional inspections, thus resulting in transitions to state OK*. Further, the estimate of π_3 can be obtained from the following relation:

$$\pi_3 = (\pi_2 \cdot q_1 + \pi_3) \cdot (1 - e^{-\sigma T}) . \quad (68.19)$$

The argument is that if $U_n = 3$, then either $U_{n-1} = 3$ *or* $U_{n-1} = 2$, and D_1 being detected, giving a transition from state 2 to 3, *and* in addition no transition has occurred in the last inspection interval. Finally we have the normalization equation.

Now, a joint estimation of the stationary distribution, $\boldsymbol{\pi}$, and the unknown rates (μ, ω, σ, ν),

are obtained by a recursive approach (see [26]), and we get the following estimates for the stationary probabilities π_j (for 1 m rail):

$$(\hat{\pi}_1,\hat{\pi}_2,...,\hat{\pi}_7) = (0.99935,\ 2.83\cdot10^{-4},\ 7.25\cdot10^{-5},\ 2.20\cdot10^{-4},\ 2.54\cdot10^{-6},\ 7.30\cdot10^{-5},\ 4.57\cdot10^{-6})\ . \quad (68.20)$$

Further we get the following estimated rates (*per* day):

$$\hat{\mu} = 5.9\cdot10^{-7}\ /\text{m}\ \hat{\lambda} = 4.4\cdot10^{-8}\ /\text{m}\ , \quad (68.21)$$

$$\hat{\omega} = 1.6\cdot10^{-3}\ , \quad (68.22)$$

$$\hat{\sigma} = 9.2\cdot10^{-4}\ , \quad (68.23)$$

$$\hat{\nu} = 9.3\cdot10^{-4}\ , \quad (68.24)$$

$$\hat{\rho} = 3.4\cdot10^{-3}, \quad (68.25)$$

Observe that the estimate for ρ was obtained directly from expert judgment (Table 68.1), and λ was estimated directly from the number of F_2 failures, (N_{F2}) the total number of days N_1, and the rail length, *i.e.*, $\hat{\lambda} = N_{F2}/(N_1\cdot L)$.

Further, observe that now the distribution of V_n is also found using the R-matrix ($\boldsymbol{\psi} = \boldsymbol{\pi}\cdot R$). There are five possible states at the start of a test interval $(\psi_6 = \psi_7 = 0)$ and

$$(\hat{\psi}_1,\hat{\psi}_2,.....,\hat{\psi}_5) = (0.99958,\ 1.7\cdot10^{-4},\ 1.9\cdot10^{-4},\ 6.6\cdot10^{-5},\ 2.5\cdot10^{-7}). \quad (68.26)$$

68.5.1.8 Maintenance Optimization

When the estimates of the rates $\lambda, \mu, \omega, \sigma$, and ν are established it is of interest to consider the effect of various levels of maintenance on basic reliability parameters like:

- the frequency (rate) of entries into failure states, and
- the mean time to failure.

Now introduce MTTFi = mean time to failure for failure mode i (*i.e.* F1 and F2). The rate 1/MTTF = (1/MTTF1 + 1/MTTF2) can also be referred to as the (asymptotic) rate of occurrence of failure, ROCOF1, (see [28]) when there is no maintenance. First observe that

$$\text{MTTF}_1 = (1/\mu+1/\omega+1/\nu) = 9.2 \text{ years}, \quad (68.27)$$

$$\text{MTTF}_2 = 1/\lambda = 62 \text{ years}, \quad (68.28)$$

$$\text{MTTF} = (1/\text{MTTF}_1 + 1/\text{MTTF}_2)^{-1} = 8.0 \text{ years}. \quad (68.29)$$

There are two parameters related to the maintenance that we can control:

- the length of inspection interval, T, and
- the frequency of additional inspections, (*cf.* ρ), when degradation in state D_1 is detected.

As the number of entries to the critically failed state F_2 does not change with the maintenance level, we keep focusing on the failures due to degradation. In particular, the asymptotic rate of entering F_1 and its inverse (MTTF_1) for various values of T is most interesting.

To find such entry rates we need the overall average probability of the time continuous process in various states. The probability for the process $X(t)$ to be in state k at time t equals (remember that $\psi_5 = \psi_6 = 0$):

$$p_k(t) = \sum_{j=1}^{5} \psi_j\, p_{jk}(t)\ . \quad (68.30)$$

Here $p_{jk}(t)$ are the elements of the transition matrix $P(t)$. Now the "average probability" to be in state k equals

$$p_k^* = \sum_{j=1}^{5} \psi_j\, p_{jk}^*\ , \quad (68.31)$$

where

$$p_{jk}^* = \tfrac{1}{T}\int_0^T p_{jk}(t)\,dt\ . \quad (68.32)$$

[1] Here we generally use *ROCOX* as the rate of occurrences of state X (the asymptotic rate of entering state X).

For example, the "overall" (average) probability of the time continuous process to be in state OK is found as

$$P(OK) = \psi 1 \cdot p_1^* = \psi 1 \cdot [1 - e^{-\mu T}] / (\mu \cdot T)$$

$$\approx [1 - e^{-\mu T}] / (\mu \cdot T). \quad (68.33)$$

The rate of entries into the degradation state D_1 (actually D_{1u}) is then found as

$$ROCOD_{1u} = P(OK) \cdot \mu \approx [1 - e^{-\mu T}] / T. \quad (68.34)$$

The most interesting results is obviously the rate of entries into the critical failure state F_1. We then need the probabilities to be in states D_{2u} or D_{2d}. Now,

$$P(D_{2u}) = \psi_1 \cdot p_{14}^* + \psi_2 \cdot p_{24}^* + \psi_4 \cdot p_{44}^* , \quad (68.35)$$

$$P(D_{2d}) = \psi_3 \cdot p_{35}^* + \psi_5 \cdot p_{55}^* \quad (68.36)$$

can be derived. The asymptotic rate into F1 equals

$$ROCOF_1 = [P(D_{2u}) + P(D_{2d})] \cdot \nu. \quad (68.37)$$

So for the maintained system, the asymptotic $MTTF_1 = 1/ ROCOF_1$ is given by these formulas.

Now ROCOD1u, ROCOD2u, ROCOF1 and MTTF1 are computed for a few values of T, and also for some alternative values of ρ. Table 68.2 gives the results for T=365 days and 730 days together with the actual value of the observations (T=537 days). The mean number of observations in state F1 for a time span corresponding to the actual data (*i.e.*, 5027 days) is also given. In Table 68.3 we use T = 537 days, but vary the rate ρ. The rate ρ is given as a percentage of the value used in the analyses above.

Thus, the estimated model shows, for instance, that the MTTF for critical degradation failures of 1 km length of rail decreases from 28.0 years when inspection interval is 1 year, to 14.8 years when the inspection interval is 2 years (Table 68.2). Similarly, mean number of failures is almost doubled when T increases from one year to two years. The frequency of increased inspections when a degraded failure is detected has less effect on the results (Table 68.3).

We note that the computed estimates are valid for the given line only; for another line with a

Table 68.2. Reliability parameters for various values of T

Parameter	Inspection interval T		
	365 days	537 days	730 days
$ROCOD_{1u}$ (per day and km)	$5.88 \cdot 10^{-4}$	$5.88 \cdot 10^{-4}$	$5.88 \cdot 10^{-4}$
$ROCOD_{2u}$ (per day and km)	$2.98 \cdot 10^{-4}$	$3.50 \cdot 10^{-4}$	$3.88 \cdot 10^{-4}$
$ROCOF_1$ (per day and km)	$0.98 \cdot 10^{-4}$	$1.42 \cdot 10^{-4}$	$1.85 \cdot 10^{-4}$
$MTTF_1$ for 1 km rail (years)	28.0	19.3	14.8
Mean no. of failures (in 5027 days)	180	261	339

Table 68.3. Reliability parameters for various values of ρ

ρ (rate of increased inspection by detecting state D_1)	$ROCOF_1$ (per day and km)	$MTTF_1$ for 1 km rail (years)	Mean no. of failures (in 5027 days)
25%	$1.50 \cdot 10^{-4}$	18.3	276
50%	$1.47 \cdot 10^{-4}$	18.6	270
100%	$1.42 \cdot 10^{-4}$	19.3	261
200%	$1.36 \cdot 10^{-4}$	20.1	250
400%	$1.31 \cdot 10^{-4}$	20.9	240

different state of the line and environment one would obviously obtain different estimates for the transition rates. The approach is, however, generally applicable, and the usefulness of analytic models to optimize maintenance is demonstrated.

68.5.2 Optimizing Track Maintenance

In this second case we will address the optimization of track geometry inspections on the Norwegian railway network. The critical failure is twist, and only one failure mechanisms are considered; critical failure occurs as the result of a degradation process. In addition a maintenance limit is defined. If the maintenance limit is reached, an action plan to maintain the degraded area should be planned so that the degraded area is maintained before it can lead to a derailment.

Various types of inspection and maintenance are performed on the line. Inspection by a self-propelled engine that uses three point laser sections to measure the track geometry (ROGER 1000) is carried out at regular intervals. Additional inspection will be initiated on a segment of the line with constant intervals. The degradation/repair process within the inspection interval is modeled as a time continuous Markov chain. Moreover, the change of state implemented at the end of an inspection interval is modeled as a (time discrete) Markov chain. The model is based on actual inspection data for a specific railway lines in Norway. The data are used to estimate the parameters of the model. The given failure/maintenance model and estimation technique should generally be useful for systems that experience deterioration and are subject to imperfect inspection.

68.5.2.1 Basic Model Description

This case resembles the case with broken rails with some differences. In this case, we follow the following assumptions:

- The system is subjected to a degradation process. The degradation is modeled as a Markov chain with 50 states, resembeling values of twist from 0−50 mm. The transition rates from one state to another is based on empirical data.
- The system is periodically inspected.
- The change in twist over time can be both increasing and decreasing, but with a drive towards a worsening state.
- The risk, in this case represented by the possibility of derailment, is given a value different for three parts of the rail. The possibility of a derailment is assumed different, given the same level of twist, depending on whether we have a straight line, a curvature, or a transition curve.
- PM and CM are modeled as perfect in the sense that the system is put back to initial distribution.

68.5.2.2 The Markov Chain Model

A Markov chain model a total of 50 states is introduced, each representing 1 mm in twist (Figure 68.15).

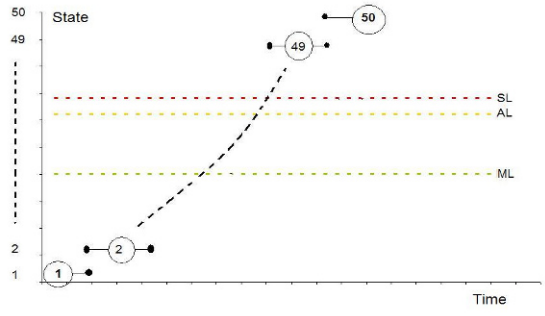

Figure 68.15. Markov state model

The next step is to find the probability that the system is in the various states as a function of time *t*. By letting $P_i(t)$ denote the probability that the system is in the state *i* at time *t*, we obtain the Markov differential equation by standard Markov considerations:

$$P_i(t+\Delta t) = P_i(t)\times(1-\lambda_i\times\Delta t) + P_{i-1}(t)\times\lambda_{i-1}\times\Delta t \,, \quad (68.38)$$

where Δt is a small time interval. However, in our case we have possible transition rates that are both positive and negative, hence the development can

be both encreasing and decreasing. Therefore (68.38) must be rewritten:

$$\begin{aligned} P_i(t+\Delta t) &= P_i(t)\times(1-(\lambda_i + \mu_i)\times\Delta t) \\ &+ P_{i-1}(t) \times \lambda_{i-1} \times \Delta t \\ &+ P_{i+1}(t) \times \mu_{i+1} \times \Delta t \ , \end{aligned} \tag{68.39}$$

where λ_i is the positive transition rate while μ_i is the negative rate. The transition rates of the *i*th state for straight lines, curvatures, and transition curves are given from data collected with the ROGER 1000 in the period from October 2003 to June 2005 on four Norwegian tracks: *Dovrebanen, Nordlandsbanen, Meråkerbanen,* and *Sørlandsbanen*. Having the devolopment of twist we can introduce the matrix, *R*, giving the possibility of changing from one state to another for straight line, curvature, and transition curves. Part of the transition matrix for curvature is given as an example in (68.40):

$$R_{Curvature} = \begin{array}{c} \\ 1 \\ 2 \\ 3 \\ . \\ 50 \end{array} \begin{array}{c} \begin{array}{ccccc} 1 & 2 & 3 & . & 50 \end{array} \\ \begin{bmatrix} 0{,}57 & 0{,}32 & 0{,}05 & . & . \\ 0{,}12 & 0{,}55 & 0{,}29 & . & . \\ 0{,}03 & 0{,}14 & 0{,}41 & . & . \\ . & . & . & . & . \\ . & . & . & . & . \end{bmatrix} \end{array}. \tag{68.40}$$

From this equation we can retrieve the transition rates $\lambda_{\text{Straight line}}$, $\lambda_{\text{Curvature}}$, $\lambda_{\text{Transition curve}}$, $\mu_{\text{Straight line}}$, $\mu_{\text{Curvature}}$, and $\mu_{\text{Transition curve}}$. The transition rates are given in days (Table 68.4).

Table 68.4. Transition rates

	Straight line	Curvature	Transition curve
λ_i	0.0017	0.0044	0.0034
μ_i	0.0006	0.0012	0.0012

68.4.2.3 Initial State Values

In this case, we use complete tracks as the system, and the tracks have a distribution of twist values to use as a starting point. In other words, we do not have a single value as a starting point, but a distribution of values. We have used the distribution given from empirical data of the track *Meråker banen* in October 2003. Figure 68.16 shows the distribution for curvatures, straight lines, and transition curves of the given level of twist. The distribution is given as meters of twist within a specific state divided by the total length.

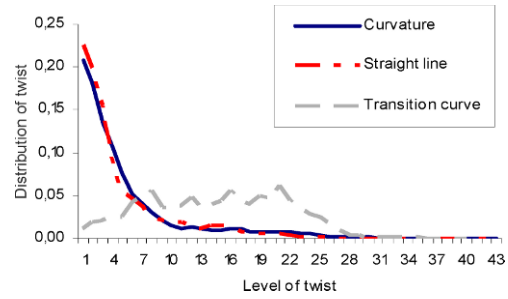

Figure 68.16. Distribution of twist

The probability of derailment is given for the three different track types. The probability is thought to be increasing exponential with the value of twist, giving a value for the probability for each state and track type.

Having these distributions and the transition rates, we can easily obtain the expected number of derailments per year, E(n_D), given different inspection intervals (τ). For this track the expected number of derailments is given in Figure 68.17.

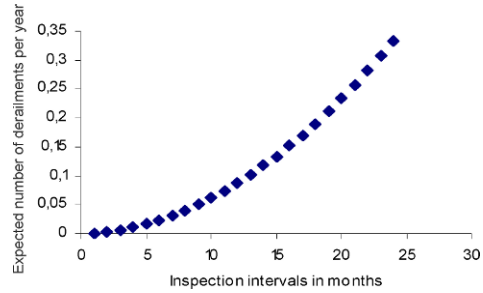

Figure 68.17. Expected number of derailments *per* year due to twist given different inspection intervals

68.4.2.4 Specification of Cost Elements

To optimize inspection intervals and intervention level we must specify the following basic cost elements:

C_D Cost per derailment (= costs for failure consequences, incl. PLL cost, material cost and cost of delay).

C_I Cost for one inspection(= fixed cost of requiring ROGER1000 and personnel operating it).

C_T Cost for one tamping action (= fixed cost of requiring the tamping machine and personnel operating it).

If E(n_D), E(n_I) and E(n_T) denote the expected number of derailments, inspections, and tamping, respectively, per year. The total costs is:

$$C_{tot} = C_D \times E(n_D) + C_I \times E(n_I) + C_T \times E(n_T). \quad (68.41)$$

The expenses were estimated for the derailment, inspection, and tamping costs of an average Norwegian railway track C_D = 15 000 000 NOK, C_I = 100 000 NOK, and C_T = 50 000 NOK, respectively. The total costs are plotted in Figure 68.18.

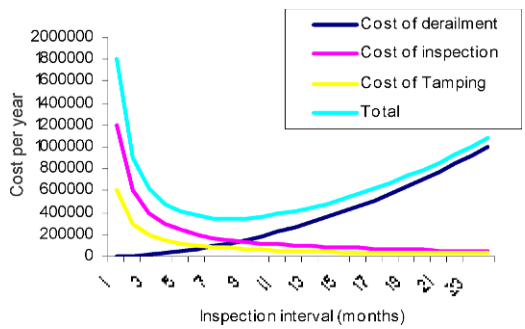

Figure 68.18. Present value of total costs and costs for CM, PM, and inspections

As can be seen from Figure 68.18, an inspection interval of approximately eight to nine months would give the lowest cost *per* year. The present inspection interval is six months, and by this calculation, about 20000 NOK per year could be saved by changing the inspection interval for this specific track.

68.6 Conclusions and Future Challenges

In this chapter we have introduced both aging/ degradation models and recent models for maintenance/renewal optimization that are relevant for railway tracks. Some of the models for maintenance optimization have been illustrated by case studies using data retrieved from inspection on Norwegian railway tracks.

However, there are some future challenges that are not addressed and require attention. The possibility for a degradation process to reverse is not included in the Markov modeling presented above. However, this could very well be the case in geometrical degradation, in particular with twist, as the forces in the track may to some degree reverse the development.

There may also be a challenge that maintenance can reduce the quality of the system. Maintenance action like tamping does not improve the quality of the ballast, but rather worsens it, making the degradation process change after the maintenance action.

Finally, the grouping of maintenance activities should be addressed. Such a grouping will not change the maintenance itself but will reduce the total costs as the logistics are improved.

Cost–Benefit Optimization Including Maintenance for Structures by a Renewal Model

Rüdiger Rackwitz and Andreas Joanni,

Technical University Munich, Munich, Germany

Abstract: This chapter develops tools for optimizing design and maintenance strategies of aging structural components. It first reviews suitable formulations for failure models in structural engineering and the basics of renewal theory. It then introduces a repair model with or without preceding (imperfect) inspections. The inspection model introduces some increasing damage indicator function. Repairs are required if it exceeds some given threshold. Objective functions are derived for systematic reconstruction after failure or maintenance by periodic repairs alone, and by periodic inspections and possibly ensuing repairs (renewals). Finite repair times with given distribution function are considered. Initial formulations for independent repair and failure events are extended to dependent no-repair/repair and failure events.

69.1 Introduction

Most civil engineering structures age because of wear, corrosion, fatigue, and other phenomena. At a certain age they need to be inspected and, possibly, repaired or replaced. Many aging phenomena are rather complex and all but fully understood in their physical and chemical context. For concrete structures the most important aging phenomena in temperate climates are corrosion due to carbonation and/or chloride attack; for steel structures it is rusting and fatigue. In general, aging phenomena are uncertain. They involve a number of random variables or random processes. Failure is defined as a first passage time failure. More specifically, failure is defined when a more or less complicated function of those variables reaches a limiting state for the first time. Failure time distributions must be determined numerically. This makes analyses rather complex and rather different from analyses where analytical failure time models based on rich data can be used.

Another area of great interest is the optimization of the cost spent in maintaining civil engineering facilities. The enormous cost required for maintaining public infrastructures, for example, call for careful cost-benefit optimization of design rules and maintenance. It should be clear that only a rigorous life-cycle consideration can fully account for all cost involved. Moreover, it should be clear that design rules and maintenance procedures strongly interact.

In the following, classical renewal theory is applied in order to set up suitable objective functions for cost–benefit optimization of maintained structures. It turns out that almost all concepts developed earlier for electronic and machine components can also be employed in

structural engineering. In the civil engineering field some basic concepts have already been developed in [1] and later in [2] for stationary failure processes without deterioration. In agreement with standard cost–benefit analyses all benefits and cost are discounted. Rigorous integration of maintenance cost of inspection and repairs for structural components was started in [3] and [4] based on the work by Cox [5], Barlow and Proschan in [6], [7] but especially by Fox [8]. This continued in [9] by extending the considerations to existing structures. Age-dependent and block repairs as well as condition-based repairs were considered. In [4] and other references successful attempts have been made to cover also series systems. In all this work it was assumed that no-repair/repair events and failure events are independent, and repair times are negligible as compared to the failure times. However, this is rarely realistic since, on the one hand, inspection results and consecutive repair decisions and failure events most often depend on the same physical deterioration processes and, therefore, become highly dependent. On the other hand, infinitely short renewal times as assumed so far are generally only a simplification. The formulations are extended to cover also finite renewal times. These limitations have recently been removed in [10], which is also the basis of this contribution.

After presenting some failure models suitable for aging structural components, reviewing renewal theory to the extent needed for the further developments, and introducing appropriate inspection and repair models, the chapter first reviews the concepts for cost benefit optimization based on the renewal model. This is then extended to include preventive and corrective maintenance including independent and dependent no-repair/repair and failure events. Thereafter, new results are derived for the case of finite renewal times. An example illustrates the main findings.

69.2 Preliminaries

69.2.1 Failure Models for Deteriorating Components

There are very few exact, time-variant failure models available. One such model with many potential applications is the so-called random disturbance model. As a special case, stationary random Poissonian disturbances (earthquakes, storms, explosions, fires, *etc.*) with occurrence rate are considered. If a disturbance hits the system, failure will occur with probability $P_f(\mathbf{p})$. $\mathbf{p}$ is a vector of suitable design parameters. The failure process will again be Poissonian with rate $\lambda P_f(\mathbf{p})$. Deterioration cannot be accounted for. It is presented here only for completeness.

For aging structures a closed-form failure time (first passage time) distribution is hardly available except for some special, usually oversimplifying cases. The log-normal, inverse Gaussian or Weibull distribution function with a suitable deterioration mechanism for the mean (and/or other parameters) have been used. However, sufficient data to support those models are rarely available in the structures area. Realistic failure models must be derived from physical multi-variable deterioration models (cumulative wear, corrosion, fatigue, *etc.*). For deteriorating structures a widely used failure model is when the deterioration function is monotonically and continuously in(de)creasing. Then, let $G(\mathbf{X},t) = g(\mathbf{U},t)$ be the (differentiable), continuously decreasing structural state function of a structural component with $G(\mathbf{X},t) = g(\mathbf{U},t) \le 0$ the failure domain. $G(\mathbf{X},t) = g(\mathbf{U},t) = 0$ is denoted as limit state. $\mathbf{X}$ is a vector of random variables with continuous distribution function and time t is a parameter. Transition from $\mathbf{X}$ to $\mathbf{U}$ denotes the usual probability transformation from the original into the standard space of variables [11]. Within FORM/SORM the probability of the time to failure is [12], [13]

$$\begin{aligned} F(t) &= P(T \le t) \\ &= P(g(\mathbf{U},t) \le 0) \approx \Phi(-\beta(t))C(t) \end{aligned} \tag{69.1}$$

for $t \ge 0$, and the corresponding failure density is

$$\begin{aligned} f(t) &= \frac{\partial F(t)}{\partial t} \\ &\approx -\varphi(\beta(t))\frac{\partial \beta(t)}{\partial t}C(t) + \Phi(-\beta(t))\frac{\partial C(t)}{\partial t} \\ &= -\varphi(\beta(t))\left(\frac{-\frac{\partial}{\partial t}g(\mathbf{u}^*,t)}{\|\nabla_{\mathbf{u}}g(\mathbf{u}^*,t)\|}\right)C(t) \\ &\qquad + \Phi(-\beta(t))\frac{\partial C(t)}{\partial t}. \end{aligned} \tag{69.2}$$

T is the time to first entrance into a failure state. $\Phi(\cdot)$ and $\varphi(\cdot)$ denote the univariate standard normal distribution function and corresponding density, respectively. $\beta(t)$ is the (geometrical) reliability index $\beta(t) = \min\{\|\mathbf{u}\|\}$ for $\{\mathbf{u} : g(\mathbf{u},t) \le 0\}$. $C(t)$ is a correction factor evaluated according to SORM (and/or importance sampling) which can be neglected in many cases. In (69.2) it frequently can be assumed that $C(t)$ does not vary with t. Throughout the paper only FORM/SORM techniques will be applied.

In some cases consideration of (stationary or non-stationary) time-variant actions and a time-variant structural state function is necessary. Let $G(\mathbf{X}(t),t)$ be the (differentiable) structural state function such that $G(\mathbf{X}(t),t) \le 0$ denotes failure states and $\mathbf{X}(t)$ a random process. Then, the failure time distribution can be computed numerically by the outcrossing approach. A well-known upper bound is [14]

$$F(t) \le \int_0^t \nu(\tau)d\tau \le 1 \tag{69.3}$$

with the outcrossing rate (more specifically, the downcrossing rate)

$$\begin{aligned} \nu(\tau) = \lim_{\Delta\to 0}\frac{1}{\Delta}P(&\{G(\mathbf{X}(t),t) > 0\} \\ &\cap \{G(\mathbf{X}(t+\Delta),t+\Delta) \le 0\}) \end{aligned} \tag{69.4}$$

with Δ some small time interval. Most frequently, however, an asymptotic result is used

$$F(t) = 1 - \exp\left[-\int_0^t \nu(\tau)d\tau\right]. \tag{69.5}$$

Equation (69.5) implies a non-homogeneous Poisson process of failure events with intensity $\nu(t)$. For stationary failure processes (69.5) reduces to a homogeneous Poisson process and simplifies somewhat. Under suitable conditions both formulae can also be evaluated using FORM/SORM provided that the dependence structure of the two events $\{G(\mathbf{X}(t),t) > 0\}$ and $\{G(\mathbf{X}(t+\Delta),t+\Delta) \le 0\}$ can be determined in terms of correlation coefficients. However, the relevant conditions must be fulfilled, *i.e.*, the outcrossing events must become independent and rare asymptotically. For example, the independence property is lost if $\mathbf{X}(t)$ contains not only (mixing) random processes but also simple random variables. Therefore, in many cases this approach yields only crude approximations.

A numerical computation scheme for first-passage time distributions under less restrictive conditions can also be given. It is based on the following lower bound formula:

$$\begin{aligned} F(t) = P(T \le t) &= 1 - P(G(\mathbf{X}(\theta),\theta) > 0 \\ &\qquad \text{for all } \theta \text{ in } [0,t]) \\ &\ge P\left(\bigcup_{i=1}^{n} P(G(\mathbf{X}(t_i),t_i) \le 0)\right) \end{aligned} \tag{69.6}$$

with $t = t_n$ and $t_i < t$ denoting a narrow not necessarily regular time spacing of the interval $[0,t]$. As demonstrated by examples, *e.g.*, in [15], the lower bound to the first-passage time distribution turns out to be surprisingly accurate for all values of $F(t)$, if the time-spacing $\tau = \theta_i - \theta_{i-1}$ is chosen sufficiently close and where $\theta_i = i\tau$ and $t = \theta_n$. Within FORM/SORM it is

$$F(t) = P(T \le t) \ge P(\bigcup_{i=0}^{n} \{g(\mathbf{U}(\theta_i), \theta_i) \le 0\})$$
$$\approx P(\bigcup_{i=0}^{n} \{\alpha(\theta_i)^T \mathbf{U}(\theta_i)) + \beta(\theta_i) \le 0\}$$
$$= 1 - P(\bigcap_{i=0}^{n} \{Z_i \le \beta(\theta_i)\}) = 1 - \Phi_{n+1}(\mathbf{b}; \mathbf{R}) \tag{69.7}$$

Here again, a probability distribution transformation from the original space into the standard space is performed and the boundaries of each failure domain are linearized. The last line represents a first order approximation where $\Phi_n(\cdot;\cdot)$ is the n-dimensional standard normal integral with $\mathbf{b} = \{\beta(\theta_i)\}$ the vector of reliability indices of the various components (elements, individual events) in the union and the dependence structure of the events is determined in terms of correlation coefficients $\mathbf{R} = \{\rho_{ij} = \alpha(\theta_i)^T \alpha(\theta_j)\}$. Suitable computation schemes for the multinormal integral for high dimensions and arbitrary probability levels have been proposed, for example, in [16], [17], [18] and [19]. This computation scheme is approximate but quite general if the correlation structure of the state functions in the different points in time can be established.

Deterioration of structural resistance is frequently preceded by an initiation phase. In this phase failure is dominated by normal (extreme-value) failure. Structural resistance is virtually unaffected. Only in the succeeding phase do resistances degrade. Examples are crack initiation and crack propagation or chloride penetration into concrete up to the reinforcement and subsequent reduction of the reinforcement cross-section by corrosion, and, similarly, for initial carbonation and subsequent corrosion. In many cases the initiation phase is much longer than the actual degradation phase. Let T_i denote the random time of initiation, T_e the random time to normal (first-passage extreme-value) failure and T_d the random time from the end of the initiation phase to deterioration failure with degraded resistance. Note, extreme-value failure during the initiation phase and failure in the deterioration phase are mutually exclusive. If the variables and T_d can be assumed independent, the following formula can be used:

$$F(t) = F_e(t)\bar{F}_i(t) + \int_0^t f_i(\tau)\left[F_e(\tau) + (1 - F_e(\tau))F_d(t-\tau)\right] d\tau . \tag{69.8}$$

69.2.2 A Review of Renewal Theory

Assume that the structure fails at a random time in the future. After failure or serious deterioration it is systematically renewed by reconstruction or retrofit/repair. Reconstruction or retrofit/repair reestablish all (stochastic) structural properties. The times between failure (renewal) events have identical distribution functions $F(t),\ t \ge 0,$ with probability densities $f(t)$ and are independent (see [3] for details). Those are precisely the conditions under which classical renewal theory holds. Renewal theory allows for the first failure time distribution being different from the others. For simplicity, this modification is not considered herein (see, however, [5]). The independence assumption needs to be verified carefully. In particular, one has to assume that loads and resistances in the system are independent for consecutive renewal periods and there is no change in the design rules after the first and all subsequent failures (renewals). Even if designs change failure time distributions must remain the same.

The renewal function based on these assumptions and which will be used extensively later on is

$$M(t) = E[N(t)] = \sum_{n=1}^{\infty} np(N(t) = n)$$
$$= \sum_{n=1}^{\infty} n[F_n(t) - F_{n+1}(t)] = \sum_{n=1}^{\infty} F_n(t)$$
$$= \sum_{n=1}^{\infty} \int_0^t F_n(t-u)dF(u) = F(t) + \int_0^t M(t-u)dF(u) \tag{69.9}$$

with $N(t)$ the random number of renewals and $p(N(t) = n)$ the probability mass function. The

last expression in (69.9) is called the "renewal equation"'. Unfortunately, (69.9) has closed-form solutions for only very few special failure models. In general, (69.9) has to be determined numerically. A particularly suitable method is proposed in [20]. It starts from the renewal equation (69.9) and solves it numerically by simply making use of the upper and lower sum in Riemann–Stieltjes integration. Because $M(t)$ is non-decreasing we have the following bounds:

$$\begin{aligned} M_L(k\tau) &= F(k\tau)+\sum_{i=1}^{k} M_L((k-i)\tau)\Delta F(i\tau) \le \\ &\le M(k\tau) \le \\ &\le F(k\tau)+\sum_{i=1}^{k} M_U((k-i+1)\tau)\Delta F(i\tau) = M_U(k\tau) \end{aligned} \tag{69.10}$$

for equal partitions of length τ in $[0,t]$ with $\Delta F(i\tau) = F(i\tau) - F((i-1)\tau)$ and $n\tau = t$. This linear equation system is solved numerically.

Another related quantity of interest is the availability of a system, *i.e.*, its probability of being in a functional state. This is particularly interesting if, as discussed later, repairs take a finite time. Let $F(t)$ be the life time distribution with density $f(t)$ and $G(t)$ the repair-time distribution with density $g(t)$ of a component so that $H(t) = \int_0^t F(t-u)g(u)du$ is the distribution of $T_F + T_G$ for independent failure and repair times. Then, an important characteristic is the (point-in-time) availability of the component

$$A(t) = 1 - F(t) + \int_0^t (1 - F(t-u))dM_H(u), \tag{69.11}$$

where $M_H(t) = \sum_{i=1}^{\infty} H_i(t)$ is the renewal function for $H(t)$. The asymptotic availability is defined as

$$A(\infty) = \frac{E[T_F]}{E[T_F] + E[T_G]}, \tag{69.12}$$

which is easily interpreted as the ratio of the fraction of working time to the total time of a renewal cycle. Usually, $A(t)$ rapidly approaches $A(\infty)$. It is also possible to compute bounds on availability by the same method as for (69.3). Since

$$\begin{aligned} A_{U,L}(k\tau) &\lessgtr 1 - F(k\tau) + \\ &+ \sum_{j=1}^{k} (1 - F((k-j)\tau))(M_{U,L}(j\tau) - M_{U,L}((j-1)\tau)) \end{aligned} \tag{69.13}$$

one may use (69.10) in (69.13) for $k\tau < t$ and $A(0) = 1$. Unfortunately, as time t becomes large the numerical bounds widen.

The renewal intensity (or, if applied to failure processes, the unconditional failure intensity)

$$\begin{aligned} m(t) &= \lim_{dt \to 0} \frac{P(\text{one renewal in}[t, t+dt])}{dt} \\ &= \frac{dM(t)}{dt} = \sum_{n=1}^{\infty} f_n(t) \end{aligned} \tag{69.14}$$

can be obtained by differentiating the renewal function. As pointed out in [5] $m(t)$ has a limit

$$m(t \to \infty) = \lim_{t \to \infty} m(t) = \frac{1}{E[T]} \tag{69.15}$$

for $f(t) \to 0$ if $t \to \infty$. In approaching the limit it can be strictly increasing, strictly decreasing or oscillate in a damped manner around $1/E[T]$. For most failure models with increasing risk function the renewal intensity is increasing. The renewal intensity (failure rate) can be used to set acceptability limits, which is not done herein.

69.2.3 Inspection and Repair

Inspections should determine the actual state of a component in order to decide whether to carry out on repair or to leave it as is. However, inspections can rarely be perfect. A decision about repair can only be reached with certain probability depending

on the inspection method used. The repair probability depends on the magnitude of one (or more) suitable damage indicators (chloride penetration depth, crack length, abrasion depth, *etc.*) measured during inspection. For cumulative damage phenomena the repair probability $P_R(t)$ increases with the time t elapsed since the beginning of the deterioration process. For example, the repair probability may be presented as

$$P_R(t) = P(S(t,\mathbf{X}) > s_c) = P(s_c - S(t,\mathbf{X}) \le 0) \tag{69.16}$$

with $S(t,\mathbf{X})$ a suitable, monotonically increasing damage indicator, $\mathbf{X}$ a random vector taking into account all uncertainties during inspection and s_c a given threshold level. The vector $\mathbf{X}$ usually also includes a random variable modeling the measurement error. Frequently, the damage indicator function $S(t,\mathbf{X})$ has a similar form as the failure function and involves, at least in part, the same random variables. In this case failure and repair events become dependent events. Generalizations of (69.16) to multiple damage indicators and more complicated decision rules are straightforward. A discussion of the details of the efficiency of various inspection methods and the corresponding repair probabilities is beyond the scope of this paper.

After failure of a system or component it is repaired unless it is given up after failure. The term "repair" is used synonymously for repair, renewal, replacement, or reconstruction. Repairs, if undertaken, restore the properties of a component to its original (stochastic) state, *i.e.*, repairs are equivalent to renewals (AGAN= as good as new), so that the life time distribution of the repaired component is again $F(t)$. The repair times can either be assumed negligibly short or have finite length.

The proposed model is a somewhat idealized model capturing the most important aspects of the decision problem. It rests on a number of assumptions the most important of which is probably that repairs fully restore the initial (stochastic) properties of the component. Imperfect repairs cannot be handled because the renewal argument repeatedly used in the following breaks down. In the literature several models for imperfect repairs are discussed, which only partially reflect the situations met in the structures area. An important case is when so-called minimal repairs not essentially changing the initial lifetime are done right after an inspection. Such repairs leave a component "as bad as old"'. Renewal (perfect repair) occurs with probability π but minimal repair with probability $1-\pi$. This model, in fact, resembles the one studied herein with $\pi = P_R(t)$. A review of other and especially imperfect repair models is given in [22].

Inspection/repair at strictly regular time intervals as assumed below is also not very realistic. However, as will be shown in the example, the objective function is rather flat in the vicinity of the optimal value so that small variations will not noticeably change the results.

Repair operations necessarily lead to discontinuities (drops) in the risk function as well as in the (unconditional) failure rate. They can substantially reduce the number of failures and, thus, corrective renewals.

69.3 Cost–Benefit Optimization

69.3.1 General

For technical facilities the following objective has been proposed by Rosenblueth and Mendoza [1] based on earlier proposals for cost–benefit analysis:

$$Z(\mathbf{p}) = B(\mathbf{p}) - C(\mathbf{p}) - D(\mathbf{p})\,. \tag{69.17}$$

A facility is financially optimal if (69.17) is maximized. It is assumed that all quantities in (69.17) can be measured in monetary units. $\mathbf{p}$ is the vector of all safety relevant parameters. $B(\mathbf{p})$ is the benefit derived from the existence of the facility, $C(\mathbf{p})$ is the cost of planning, design, and construction and $D(\mathbf{p})$ is the cost in case of failure. Statistical decision theory dictates that expected values are to be taken [23]. In the

following it is assumed that $B(\mathbf{p}), C(\mathbf{p})$ and $D(\mathbf{p})$ are differentiable in each component of **p.** This makes optimization of (69.17) easy because gradient-based optimizers can be used. The cost may differ, for the different parties involved have different economic objectives, *e.g.*, the owner, the builder, the user, and society. A facility makes sense only if $Z(\mathbf{p})$ is positive within certain parameter ranges for all parties involved.

The facility has to be optimized during design and construction at the decision point. Therefore, all costs need to be discounted. A continuous discounting function is assumed for analytical convenience, which is accurate enough for all practical purposes,

$$\delta(t) = \exp\left[-\gamma t\right],$$

Where γ is a time-independent, time-averaged interest rate. In most cost–benefit analyses a tax-free and inflation-free discount rate should be taken. If a discrete discount rate γ' is given, one converts with $\gamma = \ln(1+\gamma')$.

In contrast to strategies that do a cost–benefit analysis only for given service times or, possibly, for the time to failure after which the structure is given up it is assumed that structures will be systematically reconstructed after failure or obsolescence and/or are properly maintained by perfect repairs. This rebuilding strategy is in agreement with the principles of life-cycle engineering and also fulfills the demand for sustainability [24]. Clearly, it rests on the assumption that future preferences are the same as the present preferences. It follows that sustainable life-cycle costing not only includes the cost of one replacement but of all cost that might emerge from future failures and renewals (repairs, replacements, *etc.*). Another aspect of sustainability is that only moderate discount rates should be chosen.

69.3.2 The Standard Case

The benefit $B(\mathbf{p})$ is discounted down to the decision point. For a benefit rate $b(t)$ unaffected by possible renewals one find

$$B = \int_0^\infty b(t)\exp\left[-\gamma t\right] A(t)dt \tag{69.18}$$

assuming convergence of the integral. If the benefit rate $b = b(t)$ is constant, and repair times are negligibly short one can integrate to obtain

$$B = \int_0^\infty b\exp\left[-\gamma t\right]dt = \frac{b}{\gamma}. \tag{69.19}$$

The upper integration limit is extended to infinity because the full sequence of life-cycle benefits is considered. A more refined benefit model has been introduced in [25], which is not considered herein (see, however, [9]).

The construction costs $C(\mathbf{p})$ are generally easy to assess. If they have to be financed, the cost of financing reduces the benefit. For example, the yearly cost for full financing (as a constant annuity) are $dC_\gamma(\mathbf{p}) = C(\mathbf{p})\dfrac{\exp\left[\gamma\right]-1}{1-\exp\left[-\gamma t_f\right]}$, where t_f is the financing time. These yearly costs can be taken into account in the benefit term.

The determination of damage cost is more involved. Consider the case of systematic reconstruction (or repair). Let Y_n be the time to the n th renewal

$$Y_n = \sum_{r=1}^{n} U_r, \tag{69.20}$$

and denote by $K(U_n)$ the cost of the interval U_n. $K(U_n)$ can contain failure cost, reconstruction cost or repair cost and it can be a function of time. The total discounted cost K for an infinite length of time is the sum of all renewal cost discounted down to time 0. This gives

$$K = \sum_{n=1}^{\infty} K(U_n) e^{\left(-\gamma\sum_{r=1}^{n} U_r\right)}. \tag{69.21}$$

The expected damage costs D are computed from:

$$\begin{aligned} D &= E\left[\sum_{n=1}^{\infty} K(U_n) e^{\left(-\gamma \sum_{r=1}^{n} U_r\right)}\right] \\ &= \sum_{n=1}^{\infty} E\left[\left(\prod_{r=1}^{n-1} e^{-\gamma U_r}\right) K(U_n) e^{-\gamma U_n}\right] \\ &= \sum_{n=1}^{\infty} E\left(e^{-\gamma U}\right)^{n-1} E\left(K(U) e^{-\gamma U}\right) = \frac{E\left(K(U) e^{-\gamma U}\right)}{1 - E\left(e^{-\gamma U}\right)} \end{aligned} \tag{69.22}$$

where we used formulations proposed in [26]. The renewal model ensures that all times U_r are identically distributed and independent. In the last line the well-known relation $\sum_{n=1}^{\infty} a q^{n-1} = \frac{a}{1-q}$ is used. $E\left(e^{-\gamma U}\right) = \int_0^{\infty} \exp[-\gamma u] f_U(u) du = f^*(\gamma)$ is also denoted by the Laplace transform of $f_U(u)$. Equation (69.22) is the key result for cost benefit optimization based on the renewal model. It should be mentioned that parallel but less rich results can be obtained for discrete failure models and discrete discounting [27].

69.4 Preventive Maintenance

69.4.1 Cost Benefit Optimization for Systematic Age-dependent Repair

First it should be emphasized that preventive maintenance only makes sense for increasing risk functions $r(t) = \frac{f(t)}{1 - F(t)}$ of the failure model. If the risk function is not increasing (but is constant or even decreasing) it is more cost–benefit optimal to wait until failure.

The general case of replacements (repairs, renewals) at random times T_R with distribution $F_R(t)$ or after failure at random times T_F with distribution $F_F(t, \mathbf{p})$ is best derived as follows. The renewal time is the minimum of these times with distribution function

$$\begin{aligned} F(t, \mathbf{p}) &= 1 - (1 - F_F(t, \mathbf{p}))(1 - F_R(t)) \\ &= 1 - \bar{F}_F(t, \mathbf{p}) \bar{F}_R(t) \end{aligned} \tag{69.23}$$

for independent times T_F and T_R with density

$$f(t, \mathbf{p}) = f_F(t, \mathbf{p}) \bar{F}_R(t) + f_R(t) \bar{F}_F(t, \mathbf{p}), \tag{69.24}$$

where the notation $\bar{F}(x) = 1 - F(x)$ is used. Application of (69.22) then gives for the damage term of an ordinary renewal process

$$\begin{aligned} D(\mathbf{p}) &= \frac{E\left(K(U) e^{-\gamma U}\right)}{1 - E\left(e^{-\gamma U}\right)} \\ &= \frac{(C(\mathbf{p}) + L) f^*_{\bar{F}_R}(\gamma, \mathbf{p}) + R(\mathbf{p}) f^*_{\bar{F}_F}(\gamma, \mathbf{p})}{1 - (f^*_{\bar{F}_F}(\gamma, \mathbf{p}) + f^*_{\bar{F}_R}(\gamma, \mathbf{p}))} \end{aligned} \tag{69.25}$$

where $f^*_{\bar{F}_R}(\gamma, \mathbf{p}) = \int_0^{\infty} \exp[-\gamma t] f_F(t, \mathbf{p}) \bar{F}_R(t) dt$ and $f^*_{\bar{F}_F}(\gamma, \mathbf{p}) = \int_0^{\infty} \exp[-\gamma t] f_R(t) \bar{F}_F(t, \mathbf{p}) dt$ are the modified complete Laplace transforms of $f_F(t, \mathbf{p}) \bar{F}_R(t)$ and $f_R(t) \bar{F}_F(t, \mathbf{p})$, respectively. L is the direct loss of failure, $C(\mathbf{p})$ the reconstruction cost after failure, and $R(\mathbf{p})$ the cost of repair.

At first sight, the case of random maintenance actions has hardly any practical application. However, if there is continuous monitoring of the structural state, the times T_R can be interpreted as the times when the monitoring measurements reach a critical value for the first time and, therefore, indicate the necessity of repair actions. This case is not studied further. Alternatively, assume maintenance actions with probability one at (almost) fixed intervals $a, 2a, 3a, \ldots$ so that $f_R(t) = \delta_e(a)$ and $F_R(t) = H_e(a)$ ($\delta_e(x) =$ Dirac's delta function, and $H_e(a) =$ Heavyside's unit step function). Equation (69.25) then becomes:

$$D_M(\mathbf{p},a) = \frac{(C(\mathbf{p})+L)f^{**}(\gamma,\mathbf{p},a)+R(\mathbf{p})\exp[-\gamma a]\bar{F}(\mathbf{p},a)}{1-(f^{**}(\gamma,\mathbf{p},a)+\exp[-\gamma a]\bar{F}(\mathbf{p},a))} \tag{69.26}$$

where $f^{**}(\gamma,\mathbf{p},a)=\int_0^a \exp[-\gamma t] f_F(t,\mathbf{p})dt$ is the incomplete Laplace transform of $f_F(t,\mathbf{p})$. The derivations for (69.25) and (69.26) clearly show that systematic repairs should be interpreted as one of the two renewal modes. Equation (69.26) goes back to some early work in [5] and [6], and especially to Fox [8]. It is still the basis for further developments in cost–benefit optimization for maintained structures with discounting, as will be seen below. Optimization can be carried out with respect to the design parameter $\mathbf{p}$ and/or the maintenance interval a. Already Fox [8] pointed out that an optimum in a only exists if the risk function of the failure model is increasing. Also, the repair cost $R(\mathbf{p})$ should be substantially smaller than $C(\mathbf{p})+L$ so that it is worth making preventive repairs and, thus, avoiding large failure and reconstruction cost in the case of failure.

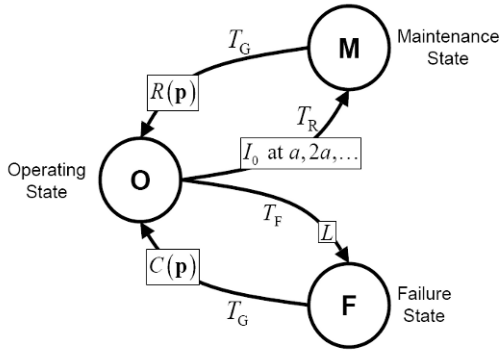

Figure 69.1. Finite repair times after failure or planned repair

Finite renewal times require only small modifications. The component behavior is modeled as shown in Figure 69.1. All repair times are identically distributed and independent of failure times. At failure costs L are involved while reconstruction cost $C(\mathbf{p})$ is incurred at the end of the repair time for each renewal cycle. It is further assumed that no failure occurs during repair. We consider first the first term in the damage function without repair actions.

The damage cost consists of two parts. Applying the reasoning for (69.22) of systematic reconstruction gives

$$D_H(\mathbf{p}) = \frac{Lf^*(\gamma,\mathbf{p})}{1-f^*(\gamma,\mathbf{p})g^*(\gamma)} + \frac{C(\mathbf{p})f^*(\gamma,\mathbf{p})g^*(\gamma)}{1-f^*(\gamma,\mathbf{p})g^*(\gamma)} = \frac{Lf^*(\gamma,\mathbf{p})+C(\mathbf{p})h^*(\gamma,\mathbf{p})}{1-h^*(\gamma,\mathbf{p})} \tag{69.27}$$

The renewal cycle now has length T_F+T_G. T_F and T_G are assumed independent. Clearly, $h^*(\gamma,\mathbf{p})=f^*(\gamma,\mathbf{p})g^*(\gamma)$ is the Laplace transform of the density $h(t,\mathbf{p})=\int_0^\infty f(t-\tau,\mathbf{p})g(\tau)d\tau$ of this alternating two-phase renewal process. Also, $g(t)$ is the density of the repair times. Deterministic renewal times of length s are included because $g^*(\gamma)=\exp[-\gamma s]$ is the Laplace transform of the density $g(t)=\delta(s)$.

With renewals after failure or systematic repairs at age a, (69.26) has to be modified

$$D_{HR}(\mathbf{p},a) = \frac{\left(\begin{array}{c} Lf^{**}(\gamma,\mathbf{p},a)+C(\mathbf{p})k^{**}(\gamma,\mathbf{p},a)+ \\ +R(\mathbf{p})g^{**}(\gamma,a)\bar{F}(\mathbf{p},a) \end{array}\right)}{1-(k^{**}(\gamma,\mathbf{p},a)+g^{**}(\gamma,a)\bar{F}(\mathbf{p},a))} \tag{69.28}$$

where

$$f^{**}(\gamma,\mathbf{p},a)=\int_0^a \exp[-\gamma t] f(t,\mathbf{p})dt,$$

$$k^{**}(\gamma,\mathbf{p},a)=\int_0^a\int_0^\infty \exp[-\gamma(t+\tau)]g(\tau)d\tau f(t,\mathbf{p})dt = f^{**}(\gamma,\mathbf{p},a)g^*(\gamma) \le h^{**}(\gamma,\mathbf{p},a)$$

$$g^{**}(\gamma,a)=\int_0^\infty \exp[-\gamma(t+a)]g(t)dt = \exp[-\gamma a]g^*(\gamma).$$

$k^{**}(\gamma,\mathbf{p},a)$ expresses the (discounted) time until the end of this renewal cycle where $C(\mathbf{p})$ becomes due and which can be larger than a. The upper bound $h^{**}(\gamma,\mathbf{p},a)$ for $k^{**}(\gamma,\mathbf{p},a)$ implies that the

reconstruction cost $C(\mathbf{p})$ fall always at a. $g^{**}(\gamma,a)$ takes account of the finite time of repair after a because, as assumed, the repair costs are only due at the end of the repair period. For many models of repair time distributions, *e.g.*, deterministic, exponential or Rayleigh, the inner integral in $k^{**}(\gamma,\mathbf{p},a)$ and the integral in $g^{**}(\gamma,a)$ are analytic. The first two terms in (69.28) represent the corrective renewal mode while the last term is the preventive renewal mode. In general, the influence of finite repair times is expected to be small, having in mind that mean repair times usually do not exceed a few percent of the failure times.

69.4.2 Cost–Benefit Optimization Including Inspections and Repair

In structures and many other areas any expensive maintenance operation is preceded by inspections involving cost I_0 if damage progression and/or changes in system performance are observable. We understand that the inspections are essential inspections eventually leading to decisions about repair or no repair. This maintenance strategy is sometimes called condition-based maintenance. If there are inspections at times $a, 2a, 3a, \ldots$ there is not necessarily a repair because aging processes and inspections are uncertain or the signs of deterioration are vague. Repairs occur only with probability $P_R(t)$ (see (69.16)). Then, inspection and repair cost must also be included in the damage term.

The objective function for independent no-repair/repair and failure events is now:

$$Z_{IM}(\mathbf{p},a) = B - C_R(\mathbf{p}) - J(a) - D_{IM}(\mathbf{p},a)\,. \tag{69.29}$$

Application of (69.22) to the inspection cost term yields

$$J(a) = \frac{I_0(\exp[-\gamma a]\bar{F}(\mathbf{p},a))}{1-(\exp[-\gamma a]\bar{F}(\mathbf{p},a))}\,. \tag{69.30}$$

The damage term is written as

$$D_{IM}(\mathbf{p},a) = \frac{N_{IM}}{D_{IM}} \tag{69.31}$$

with

$$\begin{aligned} N_{IM} \;=\; & L\left(\sum_{n=1}^{\infty}\prod_{j=0}^{n-1}\bar{P}_R(ja)f^{***}(\gamma,\mathbf{p},(n-1)a\le t\le na)\right)+ \\ & +C(\mathbf{p})\left(\sum_{n=1}^{\infty}\prod_{j=0}^{n-1}\bar{P}_R(ja)k^{***}(\gamma,\mathbf{p},(n-1)a\le t\le na)\right)+ \\ & +R(\mathbf{p})\sum_{n=1}^{\infty}g^{**}(\gamma,na)\prod_{j=0}^{n-1}P_R(na)\bar{P}_R(ja)\bar{F}(\mathbf{p},na) \end{aligned} \tag{69.32}$$

and, similarly, for the denominator

$$D_{IM} = 1-\left(\begin{array}{l}\displaystyle\sum_{n=1}^{\infty}\prod_{j=0}^{n-1}\bar{P}_R(ja)k^{***}(\gamma,\mathbf{p},(n-1)a\le t\le na) \\ \displaystyle+\sum_{n=1}^{\infty}g^{**}(\gamma,na)\prod_{j=0}^{n-1}P_R(na)\bar{P}_R(ja)\bar{F}(\mathbf{p},na)\end{array}\right) \tag{69.33}$$

Here, $P_R(0)=0$ and

$$\begin{aligned} & k^{***}(\gamma,\mathbf{p},(n-1)a\le t\le na) = \\ & = \int_{(n-1)a}^{na}\int_0^{\infty}\exp\left[-\gamma(t+\tau)\right]g(\tau)d\tau f(t,\mathbf{p})dt \\ & = f^{***}(\gamma,\mathbf{p},(n-1)a\le t\le na)g^{*}(\gamma,na) \\ & g^{**}(\gamma,na) = \int_0^{\infty}\exp\left[-\gamma(t+na)\right]g(t)dt \\ & \quad = \exp\left[-\gamma na\right]g^{*}(\gamma). \end{aligned}$$

In principle, the repair duration density $g(t)$ can be different after failure and for preventive repair.

If dependent no-repair/repair and failure events must be assumed the inspection cost remain as in (69.30). In analogy to the independent case it is

$$\begin{aligned} & f^{****}(\gamma,\mathbf{p},(n-1)a\le t\le na) = \\ & = \int_{(n-1)a}^{na}\exp\left[-\gamma t\right]\times \\ & \quad \frac{d}{d\vartheta}P\Big(\bigcap_{j=0}^{n-1}\left\{\bar{R}(ja)\right\}\cap\left\{T_F\le\vartheta\right\}\Big)_{|\vartheta=t}dt \end{aligned} \tag{69.34}$$

$$h^{****}(\gamma,\mathbf{p},(n-1)a\le t\le na)=$$
$$=\int_{(n-1)a}^{na}\exp[-\gamma t]\times \quad (69.35)$$
$$\frac{d}{d\vartheta}P(\bigcap_{j=0}^{n-1}\{\bar{R}(ja)\}\cap\{T_F+T_G\le\vartheta\})_{|\vartheta=t}\,dt$$

in

$$Z_{IMF}(\mathbf{p},a)=B-C_R(\mathbf{p})-J(a)-D_{IMD}(\mathbf{p},a)\,. \quad (69.36)$$

We further have

$$\begin{aligned}N_{IMD} &= L\left(\sum_{n=1}^{\infty}f^{****}(\gamma,\mathbf{p},(n-1)a\le t\le na)\right)\\ &+C(\mathbf{p})\left(\sum_{n=1}^{\infty}h^{****}(\gamma,\mathbf{p},(n-1)a\le t\le na)\right)\\ &+R(\mathbf{p})\sum_{n=1}^{\infty}g^{**}(\gamma,na)\times\\ &\times P(\{R(na)\}\cap\bigcap_{j=0}^{n-1}\{\bar{R}(ja)\}\cap\{T_F>na\})\end{aligned} \quad (69.37)$$

$$D_{IMD}=1-\left(\begin{aligned}&\sum_{n=1}^{\infty}h^{****}(\gamma,\mathbf{p},(n-1)a\le t\le na)\\ &+\sum_{n=1}^{\infty}g^{**}(\gamma,na)\times\\ &\times P(\{R(na)\}\cap\bigcap_{j=0}^{n-1}\{\bar{R}(ja)\}\cap\{T_F>na\})\end{aligned}\right) \quad (69.38)$$

in

$$D_{IMD}=\frac{N_{IMD}}{D_{IMD}}\quad . \quad (69.39)$$

$R(ja)$ is the repair event at ja, which takes some random time with density $g(t)$. The probabilities of the intersection events in those equations can be determined approximately by applying the FOR/SOR-methodology. Remember that a typical intersection event $\left\{\bigcap_{j=0}^{n-1}\bar{R}(ja)\cap\{T_F\le t\}\right\}$ after the probability distribution transformation is given by $\left\{\bigcap_{j=0}^{n-1}\{s_c-S(ja,\mathbf{U}_{R,j})>0\}\cap\{T_F\le t\}\right\}$ with $\{T_F\le t\}=\{g(\mathbf{U}_F,t)\le 0\}$ according to (69.1), for example. $\mathbf{U}_{R,j}$ and $\mathbf{U}_F$ denote the variables in the random vector defining the damage indicator (including measurement errors) and the variables defining failure, respectively. Because $\mathbf{U}_{R,j}$ and $\mathbf{U}_F$ have some components in common the events are dependent. These dependencies can be taken into account by linearizing the event boundaries individually or, better, in the joint β-point, if it exists, computing the correlation coefficients of the scalar event functions and evaluating the corresponding multivariate normal integrals by the methods presented in [16]–[19]. The densities required in (69.34) and (69.35) are obtained by numerical differentiation of the corresponding probabilities.

Here, we allow the cost for first construction $C_R(\mathbf{p})$ to be different from the reconstruction cost $C(\mathbf{p})$. At an inspection time ja, the inspection either remains the only action taken with probability $\bar{P}_R(ja)$ and associated cost I_0 which need to be discounted, or the inspection is followed by (immediate) repair with probability $P_R(ja)$ involving cost $R(\mathbf{p})$, again to be discounted. The first terms in the respective sums correspond to (69.25) or to (69.28). All higher order summation terms correct for the possibilities of having repair intervals longer than a. The sums are expected to converge because no-repair probabilities decrease according to (69.16). In general, only the first few terms in the infinite sums must be considered.

The effect of dependencies between no-repair/repair and failure events on optimal repair intervals can be significant. This will be demonstrated in the example. As mentioned before, a repair causes the risk function to drop at the repair time. The minimal repair model considered in (69.29) or (69.36) lets the risk function drop but not down to zero at an inspection time because there is a finite probability that there is no repair. It produces a saw tooth type behavior of the risk function or the unconditional failure rate, which ultimately approach zero, *i.e.*, no more preventive renewals occur. Some calculations of these functions are illustrated in [9].

69.5 Example

The following example from [9] with different parameters shows several interesting features and provides an appropriate test case. Chloride attack due to salting and subsequent corrosion, for example, in the entrance area of a parking house or a concrete bridge is considered. A simplified and approximate model for chloride concentration in concrete is $C(x,t) = C_s(1 - erf(\frac{x}{2\sqrt{Dt}}))$, where C_s = surface (extrapolated from measurements 0.5 to 1 cm below surface) chloride content, x = depth and D = diffusion parameter. A suitable criterion for the time to the start of chloride corrosion of the reinforcement, if the parameters are properly adjusted, is:

$$C_{cr} - C_s(1 - erf\left(\frac{c}{2\sqrt{Dt}}\right)) \le 0\,, \qquad (69.40)$$

where, C_{cr} = critical chloride content, c = concrete cover and $erf(.)$ the error function. The stochastic model is as follows:

Variable	[unit]	Distr. function	Parameters
C_{cr}	%	Uniform	0.4, 0.6
C_s	%	Uniform	0.8, 1.2
c	cm	Log-normal	5,1
Dl	$\frac{cm^2}{year}$	Uniform	0.5, 1.2

The uniform distributions reflect the large uncertainty in the variables. If C_{cr} and C_s are measured as percentages of cement content, the initiation time can be written as:

$$T_i(C_{cr}, C_s, D, c) = \frac{c^2}{4D}\left(erf^{-1}\left[1 - \frac{C_{cr}}{C_s}\right]\right)^{-2}\,, \qquad (69.41)$$

and the initiation event can be written as:

$$G_i(t) = T_i(C_{cr}, C_s, D, c) - t > 0\ . \qquad (69.42)$$

The units are such that $T_i(.)$ is in years.

During the initiation time the structure can fail due to time-variant, stationary extreme loading. It is assumed that each year there is an independent extreme realization of the load. Load effects are normally distributed with coefficient of variation of 25%. Structural resistance is also distributed normally with a mean six times as large as the mean load effect and a coefficient of variation of 25%, implying a central safety factor of 6. Once corrosion has started the mean resistance deteriorates with rate $d(t) = 1 - 0.07t + 0.00002t^2$. The distribution function of the time to first failure is computed using (69.8) with the failure time distributions in the initiation phase and in the deterioration phase determined by (69.7). The structural states in two arbitrary time steps have constant correlation coefficient of $\rho = \rho_{ij} = 0.973$. The failure time distributions and failure time densities are computed using FORM in (69.8) because the dependence between failure in the initiation phase and the deterioration phase can be neglected. Here and in all subsequent calculations curvature corrections according to SORM are small to negligible. For the given parameters one determines a mean initiation time of $E[T_i] = 41.5$ and a mean time to failure of $E[T_d] = 12.3$ so that the total mean time to failure is $E[T_i + T_d] = 53.8$ with coefficient of variation $CoV = 0.57$.

The structure is in a condition where repair is deemed necessary if, at inspection by chemical analyses of the drill dust from small bore holes, the chloride concentration in a depth of $c = 3.0$ cm exceeds the value of C_{cr} = 0.5. Therefore, the repair event at the time of inspection t corresponds to

$$G_R(t) = t - T_i(0.5(1 + 0.05U_\varepsilon(t)), C_s, D, c) \le 0 \qquad (69.43)$$

where a normally distributed measurement error $U_\varepsilon(t)$ with $m_\varepsilon = 1.0$ and $\sigma_\varepsilon = 0.05$ has been added. The measurement errors at different times are independent. Because there can be additional errors in the measurement depth it is assumed that c varies lognormally with mean $m_c = 3.0$ and standard deviation $\sigma_c = 1$. It should be noted from comparison of (69.26) and (69.28) that no-repair/repair events at the time of inspections and the failure events are closely related, because both are realizations of the same underlying physical process. Their probabilities differ because of different times and random independent measurement errors. Repair times are modeled by a Rayleigh distribution.

For demonstration purposes the erection costs are $C(m_c, m_r) = C_0 + C_1 m_c^2 + C_2 m_r$, the inspection costs are $I_0 = 0.02C_0$, and we have $C_0 = 10^6$, $C_1 = C_2 = 10^4$, $L = 10C_0$, $\gamma = 0.03$. For preventive repairs the cost are $R(m_c, m_r) = 0.6C(m_c, m_r)$. m_r is the safety factor separating the means of load effect and resistance. All costs are in appropriate currency units. The physical and cost parameters are somewhat extreme but not yet unrealistic.

The technical realization of the models described before requires some effort in order to take proper account of the various dependencies. Independent no-repair/repair and failure events can be formulated as a special case of dependent no-repair/repair and failure events.

In the following cost optimization is first done with respect to the repair interval a keeping the design parameter, for example, the concrete cover, fixed at $m_c = 5$ cm.

Figure 69.2 shows the preventive repair times, the corrective repair times, and their sum cost for the cases defined by (69.26) and (69.28). Equation (69.28) is slightly lower because of longer discounting periods (time to failure or systematic repair + renewal time). In this figure, mean repair times are assumed to be only 5% of mean failure times.

Figure 69.3 shows the maintenance cost curves (inspection + repair + failure cost) for various means of repair times and dependent no repair/repair and failure events. As expected, the influence of realistic repair times (smaller than 5% to 10% of the mean failure times) is small.

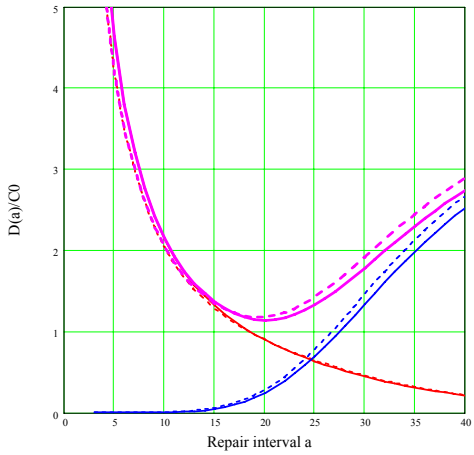

Figure 69.2. Damage costs for the model in (69.26) (*solid lines*) and. (69.28) (*dashed lines*)

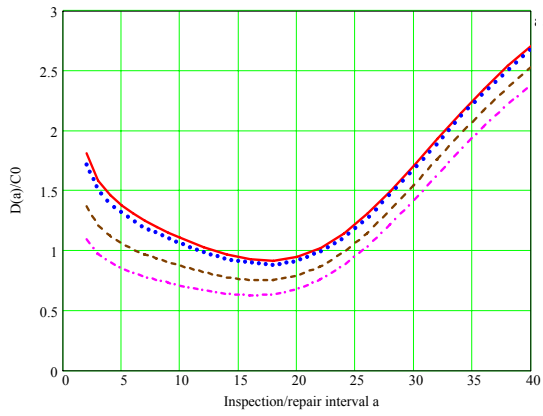

Figure 69.3. Maintenance costs for dependent no-repair/repair and failure events for different mean repair times (*solid line* = infinitely short, *dotted line* = m_R =0.5, *dashed line* = m_R =3.75, *dash-dotted line* m_R =7.2)

Figure 69.4 shows the total cost for independent no-repair/repair and failure events, for dependent no-repair/repair and failure events and for the case already discussed by Fox with finite repair times included. The mean repair time is 0.5. The optimum repair interval for the ideal case introduced by Fox and for the realistic dependent no repair/repair and failure events is 18 to 22 years,

but the total costs of maintenance are about 15% lower in the last case. For independent no repair/repair and failure events the minimum cost are for repair intervals of about 10 years but little difference is observed for repair intervals between 10 and 22 years. The total costs are about 50% higher. This illustrates that a realistic modeling is important.

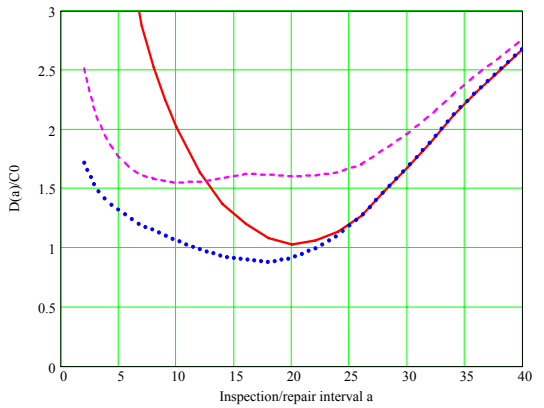

Figure 69.4. Maintenance costs for the model in (69.28) (*solid line*), (69.31) (*dashed line*) and. (69.39) (*dotted line*)

It is interesting to optimize simultaneously with respect to the inspection/repair interval, and the mean concrete cover taken as an important design parameter. Any suitable optimizer can be used for this operation. However, the mean concrete cover should have an upper limit around 6 cm to 7 cm because large concrete covers diminish the crack distributing effect of the reinforcement. Whatever this upper limit the optimum concrete cover will be at this upper limit and the optimal inspection/repair interval increases accordingly. The total maintenance costs decrease slightly. The same effect is observed if the safety factor enlarging the time T_d is increased. This demonstrates a strong interaction between the rules for design and maintenance, which, however, cannot be studied in more detail herein.

The benefit is not explicitly considered in this example. It would require numerical computation of the renewal function and from it the availability.

69.6 Summary

This chapter develops tools for optimizing design and maintenance strategies of aging structural components based on classical renewal theory. It reviews suitable formulations for failure models in structural engineering, which usually are non-analytic, and the basics of renewal theory. It then introduces a repair model with or without preceding (imperfect) inspections suitable for structural components. The inspection model introduces an increasing damage indicator function. Repairs are required if it exceeds some given threshold. Objective functions are derived for systematic reconstruction after failure or maintenance by periodic repairs alone and by periodic inspections and possibly ensuing repairs (renewals). Independent repair and failure events as well as dependent no-repair/repair and failure events are introduced. Some suitable numerical tools are also presented.

Extensions of the theory are possible with respect to facilities whose first failure time distribution is different from the other failure time distributions. Also, generalization to series systems is straightforward. Imperfect repairs cannot be handled within classical renewal theory.

Reliability and Price Assessment and the Associated Risk Control for Restructured Power Systems

Yi Ding[1], Ming J. Zuo[1], and Peng Wang[2]

[1]Department of Mechanical Engineering, University of Alberta, Canada
[2]Power Division, School of EEE, Nanyang Technological University, Singapore

Abstract: Electric utilities are experiencing restructuring throughout the world. The reliability techniques used for conventional power systems cannot be directly applied in the new environment. Moreover, electricity pricing in a restructured power system has become a major problem due to the changes in market structure. This chapter addresses reliability and price issues in restructured power systems. A technique to evaluate nodal prices and nodal reliabilities considering the correlation between price and reliability in a restructured power system with the Poolco market model is developed. The reliability network equivalent and the improved optimal power flow model for evaluation of reliabilities and prices in a restructured power system with the hybrid market structure are presented. Moreover, a penalty schema for reducing electricity price volatility and improving customer reliabilities is also discussed.

70.1 Introduction

The conventional electric power industry has been controlled and managed by large owners for nearly 100 years. In a relatively large geographical area, all the electric power facilities are usually owned by a single owner, who has a monopoly of electricity generation, transmission, and distribution systems. Electric energy and other ancillary services such as spinning reserve, frequency control, and reactive power generation are closely coordinated under the umbrella of one or more control centers. Electricity prices are usually determined by the administration and fixed for the same type of customers at different locations. Customers cannot select their suppliers and are obliged to receive services from monopoly utilities. Such power systems are called vertically integrated power systems.

Since the last decade, the restructuring of the traditional vertically integrated electric power system has been going on all over the world. The main objective of power system deregulation is to introduce competition in the power industry, where incumbent utilities have become inefficient [1], and provide more choices to market participants in the way they trade electricity and ancillary services. One traditional utility is separated into different generation companies (gencos), transmission companies (transcos) and distribution companies (discos), and retail companies [2]. Generally speaking, the market models can be classified into Poolco, bilateral contracts, and hybrid models [23].

Electric power system deregulation has occurred not only in industrialized counties but also in developing countries. South America was seen as the pioneer in the process of power industry restructuring [2], [3]. Chile was the first country to start the restructuring process in 1982 and other Latin American countries such as Argentina (1992), Peru (1993), Bolivia (1994), Colombia (1994), and Brazil (1996) followed [4]. It was shown that the power system restructuring in South America was very successful: in Chile the power losses in the transmission and distribution networks came down from 21% in 1986 to 8.6%; in Argentina the average electricity price was reduced from 39$/MWh in 1994 to 32$/MWh in 1996, and the availability of thermal generation units increased from below 47% in 1992 to 75% in 1996 [4] [5] [6].

The UK was the first developed country to start power industry deregulation. The electric power industry was the last major state-owned industry to be deregulated, and the process of privatization began in 1988 [7],[8] with the implementation of the Electricity Act. The Central Generating Board (CEGB), which owned nearly 60,000 MW of capacity and all high voltage transmission lines in Britain, was broken down into four independent companies [6], [7]: National Power, Power Gen, Nuclear Electric and the National Grid Company (NGC), with Nuclear Electric and NGC being state-owned companies. NGC operates the centralized power pool and assumes the role of the independent system operator (ISO) with the responsibility of promoting competition and managing the activities of the market [9]. The electricity distribution companies emerged from the former privatized regional area boards [7].

The USA has the largest number of electricity markets in the world. Unlike most other countries, the individual states in the USA have the right to develop their own market structures and implement the restructuring of the power industry. However, they must be directed by the Federal Energy Regulatory Authority (FERC) Acts [2]. The California power market was the first deregulated power market in USA, which opened in 1998. The PJM interconnection has the largest electric power market in the world.

Reliability is the main concern of power system planning and operation. In a conventional system, reliability is centrally controlled and managed by system operators. Most techniques focus on system reliability. System operators concentrate more on system reliability than customer reliability. Therefore generation re-dispatching and load shedding after a contingency are usually determined by a system operator based on their experience and judgment with little concern for customer requirements. The main objective of contingency management is to solve system voltage, line overloading, frequency, and power balance problems.

Restructuring and deregulation result in the functional segregation of a vertically integrated utility into distinct utilities in which each performs a single function. Economic segregation and service unbundling have changed the conventional mechanism of reliability management and system operation. One of the most important changes for the restructured power systems was the introduction of the ancillary market and customer participation in reliability management.

In the new environment, a customer can select the power and reserve providers who can satisfy his price and reliability expectations. This has changed the fundamentals of system reliability management and introduced new issues regarding electricity price. Electricity pricing has become an important issue in the restructured system due to the different usages of transmission and distribution facilities, reserve requirements, and customer choices regarding price and reliability. The system-oriented reliability assessment and management techniques developed for conventional vertically integrated systems need to be revised and improved for application in restructured power systems.

Due to the different market structures in the existing restructured power systems, the reliability and price problems for various market models are different. Therefore, the corresponding aspects considered in reliability and price assessment for various market models are different. The Poolco model and the hybrid model are the most important and popular market models in restructured power systems.

In the Poolco model, the market participants trade electricity through a centralized power pool. The electricity prices are uncertain due to the random nature of system failures and demand. Inadequate generation and transmission congestions caused by random failures may result in extreme price volatility, called "price spikes". The demand in the Poolco model is elastic. Customer response to price and reliability has changed the mechanism of load shedding from the supply side to the demand side. Therefore, the electricity price and supply point reliability are correlated due to customer participation of market trading. These aspects should be considered in the nodal price and nodal reliability evaluation of restructured power systems with the Poolco model. The techniques for evaluating reliabilities and prices for the Poolco model are discussed in Section 70.2. Part of this section has been published in [24].

In restructured power systems with hybrid market structure, generation companies (or customers) can sell (or buy) electricity either from a centralized power pool or directly through bilateral contracts. Due to market price uncertainties, risk-averse customers (or suppliers) can engage in long-term and firm bilateral contracts that guarantee supply (or selling) of power and reserve at relatively stable prices. Risk-prone customers (or suppliers) will respond to the spot market to buy (or sell) the same power and reserve for a possibly lower (or higher) price. A generation company can also sell their reserve capacity to the reserve market for system reliability requirements. In addition to reserve capacity payment, a genco will also receive the payment when its reserve capacity is utilized in contingency states. These flexible choices on reliability and prices for market participants have changed the mechanism of price and reliability managements, and have also created many new problems regarding reliability and price modeling and assessment. On the other hand, prices and reliabilities are also correlated. High reliability requirements from some customers will cause the increase of prices and higher prices will result in the decrease in demands from customers with low reliability requirements. Corresponding techniques to evaluate reliabilities, prices, and the associated risks for different participants are required to incorporate these changes. The methods for evaluating reliabilities and prices for hybrid model are discussed in Section 70.3; some parts of which have been published in [25].

The market participants in restructured power systems with Poolco or hybrid market structures may receive high price volatilities or even "price spikes" during contingency states. How to control electricity prices and mitigate high price volatilities is one of the most important problems that system operators face and are required to solve in the new environment. In restructured power systems, system operators usually do not have the power to directly control the electricity prices by setting some regulated values. In these cases, gencos may implement their market powers to raise market electricity prices to make more profit. Therefore, it is important to develop some mechanism for system operators to be able to indirectly control electricity prices and price risks in the new environment. A schema for controlling electricity price volatilities and improving system reliabilities is proposed in Section 70.4, some parts of which have been reported in [26].

Notation

j_0	normal system state index
j	contingency system state index
i,k	bus index
c	component index
g	generating unit index
s	customer sector index
N_c	number of components
N_g	number of generating buses
N_L	number of load buses
N	total number of buses
CDF	customer damage function
A_c	availability of a component
U_c	unavailability of a component
λ_c	failure rate of a component
μ_c	repair rate of a component
SN	the number of states considered

For state j_0, bus i and customer sector s of Poolco model:

p_0 state probability

P_{is}^{j0} real power demand

Q_{is}^{j0} reactive power demand

ρ_{pi}^{j0} nodal price of real power

ρ_{qi}^{j0} nodal price of reactive power

For state j, bus i ,unit g and customer sector s of Poolco model:

p_j state probability

D_j departure rate of system leaving state

d_j mean failure duration

NG_i^j number of generating units

NL_i^j number of customer sectors

C_{ig}^j cost function of a generating unit

OC_{is}^j outage cost of the customer sector

$CDF_s(d_j)$ *CDF* of customer sector s for d_j

θ_i^j voltage angle

$Y_{ik}^j = \left|Y_{ik}^j\right| \angle \delta_{ik}^j$ element of the admittance matrix

P_i^j real power injection

Q_i^j reactive power injection

P_{ig}^j real power generation of the unit

$P_{ig}^{j,\min}$ minimum real power generation of the unit

$P_{ig}^{j,\max}$ maximum real power generation of the unit

$\Delta P_{ig}^{j,low}$ lower limit on real power generation of the unit that can be changed from the normal state

$\Delta P_{ig}^{j,upp}$ upper limit on real power generation of the unit that can be changed from the normal state

Q_{ig}^j reactive power generation of the unit

$Q_{ig}^{j,\min}$ minimum reactive power output of the unit

$Q_{ig}^{j,\max}$ maximum reactive power output of the unit

LC_{pis}^j real power curtailment of the customer sector

$LC_{pis}^{j,\max}$ maximum real power curtailment of the customer sector

$V_i^j = \left|V_i^j\right| \angle \theta_i^j$ bus voltage

$\left|V_i^j\right|^{\max}$ upper limit of bus voltage

$\left|V_i^j\right|^{\min}$ lower limit of bus voltage

S_{ik}^j apparent power on line *i*-*k*

$S_{ik}^{j,\max}$ limits of apparent power transfer on line *i*-*k*

For state j and bus i of the hybrid model:

$V_i^j = \left|V_i^j\right| \angle \theta_i^j$ bus voltage

$Y_{ik}^j = \left|Y_{ik}^j\right| \angle \delta_{ik}^j$ element of the admittance matrix

NG_i^{pj} set of pool generating units

NL_i^{pj} set of pool customer sectors

C_{ig}^{pj} cost function of pool generating unit g

CC_{is}^{pj} curtailment cost of pool customer sector s

P_{ig}^j real power generation of unit g

Q_{ig}^j reactive power generation of unit g

ΔP_{ig}^j $= P_{ig}^0 - P_{ig}^j$

$\Delta P_{ig}^{j,low}$ lower limit of ΔP_{ig}^j

$\Delta P_{ig}^{j,up}$ upper limit of ΔP_{ig}^j

P_{is}^{pj} real power demand of pool customer sector s

Q_{is}^{pj} reactive power demand of pool customer sector s

CP_{is}^{pj} real power curtailment of pool customer sector s

CQ_{is}^{pj} reactive power curtailment of pool customer sector s

P_i^j nodal real power injection

RG_i^j set of reserve generating units

C_{ig}^{rj} cost function of reserve generating unit g

P_{ig}^{rj} real power provided to the pool by reserve unit g

Q_{ig}^{rj} reactive power provided to the pool by reserve unit g

$P_{ig}^{rj,\max}$ maximum real power reserve of unit g

$Q_{ig}^{rj,\max}$ maximum reactive power reserve of unit g

NL_i^{bj} set of bilateral customer sectors

For state j, and bilateral contract between bus i and k of hybrid model:

P_{ik}^{bj} real power contract

Q_{ik}^{bj} reactive power contract

CP_{iks}^{bj} real power curtailment of bilateral customer sector s

CQ_{iks}^{bj} reactive power curtailment of bilateral customer sector s

$CP_{iks}^{b,\max}$ maximum real power curtailment of bilateral customer sector s

CC_{iks}^{bj} curtailment cost function of bilateral customer sector s

70.2 Reliability and Price Assessment of Restructured Power Systems with the Poolco Market Model

In the Poolco market model, the market participants trade electricity through a centralized power pool. The real time (spot) pricing systems developed by Vickerry [10] and Schweppe, *et al.* [11] have been implemented to determine electricity prices.

There are three spot pricing systems prevalent in the present power markets [12]: the uniform marginal pricing system, the zonal marginal pricing system, and the nodal pricing system. In the first pricing system there is only one price, which is called the uniform marginal price. The electricity market in the U.K. [6] and the Alberta market have implemented such a pricing system. In the second one there are several prices in the market but only one price in a given zone, which can be named the zonal marginal price. The Norwegian market is a typical example of this model [12]. The last one is the nodal pricing system, in which different nodes have different prices. Typical examples of power markets implementing the nodal pricing system are the current California market, the Pennsylvania-New Jersey-Maryland market (PJM) [13], the New Zealand market [6] [12], and the New York market [14]. Currently the nodal pricing system is being adopted by more and more power markets because of its economical efficiency and fairness. Therefore, the techniques for nodal reliability and nodal price assessment are comprehensively discussed below.

Nodal prices in a Poolco market depend on generating unit locations, available generation capacity, and demand at each node, transmission limits, and customer response to price. Nodal price and nodal reliability are correlated. It is a complicated optimization problem to obtain the balance point between demand and price. In the following paragraphs of this section, the characteristics of customer demand response to nodal price are investigated. Nodal price and nodal reliability problems are formulated using optimal power flow and reliability evaluation techniques. Price volatilities due to random failures are investigated. The expected nodal price and associated deviation are introduced to represent the volatility of nodal prices caused by random failures. The IEEE-RTS [15] test system has been analyzed to illustrate the technique.

70.2.1 Customer Response to Price Changes

When a power system transfers from the normal operating state to a contingency state due to random failures, nodal prices may change with the system operating condition. Some customers may reduce their demands when nodal prices increase dramatically. The demand that a customer is willing to reduce is designated as the self-load curtailment in this chapter. The objective of self-load curtailment for a customer is to maximize its benefit. For state *j*, the self-load curtailment for customer i can be determined by solving the following optimization problem:

$$Max\ \Phi = B(P_{di}^0) - OC(P_{di}^0 - P_{di}^j) - \rho^j \times P_{di}^j \quad , \quad (70.1)$$

where P_{di}^0 is the equilibrium demand for the normal operating state, P_{di}^j is the demand for contingency state *j*, ($P_{di}^0 - P_{di}^j$) is the demand that a customer is willing to reduce, $B(P_{di}^0)$ is the customer benefit for the normal operating state, $OC(P_{di}^0 - P_{di}^j)$ is the cost due to load reduction, and ρ^j is the price of electricity for state *j*.

The necessary condition to maximize the welfare is:

$$\frac{\partial(OC(P_{di}^0 - P_{di}^j))}{\partial(P_{di}^0 - P_{di}^j)} = \rho^j . \quad (70.2)$$

Equation (70.2) shows that a customer will reduce his demand when the price of electricity is higher than the customer marginal cost at state *j*. This means that when a system transfers from the normal operating state to a contingency state, customer response can be indirectly measured by the customer interruption cost, which represents the customer's willingness to pay to avoid service interruption. The interruption cost is a function of customer and interruption characteristics [16], which include the diversity of customers, the nature of customer activities, and the size of the operation, *etc*. A Standard Industrial Classification (*SIC*) [16] has been used to divide customers into large user, industrial, commercial, agriculture, residential, government and institutions, and office and buildings categories. The survey data have been analyzed to give the sector customer damage functions (CDF_s).

70.2.2 Formulation of the Nodal Price and the Nodal Reliability Problem

The basic problem is to solve the nodal price and nodal reliability for each system state considering their correlation. The basic reliability technique is used to determine the state probability, departure the rate, and duration [17]. Contingency enumeration and state selection techniques have been used to determine the contingency states. Optimal power flow (OPF) techniques have been used to obtain the economical information regarding the system operation. The Lagrange multipliers evaluated by the solutions of OPF can be explained as the derivatives of the objective function with respect to the respective constraints [7]. Therefore, the Lagrangian multipliers corresponding to the power flow equations are interpreted as the marginal costs of electric power injected from the system to the corresponding nodes (nodal prices). In the proposed model customer damage functions and generation cost functions are used in the OPF problems to determine nodal price, load curtailed, and generation re-dispatched for each state. The probabilistic method is used to determine the expected values and the associated risk of nodal prices and nodal reliabilities. Considering a power system with N_c independent components, the reliability parameters for contingency state *j* with exactly *b* failed components can be determined using the following equations:

$$p^j = \prod_{c=1}^{b} U_c \prod_{c=b+1}^{N_c} A_c , \quad (70.3)$$

$$D^j = \sum_{c=1}^{b} \mu_c + \sum_{c=b+1}^{N_c} \lambda_c , \quad (70.4)$$

$$d^j = 1 \Big/ D_j . \quad (70.5)$$

For a contingency state, the objective of the optimization is to minimize the total system cost including the generation cost and customer interruption cost due to load curtailment. For system state *j*, the nodal prices, the generation re-

dispatched, and load shed considering customer requirements can be determined by solving the following optimization problem:

$$Min\ f^j = \sum_{i\in N_g}\sum_{g\in NG_i^j} C_{ig}^j(P_{ig}^j, Q_{ig}^j) + \sum_{i\in N_L}\sum_{s\in NL_i^j} OC_{is}^j(LC_{pis}^j, LC_{qis}^j) \quad (70.6)$$

where

$$OC_{is}^j(LC_{pis}^j, LC_{qis}^j) = LC_{pis}^j \times CDF_s(d_j)\ , \quad (70.7)$$

subject to the following constraints:

Load flow equations:

$$\sum_{g\in NG_i^j} P_{ig}^j - \sum_{s\in NL_i^j} P_{is}^{j_0} + \sum_{s\in NL_i^j} LC_{pis}^j = \sum_{i=1}^{N} V_i^j V_k^j \left|Y_{ik}^j\right| \cos(\theta_i^j - \theta_k^j - \delta_{ik}^j) \quad (70.8)$$

$$\sum_{g\in NG_i^j} Q_{ig}^j - \sum_{s\in NL_i^j} Q_{is}^{j_0} + \sum_{s\in NL_i^j} LC_{qis}^j = \sum_{i=1}^{N} V_i^j V_k^j \left|Y_{ik}^j\right| \sin(\theta_i^j - \theta_k^j - \delta_{ik}^j) \quad (70.9)$$

Generating unit limits:

$$P_{ig}^{j,\min} \le P_{ig}^j \le P_{ig}^{j,\max}\ , \quad (70.10)$$

$$Q_{ig}^{j,\min} \le Q_{ig}^j \le Q_{ig}^{j,\max}\ , \quad (70.11)$$

$$\Delta P_{ig}^{j,low} \le P_{ig}^j - P_{ig}^{j_0} \le \Delta P_{ig}^{j,upp}\ . \quad (70.12)$$

Load curtailment limits:

$$0 \le LC_{pis}^j \le LC_{pis}^{j,\max}\ . \quad (70.13)$$

Voltage limits:

$$\left|V_i^j\right|^{\min} \le \left|V_i^j\right| \le \left|V_i^j\right|^{\max}\ . \quad (70.14)$$

Line flow constraints:

$$\left|S_{ik}^j\right| \le S_{ik}^{j,\max}\ . \quad (70.15)$$

The nonlinear optimization problem can be solved by using various Newton methods with the second order convergence properties. However, additional algorithms have to be supplemented to search for active inequality constraints, which usually affect convergence properties of Newton methods [18].

The sequential quadratic programming (SQP) algorithm [19], which combines the Newton method with quadratic programming has been used to solve this problem. The Lagrangian function L^j of the problem (70.6)–(70.15) for state j is formed. The optimal generating unit outputs (P_{ig}^j, Q_{ig}^j), and the optimal load curtailments for customer sector (LC_{pis}^j, LC_{qis}^j) can be obtained using SQP. The nodal prices of active power and reactive power at bus i under the optimum solution are the following, respectively:

$$\rho_{pi}^j = \frac{\partial L_j}{\partial P_i^j}\ , \quad (70.16)$$

$$\rho_{qi}^j = \frac{\partial L_j}{\partial Q_i^j}\ . \quad (70.17)$$

In a Poolco market, the expected values, the standard deviation of nodal prices, and nodal reliabilities are important information for the risk analysis of market trading, planning, and operation. The expected nodal price is a weighted average of the prices for different states. Unlike many other commodities, electricity cannot be stored in a large amount and needs the continuous balance between the supply and demand at any time. The price for a contingency state might be quite different from the expected price. Inadequate generation and congestions in some contingency states result in extreme price volatility or "price spikes". The random nature of failures results in a great price uncertainty. Standard deviation of nodal prices can be used to evaluate the extent of price fluctuating around its expected value.

Considering all possible system states, the expected nodal prices, and nodal reliability indices can be determined using following equations.

The expected nodal price of real power:

$$\overline{\rho}_{pi} = \sum_{j=1}^{SN} p^j \rho_{pi}^j\ . \quad (70.18)$$

The standard deviation of $\overline{\rho}_{pi}$:

$$\sigma_{pi} = \sqrt{\sum_{j=1}^{SN} (\rho_{pi}^j - \overline{\rho}_{pi})^2 p^j}\ . \quad (70.19)$$

The expected nodal energy not supplied:

$$ENENS_i = \sum_{j=1}^{SN} D^j \times p^j \times NENS_i^j\ . \quad (70.20)$$

The expected interruption cost for the bus i :

$$ENCOST_i = \sum_{j=1}^{SN} D^j \times p^j \times NCOST_i^j \ . \quad (70.21)$$

70.2.3 System Studies

The technique has also been used to analyze a more complex system IEEE-RTS. IEEE-RTS has 10 generating (PV) buses, 17 load (PQ) buses, 33 transmission lines, 5 transformers, and 32 generating units. The total installed generating capacity for this system is 3405 MW with a system peak load of 2850 MW. System failures up to the second order have been considered in the evaluation. The nodal reliability indices, nodal prices, and the corresponding risks of the nodal prices have been calculated for each bus. The nodal prices for a representative bus (bus 3) are shown in Figures 70.1 and 70.2. The nodal prices of real power are presented therein. There are no price spikes and load shedding for the first order failures.

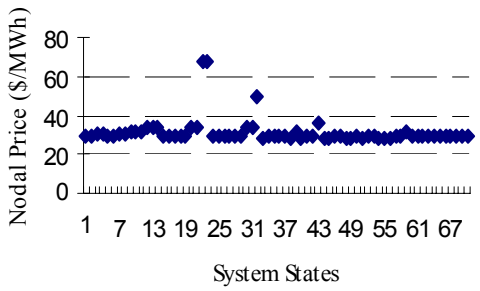

Figure 70.1. Nodal prices at bus 3 for the first order generation and transmission outages

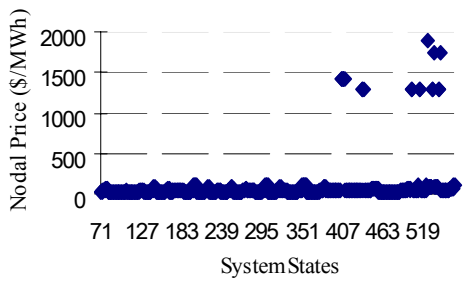

Figure 70.2. Nodal prices at bus 3 for the second order generation outages

70.3 Reliability and Price Assessment of Restructured Power Systems with the Hybrid Market Model

In restructured power systems with hybrid market structure, market participants can trade electricity either from a centralized power pool or directly through bilateral contracts. Therefore, the hybrid market model is a more flexible and complicated market structure than the Poolco model. This section reports techniques for evaluating both reliabilities and prices for the pool and bilateral customers in a hybrid power market. The reliability network equivalent techniques are extended to represent different generation suppliers in a hybrid market and to incorporate the complicated agreements or contracts among gencos in the reliability and price evaluation. The reliability and price problem for hybrid market models is formulated simultaneously using an improved OPF technique considering the correlation between reliability and price.

70.3.1 Reliability and Cost Models for Market Participants

Most power markets in the world are hybrid market models such as PJM [13], due to their flexibility to incorporate customer choices. In a hybrid power market customers can buy electricity either from the centralized power pool or directly from gencos through bilateral contracts. Different market rules and agreements are also present in this type of market. In order to clearly present the complicated relationship among these rules and agreements, and to evaluate generation and transmission reliabilities and prices, reliability and price models of market participants are introduced. There are two generation providers of the power pool and bilateral contract in a hybrid power market. All the gencos scheduled in power pool can be represented as an equivalent multi-state pool generation provider (EMPGP). A genco with bilateral contracts can be represented as an equivalent multi-state bilateral generation provider (EMBGP) as shown in Figure 70.3.

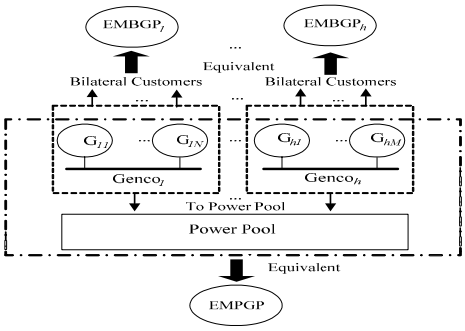

Figure 70.3. Generation system equivalent

The reliability parameters of an EMPGP or an EMBGP are represented using the state probability, departure rate and frequency. For an EMPGP with H gencos, the probability p^j, the departure rate D^j, and the frequency f^j for state j can be determined by the following equations, assuming that genco h in the pool has N_h units and M_h^j of these are out of service:

$$p^j = \prod_{h=1}^{H} \left(\prod_{g_h=1}^{M_h^j} U_{g_h} \prod_{g_h=M_h^j+1}^{N_h} A_{g_h} \right) , \tag{70.22}$$

$$D^j = \sum_{h=1}^{H} \left(\sum_{g_h=1}^{M_h^j} \mu_{g_h} + \sum_{g_h=M_h^j+1}^{N_h} \lambda_{g_h} \right) , \tag{70.23}$$

$$f^j = p^j D^j , \tag{70.24}$$

where A_{g_h}, U_{g_h}, λ_{g_h}, and μ_{g_h} are the availability, unavailability, failure rate, and repair rate of unit g in genco h, respectively. The reliability parameters of an EMBGP can be determined using similar equations. The unit operating cost is usually the function of unit output and is represented by a quadratic equation. The cost model of an EMPGP or an EMBGP is the aggregation of the cost functions of all the units in it, which changes correspondingly with the system state.

EMPGPs and EMBGPs can share their reserves to increase supply reliabilities and to reduce price risks. An EMPGP, which has reserve agreements (RA) with other EMBGPs, can be represented using an equivalent multi-state pool generation provider with reserve agreement (EMPGPWR) and an EMBGP, which has reserve agreements with other EMBGPs or the EMPGP, can be represented using an equivalent multi-state bilateral generation provider with reserve agreements (EMBGPWR).

The reliability parameters of EMPGPWR and EMBGPWR can be calculated using the reserve assisting method [17]. If the EMPGP and M EMBGPs share their reserve, the reliability parameters of the EMPGPWR or an EMBGPWR can be calculated as:

$$p_{h+l}^j = p_{h+l-1}^j p_l^k , \tag{70.25}$$

$$D_{h+l}^j = D_{h+l-1}^j + D_l^k , \tag{70.26}$$

$$f_{h+l}^j = p_{h+l}^j D_{h+l}^j , \tag{70.27}$$

where p_{h+l-1}^j and D_{h+l-1}^j are the probability and the departure rate of the assisted EMPGP (or EMBGP h) before adding the assisting EMBGP l (or EMPGP), respectively, and p_l^k and D_l^k are the probability and the departure rate of state k for EMBGP l.

The effect of the transmission network on load point reliabilities and prices can be represented using nodal reliabilities and prices. The transmission system between the EMPGP and a bulk load point (BLP) can be represented by an equivalent multi-state transmission provider for pool customers (EMTPP). The transmission system between an EMBGP and a BLP can be represented by an equivalent multi-state transmission provider for bilateral customers (EMTPB). The EMTPP (or EMTPB) considering reserve agreements is designated as EMTPPWR (or EMTPBWR), respectively. These equivalents are shown in Figure 70.4.

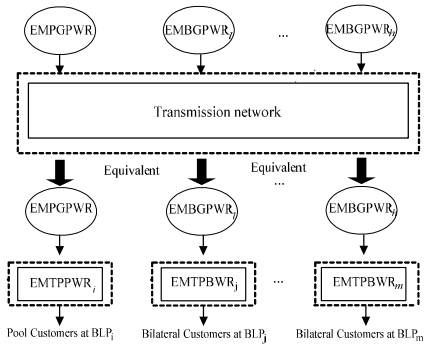

Figure 70.4. Transmission system equivalent

70.3.2 A Model of Customer Responses

If a power system transfers from the normal operating state to a contingency state due to random failures, prices may change with the system operating condition. When demand cannot be met by a power pool, the pool customers will either buy electricity from EMBGPs if there are reserve agreements or compete for the insufficient electricity. Therefore, the customer damage function (CDF_s) [16], is used to model pool customer response to load curtailment.

When generation failures in an EMBGP result in inadequate generation, bilateral customers may buy electricity from the pool or shed the load if the spot price is too high. The power transfer price may also increase due to transmission failures. If the power transfer cost is higher than the customer willingness to pay for it, the power transferred may be reduced. The bilateral sector customer damage function (BCF_s) is used to reflect the bilateral customer sector willingness to pay for the power transfer to avoid curtailing.

70.3.3 Formulations of Reliability and Price Problems

The objective of the problem is to determine customer load curtailment and nodal price through minimizing the total system cost using the OPF technique for each inadequacy state. The problems for two structures are formulated using the OPF technique based on the proposed reliability, price, cost, and response models.

Firstly the hybrid market model without reserve agreements is considered. In this model, electricity is traded through the pool and bilateral contracts, and there are no reserve agreements among market participants.

In this case, a new item is added to (70.6) to include the curtailment costs of bilateral contracts. New constraints are introduced for the bilateral contracts. The objective function becomes:

$$\begin{aligned} Min\ f^j = & \sum_{i\in N_g}\sum_{g\in NG_i^{pj}} C_{ig}^{pj}(P_{ig}^j, Q_{ig}^j) + \\ & \sum_{i\in N_L}\sum_{s\in NL_i^{pj}} CC_{is}^{pj}(CP_{is}^{pj}, CQ_{is}^{pj}) + \\ & \sum_{i\in BC_i}\sum_{\substack{k\in BC_i \\ k<i}}\sum_{s\in NL_i^{bj}} CC_{iks}^{bj}(CP_{iks}^{bj}, CQ_{iks}^{bj}) \end{aligned} \tag{70.28}$$

where the interruption costs of the pool customer are:

$$CC_{is}^{pj}(CP_{is}^{pj}, CQ_{is}^{pj}) = CP_{is}^{pj} \times CDF_s(1/D^j). \tag{70.29}$$

The curtailment cost of bilateral contract is:

$$CC_{iks}^{bj}(CP_{iks}^{bj}, CQ_{iks}^{bj}) = CP_{iks}^{bj} \times BCF_s(1/D^j) \tag{70.30}$$

subject to the following constraints.

Modified power flow constraints:

$$\begin{aligned} & \sum_{g\in NG_i^{pj}} P_{ig}^j - \sum_{s\in NL_i^{pj}}(P_{is}^{p0} - CP_{is}^{pj}) - \sum_{k\in BC_i}(-1)^{\beta}(P_{ik}^{bj} - \sum_{s\in NL_i^{bj}} CP_{iks}^{bj}) \\ & = \sum_{k=1}^{N} |V_i^j||V_k^j||Y_{ik}^j|\cos(\theta_i^j - \theta_k^j - \delta_{ik}^j) \end{aligned} \tag{70.31}$$

$$\begin{aligned} & \sum_{g\in NG_i^{pj}} Q_{ig}^j - \sum_{s\in NL_i^{pj}}(Q_{is}^{p0} - CQ_{is}^{pj}) - \sum_{k\in BC_i}(-1)^{\beta}(Q_{ik}^{bj} - \sum_{s\in NL_i^{bj}} CQ_{iks}^{bj}) \\ & = \sum_{k=1}^{N} |V_i^j||V_k^j||Y_{ik}^j|\sin(\theta_i^j - \theta_k^j - \delta_{ik}^j) \end{aligned} \tag{70.32}$$

where control variable $\beta = 0$ if i is a sink bus of bilateral contract, and $\beta = 1$ if i is a source bus for bilateral contract. The re-scheduled bilateral contracts P_{ik}^{bj} and Q_{ik}^{bj} in (70.31) and (70.32) are determined from the EMBGP using reliability equivalent techniques.

Generating unit limits:

$$P_{ig}^{\min} \le P_{ig}^j \le P_{ig}^{\max}, \tag{70.33}$$

$$Q_{ig}^{\min} \le Q_{ig}^j \le Q_{ig}^{\max}, \tag{70.34}$$

$$\Delta P_{ig}^{j,low} \le P_{ig}^j - P_{ig}^0 \le \Delta P_{ig}^{j,up}. \tag{70.35}$$

Curtailment limits of pool customer sectors:

$$0 \le CP_{is}^{pj} \le CP_{is}^{\max}. \tag{70.36}$$

Curtailment limits of bilateral customer sectors:

$$0 \le CP_{iks}^{bj} \le CP_{iks}^{b,\max}. \tag{70.37}$$

Voltage limits:

$$|V_i|^{\min} \le |V_i^j| \le |V_i|^{\max}. \tag{70.38}$$

Line flow constraints:

$$\left|S_{ik}^{j}\right| \le \left|S_{ik}^{j}\right|^{\max} . \tag{70.39}$$

The Lagrangian function L^j of the problem (70.28)–(70.39) for state j is formed and solved to provide the optimal generating unit outputs (P_{ig}^{j}, Q_{ig}^{j}), the curtailments for pool customer sector ($CP_{is}^{pj}, CQ_{is}^{pj}$), and the curtailment of bilateral contract ($CP_{iks}^{bj}, CQ_{iks}^{bj}$). The nodal prices of active power for the pool customers at bus i under the optimum solution can be obtained using the following equation:

$$\rho_i^j = \frac{\partial L^j}{\partial P_i^j} . \tag{70.40}$$

The price for a bilateral contract customer can be determined using the following equation based on the contractual price π_{ik} and the transfer price T_{ik}^{j}, which is calculated as the difference in nodal prices between bus *i* and *m:*

$$\rho_i^j = \pi_{ik} + T_{ik}^{j} . \tag{70.41}$$

Secondly the hybrid market model with reserve agreements is considered. Compared with (70.28), a new item is added to the objective function to represent the cost of the committed reserve to the pool from bilateral contracts. The reserve constraints are also introduced correspondingly. The power flow constraints (70.31) and (70.32) are modified to include the effect of reserve agreements on power flow. The objective function becomes:

$$\begin{aligned} Min\ f^j = &\sum_{i\in N_g}\sum_{g\in NG_i^{pj}} C_{ig}^{pj}(P_{ig}^{j}, Q_{ig}^{j}) + \sum_{i\in N_L}\sum_{s\in NL_i^{pj}} CC_{is}^{pj}(CP_{is}^{pj}, CQ_{is}^{pj}) \\ &+ \sum_{i\in BC_i}\sum_{\substack{k\in BC_i \\ k<i}}\sum_{s\in NL_i^{bj}} CC_{iks}^{bj}(CP_{iks}^{bj}, CQ_{iks}^{bj}) + \sum_{i\in N_g}\sum_{g\in RG_i^{rj}} C_{ig}^{rj}(P_{ig}^{rj}, Q_{ig}^{rj}) \end{aligned} \tag{70.42}$$

subject to constraints (70.33)–(70.39) and modified power flow constraints

$$\begin{aligned} &\sum_{g\in NG_i^{pj}} P_{ig}^{j} + \sum_{g\in RG_i^{j}} P_{ig}^{rj} - \sum_{k\in BC_i}(-1)^{\beta}(P_{ik}^{bj} - \sum_{s\in NL_i^{bj}} CP_{iks}^{bj}) \\ &- \sum_{s\in NL_i^{pj}}(P_{is}^{pj} - CP_{is}^{pj}) = \sum_{k=1}^{N}\left|V_i^j\right|\left|V_k^j\right|\left|Y_{ik}^j\right|\cos(\theta_i^j - \theta_k^j - \delta_{ik}^j) \end{aligned} \tag{70.43}$$

$$\begin{aligned} &\sum_{g\in NG_i^{pj}} Q_{ig}^{j} + \sum_{g\in RG_i^{j}} Q_{ig}^{rj} - \sum_{k\in BC_i}(-1)^{\beta}(Q_{ik}^{bj} - \sum_{s\in NL_i^{bj}} CQ_{iks}^{bj}) \\ &- \sum_{s\in NL_i^{pj}}(Q_{is}^{pj} - CQ_{is}^{pj}) = \sum_{k=1}^{N}\left|V_i^j\right|\left|V_k^j\right|\left|Y_{ik}^j\right|\sin(\theta_i^j - \theta_k^j - \delta_{ik}^j) \end{aligned} \tag{70.44}$$

Reserve constraints:

$$0 \le P_{ig}^{rj} \le P_{ig}^{rj,\max} , \tag{70.45}$$

$$0 \le Q_{ig}^{rj} \le Q_{ig}^{rj,\max} . \tag{70.46}$$

The pool demands change from P_{is}^{p0} and Q_{is}^{p0} to P_{is}^{pj} and Q_{is}^{pj} as some bilateral customers may buy the electricity from the pool due to inadequate generation from their EMBGPWR. The P_{is}^{pj} and Q_{is}^{pj} are determined by the states of the EMBGPWR and associated reserve agreements with the power pool.

The solution of the above optimization problem yields the pool generation outputs (P_{ig}^{j}, Q_{ig}^{j}), the pool load curtailments for customer sectors ($CP_{is}^{pj}, CQ_{is}^{pj}$), the sector curtailments of bilateral contracts ($CP_{iks}^{bj}, CQ_{iks}^{bj}$), and the reserve ($P_{ig}^{rj}, Q_{ig}^{rj}$) used.

70.3.4 System Studies

The proposed techniques, the improved OPF technique for the Poolco model (Tech1), for the hybrid model without reserve agreement (Tech2), and for the hybrid model with reserve agreement (Tech3), have been used to analyze the IEEE-RTS. The results obtained using these techniques have been compared with those obtained using the reported technique, the OPF based spot pricing technique [11], [20], [21] for the Poolco model (ETech). The generating system of the RTS is divided into five gencos. The RTS is analyzed as different market models: the Poolco model in which all gencos and customers sell and buy energy from the power pool. In the hybrid model without reserve agreements (Hymodel1), the power pool (EMPGP) consists of gencos 1, 2 and 5. Genco3 and Genco4 are represented as EMBGP1 and EMBGP2, respectively. The bilateral

customers at buses 3, 9 and 19 directly purchase electricity from Genco3 (EMBGP1) at 72 $/MWh and the customers at buses 10 and 13 from Genco4 (EMBGP2) at 75 $/MWh. Other customers buy electricity from the EMPGP at nodal prices. In the hybrid model with reserve agreements (Hymodel2), EMBGP1 and EMBGP2 share their reserve with EMPGP.

Table 70.1 lists the prices ($/MWh) and price deviations ($/MWh) of different models and techniques for the representative nodes. The table shows that the nodal prices obtained using Tech1 are higher than those obtained using ETech. The nodal prices obtained using Tech3 are higher than those obtained using ETech6. This means that system reliability has to be considered in pricing techniques. The higher expected prices and the standard deviations are due to the price spikes and the associated high probability caused by inadequate generation and line congestions.

Table 70.1. Prices and associated risk indices

BLP	ETech	Tech1		Tech3		Tech2	
	ρ_i	$\overline{\rho}_i$	σ_i	$\overline{\rho}_i$	σ_i	$\overline{\rho}_i$	σ_i

3	28.75	80.30	261.2	91.9	157.4	85.0	32.6
4	29.20	80.62	261.3	83.0	258.0	285.0	625.0
5	29.09	80.30	260.5	82.8	257.5	284.8	624.8

70.4 A Schema for Controlling Price Volatilities Based on Price Decomposition Techniques

Because of the low elasticity of system demand, inadequate generation, and line congestion due to system failures may result in price spikes. The electricity prices in a restructured power system can be highly volatile during contingency states. As discussed before, the high prices in a restructured power system have resulted in significant impact on customers. In the new environment, the system operator usually cannot directly control the electricity prices by setting regulated values. Therefore, how to the control price risk caused by system random failures can be a major problem faced by the system operator.

In this section, a schema for controlling electricity price volatility based on the price decomposition technique [22] is proposed. In this schema, generation companies (gencos) or transmission companies (transcos) will be penalized if the failures of their components result in unexpected price change. The penalty is calculated based on the difference of electricity price components between the normal state and contingency states. The motivation of the proposed penalty schema is to: 1) penalize those resulting in price volatility and hurting system reliability; 2) encourage gencos and transcos to improve their reliabilities through maintenance action, replacement of old equipments, and reserve agreements among market participants; 3) compensate the increase of customer cost caused by price volatility and load interruption; 4) provide the system operator a flexible tool to control price and reliability risk.

70.4.1 Price Decomposition Techniques

OPF is used to evaluate nodal prices. The general form of the OPF formulations for system state *j* can be formulated as [22]:

$$Min\, f^j(\mathrm{X}^j) \text{ for } \mathrm{X}^j \,. \tag{70.47}$$

Subject to:

$$\mathrm{G}^j(\mathrm{X}^j,\eta^j) = 0\,, \tag{70.48}$$

$$\mathrm{H}^j(\mathrm{X}^j,\eta^j) \le 0\,, \tag{70.49}$$

where $\boldsymbol{X^j} = (x_1^j,...x_n^j)$ represents a vector of control variables in the system operation such as real and reactive power generations, and load sheddings. $\eta^j = (\eta_1^j,...,\eta_m^j)$ represents a parameter vector in the system operation. $f(\mathrm{X})$ is the system operation cost. $\mathrm{G}^j(\mathrm{X}^j,\eta^j)$ is the vector of equality constraints such as power flow equations, and $\mathrm{H}^j(\mathrm{X}^j,\eta^j)$ is the vector of inequality constraints such as voltage limits, generation output limit, *etc*.

According to the Karush–Kuhn–Tucker (KKT) condition, the optimal solution to the OPF problem (70.47)–(70.49) must satisfy:

$$\frac{\partial f^j}{\partial \mathrm{X}^j}+\lambda^j\frac{\partial \mathrm{G}^j}{\partial \mathrm{X}^j}+\bar{\rho}^j\frac{\partial \bar{\mathrm{H}}^j}{\partial \mathrm{X}^j}=0\,, \tag{70.50}$$

$$\boldsymbol{G^j}(\boldsymbol{X^j},\boldsymbol{\eta^j})=0\,, \tag{70.51}$$

$$\bar{\mathrm{H}}^j(\mathrm{X}^j,\eta^j)=0\ , \tag{70.52}$$

where $\bar{\mathrm{H}}^j$ and $\bar{\rho}^j$ are column vectors that have active inequalities among H^j and the associated Lagrangian multipliers, respectively, and λ^j is the vector of the Lagrangian multipliers associated with equality constraints.

The Lagrangian function of (70.47)–(70.49) is defined as:

$$L^j(\mathrm{X}^j,\eta^j,\lambda^j,\rho^j)=f^j(\mathrm{X}^j)+\lambda^j G^j(\mathrm{X}^j,\eta^j)+\bar{\rho}^j\bar{H}^j(\mathrm{X}^j,\eta^j). \tag{70.53}$$

At an optimal solution, the nodal prices of real power are given as follows:

$$\pi_{pi}^j=\frac{\partial L^j}{\partial P_i^j}\,. \tag{70.54}$$

To break down the nodal prices into a more detail expression, the components we are interested in among $(\mathrm{G}^j,\bar{\mathrm{H}}^j)$ have to be provided. Let M^j be the non-tradable constraints among $(\mathrm{G}^j,\bar{\mathrm{H}}^j)$, which we are not interested in, and N^j be the tradable constraints among $(\mathrm{G}^j,\bar{\mathrm{H}}^j)$, which we are interested in. Equations (70.50)–(70.52) can be rewritten as:

$$\frac{\partial f^j}{\partial \mathrm{X}^j}+\mathrm{U}^j(\mathrm{X}^j,\eta^j,\alpha^j)=0\,, \tag{70.55}$$

$$\boldsymbol{M^j}(\boldsymbol{X^j},\boldsymbol{\eta^j})=0\,, \tag{70.56}$$

where

$$\mathrm{U}^j(\mathrm{X}^j,\eta^j,\alpha^j)=\lambda^j\frac{\partial \mathrm{G}^j}{\partial \mathrm{X}^j}+\bar{\rho}^j\frac{\partial \bar{\mathrm{H}}^j}{\partial \mathrm{X}^j}=\alpha^j\frac{\partial \mathrm{M}^j}{\partial \mathrm{X}^j}+\beta^j\frac{\partial \mathrm{N}^j}{\partial \mathrm{X}^j} \tag{70.57}$$

$\boldsymbol{\alpha^j}$ is the row vector of the Lagrangian multipliers corresponding to the constraints $\boldsymbol{M^j}$ and $\boldsymbol{\beta^j}$ is the row vector of the Lagrangian multipliers corresponding to the constraints $\boldsymbol{N^j}$.

Differentiating (70.55) and (70.56) with respect to P_i^j, the equations can be rewritten as follows:

$$\begin{bmatrix}\dfrac{\partial (f^j)^2}{\partial^2(\mathrm{X}^j)}+\dfrac{\partial \mathrm{U}^j}{\partial \mathrm{X}^j} & \dfrac{\partial \mathrm{U}^j}{\partial \alpha^j}\\ \dfrac{\partial \mathrm{M}^j}{\partial \mathrm{X}^j} & 0\end{bmatrix}\cdot\begin{bmatrix}\dfrac{\partial \mathrm{X}^j}{\partial P_i^j}\\ \dfrac{\partial \alpha^j}{\partial P_i^j}\end{bmatrix}=\begin{bmatrix}-\dfrac{\partial \mathrm{U}^j}{\partial \eta^j}\cdot\dfrac{\partial \eta^j}{\partial P_i^j}\\ -\dfrac{\partial \mathrm{M}^j}{\partial \eta^j}\cdot\dfrac{\partial \eta^j}{\partial P_i^j}\end{bmatrix}. \tag{70.58}$$

Therefore $\dfrac{\partial \boldsymbol{X^j}}{\partial P_i^j}$ and $\dfrac{\partial \boldsymbol{\alpha^j}}{\partial P_i^j}$ can be obtained.

The nodal prices of real power can be decomposed as:

$$\begin{aligned}\pi_{pi}^j&=\frac{\partial f^j}{\partial \boldsymbol{X^j}}\frac{\partial \boldsymbol{X^j}}{\partial P_i^j}+\boldsymbol{\beta^j}\left(\frac{\partial \boldsymbol{N^j}}{\partial \boldsymbol{X^j}}\frac{\partial \boldsymbol{X^j}}{\partial P_i^j}+\frac{\partial \boldsymbol{N^j}}{\partial \boldsymbol{\eta^j}}\frac{\partial \boldsymbol{\eta^j}}{\partial P_i^j}\right)\\&=\sum_{k=1}^{n1}\left(\frac{\partial f_k^j}{\partial \boldsymbol{X^j}}\frac{\partial \boldsymbol{X^j}}{\partial P_i^j}\right)+\sum_{k=1}^{m}\boldsymbol{\beta^j}\left(\frac{\partial N_k^j}{\partial \boldsymbol{X^j}}\frac{\partial \boldsymbol{X^j}}{\partial P_i^j}+\frac{\partial N_k^j}{\partial \boldsymbol{\eta^j}}\frac{\partial \boldsymbol{\eta^j}}{\partial P_i^j}\right)\end{aligned} \tag{70.59}$$

where $\dfrac{\partial f^j}{\partial \mathrm{X}^j}\dfrac{\partial \mathrm{X}^j}{\partial P_i^j}$ is the nodal price component representing the cost from generator units and $\beta^j\left(\dfrac{\partial \mathrm{N}^j}{\partial \mathrm{X}^j}\dfrac{\partial \mathrm{X}^j}{\partial P_i^j}+\dfrac{\partial \mathrm{N}^j}{\partial \eta^j}\dfrac{\partial \eta^j}{\partial P_i^j}\right)$ is the nodal price component representing the cost from constraints for the state *j*.

70.4.2 The Proposed Schema

The random nature of failures creates great price uncertainty. The nodal price components for contingency states can be significantly different from the components in the normal state. Consider a simple example as shown in Figure 70.5.

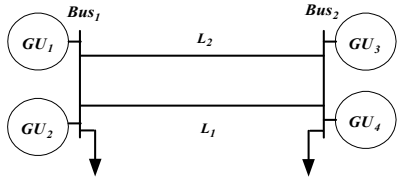

Figure 70.5. The two-bus test system

In this example, the system consists of four units belonging to two generation companies (gencos). Genco 1 owns unit 1 (250MW) at bus 1 and unit 4 (50MW) at bus 2. Genco 2 owns unit 2 (200MW) at bus 2 and unit 3 (76MW) at bus 2. There are two states considered in this example: the normal state and state 4 (unit 4 out of service).

By using the nodal price decomposition technique the nodal price can be expressed in the following form:

Nodal price at bus i = charge for power generation of GU1
+ compensation for power generation upper limit of GU1
+ charge for power generation of GU2
+ compensation for power generation upper limit of GU2
+ charge for power generation of GU3
+ compensation for power generation upper limit of GU3
+ charge for power generation of GU4
+ compensation for power generation upper limit of GU4
+ compensation for voltage lower or upper limit at bus 1
+ compensation for voltage lower or upper limit at bus 2
+ congestion charge for line 1
+ congestion charge for line 2

In the first case, it is assumed that the system is in the normal state. The nodal prices at bus 1 and at bus 2 include four non-zero terms corresponding to the charge for power generation of units and can be decomposed as:

$$\pi_{p1}^{0} = 20.313 + 0 + 12.926 + 0 + 0.11415 + 0 + 0.065229 + 0 + 0 + 0 + 0 + 0 = 33.4\$/MWh$$

$$\pi_{p2}^{0} = 0.32461 + 0 + 0.20657 + 0 + 21.029 + 0 + 12.016 + 0 + 0 + 0 + 0 + 0 = 33.6\$/MWh$$

In the normal state the profits of Genco 1 and Genco 2 are 1779.7$/h and 1154.2$/h, respectively. The customer payment for power at bus 1 and bus 2 is 1336.7$/h and 8729.8$/h, respectively.

In the second case, it is assumed that unit 4 is out of service. The nodal prices at bus 1 and at bus 2 include three non-zero terms, which can be decomposed as:

$$\pi_{p1}^{4} = 21.207 + 0 + 13.497 + 0 + 0.17797 + 0 + 0 + 0 + 0 + 0 + 0 + 0 = 34.9\$/MWh$$

$$\pi_{p2}^{4} = 0.50586 + 0 + 0.32194 + 0 + 34.234 + 0 + 0 + 0 + 0 + 0 + 0 + 0 = 35.1\$/MWh$$

In this state, the profits of Genco 1 and Genco 2 are 1860.3 $/h and 1348.9$/h, respectively. The customer payment for power at bus 1 and bus 2 is 1395.3$/h and 9116.1$/h, respectively.

Comparing the results in case 1 with the results in case 2, it can be seen that the failure of the system component results in the uncertainty of the nodal price, and the variations of nodal price components, the customer payment, and the genco's profit. The outage of a generation unit usually causes a relatively large profit increase of other generating units. In case 2 though unit 4 failed, the profit of the responsible Genco 1 still increases from 1779.7$/h in the normal state to 1860.3 $/h because of the increased nodal price at bus 1 and the output of unit 1. Obviously, the corresponding genco can use this strategy to earn more profit.

The proposed schema is to evaluate a penalty cost to the corresponding genco or transco if the failures of its components result in electricity price volatility. Two major factors are considered in the schema to evaluate the penalty cost. The first factor is the differences in the nodal price components between the normal state and the corresponding contingency state. The second factor is the responsibility of the corresponding genco or transco for the variation of nodal price components. For the variations of different components in the nodal prices, the responsibilities of genco or transco are different. Some market rules will be set up by the system operator to determine the responsibilities of a genco or a transco for the variation of nodal price components.

If contingency state j is caused by the failure in Genco or Transco z, the penalty can be defined as:

$$\text{Penalty}_{z}^{j} = \sum_{i \in N_L} \left\{ \gamma_0 \cdot (v_{i,0}^{j} - v_{i,0}^{j_0}) + \gamma_1 \cdot (v_{i,1}^{j} - v_{i,1}^{j_0}) \right\} \cdot D_i^j + \gamma_2 \cdot \left\{ \sum_{i \in N_L} \sum_{s \in NI_i^j} OC_{is}^{j} (LC_{pis}^{j}) \right\} \tag{70.60}$$

where $v_{i,0}^{j}$ and $v_{i,0}^{j_0}$ are price components at bus i related to z for the contingency state j and the normal state, respectively,

$$\nu_{i,0}^{j}=\sum_{\substack{k=1\\k\notin GS}}^{z1}\left(\frac{\partial f_k^j}{\partial \boldsymbol{X}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j}}}{\partial P_i^j}\right)+\sum_{\substack{k=1\\k\notin CS}}^{z2}\beta^j\left(\frac{\partial N_k^j}{\partial \boldsymbol{X}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j}}}{\partial P_i^j}+\frac{\partial N_k^j}{\partial \boldsymbol{\eta}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{\eta}^{\boldsymbol{j}}}{\partial P_i^j}\right) \quad (70.61)$$

$$\nu_{i,0}^{j_0}=\sum_{\substack{k=1\\k\notin GS}}^{z1}\left(\frac{\partial f_k^{j_0}}{\partial X^{j_0}}\frac{\partial X^{j_0}}{\partial P_i^{j_0}}\right)+\sum_{\substack{k=1\\k\notin CS}}^{z2}\beta^{j_0}\left(\frac{\partial N_k^{j_0}}{\partial X^{j_0}}\frac{\partial X^{j_0}}{\partial P_i^{j_0}}+\frac{\partial N_k^{j_0}}{\partial \eta^{j_0}}\frac{\partial \eta^{j_0}}{\partial P_i^{j_0}}\right) \quad (70.62)$$

It can be seen from (70.61) and (70.62) that $\nu_{i,0}^{j}$ and $\nu_{i,0}^{j_0}$ have two items. The first item represents price components for power generation of units of Genco *z*. The second item represents price components for the tradable constraints related to Genco *z* or Transco *z, e.g.,* power generation limit of units of Genco *z* or congestion charge of Transco *z*.

$\nu_{i,1}^{j}$ and $\nu_{i,1}^{j_0}$ are price components not related to *z* for contingency state *j* and the normal state, respectively,

$$\nu_{i,1}^{j}=\sum_{k=z1+1}^{n1}\left(\frac{\partial f_k^j}{\partial \boldsymbol{X}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j}}}{\partial P_i^j}\right)+\sum_{k=z2+1}^{m}\beta^j\left(\frac{\partial N_k^j}{\partial \boldsymbol{X}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j}}}{\partial P_i^j}+\frac{\partial N_k^j}{\partial \boldsymbol{\eta}^{\boldsymbol{j}}}\frac{\partial \boldsymbol{\eta}^{\boldsymbol{j}}}{\partial P_i^j}\right) \quad (70.63)$$

$$\nu_{i,1}^{j_0}=\sum_{k=z1+1}^{n1}\left(\frac{\partial f_k^{j_0}}{\partial \boldsymbol{X}^{\boldsymbol{j_0}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j_0}}}{\partial P_i^{j_0}}\right)+\sum_{k=z2+1}^{m}\beta^{j_0}\left(\frac{\partial N_k^{j_0}}{\partial \boldsymbol{X}^{\boldsymbol{j_0}}}\frac{\partial \boldsymbol{X}^{\boldsymbol{j_0}}}{\partial P_i^{j_0}}+\frac{\partial N_k^{j_0}}{\partial \boldsymbol{\eta}^{\boldsymbol{j_0}}}\frac{\partial \boldsymbol{\eta}^{\boldsymbol{j_0}}}{\partial P_i^{j_0}}\right) \quad (70.64)$$

The first item in (70.63) and (70.64) represents price components for units' power generation of other gencos and load shedding of customers. The second item in (70.63) and (70.64) represents price components for all other tradable constraints not related to Genco *z* or Transco *z, e.g.*, voltage limits and power generation limit of units of other Gencos.

γ_0 is the proportion that the Genco or Transco *z* is responsible for the increase of price components related to *z*. Usually $0\le\gamma_0\le 1$.

γ_1 is the proportion that the Genco or Transco z is responsible for the increase of price components not related to z. Usually $0\le\gamma_0\le 1$ and $\gamma_1\le\gamma_0$.

γ_2 is the proportion that the Genco or Transco z is responsible for the interruption cost of customers if there is load shedding for state j. Usually $0\le\gamma_2\le 1$.

The demand at bus *i* for state *j* can be calculated as:

$$D_i^j=\sum_{s\in NL_i^j}P_{is}^{j_0}-\sum_{s\in NL_i^j}LC_{pis}^j\ . \quad (70.65)$$

The second case is reconsidered now. For the normal state the first item of $\nu_{1,0}^{j_0}$ related to Genco 1 can be represented as $20.313+0$, where 20.313 is the price component for power generation of unit 1 at bus 1, and 0 is the price component for power generation of unit 4 at bus 1. The compensation of power generation upper limit of unit 1 is zero. In the contingency state 4 (unit 4 out of service) the first item of $\nu_{1,0}^{4}$ related to Genco 1 can be represented as $21.207+0$, where 21.207 is the price component for power generation of unit 1 at bus 1, and the price component related to the unit 4 is also zero because this unit is out of service. The compensation of power generation upper limit of unit 1 is also zero.

In the normal state the first item of $\nu_{1,1}^{j_0}$ related to unit 2 and unit 3 can be represented as $12.926+0.11415+0+0$, where 12.926 and 0.11415 are price components for power generation of units 2 and 3 at bus 1, respectively . The compensation of power generation upper limit of units 2 and 3 is zero. In the contingency state 4 the first item of $\nu_{1,1}^{4}$ related to units 2 and 3 can be represented as $13.497+0.17797+0+0$, where 13.497 and 0.17797 are price components for power generation of units 2 and 3 at bus 1, respectively. The compensation of power generation upper limit of unit 2 and unit 3 is also zero.

It is supposed that γ_0 and γ_1 are set by the system operator as 0.3 and 0.2, respectively. The penalty of Genco 1 for state 4 can be calculated as:

$$\begin{aligned}\text{Penalty}_1^4 &= \left\{\begin{matrix}0.3\times(21.207-20.313)+\\0.2\times(13.497+0.17797-12.926-0.11415)\end{matrix}\right\}\times 40\\ &+\left\{\begin{matrix}0.3\times(0.50586-0.32461)+\\0.2\times(0.32194+34.234-0.20657-21.029)\end{matrix}\right\}\times 260\\ &=722.6\$/h\end{aligned}$$

In this case the profit of Genco 1 goes from 1860.3$/h to 1860.3−722.6=1137.7$/h, which is much less than the profit in the normal state.

The system operator of the power pool will set γ_0, γ_1 and γ_2 to reflect the responsibilities of the genco or transco and to influence the price volatility. The penalty will stimulate gencos and transcos to improve their reliabilities and therefore reduce price volatilities.

Probabilistic Risk Assessment for Nuclear Power Plants

Peter Kafka

Consultant, RelConsult, Grünwald, Germany

Abstract: Probabilistic risk assessment (PRA) is a systematic and comprehensive methodology to evaluate risks associated with a complex technological entity. PRAs for nuclear power plants have a more than 30 year old success story. The present chapter outlines in depth the PRA history, the essential elements of a PRA, today's challenges, an outlook, and last but not least, some rational comments to trigger supplementary developments and further improvements in the PRA methodology and the related risk management process.

71.1 Introduction

Electric power generation using nuclear energy and associated risk assessment is one of the major engineering areas that has been practised successfully for more than 60 years.

The electricity for the first time by a nuclear reactor was generated on December 20, 1951 at the EBR-I experimental station near Arco, Idaho, in the United States. On June 27, 1954, the world's first nuclear power plant to generate electricity for an electrical power grid started operations at Obninsk in the former USSR. The world's first commercial scale nuclear power station, Calder Hall in England, opened on October 17, 1956.

Today, there are 444 nuclear power plants (NPP) in operation world-wide (status on December 31, 2005). The installed capacity is 390.931 MWe (gross). These facilities generated 2.750 Mrd. kWh in the year 2005 (net). This amount of electricity represents about 15% of the electricity demand worldwide. Related to this huge industrial undertaking, the safety record, also considering the observed nuclear disasters, is remarkably good and it is a great engineering challenge to keep it at this excellent level.

In depth safety evaluations have been growing since 1956. At that time in USA the first commercial NPPs were switched to the grid. Thus, the licensing authority in the states (at that time: USAEC; US Atomic Energy Commission) asked the Brookhaven National Laboratory to estimate the consequences of a severe nuclear accident. The results of this estimation were published in 1957 by the USAEC in the report "Theoretical Possibilities and Consequences of Major Accidents in Large Nuclear Power Plants" and coded with WASH 740 [1]. This so-called Brookhaven Report was not very helpful, because it concluded that if the containment functioned no damage to the surrounding population would occur, and if the containment failed only the upper bound of consequences could be estimated from the relief of the large quantities of fission products in the form of noble gases, radioiodine, and some fractions of

other fission products. The public impact would be enormous by such a scenario.

Realizing this overestimation the US Congress established the well known Price Anderson Act to provide the protection of public needed by the industry and in doing so it ignored the upper limit estimates of WASH 740.

A few years later it was suggested by engineers in many countries to estimate not only the consequences of severe accidents (the worst case) but also the inherent probabilities of severe scenarios and finally the consequences to a plant, the public, or the environment. As a successful promoter of this "risk-informed" approach using realistic assumptions for potential event scenarios Farmer [2] has to be honored.

This milestone for industrial safety engineering as a whole marks the beginning of probabilistic risk assessment (PRA).

In the course of these developments in the United States the Nuclear Regulatory Commission (US NRC) entrusted Norman Rasmussen from MIT to assess the risk associated with the operation of ten light water reactors in the U.S. The results of this challenging undertaking were published in 1975 in form of the "Rasmussen Report" and coded as WASH 1400 [3].

Typically for this first comprehensive and plant-wide risk study was the integrative application of event tree and fault tree methodology. Both methods were known but applied separately in system reliability studies in various technologies.

The report concluded that the risks to the individual posed by such NPPs were acceptably small, compared with other tolerated risks. Specifically, the report concluded that the probability of a complete core meltdown is about 1 in 20,000 *per* reactor *per* year.

The Rasmussen Report was peer-reviewed by the "Lewis Committee" in 1977, which broadly endorsed the methodology as the best available, but warned that the risk figures were subject to large uncertainties.

WASH 1400 steered the nuclear community, the NPP operators, and the licensing authorities around the globe to perform risk assessment for all the individual NPPs based on the PRA approach.

These worldwide plant specific PRA activities also triggered much R&D work for improving weaknesses in methodologies, to broaden the probabilistic/statistical data base, to complete the understanding of accident phenomena, and finally to reduce uncertainties in risk estimates.

Following that period of intensive and expensive R&D work in many countries, and inspired partly by the Three Mile Island Accident in 1991 WASH-1400 was replaced by NUREG-1150 [4]. In parallel in all the countries operating NPPs, PRAs for specific plants, or at least for families of similar plants, were initiated and finalized. At this time the term probabilistic risk assessment was modified into the synonym probabilistic safety assessment (PSA).

In 1995, the USNRC issued the PRA Policy Statement, which says: "The use of PRA in all regulatory requirements should be increased to the extent supported by the state-of-the-art PRA methods and data in a manner that compliments the defense-in-depth philosophy. PRA should be used to reduce unnecessary conservatism associated with current regulatory requirements." [5].

Today, there is consensus among NPP designers, operators, and licensing authorities that PRA/PSA:

- achieves a realistic description and quantification of risk;
- models performance of various safety measures;
- makes known and therefore allows weak points in system design, construction, and operation to be revealed;
- reflects the consequences of dependencies in systems, components, and man–machine in general;
- makes uncertainties explicitly visible;
- identifies the relative importance of specific accident sequences, safety features, and component failures;
- allows the assessment of operational and maintenance related aspects;
- considers and applies explicitly operational experience as a indispensable knowledge base; and
- allows monitoring the actual risk level throughout the life cycle of an NPP.

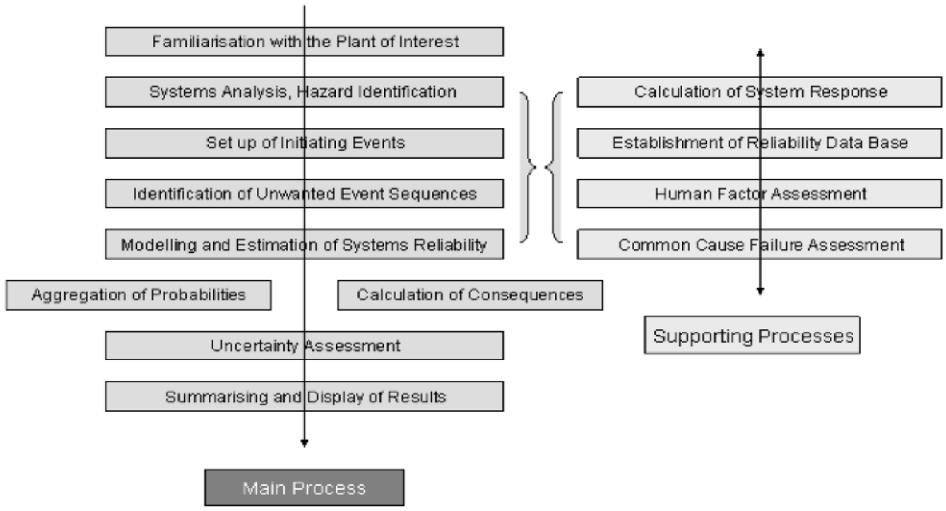

Figure 71.1. The main tasks required for a typical PRA

Remarkable for this condensed historical perspective are also the keen activities to harmonize the PRA procedure for easy review and comparisons of outcomes. Specifically, the IAEA in Vienna promoted activities and published a series of guidelines in form of: "How you should conduct a PSA…" [6].

Beyond these non-binding IAEA guidelines some countries endorsed "requirements" for doing the PRA and their utilization. As an example the "PSA Leitfaden" is referenced for Germany [7]. Additional information regarding the utilization of PRAs in licensing procedures is given in [8].

The standardization organization ASME (American Society for Mechanical Engineers) endorsed the "PRA Standard" in 2002 [9] aiming also at the use of "best practice" for PRA achievement.

Nowadays, other technologies in many countries, *e.g.*, the space industry, the oil and gas industry, dangerous goods transport, and process facilities are looking carefully at the PRA approach developed and used in nuclear industry, and are working at adopting the essence of that approach for their own safety questionnaire [10]. The NASA PRA Guideline, published in 2002 [25], is an example and a reference for that performed synergism.

In Figure 71.1, the main tasks performed in a PRA process are shown. However, the illustrated process can never be straightforward. Some iterative actions dependent on preliminary results in a given process step are always required [26].

Considering the enormous activities performed for PRA and the huge mass of publications in this field, the author is aware that this condensed historical perspective can only be a limited snapshot of the real world in PRA/PSA undertakings [27].

71.2 Essential Elements of PRA

PRA, often named PSA, is a systematic and comprehensive methodology to evaluate the risks associated with a complex technological entity [26].

Risk in a PRA is defined as a feasible adverse outcome of an event scenario triggered by a malfunction of a technical entity, a human interaction, or an environmental impact.

Risk is characterized by two quantities:

- the magnitude (severity) of the possible adverse consequence, and
- the likelihood (probability) of the occurrence of the adverse consequence.

Adverse consequences can be directed to the:

- entity itself and, therefore, to a financial loss;
- staff or the surrounding population and, therefore, to a health impact;
- environment and, therefore, to an ecological disaster, or
- entity, the humans, and the environment together.

Consequences are expressed by numbers (*e.g.*, in the form of physical parameters or number of potentially impacted people), and their likelihoods of occurrence are expressed as probabilities or frequencies (*i.e.*, the number of occurrences or the probability of occurrence *per* unit of time).

PRA usually answers three basic questions:

- What can go wrong within the entity?
- What are the adverse consequences?
- How likely are these adverse consequences?

For NPPs it is usual to perform PRAs for three different ranges [6], [28], [29]:

Level I: Risk assessment based on event scenarios that can lead to core damage.

Level II: Risk assessment based on event scenarios that can lead to core damage and consequently to a loss of containment.

Level III: Risk Assessment based on event scenarios that can lead to core damage, a loss of containment, and consequently to an impact on the surrounding public and the environment.

In Figure 71.2 a simplified PRA logic is shown. It is by rule a "cause–consequence logic" composed of fault trees and event trees. The trees are intermeshed to a global model. Normally, about 30 event trees and 100 fault trees are combined. The event trees describe a success/failure logic; the fault trees the undesired TOP events. In Figure 71.2 the summing up procedures *via* binning of similar outcomes of event trees, *etc.*, is not visualized.

The entire combination of event and fault trees represents a probabilistic model. This means all the causes (basic events), the logic gates (AND, OR, *etc.*) in the fault trees, the initiating event, the gates in the event trees (success or failure, respectively yes or no), the core damage, the containment failure, and all the various estimated consequences are characterized by quantified probabilities [9].

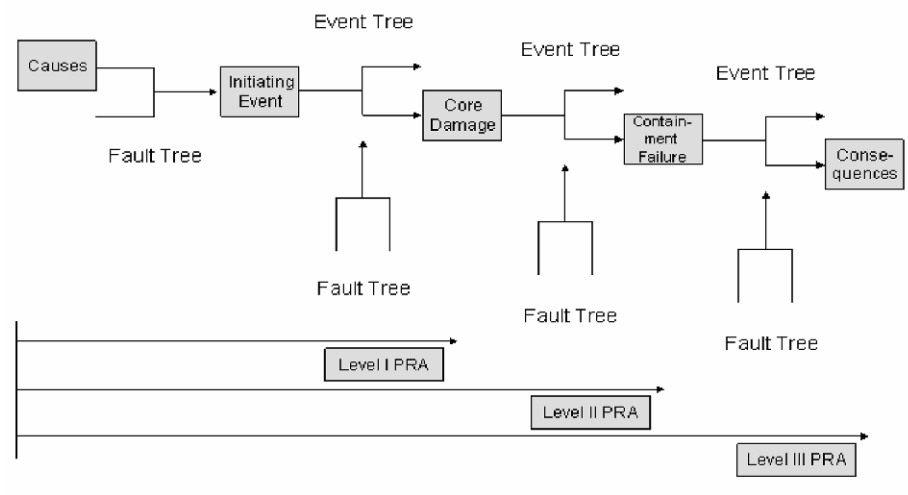

Figure 71.2. Simplified PRA logic (binning procedures are neglected)

71.2.1 Identification of Scenarios

The identification of scenarios that have be undergone for an in-depth analysis is focused on the hazards inherent in the NPP. The main hazards result from radioactive inventories of the reactor core and the fuel element storage pool. Thus, the PRA focusses on the identification of scenarios that can eventually lead to undesired consequences if some hazardous situations develop [26].

The process of identification is normally supported by a "master logic diagram" (MLD), which shows in a tree logic all the various sequences (causes) that can lead to the undesired release of radioactive products and, therefore, to unwanted consequences for the plant, the public, or the environment. This process is often not straightforward because an increase of insight perhaps leads to a re-consideration of possible event sequences.

MLG creates the so-called initiating events (IEs) triggering the unwanted sequence. These IEs are the starting point for identifying (probably the most complete) possible event scenarios, which can be modeled with the means of event tree logic. The undesired events, or end states, of the event trees are classified as plant damage states such as the un-cooled core or the core melt.

The granulation of the event trees is normally oriented on the system level. This means the event trees show what happens if a given system is functioning or if it fails.

In the real work out of PRAs the practitioners identify about 30 event trees manifesting all the identified scenarios that can lead to the unwanted release of radioactive products.

If the PRA is to answer a typical question of plant owners, *e.g.*, how can a particular plant damage be triggered, the identification process has to be focused backwards to identify the various causes for such an unwanted damage.

71.2.2 System Reliability

The assessment of system reliability is essential in the course of a PRA process. It answers main questions *e.g.*, what can go wrong and how frequent is it? Answers to these questions are not only of interest for the main task of risk assessment but also for plant availability estimations, maintenance optimizations, and life-cycle cost calculations [26],[30].

The methodology for reliability assessment is *per se* well developed and established, and has been in use for many years in various technologies, However, the number of systems and components, the complexity of interactions, and the implementation of new technologies, *e.g.*, digital control systems based on embedded software, are NPP specific and, therefore, challenging issues for reliability engineers.

Besides these facts one has to be aware that some component failures are so-called rare events and, therefore, the statistical data base for these components is associated with significant uncertainties. So far, ongoing activities to collect raw data in NPPs and to estimate the belonging reliability figures (*e.g.*, failure rates, CCF data, repair times) is of great importance.

The main approach applied for system reliability assessment is given by the fault tree methodology (FTA). Some PRA practitioners support FTA at the front end by failure mode and effect analysis (FMEA) to identify possible failure modes and their causes and consequences. However, it is surprising that this beneficial and fully formalized approach is not routinely utilized within the process of system reliability assessment for NPPs.

Some system behavior that is significantly time dependent is modeled by using the Markov approach. As is known, this approach allows for various time-dependent system stages (*e.g.*, operation, standby, repair), the explicit estimation of probabilities to be present in one of these stages.

71.2.3 System Response

For system design it is assumed every one of the installed components and system functions are working properly. Under this condition many different physical properties (*e.g.*, temperature, pressure, stress) are calculated. Accompanying sensitivity studies often illuminate often some deviation from the design purpose if a specific parameter is beyond the design value.

The PRA process raises many more questions regarding the physical behavior of the system be-

cause according to Murphy's law every component build in the system can fail and, therefore, the system response can be related to the design status very differently.

In practice it is not possible to repeat, case by case, the system response calculation for all the possible situations or combinations of component failures. Usually, event tree logic showing unwanted failure sequences creates the cases for system response calculations. However, this procedure is not a one way street because also the identification of the unwanted sequences in the event trees should take into account insight from system response calculations or system understanding. Thus, in other words, these two working steps, identification of the event sequences of interest and the calculation of system response, are usually prepared with close cooperation of reliability engineers and system designers.

Some simplifications in the form of pessimistic assumptions are regularly required if the system response is highly dynamic (time dependent) and the modeling of event sequences is quasi-static (snap shot) [26].

71.2.4 Common Cause Failure

The family of dependent failures are multiple failure events that can defeat the mechanical/ structural barriers, the diversity, and/or redundancy applied in the NPP to ensure highly reliable systems under operation or a sufficient availability of standby safety features [26].

Generally, the following major categories of dependent failures are considered within a PRA:

- Functional dependencies. This category includes dependence among systems or components due to sharing of common hardware (*e.g.*, pipe work, cables) or sharing a common process (*e.g.*, depressurization of a primary circuit for successful functioning of core cooling).
- Physical dependencies. This category couples multiple systems or components through a common environment (*e.g.*, steamy atmosphere, flooding, earthquake).
- Human interaction dependencies. This category includes dependencies caused by common procedures/actions applied for man–machine interactions (*e.g.*, misinterpretation of procedural steps).

These categories of dependencies are normally modeled explicitly in PRAs to the extent that is practicable related to the available historical information.

Besides these categories one has to be aware that similar or identical components would have a similar sensitiveness against specific environmental conditions, process parameters, stress conditions, *etc.*, named root causes. Therefore, it is known that similar or identical components can fail together if a common root cause takes place. Obviously, this type of dependent failure, named common cause failure (CCF) cannot explicitly be modeled in, *e.g.*, fault trees; one has to consult operational experience and relevant data bases to judge the probability for common failures.

For practical use in PRAs, a few similar models have been developed and the values for the associated parameters have been proposed and published. One of the simplest models is the so-called β-factor model. It says that the probability of a CCF (*i.e.*, common failure of redundant components) is a given fraction of the probability of a random failure of one of the components. It has been experienced that β-factors can be in the range of 10%.

As a consequence of this worth impact to the reliability of redundant systems great effort is being spent to estimate adequate β-factors, and *vice versa*, to improve engineering practice for reduction of CCF sensitiveness of redundant systems and components.

71.2.5 Human Factors

The PRA approach requires the quantification of system failures in the form of explicit probabilities. As a consequence, each part of the system (*i.e.*, man–machine) has to be considered as a potential source of an inadequate functional behavior. Thus, the human error probability (HEP) is *per se* a vital value of interest [33].

The HEP is defined as the number of erroneously performed tasks of type i divided by the number of all tasks of type i. However, it is indeed difficult to calculate the HEP value beforehand

because both values required for the HEP formula are fuzzy. Nevertheless, the evaluation the operational experience opens the door to estimating the HEP values retrospectively.

In PSA models normally three types of personnel actions are distinguished:

Type A: Personnel action during proper operation of the system that has led to a hidden error (example: wrong position of a standby valve).
Type B: Personnel action that has led to an initiating event (example: opening a valve and therefore creating a small leak in a primary circuit).
Type C: Personnel actions after initiating event in order to cope with it (example: switching on the emergency core cooling system).

Obviously, Type C actions have to be subdivided further because actions in this plant phase can be planned or unplanned and can mitigate or not mitigate the real accident sequence.

The most common quantification procedure for HEPs follows the THERP method published in Allan Swain's handbook. It requires a task analysis based on tree logic and the utilization of the performance shaping factors considering the environmental conditions, the training status of the operator, and the time span available for fulfilling the task. The task tree logic considers not only the success and failure path but also recovery actions to correct a wrong action into a successful one.

A significant number of other models have been published and applied to PRAs. These advanced models are summed up as second generation models (*e.g.*, ATHENA, CREAM, MERMOS, *etc.*) and are characterized as "knowledge-based models", different to the first generation of models (*e.g.*, THERP, HCR, Slim-Mod, *etc.*), characterized as skill and rule-based models.

Human reliability assessment in general has many problems to solve. For instance, the errors of commission have been for many decades been known to be important in the course of severe accidents. However, only in the last few years' has significant progress been made to cope with this type of errors by the development of the knowledge-based models of the second generation. The quantification of soft issues, like managerial aspects within the NPPs, will be a great challenge for the HRA researchers in the next years.

71.2.6 Software Reliability

In this century there has been a great turn from the utilization of hard-wired control systems to digital systems controlled by software running on computers or embedded in specific processors. Unfortunately, this movement toward digital systems has had great impact on the PRA process. It is no longer plausible and is not supported by sound operational experience that the implemented and tested software will not fail and, therefore, the reliability (risk) impact related to other failure possibilities and causes can be neglected [25].

Indeed, all the safety related control systems in NPPs are highly redundant (*e.g.*, two out of four) and, therefore, the failure of a single digital electronic device does not create a loss of function. However, common inadequacies in software specifications can easily jeopardize this precautionary principle.

Software is always in communication with sensor signals, data packages transmitting on bus systems, the computer hardware itself, and the actions required for, *e.g.*, software flashing and software maintenance actions. Thus, the question is, how reliable is the software *under the conditions of these interactions and communications*? However, for reliability engineering it is not only an open question in terms of "go and no go" (success/failure); it is also a question of "what would go wrong" (unwanted).

These shortly illuminated interactions are well under discussion and in practice often controlled, limited, or eliminated by very specific hardware or software features. Nevertheless, the complexity of highly dynamic interaction of accurate and probably erroneous (*i.e.*, failure case) signals or software functions should trigger many more warnings that the given resources for reliability assessment of digital control systems are not sufficient. Moreover, the excuse "software reliability assessment is too complex" can no longer be accepted.

In this context it is important to remember that also on the lower system level for digital control

systems does the PRA process require an answer to the three main questions for PRAs in general:

- What can go wrong within the system?
- What are the adverse consequences?
- How likely are these adverse consequen-ces?

71.2.7 Uncertainties

Engineering knowledge, judgment, mathematical modeling, and mechanistic formulations are ingredients of the PRA process and finally the results. For many years it has been tradition among physicists and engineers to perform an error analysis of both the measurements and the computations. The errors under consideration were mainly due to small fluctuations around nominal values and to, *e.g.*, rounding processes in functional relationships [9],[34].

In the case of PRA it is not only a matter of small fluctuations and of rounding, but there is also a need to simplify the real world due to a lack of knowledge. An extended error analysis or more adequately an uncertainty analysis of PRA results is, therefore, essential.

The result from the uncertainty analysis is a quantitative statement how well the answer to the PRA question can be given. However, this answer can only be given by considering the various epistemic uncertainties involved. This type of uncertainty includes the relevance of phenomena, the adequacy of the numerous models applied within the PRA, the suitability of the hundreds of parameter values used in these models, and the accuracy of the great number of reliability characteristics.

For the purposes of uncertainty analysis the state of knowledge of epistemic uncertainties is expressed by subjective probability distributions. The complex functional relationship in a PRA model makes it impossible to obtain the aggregated subjective probability distribution analytically. It is, however, possible by application of the Monte Carlo simulation technique to generate numerically the epistemic uncertainties associated with the PRA results.

In contrast to the epistemic uncertainties one has to be aware that everything that contributes to the variability within the population of considered NPPs is aleatory uncertainty. The aleatory uncertainty is that addressed when the occurrence of undesired events or phenomena with the plant are modeled in random or stochastic manner. The quantification of aleatory uncertainties is the actual purpose of the PRA itself. The measure for aleatory uncertainty is the probability in its frequentistic interpretation. The measure of the epistemic uncertainty is also probability but in its subjective interpretation as a degree of belief.

It should be stressed that the quantification process of epistemic uncertainties does not only generate the range and distribution of the numerical PRA results but also the information on how significantly a given parameter or parameter cluster contributes. In other words, the sensitivity of the various parameters can be estimated.

Today's challenges in this field are the further development of effective calculation processes, a realistic subjective judgment of parameter uncertainties, the estimation of model uncertainties, and the use of large computer/processor clusters to run simulation trials of complex mechanistic codes.

71.2.8 Probability Aggregation

Probability aggregation throughout the entire probabilistic model (*i.e.*, the coupled event and fault trees) is an ambitious task. At the beginning of PRA work the computerized support was very limited. Thus, often a linking procedure was performed by hand for the various fault trees and the corresponding event trees [9],[34].

Nowadays, the commercial software packages used for PRAs (*e.g.*,: Saphire®, Cafta®, RiskSpectrum®, Relex®, Isograph®) are ready the handle a significant number of event and fault trees and to perform the linking procedure, based on some inputted overhead, automatically. Nevertheless, the huge number of basic events involved (*e.g.*, 5000–8000 for a Level I PRA) requires that the practitioners perform, after calculations, some tricky plausibility test mostly executed by checking the Boolean cut sets responsible for the various TOP events in fault trees or the unwanted end states in event trees.

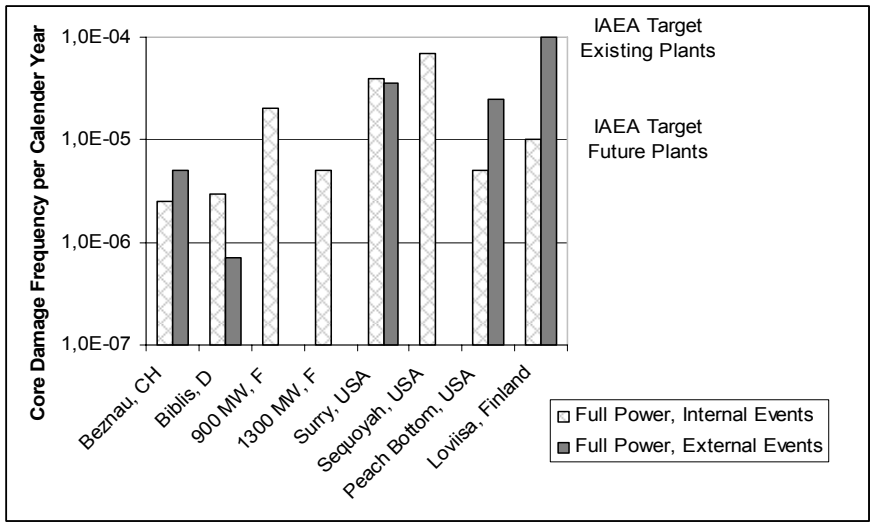

Figure 71.3. PRA Level I results in comparison for international NPPs [28]

In some cases if specific linkings and combinations of TOP events are of interest a combination of reliability software and an office spread sheet software may be a good choice.

The combinatorial explosion of different event sequences and end states in large PRA models forces a so-called binning procedure. This means the end states representing similar plant damage states (*e.g.,* loss of core cooling) are clustered together, and the resulting probability or frequency per plant year is summed up across this cluster.

Obviously, for a Level III PRA this probability aggregation is much more complex because the core melt model, the containment response, the environmental model, and the cause–consequence model for health effects come into the focus. The probability aggregation for these types of PSAs is normally performed by hand but is supported by computerized numerical procedures.

In Figure 71.3, typical results for Level I PRAs are shown. All the probabilities are aggregated to final results in form of frequencies *per* reactor year.

71.3 Today's Challenges

Existing analysis processes and approaches can never be perfect. State of knowledge is growing and PRA visionaries often create sophisticated ideas. Based on this one has to constantly look for useful improvements of the PRA methodology and the assessment process itself. In the following chapters three essential issues are picked up as main challenges for today's PRA practitioners and managers.

71.3.1 The Risk Management Process

As stated, risk is an inherent characteristic of all technical installations and processes. It has a dominant impact upon safe operation *and* economical effectiveness. It is, therefore, important that a satisfactory level of risk is achieved by an adequate risk management process [35– 42].

However, there is a worldwide discussion about the "satisfactory level" of risk and the question: "How safe is safe enough?" Nevertheless, for various industries in some countries [36, 37, 39] (or internationally) global risk goals have been established [43], [53].

To ensure that such a global risk level is achieved, realistic requirements must be set and an agreed risk management process should follow. This process must reflect continuous and evolutionary approaches to the achievement of safety and the management of all safety activities being an integral part of project activity, from the design phase throughout all phases of the life cycle of the entity.

At present, traditional engineering education teaches risk management only in a modest way. The plant engineer is trained to achieve the "function" of a product, an installation or a process. The safety engineer, on the other hand, must think about how this function can fail and, therefore, which safety measures are required and adequate to be installed for failure prevention and mitigation. To learn this way of thinking, we normally need "training on the job" and relevant publications such as lessons learned (*e.g.*, [64]). Only based on these conditions can safety engineers widen their know-how and knowledge base to keep pace with the ever more complex technical problems in NPPs.

A large volume of literature has been published related to "risk management" [36–42]. Financial risk, project risk, health risk, technical risk, and last but not least, gambling risk, have been evaluated and treated to a great extent. It is worth to mentioning that in the context of PRA the technical risk lies in the focus.

Considering advanced publications related to technical risk management one can observe that the ideal, classical, and prospective management process for *new* entities consists of four main steps:

- Risk goal setting.
- Apportionment of specific risk targets and transformation of these local risk targets into the considered entity.
- Proof of the compliance of the risk of the real entity with the goal settled.
- Controlling the risk of the real entity throughout the life cycle.

Obviously, much PRA work is performed related to *existing* entities, *e.g.*. the NPPs in operation, to assess the inherent risk. However, this retrospective process is not ideal for new NPPs.

Risk management should be a living mission at each technical entity. Therefore, it is continuously required to ask "what can go wrong?" and to adopt adequate safety measures to cope with the identified undesired events. This undertaking must be also in the interest of all the utilities to safeguard their investment.

In this context, the global term risk management should not be confused with specific project risk management (*i.e.*, investment costs and timescale risk). However, it should be noted that proper and timely application of risk management will also reduce the project risk for entities requiring a safety license prior to going into operation.

The risk management process can be subdivided into the following valuable documents and the respective managerial and technical activities required throughout the life cycle of an entity:

Document 1: The Global Risk Strategy.
Document 2: The Risk Management Program.
Document 3: The Risk Management Plan.

These three documents describe in the course of risk management the main goals, the required activities, and the results gained. They must be worked out by different parties within the establishment and can be characterized as documents followed by actions "starting from global aspects going towards detailed elements". (Remark: some Standards are calling Document 2 and Document 3 together "Program Plan" (*e.g.* [38].)

As it declares, Document 1 should be established and inaugurated by the top management of the establishment using all their competence and power. It can be generic, which means that the strategy would be binding for a given type (series) of entities. Document 2 should be established and implemented mainly by the project group for a given entity, and Document 3 should be established and the concurrent actions executed by the reliability and safety experts in the different working teams.

Document 1 must be available at least in the beginning of the life cycle (*e.g.*, the design phase); Documents 2 and 3 will be required over the life cycle, as it is dependent on the increasing information concerning the entity.

Thus, in other words, the three documents describe "what is why and how to do it" and are the results of the concurrent actions. In this sense, the documents demonstrate the qualification and the willingness of the establishment to be an organization of excellence related to the essential topic of "risk".

It must be concluded that such an ideal risk management process is really not existent within the nuclear technology and, therefore, it would be a great challenge for PRA practitioners, managers, and licensing authorities to steer developments resolving this vision.

71.3.2 Software Reliability

Conventionally, software, the related hardware, the sensors, the actuators, and the interconnection *via* a bus system are considered separately in safety assessments. This simplified approach does not model the real world adequately. Advanced insights of engineers and field experiences are pointing out that these elements should be considered as a "network" and that planned or unplanned interaction within this network should be studied.

However, such an undertaking would be an enormous step forward and can be seen as a new dimension of risk assessment. There is hope that sophisticated simulations on computer may illuminate the real world of digital control systems that is driven by software.

71.3.3 Test and Maintenance Induced Faults

It is common practice in reliability technology to perform various tests and maintenance work on real systems, thus achieving high confidence in reliability behavior throughout the life cycle. As a consequence, the reliability model for the estimation of system reliability should reflect the impact of these useful working procedures.

The classical hypothesis "as good as new after test and maintenance" is one of the related approaches to model system reliability analytically. When using this hypothesis, one has to be aware that more frequent tests and maintenance work (shorter time intervals) would improve, *e.g.*, for standby systems, the availability *per* demand, because recognized malfunctions would be immediately repaired. However, from field experience it is well known that tests and maintenance work can never be perfectly executed by the acting personnel. A given probability always exists that an additional and unforeseen fault be introduced into the system.

Thus, in other words, the "as good as new" hypothesis would not reflect the facts in the real world. Some modifications in all reliability calculation procedures would be the consequence. Therefore, it is a great challenge for PRA practitioners and managers to estimate the probability for test and maintenance induced faults based on specific field data acquisition. Some preliminary estimates for this type of introduced faults shows about a fraction of 20% of all the hidden faults.

71.4 Outlook

Risk is inherent in all the human undertakings and the man-made technological world. To assess it and to keep it under control is an essential task for sustainable welfare and successful industrial progress.

A new analytical tool based on engineering and operational experience named probabilistic risk/safety assessment has been under development for the last four decades. This methodology has found many applications and has reached a mature level of confidence, significantly expanding the insights gained by deterministic safety assessment [54]–[63]. It opens a window to see the real world of complex technologies not only in the case of perfect functioning but also in the case of malfunctions of man–machine in a given environment.

A PRA has been performed for most of the approximately 440 existing NPPs. Differences are given related to the extent (Level I, II, III) and the operational regimes considered (*e.g.*, full power, shut down stage). In so far there is a remarkable pool of PRA practitioners and related experience.

However, the ideal risk management process is largely missing for new NPPs. It should involve:

- risk goal setting,
- risk goal transformation into the plant under constriction,

- risk goal proof, and
- risk monitoring throughout the life cycle.

Obviously, this management process is interrelated with massive safety political and country specific questions, but the perception of the importance to close this significant break around the PRA process may steer fruitful developments.

It should be remembered that for various technologies, installations, or undertakings (*e.g.*, aviation, off-shore installations, ships, space modules, process plants, dangerous goods transport) national or international risk standards have been established for decision making in licensing procedures.

Software Reliability and Fault-tolerant Systems: An Overview and Perspectives

Hoang Pham

Rutgers University, USA

Abstract: This chapter outlines the basic concepts of software development process, reliability engineering, and data analysis. It also presents some of the existing NHPP software reliability models and their applications. Numerical examples are provided to illustrate the results. A generalized software reliability model considering environmental factors is presented and Sections 72.5 and 72.6 discuss briefly the software fault-tolerant concepts and software cost models, respectively.

72.1 Introduction

Today, almost everyone in the world is directly or indirectly affected by computer systems. Computers are used in diverse areas for various applications, including air traffic control, nuclear reactors, aircraft, real-time sensor networks, industrial process control, automotive mechanical and safety control, and hospital health care, affecting many millions of people. One application of computer systems to hospital health care is the monitoring of heart patients. In hospitals so equipped, sensors that detect electrical signals associated with heart activity are attached to the patient's heart area. The signals from these sensors are transmitted along wires to a computer programmed to analyze such data. If the incoming data indicate that the patient is doing well, the computer generates no output. If the data indicate the onset of serious conditions, the computer signals an alarm at the nursing station indicating which patient needs human care and the kind of help most apt to be useful.

As the functionality of computer operations becomes more essential and yet more complicated and critical applications increase in size and complexity, there is a great need for looking at ways to quantify and predict the reliability of computer systems in various complex operating environments. Faults, especially with logic, in software design thus become more subtle. Usually logic errors in the software are not hard to fix but diagnosing logic bugs is the most challenging for many reasons. The fault again is usually subtle. For example, a man wants to withdraw $50 at an automatic transfer machine (ATM) from a checking account held jointly with his wife. Almost simultaneously, at another machine, his wife also begins the deposit of $500. Both the husband's and the wife's ATM read the account balance of $100 from the memory at the bank's central computer. While the first ATM (husband's machine) subtracts the withdrawal, the second ATM adds the

deposit. Because withdrawals often take slightly longer to process than deposits, the wife's ATM records a new balance of $600 before her husband's transaction is complete. His ATM, obviously not knowing that the old balance has been changed and in fact increased, records a wrong balance of $50, instead of the new balance, which should be $550!

An error is a mental mistake made by the programmer or designer. A fault is the manifestation of that error in the code. A software failure is defined as the occurrence of an incorrect output as a result of an input value that is received with respect to the specification. Figure 72.1 demonstrates how a software fault triggered by a specific input leads to software failure.

In recent years, the cost of developing software and the penalty cost of software failure have become a major expense in the whole system [32]. Failure of the software may result in an unintended system state or course of action. A loss event could ensue in which property is damaged or destroyed, people are injured or killed, and/or monetary costs are incurred. A quantitative measure of loss is called the risk cost of failure [36]. In other words, risk cost is a quantitative measure of the severity of loss resulting from a software failure. A research study has shown that professional programmers average six software defects for every 1000 lines of code (LOC) written. At that rate, a typical commercial software application of 500,000 LOCs may contain about 3000 programming errors including memory-related errors, memory leaks, language-specific errors, extra compilation errors, standard library errors, *etc*.

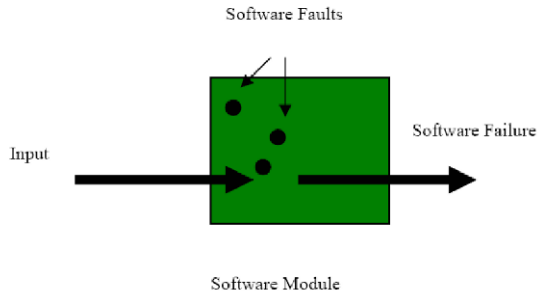

Figure 72.1. Relationship between software fault and software failure

As software projects become larger, the rate of software defects increases geometrically (see Figure 72.2). Table 72.1 shows the defect rates of several software applications *per* 100 LOC. Locating software faults is extremely difficult and costly. A study conducted by Microsoft showed that it takes about 12 programming hours to locate and correct a software defect. At this rate, it can take more than 24000 hours (or 11.4 man-years) to debug a program of 350000 LOC at a cost of over US$1 million [42].

Software errors have caused spectacular failures, some with dire consequences, such as the following examples. On 31 March 1986, a Mexicana Airlines Boeing 727 airliner crashed into a mountain because the software system did not correctly negotiate the mountain position. Between March and June 1986, the massive Therac-25 radiation therapy machines in Marietta, Georgia; Boston, Massachusetts; and Tyler, Texas overdosed cancer patients due to flaws in the computer program controlling the highly automated devices. On 26 June 1988, Air France's new A320 model, delivered just two days before, crashed into the trees at an air show near Mulhouse in France due to computer software failure while performing a low-level pass. Three passengers were killed.

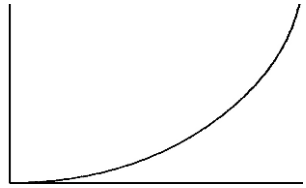

Figure 72.2. The rate of software defect changes

Table 72.1. Defect rates of several software applications

Application	Number of systems	Fault density (*per* 100 LOC)
Airborne	8	1.28
Strategic	18	0.66
Tactical	6	1.00
Process control	2	0.18
Production	9	1.30
Developmental	2	0.40

During the period 2–4 November 1988, a computer virus infected software at universities and defense research centers in the United States causing system failures. On 10 December 1990, Space Shuttle Columbia was forced to land early due to computer software problems. On 17 September 1991, a power outage at the AT&T switching facility in New York City interrupted service to 10 million telephone users for 9 hours. The problem was due to the deletion of three bits of code in a software upgrade and failure to test the software before its installation in the public network [48].

On 14 August 2003, a blackout that crippled most of the Northeast corridor of the United State and parts of Canada resulted from a software failure at First Energy Corporation, which may have contributed significantly to the outage. In 1992, the London Ambulance service switched to a voice and computer control system, which logged all its activities. However, when the traffic to the computer increased the software could not cope and slowed down; as a consequence it lost track of the ambulances. On 26 October 1992, the computer-aided dispatch system of the ambulance service in London, which handles more than 5000 requests daily in the transportation of patients in critical condition, failed after installation. This led to serious consequences for many critical patients.

A recent inquiry revealed that a software design error and insufficient software testing caused an explosion that ended the maiden flight of the European Space Agency's (ESA) Ariane 5 rocket, less than 40 seconds after lift-off on 4 June 1996. The problems occurred in the flight control system and were caused by a few lines of the Ada code containing three unprotected variables. The ESA estimates that corrective measures will amount to US$362 million [42].

Generally, software faults are more insidious and much more difficult to handle than physical defects. In theory, software can be error-free, and unlike hardware, does not degrade or wear out but deteriorates. The deterioration here, however, is not a function of time. Rather, it is a function of the results of changes made to the software during maintenance, through correcting latent defects, modifying the code to changing requirements and specifications, environments and applications, or improving software performance. All design faults are present from the time the software is installed on the computer. In principle, these faults could be removed completely, but in reality the goal of perfect software remains elusive [10]. Computer programs, which vary for fairly critical applications between hundreds and millions of lines of code, can make the wrong decision because the particular inputs that triggered the problem were not tested and corrected during the testing phase. Such inputs may even have been misunderstood or unanticipated by the designer who either correctly programmed the wrong interpretation or failed to identify the problem. These situations and other such events have made it apparent that we must determine the reliability of the software systems before putting them into operation.

72.2 The Software Development Process

As software becomes an increasingly important part of many different types of systems that perform complex and critical functions in many applications, such as military defense, nuclear reactors, *etc*., the risk and impacts of software-caused failures have increased dramatically. There is now general agreement on the need to increase software reliability by eliminating errors made during software development. Software is a collection of instructions or statements in a computer program. A program can be regarded as a function, mapping the input space to the output space, where the input space is the set of all input states, and the output space is the set of all output states. An input state can be defined as a combination of input variables or a typical transaction to the program. A software program is designed to perform specified functions. When the actual output deviates from the expected output, a failure occurs.

A software life cycle consists of five successive phases: analysis, design, coding, testing, and operation [42]. The *analysis phase* is the most important phase, the first step in the software development process and the foundation of building a successful software product. The

purpose of the analysis phase is to define the requirements and provide specifications for the subsequence phases and activities. The *design phase* is concerned with how to build the system to behave as described. The *coding phase* involves translating the design into code in a programming language. Coding can be decomposed into the following activities: identify reusable modules, code editing, code inspection, and final test plan. *The testing phase* is the verification and validation activity for the software product. Verification and validation (V&V) are the two ways to check if the design satisfies the user requirements. The *operation phase* is the final phase in the software life cycle. It involves the transfer of responsibility for the maintenance of the software from the developer to the user by installing the software product and it becomes the user's responsibility to establish a program to control and manage the software.

There are two commonly types of failure data: time-domain data and interval-domain data. Some existing software reliability models can handle both types of data. The time-domain data is characterized by recording the individual times at which the failure occurred. For example, in the real-time control system data [24], there are totally 136 faults reported and the time-between failures (TBF) in seconds are listed in Table 72.2. The interval-domain data is characterized by counting the number of failures occurring during a fixed period. The time-domain data always provides better accuracy in the parameter estimates with current existing software reliability models, but involves more data collection efforts than the interval domain approach.

72.3 Software Reliability Modeling

Since computers are being used increasingly to monitor and control both safety-critical and civilian systems, there is a great demand for high-quality software products. Reliability is a primary concern for both software developers and software users.

Research activities in software reliability engineering have been conducted, and a number of NHPP software reliability growth models [11], [26],[36],[37],[39],[40],[41],[45],[46],[47],[57], [58],[65] have been developed to assess the reliability of software. Software reliability models based on the NHPP have been quite successful tools in practical software reliability engineering. In this paper, we only discuss software reliability models based on NHPP. These models consider the debugging process as a counting process characterized by its mean value function. Software reliability, can be estimated once the mean value function is determined. Model parameters are usually estimated using either the maximum likelihood method or least squared estimate.

The following acronyms and notation will be used throughout the paper.

Acronyms

AIC	the Akaike information criterion
MLE	maximum likelihood estimate
NHPP	non-homogeneous Poisson process
SRGM	software reliability growth model
SSE	sum of squared errors

Notation

$a(t)$	time dependent fault content function
$b(t)$	time dependent fault detection-rate function *per* fault *per* unit time
$m(t)$	expected number of error detected by time t ("mean value function")
$R(x/t)$	software reliability function, *i.e.*, the conditional probability of no failure occurring during $(t, t+x)$ given that the last failure occurred at time t
^	estimates using the MLE method

72.3.1 A Generalized NHPP Model

Many existing NHPP models assume that failure intensity is proportional to the residual fault content. A general class of NHPP SRGMs can be obtained by solving the following differential equation [40]:

$$\frac{dm(t)}{dt} = b(t)[(a(t) - m(t)].$$

The general solution of the above differential equation is given by

Table 72.2. The real-time control system data for time domain approach

$$m(t) = e^{-B(t)}\left[m_0 + \int_{t_0}^{t} a(\tau)b(\tau)e^{B(\tau)}d\tau\right],$$

where $B(t) = \int_{t_0}^{t} b(\tau)d\tau$ and $m(t_0) = m_0$ is the marginal condition of the above differential equation with t_0 representing the starting time of the debugging process. The reliability function based on the NHPP is given by:

$$R(x/t) = e^{-\left[m(t+x)-m(t)\right]}.$$

Many existing NHPP models can be considered as a special case of the above general model.

An increasing function *a(t)* implies an increasing total number of faults (note that this includes those already detected and removed and those inserted during the debugging process) and reflects imperfect debugging. An increasing *b(t)* implies an increasing fault detection rate, which could be either attributed to a learning curve phenomenon, or to software process fluctuations, or a combination of both. Different *a(t)* and *b(t)* functions also reflect different assumptions of the software testing processes. A summary of the most NHPP existing models is presented in Table 72.3.

Table 72.3. Summary of the mean value functions [40]

Model name	Model type	m(t)	Comments
Goel–Okumoto (G-O)	Concave	$m(t) = a(1 - e^{-bt})$ $a(t) = a, b(t) = b$	Also called the exponential model
Delayed S-shaped	S-shaped	$m(t) = a(1 - (1 + bt)e^{-bt})$	Modification of the G-O model to make it S-shaped
Inflection S-shaped SRGM	S-shaped	$m(t) = \frac{a(1 - e^{-bt})}{1 + \beta e^{-bt}}$ $a(t) = a, b(t) = \frac{b}{1 + \beta e^{-bt}}$	Solves a technical condition with the G-O model. Becomes the same as G-O if $\beta = 0$
Yamada Exponential	S-shaped	$m(t) = a(1 - e^{-r\alpha(1 - e^{(-\beta t)})})$ $a(t) = a, b(t) = r\alpha\beta e^{-\beta t}$	Attempt to account for testing-effort
Yamada Rayleigh	S-shaped	$m(t) = a(1 - e^{-r\alpha(1 - e^{(-\beta t^2/2)})})$ $a(t) = a, b(t) = r\alpha\beta t e^{-\beta t^2/2}$	Attempt to account for testing-effort
Yamada exponential imperfect debugging model (Y-ExpI)	Concave	$m(t) = \frac{ab}{\alpha + b}(e^{\alpha t} - e^{-bt})$ $a(t) = ae^{\alpha t}, b(t) = b$	Assume exponential fault content function and constant fault detection rate
Yamada linear imperfect debugging model (Y-LinI)	Concave	$m(t) = a[1 - e^{-bt}][1 - \frac{\alpha}{b}] + \alpha a t$ $a(t) = a(1 + \alpha t), b(t) = b$	Assume constant introduction rate α and the fault detection rate
Pham–Nordmann–Zhang (P-N-Z) Model	S-shaped and concave	$m(t) = \frac{a[1 - e^{-bt}][1 - \frac{\alpha}{b}] + \alpha a t}{1 + \beta e^{-bt}}$ $a(t) = a(1 + \alpha t), b(t) = \frac{b}{1 + \beta e^{-bt}}$	Assume introduction rate is a linear function of testing time, and the fault detection rate function is non-decreasing with an inflexion S-shaped model.
Pham–Zhang (P-Z) Model	S-shaped and concave	$m(t) = \frac{1}{(1 + \beta e^{-bt})}[(c + a)(1 - e^{-bt}) - \frac{a}{b - \alpha}(e^{-\alpha t} - e^{-bt})]$ $a(t) = c + a(1 - e^{-\alpha t}), b(t) = \frac{b}{1 + \beta e^{-bt}}$	Assume introduction rate is exponential function of the testing time, and the fault detection rate is non-decreasing with an inflexion S-shaped model

72.3.2 Application 1: The Real-time Control System

We perform the model analysis using the real-time control system data given in Table 72.2. The first 122 data points are used for the goodness of fit test and the remaining data are used for the predictive power test. The results for fit and prediction are listed in Table 72.4. Although software reliability models based on the NHPP have been quite successful tools in practical software reliability engineering [42], there is a need to validate their validity with respect to other applications such as communications, manufacturing, medical monitoring, and defense systems.

72.4 Generalized Models with Environmental Factors

Most existing models, however, require considerable numbers of failure data in order to obtain an accurate reliability prediction. Information concerning the development of the software product, the method of failure detection, environmental factors, *etc*., however, are ignored to almost all the existing models. In order to develop a useful software reliability model and to make sound judgments when using the model, one needs to have an in-depth understanding of how software is produced; how errors are introduced, how software is tested, how errors occur, types of errors and environmental factors can help us in justifying the reasonableness of the assumptions, the usefulness of the model, and the applicability of the model under a given user environment [48]. In other words, these models would be valuable to software developers, users, and practitioners if they are capable of using information about the software development process, incorporating the environmental factors, and are able to give greater confidence in estimates based on small numbers of failure data.

This section discusses a generalized software reliability model with environmental factors.

Table 72.4. Parameter estimation and model comparison

Model name	SSE (fit)	SSE(Predict)	AIC	MLEs
G -O model	7615.1	704.82	426.05	$\hat{a} = \mathbf{125}$, $\hat{b} = \mathbf{0.00006}$
Delayed S-shaped	51729.23	257.67	546	$\hat{a} = \mathbf{140}$, $\hat{b} = \mathbf{0.00007}$
Inflexion S-shaped	15878.6	203.23	436.8	$\hat{a} = \mathbf{135.5}, \hat{b} = \mathbf{0.00007}, \hat{\beta} = \mathbf{1.2}$
Yamada exponential	6571.55	332.99	421.18	$\hat{a} = \mathbf{130}, \hat{\alpha} = \mathbf{10.5}, \hat{\beta} = \mathbf{5.4 \times 10^{-6}}$
Yamada Rayleigh	51759.23	258.45	548	$\hat{a} = \mathbf{130}, \hat{\alpha} = \mathbf{5 \times 10^{-10}}, \hat{\beta} = \mathbf{6.035}$
Y-ExpI model	5719.2	327.99	450	$\hat{a} = \mathbf{120}$, $\hat{b} = \mathbf{0.00006}$, $\hat{\alpha} = \mathbf{1 \times 10^{-5}}$
Y-LinI model	6819.83	482.7	416	$\hat{a} = \mathbf{120.3}, \hat{b} = \mathbf{0.00005}, \hat{\alpha} = \mathbf{3 \times 10^{-5}}$
P-N-Z Model	5755.93	106.81	415	$\hat{a} = \mathbf{121}, \hat{b} = \mathbf{0.00005}, \hat{\alpha} = \mathbf{2.5 \times 10^{-6}}, \hat{\beta} = \mathbf{0.002}$
P-Z model	14233.88	85.36	416	$\hat{a} = \mathbf{20}, \hat{b} = \mathbf{0.00007}, \hat{\alpha} = \mathbf{1.0 \times 10^{-5}}, \hat{\beta} = \mathbf{1.922}$ $\hat{c} = \mathbf{125}$

Additional Notation

$\tilde{z}$	Vector of environmental factors
$\tilde{\beta}$	Coefficient vector of environmental factors
$\Phi(\tilde{\beta}\ \tilde{z})$	Function of environmental factors
$\lambda_0(t)$	Failure intensity rate function without environmental factors
$\lambda(t,\tilde{z})$	Failure intensity rate function with environmental factors
$m_0(t)$	Mean value function without environmental factors
$m(t,\tilde{z})$	Mean value function with environmental factors
$R(x/t,\tilde{z})$	Reliability function with environmental factors

The proportional hazard model (PHM), which was first proposed in [7], has been successfully utilized to incorporate environmental factors in survival data analysis in medical field and in hardware system reliability area.

The basic assumption for PHM is that the hazard rates of any two items associated with the settings of environmental factors, say z_1 and z_2, respectively, will be proportional to each other. The environmental factors are also known as covariates in PHM. When the PHM applied to the non-homogeneous Poisson process, it becomes the proportional intensity model (PIM).

A general fault intensity rate function incorporating the environmental factors based on PIM can be constructed using the following assumptions:

(a). The new fault intensity rate function consists of two components: the fault intensity rate functions without environmental factors, $\lambda_0(t)$, and the environmental factor function, $\Phi(\tilde{\beta}\ \tilde{z})$.

(b). The fault intensity rate function $\lambda_0(t)$ and the function of the environmental factors are independent. The function $\lambda_0(t)$ is also called the baseline intensity function.

Let us assume that the fault intensity function $\lambda(t,\tilde{z})$ is given in the form:

$$\lambda(t,\tilde{z}) = \lambda_0(t)\cdot\Phi(\tilde{\beta}\ \tilde{z}),$$

where

$$\Phi(\tilde{\beta}\ \tilde{z}) = \exp(\beta_0 + \beta_1 z_1 + \beta_2 z_2 + \ldots).$$

The mean value function and reliability function with environmental factors can be obtained, respectively:

$$m(t,\tilde{z}) = \Phi(\tilde{\beta}\ \tilde{z}) m_0(t)$$

and

$$R(x/t,\tilde{z}) = [R_0(x/t)]^{\Phi(\tilde{\beta}\ \tilde{z})}$$

A widely used method, which is known as the partial likelihood estimate method, can be used to estimate the unknown parameters of the software reliability model with environmental factors. The partial likelihood method estimates the coefficients of covariates, the β_I's, separately from the parameters in the baseline intensity function. The likelihood function of the partial likelihood method is given by [7]:

$$L(\beta) = \prod_i \frac{\exp(\beta z_i)}{[\sum_{m\in R}\exp(\beta z_m)]^{d_i}},$$

where d_i represents the tie failure times.

72.4.1 Application 2: The Real-time Monitor Systems

In this section, we illustrate the software reliability model with environmental factors based on the PIM method using the software failure data collected from the real-time monitor systems [55]. The software consists of about 200 modules and each module has, on average, 1000 lines of a high-level language like FORTRAN. Total 481 software faults were detected during 111-day testing period. Both the information of testing team size and the software failure data are recorded.

The only environmental factor available in this application is the testing team size. Team size is one of the most useful measures in the software development process. It has close a relationship with the testing effort, testing efficiency and the development management issues. From the correlation analysis of the 32 environmental factors [65], team size is the only factor correlated to the

program complexity, which is the number one significant factor according to our environmental factor study. Intuitively, the more complex the software, the larger team is required. Since the testing team size ranges from 1 to 8, we first categorize the factor of team size into two levels. Let z_1 denote the factor of team size as follows:

$$z_1 = \begin{cases} 0 & \text{team size ranges from 1-4} \\ 1 & \text{team size ranges from 5-8} \end{cases}$$

After carefully examining the failure data, we find that after day 61, the software turns stable and the failures occur with a much slower frequency. Therefore, we use the first 61 data points for testing the goodness-of-fit and estimating the parameters, and use the remaining 50 data points (from day 62 to day 111) as real data for examining the predictive power of software reliability models.

In this application, we use the P-Z model listed in Table 72.3 as the baseline mean value function, that is,

$$m_0(t) = \frac{1}{(1+\beta\, e^{-bt})}[(c+a)(1-e^{-bt}) - \frac{ab}{b-\alpha}(e^{-\alpha t} - e^{-bt})]$$

and the corresponding baseline intensity function can be expressed as follows:

$$\lambda_0(t) = \frac{1}{(1+\beta\, e^{-bt})}[(c+a)(1-e^{-bt}) - \frac{ab}{b-\alpha}(e^{-\alpha t} - e^{-bt})] + \frac{-\beta b e^{-bt}}{(1+\beta e^{-bt})^2}[(c+a)(1-e^{-bt}) - \frac{ab(e^{-\alpha t} - e^{-bt})}{b-\alpha}]$$

Therefore, the intensity function with environmental factor is given by [62]:

$$\lambda(t) = \lambda_0(t) \cdot e^{\beta_1 z_1} = \left\{ \begin{array}{l} \frac{1}{(1+\beta\, e^{-bt})}[(c+a)(1-e^{-bt}) - \frac{ab}{b-\alpha}(e^{-\alpha t} - e^{-bt})] + \\ \frac{-\beta b e^{-bt}}{(1+\beta e^{-bt})^2}[(c+a)(1-e^{-bt}) - \frac{ab(e^{-\alpha t} - e^{-bt})}{b-\alpha}] \end{array} \right\} e^{\beta_1 z_1}$$

The estimate of β_1 using partial likelihood estimate method is $\hat{\beta}_1 = 0.0246$ which indicates that this factor is significant to consider. The estimates of parameters in the baseline failure intensity function above are as follows:

$\hat{a} = 40.0, \hat{b} = 0.09, \hat{\beta} = 8.0, \hat{\alpha} = 0.015, \hat{c} = 450$

The results of several existing NHPP models are also listed in Table 72.5.

The results show that incorporating the factor of team size into the P-Z model that explains the fault detection better and thus enhances the predictive power of this model. Further research is needed to incorporate application complexity, test effectiveness, test suite diversity, test coverage, code reused, and real application operational environments into the NHPP software reliability models and into the software reliability model in general [48].

72.5 Fault-tolerant Software Systems

Fault-tolerance has become one of the major concerns of computer designers. It is important to provide high reliability to critical applications such as aircraft controller and nuclear reactor controller software systems. No matter how thorough the testing, debugging, modularization, and verification of software are, design bugs still plague the software. After reaching a certain level of software refinement, any effort to increase the reliability, even by a small margin, will increase exponential cost. Over the last three decades, there has been considerable research in the area of fault-tolerant software.

Fault-tolerant software has been considered for use in a number of critical areas of application. For example, in traffic control systems, the computer aided traffic control system (COMTRAC) [20] is a fault-tolerant computer system designed to control the Japanese railways. It consists of three symmetrically interconnected computers. Two computers are synchronized at the program task level while the third acts as an active-standby. Each computer can be in one of the following states: on-line control, standby, or offline. The COMTRAC software has a symmetric configuration. The configuration system contains the configuration control program and the dual monitor system contains the state control program. When one of the computers under dual operation has a fault, the state control program switches the system to single operation and reports the completion of the system switching to the configuration control program. The configuration control program commands the state control program to switchover to dual operation with the standby computer. The latter program then executes the system switchover, transferring

Table 72.5. Model evaluation

Model name	***m*(*t*)**	**SSE(Prediction)**	**AIC**
G-O model	$m(t) = a(1 - e^{-bt}), a(t) = a, b(t) = b$	1052528	978.14
Delayed S-shaped	$m(t) = a(1 - (1 + bt)e^{-bt})$ $a(t) = a, b(t) = \frac{b^2 t}{1 + bt}$	83929.3	983.90
Inflexion S-shaped	$m(t) = \frac{a(1 - e^{-bt})}{1 + \beta e^{-bt}}, a(t) = a, b(t) = \frac{b}{1 + \beta e^{-bt}}$	1051714.7	980.14
Yamada Exponential	$m(t) = a(1 - e^{-r\alpha(1 - e^{(-\beta t)})}), a(t) = a$ $b(t) = r\alpha\beta e^{-\beta t}$	1085650.8	979.88
Yamada Rayleigh	$m(t) = a(1 - e^{-r\alpha(1 - e^{(-\beta t^2/2)})}), a(t) = a$ $b(t) = r\alpha\beta t e^{-\beta t^2/2}$	86472.3	967.92
Y-ExpI model	$m(t) = \frac{ab}{\alpha + b}(e^{\alpha t} - e^{-bt}), a(t) = ae^{\alpha t},$ $b(t) = b$	791941	981.44
Y-LinI model	$m(t) = a[1 - e^{-bt}][1 - \frac{\alpha}{b}] + \alpha a t,$ $a(t) = a(1 + \alpha t), b(t) = b$	238324	984.62
P-N-Z model	$m(t) = \frac{a}{1 + \beta e^{-bt}}[(1 - e^{-bt})(1 - \frac{\alpha}{b}) + \alpha t]$ $a(t) = a(1 + \alpha t), b(t) = \frac{b}{1 + \beta e^{-bt}}$	94112.2	965.37
P-Z model	$m(t) = \frac{1}{(1 + \beta e^{-bt})}[(c + a)(1 - e^{-bt}) - \frac{ab}{b - \alpha}(e^{-\alpha t} - e^{-bt})]$ $a(t) = c + a(1 - e^{-\alpha t}), b(t) = \frac{b}{1 + \beta e^{-bt}}$	86180.8	960.68
Environmental Factor model	$m(t) = \frac{1}{(1 + \beta e^{-bt})}[(c + a)(1 - e^{-bt}) - \frac{ab}{b - \alpha}(e^{-\alpha t} - e^{-bt})]e^{\beta_1 z_1}$ $a(t) = c + a(1 - e^{-\alpha t}), c(t) = 1 - \frac{(1 + \beta)}{(e^{bt} + \beta)}$	560.82	890.68

control to the configuration control program, which judges the accuracy of the report and indicates its own state to the other computers. COMTRAC shows that it failed seven times during a three-year period – once due to hardware failure, five times due to software failure, and once for unknown causes.

Software fault-tolerance is achieved through special programming techniques that enable the software to detect and recover from failure incidents. This section discusses a basic concept for fault-tolerant software techniques and some advanced techniques including self-checking systems.

Fault-tolerant software assures system reliability by using protective redundancy at the software level. There are two basic techniques for obtaining fault-tolerant software:

- The RB scheme
- NVP

Both schemes are based on software redundancy assuming that the events of coincidental software failures are rare.

72.5.1 The Recovery Block Scheme

The recovery block scheme, proposed by Randell [49], consists of three elements: primary module, acceptance tests, and alternate modules for a given task. The simplest scheme of the recovery block is as follows:

Ensure T
By P
Else by Q_1
Else by Q_2
.
.
.
Else by Q_{n-1}
Else Error

where T is an acceptance test condition that is expected to be met by successful execution of either the primary module P or the alternate modules $Q_1, Q_2, \ldots, Q_{n-1}$. The process begins when the output of the primary module is tested for acceptability. If the acceptance test determines that the output of the primary module is not acceptable, it recovers or rolls back the state of the system before the primary module is executed. It allows the second module Q_1, to execute. The acceptance test is repeated to check the successful execution of module Q_1. If it fails, then module Q_2 is executed, *etc*. The alternate modules are identified by the keywords "else by" When all alternate modules are exhausted, the recovery block itself is considered to have failed, and the final keywords "else error" declares the fact. In other words, when all modules execute and none produce acceptable outputs, then the system falls.

In a recovery block, a programming function is realized by n alternative programs, $P_1, P_2 \ldots, P_n$. The computational result generated by each alternative program is checked by an acceptance test, T. If the result is rejected, another alternative program is then executed. The program will be repeated until an acceptable result is generated by one of the n alternatives or until all the alternative programs fail. The probability of failure of the RB scheme, P_{rb}, is as follows [48]:

$$P_{rb} = \prod_{i=1}^{n}\left(e_i + t_{2i}\right) + \sum_{i=1}^{n} t_{1i}\ \mathrm{e_i}\left(\prod_{j=1}^{i-1}\left(e_j + t_{2j}\right)\right),$$

where

e_i = probability of failure for version P_i

t_{1i} = probability that acceptance test i judges an incorrect result as correct

t_{2i} = probability that acceptance test i judges a correct result as incorrect.

72.5.2 *N*-version Programming

The NVP was proposed by [6] for providing fault-tolerance in software. In concept, the NVP scheme is similar to the *N*-modular redundancy scheme used to provide tolerance against hardware faults [20]. The NVP is defined as the independent generation of $N \geq 2$ functionally equivalent programs, called *versions,* from the same initial specification.

Consider an NVP scheme consists of n programs and a voting mechanism, V. As opposed to the RB approach, all n alternative programs are usually executed simultaneously and their results are sent to a decision mechanism which selects the final result. The decision mechanism is normally a voter when there are more than two versions (or,

more than *k* versions, in general), and it is a comparator when there are only two versions *(k* versions). The syntactic structure of NVP is as follows:

seq
par
P_1 (version 1)
P_2 (version 2)
.
.
.
P_n (version n)
decision V

Assume that a correct result is expected where there are at least two correct results. The probability of failure of the NVP scheme, P_n, can be expressed as

$$P_{nv} = \prod_{i=1}^{n} e_i + \prod_{i=1}^{n} (1-e_i) e_i^{-1} \prod_{j=1}^{n} e_j + d \,.$$

The main difference between the recovery block scheme and the *N*-version programming is that the modules are executed sequentially in the former. The recovery block generally is not applicable to critical systems where real-time response is of great concern.

Another scheme that adopts intermediate voting is the *N*-program, self-checking scheme [59] where each version is subject to an acceptance test or checking by comparison. When $N = 2$, it is a two-version, self-checking scheme or self-checking duplex scheme. Whenever a particular version raises an exception, the correct result is obtained from the remaining versions and execution is continued. This method is similar to the CER approach, with the only difference being the on-line detection in the former by an acceptance test rather than a comparison.

72.6 Cost Modeling

It is important to determine when to stop testing based on the reliability and cost assessment. Several software cost models and optimal release policies have been studied in the past two decades. [28] discussed a simple cost model addressing linear developing cost during testing and operational period. [27] also discussed the optimum software-release time problem with a fault-detection phenomenon during operation. [22] discussed optimal software release time with consideration of a given cost budget. [8]studied the stop-testing problem for large software systems with changing code using graphical methods. They reported the details of a real time trial of a large software system that had a substantial amount of code added during testing. [36]developed a cost model with an imperfect debugging and random life cycle as well as a penalty cost to determine the optimal release policies for a software system. [39] developed the expected total net gain in reliability of the software development process, as the economical net gain in software reliability that exceeds the expected total cost of the software development, that uses to determine the optimal software release time which maximizes the expected total gain of the software system. [41] presented a generalized cost model addressing the fault removal cost, warranty cost and software risk cost due to software failures for the first time. Such model is given by:

$$E(T) = C_0 + C_1 T^{\alpha} + C_2 m(T)\mu_y + C_3 \mu_w [m(T+T_w) - m(T)] + C_R [1 - R(x/T)]$$

where

C_0	set-up cost for software testing
C_1	software test cost *per* unit time
C_2	cost of removing each fault *per* unit time during testing
C_3	cost to remove an fault detected during warranty period
CR	loss due to software failure
E(T)	expected total cost of a software system at time T
μ_y	expected time to remove a fault during the testing period
μ_w	expected time to remove a fault during the warranty period.

The detailed results to obtain the optimal software release time that minimizes the expected total cost can be obtained in [41].

72.6.1 The Gain Model with Random Field Environments

[53] recently developed a software gain model under random field environment [47] with consideration of not only time to remove faults during in-house testing, cost of removing faults

during beta testing, risk cost due to software failure, but also the benefits from reliable executions of the software during both beta testing and field operation. This model addresses both beta testing and operation phases in the software systems. During beta testing, not only can software faults still be removed from the software after failures occur, but they are also likely to be conducted in an environment that is the same as (or close to) the end-user environment. Note that the previous model in this section considers both the warranty cost and the penalty cost after releasing the software, which are overlapped with each other. The model in [53] is indeed slightly different, it does not consider a warranty cost, but instead considers a similar concept — the cost associated with the beta testing that is conducted in the field environment. The beta testing cost and the penalty cost after the software is released are not overlapped with each other. Details can be obtained in [54].

72.6.2 Other Cost Models

[43] presented a software cost model based on the quasi renewal processes. If the inter-arrival time represents the error-free time (time between errors), a quasi renewal process can be used to model reliability growth for software. For example, suppose that all faults of the software have the same chance of being detected. If the inter-arrival times of a quasi renewal process represent the error-free times of the software, the expected cumulative number of software faults in [0, t] can be described by the renewal function $M(t)$ with parameter $\alpha > 1$. Let $\overline{M}(t)$ be the number of remaining software faults at time t. It follows that $\overline{M}(t) = M(\tau) - M(t)$, where $M(\tau)$ is the number of faults which can be detected through a long testing time τ, relative to t.

Additional Notation

c_1	The cost of fixing a fault during testing phase
c_2	The cost of fixing a fault during operation phase
c_3	The cost of testing *per* unit time
T	The software release time
T_d	The scheduled delivery time
$g(t)$	The probability density function of the life-cycle length ($t > 0$)

Recovery block	Laprie (1990); Pham (1989); Randell (1975)
Other fault tolerant techniques	Eckhardt (1985); Hua (1986); Kim (1989); Pham (1991b, 1992); Tai (1993); Teng (2003)

$c_p(t)$ A penalty cost for a delay of delivering software

M(t) Number of faults which can be detected through a period of testing time t.

The expected total software life-cycle cost can be defined as follows:

$$C(T) = c_3 T + c_1 M(T) + \int_T^\infty c_2 [M(t) - M(T)] g(t) dt + I(T - T_d) c_p (T - T_d)$$

where $I(t)$ is an indicator function, that is,

$$I(t) = \begin{cases} 1 & \text{if } t \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

$M(t)$ and Var[$N(t)$] contain some unknown parameters. Those unknown parameters can be obtained by using the method of MLE or least squares methods. Detailed optimal release policies and findings can be found in [43].

The benefits of using the above cost models are that they provide: (1) assurance that the software has achieved safety goals, and (2) a means of rationalizing when to stop testing the software. Further research is worth to look at what the risk cost due to the software failures after release with a specified reliability level is. And how should marketing efforts – including advertising, public relations, trade-show participation, direct mail, and related initiatives – be allocated to support the release of a new software product effectively?

A brief, but not exhaustive, list of references on software reliability models, cost models and fault-tolerant systems discussed in this chapter is given in Table 72.6 for a quick reference to readers.

Application of the Lognormal Distribution to Software Reliability Engineering

Swapna S. Gokhale[1] and Robert E. Mullen[2]

[1]University of Connecticut, Storrs, CT, 06269, USA
[2]New England Development Centre, Cisco Systems, Inc., Boxborough, MA, 01719, USA

Abstract: The theoretical foundations underlying the lognormal distribution suggest that it can be applied to important problems in software reliability engineering. Further, an overwhelming amount of evidence has emerged to confirm the lognormal hypothesis. In this chapter we provide an overview of the lognormal distribution and its transformations. We then summarize the previous evidence, place the most recent evidence in context, discuss the set of issues to which it has been successfully applied, and call attention to the unified perspective the lognormal affords. Finally, we outline potential applications of the lognormal and suggest enabling research.

73.1 Introduction

Reliable operation is required of many engineering systems which offer essential services. As software systems continue to assume increasing responsibility for providing these critical services, they will also be expected to meet such stringent reliability expectations.

In most engineering domains, a systematic, quantitative system reliability analysis is often based on mathematical models of a system. For most systems, these mathematical models are derived from a few underlying physical processes. Similar to other engineering disciplines, software reliability analysis is based on stochastic models, commonly known as software reliability growth models [1] [2]. A striking difference between software reliability engineering and other engineering disciplines, however, is that the mathematical models used in other disciplines are grounded in the physical and observable structures, properties, and behavior of the systems, whereas most of the software reliability models do not connect mathematics to observable constructs.

In this chapter we demonstrate that several observable properties of software systems are in fact related, being grounded in the conditional nature of software execution. This leads to the emergence of a lognormal distribution of rates of events in software systems. These include failure rates of defects and execution rates of code elements. We discuss how the lognormal growth model can be obtained from the distribution of the first occurrence times of defects and apply it to reliability growth. The application of the lognormal growth model to describe code coverage growth as a function of testing is also described. We extend

the lognormal further and describe the derivation and application of the discrete lognormal model for the distribution of occurrence counts of defects. The chapter concludes by identifying opportunities for further research and wider application of the lognormal.

73.2 Overview of the Lognormal

The lognormal distribution is well known in many fields including ecology, economics, and risk analysis [3]. It is used in hardware reliability, though less than the Weibull [4]. It arises in a natural way when the variant's value is determined by the multiplicative effect of many random factors, just as the normal distribution arises as a consequence of the additive effect of many random factors. Johnson, Kotz and Balakrishnan [5] provide an introduction to the lognormal distribution and the ways it can be generated.

Theorems about the conditions under which products of random variables asymptotically approach a lognormal distribution are restatements of theorems about the conditions under which sums of random variables asymptotically approach a normal distribution. Products are treated as exponentiations of sums of logarithms. If the logarithms of the factors meet the conditions that make the distribution of their sum normal, then the product of the random variables by definition follows a lognormal distribution. Two forms of the central limit theorem (CLT) are presented in Aitchison and Brown's monograph [6] on the lognormal. Each states conditions under which a product of random variables $\prod_{j=1}^{n} X_j$ is asymptotically lognormal as L($n\cdot\mu$, $n\cdot\sigma^2$). The Lindeberg–Levy form of the CLT requires that all the X_j be from the same distribution, but the Lyapunov form removes that condition and adds a condition on the expectation of the third moment of the X_j. Petrov [7] provides additional theorems in which the variables are not necessarily identically distributed. Loeve [8] establishes alternatives to the assumption of independence. Patel and Read [9] outline additional extensions. Feller [10] shows the number of factors, n, need not be constant but can be an independent Poisson variable. This is important because software conditionals may be nested at many different levels. Figure 73.1 illustrates that in a tree which is created by 10,000 branchings of randomly selected leaf nodes, the number of leaves at each level approaches a Poisson distribution.

To summarize, the key assumptions which lead to the lognormal distribution are the multiplicative effect of many relatively independent random factors, with no one factor effectively dominating the others and each being from the same distribution or having uniformly small moments.

73.3 Why Are Software Event Rates Lognormal?

In this section we illustrate the wide variety of ways analysts routinely and successfully model software by making the same assumptions that lead to a lognormal distribution. At the typical level of detail to which analysts analyze software systems we find event rates being determined by multiplicative processes, and that the factors are sufficiently numerous and independent that their product approaches the lognormal. Furthermore, we suggest that refining the following analyses to a greater level of detail would merely increase the number of factors. In real systems the number of factors is not infinite but so large as to make the lognormal distribution an adequate approximation.

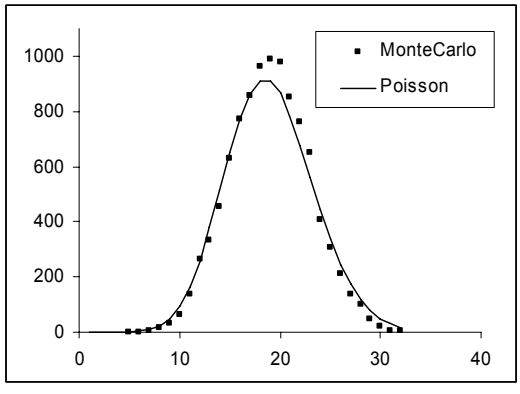

Figure 73.1. Example of a Poisson distribution of leaf depths

The assumption of independence is the most questionable, yet we find that assumption being used successfully in the following examples. It may not be fully satisfying that there are forms of the central limit theorem that do not require independence since those theorems make other even less familiar assumptions. Intuitively, if the variance of the problematic factors is overwhelmed by the total variance, any deviation from the lognormal will be difficult to detect.

73.3.1 Graphical Operational Profile

Operational profiles of customer usage [11] [12] were approved as a best current practice at AT&T. In the *graphical* or *implicit* operational profile method an event is characterized by a path through a network of operational possibilities. Specifying a set of "key input variables" is equivalent to specifying a path through the network. This method assumes that the occurrence probabilities of the key input variables are independent of each other (at least approximately so) [12]. Occurrence probabilities for each path are computed by multiplying the probabilities of those levels of key input variables corresponding to the path.

Using a call tree example, both papers [11] [12] show clearly how the network of conditioned probabilities is constructed. Figure 73.2 presents a partial depiction of a user event tree. There is a .35 chance of a call being an internal incoming call; conditioned on that, there is a .30 chance it is generated by standard dialing, and a .70 chance it is generated by abbreviated dialing; conditioned on it being generated by abbreviated dialing, there is a .10 chance of busy-no-answer, a .30 chance of ring-no-answer, and a .60 chance of being answered; conditioned on the call being answered, there is a .80 chance of talking, a .10 chance of being put on hold, and a .10 chance of it being a conference call. Thus the probability of the event "internal incoming call generated by abbreviated dialing being answered and put on hold" is given by .35 * .70 * .60 * .10 = .0147, the product of the conditional probabilities. The probabilities must be conditioned because the chance of a phone being answered differs (in the example) between the cases of internal and external calls. At each division or refinement into sub-cases, paths branch and a probability is assigned to each new path. However, the total probability over all paths remains one.

Such a process of dividing a whole into parts by repeated division is called a breakage process. The mathematical foundation of breakage processes has been studied, and Kolmogorov [6] [13] is credited with explaining why the distribution of sizes of particles resulting from rock crushing is lognormal. For software events, such as operations in an operational profile, it is not rock mass which is being split but probability.

73.3.2 Multidimensional Operational Profiles

Another way to construct an operational profile is to model the input domain of a program as having one dimension *per* input variable. Cukic and Bastani [14] use this technique to estimate how the distribution of the values of input variables affects the spread of frequencies of events in the operational profile. They studied how reducing the dimensionality of the profile reduces testing effort. They assigned values taken by the input variables to 10 bins and assumed the relative frequencies of each bin in the operational profile followed the normal distribution. For example for three dimensions there are 1000 cells, each one holding the product of three factors, namely the values of the normal distribution at that coordinate in each dimension. They assumed the three normal distributions were independent.

This process also leads to a lognormal distribution of event rates. In particular, the product of

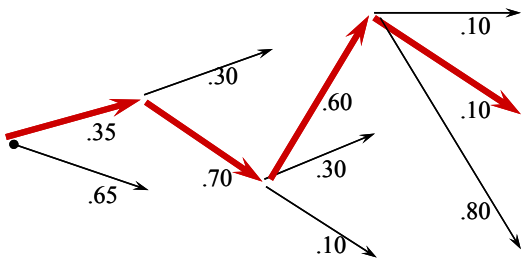

Figure 73.2. Example of a graphical operational profile or user event tree

variables from a distribution with central tendencies, such as the normal, quickly approaches the lognormal. Note that if we randomly zero some of the cells (to represent events that are somehow known to be impossible) and renormalize the operational profile, what remains are samples from a lognormal distribution. Similarly if we randomly tag some of the cells as faults and study their rates we will also find samples from a lognormal distribution.

73.3.3 Program Control Flow

A program can be viewed as a set of code blocks. A *basic block* is defined as a sequence of instructions in which only the first is a branch target and only the last is a branch or function call [15]. When a program is executed, the probability of execution flowing to a given block in the code is the product of the probabilities of the conditions needed to be met on the execution path leading to that block. There are a large number of conditional statements guarding the execution of typical code blocks, therefore a large number of factors will be multiplied to determine the probability. The central limit theorem tells us that under very general conditions the distribution of the products of those factors is asymptotically lognormal. Thus, the branching nature of software programs tends to generate a lognormal distribution of block execution rates. Similar reasoning indicates that the execution rates of other data flow elements such as decisions are lognormal [16].

Bishop and Bloomfield [17] provide a more detailed and sophisticated model of these processes. In their simplest example they modeled program structure as a branching binary tree of uniform depth and assumed branch probabilities to be uniformly distributed over (0:1). Even this simple model approached a lognormal distribution. Further, the parameters measured in real programs of known size were quantitatively consistent with relationships they derived from the simple model. The authors provide further reasons and evidence that the distribution remains lognormal even in the presence of loops and other variations in program structure.

73.3.4 Sequences of Operations

The sequences of operations or events within a system during operation are often captured in logs and traces. Examples of such event logs include packet traces flowing over a network, kernel events generated by an operating system or user-level events triggered by application software. A careful analysis and an adequate representation of such event chains is necessary to capture long term patterns of typical behavior, which can then be used to uncover unusual, perhaps intrusive, activities. For example, Ye, Zhang and Borer [18] represent the sequence of events using a Markov chain and compute the probability of a specific sequence occurring in ordinary operation as a product of the probability of the initial state in the sequence and the subsequent transition probabilities. The probability of each event sequence that occurs is compared to a threshold for intrusion detection. This threshold must be carefully set in order to achieve the desired balance between detection and false alarms.

These researchers recognized that because long sequences of events are considered, the sum of the logarithms of the probabilities follows the normal distribution, and used this fact to set control limits for anomaly detection. This example indicates that system behavior, as observed from multiple levels (network, operating system, end user/application), approaches the lognormal and that that fact can be used to inform and optimize engineering decisions.

73.3.5 Queuing Network Models

Complex systems have many queues for serializing access to IO devices, processors, locks, servers, *etc.* Queuing network models are considered sufficiently accurate descriptions of system behavior to be widely used. Many of them have product form solutions, in which the queue lengths are independent [19]. Suppose there are n queues and that we represent the state of the system as a vector where the ith component is <*zero*> if the queue is empty, and <*one*> otherwise. The defined states are interesting since some defects (*e.g.*, timing races) are conditioned on waiting by one process, other defects (*e.g.*, deadlocks) are

conditioned on two or more resources having processes waiting. Because the queue lengths are independent, the probability of the state corresponding to a given vector is the product of the probabilities of each queue being in the state defined by the given vector. As *n* becomes large, the distribution of probabilities of the states in *n*-space becomes lognormal.

73.3.6 System State Vectors

Avritzer and Larson [20] describe a telecommunications application in which up to 24 calls of five types are handled in parallel. They represented the system state as a vector of the number of calls of each type being handled. The probabilities of the state vectors were computed under the assumption of a product form solution, and the most probable states were tested. The utility of the assumptions and analysis was confirmed by the positive effect on product quality.

They implicitly assumed independence when they used Kleinrock's independence approximation [21]. Another underlying assumption was that faults are a subset of events, and that the most probable faults are a subset of the most probable events. This represents a solid example of how multiplying rates of constituent events, drawn from their own distributions, generates the distribution of rates of complex events.

In this instance the number of types of calls (five) is too small for the distribution of rates of the defined states to be lognormal. It would be expected that if the dimensionality of the state space were increased, either by having more types of calls or by admitting other state variables, the lognormal distribution would become an increasingly good approximation.

73.3.7 Fault Detection Process

Detection of a fault is not always immediate. Often a fault is not detected until the occurrence of another event that depends on an output or side effect of the fault [22]. The actual detection of the fault, therefore, depends not only on the chain of conditionals resulting in the fault, but also on a second chain involving detection of the fault. This has the effect of making the observable failure rate of faults depend on the multiplication of additional factors, and therefore approach the lognormal distribution more surely.

In summary, the perspectives offered here include queuing network models, operational profiles, and conditionals embedded in software. These exemplify the perspectives of internal state space, input space, and the path of computation, respectively. The specific examples illuminate the mechanism by which important white-box views of software operations, when taken to the limit, all approach the same black box model, one sufficiently described by the lognormal distribution and its parameters.

73.4 Lognormal Hypotheses

In Section 73.3 we discussed ways in which lognormal distributions of event rates arise. For reliability engineering we are particularly interested in faults. Faults are merely a subset of events, therefore faults have failure rates that are a sample from the rates of all events. If event rates are lognormal, then failure rates of faults are also lognormal. In this section we present a mathematical formulation of the lognormal hypotheses in software.

73.4.1 Failure Rate Model

Each defect (or fault) in a given system, against its overall operational profile, has a characteristic failure rate λ. To say that the distribution of failure rates of software faults is lognormal is to say that the logarithms of the failure rates $\ln(\lambda)$, follow the Gaussian or normal probability distribution function (pdf). For $(\lambda > 0)$:

$$dL(\lambda) = \frac{1}{\lambda\sigma\sqrt{2\pi}} e^{-\left(\ln(\lambda)-\mu\right)^2/2\sigma^2} d\lambda . \quad (73.1)$$

For the lognormal, the mean, median, and mode of the log-rate are identical and equal to μ. The variance of the log-rate is σ^2. The mean rate is exp $(\mu+\sigma^2/2)$, the median rate is exp (μ), and the mode is exp $(\mu-\sigma^2)$.

73.4.2 Growth Model

We now derive the lognormal growth model based on the failure rate model in 0. Let N denote the number of faults. The probability a single fault of failure rate λ is not encountered (does not result in a failure) until time t or later is exp $(-\lambda t)$.

The probability that fault was encountered for the first time before time t is $1 - \exp(-\lambda t)$. The mean contribution of that fault to the fault discovery rate of the system at time t is $\lambda\exp(-\lambda t)$. If λ is distributed as $L(\lambda|\mu, \sigma^2)$ then $M(t)$, the mean number of faults found (that is, having at least one failure) by time t, is given by

$$M(t) = N - N \cdot \int_{\lambda=0}^{\infty} \exp(-\lambda t) dL(\lambda). \quad (73.2)$$

This integral is formally equivalent to the Laplace transform of the lognormal, which is a transformation from a rate distribution to first occurrence time (discovery distribution) [23]. This integral has no simple form. Clearly, $M(0) = 0$, and $M(\infty) = N$. The mean fault discovery rate of the system at time t, $m(t)$, is given by dM/dt or equivalently

$$m(t) = N \cdot \int_{\lambda=0}^{\infty} \lambda \cdot \exp(-\lambda t) dL(\lambda). \quad (73.3)$$

This integral is also intractable. The intractable integrals are computed numerically by changing variables so the integrals are of the standard normal distribution and computing its height at regular intervals. A detailed discussion of this approach can be found in [24].

Note $m(0) = N\exp(\mu+\sigma^2/2)$, *i.e.,* the initial discovery rate is the product of the number of faults and their mean rate.

Unlike hardware, the mean overall failure rate for software systems as a function of time is generally at a maximum when the product is newest, since reliability growth has not yet commenced. The derivative of the Laplace transform of the lognormal, (73.3), meets this boundary condition – the lognormal itself does not. The fact that the lognormal itself is zero at zero impedes its direct use in many software engineering applications.

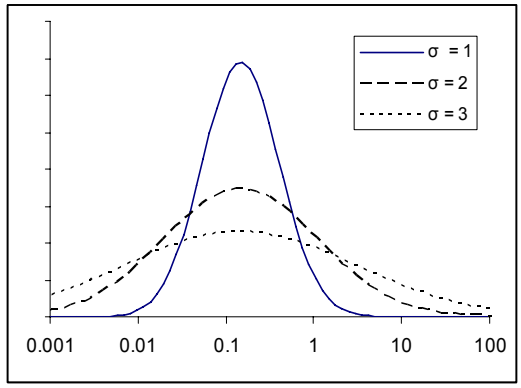

Figure 73.3. Lognormal distribution of rates, $\mu = -2$. Application: failure rates. Code execution, operational profile

73.4.3 Occurrence Count Model

Reliability growth models capture the first occurrence times of defects, usually during testing. Despite extensive testing, however, inevitably software systems are released into the field with latent defects. A shipped latent defect may cause multiple field failures until it is fixed. Modeling the defect occurrence phenomenon in the field can help answer questions that may be valuable in planning maintenance activities, for example, what percentage of defects will cause two or more field failures? The lognormal occurrence count model represents this phenomenon.

We assume each defect has a rate λ against the overall operational profile and that each specific failure, *i.e.*, each manifestation of that defect, is an event in a Poisson process with that rate. We also assume the defect is not repaired (or the repairs are not put in service) during the interval considered. Since the rates follow the lognormal, the overall occurrence count distribution is a mixture of Poisson distributions, which can be represented using the notation of [25].

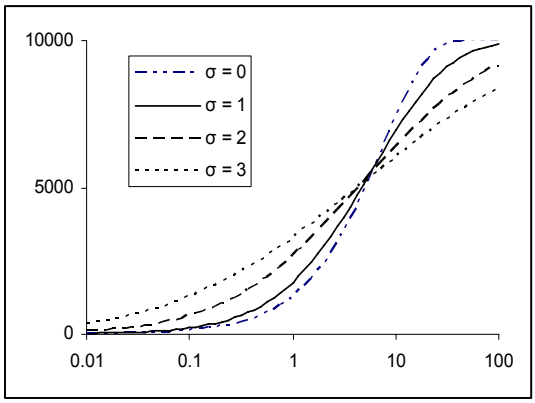

Figure 73.4. Cumulative first occurrences, x-axis: years. Laplace transform of lognormal for μ = –2, N=10000. Application: software reliability growth model

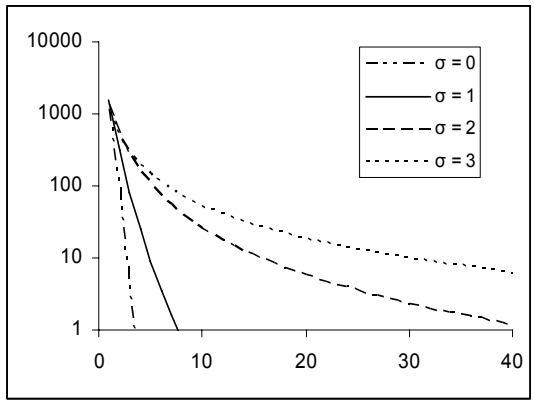

Figure 73.5. N defects having x (1:40) occurrences. Discrete lognormal for μ = –2, N = 10000, at time T = 1 year. Application: occurrence counts

$$Poisson(\lambda) \bigwedge_{\lambda} Lognormal(\mu, \sigma) \qquad (73.4)$$

This distribution is called a discrete-lognormal or Poisson-lognormal. Defining i to be the number of occurrences, the pdf of occurrences, *DLN(i),* is the integral of Poisson distributions, the rates of which follow a lognormal distribution, each evaluated at i. For ($i >= 0$, integer)

$$DLN(i) = \int_0^{\infty} Poisson(i, \lambda) \bullet dL(\lambda). \qquad (73.5)$$

73.4.4 Interpretation of Parameters

Conceptual advantages of the lognormal include the relative straightforwardness of its parameters and the way it links various observed properties of software defects.We provide a summary of how the parameter values are related to software behavior.

Figures 73.3 to 73.5 show examples of the lognormal and its two transformations. Figure 73.3 illustrates the wide range in rates which are possible for the larger values of σ. Figure 73.4 shows the reliability growth model, based on the Laplace transform from Section 73.4.2. Figure 73.5 shows the corresponding occurrence count distributions, hypothesized to be discrete lognormal, derived in Section 73.4.3.

The parameter σ makes the greatest qualitative difference and allows the lognormal its flexibility. σ, the standard deviation of the log rates, increases with increasing complexity of the software, in particular with greater depth of conditionals [17]. If σ is zero, all defects have the same occurrence rate (not shown in Figure 73.3) leading to the exponential model [26] of software reliability growth (Figure 74.4, $\sigma = 0$). In this case, the distribution of occurrences will be an ordinary Poisson distribution with rate λ = exp(μ) (Figure 73.5, $\sigma = 0$). Values of σ from 1.0 to 3.0 are more common and greater than four are unusual and problematic [27].

The contribution to the initial overall failure rate, integrated over all defects, will be dominated by contributions from the high rate defects. If σ is 2.0, more than 2% have rates more than exp(4) times the median. On the other side of the median are an equal percentage of defects with lower rates by a factor of exp(−4). The ratio of rates between the second percentile and the 98th percentile exceeds exp(8), a factor of nearly 3000. The spread is more dramatic for σ > 3.0. σ determines the ratio of the highest and the lowest occurrence rates of the defects, however defined.

Bishop and Bloomfield [17] observed and explained a rough relationship between program

size and σ: *The depth of conditionals is proportional to the log of the program size, and σ, the spread in rates, is proportional to the square root of that.* Thus a key parameter can be estimated based on information available prior to execution.

The parameter μ has a straightforward interpretation: if rates are plotted on a log scale, as in Figures 73.3 and 73.4, changing μ merely moves the distribution to the right or left with no change in shape. A system speedup or using different units of time changes μ . For $\mu = -2$, the median rate is exp(−2) or **.**14 *per* year (Figure 73.3) and fewer than half have been found by T=1 year (Figure 73.4) for all σ. In terms of occurrence counts, a majority of the 10,000 defects have not occurred even once (Figure 73.5).

Changing either μ or σ, both of which relate to ln(rate), does not affect the other. However, changing either μ or σ affects *both* the mean and variance of the rates themselves [6].

The final parameter is ***N***, the number of defects, which scales the pdf. For Figures 73.3, 73.4, and 73.5, changing *N* changes only the height of the curve, not its shape or position. In this paper, and in most situations, *N* is not a given but must be estimated in conjunction with the other parameters of the model. *N* should be understood physically as the total number of defects, including both found and latent. If the number of latent defects is large, their average rate often is low [28] This does not mean they all will occur in the practical lifetime of the product—most will not—but it is possible to use a software reliability growth model (Figure 73.4) to estimate how many will occur as a function of further exposure.

73.5 Empirical Validation

This section discusses the empirical validation of the lognormal hypotheses in software.

73.5.1 Failure Rate Model

The failure rate model was validated using two published data sets [29]. We briefly discuss validation using the data from nine IBM software products [30] here. These products consisted hundreds of thousands of lines of code and were being used at hundreds of customer sites. For each product, the data consisted of percentages of faults in eight rate classes. The fractional percentages in the highest rate buckets indicated the presence of at least several hundred defects. The means of each class formed a geometric progression. This data arrangement is equivalent to grouping the faults by log of their rates, therefore we expected to see a normal distribution of log-rates.

We used the method of minimizing Chi-square [31] to fit the distribution. It is reasonable [32] to expect a fit to be *relatively* more accurate when there are higher counts, and *absolutely* more accurate when there are lower counts. Because the Chi-square statistic is exactly the product of the relative and absolute errors, it has this desirable property.

Figure 73.6 compares the data with a fitted lognormal. The data, in log-buckets, look like a truncated Normal distribution. The fitted lognormal suggests that for every 100 faults assigned to the 8 highest rate buckets, there may be 85 more faults in lower rate buckets which were not measured. It was estimated that 55 of those faults are in the next two rate buckets.

It is impossible to perform a test of statistical significance on the resulting values of the Chi-square statistic without knowing the number of faults in each bucket. An alternative is to compute the coefficient of determination, which indicates what fraction of the variance (between buckets) is explained by the model. For the example set, the coefficient of determination was 0.99, indicating that the lognormal model explains over 99% of the variance between buckets. Similar coefficients of determination were obtained for the remaining products as well. This suggests that each product is fit very well by the lognormal, providing a better fit than Trachtenberg [33] achieved with a power-law model.

The second set used for validation consisted of data collected from replicated experiments on 12 programs reported in Nagel *et al.* [34] [35]. The programs were executed tens of thousands of times against an operational profile in order to accurately determine the frequency at which each fault occurred. Pooled *z*-scores of those rates (Figure 73.7) visually suggest overall normality, but are

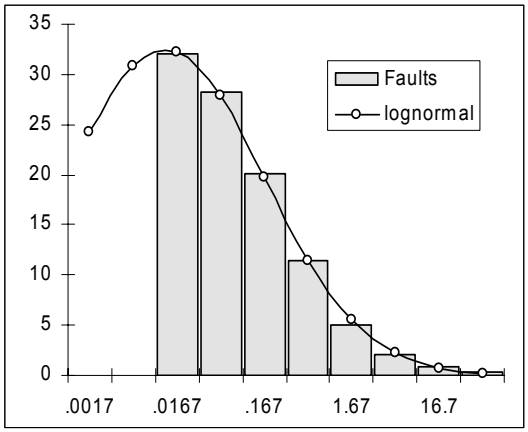

Figure 73.6. Adams [32] product 2.6: relative number of defects *per* rate bucket

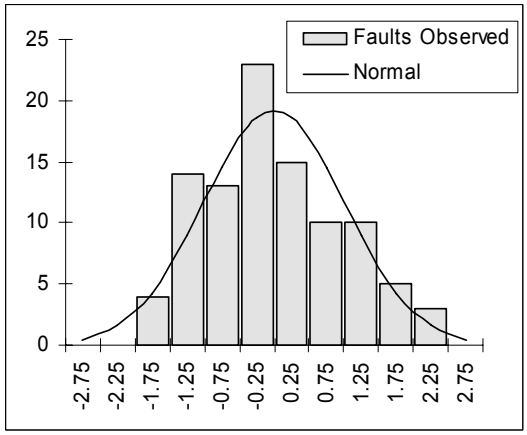

Figure 73.7. Nagel data: pooled *z*-scores of faults *per* log-rate bucket in repetitive run experiments

not conclusive. The Shapiro–Wilk [36] [37] test for normality of small samples found the distribution of rates of faults in each program were plausibly generated from a lognormal. Finally, a comparison of the lognormal distribution with the gamma family of models [23], using the same data, demonstrated that the lognormal was significantly more likely to generate the data than any of the models in gamma family, which consists of some of the well-known, commonly used software reliability models including power law models [33], Musa–Okumoto [26], Littlewood's Pareto model [23], Jelinski–Moranda [38], and Goel–Okumoto [39]. Moreover, the lognormal was more likely to generate the data than a strategy of selecting the best fitting of the gamma models in each case.

Rigorous studies of the failure rate distribution of faults such as those by Adams or Nagel *et al*., are rare. A recent detailed study by Bishop and Bloomfield [17] measured the failure rates of faults in the 10,000 line PREPRO application of the European Space Agency, as well as the distribution of execution rates of code blocks. They found both to be lognormal and elaborated many additional insights into how the parameters of the lognormal will be affected by code size, depth of conditionals, and the presence of loops.

Previously, several researchers hinted at the multiplicative origin of failure rates of rare events, but stopped short of formally modeling these rates using the lognormal. For example, Iyer and Rossetti [40] note that during periods of stress or uncommon workload patterns, rarely used code can be executed, leading to the discovery of errors, and they remark throughout on problems caused by complex sets of events, complex sets of interactions, or complex workloads. Similarly, Adams [30], in his classic paper on preventative maintenance, states that in production code the typical design error requires very unusual circumstances to manifest itself, possibly in many cases the coincidence of very unusual circumstances. Their crucial insight is that the failure rate of a fault is proportional to the product of the probabilities of its preconditions. Although they stated it in terms of rare events, in this chapter we have discussed why the multiplicative insight is applicable to common events as well.

A few efforts have also focused on estimating and modeling the distribution of failure or event rates using various approaches to achieve specific purposes. Musa [12] and Juhlin [11] estimated rates to model the operational profile. Avritzer and Larson [20] determined the distribution of occurrence rates of internal states to increase the effectiveness of testing. Although these efforts, already noted in Section 73.2, share many of the assumptions that lead to the lognormal, these authors did not explicitly study the form of the

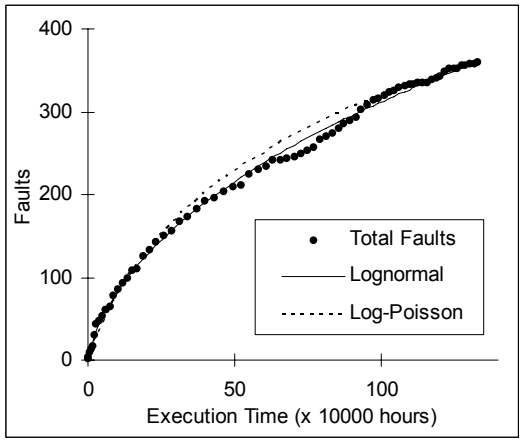

Figure 73.8. Status data: cumulative faults discovered as a function of customer execution time

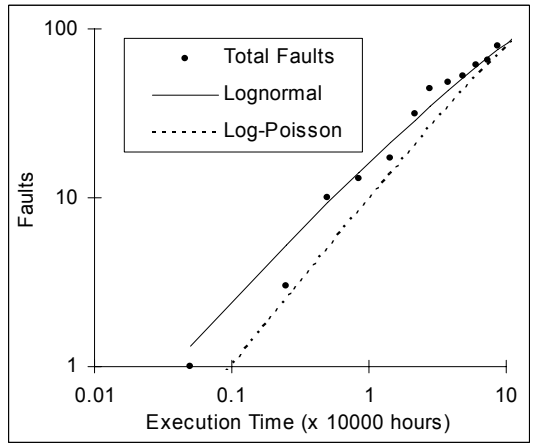

Figure 73.9. Stratus data: log scale showing early data with slight advantage to lognormal

distribution. Everett [41] measured the distribution of execution rates of lines of code and fitted it with a power-law to establish the parameters of a flexible reliability growth model with a known mathematical function.

By contrast, we have used a general-principled approach which takes the multiplicative process to the limit and finds the distribution of the event rates to be lognormal.

73.5.2 Growth Model

A detailed description of the validation of the lognormal reliability growth model using Stratus and Musa data sets is provided in [24]. First we present a synopsis of validation using one of the Stratus data sets. The Stratus data are collected from several hundred module-years of customer exposure on an operating system release. A module consists of one or more processors, peripheral controllers, and memories, all of which are typically duplexed (*i.e.,* in lockstep). The operating system itself is over one million lines of code, supports fault-tolerant hardware and is complex. The data series provides the cumulative execution time (*i.e.,* number of module-hours) and cumulative number of distinct faults discovered on a weekly basis. Each machine was attached to the Stratus Remote Service Network (RSN); failures reported by customers are logged in a call database, and when a call is resolved to be due to a fault a bug number is assigned to the call. If the fault has not been seen before, a new bug number is assigned. The earliest call for each fault (bug number) identifies the calendar week in which a failure due to the fault first occurred.

The number of machines on a given release was determined by analyzing RSN calls placed when a new release was installed, therefore only failures occurring in a specific release were counted, and each failure was counted only if it was the first time a failure due to that fault occurred in that release. Thus the data series represents the cumulative number of first-failures as a function of execution time.

The Stratus systems from which the data were collected represent initial versions of a yearly release. No new functionality was added. Only the most urgent fixes were made to the software during the course of its life in the field; most fixes were made to subsequent maintenance releases. Thus the code in question was essentially unchanged through the course of its field exposure. Stratus systems are used for continuous processing of stable, mission-critical applications so execution time on a release during a given week is equal to 168 hours times the number of machines on which the release was running. Common applications are telecommunications, banking, and brokerage. No attempt is made here to correct for the effect

processor speed may have on the observed failure rate. This would be an issue if the mean processor speed over the installed base varied widely during the life of the release, which was not the case.

The log-Poisson model, which is an infinite failures model, was used as the competing model for comparison, because it does not have an underlying failure rate distribution and is yet very successful in practice. The parameters of both the lognormal and log-Poisson models were estimated using the maximum likelihood method. Figure 73.8 shows the data and the fits obtained using the lognormal and log-Poisson models. Figure 73.9 illustrates the ability of the lognormal to fit the earliest data as well as the rest.

The models were compared objectively using log likelihood and Akaike Information Criteria (AIC) [42]. The AIC provides a natural way to compare the adequacy of models which are unrelated or have different numbers of parameters. The best model is the one with the minimum AIC value. By penalizing models that have more parameters, the AIC embodies the principle that adding more parameters may increase the ability to fit the past at the expense of decreasing the ability to fit the future. Akaike [42] provides theoretical reasons why this definition is appropriate.

When interpreting the AIC values of competing models, what matters is their difference [43]. A difference of less than one is not significant, but a difference larger than one or two is considered to be significant. For one of the Stratus data sets, the difference in AIC values is greater than 8 units in favor of the lognormal. For the second data set [24], the lognormal has an advantage, even though the AIC penalizes it for the extra parameter, but the advantage is not significant. Together these two data sets suggest the lognormal growth model has the potential to greatly exceed the performance of the log-Poisson model.

The fitted parameters of the lognormal and their standard deviations are σ (3.275, 0.305), μ (−19.31, 0.95) and N (3808, 1280). This implies the total number of defects may be over ten times the number of defects already found, and the uncertainty in that estimate is 30%. Figure 73.10 shows the uncertainty is due to the high degree of covariance between the parameters when the data

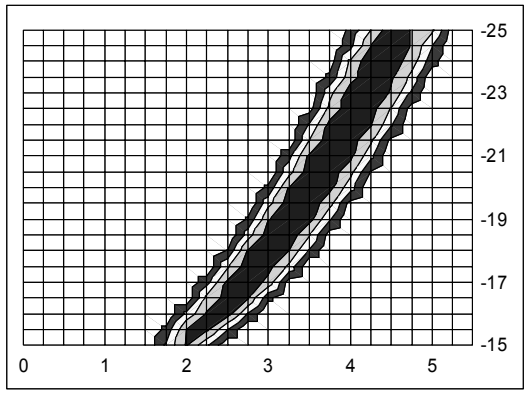

Figure 73.10. Stratus data: relative log-likelihood as a function of (σ, μ.). A long peak (*dark*) from (2, –15) to (4.5, –25) represents values within two units of the maximum log-likelihood

are not conclusive. At all points along the ridge there must be a good fit to the already observed initial discovery rate $m(0) = N \cdot \exp(\mu+\sigma^2/2)$. But as σ increases (and μ decreases) the mean rate exp $(\mu+\sigma^2/2)$ decreases and N increases leading to a much larger value of N. On the other hand, decreases in σ yield a decline in N.

A three-way comparison was conducted between the lognormal, log-Poisson and exponential models using 10 Musa data sets. In nine out of ten sets, the lognormal model fit the data better or as well as the other two models [24].

Despite the variety of models of software reliability growth proposed in the literature, there is an undercurrent of dissatisfaction. Each model has strengths, but the very existence of so many models implies that no single model is flexible enough to model software reliability growth in general. Levendel [44] has recognized earlier models as being either too optimistic or too pessimistic. The dividing line is related, if not identical, to the division between finite and infinite failure models. The problem cannot be escaped by combining or weighting models to create super models. Levendel's [44] case against super models is supported by Keiller and Miller's [32] evaluation of 6 models and 8 super models against 20 data sets, which found super models offered no improvement in prediction. The lognormal reli-

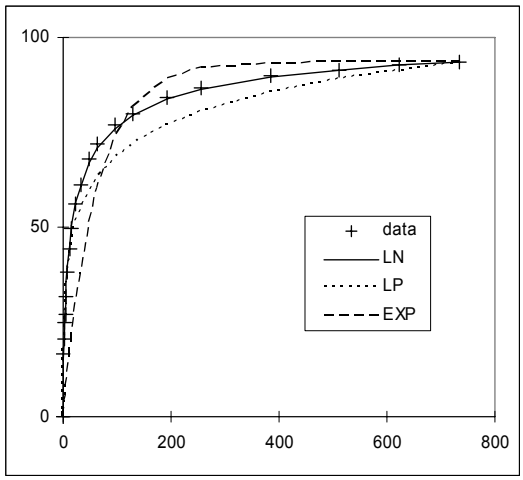

Figure 73.11. SHARPE Coverage data: growth of percent block coverage with number of tests, average of ten replications

ability growth model is attractive compared to earlier alternatives because of its robust origin, its relationship to how software works, and the fact that it is supported by failure rate distribution data.

When used to model the growth of four coverage types, namely, block, decision, c-use and p-use [27] [45], the lognormal growth model significantly outperformed the log-Poisson and the basic execution time models. Figure 73.11 compares the maximum likelihood fits for the three models to the growth of cumulative block coverage F in the 30,000 line SHARPE application. It is shown in a linear form to illustrate the ability of the lognormal to fit both early and late data. Visually, the lognormal is a better fit. Using statistical tests, the superiority of the lognormal [16] over the other models, for the entire SHARPE application and most of its constituent files was confirmed.

The significant evidence in favor of the lognormal in coverage growth is particularly interesting because it was based on data generated from replicated run experiments. As pointed out by Miller [23], a comparison of models using a single realization may not be conclusive, because the statistical fluctuations within a single realization would often mask differences among the models due to their similarity.

73.5.3 Occurrence Count Model

A synopsis of the validation of the occurrence count model is provided here, details can be obtained from [46]. The data was collected in the ordinary course of recording the occurrence of software defects in two operational databases. The first is a defect tracking system with one record for each defect. The second system uses trouble-tickets to track the occurrence of incidents at customer sites. When a customer incident is due to a defect, a bidirectional link is established between the incident and the appropriate defect. The defects for which there was a least one trouble-ticket were included, counting the initial discovery as well as rediscoveries. Each defect contains the identifiers of all trouble-tickets associated with the defect and, implicitly, the count. The data were collected for four sets of defects, each divided into three subsets.

The data showed that a relatively small percentage of defects cause a large number of incidents *per* defect and *vice versa*. This indicates that the distribution of the occurrence counts of defects is likely to be skewed, even "heavy-tailed" suggesting that the lognormal may provide a reasonable fit. The alternative model used for comparison is discrete Pareto, since the Pareto distribution is an often-used heavy tailed distribution [47].

Figure 73.12, which depicts the fits provided by the two models, shows a clear problem for the Pareto in the high count tail. It also shows error bars on each data point equal to the standard deviation of the lognormal fitted value. This illustrates that in this case, within statistical variation, the data follow the lognormal rather than the Pareto. The Chi-square, which was used to objectively compare the quality of fits of the two models, significantly favored the lognormal in three subsets at significance levels of .0001, .01, and .05. The data never reject the lognormal even at the .05 level. Thus, the data are consistent with the discrete lognormal (DLN) but not the discrete Pareto. The DLN model was also shown to be an adequate fit to the occurrence phenomenon of

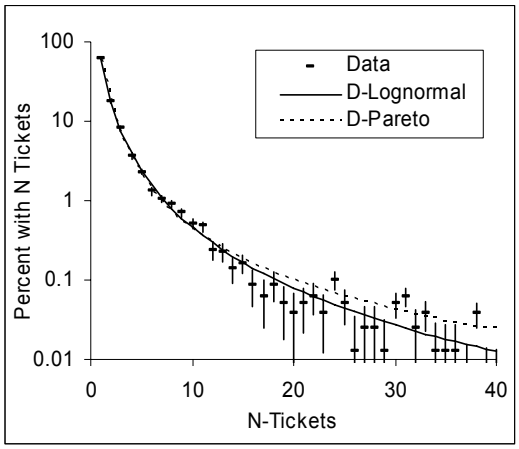

Figure 73.12. Cisco occurrence count data: percent of defects with N (0:40) occurrences

network security defects, though the data were not sufficient to discriminate against the Pareto [48].

The DLN occurrence count model could be used to predict the number of occurrences of defects and the number of latent defects that have not yet occurred. These predictions could be used to guide the allocation of resources for software maintenance activities, which will allow expeditious resolution of defects that cause field failures and improve customer satisfaction [49]. The parameters found in this manner can be used in fitting or bounding the lognormal reliability growth model for the same software.

73.6 Future Research Directions

This section summarizes the advantages and current evidence of the application of the lognormal. It also discusses future opportunities.

The lognormal model has several advantages over earlier models. Its genesis is apparent, since the mathematical form of the model is directly traceable to the structure of the subject of the model. This mathematical link between software structures and the lognormal distribution is based on the central limit theorem, a profound result of probability theory. The assumptions about software systems on which the model is founded are equivalent or similar to those successfully used within many sub-disciplines of software engineering. The lognormal distribution has also been applied in hardware reliability modeling as well as a variety of other disciplines.

Presently, the lognormal and its transformations have been successfully used to model distributions of failure rates, execution rates of code elements, reliability and coverage growth and the occurrence frequencies of software defects in both controlled and commercial environments.

Many opportunities for future research exist. Some re-validate or apply either the rate or one of the derived distributions thereby increasing confidence in the application of the lognormal, while others attempt to unlock the value of the insight by exploiting the analytical properties of the lognormal or its origins in software structure. If the lognormal appears to be nearly ubiquitous then the challenge is no longer to find it but rather to apply it. These opportunities include:

The ability of the model to predict future fault count should be assessed, using prequential likelihood [50].

Prior research has indicated that predictions using limited data from early testing, tend to be inaccurate [51]. Questions such as how much data is needed for the lognormal to ensure predictions of a given level of accuracy also merit further consideration. The effect of slow convergence in the tail as implied by the CLT [52] on predictions based on early data also needs to be explored.

A central assumption underlying software reliability models is that the software is tested according to its operational profile. Since an accurate profile is usually not available, it is necessary to assess the sensitivity of the reliability to variation in the operational profile [14]. Can the lognormal be used to assess the impact of such variations quantitatively?

It would also be useful to assess the extent to which applying priors to the lognormal parameters will improve prediction. Since the lognormal has its roots in the complexity of software states, program flows, and operational profiles, there is an opportunity to use such information to estimate the parameters in advance of execution. For this purpose, methods to estimate the parameters,

especially σ, given such preliminary information are needed. Although the "true" operational profile is usually more complex than that of any analyst, an analyst's operational profile may be used to establish a lower bound on the variance of the log-rates of operations within the actual system.

When used to model software reliability growth, the parameter N represents the ultimate number of defects, which may be estimated based on many techniques in the extensive available literature. In the case of code coverage growth, N is either the total number of code elements or the maximum percentage of code coverage that can be achieved. An exact value of the total number of elements can be obtained directly from the code, while the maximum percentage of coverage is always 100%, reduced by unreachable code.

Finally, the parameter μ, which is a location parameter in the case of reliability growth and a measure of individual test efficiency in case of code coverage growth, may be obtained from prior releases or similar products. It is likely that similar systems will have similar parameters, allowing real use of prior information**.** Because it scales rates, μ will change as processing speeds change.

The conditions under which the bounds on the lognormal parameters obtained from different data types are tight or loose needs to be determined. In particular, the covariance structure between the lognormal parameters needs to be studied in the context of estimating the parameters from first-occurrence times, especially in the practical case in which only truncated (*i.e.,* early) data are available. Reparameterizations may lead to sharper characterizations of their interrelationships.

The lognormal distribution provides a unique potential to share information from structural knowledge (or size), operational profile, code coverage growth, occurrence counts, and so on, when determining parameters within a given system, and then being able to apply those parameters with additional confidence in other contexts. To assess this potential, it is necessary to compare the parameters of the lognormal, estimated from different perspectives (measured by direct rate, *via* the Laplace transform in software reliability and code coverage growth or *via* discrete lognormal using the occurrence counts) for a single system. Further, this exercise must be repeated for several systems.

The impact of process characteristics on the lognormal parameters needs to be studied. For example, the σ values estimated from occurrence count data were generally less than 2.0, which seemed low for the large product size [46]. Could this be due to heavy prior testing? Will this model still hold if fix-times are variable?

The Pareto distribution is an alternative heavy tailed distribution [47], and a close competitor to the discrete lognormal occurrence count model. Other conditions under which that relationship holds need to be determined.

Studies similar to the other models, including methods to determine the optimal release time and the optimization of test strategies, are needed for the lognormal. Robust solutions to these problems depend on using the correct form of the distribution of the failure rates of defects. Can the knowledge of the form of the occurrence count distribution and its parameters be used to quantitatively evaluate defect repair/ship strategies or even deduce optimal ones?

The lognormal is presented as an execution time, or as a closely related test-effort model. If execution time or test effort were a known function of real time, it may be worth exploring whether simple parametric substitution yields functions with useful, recognizable, or simple forms. Among these, assumptions of linearly or exponentially ramping usage may be of practical applicability.

Adams [30] noted defects arising from imperfect repair (*i.e.,* bad fixes) have failure rates drawn from the original distribution rather than having the lower rates characteristic of the defects being repaired. Confirming this, [46] found occurrence counts of defects originating as bad fixes are well fit by the DLN, and have both a wider rate spread and higher average rate than the defects being repaired. The practical challenge is to determine the point in the lifecycle when the benefit of repairing a low-rate defect is offset by the risk of introducing a new high-rate defect.

A number of these opportunities may exploit the analytical properties of the lognormal and its related functions.

73.7 Conclusions

This chapter discussed emerging applications of the lognormal and its transformations in software reliability engineering. Software, being essentially massless, a skeleton of conditionals implementing a breakage process, is an ideal generator of the lognormal. The lognormal is widely used in other disciplines and the knowledge and the experience gained from those applications should be valuable in applying it to software engineering problems. The array of enabling research opportunities identified provides an insight into the potential of the lognormal. It is likely that the application of the lognormal to software engineering may eventually serve as a model for other disciplines.

Acknowledgments

Thanks are due to Dom Grieco, John Intintolo, and Jim Lambert of Cisco Systems, Inc., for their insight and support. Thanks are also due to Dr. William Everett, Los Alamos National Laboratory, and Professor Mark Lepper, Stanford University, for many constructive comments. The research at University of Connecticut is supported in part by a CAREER award from the National Science Foundation (#CNS-0643971).

Early-stage Software Product Quality Prediction Based on Process Measurement Data

Shigeru Yamada

Department of Social Systems Engineering, Tottori University, Tottori, Japan

Abstract: In recent years, delivery time has become shorter in software development in spite of high-quality requirements. In order to improve software product quality during a limited period, we have to manage process quality and control product quality in the early-stage of software development. Software product quality can be achieved in the development process. Then, it is important for us to predict the product quality in the early-stage and to execute effective management. In this chapter, we conduct multivariate linear analysis by using process measurement data, derive effective process factors affecting product quality, and obtain quantitative relationships between quality assurance/management activity and final product quality.

74.1 Introduction

Software product quality can be achieved in the development process [1], [2]. According to quality management, software faults introduced in the development process need to be decreased by reviewing intermediate products after finishing each process in the early-stage of software development. Moreover, it is important to detect most of the remaining faults in the testing process. Then, in order to improve the product quality during the limited period, we have to control the development process and predict product quality in the early-stage of software development [3]–[10].

To control and predict product quality in the early-stage of software development, Fukushima *et al*. [8] and Yamada and Fukushima [9] have implemented risk management, process quality management, and product quality assurance activities. Through these activities, they have discussed multiple linear regression analysis by using these process measurement data and have derived a relational expression that can predict the quality of software products quantitatively. From this analysis, they examined the effects on software products quality of these management factors and quality assurance factors, and obtained a clear correlation between these activities and software product quality. That is, a prediction of product quality by using process measurement data is shown to be very effective to clarify the process factors that affect product quality and to promote the improvement of these process factors.

In this chapter, based on the results of Fukushima *et al.* [8] and Yamada and Fukushima [9], we analyze the process measurement data by using principal component analysis and multiple regression analysis according to the derivation

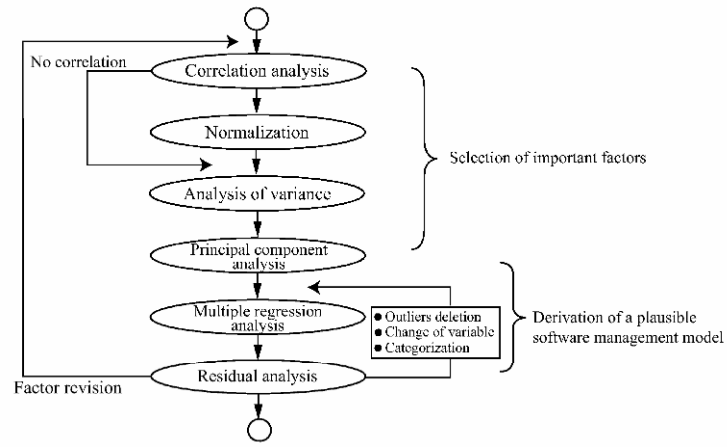

Figure 74.1. Derivation procedures

Table 74.1. Analyzed quality assurance process data

	Management of review		Rreviw technique	Test technique	Software products quality
Project No.	Rate of design review delay X_1 (0∼1.00)	Frequency of review X_2	Average score of review X_3 (0∼100)	Number of test items X_4	Number of faults detected in testing Y
1	0.50	5	80.50	71	38
2	-0.07	12	82.50	48	3
3	-0.12	4	64.00	12	7
4	0.10	1	35.50	44	20
5	0.09	3	62.00	138	26
6	0.08	14	89.25	25	0
7	0.00	3	44.25	33	22

procedures for a software management model [2] (as shown in Figure 74.1). Further, deriving the factors affecting product quality, we validate the results of Fukushima *et al*. [8] and propose more effective measures to apply project management techniques. Further, we conduct a discriminant analysis by using the observed data reflecting the management process to derive a discriminant expression judging whether or not the software project has a quality process.

74.2 Quality Prediction Based on Quality Assurance Factors

74.2.1 Data Analysis

First, we predict the software product quality by using process measurement data of quality assurance factors (as shown in Table 74.1). The factor tree diagram for software quality improvement is given by Figure 74.2. The number of faults detected in testing as the metric of software product quality is used as an objective variable.

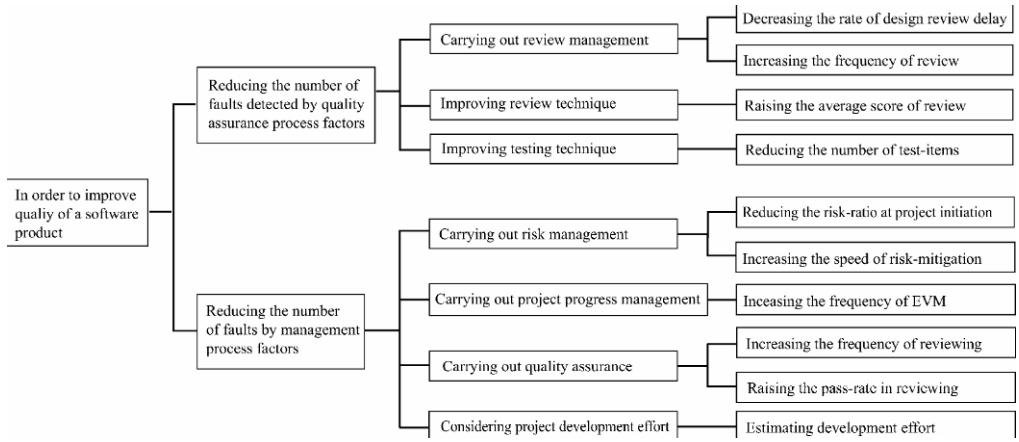

Figure 74.2. The factor tree diagram for software quality improvement

Four control variables, *i.e.*, the rate of the design review delay, the frequency of review, the average score of review, and the number of test items, are used as explanatory variables. These variables introduced above are explained in the following when the actual review has finished earlier than the planning.

X_2: the frequency of review (the frequency of review-assessment *per* development size).

Y: the number of faults detected during system testing and quality assurance testing.

X_4: the number of test items (the number of system test items and the number of quality assurance test items).

X_1: the rate of design review delay [0,1.00] (the averaged delay period/the development period). The computed value is negative X_3: the average score of review [0,100.0] (the average score of design reviews). The review score is measured by using the review checklist (maximum 100 points).

74.2.2 Correlation Analysis

A result of conducting the test of correlation analysis among the explanatory and objective variables is shown in Table 74.2, from which we can consider the correlation as follows:

Table 74.2. Correlation matrix for quality assurance factors

	X_1	X_2	X_3	X_4	Y
X_1	1				
X_2	-0.1343	1			
X_3	0.2088	0.8384	1		
X_4	0.3694	-0.2725	-0.0041	1	
Y	0.7576	-0.6769	-0.3234	0.5695	1

(1) X_1 and X_2 have shown a strong correlation to Y.
(2) X_3 has not shown a correlation to Y.
(3) X_2 and X_3 have also shown a strong correlation.

Based on the correlation analysis, X_1, X_2, and X_4 are selected as the important factors for estimating a quality prediction model because X_3 has multicollinearity with X_2 and has a low correlation to Y.

74.2.3 Principal Component Analysis

Regarding variable Y as the explanatory variable, we conduct the test of independence among explanatory variables X_i (i = 1, 2, 3, 4) by the principal component analysis. We find that the precision of analysis is high from Table 74.3. And factor loading values are obtained in Table 74.4. Let newly denote the first and second principal components as follows:

Table 74.3. Summary of eigenvalues and principal components

Component	Eigenvalue	Contribution ratio	Cumulative contribution ratio
1	2.615	0.523	0.523
2	1.615	0.323	0.846
3	0.646	0.129	0.975
4	0.091	0.018	0.993
5	0.033	0.007	1.000

Table 74.4. Factor loading values

	Component 1	Component 2
X_1	0.584	0.693
X_2	-0.835	0.514
X_3	-0.550	0.809
X_4	0.611	0.402
Y	0.949	0.236

- The first principal component is defined by the measure for evaluating total quality characteristics.
- The second principal component is defined by the measure for discriminating the process factors as the quality management activity factors(X_2, X_4) and the review management activity factors (X_1, X_3).

We have evaluated seven actual software projects by the first principal component. Then, we can confirm that several projects, *i.e.*, project numbers 2, 3, and 6, experience a small number of faults detected in testing (see Tables 74.1 and 74.5). From relations among factor loading values for the first principal component in Table 74.4, it is found that the rate of design review delay (X_1), the frequency of review (X_2), and the number of test items (X_4) affect the number of faults detected in testing (Y).

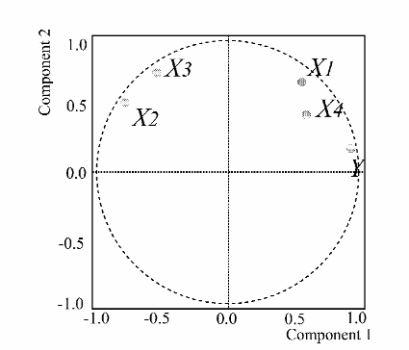

Figure 74.3. Scatter plot of the factor loading values

Table 74.5. Principal component scores

Project No.	Component 1	Component 2
1	1.032	1.528
2	-1.118	0.310
3	-0.561	-0.939
4	0.692	-1.043
5	0.959	0.342
6	-1.359	0.755
7	0.354	-0.954

We obtain a scatter plot in Figure 74.3 showing that these explanatory variables are independent each other. As a result of correlation analysis and principal component analysis, we can select X_1, X_2, and X_4 as the important factors of a software quality prediction model.

74.2.4 Multiple Linear Regression

A multiple linear regression analysis is applied to the process data as shown in Table 74.1. Then, using X_1, X_2, and X_4, we estimate the multiple regression equation predicting software product quality, $\hat{Y}$, given by (74.1) as well as the normalized multiple regression expression, $\hat{Y}^N$, given by (74.2):

$$\hat{Y} = 18.712 + 41.718X_1 - 1.502X_2 + 0.064X_4, \quad (74.1)$$

$$\hat{Y}^N = 0.613X_1 - 0.541X_2 - 0.196X_4. \quad (74.2)$$

In order to check the goodness-of-fit adequacy of our model, the coefficient of multiple determination (R^2) is calculated as 0.9419. Furthermore, the squared multiple correlation coefficient, called the contribution ratio, adjusted for degrees of freedom (adjusted R^2), is given by 0.8839. The result of multiple linear regression analysis is summarized in Tables 74.6 and 74.7.

From Table 74.7, it is found that the reliability of these multiple regression equations is high. Then, we can predict the number of faults detected in testing for the final products by using (74.1). From (74.2), the explanatory variables affecting the objective variable Y are X_1 and X_2. Therefore, we conclude that "the rate of design review delay" and "the frequency of review" have an important impact on the product quality.

Table 74.6. Estimated parameters

Factor	Coefficient	SE	t-value	Standard coefficient
Intercept	18.712	4.315	4.337	0.000
X_1	41.718	10.202	4.089	0.613
X_2	-1.502	0.402	-3.741	-0.541
X_4	0.064	0.051	1.269	0.196

By using (74.2) the predicted and actual measurement values are given in Figure 74.4 which shows that the number of faults can be predicted with high accuracy.

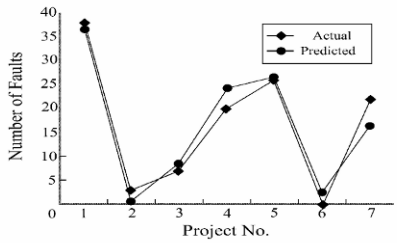

Figure 74.4. Accuracy for predicting the number of faults

Table 74.7. Analysis of variance

Source of variation	SSq	DF	MSq	F-value
Due to regression	1073.6	3	357.9	16.23 *
Error	66.2	3	22.05	
Total	1139.7	6		

74.2.5 The Effect of Quality Assurance Process Factors

We have shown the following correlation between quality assurance process factors and product quality:

- Through a regression analysis, it has become clear that the design review delay has had an important impact factor on software product quality. The review management and progress management influence the number of faults detected in testing.
- The frequency of review has also affected the number of faults detected in testing. So, we consider that the number of inspection review by the quality assurance department is insufficient.
- The average score of review has not influenced the number of faults detected in testing. We consider that the issue is in the assessment method of design review activities. Then, we have to investigate this cause.

74.3. Quality Prediction Based on Management Factors

74.3.1 Data Analysis

Secondly, we predict software product quality by using process measurement data of management process factors (see Figure 74.2) as shown in Table 74.8.

The number of faults as the metric of software products quality is used as the objective variable. Six variables (*i.e.*, the risk ratio of project initiation, the speed of risk mitigation, the frequency of EVM (earned value management), the frequency of review, the pass rate of review, and the development effort) are used as the explanatory variables. The variables introduced above and another two objective variables in addition to the number of faults are explained in the following:

Y_1: the number of faults detected during acceptance testing in operation.
Y_2: the development cost (the difference between predicted and actual development costs).
Y_3: the delivery date (the difference between predicted and actual delivery date).

X_1: the risk ratio of project initiation. The risk ratio is given by

$$R = \sum_i \{\text{risk item}(i) \times \text{weight}(i)\}, \quad (74.3)$$

where the risk estimation checklist has weight (i) in each risk item (i), and the risk ratio ranges between 0 and 100 points. Project risks are identified by interviewing the project manager using the risk estimation checklist. From the identified risks, the risk ratio of a project is calculated by (74.3).

Table 74.8. Analyzed management process data

	Risk management		Project management	Quality assurance		project scale	Software products quality		
Project NO.	Risk ratio of project initiation X_1 (0〜100)	Speed of risk mitigation X_2 (0〜1.00)	Frequency of EVM X_3	Frequency of review X_4	Pass rate of review X_5 (0〜1.00)	development size X_6	Number of faults Y_1	Development cost Y_2	Delivery date Y_3
1	73	1.00	0.21	0.05	0.50	42.8	12	113	125
2	47	0.33	0.78	0.01	0.50	20.9	0	92	91
3	38	0.87	1.18	0.14	0.50	14.0	13	112	100
4	35	0.95	0.74	0.12	1.00	8.2	3	104	100
5	34	0.51	2.70	0.22	0.50	18.2	0	93	100
6	32	1.00	1.70	1.71	0.67	1.8	1	119	108
7	32	0.28	0.79	0.07	0.00	28.1	0	92	100
8	24	0.00	0.99	0.62	0.74	6.5	0	103	100
9	23	0.00	1.84	0.31	0.50	50.2	0	82	100
10	13	0.00	2.42	0.54	1.00	5.6	0	100	102

X_2: the speed of risk mitigation (the period for which the risk ratio reached 30 or less points/the development period). The reason why we use 30 points as a benchmark is because almost all projects which have reached their QCD (quality, cost, delivery) targets had a risk ratio of 30 points or less. When the risk ratio is 30 points or less from project beginning, X_2 is 0. When the risk ratio is 30 or more points until project completing, X_2 is 1.

X_3: the frequency of EVM (the frequency of EV analysis per development effort). We have some experiences that we can mitigate project risks with more frequent EV analysis because the manager can deal with problems early on.

X_4: the frequency of review (the frequency of review *per* development effort). We have some experiences that a quality project makes review activity frequently.

X_5: the pass rate of review (the pass rate of the first review). The judgment level of the review ranges between 0 and 1.00.

X_6: the development effort measured by man-months.

74.3.2 Correlation Analysis

A result of correlation analysis among the explanatory and objective variables is shown in Table 74.9. From Table 74.9, we can consider the correlation as follows:

(1) X_1 has shown a strong correlation to X_2 and X_3.

(2) X_6 has also shown a strong correlation to X_4 and X_5.

(3) Y_2 out of three objective variables is influenced by X_6.

(4) X_1 and X_2 has shown a strong positive correlation to Y_1.

Based on the correlation analysis, X_2, X_3, X_4, and X_5 are selected as the important factors for estimating a quality prediction model because X_1 and X_6 have multicollinearity with explanatory variables X_i (i = 2, 3, 4, 5).

74.3.3 Principal Component Analysis

In a similar discussion to that in Section 74.2.3, we conduct the test of independence among explanatory variables X_i (i= 2, 3, 4, 5) for the principal component analysis. Then, we find that the precision of analysis is high from Table 74.10. Moreover, factor loading values are obtained as shown in Table 74.11. Let us denote the first and second principal components as follows:

Table 74.9. Correlation matrix for management process factors

	X_1	X_2	X_3	X_4	X_5	X_6	Y_1	Y_2	Y_3
X_1	1								
X_2	0.633	1							
X_3	-0.656	-0.354	1						
X_4	-0.338	0.125	0.332	1					
X_5	-0.302	0.050	0.238	0.290	1				
X_6	0.418	-0.132	-0.233	-0.504	-0.545	1			
Y_1	0.651	0.643	-0.455	-0.289	-0.072	0.202	1		
Y_2	0.352	0.738	-0.275	0.475	0.302	-0.479	0.589	1	
Y_3	0.597	0.501	-0.282	0.125	-0.000	0.305	0.566	0.570	1

- The first principal component is defined by the measure for evaluating total project management.
- The second principal component is defined by the measure for discriminating the process factors as the risk management activity factors (X_2, X_4, X_5) and the project management activity factor (X_3).

As a result of correlation analysis and principal component analysis, X_2, X_3, and X_4 are selected as the important factors for a software management model because X_4 and X_5 have not a high degree of independence as shown in Figure 74.5, and X_5 has a low correlation to Y_1, Y_2, and Y_3 from the correlation analysis.

Table 74.10. Summary of eigenvalues and principal components

Component	Eigenvalue	Contribution ratio	Cumulative contribution ratio
1	1.598	0.399	0.399
2	1.226	0.307	0.706
3	0.730	0.183	0.889
4	0.446	0.111	1.000

Table 74.11. Factor loading values

	Component 1	Component 2
X_2	-0.276	0.881
X_3	0.800	-0.360
X_4	0.694	0.431
X_5	0.632	0.368

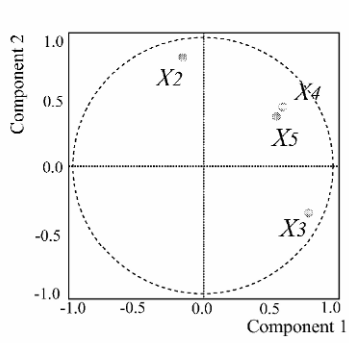

Figure 74.5. Scatter plot of the factor loading values

74.3.4 Multiple Linear Regression

A multiple linear regression analysis is applied to the management process data as shown in Table 74.8. However, the goodness-of-fit adequacy of two models about Y_1 and Y_3 is not so good because R^2 is calculated as 0.563 for Y_1 and 0.277 for Y_3, and adjusted R^2 is calculated as 0.344 for Y_1 and -0.084 for Y_3. As a result, the estimated multiple regression equation is obtained by using X_2, X_3, and X_4 as explanatory variables, and development cost (Y_2) as on objective variable. Then, we have the estimated multiple-regression equation for predicting the development cost of software project, $\hat{Y}_2$, given by (74.4) as well as the normalized multiple regression expression, $\hat{Y}_2^N$, given by (74.5):

$$\widehat{Y}_2 = 93.069 + 16.067X_2 - 3.136X_3 + 10.773X_4, \quad (74.4)$$

$$\widehat{Y}_2^N = 0.601X_2 - 0.219X_3 + 0.473X_4. \quad (74.5)$$

In order to check the goodness-of-fit adequacy of our model, R^2 calculated as 0.728. Furthermore, adjusted R^2 is given by 0.592. The results of multiple linear regression analysis are summarized in Tables 74.12 and 74.13.

From (74.5), the explanatory variables affecting the objective variable Y_2 are X_2 and X_4. It is found that "the speed of risk mitigation" and "the frequency of review" have an important impact on Y_2.

By using (74.5) the predicted and actual measurement values are as shown in Figure 74.6, which shows that the development cost can be predicted with high accuracy.

Table 74.12. Estimated parameters

Factors	Coefficient	SE	t-value	Standard coefficient
Intercept	93.069	6.568	14.171	0.000
X_2	16.067	6.325	2.540	0.601
X_3	-3.136	3.567	-0.879	-0.219
X_4	10.773	5.349	2.014	0.473

Table 74.13. Table of analysis of variance

Error	323.512	6	53.919	
Total	1190.0	9		

74.3.5 The Effect of Management Process Factors

We have shown the following correlation between management process factors and the development cost:

- Through a regression analysis, it has become clear that the speed of risk mitigation has had an important impact factor on the development cost.
- Early-stage risk mitigation in software projects is important in shortening the difference between predicted and actual development costs.
- We have found that the review activity is very important as a management process factor as well as a quality assurance process factor because the frequency of review affects the development cost.
- The passing status of reviews has not affected the development cost. Then, we have to consider this issue in the assessment method of review activities.

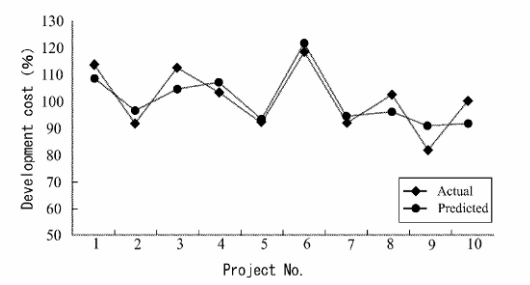

Figure 74.6. Accuracy for predicting the development cost

74.3.6 Relationship Between Development Cost and Effort

As a result of correlation analysis, we find that the development cost (Y_2) and the development effort (X_6) have a correction. Then, a multiple linear regression analysis has conducted again by normalizing the development cost as $Z_2 \equiv Y_2/X_6$. That is, a multiple linear regression analysis is conducted based on explanatory variables of X_2, X_3, and X_4, and a objective variable of Z_2. Then, we have the estimated multiple regression (for the normalized development cost, $\hat{Z}_2$, given by (74.6) as well as the normalized multiple regression expression, $\hat{Z}_2^N$, given by (74.7):

$$\hat{Z}_2 = -3.907 + 9.148X_2 - 0.659X_3 + 36.142X_4, \quad (74.6)$$

$$\hat{Z}_2^N = 0.204X_2 - 0.027X_3 + 0.947X_4. \quad (74.7)$$

In order to check the goodness-of-fit adequacy of our model, R^2 is calculated as 0.974. Furthermore, adjusted R^2 is given by 0.960. The result of multiple linear regression analysis is summarized in Tables 74.14 and 74.15.

From (74.7) the explanatory variable affecting the objective variable is X_4. It is found that the frequency of review has an important impact on $\hat{Z}_2$.

By using (74.6) the predicted value and actual measurement values are as shown in Figure 74.7, which shows that the normalized development cost can be predicted with high accuracy.

Table 74.14. Estimated parameters

Factor	Coefficient	SE	t-value	Standard coefficient
Intercept	-3.907	3.431	-1.139	0.000
X_2	9.148	3.304	2.769	0.204
X_3	-0.659	1.863	-0.353	-0.027
X_4	36.142	2.794	12.933	0.947

Error	88.29	6	14.71	
Total	3339.17	9		

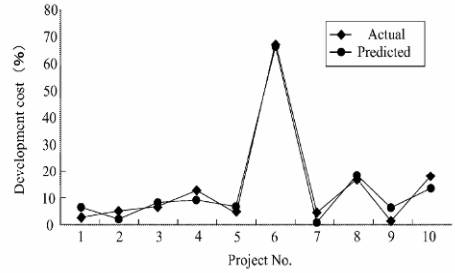

Figure 74.7. Accuracy for predicting the development cost

74.4. Relationship Between Product Quality and Development Cost

In the preceding section, we have shown the relationship between management process factors and the development cost (Y_2) instead of the number of faults (Y_1). Assuming that there is a logarithmic linearity relation between the number of faults and the development cost (Y_2), we conduct logarithmic linear regression analysis by using the mathematical expression:

$$Y_2 = a(1 + Y_1)^b. \tag{74.8}$$

Then, we have the estimated regression and 95% confidence limits as shown in Figure 74.8,

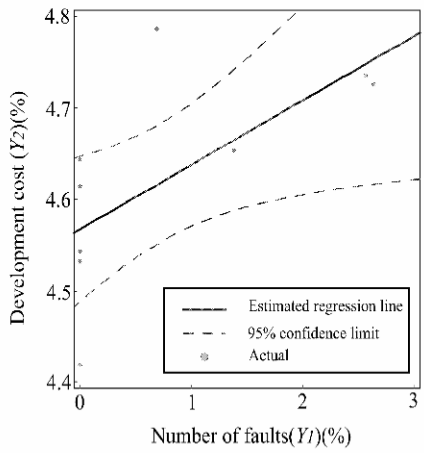

Figure 74.8. Relationship between the number of faults (Y_1) and the development cost (Y_2)

where the estimated parameters are given as $a = 0.07$ and $b = 4.57$.

As a result of analysis of variance, we find that the reliability of regression analysis is high as shown in Table 74.16. And we also have the estimated exponential curve in Figure 74.9, which shows the interdependency between the number of faults (Y_1) and the development cost (Y_2).

74.5 Discriminant Analysis

A discriminant analysis is conducted by using the process data as shown in Table 74.8. Based on the same selected explanatory variables as the multiple regression analysis, X_2, X_3, and X_4 are selected for explanatory variables. The response variable for a discriminant analysis, Z, is defined as follows:

- Z=1: The software product released for user operation will experience no software failure.
- Z=2: The software product released for user operation will experience more than 0 of software failures.

Then, we have the estimated discriminant (for software product quality given by (74.9) as follows:

$$Z = -27.059X_2 + 2.588X_3 - 3.903X_4 + 13.745. \quad (74.9)$$

In order to check the goodness-of fit adequacy of our model, the Mahalanobis distance (D_2) is checked, and given as 39.519. Furthermore, the discrimination error rate has been checked, and given as 0.084. Therefore, the goodness-of-fit of this discriminant (is very high.

If the discrimination score in (74.9) is more than 0, the response variable is discriminated 1, otherwise 2. The discriminated response variables in (74.9 and actual measurement values are shown in Table 74.17 where we apply actual measurement values in all ten projects to the discriminated variables. Therefore, the discriminant (in (74.9) can judge whether or not the software project has a quality process with high accuracy.

74.6 Conclusion

In this chapter we have derived quality prediction models by using early-stage process measurement data. As a result of analysis of variance for quality assurance process factors, we have obtained a quality prediction model with five levels of significant. Based on the quality prediction model, we have found that the rate of design review delay and the frequency of review have an impact on product quality; that is, effective quality and review management can reduce the number of faults detected in the final testing.

As a result of analysis for management process factors, we have obtained a software management model with five levels of significance. Based on the software management model, we have found that the speed of risk mitigation and the frequency of review have an impact on the development cost on management activity. That is, it is very important to involve early-stage mitigation of risk and frequent review activities in software project management. Furthermore, we have been able to establish the relationship between product quality and the development cost.

Finally, based on the process data derived from effective management process factors, we have derived a discriminant expression that can judge whether or not the software project has a quality process.

Abstract: In this chapter we discuss the software reliability growth models (SRGMs) that describe the relationship between the number of faults removed and the number of test cases used. Firstly we describe the discrete exponential and S-shaped models in a perfect debugging environment. We also discuss flexible discrete SRGM, which can depict either exponential or S-shaped growth curves, depending upon the parameter values estimated from the past failure data. Further, we describe an SRGM for the fault removal phenomenon in a perfect debugging environment. Most testing processes are imperfect in practice, therefore we also discuss a discrete model that incorporates the impact of imperfect debugging and fault generation into software reliability growth modeling. Faults in the software are generally not of the same type, rather the faults contained in a large software may differ from each other in terms of the amount of time and skill of the removal team required to remove them. Three discrete models: the generalized Erlang model, modeling severity of faults with respect to testing time, and a model with faults of different severity incorporating logistic learning function have been discussed. A discrete model in a distributed environment is also discussed. The above discrete SRGMs assume a constant fault detection rate while testing the software under consideration. In practice, however, the fault detection rate varies because of changes in the testing skill, the system environment, and the testing strategy used to test the software. SRGMs for the fault removal phenomenon, the generalized Erlang model, and the generalized Erlang model with logistic function are discussed, incorporating the concept of change point. It is also shown how equivalent continuous models can be derived. This chapter describes the state-of-the-art in discrete modeling.

75.1 Introduction

In the last two decades of the 20th century the proliferation of information technology has gone far beyond even the most outrageously optimistic forecasts. Consequently, computers and computer-based systems now pervade every aspect of our daily lives. While this has benefited society and increased our productivity, it has also made our lives more critically dependent on the correct functioning of these systems. There are already numerous instances where the failure of computer-controlled systems has led to colossal loss of human lives and money.

The successful operation of any computer system depends largely on its software components. The revolutionary advancement in the

computer technology has posed several challenges to the management of software crisis. In the early 1970s, the software engineering discipline emerged to establish and use sound engineering principles in order to economically obtain software systems that are not only reliable but also work efficiently in real machines, thus bringing the software development under the engineering umbrella. The immediate concern of software engineering was aimed at developing highly reliable software, scheduling and systematizing the software development process at reduced costs.

The most desirable attribute of software is quality. Using well-established software engineering methodologies developers can design high quality software. Software engineering is the discipline that aims to provide methods and procedures for developing quality software systems. There exist a number of models describing the software development process, commonly known as life cycle models. Most of the models model the SDLC in the following stages: requirement analysis and definition, system design, program design, coding, testing, and system delivery, maintenance. Even though highly skilled professionals develop software under an efficient management, the developer must measure the quality of software before release in order to provide guarantees and reduce the loss of finance and goodwill.

The testing phase is an extremely important stage of SDLC, in which around half the development resources are consumed. Testing consists of three successive stages: unit testing, integration testing, and system testing. In the phase test, cases that simulate the user environment are run on the software, and any departure from specifications or requirements is called a failure, and an effort is immediately an effort to remove the cause of that failure. Therefore, it is important to understand the failure pattern and faults causing the failures. Reliability is the most important quality metric used to measure the quality of software. It can provide vital information for the software release decision.

Many software reliability growth models (SRGMs) have been developed in the last two decades and can describe the reliability growth during the testing phase of the software development. Most of these models describe either exponential or S-shaped reliability growth curves. A large munber of proposed SRGMs are based on the non-homogeneous Poisson process (NHPP). NHPP based SRGMs are generally classified into two categories. The first category of the models, which use calendar/execution time as a unit of the failure/fault removal process, are known as continuous time SRGMs. The other category of models, which use the test cases as a unit of the failure/fault removal process, are known as discrete time SRGMs.

Among all SRGMs a large family of stochastic reliability models based on NHPP [11] reliability models, has been widely used. SRGMs based on NHPP are fault-counting models. Goel and Okumoto [2] have proposed NHPP based SRGM assuming that the failure intensity is proportional to the number of faults remaining in the software describing exponential failure curves. Ohba [21] refined the Goel–Okumoto model by assuming that the fault detection/removal rate increases with time, and that there are two types of faults in the software. The SRGM proposed in [1] has similar forms as that in [21], but is developed under a different set of assumptions. These models can describe both exponential and S-shaped growth curves and, therefore, are termed flexible models. Similar SRGMs that describe the failure phenomenon with respect to testing efforts have been developed in the literature [3], [20], and [22]. Models proposed in [5], [10], [11] and [18] incorporate some realistic issues such as imperfect debugging, fault generation and learning phenomenon of software testing team. Categorization of faults, faults of different severity, faults removal as two-stage and three-stage process, *etc*., has also been developed [17].

NHPP based SRGMs are generally classified into two groups. First, models that use the execution time (*i.e.*, CPU time) or calendar time. Such models are called continuous time models. Second, models, which use the test cases as a unit of fault removal period. Such models are called discrete time models [4], [9], and [20]. A test case can be a single computer test run executed in an hour, day, week, or even month. Therefore, it

includes the computer test run and the length of time spent on its execution. A large number of models have been developed in the first group, while there are fewer in the second group due to the difficulties in terms of the mathematical complexity involved. The utility of discrete reliability growth models cannot be underestimated. As the software failure data sets are discrete, these models many a time provide better fit than their continuous time counterparts. In this chapter, we discuss briefly several discrete SRGMs based on NHPP, developed in the literature.

75.1.1 Notation

a : Initial fault-content of the software

b : Constant fault removal rate *per* remaining fault *per* test case.

$m(n)$: The expected mean number of faults removed by the *n*th test case.

$m_f(n)$: The expected mean number of failures incurred by the *n*th test case.

$m_r(n)$: The expected mean number of removals incurred by the *n*th test case

d : Constant for rate of increase in delay

p : Proportion of leading faults in the software

$m_1(t)$: Expected number of leading faults detected in the interval (0, t].

$m_2(t)$: Expected number of dependent faults detected in the interval (0, t].

n : Number of test occasions.

a_i: Fault-content of type $_i$ and $\left(\sum_{i=1}^{k} a_i = a\right)$, where a is the total fault-content

b_i: Proportionality constant failure rate/fault isolation rate *per* fault of type i

$b_i(n)$: Logistic learning function, *i.e.*, fault removal rate *per* fault of type i

$m_{if}(n)$: Mean number of failure caused by fault-type i by n test cases.

$m_{ii}(n)$: Mean number of fault-isolated of fault-type i by n test cases.

$m_{ir}(n)$: Mean number of faults removed of fault-type i by n test cases.

β: Constant parameter in the logistic learning-process function.

$W(n)$: The cumulative testing resources spent up to the *n*th test run.

$w(n)$: The testing resources spent on the n^{th} test run

Definition: We define $t = n\delta$ and $\lim_{x \to 0} (1+x)^{\frac{1}{x}} = e$.

75.2 Discrete Software Reliability Growth Models

SRGM describes the failure or a removal phenomenon during the testing and operational phases. Using the data collected over a period of time of the on-going testing and based on some assumption of the testing environment, one can estimate the number of faults that can be removed by a specific time t and hence the reliability. Several discrete SRGMs have been proposed in literature under different sets of assumptions. Here we discuss and review briefly discrete SRGM based on NHPP.

The general assumptions of discrete NHPP based SRGM are:

1. The failure observation/fault removal phenomenon is modeled by NHPP with the mean value function $m(n)$.
2. Software is subject to failures during execution caused by faults remaining in the software.
3. Each time a failure is observed, an immediate effort takes place to remove the cause of failure.
4. The failure rate is equally affected by faults remaining in the software.

Under these general assumptions and some specific assumptions based on the testing environment different models are developed.

75.2.1 Discrete SRGM in a Perfect Debugging Environment

During the debugging process on a failure, the testing team reports the failure to the fault removal team (programmers), who identify the corresponding fault and make attempts to remove them. Most SRGM assume a perfect debugging environment, *i.e.*, whenever an attempt is made to remove a fault it is removed perfectly. However, in practical situations three possibilities are observed. First the fault is removed perfectly, secondly the fault is not removed perfectly due to which the fault content remains unchanged, known as imperfect fault debugging, and third, the fault is removed perfectly, but a new fault is generated during removal, known as fault generation. In the next section we discuss some discrete SRGMs that assume a perfect debugging environment. During the removal process, however, the testing team may remove some additional faults without these faults causing failure while removing an identified fault. These models are also discussed here

75.2.1.1 The Discrete Exponential Model [25]

Under the basic assumption, the expected cumulative number of faults removed between the nth and the (n+1)th test cases is proportional to the number of faults remaining after the execution of the nth test run , satisfies the following difference equation:

$$\frac{m(n+1)-m(n)}{\delta} = b(a-m(n)) \qquad (75.1)$$

Multiplying both sides of (75.1) by z^n and summing over n from 0 to ∞ , we get

$$\sum_{n=0}^{\infty} z^n m(n+1) - \sum_{n=0}^{\infty} z^n m(n) = ab\delta \sum_{n=0}^{\infty} z^n - b\delta \sum_{n=0}^{\infty} z^n m(n)$$

Solving the above difference equation under the initial condition $m(n=0)=0$ and using a probability generating function (PGF) given as

$$P(z) = \sum_{n=0}^{\infty} z^n m(n) \qquad (75.2)$$

we get the solution as

$$m(n) = a(1-(1-b\delta)^n) \qquad (75.3)$$

The model describes an exponential failure growth curve. The equivalent continuous SRGM [2] corresponding to (75.3), is obtained taking limit $\delta \to 0$

$$m(n) = a(1-(1-b\delta)^n) \to a(1-e^{-bt}) \qquad (75.4)$$

75.2.1.2 The Discrete Modified Exponential Model [25]

Assuming that the software contains two types of faults, type I and type II, we can write the differential equation corresponding to faults of each type as

$$\frac{m_1(n+1)-m_1(n)}{\delta} = b_1(a_1 - m_1(n)) \qquad (75.5)$$

and

$$\frac{m_2(n+1)-m_2(n)}{\delta} = b_2(a_2 - m_2(n)) \qquad (75.6)$$

where $a = a_1 + a_2$ and $b_1 > b_2$

On solving the above equation by the method of PGF we get

$$m_1(n) = a_1(1-(1-b_1\delta)^n)$$

$m_2(n) = a_2(1-(1-b_2\delta)^n)$, So

$$m(n) = m_1(n) + m_2(n) = \sum_{i=1}^{2} a_i(1-(1-b_i\delta)^n) \qquad (75.7)$$

The equivalent continuous SRGM proposed in [24] corresponding to (75.7), is obtained taking limit $\delta \to 0$.

$$m(n) = \sum_{i=1}^{2} a_i\left(1-(1-b_i\delta)^n\right) \to \sum_{i=1}^{2} a_i\left(1-e^{-b_i t}\right)$$

(75.8)

75.2.1.3 The Discrete Delayed S–shaped Model [6]

This model describes the debugging process in two phases. First, on the execution of a test case a failure is observed, and second, on a failure the corresponding fault is removed.

Accordingly, following the general assumptions of a discrete SRGM the testing process can be modeled as a two-stage process. The difference equations corresponding to each phase are given as

$$\frac{m_f(n+1)-m_f(n)}{\delta} = b(a-m_f(n)) \qquad (75.9)$$

and

$$\frac{m_r(n+1)-m_r(n)}{\delta} = b(m_f(n+1)-m_r(n)) \qquad (75.10)$$

Solving (75.9) by the method of PGF and the initial condition $m_f(n=0)=0$, we get

$$m_f(n) = a(1-(1-b\delta)^n) \qquad (75.11)$$

Substituting value of $m_f(n+1)$ from (75.11) in (75.10) and solving by the method of PGF with initial condition $m_r(n=0)=0$ we get

$$m_r(n) = a[1-(1+bn\delta)(1-b\delta)^n] \qquad (75.12)$$

The equivalent continuous SRGM corresponding to (75.12), is obtained taking limit $\delta \to 0$, *i.e.*,

$$m_r(n)=a[1-(1+bn\delta)(1-b\delta)^n] \to a(1-(1+bt)e^{-bt}) \qquad (75.13)$$

The continuous model is due to [23] and describes the delayed fault removal phenomenon.

75.2.1.4 The Modeling Fault Removal Phenomenon

The test team can remove some additional faults in the software, without these faults causing any failure during the removal of identified faults, although this may involve some additional effort. A fault that is removed consequent to a failure, is known as a leading fault, whereas the additional faults removed, which may have caused failures in future, are known as dependent faults. Models discussed in this section consider the effect of removing dependent faults while removing leading faults.

Discrete SRGM for the Fault Removal Phenomenon [15]

Under the assumption that while removing leading faults the testing team may remove some dependent faults, the difference equation for the model can be written as

$$m_r(n+1)-m_r(n)=b[a-m_r(n)]+\frac{c}{a}m_r(n+1)[a-m_r(n)] \qquad (75.14)$$

where b and c are the rates of leading and dependent fault detection, respectively.

Solving (75.14) by the method of PGF and initial condition $m(n=0)=0$, we have

$$m_r(n) = a\left[\frac{1-\{1-(b+c)\}^n}{1+\frac{c}{b}\{1-(b+c)\}^n}\right] \qquad (75.15)$$

If the difference equation (75.14) is rewritten as

$$\frac{m_r(n+1)-m_r(n)}{\delta}=b[a-m_r(n)]+\frac{c}{a}m_r(n+1)[a-m_r(n)] \qquad (75.16)$$

we get $$m_r(n) = a\left[\frac{1-\{1-\delta(b+c)\}^n}{1+\frac{c}{b}\{1-\delta(b+c)\}^n}\right] \qquad (75.17)$$

The equivalent continuous SRGM [5], corresponding to (75.17) is obtained taking, *i.e.,* limit $\delta \to 0$.

$$m_r(n)=a\left[\frac{1-\{1-\delta(b+c)\}^n}{1+\frac{c}{b}\{1-\delta(b+c)\}^n}\right] \to a\left[\frac{1-e^{-(b+c)t}}{1+\frac{c}{b}e^{-(b+c)t}}\right] \qquad (75.18)$$

Discrete SRGM with Fault Dependency using Lag Function [12]

This model is based on the assumption that there exists definite time lag between the detection of leading faults and the corresponding dependent faults. Assuming that the intensity of dependent fault detection is proportional to the number of dependent faults remaining in the software and the ratio of leading faults removed to the total leading faults, the difference equation for leading faults is given as

$$m_1(n+1)-m_1(n) = b[ap-m_1(n)] \qquad (75.19)$$

Solving (75.19) with the initial condition $m_1(n=0)=0$, we get

$$m_1(n) = ap\left[1-(1-b)^n\right] \qquad (75.20)$$

The dependent fault detection can be put as the following differential equation:

$$m_2(n+1)-m_2(n)=c[a(1-p)-m_2(n)]\frac{m_1(n+1-\Delta n)}{ap} \qquad (75.21)$$

where Δn is the lag depending upon the number of test occasions.

When $\Delta n = \log_{(1-b)^{-1}}(1 + dn)$, we get $m_2(n)$ under with the initial condition $m_2(n = 0) = 0$ as

$$m_2(n) = a(1-p)\left[1 - \prod_{i=1}^{n}\left\{1 - c\left(1 - (1-b)^{i}(1+(i-1)d)\right)\right\}\right] \quad (75.22)$$

Hence, the expected total number of faults removed in n test cases is

$$m(n) = a\left[1 - p(1-b)^{n} + (1-p)\prod_{i=1}^{n}\left\{1 - c(1-(1-b)^{i}(1+(i-1)d)\right\}\right] \quad (75.23)$$

The equivalent continuous SRGM due to [12] corresponding to discrete mean value function given by (75.23) is due to [2]

$$m(t) = a\left[1 - pe^{-bt} - (1-p)e^{-cf(t)}\right] \quad (75.24)$$

Where $f(t) = t + \frac{1}{b}(1+\frac{d}{b})(e^{-bt} - 1) + \frac{d}{b}te^{-bt}$

Discrete SRGM In an Imperfect Debugging Environment [18]

In this section we discuss discrete SRGM with two types of imperfect debugging, namely imperfect fault debugging and fault generation. During the removal process if a fault is repaired imperfectly we reencounter a failure on execution of the same input due to which the actual fault removal is less than the removal attempts. Therefore, the FRR is reduced by the probability of imperfect fault debugging. Besides, there is a good chance that some new faults will be introduced during removal. The difference equation for a discrete SRGM in an imperfect debugging environment incorporating two types of imperfect debugging and learning process of the testing team as testing progresses is given by:

$$\frac{m_r(n+1) - m_r(n)}{\delta} = b(n+1)\left(a(n) - m_r(n)\right) \quad (75.25)$$

Let us define

$$a(n) = a_0(1 + \alpha\delta)^n \quad (75.26)$$

$$b(n+1) = \frac{b_0 p}{1 + \beta(1 - b_0 p\delta)^{n+1}} \quad (75.27)$$

An increasing *a(n)* implies an increasing total number of faults, and thus reflects fault generation. Whereas, *b(n+1)* is a logistic learning function representing the learning of the testing team and is affected by the probability of fault removal on a failure.

Substituting the above forms of *a*(*n*) and b(*n+1*) in the difference equation (75.25) and solving by the PGF method, the closed form solution is

$$m_r(n) = \frac{a_0 b_0 p\delta}{1+\beta(1-b_0 p\delta)^n}\left[\frac{(1+\alpha\delta)^n - (1-b_0 p\delta)^n}{(\alpha\delta + b_0 p\delta)}\right] \quad (75.28)$$

where $mr(n = 0) = 0$ and $mr(n = \infty) = \infty$.

If the imperfect fault debugging parameter $p = 1$ and fault generation rate $\alpha = 0$, *i.e.*, the testing process is perfect, then *mr*(*n*) given by expression (75.28) reduces to

$$m_r(n) = a_0\left[\frac{1 - (1 - b_0\delta)^n}{1 + \beta(1 - b_0\delta)^n}\right] \quad (75.29)$$

which is perfect debugging discrete SRGM with logistic learning function. The equivalent continuous SRGM corresponding to (75.29) is obtained taking limit $\delta \to 0$

$$\frac{a_0 b_0 p\delta}{1+\beta(1-b_0 p\delta)^n}\left[\frac{(1+\alpha\delta)^n - (1-b_0 p\delta)^n}{(\alpha\delta + b_0 p\delta)}\right] \to \frac{a_0 b_0 p}{1+\beta e^{-b_0 p t}}\left[\frac{e^{\alpha t} - e^{-b_0 p t}}{\alpha + b_0 p}\right] \quad (75.30)$$

The equivalent continuous model is an extension of [6] with imperfect fault removal and fault generation [17]. Besides its interpretation as a flexible S-shaped fault removal model, this model has the exponential model [23] and the imperfect debugging model [13] as special cases.

75.2.2 Discrete SRGM with Testing Effort

During testing, resources such as manpower and time (computer time) are consumed. The failure, fault identification, and removal are dependent upon the nature and amount of resources spent. The time dependent behavior of the testing effort has been studied earlier in [3], [20], and [22] for continuous time models. exponential, Rayleigh, logistic, and Weibull functions are used to describe the relationship between the testing effort consumption and testing time (the calendar time). Here we discuss a discrete SRGM with testing

effort. Assuming $w(n)$ is described by a discrete Rayleigh curve, we may write

$$w(n+1) = W(n+1) - W(n) = \beta(n+1)\left[\alpha - W(n)\right] \quad (75.31)$$

Solving (75.31) using PGF, we get

$$W(n) = \alpha\left(1 - \prod_{i=0}^{n}(1 - i\beta)\right) \quad (75.32)$$

and hence

$$w(n) = \alpha\beta n\prod_{i=0}^{n-1}(1 - i\beta) \quad (75.33)$$

Under the above assumptions, the difference equation for the SRGM is written as

$$\frac{m(n+1) - m(n)}{w(n)} = b\left(a - m(n)\right) \quad (75.34)$$

Solving (75.34) using PGF we get [7]

$$m(n) = a\left(1 - \prod_{i=0}^{n}\left(1 - bw(i)\right)\right) \quad (75.35)$$

75.2.3 Modeling Faults of Different Severity

The SRGMs discussed above assume that the faults in the software are of the same type. This assumption implies that the fault removal rate *per* remaining fault is independent of the testing time. However, this assumption is not truly representative of reality. The faults contained in large software may differ from each other in terms of the amount of time and skill of the removal team required to remove the fault. Accordingly, the faults can be distinguished as simple (fault type I), hard (fault type II), complex faults (fault type III), and so on. In the next section we discuss the models conceptualizing the concept of faults of different severity.

75.2.3.1 Generalized Discrete Erlang SRGM [11]

Assuming that the software consists of n different types of faults and on each type of fault a different strategy is required to remove the cause of failure due to that fault. We assume that for a type i (i =I, II,..., k) fault, i different processes (stages) are required to remove the cause of failure. Accordingly we may write the following difference equations for faults of each type .

Modeling Simple Faults (Fault Type I)

The simple fault removal is modeled as a one-stage process

$$m_{i1}(n+1) - m_{i1}(n) = b_i(a_i - m_{i1}(n)) \quad (75.36)$$

Modeling Hard Faults (Fault Type II)

The harder type of faults is assumed to require more testing effort. The removal process for such faults is modelled as a two-stage process.

$$\begin{aligned} m_{i1}(n+1) - m_{i1}(n) &= b_i(a_i - m_{i1}(n)) \\ m_{i2}(n+1) - m_{i2}(n) &= b_i(m_{i1}(n+1) - m_{i2}(n)) \end{aligned} \quad (75.37)$$

Modeling Fault Type k

The modeling procedure of the hard fault can be extended to formulate a model that describes the removal of a fault type k with k stages of removal.

$$\begin{aligned} m_{i1}(n+1) - m_{i1}(n) &= b_i(a_i - m_{i1}(n)) \\ m_{ik}(n+1) - m_{ik}(n) &= b_i(m_{ik-1}(n+1) - m_{ik}(n)) \end{aligned} \quad (75.38)$$

The first subscript stands for the type of fault and the second subscript stands for the number of processes (stages).

Solving the above difference equation, we get

$$m_k(n) = m_{kk}(n) = a_k(1 - (1 - b_k)^n \left(\sum_{j=0}^{k-1}\frac{b_k^j}{j!(n+j)}\prod_{l=0}^{j}(n+l)\right) \quad (75.39)$$

Since $m(n) = \sum_{i=1}^{k} m_i(n)$, we get

$$m(n) = \sum_{i=1}^{k} a_i(1 - (1 - b_i)^n)\left(\sum_{j=0}^{i-1}\frac{b_i^j}{j!(n+j)}\prod_{l=0}^{j}(n+l)\right) \quad (75.40)$$

In particular, we have

$$m_1(n) = m_{11}(n) = m_1(1 - (1 - b_1)^n)$$

$$m_2(n) = m_{22}(n) = a_2(1 - (1 + b_2 n)(1 - b_2)^n) \text{ and}$$

$$m_3(n) = m_{33}(n) = a_3\left(1 - \left(1 + b_3 n + \frac{b_3^2 n(n+1)}{2}\right)(1 - b_3)^n\right)$$

The removal rate per fault for the above three types of faults is given as

$$d_1(n) = b, \qquad d_2(n) = \frac{b_2^2(n+1)}{b_2 n\delta + 1} \qquad \text{and}$$

$$d_3(n) = \frac{b_3^3(n^2+3n+2)}{2(b_3^2 \frac{n(n+1)}{2} + b_3 n + 1)}$$

respectively. We observe that $d_1(n)$ is constant with respect to n_1 while $d_2(n)$ and $d_3(n)$ increase with n and tend to b_2 and b_3 as $n \to \infty$. Thus in the steady state, $m_2(n)$ and $m_3(n)$ behave similarly to $m_1(n)$ and hence there is no loss of generality in assuming steady state rates b_2 and b_3 equal to b_1. Generalizing for arbitrary k, we can assume $b_1 = b_2 = ... = b_k = b$ (say). We thus have

$$m_k(n) \equiv m_{kk}(n) = a_k(1-(1-b)^n \left(\sum_{j=0}^{k-1} \frac{b^j}{j!(n+j)} \prod_{l=0}^{j} (n+l) \right)$$

(75.41)

and

$$m(n) = \sum_{i=1}^{k} a_i (1-(1-b)^n \left(\sum_{j=0}^{i-1} \frac{b^j}{j!(n+j)} \prod_{l=0}^{j} (n+l) \right) \quad (75.42)$$

The equivalent continuous time model [8], modeling faults of different severity is

$$m(t) = \sum_{i=1}^{k} a_i \left[1 - e^{-b_i t} \left(\sum_{j=0}^{i-1} \frac{(b_i t)^j}{j!} \right) \right] \quad (75.43)$$

which can be derived as a limiting case of discrete model substituting $t = n\delta$ and taking limit $\delta \to 0$.

Discrete SRGM with Faults of Different Severity Incorporating Logistic Learning Function [14]

Kapur *et al*., incorporated a logistic learning function during the removal phase, for capturing variability in the growth curves depending upon the environment it is being used and learning-process of the test team as the number of test run executed increases for modeling faults of different severity. Such a framework is very much suited for object-oriented programming and distributed development environments. Assuming that the software contains finite number of fault types and that the time delay between the failure observations and its subsequent removal represents the severity of the faults, the concept of faults of different severity can be modeled as follows:

Modeling the Simple Faults (i.e., Fault Type I)

The simple fault removal is modeled as a one-stage process

$$m_{1r}(n+1) - m_{1r}(n) = b_1(n+1)(a_1 - m_{1r}(n)) \quad (75.44)$$

where $b_1(n+1) = b_1$

Solving the above difference equation using the PGF with the initial condition, $m_{1r}(n=0)=0$, we get

$$m_{1r}(n) = a_1(1-(1-b_1)^n) \quad (75.45)$$

Modeling Hard Faults (Fault Type II)

The harder type of faults is assumed to take more testing effort. The removal process for such faults is modelled as a two-stage process,

$$m_{2f}(n+1) - m_{2f}(n) = b_2(a_2 - m_{2f}(n)) \quad (75.46)$$

$$m_{2r}(n+1) - m_{2r}(n) = b_2(n+1)(m_{2f}(n+1) - m_{2r}(n))$$

where $b_2(n+1) = \frac{b_2}{1+\beta(1-b_2)^{n+1}}$.

Solving the above system of difference equations using the PGF with the initial conditions $m_{2f}(n=0)=0$ and $m_{2r}(n=0)=0$ we get

$$m_{2r}(n) = a_2 \frac{1-(1-b_2 n)(1-b_2)^n}{1+\beta(1-b_2)^n} \quad (75.47)$$

Modeling Complex Faults (Fault Type III)

The complex fault removal process is modelled as a three-stage process,

$$m_{3f}(n+1) - m_{3f}(n) = b_3(a_3 - m_{3f}(n)) \quad (75.48)$$

$$\frac{m_{3i}(n+1) - m_{3i}(n)}{\delta} = b_3(m_{3f}(n+1) - m_{3i}(n)) \quad (75.49)$$

$$m_{3r}(n+1) - m_{3r}(n) = b_3(n+1)(m_{3i}(n+1) - m_{3r}(n)) \quad (75.50)$$

where $b_3(n+1) = \frac{b_3}{1+\beta(1-b_3)^{n+1}}$

Solving the above system of difference equations using the PGF with the initial conditions $m_{3f}(n=0)=0$, $m_{3i}(n=0)=0$ and $m_{3r}(n=0)=0$, we get

$$m_{3r}(n) = a_3 \frac{1-(1-b_3 n + \frac{b_3^2 n(n+1)}{2})(1-b_3)^n}{1+\beta(1-b_3)^n} \quad (75.51)$$

Modeling Fault Type k

The modeling procedure of the complex fault can be extended to formulate a model that describes the removal of a fault type *k* with *r* stages of removal.

$$m_{kf}(n+1)-m_{kf}(n)=b_k(a_k-m_{kf}(n)) \quad (75.52)$$

$$m_{kq}(n+1)-m_{kq}(n)=b_k(m_{kf}(n+1)-m_{kq}(n)) \quad (75.53)$$

$$m_{kr}(n+1)-m_{kr}(n)=b_k(n+1)(m_{k(r-1)}(n+1)-m_{kr}(n)) \quad (75.54)$$

where $b_k(n+1)=\dfrac{b_k}{1+\beta(1-b_k)^{r+1}}$

Solving the above system of difference equations using the PGF with the initial conditions, $m_{kf}(n=0)=m_{kf}(n=0)=m_{kr}(n=0)=0$, we get

$$m_{kr}(n)=a_k\frac{1-\left(1+\sum_{j=1}^{k-1}\frac{b_k^j}{j!(n+j)}\prod_{l=0}^{j}(n+l)\right)(1-b_k)^n}{(1+\beta(1-b_k)^n)} \quad (75.55)$$

Modeling the Total Fault Removal Phenomenon

The proposed framework is the superposition of the NHPP with mean value functions given in (75.45), (75.47), (75.51), and (75.55) Thus, the mean value function of the superposed NHPP is

$$m_{GF-k}(n)=\sum_{i=1}^{k}m_{ir}(n)=a_1(1-(1-b_1)^n)+\sum_{i=2}^{k}a_i\frac{1-\left(1+\sum_{j=1}^{i-1}\frac{b_i^j}{j!(n+j)}\prod_{l=0}^{j}(n+l)\right)(1-b_i)^n}{(1+\beta(1-b_i)^n)} \quad (75.56)$$

where $m_{GF-k}(n)$ provides the general framework with *k* types of faults.

The fault removal rate per fault for fault types 2 and 3 are given, respectively, as follows

$$d_1(n)=\frac{m_1(n+1)-m_1(n)}{a_i-m_1(n)}=b_i \quad (75.57)$$

$$d_2(n)=\frac{m_2(n+1)-m_2(n)}{a_2-m_1(n)}=\frac{b_2(1+\beta+b_2n)-b_2(1+\beta(1-b_2)^n)}{(1+\beta(1-b_2)^n)(1+\beta+b_2n)} \quad (75.58)$$

$$d_3(n)=\frac{b_3(1+\beta+b_3n+\frac{b_3^2n(n+1)}{2})-b_3(1+\beta(1-b_3)^n)(1+b_3n)}{(1+\beta(1-b_3)^n)(1+\beta+b_3n+\frac{b_3^2n(n+1)}{2})} \quad (75.59)$$

It is observed that $d_1(n)$ is constant with respect to *n,* while $d_2(n)$ and $d_3(n)$ increase monotonically with *n* and tend to constants b_2 and b_3 as $n\to\infty$. Thus, in the steady state, $m_{2r}(n)$ and $m_{3r}(n)$ behave similarly to $m_{1r}(n)$ and hence there is no loss of generality in assuming the steady state rates b_2 and b_3 to be equal to b_1. After substituting $b_2=b_3=b_1$ in the right hand side of (75.58) and (75.59), one can see that $b_1>d_2(n)>d_3(n)$, which is in accordance with the severity of the faults. Generalizing for arbitrary *k,* assuming $b_1=b_2=b_k=b$ (say) we may write (75.56) as follows:

$$m_{GF-k}(n)=\sum_{i=1}^{n}m_{ir}(n)=a_1\left(1-(1-b)^n\right)+\sum_{i=2}^{k}a_i\frac{1-\left(1+\sum_{j=1}^{i-1}\frac{b^j}{j!(n+j)}\prod_{l=1}^{j}(n+l)\right)(1-b)^n}{(1+\beta(1-b)^n)} \quad (75.60)$$

The equivalent continuous time model, modeling faults of different severity is

$$m_{GF-k}(t)=\sum_{i=1}^{n}m_{ir}(t)=a_1\left(1-e^{-bt}\right)+\sum_{i=2}^{k}a_i\frac{1-\left(\sum_{j=0}^{k-1}\frac{(bt)^j}{j!}\right)e^{-bt}}{(1+\beta e^{-bt})} \quad (75.61)$$

which can be derived as a limiting case of discrete model substituting $t=n\delta$ and taking, *limit* $\delta\to 0$.

75.2.3.2 Discrete SRGM Modeling Severity of Faults With Respect to Testing Time [17]

Faults can be categorized on the basis of their time to detection. During testing the faults, which are easily detected at the early stages of testing, are called simple faults or trivial faults. However, as the complexity of faults increases, so does the

detection time. Faults, which take maximum time for detection, are termed as complex faults.

For classification of faults, first we define non-cumulative instantaneous fault detection function $f(n)$ using discrete SRGM for fault removal phenomenon discussed in Section 75.2.1.4, which is given by first order difference equation of $m(n)$.

$$f(n)=\Delta m(n)=\frac{m(n+1)-m(n)}{\delta}= \frac{\overline{N}p(p+q)^2\left[1-\delta(p+q)\right]^n}{\left[p+q\left(1-\delta(p+q)\right)^n\right]\left[p+q\left(1-\delta(p+q)\right)^{n+1}\right]} \quad (75.62)$$

Above, $f(n)$ defines the mass function for non-cumulative fault detection. It takes the form of a bell-shaped curve and represents the rate of fault removal for n.

The peak of $f(n)$ occurs when

$$n=\begin{cases}[n^*] & \text{if } f[n^*])\geq f([n^*]+1)\\ [n^*]+1 & \text{otherwise}\end{cases} \quad (75.63)$$

Where $n^* = \dfrac{\log(p/q)}{\log(1-\delta(p+q))}-1$

and $\left[n^*\right]=\left\{n:\max\left(n\leq n^*\right),n\in Z\right\}$

Then as $\delta\to\mathbf{0}$, *i.e.* n^* converges to the inflection point of continuous S-shaped SRGM [5]

$$t^*=\frac{\delta\log(p/q)}{\log\left(1-\delta(p+q)\right)}-\delta \to -\frac{\log(p/q)}{p+q} \qquad as\,\delta\to 0$$

The corresponding $f(n^*)$ is given by

$$f(n^*)=\frac{\overline{N}(p+q)^2}{2q\left(2-\delta(p+q)\right)}\to f(t^*)=\frac{\overline{N}(p+q)^2}{4q}\ \text{s}\ \delta\to 0$$

The curve for $f(n)$, the non-cumulative fault detection is symmetric about point n^* up to $2n^*+1$.

Here $f(0)=f\left(2n^*+1\right)=\overline{N}p/\left(1-\delta q\right)$

As $\delta\to\mathbf{0}, f(t)$ is symmetric about t^* up to $2t^*$ then, $f(t=\mathbf{0})=f\left(\mathbf{2}t^*\right)=\overline{N}p$

To get the insight into type of trend shown by $f(n)$, we need to find $\Delta f(n)$, *i.e.*, the rate of change in non-cumulative fault detection $f(n)$.

$$\Delta f(n)=\frac{f(n+1)-f(n)}{\delta}=\frac{f_1}{f_2},\ \text{where}$$

$$f_1=-\overline{N}p(p+q)^3\left[1-\delta(p+q)\right]^n.\left[p-q\left(1-\delta(p+q)\right)^{n+1}\right] \quad (75.64)$$

$$f_2=\left[p+q\left(1-\delta(p+q)\right)^n\right]\left[p+q\left(1-\delta(p+q)\right)^{n+1}\right].\left[p+q\left(1-\delta(p+q)\right)^{n+2}\right]$$

Here we observe that the fault removal rate increases for (0, n_1^*) with increasing rate and decreasing rate for (n_1^*+1 to n^*). This is because of the fact that as the testing grows, so does the skill of the testing term. The faults detected during (0, n_1^*) are relatively easy faults, while those detected during (n_1^*+1, n^* n^*) are relatively difficult faults. The trend shown by $f(n)$ can be summarized as in Table 75.1

Table 75.1. The trend shown by $f(n)$

No. of test cases	Trends in $f(n)$
Zero to n_1^*	Increasing at an increasing rate
n_1^*+1 to n^*	Increasing at a decreasing
$n^*+\mathbf{1}$ to n_2^*	Decreasing at an increasing rate
n_2^*+1 to ∞	Decreasing at a decreasing rate

In Table 75.1 n^* is the point of maxima for $f(n)$. For (n_1^*+1, n_2), the fault detection rate decreases, *i.e.*, a fewer number of faults are detected upon failure. These faults can be defined as relatively hard faults. For (n_2^*+1, ∞), very few faults are detected upon failure. So testing is terminated. Faults detected beyond n_2^*+1 are relatively

complex faults. The results are summarized in Table 75.2. Here, n_1^* and n_2^* are points of inflection for $f(n)$.

Point of Maxima of Δf(n)

$$n_1^* = \begin{cases} [n_1] & \text{if } \Delta f[n_1]) \geq \Delta f([n_1]+1) \\ [n_1]+1 & \text{otherwise} \end{cases} \quad (75.65)$$

where

$$n_1 = \frac{1}{\log(1-\delta(p+q))} \log\left[\frac{p}{q}\left\{\frac{g_1}{(1-\delta(p+q))}\right\}\right] - 1$$

$$\text{where } g_1 = (2-\delta(p+q)) + \sqrt{(1-\delta(p+q))^2 + (2-\delta(p+q))}$$

And $[n_1] = \{n \mid \max(n \leq n_1), n \in Z\}$

Point of Minima of Δf(n)

$$n_2^* = \begin{cases} [n_2] & \text{if } \Delta f[n_2]) \geq \Delta f([n_2]+1) \\ [n_2]+1 & \text{otherwise} \end{cases} \quad (75.66)$$

where

$$n_2 = \frac{1}{\log(1-\delta(p+q))} \log\left[\frac{p}{q}\left\{\frac{g_1}{(1-\delta(p+q))}\right\}\right] - 1$$ and

$$g_{1=}(2-\delta(p+q)) - \sqrt{\left(1-\left(\overline{p+q}\right)\delta\right)^2 + (2-\delta(p+q))}$$

$$[n_2] = \{n \mid \max(n \leq n_2), n \in Z\}$$

Table 75.2. Size of each fault category

No. of test cases	Fault category	Expression for the fault category size
0 to n_1^*	Easy faults	$m(n_1)$
n_1^*+1 to n^*	Difficult faults	$m(n^*) - m(n_1)$
$n^* + 1$ to n_2^*	Hard faults	$m(n_2) - m(n^*)$
Beyond n_2^*	Complex fault	$\overline{N} - m(n_2)$

It may be noted that the corresponding inflection points T_1 and T_2, for the continuous case can be derived from n_1 and n_2 as δ→0, *i.e.*,

$$n_1 \to T_1 = \frac{-1}{p+q} \log\left(\frac{p}{q}(2+\sqrt{3})\right) \qquad s \quad \delta \to 0$$

75.2.4 Discrete Software Reliability Growth Models for Distributed Systems [16]

Computing has now reached the state of distributed computing, which is built on the following three components: (a) personal computers, (b) local and fast wide area networks, and (c) system and application software. By amalgamating computers and networks into one single computing system, and providing appropriate system software, a distributed computing system has created the possibility of sharing information and peripheral resources. Furthermore, these systems have improved the performance of a computing system and individual users. Distributed computing systems are also characterized by enhanced availability and increased reliability. A distributed development project with some or all of the software components generated by different teams presents complex issues of quality and reliability of the software.

The SRGM for distributed development environment discussed in this section considers that software system consists of finite number of reused and newly developed components and takes into account the time lag between the failure and fault isolation/removal processes for the newly developed components. The fault removal rate of the reused sub-system is proportionality constant, and the fault removal rate of newly developed sub-system is a discrete logistic learning function, as it is expected the learning process will grow with time.

Additional Notation

a_i : Initial fault content of type i reused component.

a_j : Initial fault content of type j newly developed components with hard faults.

a_k : Initial fault content of type *k* newly developed component with complex faults.

b_i : Proportionality constant failure rate *per* fault of *i*th reused component.

b_j : Proportionality constant failure rate *per* fault of *j*th newly developed component.

b_k : Proportionality constant failure rate *per* fault of *k*th newly developed component.

$b_j(n)$: Fault removal rate *per* fault of *j*th newly developed component.

$b_k(n)$:Fault removal rate *per* fault of *k*th newly developed component.

$m_{ir}(n)$:Mean number of faults removed from *i*th reused component by *n* test cases.

$m_j f(n)$:Mean number of failures caused by *j*th newly developed component by n test cases.

$m_{jr}(n)$:Mean number of faults removed from *j*th newly developed component by n test cases.

$m_k f(n)$:Mean number of failures caused by *k*th newly developed component by n test cases.

$m_k u(n)$:Mean number of faults isolated from *k*th newly developed component by n test cases.

$m_k r(n)$:Mean number of faults removed from *k*th newly developed component by *n* test cases.

75.2.4.1 Modeling the Fault Removal of Reused Components Modeling

Simple Faults

Fault removal of reused components is modeled as one-stage processes

$$\frac{m_{ir}(n+1)-m_{ir}(n)}{\delta} = b_i(n+1)\left(a_i - m_{ir}(n)\right)$$

$$\text{Where } b_i(n+1) = b_i \tag{75.67}$$

Solving the above difference equation using PGF with the initial condition $m_{ir}(n = 0) = 0$, we get

$$m_{ir}(n) = a_i\left(1-(1-\delta b_i)^n\right) \tag{75.68}$$

75.2.4.2 Modeling the Fault Removal of Newly Developed Components

Software faults in the newly developed software component can be of different severity. Time required for fault removal depends on the severity of faults. The faults can either be modeled as two stage or three-stage process according to the time lag for removal.

Components Containing Hard Faults

The removal process for hard faults is modeled as a a two-stage process, given as

$$\frac{m_{jf}(n+1)-m_{jf}(n)}{\delta} = b_j\left(a_j - m_{jf}(n)\right) \tag{75.69}$$

$$\frac{m_{jr}(n+1)-m_{jr}(n)}{\delta} = b_j(n+1)\left(m_{jf}(n+1)-m_{jr}(n)\right)$$

where

$$b_j(n+1) = b_j \Big/ \left(1+\beta(1-b_j)^{n+1}\right) \tag{75.70}$$

Solving the above system of difference equations using PGF with the initial conditions $m_{if}(n = 0) = 0$ and $m_{jr}(n = 0) = 0$, we get

$$m_{jr}(n) = a_j \frac{1-\left(1+\delta b_j n\right)\left(1-\delta b_j\right)^n}{1+\beta\left(1-b_j\right)^n} \tag{75.71}$$

Components Containing Complex Faults

There can be components having still harder faults or complex faults. These faults can require more effort for removal after isolation. Hence they need to be modeled with greater time lag between failure observation and removal. The third stage added below to the model serves the purpose.

$$\frac{m_{kf}(n+1)-m_{kf}(n)}{\delta} = b_k\left(a_k - m_{kf}(n)\right) \tag{75.72}$$

$$\frac{m_{ku}(n+1)-m_{ku}(n)}{\delta} = b_k\left(m_{kf}(n+1)-m_{ku}(n)\right) \tag{75.73}$$

$$\frac{m_{kr}(n+1)-m_{kr}(n)}{\delta} = b_k(n+1)\left(m_{ku}(n+1)-m_{kr}(n)\right)$$

$$\text{where } b_k(n+1) = \frac{b_k}{1+\beta(1-b_k)^{n+1}} \tag{75.74}$$

Solving the above system of difference equations using PGF with the initial conditions $m_{kf}(n = 0) = 0$, $m_{ku}(n = 0) = 0$ and $m_{kr}(n = 0) = 0$, we get

$$m_{kr}(n) = a_3 \frac{1-\left(1+b_k n\delta+\left(b_k^2 n\delta(n+1)\delta\right)/2\right)(1-\delta b_k)^n}{1+\beta(1-b_k)^n} \quad (75.75)$$

Modeling the Total Fault Removal Phenomenon

The model is the superposition of the NHPP of "*p*" reused and "*q*" newly developed components with hard faults and "*s*" newly developed components with complex faults with the mean value function of superposed NHPP being:

$$m(n) = \sum_{i=1}^{p} m_{ir}(n) + \sum_{j=p+1}^{p+q} m_{jr}(n) + \sum_{k=p+q+1}^{p+q+s} m_{kr}(n) \text{ Or}$$

$$m(n) = \sum_{i=1}^{p} a_i \left(1-(1-\delta b_i)^n\right) + \sum_{j=p+1}^{p+q} a_j \frac{1-(1+\delta b_j n)(1-\delta b_j)^n}{1+\beta(1-b_j)^n}$$

$$+ \sum_{k=p+q+1}^{p+q+s} a_k \frac{1-\left(1+\delta b_k n+\frac{b_k^2 n\delta(n+1)\delta}{2}\right)(1-\delta b_k)^n}{1+\beta(1-b_k)^n} \quad (75.76)$$

where $\sum_{i=1}^{p+q+s} a_i = a$ (the total fault content of the software). Note that a distributed system can have any number of used and newly developed components.

The equivalent continuous model can be derived (75.76) taking limit $\delta \to 0$, [11], *i.e.*

$$m(n) \to m(t) = \left(\sum_{i=1}^{p} a_i\left(1-e^{-bt}\right) + \sum_{j=p+1}^{p+q} a_j \frac{1-(1+bt)e^{-bt}}{1+\beta e^{-bt}} + \sum_{k=p+q+1}^{p+q+s} a_k \frac{g_1}{1+\beta e^{-bt}},\right)$$

$$\text{where } g_1 = 1-\left(1+bt+\left(b^2 t^2\right)/2\right)e^{-bt} \quad (75.77)$$

75.2.5 Discrete SRGM with Change Points

The discrete SRGMs discussed above assume a constant fault detection rate, duing testing the software under consideration. Whereas, in practice, the fault detection rate varies because of change in the testing skill, the system environment, and the testing strategy used to test the software. Several questions arise: Has a change occurred? Has more than one change occurred? When did the change occur? These questions can be answered by performing a change-point analysis. A change-point analysis is capable of detecting changes. The change point characterizes the changes and controls the overall fault rate.

75.2.5.1 Discrete SRGM with a Change Point for the Fault Removal Phenomenon [19]

The delayed S-shaped discrete SRGM discussed in Section 75.2.1.3 due to Yamada *et al*., can be derived alternatively in one stage as follows

$$\frac{m_r(n+1) - m_r(n)}{\delta} = b(n)\left(a - m_r(n)\right)$$

$$\text{Where } b(n) = \frac{b^2(n+1)}{1+bn} \quad (75.78)$$

However, to incorporate the concept of change point into software reliability growth modeling it is assumed that the fault detection rate during testing may vary. As a consequence, the fault detection rate before the change point is different from the fault detection rate after the change point. Under this basic assumption, the expected cumulative number of faults removed between the *n*th and the $(n+1)$th test cases is proportional to the number of faults remaining after the execution of the *n*th test run , satisfies the following difference equation:

$$\frac{m(n+1) - m(n)}{\delta} = b(n)\left(a - m(n)\right) \quad (75.79)$$

where

$$b(n) = \frac{{b_1}^2(n+1)}{1+b_1 n}; \; 0 \le n < \eta_1 \quad (75.80)$$

$$b(n) = \frac{{b_2}^2(n+1)}{1+b_2 n}; \quad n \ge \eta_1 \quad (75.81)$$

Case 1: ($\mathbf{0 \le n < \eta_1}$*)*

Solving the difference equation (75.79), substituting *b(n)* from (75.80), and using the probability generating function under the initial condition at $n = 0$, $m(n) = 0$, we get

$$m(n) = a\left(1-\left(1+\delta b_1 n\right)\left(1-\delta b_1\right)^n\right) \quad (75.82)$$

The equivalent continuous model of (75.82) can be derived taking *limit* $\delta \to 0$, *i.e.*

$$m(n) = a\left(1-(1+\delta b_1 n)(1-\delta b_1)^n\right) \to a\left(1-(1+bt)e^{-bt}\right)$$

Case 2: ($n \geq \eta_1$)

Solving the difference equation (75.79) substituting *b(n)* from (75.81), and using the probability generating function with the initial condition at $n = \eta_1$, $m(n) = m(\eta_1)$, we get

$$m(n) = a\left[1-\frac{(1+\delta b_1 \eta_1)}{(1+\delta b_2 \eta_1)}(1+\delta b_2 n)(1-\delta b_2)^{(n-\eta_1)}(1-\delta b_1)^{\eta_1}\right] \quad (75.83)$$

The equivalent continuous of (75.83) can be derived taking limit $\delta \to 0$, *i.e.*

$$m(n) \to m(t) = a\left(1-\left(\frac{1+b_1 t_1}{1+b_2 t_1}\right)(1+b_2 t)\, e^{-(b_1 t_1 + b_2 (t-t_1))}\right)$$

75.2.5.2 Discrete SRGM with a Change Point for Modeling Faults of Different Severity

There are many factors that affect software testing. These factors are unlikely to be kept stable during the entire process of software testing, with the result that the underlying statistics of the failure process is likely to experience major changes. The fault detection rate for all the faults lying in the software differs on the basis of their severity. Therefore there is the need to define the different fault detection rates to cater the faults of different severity. In most NHPP software reliability growth models, the fault detection rate is constant. However, during the testing, the fault detection rate can change at some point, say n_1, n_2. The concept of the change point is introduced in the generalized Erlang model, see Section 75.2.4.1, and the generalized Erlang model with logistic function, see Section 75.2.4.2. The position of the change point can be judged by the graph of actual failure data.

Discrete SRGM with a Change Point for the Generalized Erlang Model

The model is described by the following difference equation:

$$m(n+1) - m(n) = b(n)\left(a - m(n)\right) \quad (75.84)$$

where

$$b(n+1) = b_1; \quad 0 \leq n < \eta_1 \quad (75.85)$$

$$b(n+1) = \frac{b_2{}^2 (n+1)}{1 + b_2 n}; \quad n_1 < n \leq n_2 \quad (75.86)$$

$$b(n+1) = \frac{\frac{b_3{}^2 (n+1)(n+2)}{2}}{1 + b_3 n + \frac{b_3{}^2 (n+1)(n+2)}{2}}; \quad n > n_2 \quad (75.87)$$

Case 1: $\mathbf{0} \leq n \leq n_1$

Solving the difference equation (75.84) substituting *b(n)* from (75.85), using the PGF with the initial condition at $n = 0$, $m(n) = 0$, we get

$$m(n) = a\left[\mathbf{1} - (\mathbf{1} - b_1)^n\right] \quad (75.88)$$

Case 2: $n_1 < n \leq n_2$

Solving the difference equation (75.84) substituting *b(n)* from (75.86), using the probability generating function with the initial condition at $n = \eta_1$, $m(n) = m(\eta_1)$, we get

$$m(n) = a\left[1-\left(\frac{1+b_2 n}{1+b_2 n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n-n_1}\right] \quad (75.89)$$

Case 3: $n > n_2$

Further solving the difference equation (75.84) substituting *b(n)* from (75.87), using the probability generating function with the initial condition $n = n_2$, $m(n) = m(n_2)$ we get

$$m(n) = a\left[1-\left(\frac{1+b_2 n_2}{1+b_2 n_1}\right)\left(\frac{1+b_3 n + \frac{b_3{}^2 n(n+1)}{2}}{1+b_3 n_2 + \frac{b_3{}^2 n_2 (n_2+1)}{2}}\right)\cdot (1-b_1)^{n_1}(1-b_2)^{n_2-n_1}(1-b_3)^{n-n_2}\right] \quad (75.90)$$

Modeling the Total Fault Removal Phenomenon

The model framework is the superposition of NHPP with mean value functions given in (75.88), (75.89), and (75.90). Thus, the mean value function of the superposed NHPP is

$$m(n) = m_1(n) + m_2(n) + m_3(n) \quad (75.91)$$

$$\text{or}\quad m(n)=a_1\left[1-(1-b_1)^n\right]+a_2\left[1-\left(\frac{1+b_2n}{1+b_2n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n-n_1}\right]$$
$$+a_3\left[1-\left(\frac{1+b_2n_2}{1+b_2n_1}\right)\left(\frac{1+b_3n+\frac{b_3^2n(n+1)}{2}}{1+b_3n_2+\frac{b_3^2n_2(n_2+1)}{2}}\right)(1-b_1)^{n_1}(1-b_2)^{n_2-n_1}(1-b_3)^{n-n_2}\right] \quad (75.92)$$

where $a_1 + a_2 + a_3 = a$.

Discrete SRGM with a Change Point for the Generalized Erlang Model with Logistic Function

The model is described by the following difference equation:

$$m(n+1)-m(n)=b(n)\left(a-m(n)\right) \quad (75.93)$$

$$\text{where } b(n+1)=b_1;\quad 0\le n<\eta_1 \quad (75.94)$$

$$b(n+1)=\frac{b_2\left(1+\beta+b_2n\right)-b_2\left(1+\beta(1-b_2)^{n+1}\right)}{\left(1+\beta+b_2n\right)\left(1+\beta(1-b_2)^{n+1}\right)};\quad n_1<n\le n_2 \quad (75.95)$$

$$b(n+1)=\frac{b_3\left(1+\beta+b_3n+\frac{b_3^2n(n+1)}{2}\right)-g_1}{\left(1+\beta+b_3n+\frac{b_3^2n(n+1)}{2}\right)\left(1+\beta(1-b_3)^{n+1}\right)};\quad n>n_2$$
$$where\quad g_1=b_3\left(1+\beta(1-b_3)^{n+1}\right)(1+b_3n) \quad (75.96)$$

Case 1: $0 \le n \le n_1$

Solving the difference equation (75.93) substituting *b(n)* from (75.94), using the PGF with the initial condition at $n = 0$, $m(n) = 0$, we get

$$m(n)=a\left[1-(1-b_1)^n\right] \quad (75.97)$$

Case 2: $n_1 < n \le n_2$

Solving the difference equation (75.93) substituting *b(n)* from (75.95), using the probability generating function with the initial condition at $n = \eta_1$, $m(n) = m(\eta_1)$ we get

$$m(n)=a\left[1-\left(\frac{1+\beta(1-b_2)^{n_1}}{1+\beta(1-b_2)^n}\right)\left(\frac{1+\beta+b_2n}{1+\beta+b_2n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n-n_1}\right] \quad (75.98)$$

Case 3: $n > n_2$

Further solving the difference equation (75.93) substituting $b(n)$ from (75.96), using the PGF with the initial condition $n = n_2$, $m(n) = m(n_2)$ we get

$$m(n)=a\left[1-\left(\frac{1+\beta(1-b_2)^{n_1}}{1+\beta(1-b_2)^{n_2}}\right)\left(\frac{1+\beta(1-b_3)^{n_2}}{1+\beta(1-b_3)^n}\right)\left(\frac{1+\beta+b_3n+\frac{b_3^2n(n+1)}{2}}{1+\beta+b_3n_2+\frac{b_3^2n_2(n_2+1)}{2}}\right)\left(\frac{1+\beta+b_2n_2}{1+\beta+b_2n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n_2-n_1}(1-b_3)^{n-n_2}\right] \quad (75.99)$$

Modeling the Total Fault Removal Phenomenon

The model framework is the superposition of the NHPP with mean value functions given in (75.97), (75.98), and (75.99). Thus, the mean value function of the superposed NHPP is

$$m(n) = m_1(n) + m_2(n) + m_3(n) \quad (75.100)$$

or

$$m(n)=a_1\left[1-(1-b_1)^n\right]+a_2\left[1-\left(\frac{1+\beta(1-b_2)^{n_1}}{1+\beta(1-b_2)^n}\right)\left(\frac{1+\beta+b_2n}{1+\beta+b_2n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n-n_1}\right]$$
$$+a_3\left[1-\left(\frac{1+\beta(1-b_2)^{n_1}}{1+\beta(1-b_2)^{n_2}}\right)\left(\frac{1+\beta(1-b_3)^{n_2}}{1+\beta(1-b_3)^n}\right)\left(\frac{1+\beta+b_3n+\frac{b_3^2n(n+1)}{2}}{1+\beta+b_3n_2+\frac{b_3^2n_2(n_2+1)}{2}}\right)\left(\frac{1+\beta+b_2n_2}{1+\beta+b_2n_1}\right)(1-b_1)^{n_1}(1-b_2)^{n_2-n_1}(1-b_3)^{n-n_2}\right] \quad (75.101)$$

where $a_1 + a_2 + a_3 = a$.

75.3 Conclusion

In this chapter we have discussed a wide range of discrete SRGMs, which describe the relationship between the number of faults removed and the number of test cases used. These include flexible discrete SRGMs in perfect and imperfect debugging environments. A new discrete model is also introduced, which incorporates the effect of imperfect debugging and fault generation. Another category of SRGMS incorporating faults of

different severity and distributed environment is also been discussed. Lastly, SRGM incorporating the concept of the change point has been introduced. The chapter describes the state-of-the-art in the discrete modeling. release time problem, Allocation and control of testing resources have so far not been discussed in the literature. The authors propose to bring them out in their future research effort.

Epilogue

Krishna B. Misra

RAMS Consultants, Jaipur, India.

Abstract: This chapter outlines the inferences that we can now draw at the end of the presentation of the 75 chapters included in this handbook on various aspects of performability engineering. The chapter projects the direction that the technologies currently being developed can lead us in realizing the objectives of sustainable world. It also attempts to paint the scenario that may be developing in the near future.

76.1 Mere Dependability Is Not Enough

Since World War II, engineers and technologists have been concerned about the poor performance of engineering products, systems and services, and about the cost of producing and running them successfully. Although the quality of a product was always in the minds of manufacturers right from the beginning of the past century, on account of business competition, reliability got prominence only during the post war period. Consequently, design for reliability became an important consideration for products, systems, and services, particularly to offset the cost of maintenance that was rising exponentially. Consequently, designers started considering quality, reliability, and maintainability as essential attributes of products and systems, and optimizing these with respect to the cost of achieving them. In other words, survivability was their prime concern. With the increased incidences of some serious accidents, the frequencies of which were increasing, designers also had to consider stringent safety measures, and safety was incorporated into the design of products and systems along with other attributes. This led to the era of dependability-based designs, and optimization was confined in relation to the cost. Thus the performance of products, systems, or services, as of now, is being assessed mainly by dependability, which is an aggregate of the attributes of survivability and safety. However, survivability in turn is dependent on quality, reliability, maintainability (or availability), *etc*. Of course, we try to optimize the cost of physically realizing these attributes; however this is not really a true optimization of the product in relation to resources employed in creating it, as we are rarely concerned about the processes employed to produce them and their environmental consequences. One must realize that these attributes are very much influenced by the design, raw material, fabrication, techniques and manufacturing processes and their control, and finally by the usage. These attributes are interrelated and reflect the level or grade of the product so designed and utilized, which is expressed through dependability.

In fact, as of now, dependability and cost effectiveness are primarily seen as instruments for conducting international trade in the free market regime and thereby deciding the economic prosperity of a nation. However, in order to preserve our environment for future generations, the internalization of the hidden costs of environment preservation will have to be accounted for, sooner or later, in order to be able to produce sustainable products in the long run. Therefore, we can no longer rely solely on the criteria of dependability for optimizing the performance of a product, system, or service. We require the introduction of sustainability as a performance criterion that would take a holistic view of the performance enhancement along with the associated environmental consequences.

76.2 Sustainability: A Measure to Save the World from Further Deprivation

From the chapters included in this handbook, it is amply clear that the state of our environment is not very conducive for sustaining our own future generations and to provide them a decent life. We have already deteriorated the environment of the planet in the name of development and achievement of materialistic prosperity. We cannot go back to the past but we can act for the future by preventing further degradation. We should not be insensitive to investments or even sacrifices needed in order for our own grandchildren to flourish in future. Let us not be so selfish as to satisfy our present needs; we will deprive future generations of all those comforts and standards of life that we are enjoying today. Therefore, it is time that we look beyond our own needs to make the future world livable. To do so, we must follow the principles of sustainability.

Some of the basic principles of sustainability are:

- Not using non-renewable, non-abundant resources faster than substitutes can be discovered.
- Not using renewable resources faster than they are replenished.
- Not releasing wastes (solid, liquid or gaseous) faster than the planet can assimilate them.
- Not disturbing the ecological balance of the earth and depleting the diversity of life that exists on the planet.

These principles must be adhered to while designing products and processes. Old polluting technologies that are have considered the earth as a large sink must be abandoned and replaced by non-polluting technologies.

We can only start with whatever technology we have today. We know that at every stage of the life-cycle of a product, be it extraction of material, manufacturing, use or disposal, energy and materials are required as inputs, and emissions (gaseous, solid effluents or residues) are always associated with these, which influence the environmental health of our habitat. Unless we consider all these factors in our plans of creating a product, we cannot call the design of products, systems, and services truly optimal from the engineering point of view. This would necessitate bringing in sustainability principles along with other performance enhancement initiatives.

Pollution prevention is just one principle of sustainability and involves developing economically viable and safe processes (clean production and clean technologies) that entail minimal environmental pollution, require minimum quantities of raw material and energy, and yield safe products of acceptable quality and reliability that can be disposed of at the end of their life without causing any adverse effects to the environment.

The U.S. Environmental Protection Agency has laid down certain priorities to prevent pollution:

- Avoidance (search for an alternative),
- Reduction (dematerialization, better quality and reliability, better tools, *etc*.),
- Re-use, recycling and recovery,
- Energy recovery (optimum utilization),
- Treatment (hopefully down to innocuous products),
- Safe disposal.

These would necessitate the efficient use of natural resources and the use of non-waste technologies,

which would ensure that all raw materials and energy are used in a most rational and integrated way to curb all kinds of wastages while maximizing the performance. Obviously, less material and energy consumption – either through dematerialization, reuse or, recycling, or through proper treatment (clean up technology) – would lead to a lesser degree of environmental degradation. Similarly, a better design would result in prolonging the lifespan of a product and hence would ensure less adverse effects on the environment over a given period of time. In other words, we must integrate the entire life cycle of activities of survivability with that of environmental lifecycle considerations to improve product or system performance within the technological barriers with minimum cost. Last but not least, at the end of life, all products must be disposed off safely so as not to create pollution after use. All systems must be decommissioned safely so as not to interfere with the biotic and abiotic environment of the earth.

Design is the most important activity to affect new changes in products, systems, or services. It is an established fact that about 70% of costs of product development, manufacture, and use are decided in the early design stages.

To achieve these objectives, we need to introduce a performability criterion of products, systems, or services (as discussed in Chapter 1), which alone would take a holistic view of their designs for performance enhancement along with the associated problems of preventing environmental degradation.

76.3 Design for Performability: A Long-term Measure

The design of products, systems, and services for dependability is not enough, and we must design them for performability so as to include sustainability principles, since these alone can guarantee permanence. Performability is thus a long-term measure for the well-being and prosperity of people living on the earth. In fact, we should redesign all our products and systems for performability, which means designing them not only for dependability but also for the sustainability. This would require making the same product in a different way so as to minimize raw materials and energy requirement, either by the product itself or by the processes that create the product, and produce minimum byproducts or effluents.

In fact a product must be designed for:

- manufacturability (ease of production),
- logistics (production activities can be well-orchestrated),
- testability (the quality can be checked),
- reliability and maintainability (works well),
- serviceability (service after sale at reasonable cost to the company),
- safety and liability (the product is safe to use), and
- the environment (reduce or eliminate environmental impacts from cradle to grave).

Except for the design for environment other factors of design are common with design for dependability. Therefore we must elaboarte on the design for environment.

Design for Environment

To improve on current design practices that fail to consider the broad environmental implications of products (and the processes that create them), Allenby and Graedel [7] suggested the implementation of DFE as a means to "integrate decision making across all environmental impacts of a product".

Under this regime, various factors discussed earlier would involve some other considerations as well. For example, design for manufacturing would involve less material, the use of fewer different materials, and safer materials and processes in order to achieve the goal of pollution prevention. Similarly, design for serviceability would involve longevity or reliability, reuse and recycling of components or parts. It should also involve ease of dissembly, and a product must be designed for dissembly (European Community Directive: WEEE is to facilitate this), so that it can be easily and quickly dissembled, and also its parts can be reused elsewhere. A product must be designed for modularity for the ease of upgrading equipment and for its serviceability. For recovery of materials

and for safer disposal of non-recyclables, a product must be designed for recycling. A product should also be designed for energy efficiency in order to reduce energy demand during its use, and for flexible energy use. Additionally, a product should also be designed for energy recovery, for safe incineration of residues, and for composting of residues.

Quite often the only way a product can be redesigned is by rethinking the way the product is made or by considering alternative technologies, materials, and taking stock of what goes into making it (raw material), the process of manufacturing it, and finally what is created as by-product or waste besides the useful product. Waste must be minimized, as it basically adds to the cost of production.

The strategy that can be followed for minimization of waste is the following:

- Waste can be reduced by application of more efficient production technologies.
- Internal recycling of waste produced during production process.
- Source oriented improvement of waste quality, *e.g.,* substitution of hazardous substances.
- Re-use of products or parts of products, for the same purpose.

Valorization of waste and effluents has a role in making designs environment friendly as well as reducing the overall cost.

Recycling can be used to conserve resources. Recycling actually returns waste material to the original process. It helps use the waste material as a raw material substitute for another process, and processes waste material for resource recovery besides processing waste material as a by-product. However, unless it is proved to beneficial on the assumption that recycling would require very few raw materials and energy, and will release less emission into the environment, than mining and manufacturing new material, recycling should not be resorted to. Recycling is not environmentally sound when additional transportation using non-renewable fossil fuels is required to collect the material prior to recycling. Therefore, for recycling to be environmentally beneficial, the effects of collection, transportation, and reprocessing operations must be considered and proved to be less harmful than those resulting from the extraction and processing of the mined material.

Another important activity to protect the environment [3] is proper disposal of waste. This may include tipping above or underground (*e.g.,* landfills, *etc.*) or biodegradation of liquid or sludge discards in soils, or deep injection into wells or release into seas/oceans including seabed insertion, or may include biological treatment or incineration, or physio-chemical treatment, or permanent storage in containers placed in a mine pit or on the ocean bed.

The progress made by the Japanese in the past can be attributed to their strategy of not only redesigning the products but also the processes of production, so that the product can not only be made reliable but also cheap. Now our priority should be on designing products and processes that are eco-friendly. A question that often haunts a designer is at what level this can be implemented. In fact, it can be implemented at the *microscale*, which means at the level of a part of a product or at the level of a unit of production. It can also be implemented at the *mesoscale,* which means at the level of a product or at the level of a factory. It can also be implemented at the *macroscale,* which means meeting the function (service) in a new way.

If a manufacturing process allows reducing the quantity of effluents, which pollute the environment, and makes rational use of raw materials and energy at a reasonable and economic cost, the process is called *cleaner production.*

According to United Nations Environment Program (UNEP), 1989, cleaner production is the continuous application of an integrated preventive environmental strategy applied to processes, products, and services to increase overall efficiency and reduce risks to humans and the environment.

- For production processes, the strategy includes conserving raw materials and energy, eliminating toxic raw materials, and reducing the quantity and toxicity of all emissions and wastes.
- For products, the strategy focuses on reducing negative impacts along the life cycle of a

product, from raw materials extraction to its ultimate disposal.
- For services, the strategy involves incorporating environmental concerns into designing and delivering services.

Cleaner production requires changing attitudes, responsible environmental management, and evaluating technology options.

More and more companies are taking recourse to clean production. The implementation of clean production is possible in any type of industrial activity regardless of its size. Implementation comprises three steps: optimizing an existing process to provide better yields and to avoid pollution due to human error through monitoring and activation of alarms; modifying the upstream and downstream processes with the purpose of recycling or recovery, or use of waste as secondary materials; and finally designing a new process based on the two earlier steps.

Another approach that is emerging in addition to the concerns indicated above is called industrial ecology (IE). In fact, IE can be called the science of sustainability, according to Graedel and Allenby [5].
The three tenets on which IE rests are [1]:

- optimization of resources (less consumption, less waste),
- optimization of energy, and
- optimization of capital (humans and capital).

IE signifies a shift in paradigm from "end-of-pipe" pollution control methods towards holistic strategies for prevention and planning of more environmentally sound industrial development. IE is advanced as a holistic approach to redesigning industrial activities. Governments, scientists, policy-makers, and the general public are becoming increasingly aware of the environmental damage associated with the large and growing material through-put required in modern industrial society. IE helps address this concern. In the traditional model of industrial activity, individual manufacturing processes take in raw materials and generate useful products to be sold, plus waste or by-products to be disposed of. In an IE model, it should be transformed into a more integrated an industrial ecosystem. In such a system the consumption of energy and materials is optimized, waste generation is minimized, and the effluents of one process serve as the raw material for another process.

Allenby [2] defines industrial ecology as the means by which a state of sustainable development is approached and maintained. It consists of a system's view of human economic activity and its interrelationship with fundamental biological, chemical, and physical systems with the goal of establishing and maintaining the human species at levels that can be sustained indefinitely, given continued economic, cultural, and technological evolution. It is a systems' view in which one seeks to optimize the total materials cycle from virgin material, to finished material, to component, to product, to obsolete product, and to ultimate disposal. Factors to be optimized include resources, energy, and capital.

76.3.1 Recourse to Alternative Technologies

Notwithstanding what we may do to prevent pollution, the maximum impact that our efforts will have will be decided by the choice of technology [4] that we employ in our production. It is here that the success of our efforts will be decided by the choice of out technology. Whatever technology we might eventually use in production processes, it must be non-polluting and should have all the advantage of clean production. There appear two seemingly very useful and powerful technologies on the horizon that are likely to change the way products and systems will be produced in the 21st century. The revolution is just around the corner and will change the way we look at products today. Undoubtedly, these are likely to be clean and sustainable technologies.

76.3.1.1 Uses of Industrial Biotechnology

We shall not discuss here the uses of biotechnology in food and agriculture, and medicines where it has done wonders, but rather we shall discuss very briefly its implication for manufacturing companies or for industrial uses. Although *industrial biotechnology* is in the early stages of development, its innovative applications are increasing rapidly into all areas of manufacturing

and it is providing useful tools for cleaner and sustainable production techniques.

The world is reverting to the use of bioprocesses in comparison to chemical processes to produce a number of useful industrial products, since it is not only environmentally cleaner but also economically viable as non-renewable resources become scarce. Biotechnology, for instance, with the advent of genetic engineering and recombinant DNA technology has opened up several vistas for new industrial applications. Even non-bio-degradable products like plastics, which once were considered environmental unfriendly, have now been made environmentally friendly by the production of biodegradable plastics based on polyhydroxybutyrate made by bacteria [6] from renewable food stock and polymeric carbohydrates such as Xanthan. Ammonia today can be produced by nitrogen-fixing bacteria and thus can be a cleaner way of producing fertilizers, whose production through chemical processes have never been environmentally friendly.

Biological leaching in extracting metals from ores can be of tremendous advantage, particularly when grades of ore are becoming poorer day by day, as we have already mined minerals extensively earlier. Biotechnology as we know can help to clean up the environmental mess especially in the case of contaminated soils, removal of heavy metal sulfates from water, and removal of hazardous elements from gaseous emissions using bio-filters or from wastewater. Chlorine bleaching in the pulp and paper industry is being substituted by biotechnology processes. Some of the industrial processes developed by companies have been very successful in using biotechnology to prevent environmental pollution.

Bio-fuels, like bio-ethanol and bio-diesel [8], are likely to become popular and help meet increasing fuel demands. Ethanol is currently produced by fermenting grain (old technology). The cellulose enzyme technology developed by Iogen, Canada allows the conversion of crop residues (stems, leaves, and hulls) to ethanol. This results in reduced CO_2 emissions by more than 90% (compared to oil) and also allows greater domestic energy production as it uses a renewable feedstock. The process is in the scale-up phase of the technology and it is likely to result in the cost of ethanol produced in this manner being competitive with the cost of gasoline produced from oil, costing USD 25 per barrel.

The vegetable oil degumming process [8] developed by Cerol, Germany, has reduced amounts of caustic soda, phosphoric acid, and sulphuric acid used compared to conventional processes. The enzymatic process has reduced the amount of water needed in washing and as dilution water. Sludge production has been reduced by a factor of 8. Hydrogen peroxide used for bleaching textiles usually requires several rinsing cycles.

A new enzyme process developed by Windel, Germany, requires only one high temperature rinsing to remove bleach residues. This has helped reduce the energy consumption by 14% and water consumption by 18%, and thereby the production costs and pollution. In the old process of refining zinc, the finishing wastewater contains heavy metals, sulfuric acid, and gypsum used to precipitate sulfates. A new biological process developed by Budel Zinc, The Netherlands, uses sulfate reducing bacterial enzymes for sulfate reduction. This process allows zinc and sulfate to be converted to zinc sulfide, which is recycled to the refinery. This process has resulted in a 10 to 40-fold decrease in the concentration of heavy metals in the refinery wastewater, gypsum is produced, and valuable zinc is recycled.

Thus *industrial biotechnology* is also in the early stages of development and its innovative applications are increasing very rapidly into all areas of manufacturing. It is providing useful tools for cleaner and sustainable production and it is expected to continue to do so in the future as well. The day is not distant when biotechnology will take over all production technologies completely and help preserve a clean environment.

The Organization for Economic Cooperation and Development (OECD) with headquarters in Paris has constituted a Task Force on Bio-technology for Sustainable Industrial Develop-ment, whose mission is to assist developed and developing countries of the world to achieve sustainable development. It is expected to play a key role in achieving the objectives of promoting clean technologies.

76.3.1.2 Industrial Uses of Nanotechnology

Nanotechnology is known as the frontier area of science in the coming years. Nanoscale materials have been used for decades in applications ranging from window glass and sunglasses to car bumpers and paints. However, the convergence of scientific disciplines (chemistry, biology, electronics, physics, engineering, *etc*.) is leading to numerous applications in materials manufacturing, computer chips, medical diagnosis and health care, energy, biotechnology, space exploration, security, and so on. Hence, nanotechnology is expected to have a significant impact on our economy and society within the next 10 to 15 years, growing in importance over the longer term as further scientific and technology breakthroughs are achieved. The US National Science Foundation has predicted that the global market for nanotechnologies will reach $1 trillion or more within 20 years. Sales of emerging nanotechnology products have been estimated by private research to have risen to 15% of global manufacturing output in 2014.

Currently, nanotechnology [9] is being incorporated selectively into high-end products, especially in automotive and aerospace applications. Forecasts indicate that by 2009, commercial breakthroughs are likely to unlock markets for nanotechnology innovations, and microprocessors and memory chips built using new nanoscale processes will appear on the market. From 2010 onwards, nanotechnology will have become commonplace in manufactured goods. Health care and life science applications are finally becoming significant as nano-enabled pharmaceuticals and medical devices emerge from lengthy human trials.

The basic building blocks of nanotechnology are carbon nanotubes, nanoparticles, and quantum dots.

Nanotubes

Carbon nanotubes, long thin cylinders of atomic layers of graphite, may be the most significant new material since plastics and are the most significant of today's nanomaterials. They come in a range of different structures, allowing a wide variety of properties. They are generally classified as single-walled (SWNT), consisting of a single cylindrical wall, or multiwalled nanotubes (MWNT), which have cylinders within the cylinders.

SWNT has amazing properties such as its size of 0.6 to 1.8 nanometers in diameter and has a density of 1.33 to 1.40 g/cm^3, whereas aluminium has a density of 2.7 g/cm^3. It has heat transmission capability is 6,000 W/m/K at room temperature, whereas pure diamond transmits 3,320 W/m/K. The current carrying capacity is estimated at 1 billion A/cm^2, whereas copper wire burns out at about 1 million A/cm^2. It has a tensile strength of 45 billion Pa, whereas high-strength steel alloys break at about 2 billion Pa. It has a temperature stability of 2,800°C in vacuum, and 750°C in air, whereas metal wires in microchips melt at 600 to 1,000°C. With all these desirable properties, SWNTs are more difficult to manufacture than MWNT. Carbon Nanotechnologies of Houston, one of the world's leading producers, only makes up to 500 g *per* day. The other drawback is that it is difficult to make nanotubes interact with other materials. For example, to fully exploit their strength in composite materials, nanotubes need to be *attached* to a polymer. They are chemically modified to facilitate this (a process known as *functionalization*), but this process reduces the very properties the nanotubes may be used for.

The most promising applications of nanotubes may be in electronics and optoelectronics. Today, the electronics industry is producing MOSFETs (metal oxide semiconductor field effect transistors) with critical dimensions of just under 100 nm, with half that size projected by 2009 and 22 nm by 2016. However, the industry will then encounter technological barriers and fundamental physical limitations to size reduction. With carbon nanotubes, it is possible to achieve higher performance without having to use ultra thin silicon dioxide gate insulating films. In addition, semiconducting SWNTs, unlike silicon, directly absorb and emit light, thus possibly enabling a future opto-electronics technology. SWNT devices would still pose manufacturing problems due to quantum effects at the nanoscale, so the most likely advantage in the foreseeable future is that carbon nanotubes will allow a simpler fabrication of

devices with superior performance at about the same length as their scaled silicon counterparts.
Carbon nanotubes have been demonstrated to be efficient field emitters and are currently being incorporated in several applications, including flat-panel display for television sets or computers, or any devices requiring an electron producing cathode such as X-ray sources (*e.g*., for medical applications).

Semiconducting nanotubes change their electrical resistance dramatically when exposed to alkalis, halogens, and other gases at room temperature, which raises hopes for better chemical sensors. The sensitivity of these devices is 1,000 times that of standard solid state devices.

There are still many technical obstacles to overcome before carbon nanotubes can be used on an industrial scale, but their enormous potential in a wide variety of applications has made them the "star" of the nano-world and encouraged many companies to commit the resources needed to ensure that the problems will be solved. Fujitsu, for example, expects to use carbon nanotubes in 45 nm chips by 2010 and in 32 nm devices by 2013.

Nanoparticles

The metal oxide ceramic, metal, and silicate nanoparticles constitute the most common of the new generation of nanoparticles. Moving to nanoscale changes the physical properties of particles, notably by increasing the ratio of surface area to volume, and the emergence of quantum effects. A high surface area is a critical factor in the performance of catalysis and structures such as electrodes, allowing improvement in performance of such technologies as fuel cells and batteries.

Nansulate is an insulative coating by Industrial Nanotech, which incorporates nanoparticles that give it unique performance characteristics in a translucent, thin film coating, which uses nano-sized particles that have been engineered to inhibit the solid, gaseous, and radiative (infrared) heat transfer through an insulator. Nansulate repels moisture from the coating itself, effectively creating a moisture-free barrier against the pipe or tank or piece of equipment being insulated. This coating has the advantage of being corrosion and mould resistant. It is reported in [13] that nansulate high heat was applied to the heat exchangers of dyeing machines in a dye house in the Trakya region of Turkey. A coating of an average thickness of 70 microns was applied to provide insulation to the equipment. This resulted in a reduction of 20% of liquid natural gas (LNG) consumption over a period of five months, which amounted to a saving of approximately US$ 40,000 per month to the company. This film may have uses in energy sector to meet air quality and energy-use restrictions; a multi-use thin film insulating coating holds many benefits for reducing energy use. Bio-fuel facilities use processing equipment as well as miles of pipelines that can benefit from the combined insulating and corrosion resistance property of nanotechnology coatings. One area currently in research is called "intelligent coatings". Intelligent coatings are coatings that self repair and self report. For example, a coating that is able to repair itself upon being scratched, removed, or damaged and then changes color in that area as an indicator of the area of damage.

This type of coating would be especially useful in areas where failure of a coating protecting a pipeline or tank could cause significant damage.

Quantum Dots

Just as carbon nanotubes are often described as the new plastics, so quantum dots can be defined as the ball bearings of the nano-age. They are 1 nm structures made of materials such as silicon, capable of containing a single electron, or a few thousand, whose energy states can be controlled by applying a given voltage. In theory, this could be used to fulfil dream of changing the chemical nature of a material, making lead into gold. It is possible to make light-emitting diodes (LEDs) from quantum dots, which may produce white light, *e.g.,* for buildings or cars. Quantum dots can be used for making ultra fast, all-optical switches and logic gates that work faster than 15 terabits a second. The Ethernet usually handles only 10 megabits per second. Other possible applications are all-optical demultiplexers (for separating various multiplexed signals in an optical fibre), all-optical computing, and encryption, whereby the spin of an electron in a quantum dot represents a quantum bit or qubit of information.

Biologists are experimenting with composites of living cells and quantum dots. These could

possibly be used to repair damaged neural pathways or to deliver drugs by activating the dots with light.

There are hundreds of applications possible for nanotechnology [11], but as the technology is still being developed, it serves no useful purpose to list all possible future applications here. The idea of discussion is to stimulate imagination of what is going to come in the near future, not in the distant future but within a couple of decades.

There is much to come by way of marriage between the two leading technologies of the future, *i.e.,* biotechnology and nanotechnology.

76.4 Parallelism Between Biotechnology and Nanotechnology

Since the discovery of deoxyribonucleic acid (DNA) in 1953, there have been tremendous advances in the field of biotechnology. DNA is a nucleic acid and is identified as the genetic material in all life. It contains the genetic instructions for the biological development of a cellular form of life or a virus. All known cellular life and some viruses have DNAs. DNA is a long polymer of nucleotides (a polynucleotide) that encodes the sequence of amino acid residues in proteins, using the genetic code. DNA is the master molecule of life that controls the development and functioning of organisms. DNA is responsible for the genetic propagation of most inherited traits. In humans, these traits range from hair color to disease susceptibility. This threadlike molecule is present in chromosomes of all organisms. It is made up of two strands that are coiled clockwise in a double helical manner like a spiral staircase. The two strands are made of phosphate and sugar called deoxyribose.

Four nitrogen compunds called “bases” form the rungs of the DNA ladder: adenine (A), guanine (G), cystosine (C), and thymine (T). The bases always join in a specific manner: A pairs with T; G pairs with C. Thus there are only four kinds of base-pair combinations: A-T, C-G, T-A and G-C. However, the sequence of base pairs along the length of the strands is not the same in DNAs of different organisms. It is this difference that is responsible for the difference between one gene and another. A gene is a segment of a DNA chain that contains codes for the production of a complete protein.

The DNA molecule is not directly involved in the functioning of the cell. Rather, it instructs the machinery of the cell to make required proteins (including enzymes). These proteins, in turn, control all chemical processes in the cell. This is actually done by DNA with the help of RNA. RNA is a complex single strand molecule found in the cytoplasm of the cell. RNA is made of the same bases as DNA except that the base T is replaced by the base uracil (U), which can also pair with A. There are many types of RNA, including m-RNA (messenger RNA), rRNA (ribosomal RNA) and tRNA (transfer RNA). The m-RNA carries information out of the nucleus and into the cytoplasm, where proteins are made. The r-RNA forms the structure of ribosomes in the cells. The t-RNA brings to the ribosomes the amonoacids needed for making protein.

The DNA molecule directs the machinery of the cell in the following way: it makes a messenger RNA (m-RNA) molecule carry the genetic information from the nucleus out into the cytoplasm, the part of the cell which makes proteins. In cytoplams , the m-RNA serves as the blueprint for making protein molecules needed by the cell. The instructions on m-RNA are in the form of a code which consistes of 64 three-base combinations available on DNA molecules.

The genetic code is the set of rules by which information encoded in genetic material (DNA or RNA sequences) is translated into proteins (amino acid sequences) by living cells. Specifically, the code defines a mapping between tri-nucleotide sequences called codons and amino acids; every triplet of nucleotides in a nucleic acid sequence specifies a single amino acid. Most organisms use a nearly universal code that is referred to as the standard genetic code. Even viruses, which are not cellular and do not synthesize proteins themselves, have proteins made using this standard code The genetic information carried by an organism, its genome, is inscribed in one or more DNA, or in some cases RNA, molecules.

The genetic information encoded by an organism's DNA is called its genome. During cell division, DNA is replicated, and during reproduction is transmitted to offspring. Genes are the units of heredity and can be loosely viewed as the organism's "cookbook" or "blueprint". DNA is often referred to as the molecule of heredity. Within a gene, the sequence of nucleotides along a DNA strand defines a messenger RNA sequence which then defines a protein that an organism is liable to manufacture or *express* at one or several points in its life using the information of the sequence.

Parallelism

The goal of molecular nanotechnology (MNT) is to manufacture complex products with almost every atom in its proper place. This requires building large molecular shapes and then assembling them into products. The molecules must be built by some form of chemistry. The MNT assumes that building shapes of the required variety and complexity will require robotic placement (covalent bonding) of small chemical pieces. Once the molecular shapes are made, they can be combined to form structures and machines. This probably will be done again by robotic assembly. It probably can be done by building diamond lattice by mechanically guided chemistry, or mechano-chemistry. By building the lattice in various directions, a wide variety of parts can be made: the parts that would be familiar to a mechanical engineer, such as levers, *etc*. The robotic system used for building the molecular parts can also be used to assemble the parts into a machine.

In fact, there is no reason why a robotic system cannot build a copy of itself. In sharp contrast to conventional manufacturing, only a few (chemical) processes are needed to make any required shape. Moroever, with each atom in the right place, each manufactured part will be precisely the right size,so robotic assembly plans may be easy to program. A small nano-robotic device that can use supplied chemicals to manufacture nanoscale products under external control is called a fabricator. A personal nanofactory will consist of trillions of fabricators, and could only be built by another nanofactory. But a fabricator could build a very small nanofactory, with just a few fabricators in it. A smaller nanofactory could build a bigger one, and so on.

The mechanical designs proposed for nano-technology are more like a factory than a living system. Molecular scale robotic arms able to move and position molecular parts would assemble rather rigid molecular products using methods more familiar to a machine shop than the complex brew of chemicals found in a cell. Although we are inspired by living systems, the actual designs are likely to owe more to design constraints and our human objectives than to living systems. Self replication is but one of many abilities that living systems exhibit. Copying that one ability in an artificial system will be challenge enough without attempting to emulate their many other remarkable abilities.

Von Neumann designed a self-replicating device that existed in a two-dimensional "cellular automata" world. The device had an "arm" capable of creating arbitrary structures, and a computer capable of executing arbitrary programs. The computer, under program control, would issue detailed instructions to the arm. The resulting universal constructor was self-replicating almost as a by-product of its ability to create any structure in the two-dimensional world in which it lived. If it could build any structure it could easily build a copy of itself, and hence was self-replicating.

One interesting aspect of von Neumann's work is the relative simplicity of the resulting device: a few hundred kilobits to a megabit. Self-replicating systems need not inherently be vastly complex. Simple existing biological systems, such as bacteria, have a complexity of about 10 million bits. Of course, a significant part of this complexity is devoted to mechanisms for synthesizing all the chemicals needed to build bacteria from any one of several simple sugars and a few inorganic salts, and other mechanisms for detecting and moving to nutrients. Bacteria are more complex than strictly necessary simply to self-reproduce.

When we contrast this with a bacterium, much of the additional complexity is relatively easy to explain. Bacteria use a relatively small number of well defined chemical components which are brought to them by diffusion. This eliminates the

mining, hauling, leaching, casting, molding, finishing, and so forth. The molecular "parts" are readily available and identical, which greatly simplifies parts inspection and handling. The actual assembly of the parts uses a single relatively simple programmable device, the ribosome, which performs only a simple rigid sequence of assembly operations (no AI in a ribosome!). Parts assembly is done primarily with "self-assembly" methods, which involve no further parts-handling. Self replication is used here as a means to an end, not as an end in itself. A system able to make copies of itself but unable to make much of anything else would not be very useful and would not satisfy our objectives. The purpose of self replication in the context of manufacturing is to permit the low cost replication of a flexible and programmable manufacturing system; a system that can be reprogrammed to make a very wide range of molecularly precise structures. This lets us economically build a very wide range of products.

A person who saw DNA's potential beyond biology was Naiman Seeman, a chemist at New York University, who theorized the concept of nanofabrication [10] some 20 years ago. Seeman began imagining how the genetic information in DNA can be engineered to perform useful tasks. DNA comes with a built-in code that researchers can re-formulate to control which DNA molecules bond with each other. The goal of this DNA tinkering is to develop microscopic factories that can produce *made-to-order* molecules, as well as electronic components ten times smaller than current limits. The ability to attach particles to DNA pieces is a step towards fabricating nano-electronics. Scientists can hitch functional materials like metals, semiconductors, and insulators to specific DNA molecules, which can then carry their cargo to pre-specified positions.

More recently, Seeman and colleagues have put DNA robots to work by incorporating them into a self-assembling array. The composite device grabs various molecular chains, or "polymers", from a solution and fuses them together. By controlling the position of the nano-bots (as these tiny robot are called), the researchers can specify the arrangement of the finished polymer. Seeman hopes this tiny assembly line can be expanded into nano-factories that would synthesize whole suites of polymers in parallel. This technique has already been used to make a simple transistor, as well as metallic wires.

Researchers have built an inchworm-like robot so small you need a microscope just to see it. The tiny bot measures about 60 micrometers wide (about the width of a human hair) by 250 micrometers long, making it the smallest controllable micro-robot. Scientists recently built the tiniest electric motor ever. One could stuff hundreds of them into the period at the end of this sentence.

76.5 A Peep into the Future

In this section, the author would like to take a journey into a future full of strange possibilities, which in his opinion may become realities some day. These are based on the current state of science and trends that are being visualized keeping the objective of sustainable development in mind.

With nanotechnology coming in vogue, our energy requirements could be slashed considerably and sustainable energy sources like solar cells would not only prove to be economical but will be a clean source of energy. Solar solutions can be implemented on an individual, village, or national scale. The energy of direct sunlight is approximately 1 kW/m^2. Dividing that by ten to account for nights, cloudy days, and system inefficiencies, present-day American power demands (about 10 kW per person) would require about 100 m^2 of collector surface per person. Multiplying this figure by a population of 325 million (estimated by the US Census Bureau for 2020) yields a requirement for approximately 12,500 square miles of area to be covered with solar collectors. This represents 0.35% of total US land surface area. Much of this could be implemented on rooftops, and conceivably even on road surfaces. Storable solar energy will reduce ash, soot, hydrocarbon, NOx, and CO_2 emissions, as well as oil spills. The system can be totally decentralized with no loss of power in long transmission lines, or distribution systems, or risk of theft or sabotage, besides saving lots of copper

and steel and release land which they occupy for giving them right of way and substations.

Molecular manufacturing can be self-contained and clean; a single suitcase could contain all equipment required for a village-scale industrial revolution. Finally, MNT will provide cheap and advanced equipment for medical research and health care, making improved medicine widely available. Even in areas that currently do not have a technological infrastructure, self-contained molecular manufacturing will allow the rapid deployment of environment-friendly technology.

Eventually, we may hope that MNT will be able to directly edit the DNA of living cells in the body. However, even without that level of sophistication, massively parallel scanning may enable the sorting of cells modified outside the body. The ability to inject only non-cancerous cells would make some kinds of genetic therapy much safer. Microsurgical techniques [12] could allow the implantation of modified cells directly into the target tissues. In fact humans can prolong their life as much they desire to live without having any kind of disease. Probably limbs and organs could be grown or renewed. Of course this will have to conform to the requirement of carrying capacity of the earth to ensure sustainability.

There will be a fusion of biotechnology and nanotechnology and this will lead to all products and systems becoming biodegradable in future so that their manufacturing and disposal does not create any environmental pollution. Development of biodegradable plastic is a step in that direction. In fact all items of daily use can be made biodegradable and possibly grown using the technology based on bio-nano-technology. We will possibly be able to make tables, chairs, beds, clothes, and anything else by molecular manipulation.

If most structures and functions can be built out of carbon and hydrogen, there will be far less use for minerals, and mining operations can be mostly shut down. Manufacturing technologies that pollute can also be scaled back.

Remembering the most complex, reliable, and sustainable machine that this planet has evolved over 3.5 billion years starting from from simple living cells through correct and unique combinations of molecules, is human not to talk of other living creatures. This biological machine (which is highly complex and biodegradable, less polluting and requires less energy for all its functions) is a marvel in many respects, and can hardly be achieved through any artificial manufacturing methods or inorganic processes. No mechanical pump can ever surpass the performance of the heart pumping blood through entire body ceaselessly for years. A three-dimensional camera like the human eyes, a stereo system like the of ears, and many such subsystems can hardly be built or copied by the technology that humans or living being are capable of having. This human machine has all the intelligence, senses, locomotion and replicating capabilities (all biologically grown or developed) that we are trying to copy or achieve through extraneous means like robots or machines (inorganic means). Why cannot the same analogy be used to create futuristic systems, accessories and services biologically using biotechnology and nanotechnology that will help satisfy our needs and make life comfortable and happier? We have not learn much from natural biological processes of product development. Like making of honey by bees or building miles and miles long silk threads. Maybe we are eventually heading towards that. that.

About the Editor

Krishna B. Misra is at present the Principal Consultant for RAMS Consultants. He established the company in Jaipur in 2005 and since then he was also been working as the Editor-in-Chief of the quarterly International Journal of Performability Engineering, published by RAMS Consultants. He has held the position of a full professor since 1976 at IIT Roorkee and also at IIT Kharagpur. He was also Director of North Eastern Regional Institute of Science and Technology (a Deemed University) from 1995 to 1998. During the period 1992–1994, he was Director-grade-Scientist at the National Environmental Engineering Research Institute (NEERI, Nagpur, India) where he set up two divisions, *viz*, the *Disaster Prevention and Impact Minimization Division* and the *Information Division*. He has been Coordinator of the Ministry of Human Resource Development Project on *Reliability Engineering* since 1983 at IIT Karagpur. He also served as Dean of the Institute of Planning and Development at IIT, Kharagpur. Dr. Misra has been working in the area of reliability engineering since 1967 and has been making efforts to popularize reliability, safety, and allied concepts in India, both in the industry and in engineering education. It was due to his efforts that a master's degree program in reliability engineering was conceptualized and started for the first time in India at IIT, Kharagpur in 1982. This program has been running successfully to date. In 1983, he also founded the Reliability Engineering Center at IIT, Kharagpur, which is the first of its kind to promote research, consultancy, and teaching at an advanced level in the area of reliability, quality, and safety engineering in India.

Since 1963, he has taught and/or researched at the oldest and reputed engineering institutions of the country, which include IIT-Roorkee, IIT-Kharagpur, and NEERI, Nagpur. He has also worked in Germany at four different institutions, *viz,* GRS-Garching, Technical University-Munich, RWTH-Aachen, and Kernforschungszentrum, Karlsruhe. On invitation, he has delivered lectures in USA, England, Finland, France, Germany, Greece, Holland, Italy, Poland, and Sweden.

Dr. Misra has published over 200 technical papers in reputed international journals such as IEEE Transactions on Reliability, Microelectronics and Reliability, the International Journal of System Science, the International Journal of Control, Reliability Engineering and System Safety, the International Journal of Quality and Reliability Management, the International Journal of Reliability, Quality, and Safety Engineering, Fuzzy Sets and Systems, *etc*. Dr. Misra's research papers are widely quoted in international journals and books.

Besides being an Associate Editor of IEEE Transactions on Reliability, Dr. Misra has served as reviewer for IEEE Transactions on Reliability for nearly four decades and had also served on the editorial board of several international journals, including Microelectronics and Reliability (for more than 25 years), Reliability Engineering and System Safety, Quality and Reliability Management, the International Journal of Reliability, Quality, and Safety Engineering, the International Journal of Fuzzy Mathematics,

the Electrical Power Research Journal, *etc*. He has also been a reviewer for Fuzzy Sets and Systems, the European Journal on Operational Research, the International Journal on General Systems, *etc*. In 2005, he started the quarterly International Journal of Performability Engineering. Dr. Misra introduced the concept of performability as a holistic attribute of performance.

In 1992, Professor Misra authored a 889-page state-of-the-art book on *Reliability Analysis and Prediction: A Methodology Oriented Treatment*, published by *Elsevier Science Publishers*, Amsterdam. In 1993, Prof. Misra edited a 715-page book, *New Trends in System Reliability Evaluation*, which was also published by *Elsevier Science Publishers*. These books have received excellent reviews from the scientific community. In 1995, Professor Misra edited another 853-page book, *Clean Production: Environmental and Economic Perspectives*, published by Springer, Germany. In 2004, he authored another book, *Principles of Reliability Engineering*, which is mainly aimed at practicing engineers.

Dr. Misra is a recipient of a several best paper awards and prizes in addition to the first *Lal C. Verman Award* in 1983 by the Institution of Electronics and Telecommunications Engineering *for his pioneering work in reliability engineering in the country*. In 1995, in recognition of his *meritorious* and *outstanding contributions* to reliability research and education in India, he was awarded a plaque by the IEEE Reliability Engineering Society, USA.

Prof. Misra is a fellow of the Indian Academy of Sciences, the Indian National Academy of Engineering, the Institution of Electronics and Telecommunications (India), the Institutions of Engineers (India) and Safety and Reliability Society (UK). He has been vice president of the System Society of India, of which he is a life member. He is also a life member of the National Institute of Quality and Reliability.

Currently, Dr. Misra is the Chairman of the Indian Bureau of Standards Committee LTDC 3 on Reliability of Electrical and Electronic Components and Equipments. For several years, he served as a member of the Environmental Appraisal Committee (for nuclear power plants in India), the Ministry of Environment and Forests, Government of India, New Delhi. In 1976, Prof. Misra was invited by the Department of Science and Technology, New Delhi, to serve as the convener of the NCST *working group on Reliability Engineering in India*, set up by the Government of India. This group submitted two reports (Part Is and II) in 1978 on *the Reliability Implementation Program for India.* He also served as member of Task Force Committee on Reliability Engineering of the Department of Science and Technology, in 1979. He has served as member on the Project Assessment Committee for the National Radar Council, the Department of Electronics, CSIR, UGC, *etc*. Dr. Misra is listed in *Indo-American Who's Who.*

About the Contributors

Amari, Suprasad V., is a senior reliability engineer at Relex Software Corporation. He pursued his MS and PhD in reliability engineering at the Reliability Engineering Centre, Indian Institute of Technology, Kharagpur. He has published over 35 research papers in reputed international journals and conferences. He is an editorial board member of the International Journal of Reliability, Quality and Safety Engineering, an area editor of the International Journal of Performability Engineering, and a management committee member of RAMS. He is a member of the US Technical Advisory Group (TAG) to the IEC Technical Committee on Dependability Standards (TC 56), an advisory board member of several international conferences, and a reviewer for several journals on reliability and safety. He is a senior member of ASQ, IEEE, and IIE; and a member of ACM, ASA, SSS, SRE, and SOLE. He is also an ASQ-certified reliability engineer. E-mail: suprasad.amari@relex.com

Ang, B.W., is Professor of Industrial and Systems Engineering at the National University of Singapore. His primary research interest is systems modeling and forecasting. He has developed several index decomposition analysis techniques for quantifying factors contributing to changes in aggregate measures These techniques have been widely used to study changes in national energy consumption and energy-related greenhouse house gas emissions by researchers and national energy agencies. He is an associate editor of Energy – The International Journal and Energy Economics, and a member of the editorial boards of Energy Policy, Energy and Environment, International Journal of Performability Engineering, and the Journal of Urban Technology.

Aven, Terje, is Professor of Risk analysis and Risk Management at the University of Stavanger, Norway. He is also a principal researcher at the International Research Institute of Stavanger (IRIS). He was professor II (adjunct professor) in reliability and safety at the University of Trondheim (Norwegian Institute of Technology) from 1990 to 1995 and professor II in reliability and risk analysis at the University of Oslo from 1990 to 2000. He was the dean of the faculty of technology and science, Stavanger University College from 1994 to 1996. Dr. Aven has many years of experience in the petroleum industry (the Norwegian State Oil Company, Statoil). He has published a large number of papers in international journals on probabilistic modelling, reliability, risk and safety. He is the author of several reliability and safety related books, including Stochastic Models in Reliability, Springer, 1999 (co-author U. Jensen), Foundations of Risk Analysis, Wiley, 2003, and Risk Management, Springer, 2007 (co-author J.E. Vinnem). He is a member of the editorial boards of Reliability Engineering and System Safety, and the Journal of Risk and Reliability. He is an associate editor of the Journal of Applied Probability on Reliability Theory and an area editor (within risk management) of the International Journal of

Performability Engineering. He is a member of the Norwegian Academy of Technological Sciences and Head of the Stavanger Chapter 2005–2007. He has supervised about 20 Ph.D. students in risk and safety. He received his Master's degree (cand. real) and Ph.D (dr. philos) in mathematical statistics (reliability) from the University of Oslo in 1980 and 1984, respectively.

Ba, Dechun, obtained his Bachelor's degree from Northeastern University in July of 1977, majoring in mechanical design and manufacture, post graduated from Northeastern University in July of 1985, majoring in vacuum and fluid engineering and received his Ph.D. from Northeastern University in September of 1997. Professor Ba has a wide range of interests, including synthesis of function films and plasma modeling. Professor Ba is the member of American Vacuum Society.

Baas, Leo (1946), has a Master's of Science degree in sociology of industry and business management with a specialization in environmental sciences and a Ph.D. in social sciences on the subject of the dynamics of the introduction and dissemination of the new concepts of cleaner production and industrial ecology in industrial practice. He has been working at the Erasmus Centre on Sustainability and Management (ESM) at Erasmus University Rotterdam since April 1986. He has performed research on cleaner production since 1988 and on industrial ecology since 1994. He has been an advisor of the UNEP/UNIDO National Cleaner Production Centres Programme since 1994, and a member of UNEP's High Level Expert Forum on Sustainable Consumption and Production. He is a member of the strategic decision-making platform of the long-term innovation programme Sustainable Enterprises in the Rotterdam Harbour and Industry Complex in the Netherlands. He co-ordinates the International Off-Campus Ph.D. Programme on Cleaner Production, Cleaner Products, Industrial Ecology & Sustainability, and the Social Science Track of the International Inter-University M.Sc. Industrial Ecology (in co-operation with Delft University of Technology and Leiden University) at Erasmus University. He is responsible for the module Corporate Environmental Management at the International Institute for Housing and Urban Development. Dr Baas is an area editor (industrial ecology) of the International Journal of Performability Engineering.

Barbu, Vlad Stefan, is associate professor in statistics at the University of Rouen, France, Laboratory of Mathematics "Raphaël Salem". He received his B.Sc. in mathematics from the University of Bucharest, Romania (1997) and his M.Sc. in applied statistics and optimization from the same university (1998). He worked for three years (1998–2001) as an assistant professor in mathematics at the University "Politehnica" of Bucharest, Romania. In 2005 he received his Ph.D. in applied statistics from the University of Technology of Compiègne, France. His research focuses mainly on stochastic processes and associated statistical problems, with a particular interest in reliability and DNA analysis. He has published several papers in the field.

Barratt, Rod S., BSc PhD CSci CChem FRSC, is a chartered chemist by profession, and has spent most of his career in the teaching and practice of air quality management. He built a practical foundation in his subject in local government environmental protection and energy consultancy. At the Open University, he is Head of the Department of Environmental and Mechanical Engineering. His teaching interests focus on air quality management and wider aspects of safety, health and environmental management and he supervises several part-time research students working in these areas. In addition to about 40 journal publications, he has written two books dealing with environmental management, one on atmospheric dispersion modelling and various book chapters. As an expert witness, he has used atmospheric dispersion modelling in developing evidence for public inquiries relating to the planning aspects of road, industrial and mineral working activities. Dr. Barratt is the area editor (sustainability) of the International Journal of Performability Engineering.

Bettley, Alison, Ph.D., is a senior lecturer in Technology Management in the Faculty of Technology of the Open University. She currently chairs the university's master's course in business operations and pursues research interests in operations management, knowledge management, technology strategy, and the marketing of high technology services. As well as her academic interests, she has extensive professional experience as an R&D and technical services manager in the fields of environmental technology and management.

Brooks, Richard R., is an associate professor in the Holcombe Department of Electrical and Computer Engineering of Clemson University. His research is in adversarial systems and security technologies. He has a B.A. in mathematical sciences from The Johns Hopkins University and a Ph.D. in computer science from Louisiana State University.

Burnley, Stephen, Ph.D., is a senior lecturer in Environmental Engineering in the Faculty of Technology of the Open University. He is responsible for teaching solid waste management at undergraduate and postgraduate levels. His research interests cover municipal waste surveys and statistics, the impact of legislation on waste management practices, and the use of information and computing technology in teaching environmental engineering.

Butte, Vijay Kumar, received the B.E. degree with distinction in mechanical engineering from University of Mysore, India in 2001. He is currently pursuing his Ph.D. in the Department of Industrial and Systems Engineering at the National University of Singapore. His research interests include statistical quality control, engineering process control and time series analysis.

Chaturvedi, S.K., is currently working as Assistant Professor at the Reliability Engineering Centre, Indian Institute of Technology, Kharagpur (India). He received his Ph.D. degree from the Reliability Engineering Centre, IIT, Kharagpur (India) in 2003. His research interests include network reliability, life-data analysis, and optimization, and has published papers in international and national journals. He is an assistant editor of International Journal of Performability Engineering and reviewer for the International Journal of Quality and Reliability Management.

Coffelt, Jeremy, is pursuing a Ph.D. in Water Resources Engineering at Texas A&M University. His interests are in risk and reliability analysis of water distribution systems and characterization of uncertainty in water availability modeling. He has an M.S. degree in mathematics from Kansas State University and a B.S. in mathematics and biology from Midwestern State University.

Cui, **Lirong,** is a professor in the School of Management and Economics, Beijing Institute of Technology. He received his Ph.D. degree in statistics from the University of Wales, UK, in 1994, his M.S.degree in operations research and control theory from the Institute of System Sciences, Chinese Academy of Sciences, in 1986, his B.E. degree in textile engineering in 1983 from Tianjin Polytechnic University, P.R. China. He has been working on reliability related problems since 1986. He has more than 15 years industrial working experience in quality and reliability. In 2000 he coauthored the book "Reliabilities of Consecutive-*k* Systems" published by Kluwer. His recent research interests are in stochastic modeling, quality and reliability engineering, simulation and optimization, risk management, software development for quality and reliability, operations research, supply chain management, and applications of probability and statistics in various fields. He is currently serving as an associated editor of IEEE Transactions on Reliability.

Dai, Y.S., is a faculty member of the Computer Science Department of Purdue University School of Science at IUPUI, USA. He received his Ph.D. degree from the National University of Singapore, and his bachelor degree from Tsinghua University. His research interests lie in the fields of dependability, grid computing, security, and autonomic computing. He has published 4 books, and over 70 articles in these areas. His research has been featured in the Industrial Engineer Magazine (p. 51, December, 2004). Dr. Dai is a Program Chair for the 12th IEEE Pacific Rim Symposium on Dependable Computing (PRDC2006) and a General Chair for the 2nd IEEE Symposium on Dependable Autonomic and Secure Computing (DASC06), and for the DASC07. He also chairs many other conferences and is a member of the editorial board of the International Journal of Performability Engineering. He is on the editorial board of some other journals, *e.g.,* Guest Editor for IEEE Transactions on Reliability, Lecture Notes in Computer Science, the Journal of Computer Science, and the International Journal of Autonomic and Trusted Computing. He is a member of IEEE.

Dam-Mieras, Rietje van, was born in 1948, studied chemistry at Utrecht University and obtained her Ph.D. degree in biochemistry at the same university. In 1992 she was nominated Professor of Natural Sciences, especially biochemistry and biotechnology at the Open University of the Netherlands. Her activities at this institute are in the fields of molecular sciences, sustainable development, and innovative ways of e-enhanced learning. She is actively involved in the Regional Centre of Expertise (RCE) on Learning for Sustainable Development in the region Eindhoven (NL)–Cologne (G)–Leuven (B). In addition to her work at the Open University of the Netherlands she has several advisory and supervisory functions. From 1992–1997, she was a member of the Programme Committee Science and Technology of the European Association of Distance Teaching Universities (EADTU). In 1997 she became a member of the Supervisory Board of Akzo Nobel Netherlands. From 1997–2004 she was the chairperson of the Copernicus-campus network of European universities and through this became one of the founding members of GHESP, the Global Higher Education for Sustainable Development Partnership. From 1998 until 2003 she was a member of the Dutch Scientific Council for Government Policy. Since 2000 she has been a member of the Supervisory Board of the Netherlands Organization for Applied Scientific Research (TNO). In 2002 she became a member of the program committee The Social Component in Genomics Research of the Netherlands Council for Scientific Research (NWO) and in 2005 she became a member of the Supervisory Board of Unilever Netherlands.

Dill, Glenn, is a senior software engineer for Relex Software Corporation. He is responsible for designing and programming the highly sophisticated calculation models within the Relex reliability analysis modules. He has a B.S. degree in mathematics and computer science from California University of Pennsylvania. A professional software engineer for 17 years, his previous career experiences include writing codes for high-performance computer games. His research interests include software engineering, software reliability, and high performance computing. He is a member of the IEEE Computer Society.

Ding, Yi, received his B.S. degree from Shanghai Jiaotong University, China, and his Ph.D. degree from Nanyang Technological University, Singapore. He is currently a research fellow in the Department of Mechanical Engineering University of Alberta, Canada.

El-Azzouzi, Tarik, is a research scientist, at ReliaSoft Corporation, USA. Mr. El-Azzouzi is involved in the theoretical formulation and validation of ReliaSoft's reliability analysis and modeling software products and provides reliability expertise to ReliaSoft's clients. Mr. El-Azzouzi regularly trains and lectures about various subjects of reliability and is involved in the development of courses and in the writing of reliability reference books and articles for magazines about reliability. He also has experience

with implementing reliability programs in addition to being part of reliability consulting projects for major companies. He holds an M.S. degree in reliability and quality engineering from the University of Arizona.

Feng, Qianmei, is an assistant professor in the Department of Industrial Engineering at the University of Houston, Texas. Her research interests are quality and reliability engineering, especially inspection strategies, optimization of specifications, tolerance design and optimization, reliability modeling and optimization, and Six Sigma. She received the Ph.D. degree in industrial engineering from the University of Washington, Seattle, Washington in 2005. She received her double Bachelor degrees in mechanical engineering and industrial engineering from Tsinghua University, Beijing, China (1998) with *summa cum laude*, and her Master's degree in management science from Tsinghua University (2000). Her research has been published in peer-reviewed journals such as IIE Transactions, the International Journal of Reliability, Quality and Safety Engineering, Quality Technology and Quantitative Management, and the International Journal of Six Sigma and Competitive Advantage. She is a member of IIE, INFORMS, ASQ, and Alpha Pi Mu. E-mail: qmfeng@uh.edu

Fidler, Jan, is a Ph.D. student in the Department of Industrial Technology, Ecology at the Royal Institute of Technology (KTH) in Stockholm, Sweden. Her research is focusses on risk assessment.

Fitzgerald, Daniel P., earned his M.S. degree in mechanical engineering from the University of Maryland in December 2006 and is currently a Ph.D. student at the University of Maryland. His research interests include design for environment and decision-making systems in product development.

Gogoll, Thornton H. (Ted), is the Director, Engineering Standards for the North American Power Tool and Accessories Business at Black & Decker. He reports to the Vice President of Engineering, DeWalt, and is responsible for the development and management of key global standards and processes related to the environmental, quality, and safety performance of new and existing products. Ted has a background in product development in the aerospace and consumer product areas and holds a Master's of Science degree in Mechanical Engineering from Virginia Tech.

Goh, Thong-Ngee, BE (University of Saskatchewan), PhD (University of Wisconsin-Madison), is Director at the Centre for Design Technology, and Professor of Industrial and Systems Engineering. Dr. Goh is a former dean of engineering and director of the Office of Quality Management at the National University of Singapore. He is a GE-certified Six Sigma trainer. Professor Goh is an academician of the International Academy for Quality, Fellow of the American Society for Quality (ASQ), and associate editor (Western Pacific Rim) of the ASQ Quality Engineering Journal. He is also on the editorial boards of several other international journals, such as Quality and Reliability Engineering International, International Journal of Production Economics, International Journal of Reliability, Quality, and Safety Engineering, and the TQM Magazine.

Gokhale, Swapna S., is currently an assistant professor in the Department of Computer Science and Engineering at the University of Connecticut. She received her B.E. (Hons.) in electrical and electronic engineering and computer science from the Birla Institute of Technology and Science, Pilani, India in 1994, and M.S. and Ph.D. degrees in electrical and computer engineering from Duke University in 1996 and 1998, respectively. Prior to joining the University of Connecticut, she spent one year as a post-graduate researcher at the University of California, Riverside and three years as a research scientist at Telcordia Technologies (Bell Communications Research), New Jersey. Her research interests lie in the areas of system and software reliability analysis, performance analysis of middleware and web-based

systems, and QoS issues in wireless and wire-line networks. She has published over 75 journal and conference papers on these topics.

Guikema, Seth D., is an assistant professor in the Zachry Department of Civil Engineering at Texas A&M University. His areas of expertise are risk and decision analysis, Bayesian probability modeling, and resource allocation for critical infrastructure systems. He has a Ph.D. in engineering risk and decision analysis from the Department of Management Science and Engineering at Stanford University, an M.S. in civil engineering from Stanford University, an M.E. in civil engineering from the University of Canterbury, and a B.S. in civil and environmental Engineering from Cornell University.

Haldar, Achintya, is Professor of Civil Engineering and Engineering Mechanics and a da Vinci Fellow at the College of Engineering at the University of Arizona. He received his graduate degrees (M.S., 1973 and Ph.D., 1976) from the University of Illinois, Urbana-Champaign. He also taught at Illinois Institute of Technology and at Georgia Institute of Technology. Dr. Haldar has over five years of industrial experience including working for Bechtel Power Corporation in their nuclear power division. Dr. Haldar has received many awards for his research, including the first Presidential Young Investigator Award and the ASCE's Huber Civil Engineering Research prize. He received an Honorable Diploma from the Czech Society for Mechanics. Dr. Haldar received Graduate Advisor of the Year award from the University of Arizona. He also received the Honorable Recognition Award from ASME. He received the Distinguished Alumnus award from the Civil and Environmental Engineering Alumni Association, the University of Illinois. Dr. Haldar has received numerous recognitions for his exceptional teaching including the Burlington North Foundation Faculty Achievement Award, Outstanding Faculty Member Award in 1991, 2004, and 2006, the Professor of the Year Award in 1998, and the Award for Excellence at the Student Interface in 2004 and 2005. At Gerogia Tech, Dr. Haldar received the Outstanding Teacher Award for being the best professor. He also received the Outstanding Civil Engineering Faculty Member Award in 1982 and 1987. For his services, Dr. Haldar received the Outstanding Faculty Award from the UA Asian American Faculty, Staff and Alumni Association, the Governor's Recognition Award from Governor Fife Symington of the State of Arizona, and the Service Award from the Structural Engineering Institute of ASCE. An ASCE Fellow, Dr. Haldar is a registered professional engineer in several states in the U.S. Professor Haldar is a member of the editorial board of International Journal of Performability Engineering.

He, Liping, is a Ph.D. scholar of the School of Mechanical Engineering, Dalian University of Technology, Dalian, Liaoning, 116023, China. Her research interests include reliability engineering, product warranty, design optimization, total quality management, and production and engineering management.

Hegde, Vaishali, is a member of the Reliability Department at Respironics Inc. In her role as a Senior Reliability Engineer, she is responsible for ensuring that all new medical products introduced onto the market meet the high reliability standards set by Respironics. Prior to joining Respironics, she worked as an application engineer at Relex Software Corporation. She was responsible for consulting services and assisting customers with reliability theory and reliability software. Vaishali has also worked at R&D labs in the defense industry. She has over ten years of experience in design, testing, manufacturing, and consulting. She has co-authored two papers and presented at the Reliability and Maintainability Symposium .She received her B.S. in electrical engineering from West Virginia University. She is an ASQ certified reliability engineer. Vaishali is an active member of the American Society of Quality. She has been serving on the Executive Committee of the ASQ Pittsburgh Chapter for the past three years.

Herrmann, Jeffrey W., is an associate professor at the University of Maryland, where he holds a joint appointment with the Department of Mechanical Engineering and the Institute for Systems Research. He is the director of the Computer Integrated Manufacturing Laboratory. Dr. Herrmann earned his B.S. in applied mathematics from Georgia Institute of Technology. As a National Science Foundation Graduate Research Fellow from 1990 to 1993, he received his Ph.D. in industrial and systems engineering from the University of Florida. His current research interests include the design and control of manufacturing systems, the integration of product design and manufacturing system design, and decision-making systems in product development.

Hobbs, Gregg K., Ph.D., P.E., is the originator of the principles of HALT and HASS. He has been a consulting engineer since 1978, specializing in the fields of stress screening, robust and flaw tolerant design, dynamic analysis and testing. He has been employed as a consultant by many leading companies in the aerospace, commercial, military, and industrial fields. He has introduced, and continues to introduce many new concepts, techniques, and equipment. He has authored 13 patents on equipment to perform HALT and HASS. He has also written hundreds of papers in many fields. He is the author of the book "HALT and HASS, Accelerated Reliability Engineering".

Hokstad, Per, was born July 3, 1942 in Oslo, Norway. He received his M.Sc. degree in mathematical statistics from the University of Oslo in 1968. He then had a position at the University of Science and Technology (NTNU), Trondheim, Norway until 1985, and since then he has been employed at SINTEF Safety and Reliability. During the period 1990–2000, he was also adjunct professor at NTNU. He has broad experience with both theory and applications of reliability, safety, and risk analyses. The main application areas are offshore oil and gas industry and transportation. Mr. Hokstad is a member of the editorial board of International Journal of Performability Engineering.

Huang, Hong-Zhong, is a full professor and the Dean of the School of Mechanical, Electronic, and Industrial Engineering, University of Electronic Science and Technology of China, Chengdu, Sichuan, 610054, China. He has held visiting appointments at several universities in Canada, USA, and Asia. He received a Ph.D. degree in reliability engineering from Shanghai Jiaotong University, China in 1999. He has published 120 journal papers and 5 books in fields of reliability engineering, optimization design, fuzzy sets theory, and product development. He is a (senior) member of several professional societies, and has served on the boards of professional societies. He received the Golomski Award from the Institute of Industrial Engineers in 2006. His current research interests include system reliability analysis, warranty, maintenance planning and optimization, and computational intelligence in product design. Professor Huang is a member of the editorial board of International Journal of Performability Engineering.

Jha, P.C., is a reader in the Department of Operational Research, University of Delhi. He obtained his Master's degree, M. Phil., and Ph. D. from the University of Delhi. He has published more than 25 research papers in the areas of software reliability, marketing, and optimization in Indian and international journals and has edited books. He has guided M.B.A. dissertations and is also supervising Ph.D. students in operational research.

Joanni, **Andreas** studied civil engineering at the Technical University of Munich and is presently a research assistant and Ph.D. student at the same university. He has authored of a number of important publications in structural reliability.

Jugulum, Rajesh, is a researcher in the Department of Mechanical Engineering at MIT and a Vice President of Global Wealth and Investment Division of Bank of America. Rajesh earned his doctorate

degree under the guidance of Dr. Genichi Taguchi. He has published several articles in leading technical journals and magazines. He co-authored a book on pattern information technology and a book on computer-based robust engineering, and holds a US patent. He is a senior member of the American Society for Quality (ASQ) and the Japanese Quality Engineering Society, and is a Fellow of the Royal Statistical Society and International Technology Institute (ITI). He was featured as "Face of Quality" in the September 2001 issue of Quality Progress. He is the recipient of ASQ's Richard A. Freund international scholarship (2000), ASQ's Feigenbaum medal (2002), and ITI's Rockwell medal (2006). He was inducted into the world level of the Hall of Fame for science, engineering and technology in 2006 and in the same year he was listed in the "Who's Who in the World" list by Marquis.

Kafka, Peter, earned his Master's degree in mechanical engineering and his Ph.D. in thermal hydraulics from the Technical University of Graz, Austria. He worked for nine years at the Reactor Development Branch at Siemens Erlangen (D). From 1971, he worked for GRS, GmbH (Company for Plant and Reactor Safety) in the field of reliability, risk issues and probabilistic safety assessment (PSA) mainly for nuclear power plants but also for non-nuclear industries. After retirement from GRS in 2001, he is now working as an independent consultant for safety, risk and reliability (RAMS) issues for different type of systems and industries. He was General Chairman of the ESREL'99 Conference in Munich. He is Founding Member and a past Chairman of the European Safety and Reliability Association (ESRA). He is a member of the editorial board of the International Journal of Performability Engineering. For more details see www.relconsult.de.

Kapur, Kailash C. (Kal) is Professor in the Industrial Engineering Department at the University of Washington, Seattle, Washington. He was the Director of Industrial Engineering at the University of Washington from January 1993 to September 1999. He was Professor and the Director of the School of Industrial Engineering, University of Oklahoma (Norman, Oklahoma) from 1989–1992 and a professor in the Department of Industrial and Manufacturing Engineering at Wayne State University, Detroit, Michigan from1970–1989. Dr. Kapur has worked with General Motors Research Laboratories as a senior research engineer, with Ford Motor Company as a visiting scholar, and the U.S. Army, Tank-Automotive Command as a reliability engineer. Dr. Kapur has served on the Board of Directors of the American Supplier Institute, Inc., Michingan. He received his Bachelor's degree (1963) in mechanical engineering with distinction from Delhi University, his M. Tech. degree (1965) in industrial engineering from the Indian Institute of Technology, Kharagpur, his M.S. degree (1967) in operations research, and his Ph.D. degree (1969) in industrial engineering from the University of California, Berkeley. He co-authored the book Reliability in Engineering Design, published by Wiley in 1977. He has written chapters on reliability and quality engineering for several handbooks such as Industrial Engineering and Mechanical Design. He has published over 60 papers in technical, research, and professional journals. He received the Allan Chop Technical Advancement Award from the Reliability Division and the Craig Award from the Automotive Division of American Society for Quality. He is a Fellow of American Society for Quality, a Fellow of the Institute of Industrial Engineers, and a registered professional engineer. Prof. Kapur is on the editorial board of International Journal of Performability Engineering. E-mail: kkapur@u.washington.edu

Kapur, P.K., is a professor and former Head in the Department of Operational Research, University of Delhi. He is a former president of the Operational Research Society of India. He obtained his Ph.D. from the University of Delhi in 1977. He has published more than 125 research papers in the areas of hardware reliability, optimization, queueing theory, and maintenance and software reliability. He has edited three volumes and is currently editing fourth volume of Quality, Reliability and IT. He has co-authored the book Contributions to Hardware and Software Reliability, published by World Scientific, Singapore. He has edited special issues of the International Journal of Quality Reliability and Safety Engineering

(IQRSE, USA-2004) OPSEARCH, India (2005) and the International Journal of Performability Engineering (July, 2006), and is on the editorial board of the International Journal of Performability Engineering. He organized three international conferences successively in the years 2000, 2003, and 2006 on quality reliability and information technology. He has guided M.Tech./Ph.D. theses in computer science as well as in operations research. He has been invited to edit a special issue of IQRSE (2007) and a special issue of Communications on Dependability and Quality Management, Belgrade, Serbia. He has traveled extensively in India and abroad, and delivered invited talks. He is cited in "Marquis Who's Who in the World".

Kleyner, Andre, has over 20 years of experience as a mechanical engineer specializing in reliability of mechanical and electronic systems designed to operate in severe environments. He received his Doctorate in mechanical engineering from the University of Maryland, and his Master's in business administration from Ball State University, USA. Dr. Kleyner is currently employed by Delphi Corporation as a reliability and quality sciences manager, and as part of his job responsibilities he has developed and taught several training courses on reliability, quality, and design. He is a senior member of the American Society for Quality and is a certified reliability engineer. Dr. Kleyner is a recipient of the P.K. McElroy award for the best paper at the 2003 Reliability and Maintainability Symposium (RAMS). He holds several US and foreign patents, and has authored multiple papers on the topics of vibration, statistics, reliability, warranty, and lifecycle cost analysis.

Kohda, Takehisa, is an associate professor in the Department of Aeronautics and Astronautics, Kyoto University. He received his B.Eng., M.Eng., and Dr.Eng. degrees all in precision mechanics from Kyoto University in 1978, 1980, and 1983, respectively. Prior to joining Kyoto University in 1988, he worked with the National Mechanical Engineering Laboratory, Japan, as a researcher from 1983 to 1988. From 1985 to 1986, he was with the Department of Chemical Engineering, University of Houston. From 1999 to 2002, he was an associate editor of IEEE Transactions on Reliability. Since 2001, he has been a chair of the Technical Committee System Safety of the IEEE Reliability Society. Since 2004, he has been an area editor of International Journal of Performability Engineering. His interests lie in systems safety, reliability, and risk analysis. E-mail: kohda@kuaero.kyoto-u.ac.jp

Kontoleon, John, is Professor of Electronics in the Department of Electrical and Computer Engineering at the Aristotle University of Thessaloniki, Greece. He obtained his degree in physics from the University of Athens (Greece) and his Ph.D. in Electrical Engineering and Electronics from the University of Liverpool (UK). From 1972–1974, he was with the research group of the Research Directorate of the Hellenic Telecommunications Organization and from 1974–1981 he was with the Department of Electrical Engineering at the University of Wollongong (Australia). He served for many years as a member of the Executive Committee at the International Centre of Technical Co-operation (ITCC) and as a member of the Executive Committee in the European Safety and Reliability Association. He is the author of numerous research papers and is a member on the editorial boards of the International Journal of Performability Engineering, the International Journal of Reliability and Quality Management, and Facta Universitatis. His research interests include digital systems, fault tolerant systems, reliability modeling, and optimization of networks and systems.

Kulkarni, M.S., is currently working as an assistant professor at the Indian Institute of Technology Delhi in the Mechanical Engineering Department. He received his Ph.D., in manufacturing from the Indian Institute of Technology Bombay. His research interests include quality, reliability, and maintenance engineering, and their integration with operation planning.

Kumar, U. Dinesh, is Professor of Quantitative Methods and Information Systems at the Indian Institute of Management Bangalore. Professor Dinesh Kumar holds a Ph.D. in mathematics from IIT Bombay and an M.Sc. in applied sciences (Operations Research) from P.S.G. College of Technology, Coimbatore, India. Dr. Kumar has over 11 years of teaching and research experience. Prior to joining IIM Bangalore, Dr. Kumar has worked at several institutes across the world including Stevens Institute of Technology, USA, the University of Exeter, UK, the University of Toronto, Canada, the Federal Institute of Technology, Zurich, Switzerland, Queensland University of Technology, Australia, the Australian National University, Australia, and the Indian Institute of Management Calcutta. Dr. Kumar's research interests include pricing and revenue management, defense logistics, reliability, maintainability, logistics support, spare parts provisioning, Six Sigma, supply chain architecture, decision making and systems thinking. Dr. Kumar has written two books and over 50 articles in refereed International journals. Dr. Kumar is one of the leading authors of the books Reliability and Six Sigma, published by Springer, USA, and Reliability, Maintainability, and Logistic Support – A Life Cycle Approach, published by Kluwer. Dr. Kumar is Associate Editor of the Journal OPSEARCH, the Journal of the Operational Research Society of India. He is also an editorial member of the Journal Risk and Reliability published by the Institution of Mechanical Engineers (IMechE), UK, and an *ad hoc* referee for several international journals in operations research and systems engineering. Dr. Kumar was awarded the Best Young Teacher award by the Association of Indian Management Schools in 2003. E-mail: dineshk@iimb.ernet.in

Kumar, Udai, is Professor of Operation and Maintenance Engineering at Luleå University of Technology, Sweden. He is also director of The Center for Maintenance and Industrial Services, an industry sponsored neutral platform established with a main goal to facilitate exchange of maintenance related knowledge and experiences. He is also chairman of the Scientific Council of the Swedish Maintenance Society. Dr. Kumar has more than 25 years of experience in consulting and finding solutions to industrial problems directly or indirectly related to maintenance. His research and consulting efforts are mainly focused on enhancing the effectiveness and efficiency of maintenance process at both operational and strategic levels, and visualizing the contribution of maintenance in an industrial organization. Some of the manufacturing and process industries he has advised through sponsored R&D projects are ABB, Atlas Copco, SAAB Aerosystem, Statoil, LKAB, Vattenfall AB, Swedish Rail Road Administration, *etc*. Dr. Kumar has been a guest lecturer and invited speaker at numerous seminars, industrial forums, workshops, and academic institutions both in Scandinavia and overseas. He has published more than 125 papers in peer reviewed international fournals and chapters in books. He is a reviewer and member of the editorial advisory boards of several international journals, including the International Journal of Performability Engineering. His research interests are maintenance management and engineering, reliability and maintainability analysis, LCC, *etc*.

Lad, Bhupesh Kumar, received his M.E. in industrial engineering and management from Ujjain Engineering College, Ujjain, and is currently a research scholar at the Indian Institute of Technology, Delhi in the Mechanical Engineering Department. His current research interests are in the field of reliability, maintenance, and quality engineering.

Lam, Shao-Wei, holds a Bachelor's degree in mechanical engineering and a Master's degree in industrial and systems engineering from the National University of Singapore, and is a research fellow and Ph.D. candidate in the Department of Industrial and Systems Engineering, National University of Singapore. His current research interests are in the fields of quality and reliability by design and operations research in supply chain management. He has many years of experience in research, training, and consultancy, particularly in the areas of Six Sigma, robust design and statistical reliability engineering. He is a Certified Reliability Engineer (CRE) of the American Society of Quality (ASQ) and a member of the IEEE.

Levitin, Gregory, received the B.S. and M.S. degrees in electrical engineering from Kharkov Politechnic Institute (Ukraine) in 1982, a B.S. degree in mathematics from Kharkov State University in 1986, and a Ph.D. degree in industrial automation from Moscow Research Institute of Metalworking Machines in 1989. From 1982 to 1990, he worked as software engineer and researcher in the field of industrial automation. From 1991 to 1993, he worked at the Technion (Israel Institute of Technology) as a postdoctoral fellow in the Faculty of Industrial Engineering and Management. Dr. Levitin is presently an engineer-expert in the Reliability Department of the Israel Electric Corporation and an adjunct senior lecturer at the Technion. His current interests are in operations research and artificial intelligence applications in reliability and power engineering. In this field, Dr. Levitin has published more than 120 papers and four books. He is a senior member of IEEE. He serves on the editorial boards of IEEE Transactions on Reliability, Reliability Engineering and System Safety and the International Journal of Performability Engineering.

Limnios, Nikolaos, is Professor in Applied Mathematics at the University of Technology of Compiègne, France. His research interest is stochastic processes and statistics with application to reliability. He is (co-)author of the books: Semi-Markov Processes and Reliability (Birkhäuser, 2001, with G. Oprisan), Stochastic Systems in Merging Phase Space (World Scientific, 2005, with V.S.Koroliuk) and Fault Trees (ISTE, 1991, 2004, 2007). Professor Limnios is a member of the editorial board of the International Journal of Performability Engineering.

Lin, Zeng, received his Bachelor's degree majoring in mechanical design and manufacture from Jinan University in July 1997 and obtained his Master's degree majoring in motor vehicle engineering from Northeastern University in July 2001. He earned his Ph.D. in the area of vacuum and fluid engineering from Northeastern University in September 2004. Dr. Lin has a strong interest in hydrogenated amorphous carbon (a-C:H) nanofilms. He has recently worked on the models of the plasma enhanced chemical vapor deposition process in a-C:H, in order to try to understand the controlled synthesis of these materials. He has written ten papers and hold two patents on a-C:H films.

Liu, Yung-Wen, is an assistant professor in the Department of Industrial and Manufacturing Systems Engineering at the University of Michigan-Dearborn. He received his Ph.D. degree in industrial engineering from the University of Washington in 2006. He also received both his M.A. degrees in applied statistics and applied economics from the University of Michigan-Ann Arbor in 2000. His research interests include reliability theory, stochastic modeling, applied statistics, and healthcare modeling.
E-mail: ywliu@umich.edu

Lyngby, Narve, was born on January 12, 1976 in Oslo, Norway. He received his MSc degree in HSE (health, safety, and environment studies) from the University of Science and Technology (NTNU), Trondheim, Norway in 2002. Currently, he is a PhD student at the Norwegian University of Science and Technology (NTNU) in the Department of Production and Quality Engineering. He is working with degradation models for railway tracks, maintenance planning, and optimization.

Makis, Viliam, is a professor in the Department of Mechanical and Industrial Engineering, University of Toronto. His research and teaching interests are in the areas of quality assurance, stochastic OR modeling, maintenance, reliability, and production control with a special interest in investigating the optimal operating policies for stochastic controlled systems. His recent contributions have been in the area of modeling and optimization of partially observable processes with applications in CBM and multivariate

quality control. He has also contributed to the development of EMQ and other production models with inspections and random machine failures, joint SPC and APC for deteriorating production processes, scheduling of operations in FMS, reliability assessment of systems operating under varying conditions, and modeling and control of queuing systems. He was a founding member of the CBM Consortium at the University of Toronto in 1995. He is an area editor of the International Journal of Performability Engineering and has served for many years on the editorial advisory board of JQME. He is also on the advisory boards of several international conferences. He is a senior member of IIE and ASQ.

Mettas, Adamantios, is the Vice President of Product Development at ReliaSoft Corporation, USA and fulfills a critical role in the advancement of ReliaSoft's theoretical research efforts and formulations in the subjects of life data analysis, accelerated life testing and system reliability and maintainability. He has played a key role in the development of ReliaSoft's software including Weibull++, ALTA and BlockSim, and has published numerous papers on various reliability methods. Mr. Mettas holds an M.S. in reliability engineering from the University of Arizona.

Modarres, Mohammad, is Professor of Nuclear Engineering and Reliability Engineering and Director of the Center for Technology Risk Studies at the University of Maryland, College Park. His research areas are probabilistic risk assessment, uncertainty analysis, and physics of failure modeling. In the past 23 years that he has been with the University of Maryland, served as a consultant to several governmental agencies, private organizations, and national laboratories in areas related to risk analysis, especially applications to complex systems and processes such as nuclear power plants. Professor Modarres has authored over 200 papers in archival journals and proceedings of conferences, and three books in various areas of risk and reliability engineering. He is a University of Maryland Distinguished Scholar-Teacher. Professor Modarres is a member of the editorial board of International Journal of Performability Engineering. Dr. Modarres received his Ph.D. in nuclear engineering from Massachusetts Institute of Technology in 1980, his M.S. in mechanical engineering from Massachusetts Institute of Technology in 1977.

Moon, Hwy-Chang, received his Ph.D. from the University of Washington and is currently Professor of International Business and Strategy in the Graduate School of International Studies at Seoul National University. He has also taught at the University of Washington, the University of the Pacific, State University of New York at Stony Brook, Helsinki School of Economics, Kyushu University, and Keio University. Professor Moon has published numerous journal articles and books on topics such as international business strategy, foreign direct investment, and cross-cultural management. Dr. Moon is currently the Editor-in-Chief of the Journal of International Business and Economy, and is a member of the editorial board of the International Journal of Performability Engineering. He has provided consultancy to many international companies, international organizations (APEC, World Bank, UNCTAD), and governments (Korea, Malaysia).

Mullen, Robert E., is a Quality Systems Staff Engineer, Software Operations, at Cisco Systems. He received a B.A. from Princeton University and an M.S. (nuclear engineering) from Northwestern University. Prior to joining Cisco, he was the Director, Engineering. Software Support at Stratus Computers and a consulting engineer at Honeywell Multics. He is now involved with addressing software reliability issues both within Cisco and externally. At Cisco, he architected and prototyped SHARC and NARC reliability calculators for hardware and networks implemented orthogonal defect classification (ODC) and integrated software reliability growth models into the defect tracking system. He has empirically demonstrated the application of the lognormal distribution to software reliability growth.

Myers, Albert F., retired in 2006 as Corporate Vice President of Strategy and Technology for Northrop Grumman Corporation. He also served as B-2 chief project engineer, deputy program manager, and vice president of test operations. Myers earned B.S. and M.S. degrees in mechanical engineering from the University of Idaho. He was a Sloan Fellow at the Massachusetts Institute of Technology. In 2006, Myers was elected as a member of the National Academy of Engineering. Myers served from 1989 through 1998 on the NASA Aeronautics Advisory Board. He received the NASA Exceptional Service Medal and the 1981 Dryden Director's Award, and was elected to the University of Idaho Alumni Hall of Fame in 1997. E-mail: Al.Myers@ngc.com

Myers, Jessica, received her B.S. degree in mechanical engineering in 2005 from the University of Maryland, College Park. She is currently completing a MS degree in mechanical engineering at the University of Maryland. Ms. Myers research work is on obsolescence driven design refresh planning and the connection of technology road-mapping to the design refresh optimization process. E-mail: jlmyers@wam.umd.edu

Naikan, V.N.A., is currently an associate professor in the Reliability Engineering Centre of the Indian Institute of Technology, Kharagpur, India, where he teaches quality and reliability engineering to undergraduate and post-graduate students. He was born in the Indian state of Kerala in 1965 and graduated in mechanical engineering from the University of Kerala with second rank and pursued his M.Tech. and Ph.D. studies in reliability engineering at the Reliability Engineering Centre and obtained these degrees from the Indian Institute of Technology, Kharagpur. He started his professional carrier with Union Carbide India Limited and thereafter worked in the Indian Space Research Organization and the Indian Institute of Management, Ahmedabad, India. Thereafter, he joined the Indian Institute of Technology Kharagpur as a faculty member. He has published more than 50 research papers, organized several short term courses, has done research projects and consultancies in related areas. He has been a referee for many international journals.

Nakagawa, Toshio, is currently Professor of Information Science at Aichi Institute of Technology in Toyota. He received his Ph.D. from Kyoto University in 1977. He has authored two books entitled on "Maintenance Theory of Reliability" (2005) and "Shock and Damage Models in Reliability Theory" (2007). Springer will publish his book entitled "Advanced Reliability Models and Maintenance Policies" in 2008. He also has 6 book chapters and more than 150 journal research papers to his credit. His research interests lie in the area of optimization problems, applications to actual models, and computer and information systems in reliability and maintenance theory. He now researching new and latest topics in reliability engineering, computer and management sciences, and discusses them. Dr. Nakagawa is a member of the editorial board of the International Journal of Performability Engineering.

Nanda, Vivek (Vic), is a Quality Manager at Motorola at Horsham, PA, USA. He is a CMQ/OE, CSQE, CQA, Certified ISO 9000 Lead Auditor, and Certified in ITIL Foundations. He is the author of the books ISO 9001:2000 Achieving Compliance and Continuous Improvement in Software Development Companies (ASQ Quality Press, 2003), and Quality Management System Handbook for Product Development Companies (CRC Press, 2005). He is a member of the editorial review board of the Software Quality Professional Journal, and a member of the reviewer panels of IEEE Software, and ASQ Quality Press. Vic is a Senior Member of the ASQ and a Steering Committee member of the Philadelphia SPIN. Vic has been awarded the Feigenbaum medal (2006) by the American Society for Quality. He is listed in the 60th and 61st editions of "Marquis Who's Who in America", in the ninth edition of "Marquis Who's Who in Science and Engineering (2006–2007)", and in the first edition of "Marquis Who's Who of

Emerging Leaders", 2007. Vic has a MS degree in computer science from McGill University (Canada) and Bachelor's degree in engineering from the University of Pune (India).

Nathan, Swami, is a senior staff engineer at Sun Microsystems. His field of interest is field data analysis, statistical analysis and reliability/availability modeling of complex systems. He received his B.Tech. from the Indian Institute of Technology, and M.S. and Ph.D. degrees in reliability engineering from the University of Maryland, College Park. He has authored over 20 papers in peer reviewed journals and international conferences and holds two patents.

O'Connor, Patrick, received his engineering training at the UK Royal Air Force Technical College. He served for 16 years in the RAF Engineer Branch, including tours on aircraft maintenance and in the Reliability and Maintainability office of the Ministry of Defence (Air). He joined British Aerospace Dynamics in 1975, and was appointed Reliability Manager in 1980. In March 1993 he joined British Rail Research as Reliability Manager. Since 1995 he has worked as an independent consultant on engineering management, reliability, quality, and safety. He is the author of "Practical Reliability Engineering", published by Wiley (4th edition 2002), "Test Engineering" (Wiley 2001), and "The Practice of Engineering Management", (Wiley 1994) (updated and re-published as "The New Management of Engineering" in 2005). He is also the author of the chapter on reliability and quality engineering in the Academic Press Encyclopaedia of Physical Science and Technology, and until 1999 was the UK editor of the Wiley journal Quality and Reliability Engineering International. He has written many papers and articles on quality and reliability engineering and management, and he lectures at universities and at other venues on these subjects. In 1984 he received the Allen Chop Award, presented by the American Society for Quality, for his contributions to reliability science and technology. For a more detailed description of his past and current work, visit www.pat-oconnor.co.uk.

Pecht, Michael G., is Chair Professor and the Director of the CALCE Electronic Products and Systems Center at the University of Maryland. Dr. Pecht has an MS in electrical engineering and MS and PhD degrees in engineering mechanics from the University of Wisconsin at Madison. He is a Professional Engineer, an IEEE Fellow, an ASME Fellow, and a Westinghouse Fellow. He has written 11 books on electronics products development. He has written six books on the electronics industry in S.E. Asia. He served as chief editor of the IEEE Transactions on Reliability for eight years and on the advisory board of IEEE Spectrum. He is currently the chief editor of Microelectronics Reliability and is a member of the editorial board of the International Journal of Performability Engineering. He serves as a consultant for various companies, providing expertise in strategic planning, design, test, and risk assessment of electronic products and systems.

Pham, Hoang, is Professor and Director of the undergraduate program of the Department of Industrial and Systems Engineering at Rutgers University, Piscataway, NJ. Before joining Rutgers, he was a senior engineering specialist at the Boeing Company, Seattle, and the Idaho National Engineering Laboratory, Idaho Falls. He has authored and coauthored over 150 papers, 4 books, 2 handbooks, and 10 edited books. He is editor-in-chief of the International Journal of Reliability, Quality and Safety Engineering, associate editor of the IEEE Transactoins on Systems, Man, and Cybernetics, and the editor of the Springer Series in Reliability Engineering. He has served on the editorial boards of over 10 international journals including the International Journal of Performability Engineering, and as conference chair and program chair of over 30 international conferences and workshops. He is a Fellow of the IEEE.

Rackwitz, Rüdiger, has been Professor of Structural Reliability at the Technical University of Munich since 1985. He studied civil engineering at the Technical University of Munich and continued there as a

principal research associate working primarily in the development of structural reliability methods and modeling of uncertain phenomena. He is author of over 100 reviewed publications and even more for conferences and symposia. He is a member of the editorial board of the International Journal of Performability Engineering.

Rai, Suresh, is a professor with the Department of Electrical and Computer Engineering at Louisiana State University, Baton Rouge, Louisiana. Dr. Rai has taught and researched in the area of network traffic engineering, ATM, reliability engineering, fault diagnosis, neural net-based logic testing, and parallel and distributed processing. He is a co-author of the book "Wave Shaping and Digital Circuits", and the tutorial texts "Distributed Computing Network Reliability" and "Advances in Distributed System Reliability". He was an associate editor for IEEE Transactions on Reliability from 1990 to 2004. Currently, he is on the editorial board of the International Journal of Performability Engineering. Dr. Rai is a senior member of the IEEE.

Ramirez-Marquez, Jose E., is an assistant professor at Stevens Institute of Technology in the Department of Systems Engineering and Engineering Management. His research interests include system reliability and quality assurance, uncertainty modeling, meta-heuristics for optimization, applied probability and statistical models, and applied operations research. He has authored more than 20 articles in leading refereed technical journals and has conducted funded research for the both government and commercial organizations on these topics. He obtained his Ph.D. degree at Rutgers University in industrial and systems engineering and received his B.S. degree in actuarial science from UNAM in Mexico City in 1998. He also holds M.S. degrees in industrial engineering and statistics from Rutgers University. He is a member of IIE, IFORS, and INFORMS.

Rausand, Marvin, was born on December 20, 1949 in Nesset, Norway. He was educated at the University of Oslo and was employed at SINTEF Safety and Reliability for ten years until 1989. The last four years of this period, he was head of this department. Since 1989 he has been a professor in reliability engineering at the Norwegian University of Science and Technology. His research activities have mainly been related to safety and reliability issues in the offshore oil and gas industry.

Rauzy, Antoine, received his Ph.D. in computer sciences in 1989 and a "habilitation à diriger des recherches" in 1996. He joined the Centre National de la Recherche Scientifique in 1991 and the Institut de Mathématiques de Luminy in 2000. His topics of research are reliability engineering, formal methods, and algorithms. He has authored more than 100 articles for international conferences and journals. His main contributions lie in the area of design of algorithms and high level formalisms for risk analysis. He has designed various software products including the fault tree assessment tool Aralia. Since 2001, he has been the president of the ARBoost Technologies Company. http://iml.univ-mrs.fr/~arauzy/; E-mail: arauzy@iml.univ-mrs.fr

Renn, Ortwin, serves as full professor and chair of environmental sociology at Stuttgart University, Germany. He directs the Interdisciplinary Research Unit for Risk Governance and Sustainable Technology Development (ZIRN) at the University of Stuttgart and the non-profit company DIALOGIK, a research institute for the investigation of communication and participation processes in environmental policy making. Ortwin Renn has a doctoral degree in sociology and social psychology from the University of Cologne. His professional career began with an appointment at the National Research Center, Julich; he served as professor at Clark University (Worcester, USA)and at the Swiss Institute of Technology (Zurich), and directed the Center of Technology Assessment in Stuttgart for ten years. He is a member of the panel on Public Participation in Environmental Assessment and Decision Making of the U.S. National

Academy of Sciences in Washington, D.C., an ordinary member of the Berlin-Brandenburg Academy of Sciences (Berlin), the German Academy for Technology and Engineering, and the European Academy of Science and Arts (Vienna and Salzburg). His honors include the Distinguished Achievement Award of the Society for Risk Analysis (SRA) and the Outstanding Publication Award from the Environment and Technology Section of the American Sociological Association. Professor Renn is primarily interested in risk governance, political participation, and technology assessment. He has published more than 30 books and 200 articles.

Sandborn, Peter A., is an associate professor and the Research Director for the CALCE Electronic Products and Systems Center (EPSC) at the University of Maryland. His interests include technology tradeoff analysis for electronic packaging, virtual qualification of electronic systems, parts selection and management for electronic systems, including electronic part obsolescence forecasting and management, supply chain management and design for environment of electronic systems, and microelectromechanical systems (MEMS), system lifecycle and risk economics. Prior to joining the University of Maryland, he was a founder and Chief Technical Officer of Savantage, Inc. Prof. Sandborn has a Ph.D. degree in electrical engineering from the University of Michigan and is the author of over 100 technical publications and several books on multichip module design and electronic parts. He is an associate editor for the IEEE Transactions on Electronics Packaging Manufacturing and a member of the editorial board of the International Journal of Performability Engineering. E-mail: sandborn@umd.edu

Schmidt, Linda C., is an associate professor at the University of Maryland, where she holds a joint appointment with the Department of Mechanical Engineering and the Institute for Systems Research. She is the founder and director of the Designer Assistance Tool Laboratory. She completed her doctorate in mechanical engineering at Carnegie Mellon University and developed a grammar-based, generate and optimize approach to mechanical design. Her B.S. and M.S. degrees were granted by Iowa State University for work in industrial engineering with a specialization in queuing theory, the theory of waiting in lines. Her research interests include computational design, design optimization, and developing formal methods for design.

Sharit, Joseph, received his B.S. degree in chemistry and psychology from Brooklyn College and his M.S. and Ph.D. degrees from the School of Industrial Engineering at Purdue University. He is currently a research professor in the Department of Industrial Engineering at the University of Miami. He also holds secondary appointments in the Department of Anesthesiology and in the Department of Psychiatry and Behavioral Sciences at the University of Miami Miller School of Medicine. He is involved in research with the Center on Research and Education for Aging and Technology Enhancement, the Ryder Trauma Center, and the Miami Patient Safety Center. His research interests include human–machine interaction, human reliability analysis and system safety, aging and performance on technologically-based tasks, and human decision making. His current teaching responsibilities include the areas of probability and statistics, system safety engineering, human factors engineering and occupational ergonomics, and engineering economy.

Singh, Jagmeet, received his Ph.D. degree from the Department of Mechanical Engineering at MIT, U.S.A. He received a S.M. degree in mechanical engineering from MIT, in 2003 and a B.Tech. degree in mechanical engineering from the Indian Institute of Technology, Kanpur, India. He worked on the subject of his chapter as a part of his research towards his Ph.D. His areas of expertise include assembly architecture, datum flow chains, and noise strategies in large scale systems.

Singh, V.B., is a lecturer in the Department of Computer Science, Delhi College of Arts and Commerce (University of Delhi). He obtained his M.C.A degree from the M.M.M. Engineering College, Gorakhpur, India. Presently, he is working towards a Ph.D. degree at the University of Delhi. His area of research is software reliability.

Soh, Sieteng, is a lecturer with the Department of Computing at Curtin University of Technology, Perth, Australia. He was a faculty member (1993–2000), and the Director of the Research Institute (1998–2000) at Tarumanagara University, Indonesia. He has a B.S. degree in electrical engineering from the University of Wisconsin, Madison, and M.S. and Ph.D. degrees in electrical engineering from Louisiana State University, Baton Rouge. His research interests include network reliability, and parallel and distributed processing. He is a member of the IEEE.

Spitsyna, Anna is currently a Ph.D. student in the Department of Industrial Technology, Ecology at the Royal Institute of Technology (KTH) in Stockholm, Sweden. Her research interest is focussed on sustainable technology.

Stahel, Walter R., founded the Product-Life Institute in Geneva in 1982 and has been its director since then. He is visiting professor in the School of Engineering, University of Surrey, UK, head of the Geneva Association's Risk Management Research program, guest lecturer at Tohoku University, and lecturer at University Pforzheim, Germany. A graduate of the Swiss Federal Institute of Technology in Zurich, he has authored several prize-winning papers, and the books The Performance Economy (2006, in English and Chinese) and The Limits to Certainty (with Orio Giarini 1992), published in six languages. Websites: http://product-life.org http://performance-economy.org http://genevaassociation.org

Tang, Loon-Ching, is an associate professor and Deputy Head (Research) of the Department of Industrial and Systems Engineering. He obtained a Ph.D. degree in 1992 from Cornell University in the field of operations research with minors in statistics and civil engineering. Dr. Tang has published widely in more than 20 international peer-reviewed journals, including IEEE Transactions on Reliability, Journal of Quality Technology, Naval Research Logistics and Queueing Systems. Besides being the area editor (quality engineering) of the International Journal of Performability Engineering since its inception, Professor Tang is on the editorial review board of the Journal of Quality Technology and has been an active reviewer for a number of international journals. He has been consulted on problems demanding innovative application of probability, statistics and other operations research techniques, and is also a well-known trainer in Six Sigma. He is the main author of the book "Six Sigma: Advance Tools for Black Belts and Master Black Belts" (Wiley). His research interest includes the application of operations research tools, particularly statistics, probability and optimization techniques, to problems with high degree of uncertainty. His research is motivated by actual problems from industries, ranging from those in the area of quality and reliability to those related to business processes and operations strategies.

Trindade, David, is a Distinguished Engineer at Sun Microsystems. Formerly, he was a Senior Fellow at AMD. His fields of expertise include reliability, statistical analysis, and modeling of components, systems, and software, and applied statistics, especially design of experiments (DOE) and statistical process control (SPC). He is co-author (with Dr. Paul Tobias) of the book Applied Reliability (second edition, published in 1995). He has a B.S. degree in physics, an M.S. degree in statistics, an M.S. degree in material sciences and semiconductor physics, and a Ph.D. degree in ,mechanical engineering and statistics. He has been an adjunct lecturer at the University of Vermont and Santa Clara University.

Trivedi, Kishor S., holds the Hudson Chair in the Department of Electrical and Computer Engineering at Duke University, Durham, NC. He has been on the Duke faculty since 1975. He is the author of a well known text entitled Probability and Statistics with Reliability, Queuing and Computer Science Applications (published by Prentice-Hall; a thoroughly revised second edition (including its Indian edition) of this book has been published by Wiley. He has also published two other books entitled Performance and Reliability Analysis of Computer Systems (published by Kluwer) and Queueing Networks and Markov Chains (published by Wiley). He is a Fellow of the Institute of Electrical and Electronics Engineers. He is a Golden Core Member of the IEEE Computer Society. He has published over 400 articles and has supervised 40 Ph.D. dissertations. He is on the editorial boards of IEEE Transactions on Dependable and Secure Computing, the Journal of Risk and Reliability, the International Journal of Performability Engineering, and the International Journal of Reliability, Quality and Safety Engineering. He has made seminal contributions in software rejuvenation, solution techniques for Markov chains, fault trees, stochastic Petri nets, and performability models. He has actively contributed to the quantification of security and survivability. He was an editor of the IEEE Transactions on Computers from 1983–1987. He is a co-designer of the HARP, SAVE, SHARPE, and SPNP software packages that have been well circulated. e-mail: kst@ee.duke.edu

Tuchband, Brian, received the B.S. degree in mechanical engineering from the University of Delaware in 2005. He is currently working towards the M.S. degree in mechanical engineering at the University of Maryland, College Park. His research interests include health and usage monitoring systems, and prognostic solutions for military electronic systems.

Vassiliou, Pantelis, is President and CEO, ReliaSoft Corporation, USA. Mr. Pantelis Vassiliou directs and coordinates ReliaSoft's R&D efforts to deliver state-of-the-art software tools for applying reliability engineering concepts and methodologies. He is the original architect of ReliaSoft's Weibull++, a renowned expert and lecturer on reliability engineering and is ReliaSoft's founder. He is currently spearheading the development of new technologically advanced products and services. In addition, he also consults, trains, and lectures on reliability engineering topics to Fortune 1000 companies worldwide. Mr. Vassiliou holds an M.S. degree in reliability engineering from the University of Arizona.

Vatn, Jørn, was born on January 24, 1961 in Inderøy, Norway. He received his M.Sc. degree in mathematical statistics from the University of Science and Technology (NTNU), Trondheim, Norway in 1986, and his Ph.D. degree from the same university in 1996, with a thesis on maintenance optimization. He has almost 20 years of experience as a researcher at SINTEF Safety and Reliability, and currently he holds the position of a professor at NTNU, Department of Production and Quality Engineering.

Vichare, Nikhil M., received the B.S. degree in production engineering from the University of Mumbai, India, and the M.S. degree in industrial engineering from the State University of New York at Binghamton. He is currently working towards the Ph.D. degree in mechanical engineering at the University of Maryland, College Park, in the area of electronic prognostics.

Wang, Peng, received his B.Sc. degree from Xian Jiaotong University, China, in 1978, the M. Sc. degree from Taiyuan University of Technology, China, in 1987, and also M.Sc. and Ph.D. degrees from the University of Saskatchewan, Canada, in 1995 and 1998, respectively. Currently, he is an associate professor of Nanyang Technological University, Singapore.

Wang, Zheng, received his B.S. in Mmchanical design from Shenyang Institute of Technology, China in 2003 and is currently a Ph.D. candidate in the Mechanical Engineering Department of Northeastern

University, Shenyang, China. His research interests are in mechanical system reliability and structural fatigue.

Wennersten, Ronald, is head of the Department of Industrial Ecology at Royal Institute of Technology (KTH) in Stockholm, Sweden. He received his Ph.D. in chemical engineering at Lund University in 1981. After working in the industry for some time, he came to KTH in 1996. Afterwards, he became head of the Department of Industrial Ecology in 2000. His ambition has been to merge existing research in the areas of environmental management and environmental system analysis with his own research on risk management within the framework of industrial ecology and sustainable development. He is head of the Joint Research Center for Industrial Ecology at Shandong University in China, where he is a guest professor.

Wu, Jianmou, is a recent Ph.D. graduate from the Department of Mechanical and Industrial Engineering, University of Toronto. His research interests are CBM modeling and optimization, development of condition monitoring and fault detection schemes for deteriorating equipment, statistical data analysis, multivariate time series modeling, and stochastic OR modeling.

Xie, Liyang, has been a professor in the Department of Mechanical Engineering at Northeastern University, Shenyang, China, since 1992. He received his B.S. degree (1982) in mechanical manufacturing, his M.S. (1985) and Ph.D. (1988) degrees in mechanical fatigue and reliability from Northeastern University, Shenyang, China. He has published more than 100 papers in journals such as IEEE Transactions on Reliability, Reliability Engineering and System Safety, Fatigue and Fracture of Engineering Materials and Structures, the International Journal of Performability Engineering, and the International Journal of Reliability, Quality and Safety Engineering. His research interests are in structural fatigue, system reliability, and probability risk assessment. E-mail: lyxie@me.neu.edu.cn

Xing, Liudong, received her B.E. degree in computer science from Zhengzhou University, China, in 1996, and was a research assistant at the Chinese Academy of Sciences from 1996 to 1998. She was awarded M.S. and Ph.D. degrees in electrical engineering from the University of Virginia, Charlottesville, in 2000 and 2002, respectively. Since 2002, Dr. Xing has been an assistant professor in the Electrical and Computer Engineering Department, University of Massachusetts Dartmouth. Dr. Xing served as an associate guest editor for the Journal of Computer Science for a special issue of Reliability and Autonomic Management, and program co-chair for the IEEE International Symposium on Dependable, Autonomic and Secure Computing in 2006. She also serves as a program vice chair for the 2007 International Conference on Embedded Software and Systems. She is an editor of short communications in the International Journal of Performability Engineering. She is a member of IEEE and Eta Kappa Nu. E-mail: ldxing@ieee.org

Yamada, Shigeru, was born in Japan, on July 6, 1952. He received the B.S.E., M.S., and Ph.D. degrees from Hiroshima University, Hiroshima, Japan, in 1975, 1977, and 1985, respectively. From 1977 to 1980, he worked at the Quality Assurance Department of Nippondenso Company, Japan. From 1983 to 1988, he was an assistant professor of the Okayama University of Science, Okayama, Japan. From 1988 to 1993, he was an associate professor at the Faculty of Engineering, Hiroshima University. Since 1993, he has been working as professor with the Faculty of Engineering, Tottori University, Tottori, Japan. He has published numerous technical papers in the areas of software reliability engineering, project management, reliability engineering, and quality control. He has authored several books entitled Software Reliability: Theory and Practical Application (Soft Research Center, 1990), Introduction to Software Management Model (Kyouritsu Shuppan, 1993), Software Reliability Models: Fundamentals and Applications (JUSE, 1994),

Statistical Quality Control for TQM (Corona Publishing, 1998), Software Reliability: Model, Tool, Management (The Society of Project Management, 2004), and Quality–Oriented Management Technology for toftware Projects (Morikita Publishing, 2007). Dr. Yamada is the recipient of the Best Author Award from the Information Processing Society of Japan in 1992, the TELECOM System Technology Award from the Telecommunications Advancement Foundation in 1993, the Best Paper Award from the Reliability Engineering Association of Japan in 1999, the International Leadership Award in Reliability Engineering Research from the ICQRIT/SRECOM in 2003, and the Best Paper Award from the Society of Project Management in 2006. He is a regular member of IEICE, the IPSJ, the ORSJ, the Japan SIAM, the REAJ, the JIMA, the JSQC, the Society of Project Management, and the IEEE. He is on the editorial board of the International Journal of Performability Engineering.

Yoshimura, Masataka, earned his Bachelor of Engineering degree in mechanical engineering, his Master of Engineering Degree in precision engineering from Kyoto University, and received his Doctor of Engineering degree from Kyoto University in 1976. He is currently a professor in the Graduate School of Engineering at Kyoto University. His research interests include concurrent optimization of product design and manufacturing, information systems for manufacturing, collaborative optimization, concurrent engineering, and the dynamics of machine tools and industrial robots. He has published more than 180 papers in journals and proceedings of the ASME, AIAA, IJPR, CERA (Concurrent Engineering: Research and Applications), Structural Optimization, JSME (Japan Society of Mechanical Engineers), and JSPE (Japan Society for Precision Engineering), and elsewhere. He has received awards from the JSPE and the Japan Society for the Promotion of Machine Tool Engineering, an achievement award from the Design Engineering Division of JSME, and remarkable service awards from the Design Engineering Division of ASME. He is a Fellow of ASME, JSME, and JSPE.

Yuanbo, Li, is Ph.D. candidate in Department of Industrial Engineering & Management, School of Mechanical Engineering, Shanghai Jiao Tong University, China. His main research interests include semiconductor manufacturing scheduling and simulation.

Zhibin, Jiang, is Professor and Chairman of Industrial Engineering and Management at Shanghai Jiao Tong University (SJTU). He obtained his Ph.D. degree in manufacturing engineering and engineering management from City University of Hong Kong in 1999. He is a senior member of IEEE and IIE, and 2006–2007 President of the Beijing (China) chapter of IIE. He is member of the editorial boards of the International Journal of Performability Engineering and IJOE. He has authored more than 100 papers in international journals and at conferences. His research interests include system modeling and simulation, production planning and scheduling, and system reliability. He has been included in the 2006–2007 edition of "Who's Who in Science and Engineering".

Zhou, P., received the B.S. degree in computational mathematics and the M.S. degree in operations research from Dalian University of Technology, China, in 2000 and 2003, respectively. Currently, he is a Ph.D. candidate in the Department of Industrial and Systems Engineering, National University of Singapore. His main research interests include energy and environmental systems analysis, efficiency and productivity analysis, performance measurement, and multiple criteria decision analysis.

Zuo, Ming J., received the Bachelor of Science degree in agricultural engineering in 1982 from Shandong Institute of Technology, China, and the Master of Science degree in 1986 and the Ph.D. degree in 1989 both in industrial engineering from Iowa State University, Ames, Iowa, USA. He is currently a professor in the Department of Mechanical Engineering at the University of Alberta, Canada. His research interests include system reliability analysis, maintenance planning and optimization, signal processing, and fault

diagnosis. He is Associate Editor of IEEE Transactions on Reliability, Department Editor of IIE Transactions, area editor of the International Journal of Performability Engineering, and editorial board Member of International Journal of Quality, Reliability and Safety Engineering. He is a senior member of IEEE and IIE. He received the Killam Professorship Award in 2004 and the McCalla Professorship Award in 2002 at the University of Alberta. He received the 2006 IIE Golomski Award and the Best Paper Award at the 2005 IIE Industrial Engineering Research Conference.
