This handbook is dedicated very fondly to
my grandson and to my lovely grandchildren
Meesha and Meera Trivedi,
Paridhi Misra,
Cyrus, Anushka and Xenia Chinoy,
and to their successive generations,
who will be the beneficiaries of the concepts
presented in this handbook
in sustaining humanity on this beautiful planet, Earth
and in preserving its environment for the future.

Foreword

The editor of the Handbook of Performability Engineering, Dr. Krishna B. Misra, a retired eminent professor of the Indian Institute of Technology, took to reliability nearly four decades ago and is a renowned scholar of reliability. Professor Misra was awarded a plaque by the IEEE Reliability Society in 1995 *"in recognition of his meritorious and outstanding contributions to reliability engineering and furthering of reliability engineering education and development in India"*. Upon his retirement in 2005 from IIT, Kharagpur, where he established the first ever postgraduate course on reliability engineering in India in 1982, and Reliability Engineering Centre in 1983, he launched the *International Journal of Performability Engineering* in 2005 and has since led the journal as its inaugural Editor-in-Chief.

Two years after successfully establishing the *International Journal of Performability Engineering,* Prof. Misra has now taken up the responsibility of editing the Handbook of Performability Engineering, which is being published by Springer. The timely publication of this handbook necessarily reflects the changing scenario of the 21st century's holistic view of designing, producing and using products, systems, or services which satisfy the performance requirements of a customer to the best possible extent.

The word "performability" was not commonly used or found in the reliability dictionary until its first use was made in 1978 by John Meyer in the context of performance (meaning reliability and maintainability) evaluation of aircraft control computers at NASA. However, Professor Misra has extended the use of word performability to reflect an amalgamation of reliability and other reliability-related performance attributes, such as quality, availability, maintainability, dependability, and sustainability. Therefore, performability can be considered as the best and most appropriate means to extend the meaning of effectiveness and overall performance of a modern complex and complicated system in which mechanical, electrical, and biological elements become increasingly harder to differentiate.

Having reviewed the contents of this voluminous handbook, and its contributed chapters, I find that it clearly covers the entire canvas of performability: quality, reliability, maintainability, safety, and sustainability. I understand that the motivation for this handbook came from the editorial that Dr. Misra wrote in the very first issue of the International Journal of Performability. The handbook addresses how today's systems need to be not only *dependable* (implying survivability and safety) but also *sustainable*. Modern systems need to be addressed in a practical way instead of simply as a mathematical abstract, often bearing no physical meaning at all. In fact, performability engineering not only aims at producing products, systems, and services that are dependable but also involves developing economically viable and safe processes of modern technologies, including clean production that entails minimal environmental pollution. Performability engineering extends the traditionally defined performance requirements to incorporate the modern notion of requiring optimal quantities of material and energy in order to yield safe

and reliable products that can be disposed of without causing any adverse effects on the environment at the end of their life cycle.

The chapters included in this handbook have undergone a thorough review and have been carefully devised. These chapters collectively address the issues related to performability engineering. I expect that the handbook will create an interest in performability and will bring about the intended interaction between various players of performability engineering.

I am glad to write the Foreword and firmly believe that this handbook will be widely used by practising engineers as well as serve as a guide to students and teachers with an interest in conducting research in the totality of performance requirements of the modern systems of practical use. I would like to congratulate Dr. Misra for taking the bold initiative of editing this historical volume.

July 24, 2007

Way Kuo
President of City University of Hong Kong
Editor-in-Chief, IEEE Transactions on Reliability

Prologue

Performability Engineering: Its Promise and Challenge

Performability engineering has as its scope the evaluation of all aspects of system performance. This encompasses the evaluation of the reliability of the system, its costs, its sustainability, its quality, its safety, its risk, and all of its performance outputs. In covering this broad scope, the objective is to provide a unified framework for comparing and integrating all aspects of system performance. This provides the manager and decision-maker with a complete, consistent picture of the system. This is the promise and exciting prospect of performability engineering.

The challenge involves unifying the diversity of the different disciplines that performability engineering covers. These disciplines cover reliability analysis, cost analysis, quality analysis, safety analysis, risk analysis, performance output analysis, not to mention data analysis, statistical analysis, and decision analysis. The challenge is to provide a unified framework for these different disciplines so that there is cohesiveness in the interfaces between the disciplines.

The first step in meeting this challenge is to provide a common portal through which workers in these diverse disciplines can contribute their ideas and work. This was implemented by the introduction of the International Journal of Performability Engineering, whose Editor-in-Chief is Professor Krishna B. Misra, who is also the inspiration and driver for the Handbook of Performability Engineering. This Handbook of Performability Engineering is another important step in addressing the challenge by presenting an integrated collection of chapters on the various disciplines and topics covered by performability engineering.

The chapters included in this handbook are diverse and represent the vitality of the different aspects of performability engineering. There are management-oriented chapters on the roles of reliability, safety, quality assurance, risk management, and performance management in the realm of performability management. There are chapters providing overview and the state-of-the-art on basic approaches being used in various disciplines. There are original technical contributions describing new methods and tools. Finally, there are chapters focusing on design and operational applications. The reader therefore has a veritable garden from which to feast from in impressive collection of chapters in the handbook.

In short, it is expected that this handbook will be found to be very useful by practicing engineers and researchers of the 21st century in pursuing this challenging and relevant area for sustainable development.

William Vesely, Ph.D.
Manager, Risk Assessment, Office of Safety and Mission Assurance
NASA Headquarters, 300 E Street SW,Washington, DC 20546

Preface

This handbook is unique in many respects. First of all, the title and the scope of subject matter is unique and is not to be found in a single volume in the existing literature. It is about a subject that is becoming very relevant and important in the 21st century. Secondly, the theme is unique and comprises a well-knitted theme of diverse yet related areas like quality, reliability, maintainability, safety, risk, environmental impacts, and sustainability. Thirdly, this handbook is about bringing together contributors of very diverse expertise, interests, and hail from different parts of the world to a common platform in executing a unifying and meaningful project. This initiative is expected to facilitate intense interaction between the experts from the diverse areas of performability engineering and break open the watertight compartments that exist today in an effort to present a holistic approach to performace assessment and design. It is also heartening to see that some of the contributors are founders of the areas that they represent. Therefore, the editor considers it a rewarding experience and a very encouraging step towards the realization of the objective for which this handbook is intended.

There are hundreds of books available on the subject of dependability and constituent areas such as quality, reliability, maintainability, safety, *etc.,* related to the performance of a product, system or a service. Dependability is primarily considered an aggregate of one or more of the attributes of survivability, like quality, reliability, maintainability, *etc*., and safety. However, these attributes are interrelated and reflect the level or grade of the product so designed and utilized, which is expressed through dependability. Nevertheless these attributes are very much influenced by the raw material, fabrication, technology, techniques, and manufacturing processes and their control, and also by the nature and the manner of usage. Currently, dependability and cost effectiveness are primarily seen as instruments for conducting international trade in the free market regime, thereby deciding the economic prosperity of a nation. This makes one realize that optimal design of a product, system, or service is one where one optimizes dependability with respect to costs incurred and sometimes with respect to other techno-economic constraints. This can at best be called partial optimization of the design of a product, system, or service. The material and energy requirements, waste generated, processes employed, and disposability are rarely considered for arriving at an optimal design or configuration of a product or a system.

With world resources declining, the cost of raw materials is likely to escalate spirally in the near future as mining becomes more and more costly and energy intensive due to grades of ore becoming poorer than before. To keep pace with the rising population, the increased volume of production is bound to affect the world environmental health further unless pollution prevention measures are vigorously pursued. At every stage of the life-cycle of a product, be it extraction of material, manufacturing, use, or disposal, energy and materials are required as inputs, and emissions (gaseous, solid effluents, or residues) are always associated with this, which influences the environmental health of our habitat. Therefore, the importance

of minimization of material and energy requirements along with the importance of control of effluents and waste management can hardly be emphasized enough while designing products and systems with acceptable levels of performance. Unless we consider all these factors together, we cannot call the design of products, systems, and services truly optimal from the engineering point of view.

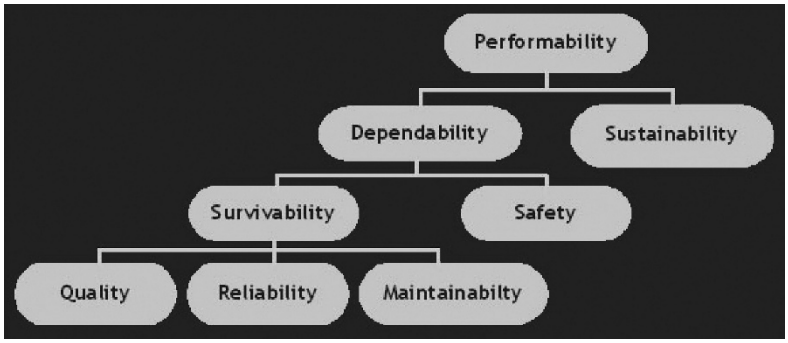
Certainly, these factors cannot be considered in isolation of each other. Therefore, emphasis has to be placed on a holistic view of the entire life cycle of activities of a product or system along with the associated cost of environmental preservation at each stage while maximizing the product performance. It must be emphasized here that to preserve our environment for our future generations, the internalization of the hidden costs of environment preservation will have to be accounted for, sooner or later, in order to be able to produce sustainable products in the long run. Open access resources can no longer be treated as freely available, unless we account for their restoration costs as well. In short, we can no longer rely solely on the criteria of dependability for optimizing the performance of a product, system, or service. We need to introduce and define a new performance criterion that will take a holistic view of the performance enhancement along with the associated environmental aspects.

Fortunately, we have the concept of sustainability that provides us with the framework to consider subjects like dematerialization, energy auditing, waste minimization, reuse and recycling, and other environmental considerations that can be of immense use in exploring means of clean production. The concepts of industrial ecology can be of great help in reducing the overall impact on the environment and to sustain development. Therefore, we have to explore ways of including dependability and sustainability in our criteria for the design of all future products, systems, and services, and to start with we need a term to represent all these activities.

In 1980, John Meyer introduced the term *performability* in the context of the performance evaluation of aircraft control computers for use by NASA. At the time this term was mainly used to reflect a composite attribute implying reliability and other associated attributes like availability, maintainability, *etc*., although dependability had been used at times to include a greater number of the attributes related to performance. Therefore, it was considered appropriate and logical to extend the meaning of this term to include attributes such as dependability and sustainability, rather than inventing a new term. Performability now would not only mean to include reliability, maintainability, or availability as was originally proposed, but also to include the whole gamut of attributes, like quality, reliability, maintainability, safety, and sustainability.

This handbook has been conceived to stimulate further thinking in this direction and to spur research and developmental effort in making sustainable products, systems, and services, which is the foremost need of the 21st century if humans are to survive and future generations are to have the same or better quality of life to prosper on this planet. The objective of this handbook is to introduce engineers, designers, producers, users, and researchers to visualize the interrelationships of all the performance attributes, to bring a synergetic interaction between various players of constituent areas of performability, and to exhort them to launch their activities in the direction of furthering performability engineering.

Today, there is hardly any book available on the market that deals with this subject in its entirety and provides a holistic perspective of the problem. Neither do the existing books on the subject of survivability and safety or dependability ever deliberate the issues related to sustainability. Nor do the books on the subject of sustainability and related areas touch upon problems of survivability and safety or dependability. For instance, while designing for survivability or dependability, internalization of environmental costs is not even mentioned, let alone considered. A truly optimal product design must balance out all the conflicting conditions imposed upon product development by the manufacturing processes. Obviously, the basic platform for addressing the inherently complex problems of this nature should emerge from the perspectives of performance, environment, and economics, as these products have to be produced in a competitive world market.



This handbook is primarily aimed at facilitating interactions and linkages between these diverse areas and helps promote the objective of designing, producing, operating, and using sustainable and dependable products, systems, and services.

Also with this handbook, a person intending to have introduction to performability engineering will not have to search extensively for relevant information to start his work. It is hoped that this handbook will offer a reader the necessary background in the subject just at one place. This is, therefore, the first book of its kind. It is also true that if we have to take to performability engineering as a profession, we need to create manpower in this discipline and introduce this subject for serious studies in the present day engineering curriculum. This handbook offers that opportunity to start with.

The handbook is organized in ten distinct sections as follows:

1. System design (7 chapters)
2. Engineering management (3 chapters)
3. Quality engineering and management (7 chapters)
4. Reliability engineering (18 chapters)
5. Reliability and risk methodology (4 chapters)
6. Risk management and safety (5 chapters)
7. Maintenance engineering and maintainability (5 chapters)
8. Sustainability and future technologies (9 chapters)
9. Performability applications (12 chapters)
10. Software engineering and applications (4 chapters)
11. Epilogue

The subject matter contained in the chapters has been selected to provide a balanced coverage of the entire spectrum of performability engineering. The chapters have been designed to provide up-to-date information on the subject being discussed. It is expected that this coverage will help achieve the objective for which this handbook is intended.

In spite of best efforts to make a cohesive presentation, there are bound to be lapses here and there in such a voluminous work; the editor takes the blame for all these shortcomings. However, if the handbook is able to create interest among the readers in performability engineering, it should be a matter of great achievement and pleasure to the editor. Eventually, it would prove to be a good idea that all engineers, irrespective of their areas of activity or discipline, are exposed to the subject of performability engineering to offer them with a wider vision of the requirement of sustainable and dependable products, systems, and services in the 21st century.

Krishna B. Misra

Acknowledgements

The editor would like to express his sincere thanks to all the contributors (99 in addition to the editor), who so generously and expeditiously came forward to share their ideas and work. I am deeply appreciative of their outstanding contributions, and it has been a tremendously satisfying experience to bring together such a large group of experts to produce a well-knitted theme consisting of diverse yet related areas in the form of the Handbook of Performability Engineering. The realization of this unique work of unprecedented scope and magnitude would have been impossible without the cooperation and counsel of many minds. The editor considers it his privilege to have worked with such a distinguished group of experts. The contributors, to whom the editor at times might have appeared to be unreasonable and more demanding but without which the handbook may not have seen the light of the day, deserve a great deal of appreciation.

In presenting the state-of-art, it is usually necessary to discuss and describe the work done by several authors and researchers and published in the literature. As it is not possible to list them all individually, the editor would like to record his appreciation and thanks *en bloc* to all those, whose works find a place of mention in this handbook.

The editor would like to thank Dr. Suprasad V. Amari of Relex Software Corporation, who incidentally has been the editor's student of reliability engineering, gave inputs at the several stages of conceiving the handbook, and also to Professor Hoang Pham of Rutgers University for encouraging and supporting the idea. My former student and colleague, Dr. Sanjay K. Chaturvedi, at the Reliability Engineering Centre, the Indian Institute of Technology, Kharagpur and postgraduate students, in particular, Mr. Rajshekhar Sankati and Mr. K. Kiran Pradeep deserve thanks for providing assistance whenever it was needed.

As in my past academic pursuits, my wife Veena has been a tremendous source of encouragement and strength. To her, I offer my deep gratitude and appreciation for her support in making this voluminous handbook a reality. Thanks are also due to my loving children, Vinita, Vivek, and Kavita, and to my daughter-in-law, Michelle, and sons-in-law, Rayomond Chinoy and Manoj Trivedi, who helped me on and off during the course of preparation of this handbook.

Finally, the editor would like to express his sincere thanks to Springer, UK and particularly to Dr. Anthony Doyle, Senior Editor in Engineering and to Mr. Simon Rees, Editorial Assistant in Engineering, who have been always prompt and courteous in responding to the several questions related to the production of this handbook. The production department of Springer and particularly Ms. Sorina Moosdorf deserve special mention in the production of the handbook and for the nice get up.

October 4, 2007 Krishna B. Misra

Performability Engineering: An Essential Concept in the 21st Century

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: The concept of performability is explained and the desirability of using this attribute in pursuing the design of engineering products, systems, and services is emphasized in order to meet the challenges of the 21st century. Today a new revolution is taking place where the leaders will be those nations that provide priority to the principles of sustainability in order to design, develop and use products, systems and services that are not only dependable but do not lead to disrupt the delicate ecological balance in nature. New materials, technologies and processes in consonance with environmental protection hold the key to future progress and prosperity.

1.1 Introduction

Over thousands of years, man has constantly innovated and contrived to exploit Earth's natural resources to improve his quality of life, well-being and prosperity. Whereas the last industrial revolution helped improve the living standard of man, it also caused immense damage to the environmental health of the Earth. Today another revolution is in the offing and the world is witnessing an unprecedented development in all scientific and technological fields. This can be attributed primarily to phenomenal advances made in the area of computer hardware and software, communications and information technology. It goes without saying that new areas like genetic engineering, biotechnology, nanotechnology hold the key to the development of sustainable products, systems and services in future. In fact all future technological pathways would aim to prevent and minimize, if not reverse the damage that was already done to the Earth's environment during the last industrial revolution.

1.1.1 The Fast Increasing Population

The rapid increase in the human population is a matter of concern for the people living on this planet since in the entire solar system Earth alone has a habitable atmosphere for sustaining life, which actually evolved thorough a series of delicate balances of several factors over billions of years; it took some 3.5 billion years before human life emerged from simple living cells, which themselves emerged through a unique sequence of combinations of molecules after the Earth was formed.

Since the appearance of *Homo Sapiens* on Earth, until 1900 the world population could only grow to a level of 1.6 billion people. However, by 1930, it had risen to two billion and by 1960 it had reached three billion. By 1975 it had risen to a level of four

billion, and by 1986 it was five billion; in 1999 it had already crossed the level of 6 billion. In fact, now we are adding more than 200,000 people every day. Today, we are about 6.5 billion people on Earth. Thus there has been an exponential growth in the last century as compared to the earlier centuries. The United Nations medium population projections show that the world population will reach the level of 8.9 billion by 2030 and is likely to level off at 14.5 billion by 2150. Also, even according to the U.N. Long-Range World Population Projections, the world population, under the most favorable conditions, is likely to reach a stable level of 11.5 billion by 2150. In any case, the increase in population even on the basis of most conservative estimates is likely to put tremendous pressure on the Earth's resources and will threaten the ecological balance that exists on Earth. Needless to say, every inhabitant of this planet needs to share the available resources on this planet and the Earth is the last habitat of humanity in the entire solar system as we have nowhere else to go.

Many planners think that populating other planets may be a solution to ease the population pressure on Earth. However, the technology to transport even a limited proportion of the population to any nearby planet where conditions may be favorable for humanity to survive, is non-existent and by the best technological forecasts, it cannot be developed at least for next 100–150 years. In fact by that time, we would have already done irreversible and irreparable damage to our planet.

Therefore, we have to find ways and means to sustain the human population on Earth without further damaging its environment and must even try to regenerate, if possible, its environmental health. It must dawn on all human beings living on this planet that we are living on an island in space, called Earth and that we cannot possibly escape living on it. The only recourse left is that we must mend our ways if we, and our future generations, regardless of their geographical location or nationalities, are to survive and flourish on this planet. Our problems are the problems of the planet Earth.

As the human population grows, there will be less for everyone in terms of food, clothing, materials and energy. People in the USA, who enjoy the benefits of a rich life style, might have to reconcile to being satisfied with less. Ideally, everyone on this Earth would like to maintain a wonderful lifestyle. With resources shrinking, the cost of raw materials is likely to escalate in a spiral fashion in future and the *per capita* share of world resources will also decrease. We have already witnessed this phenomenon in the case of oil prices, which have been steadily increasing over the past few decades and have more than doubled in the past few years. Likewise, other exhaustible resources are also likely to cost more in the near future.

1.1.2 Limited World Resources

The fast population growth of human beings has resulted in a fast depletion of resources on Earth. For resources of the Earth, whether they are renewable or non-renewable, if adequate care is not taken to control the rate of their use, there will always be a risk of degradation of the environment. Renewable resources can maintain themselves or can continuously be replenished, if managed properly and wisely. Food, crops animals, wildlife, forests along with solids, water and air belong to this category. We must not forget that the resources on Earth were not only meant for human beings alone but were also meant to sustain the rest of the living creatures on this planet. For this category of resources, the point of concern is not that we may run out of their supplies but that we may use them faster than they can be regenerated and if humans do not restrict to their equitable share of resources, other living beings or species on Earth will be endangered.

On the other hand, non-renewable resources like coal, oil, iron, aluminum, copper, tin, zinc, phosphates, *etc*., are exhaustible and can become depleted and their exploitation beyond sustainable levels may create severe adverse environmental effects threatening to cause irreparable damage to fragile eco-systems through which life on Earth is sustained.

There are several compulsions for using Earth's resources wisely, more efficiently, distributing them more equitably, reducing wastage and in fact reducing their overall consumption levels. The gap between developed nations and developing nations is widening. While writing these paragraphs, I have a newspaper item before me stating that Britons waste one third of all the food they buy (which is estimated at about 3 million tonnes), thereby wasting the money and energy used in producing it. On the other hand, there are undernourished people in Africa and Asia. Any kind of wastage either of materials, energy or food must be curbed. This is not only necessary for our survival and existence but also to have sustainable development so that human beings and their future generations can live and prosper without tension or wars over sharing the limited resources on this planet.

In any case, we have entered an era in which global prosperity will depend increasingly on using the Earth's resources wisely and more efficiently, distributing them more equitably, reducing wastage and in fact reducing their overall consumption levels. Unless we can accelerate this process, serious social tension is likely to arise, leading to wars and destruction of resources. The Gulf War is an example resulting from increased competition for the right of sharing scarce resources like oil. Eventually, the world might even be heading for an unforeseen catastrophe. The next scarce resource on the list may be water and sharing it may lead nations to strife.

1.1.3 The Carrying Capacity of Earth

The *carrying capacity* is defined as "The number of individuals of a given species that can be sustained indefinitely in a given space". This in the context of the number of human beings being sustained indefinitely on the planet Earth is called the *carrying capacity of Earth*. In other words, a population below the carrying capacity of the Earth can survive forever. We know that the Earth today has about 6.5 billion people. What we may want to know is how many people can survive on the Earth without damaging the Earth as the habitat of human beings. If we crowd the Earth too much, then it may affect the Earth's ability to support human beings indefinitely. Life will get worse and after a while, humans might start decreasing in number, or may even become extinct, as is happening with several other species.

On the other hand, if we find the right number of people and the right type of resources and energy to meet their requirements, then we will be able to support many people on Earth for a very long time – the humanity will be able to survive for thousands of years without compromising the standards of living. Of course, there are several controversial estimates for the carrying capacity of Earth. Some scientists put it at 40 billion and some put it merely at 2 billion – a level that we have already crossed, but what is certain is that if we do not bother about it, sooner or later we will have to face that impending disaster. If we conserve the Earth's resources, clean up pollution, and apply our present knowledge and technological advancement to finding less damaging ways of satisfying our needs, the carrying capacity can be improved. For instance, if we prevent pollution of water (also air and land) and clean up water that is already polluted, then we will be able to grow more food and more people can be supported. We know that the last industrial revolution improved the standard of living for some but damaged the pristine environment of several industrialized nations. All this happened since nobody bothered about pollution of free resources (we do not pay for preserving them) like air and water. Sustainable development would not allow that to happen again.

1.1.4 Environmental Consequences

On the other hand, the unprecedented technological developments during the last century have dealt a severe blow to the environmental health of the Earth; man's insatiable quest for a better quality of life coupled with economic disparities between people [1] has further changed the consumption pattern drastically and the choice of technologies. There has been more over-exploitation causing serious environmental consequences and wastage of resources during the past two decades than any time during the history of mankind. The depletion of ozone layer, CO_2 concentrations and pollution of rivers and water bodies including ground water

makes drinking water a valuable commodity. The winter of 2007 has been the warmest since 1880. Glaciers are receding and snow is melting. There are severe floods, forest fires and landslides in places least thought of earlier. These consequences flow from environmental degradation. In fact this phenomenon has led man to surpass the carrying capacity of Earth. The Brundland report [2] was an eye opener for all of us. In fact, realizing the gravity of the situation as early as 1992, more than 1600 scientists, including 102 Noble laureates collectively signed a Warning to Humanity, which reads as follows:

"No more than one or a few decades remain before the chance to avert the threats we confront, will be lost and the prospects for humanity immeasurably diminished… A new ethics is required – a new attitude towards discharging responsibility for caring for ourselves and for Earth… this ethics must motivate a great movement, convincing reluctant leaders, reluctant governments and reluctant people themselves to affect the needed changes".

However, due to the lack of political will and a clear understanding of the consequences of our inaction, not much has been done in the direction of taking some firm steps towards the implementation of resolutions made at several world meetings attended by world leaders. Developed countries and developing countries instead keep blaming each other for the present malaise and never come an agreement and precious time for humanity is being lost for ever.

1.2 Technology Can Help

Naturally, to keep pace with rising population, the increased volume of production to meet the demand is likely to affect the world environmental health further unless technology is put to use and pollution prevention measures are vigorously pursued. Therefore, the importance of the control of effluents and waste management along with minimization of energy and material requirements (dematerialization) requirements can hardly be emphasized while ensuring an acceptable level of performance of systems, products and services.

Technology can certainly help increase the carrying capacity in several ways, if we are able to improve upon the technology and use it wisely. For instance:

- Since we have a limited reserve of gasoline on the planet Earth, we need to build cars that will give better mileage. If each car uses less fuel, then we can serve more people with the same amount of gasoline.
- Also using newer catalytic converters, we can make vehicular emission, which contributes 25% of the world's total CO_2, which is the single major factor leading to global warming, completely free of gases causing air pollution and carbon loads.
- If we were to increase the number of telephones by using old-fashioned standard phones, we would need many, many kilometers of wire to connect all those phones and the copper for the wires will have to be mined and the process of mining uses a huge amount of fuel energy and would cause a considerable amount of pollution of land, water and air. On the other hand, if we use wireless cell phones, we do not need wires, and we can save all that fuel and pollution. Fortunately, this revolution has already taken place.
- If we use new genetically engineered plants that can be grown in dry climates and are resistant to disease, or with increased nutrition, we can grow the plants on new farms, without the use of pesticides, and produce a better crop. Of course, we will have to ensure that this happens without any risk to humans and that these new plants in themselves do not harm our environment.
- In fact, new sustainable technologies have the promise of reducing energy requirements of products and systems considerably. This has happened in the case of micro-miniaturization of electronic devices. A laptop today consumes negligibly less power than a computer of 1960, which used tubes and was highly inefficient and unreliable. After all Moore's law applies to electronic hardware development. Why will

this not happen if move over to the use of nano-devices?

Therefore, it is quite understandable that several possibilities exist for using technology to our advantage to prevent pollution and wastage of resources to help increase the carrying capacity of Earth.

1.3 Sustainability Principles

It is true that no development activity for the benefit of human beings can possibly be carried out without incurring a certain amount of risk. This risk may be in terms of environmental degradation in terms of pollution of land, water, air, depletion of resources, cost of replenishment or restoration to acceptable levels both during normal operating conditions and under the conditions of sudden hazardous releases on account of catastrophic failures or accidents. In the past, we have witnessed several technological (man-made) disasters, which had their origin in our underscoring the importance of ensuring the best level of system performance and its linkages to environmental risk.

There is a severe requirement of material conservation, waste minimization and energy efficient systems. Recycling and reuse must be given serious consideration if nonrenewable resource consumption is to be minimized or energy use associated with material extraction is to be conserved. Use of renewable energy sources has to become the order of the day. The same is true about the prevention of pollution of *free resources* like water and air, which are also required for sustaining life support system of the planet we live up on.

One of the important strategies of implementing sustainability is to prevent pollution (*rather than controlling* it) and this by itself cannot be viewed in isolation with the system performance. A better system performance would necessarily imply less environmental pollution on account of system longevity and optimum utilization of material and energy for limited resources scenario that governs the development of future systems. It is also naturally an economic proposition. In other words, sustainability depends very heavily on the performance characteristic of a system. Therefore, the objective of a system designer should be to incorporate the strategy of sustainability in all future system performance improvement programs and designs.

The key issues associated with the implementation of the sustainability characteristics of a system appear to revolve around:

- The need to conserve essential natural resources, minimize the use of materials, develop renewal energy sources and avoid overexploitation of vulnerable resource reserves.
- The need to minimize the use of processes and products that degrade or may degrade the environmental quality.
- The need to reduce the volume of waste produced by economic activities entering the environment. The quantum of waste is colossal. For example, every three months, enough aluminum is discarded in North America to rebuild the entire North American commercial airline fleet.
- The need to conserve and minimize the use of energy. For example, if recycled the energy requirement for aluminum is just 5% of the energy used in original production.
- The need to reduce or prevent activities that endanger the critical ecological processes on which life on this planet depends.

1.4 Sustainable Products and Systems

The sustainability principle requires that the products and systems use minimum material (dematerialization), and minimize the use of energy throughout their entire life cycle (extraction phase, manufacturing phase, use phase) and they should use non-hazardous materials and should be highly recyclable at the end of their life. Minimizing the use of matter minimizes the impact of the extraction phase and minimizes total material flows. Historically, the United States environmental activities have been driven by

regulation. They were focused more on the factory, on emissions from the factory. Consequently, R&D in the United States has focused very much on activities like the factory-eliminating CFCs, reducing the emissions of volatile organic compounds (VOCs), improving water quality and such types of issues. Whereas in Europe, environmental policies are being increasingly pursued to address the overall environmental impacts of a product over its entire life cycle right from raw materials extraction, product manufacturing, product use, and disposal or recycling.

The European Union's Integrated Product Policy (IPP), which seeks to stimulate demand for greener products and to promote greener design and production (Commission of the European Communities, 2001) is a step in that direction. European Union's WEEE directives also can be considered as a step in that direction. In Japan, much emphasis is being put on the environmental design of products and systems, driven both by the concern over scarce resources and as a business strategy. The emphasis is on extensive recycling of products and environmental attributes such as energy efficiency and the use of non-toxic materials. In Europe and Japan, increasing attention is being paid to materials flow analysis as a means of assessing resource efficacy and sustainability. Materials flow analysis, the calculation of flows of materials from cradle to grave, is being used to complement risk analysis and to provide insight into the challenges of sustainable use of resources. These developments indicate an international shift in emphasis from managing individual manufacturing wastes and emissions to managing the overall environmental impacts of industrial sectors and of products over their life cycles. In response, global industrial firms in the United States, Europe, and Japan, are beginning to apply these concepts to their products, manufacturing processes, and environmental programs. Since the 1970s, there is growing evidence to suggest that greater material efficiency, the use of better materials, and the growth of the service economy are contributing to the *dematerialization* of the economy.

The economic growth in developed countries is no longer accompanied by an increased consumption of basic materials. This dematerialization has been investigated for a range of materials including steel, plastics, paper, cement, and a number of metals. Also, as the sources of energy have shifted from wood and coal to petroleum, nuclear energy, and natural gas, the average amount of carbon per unit energy produced has declined, resulting in a *decarbonization* of world energy. These strategies will influence the way product and system designs are designed and manufactured in future.

In fact products, systems and services will be evaluated based on a life-cycle assessment of a product. A life-cycle assessment (LCA) evaluates the entire environmental impact of a product through its life cycle, including manufacturing, use and disposal. A great deal of work has been done to develop the technical foundations for LCA of products and processes, and to develop the databases necessary to support such assessments. The International Organization for Standardization (ISO) is working on formalizing LCA methods. Future products and systems would have to confirm to tenets of DfE (Design for Environment) methodologies.

The phenomenal advances made in information technology have built up great hopes in other technological pathways for sustainable development. Today, newer and smart materials that include composites, high strength plastics and biodegradable materials combined with material recycling and minimum effluent and waste-producing processes, the use of clean energy sources and ever-decreasing levels of energy requirement are some of the strategies that will govern the design and use of all future products, systems and services in the 21st century. New, renewable energy sources are likely to influence the design of future products and systems. It is expected that clean fusion technology will replace the present dirty fission technology in future, provided that the same is proved to be dependable, safe and sustainable.

As stated before, genetic engineering, biotechnology, nanotechnology and molecular manufacturing may provide immense possibilities to developing sustainable products, systems and services that may create minimum adverse effects

on environment and last long while using minimum material and energy requirements. All this would require new technological pathways to minimize if not reverse the damage that has already been done to the Earth's environment, if humanity is to survive on this planet.

Certainly, these factors cannot be considered in isolation of each other. Therefore, it is time to take a holistic view of the entire life cycle of activities of a product or system along with the associated cost of environmental preservation at each stage, while maximizing the product/system performance.

1.5 Economic and Performance Aspects

Classical economic theories that have treated nature as a bottomless well of resources and infinite sink for waste have to be discarded. Environmental costs, *i.e.*, the cost of preventing or controlling pollution and ecological disruption, must be internalized. In fact, it is our incapability to deal with the economic nature of environmental pollution that has been largely responsible in destroying the Earths' ecological systems. Many hidden environmental costs incurred on resource exploitation need to be passed on to the consumer or user.

To preserve our environment for future generations, the internalization of hidden costs of environment preservation will have to be accounted for, sooner or later, in order to be able to produce sustainable products in the long run. It is therefore logical to add these hidden costs to the cost of acquisitioning a product or a system.

Also, technological innovations are not without cost to the society. In fact, today leadership among the industrialized nations is judged by the amount of money a country spends on the R and D and by the number of personnel it employs for this effort. In the past, Japan was known as a nation that has turned technologies and know-how into the world's highest quality products. Now, the Chinese have excelled in the skill of making products that are known for being cheaper in cost and better in quality than their counterparts elsewhere in the world. They have invested very heavily in the development of industrial infrastructure over a period.

A recent survey shows that consumers are willing to pay up to 10% more to have an environmentally preferred product. But what does an environmentally preferred product mean, what characteristics of a product will a consumer pay more money for? It is known that consumers in Europe are more willing to pay a premium than consumers in the United States, but the definition of what attributes are important is still just at the beginning.

As of now, the performance of a product, system or a service is usually judged in terms of dependability, which can be called an aggregate of one or more of the attributes of survivability, like quality, reliability, maintainability, *etc*., and safety, of course, not overlooking the cost of physically realizing these attributes. These attributes are very much influenced by the design, raw material, fabrication, techniques and manufacturing processes and their control and, finally, by the usage. These attributes are interrelated and reflect the level or grade of the product so designed and utilized, which is expressed through dependability. In fact, as of now, dependability and cost effectiveness are primarily seen as instruments for conducting the international trade in the free market regime and thereby deciding the economic prosperity of a nation. Therefore, we can no longer rely solely on the criteria of dependability for optimizing the performance of a product, system or service. We need to introduce and define a new performance criterion that would take the sustainability aspect of developing a product or system into consideration in order to take a holistic view of the performance enhancement along with the remedial or preventive costs associated with environmental pollution.

The ever-increasing complexity of systems has further necessitated reliability of components and subsystems, the safety of human beings and the protection of our environment. Especially high-risk systems such as nuclear power plants and other chemical plants have warranted operational safety of the highest order. Besides economically endangering environmental safety or human life, costly projects such space probes can be

economically disastrous when such a system fails. Even on the basis of economic considerations, a designer is left with no option but to look for high reliability of systems as the cost of down time results in a crushing sum. For example, the power replacement cost when a moderate-sized nuclear plant is shut down may run over U.S. $80,000. The loss of several billion dollars besides the loss of human lives was involved in the total failure of the Challenger mission.

Another economic consideration that is important for developing future products and systems is to utilize obsolete products at the end of their life for recycling or reuse. If obsolete materials are not recycled, raw materials have to be processed afresh to make new products. This represents a colossal loss of resources as the energy, transport and environmental damage caused by these processes is large. In 1998, it was estimated that six million tonnes of electrical equipment waste causing a loss of resources in Europe was:

- 2.4 million tonnes of ferrous metal
- 1.2 million tonnes of plastic
- 652,000 tonnes of copper
- 336,000 tonnes of aluminum
- 336,000 tonnes of glass

besides the loss of heavy metals such as lead, mercury, *etc*. The production of all these raw materials and the goods made from them would have caused enormous environmental damage through mining, transport and energy use. In fact, recycling 1 kg of aluminium saves 8 kg of bauxite, 4 kg of chemical products and 14 kW of electricity. Therefore consideration of end-of-life treatment will soon become an integral part of product design.

Another major concern is the toxic nature of many substances such as arsenic, bromine, cadmium, lead, mercury and HCFCs, *etc*. Even in the consumer products' category, the number of refrigerators and freezers that are disposed of annually in the UK is 2.4 million units and these units contain gases like chlorofluorocarbons (CFCs) and hydro chlorofluorocarbons (HCFCs) used for cooling and insulation. Both are greenhouse gases, which when released into the atmosphere contribute to ozone layer depletion, leading to climatic changes. The European Council regulation No. 2037/2000 on substances that deplete ozone layer came into effect in October 2001.

Another example of household items is fluorescent tubes, which contain toxic heavy metals such as lead, mercury and cadmium and if these substances enter the human body they may damage liver, kidneys or brain. Mercury is a neurotoxin and can build up in the food chain. A four feet fluorescent tube may contain over 30 milligrams of mercury. The EC permissible limit for mercury in drinking water is one part per billion or 0.001 mg a liter. Here again, we have the ROHS EC directive (2002/95/EC) on hazardous substances.

In fact, end-of-life treatment will become the liability of the manufacturer and distributor of all products eventually. The WEEE directive of the European Union is the first step in this direction at least in the electrical and electronic sector. The WEEE directive (2002/96/EC) as passed by the European Community is aimed to prevent waste electrical and electronic equipment from ending up in landfills and to promote the level of recycling and reuse in the electrical and electronic sector. This directive requires all manufacturers and importers of electric and electronic equipment to meet the costs of collection, treatment and recovery of their waste electrical and electronic equipment at the end of their useful life.

The waste generated in this sector is not small either. For example, in a small country like Ireland, an estimated 35,000 to 82,000 tonnes of waste electrical and electronic equipment was generated in 2001. This amounted to 9 to 18 kg per person. Each year, more than 100 million computers are sold and over 1 million computers are disposed of in landfill sites. The rest are recycled for parts or material. Ecomicro – a recycling company in Bordeaux, France is reported to resort to recycling of components out of 1500 tonnes of obsolete or unusable computers annually. In fact, the market for refurbished computers has increased by 500% since 1996 but less than 20% of all discarded computers are recycled. Currently, a total of 40%,

which is 1.5 million printer cartridges, are recycled annually.

1.6 Futuristic System Designs

One of the ways of arresting environmental degradation is to discard old polluting technologies and production processes. The other way of slowing down the environmental degradation would be to prolong the life span of all products and systems so that we conserve energy and materials to satisfy our needs when reckoned over a given interval of time. In other words, the old principle *use and throw,* which was considered indispensable to keep the wheels of industry running and for economic prosperity of nations has eventually given way to the philosophy of reuse, recycle, and conservation if we do not intend to damage the life support system [3], of planet Earth. In short, we must be able to design highly reliable products and systems. Earlier reliability of products and systems was considered an economic compulsion to remain in business and to compete in the market but now it also an environmental compulsion

Other pathways to achieve sustainable products and systems and to minimize environmental impacts would be to use the concept of *industrial ecology,* which would entail clustering selected industries and have their *inputs* and *outputs* interlinked and mutually supported in order to preserve and conserve energy and materials including waste. We have also to work out methods of efficient energy generation and utilization, cleaner transportation, and improved materials. The use of biotechnology for improving products and cleanup process for taking care of effluents, extensive use of biodegradable materials and plastics would have to become quite common in future to prevent environmental degradation. Molecular manufacturing is being seen as clean process and a potential pathway for developing sustainable products and systems.

Several industrialized nations are taking a lead in the development of future products, processes, systems and services that are not only environmentally benign but have the advantage of economy and efficiency. Instead of mining; recycling, recovery and reuse are all becoming more and more common, as these are not only cost effective but less energy intensive and less polluting. Waste minimization, waste processing and safe disposal while conserving natural resources, the optimum and efficient use of energy including natural sources of energy, product and process, eco-friendly designs and improvement of performance of systems, for longevity and conservation of resources, are becoming increasingly important means of achieving sustainable products and systems.

Due to the existing fierce competition and improving technologies, modern systems are becoming more and more reliable than before. Today, we must recognize that unless we integrate the concept of economy reflected through material, resources and energy audit with performance audit reflected through quality, reliability, safety audits and finally with the environmental audit for sustainability, we would only be having wasteful and imperfect system designs. Therefore, it is time that we take the initiative in making system designers visualize the linkages or interdependence between environment, economy and performance.

Design for end-of-life requires manufacturers to reclaim responsibility for their products at the end-of-life. The alternatives to landfill or incineration include: maintenance, recycling for scrap material, and remanufacturing. This is shown in Figure 1.1.

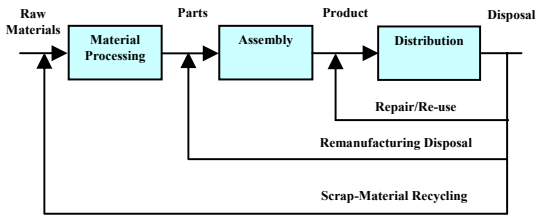

Figure 1.1. End-of-life options

Maintenance extends product life through individual upkeep or repair of specific failures. Remanufacturing is a production batch process of disassembly, cleaning, refurbishment and replacement of worn out parts, in defective or obsolete products. Scrap material recycling

involves separating a product into its constituent materials and reprocessing the material. Remanufacturing involves recycling at parts level as opposed to scrap material level. It is actually in effect recycling of materials while preserving value-added components. Remanufacturing also postpones the eventual degradation of the raw materials through contamination and molecular break down, which are the characteristics of scrap material recycling. Since remanufacturing saves 40–60% of the cost of manufacturing a completely new product and requires only 20% energy, several big companies are resorting to remanufacturing. Xerox is an example of this case. IBM has also established a facility in Endicott, New York as a reutilization and remanufacturing center. UNISYS and Hewlett Packard also use this strategy. It must, however, be stated that remanufacturing is not suitable for all types of products; it is appropriate only for those products that are technologically mature and where a large fraction of the product can be used after refurbishment.

It should be mentioned here that a designer must account for the various costs associated with recycling and remanufacturing including the first cost, recycling cost, and the cost of failure during disassembly and reassembly. The first cost is the cost of manufacturing and the first assembly. Recycling cost includes the cost of extracting material or cost of separating parts of different materials. Both maintenance and remanufacturing involve disassembly and reassembly and part reuse and failures can occur during these phases. Therefore, the consequences of the above failures are weighted by their probabilities of occurrence. For example, rivets and welds are usually destroyed during the disassembly. Another part of the cost includes the cost of a part being damaged during assembly or disassembly. Cost also includes the cost of damage caused to a part when a fastener is extracted. Maintenance costs are the costs associated with disassembly or assembly, whereas the remanufacturing cost is the total cost under all the mentioned heads.

While modeling for reliability, an analyst will have consider the fact that for a product or system with brand new components, we usually assume that the population size is constant and has the same probability density function *f(x)*. In remanufactured systems, part failure results in replacement of a part of the same type or different type. The remaining system remains unchanged or is reconfigured to accommodate the replaced part. Thus there are two different failure density functions to consider. Also the age distributions of each of the part populations are tracked to determine the reliability of the composite system population.

In short, prudence in designing systems that have less environmental consequences is the necessity of today. Longer life or durability with less pollution is also economically beneficial in the long run and would yield minimum life-cycle costs. The criterion of sustainability for judging the performance of system would imply less pollution, optimum utilization of materials and energy, waste minimization and a longer life for the system and above all minimum risks to our life support system. This would also be an economic proposition as *sustainability* is interlinked with other performance attributes.

1.7 Performability

In search of a simple, suitable and appropriate term for reflecting this new concept, several terms defined from time to time were explored but none was found more appropriate than the term *performability*. In 1980, John Meyer [4] introduced the term *performability* in the context of evaluation of highly reliable aircraft control computers for use by NASA. Originally, Meyer [4] used this term mainly to reflect attributes like reliability and other associated performance attributes like availability, maintainability, *etc*. However, this reflected only partially the performance measures that we now would like the word to mean. Also, since that time dependability has been used to include more attributes related to performance. Therefore, it was considered logical and appropriate to extend the meaning of performability to include attributes like dependability and sustainability.

Thus, the definition of the term *performability* has been widened to include sustainability in the context of the changed scenario of the 21st century

in order to reflect a holistic view of designing, producing and using products, systems or services, which will satisfy the performance requirements of a customer to the best possible extent and are not only dependable (implying survivability and safety) but are also sustainable.

1.8 Performability Engineering

Performance engineering can be defined as the entire engineering effort that goes into improving the performance of a system that not only ensures high quality, reliability, maintainability and safety but is also sustainable.

Implicit with this definition is not only the high performance of a system but also its minimum life-cycle costs. Performance engineering addresses sustainability along with other factors like quality, reliability, maintainability, and safety. We cannot separate environmental problems from the economics of clean production and clean technologies. Likewise, improved performance should necessarily imply less environmental pollution, less material and energy requirements, waste minimization, and finally conservation and efficient utilization of available resources, which in turn result in minimum life-cycle costs. These problems are best tackled at the design stage of a system.

When an aggregate attribute such as *performability* reflects a designer's entire effort in achieving sustainability for a dependable product, we could call this effort *performability engineering*, which in other words is meant to reflect the entire engineering effort of a producer to achieve the performability of a product, system or service, which in fact can be called improving 3-S, namely, survivability, safety and sustainability. This concept is depicted in Figure 1.2. It may be emphasized here that the usual definition of dependability ignores the accompanying environmental consequences while creating products, systems and services. It is evident that in order to produce a truly optimal design economically, consideration sustainability should not be overlooked. These attributes are very much influenced by the design, raw materials, fabrication, techniques and manufacturing processes. They are interrelated and reflect the level or grade of the product so designed and utilized which is expressed through dependability.

The life-cycle activities of a product or system are depicted in Figure 1.3. Performability takes a holistic view of various activities and processes and takes stock of what is being produced and what is being wasted. We conserve and economize materials, energy, avoid waste to optimize a product or system's design over its entire life cycle.

In fact, performability engineering not only aims at producing products, systems and services that are dependable but involves developing economically viable and safe processes (clean production and clean technologies) that entail minimal environmental pollution, require

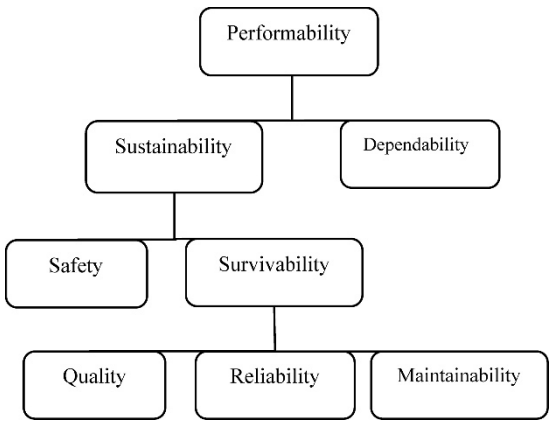

Figure 1.2. Implication of performability

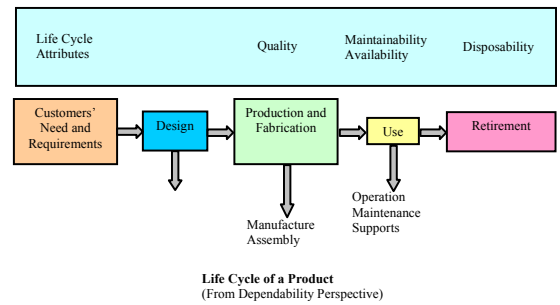

Figure 1.3. Life-cycle activities

minimum quantities of raw material and energy and yield safe products of acceptable quality and reliability that can be disposed of at the end of their life without causing any adverse effects on the environment. The WEEE directives of the European Community are a step this direction.

This would also necessitate the efficient use of natural resources and the use of non-waste technologies, which would ensure that all raw materials and energy are used in a most rational and integrated way to curb all kinds of wastages while maximizing the performance.

Obviously, less material and energy consumption, either through dematerialization, reuse or recycling or through proper treatment (clean up technology), would lead to a lesser degree of environmental degradation. Similarly, a better design would result in prolonging the life span of a product and hence would ensure less adverse effects on the environment over a given period of time. In other words, we must integrate the entire life cycle of activities of survivability with that of environmental cycle considerations to improve the product or system performance within the technological barriers with minimum cost.

At every stage of the life cycle of a product, be it extraction of material, manufacturing, use or disposal, energy and materials are required as inputs and emissions (gaseous, solid effluents or residues) and these influence environmental health of our planet.

Unless we consider all these factors, we cannot call the design of products, systems and services truly optimal from an engineering point of view. This necessitates bringing synergetic interaction between the constituent areas of performability.

1.9 Conclusion

Long-term product, system or service development strategies necessitate the consideration of performance attributes like performability, which takes a holistic view of the entire life-cycle activities and their influence on our environment and in fact on our own existence and that of future generations on this planet. Truly optimal design should necessarily consider sustainability along with dependability as the design criteria for all future products, systems and services.

Engineering Design: A Systems Approach

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: The purpose of this chapter is not to deal with all the aspects of design of an engineering system, but to discuss the design process using the systems approach, which the design department or section of a manufacturing concern, particularly in the electronics, aerospace, machine tool sector and the producers of consumer goods such as automobiles, office equipment, and household appliances and in many other areas, can use. For a manufacturer, the *research function* helps develop new products or useful design modifications to an existing product range and *development activity*, which is basically an engineering function aimed at converting the research concept into a viable product, is known as an R&D activity and sometimes it may be associated with design engineering as a project design and development function.

2.1 Introduction

The subject of system design has been dealt and discussed with in great detail ever since the dawn of the system age around 1940. The purpose of this chapter is to provide a broader outline of a scientific approach to the planning, design, development, manufacture and evaluation of engineering systems. It is basically aimed at realizing a coherent total system to achieve a specified objective subject to physical, environmental, state-of-the art techno-economic constraints. Any other approach may prove costly and untenable.

Historically, two approaches have been helpful in understanding the world around us. The first is called *reductionism* and is based on the assumption that everything can be reduced, decomposed, or disassembled to simple indivisible parts. Reductionism is basically an analytical approach and involves disassembling of what is to be explained down to independent and indivisible parts of which it is composed; and offers the explanation of the whole by aggregating the explanations of the behaviour of these indivisible parts.

The other approach is that of the *mechanism,* in which all phenomena are explained by using a cause and effect relationship. An event or a thing is considered to be the *cause* of another event or thing (called the *effect*) and a cause is sufficient to explain its effect and nothing else is required. It employs what is known as c*losed-system* thinking in which the search for causes is environment free and the laws for the phenomena are formulated in laboratories so as to exclude environmental effects. It is *mechanization* that brought about the *industrial revolution,* which in effect helped substitute men by machines in order reduce physical labour. However, with the decline of the machine age, a concept came into existence that heralded the dawn of the system age, which

considers all objects and events, and all of their experiences, are parts of a larger whole. This concept is better known as *expansionism* and provides another way of viewing things around us; a way that is different from reductionism but compatible with it. However, this does not mean that there are no parts, but that focus is on the whole. It shifts the focus from ultimate elements to a whole with interrelated parts-to-systems.

2.1.1 Analytic Versus Synthetic Thinking

In the *analytic* approach that was associated with reductionism, an explanation of the whole was derived from explanations of its parts, whereas the systems approach has provided us with a *synthetic* mode of thinking and in this approach, one is more interested in putting things together rather than in tearing them apart analytically. In fact, *analytic thinking* can be considered as an *outside-in approach* whereas *synthetic thinking* is an *inside-out* approach of thinking.

The synthetic mode of thinking [1], when applied to physical problems is known as the *systems approach* and is based on the fact that even if each part of a system performs as well as possible, the system as a whole may not perform as well as possible. This follows from the observation that the sum of the functioning of the parts is quite often not equal to the functioning of the whole. Therefore, the synthetic mode seeks to overcome the often-observed predisposition to perfect details and ignore system outcomes.

All man-made artefacts, including products, equipment and processes are often termed *technical systems*. Engineering activities such as analysis and design for man-made or technical systems are not an end in them and may be viewed as means for satisfying human needs. Therefore, modern engineering has two aspects. One aspect addresses itself to materials and forces of nature whereas the other addresses itself to the needs of people. Successful accomplishment of engineering objectives requires a combination of technical specialties and expertise. Engineering in the systems approach necessarily has to be teamwork, where the involved individuals are aware of the relationships between the specialties, economic considerations, and ecological, political, and social factors. Today, engineering decisions require serious consideration of all these factors right in the early stage of system design and development as these decisions have a definite impact subsequently. Conversely, these factors usually impose constraints on the design process. Thus, technical aspects not only include the basic knowledge of the concerned specialties of engineering but also the knowledge of the context of the system being developed.

2.2 The Concept of a System

The word "*system*" has a very wide connotation. Broadly speaking, we have a wide variety of systems around us. Several of them have been created by man to satisfy his needs while others exist in nature. *Natural systems* are those that came into existence through natural processes whereas *man-made systems* are those in which human beings intervene through components, attributes, or relationships. Examples of man-made systems are highways, railways, waterways, marine and air transport, space projects, chemical plants, nuclear plants, electrical power generation, distribution and utilization, housing and office complexes, mining and oil extraction, *etc*. Even in the context of nanotechnology [2], nanosystems are systems and the principles of system engineering naturally apply to them. Solid mechanics, system dynamics, mechanisms and control theory are all relevant to nanotechnology and all enable technologies in future. Therefore, the word system may connote anything ranging from simple, artificial or composite, physical systems to conceptual, static and dynamic systems or even organizational and information systems. However, man-made systems are invariably imbedded into the nature [3], therefore interfaces exist between man-made systems and natural systems, and man-made systems in turn influence natural systems.

2.2.1 Definition of a System

A system can be defined as an aggregation of parts or elements, connected in some form of interaction

or interdependence to form a complex or unitary whole. In other words, *a system is a set of mutually related elements or parts assembled together in some specified order to perform an intended function*. Not only do we have systems that are assemblies of hardwired units but we also have abstract systems such as the education system, the social system, the monitory system, a scheme of procedures, *etc*. Not every set of items, facts, methods or procedures is a system. A random collection of items cannot be called a system because of the absence of purpose and unit's functional relationship. At most, it can be called a set of objects but not a system. This is a very broad definition and allows anything from a power system down to an incandescent lamp to be classified as a system provided a system must have an objective or a function to perform

2.2.2 Classification of Systems

In order to provide a better understanding of the systems that we shall be concerned with, it would not be out of place to mention here the broad classification of systems. Physical systems are those that manifest themselves in some physical form while conceptual systems are those, where the attributes of components are represented by symbols, ideas, plans, concepts and hypotheses. A physical system occupies physical space whereas conceptual systems are organizations of ideas. Conceptual systems often play an important role in the operations of physical systems in the real world. A static system has a structure without any activity whereas a dynamic system constitutes structural arrangement with some activity. Many systems may not be classified in this broad category because they may lack the notion used here. For example, a highway is a static system yet it constitutes of components, attributes and relation of dynamic systems.

A closed system is one that does not interact significantly with its environment and it exhibits the characteristics of equilibrium resulting from the internal rigidity that maintains the system in spite of influences from the environment. In contrast, an open system allows information, energy and matter to cross its boundaries. Open systems interact with their environment. They display steady state characteristics whereas in a dynamic interaction of systems, the elements adjust to the changes in the environment. Both closed and open systems exhibit the property of entropy, which may be defined as the degree of disorganization in a system and uses the term analogously to thermodynamics. Actually, entropy is the energy not available for work when energy transformation takes place from one form to the other.

In a large variety of natural or man-made systems, the inputs, processes and the outputs are described mostly in statistical terms and uncertainty exists in both the number of inputs and their distribution over time. Therefore, these features can be best described in terms of probability distributions and the system operation is known to be probabilistic.

Many of the existing systems today in the sphere of energy, transportation, information, computer communication, production, *etc.,* are all artificial or man-made. However, they can influence or be influenced by natural systems at the same time and can also be composite.

As far as this handbook is concerned, we shall deal exclusively with engineering systems. However, the system concepts and analyses presented here may be applicable to any other category of systems as well. The scope of engineering systems itself is so vast that no generalization is possible to handle such systems. However, one specific feature of engineering systems, unambiguously and strikingly, is that they are all man-made and both their elements and the system as a whole can be called products. Nevertheless, man's presence in an engineering system and his role in its functioning, may change from system to system. In any case, man shall always be regarded as an element of the system. Secondly, an engineering system must be trustworthy and dependable otherwise it cannot serve the purpose it was intended.

2.3 Characterization of a System

Most of the engineering systems today belong to the category of *complex* systems. Although such a

distinction between simple and complex systems is totally arbitrary, the degree of complexity of a system relates to the number of elements, their physical dimensions, multiplicity of links or connections of the constituent elements within the system, multiple functions, *etc*. The complexity of a system can be best defined based on the complexity of its structure and the functions performed by the system.

2.3.1 System Hierarchy

A system is a top-down approach and has basically three levels of hierarchy [4], *i.e., systems, subsystems* and *components*. In such a hierarchy, a *component* is defined as the lowest level of hierarchy in a system and is a basic functional unit of a system. Components, in the system definition should be regarded as those units of the system, which can be assumed indivisible in context of the problem being considered at hand. Sometimes we may use the word *element* (the fundamental unit) to mean a component. The assembly of components connected to produce a functional unit is designated as a *subsystem*. It is the next higher level of hierarchy in a system, after the component. Finally, an assembly of subsystems connected functionally to achieve an objective is called a *system*. It is the highest level of hierarchy in the concept of a system.

Sometimes terms like *element*, *product*, *unit*, *equipment, etc*., are also used interchangeably to mean a system, a subsystem or even a component depending upon the context of level of system hierarchy.

2.3.2 System Elements

Regardless of the level of hierarchy of a system, it always comprises *items*, *attributes* and *relationships* to accomplish a function, where:

- *Items* are the operational parts of a system consisting of input, process and output;
- *Attributes* are the properties of the items or components of a system that are discernible,
- *Relationships* are the links between items and attributes.

Therefore, a system can be considered as a set of interrelated items or units working together to accomplish some common objective, purpose or goal. The purposeful action performed by a system is called as its *function*. Once the objective of a system is defined, system items can be selected to provide the intended output for each specified set of inputs. The objective also makes it possible to establish a measure of effectiveness, which indicates how well the system will perform.

A system usually involves transformation of material, energy or information, which in turn involves *input*, *process* and *output*. In fact, a system that converts material, energy or information involves structural components, operating components and flow components. Standard components are usually the static parts.

A system has [5] its limits and boundaries. Any thing outside the boundaries of a system is called its *environmen*t and no system can ever remain isolated from it. Materials, energy or information must pass through the boundaries as an *input* to the system whereas material, energy or information that passes from the system to the environment is called its *output*. However, the constraints imposed on the system limit its operation and define the boundary within which it has to operate. In turn, the system imposes constraints on the operation of its subsystems and consequently on its components. Therefore, at all levels of the system hierarchy, there are inputs and outputs. The output of one item can be input to another. Inputs can be physical entities like materials, stresses or even information.

2.3.3 System Inputs and Outputs

An input to a system can be defined as any stimulus, or any factor whose change will invoke some kind of response from the system.

Usually, we have three groups of inputs, namely,

- *Component parameters,*
- *Operating condition parameters,*
- *External inputs.*

The component parameters are those variables that are generally determined by the hardware design, whereas the operating condition parameters

determine the state of the system in terms of operating conditions and environmental parameters, and the external inputs are the inputs, such as power supply voltage, input signal voltage, *etc*.

An input applied to the system will result in a response, which depends on the system condition and the input. This result is called the output of the system. Here again, we may have the following subdivisions:

- Primary outputs,
- Secondary outputs.

For example, primary outputs could be the power output of an amplifier or the output voltage of a stabilized power supply, whereas the secondary outputs may be regarded as the power dissipated in components, the voltage across a capacitor, noise or vibrations generated, *etc*.

2.4 Design Characteristics

Engineering design is a function that usually employs established practices to produce hardware specifications for the solution of a given problem. The design should be *functional* and must be one which, when translated into hardware, will satisfactorily perform the functions for which it was designed. The design should be *reliable*, which means when the design is translated into hardware, it must not only function but also continue to meet the full-range functional requirements over the required period of time throughout the specified range of environments. If the system is maintainable and its maintenance is anticipated, the design must provide adequately for *maintainability.*

The design must be *producible* and should be economically produced by the available production facilities and supplies. The design must be *timely* and should be completed and released within the established time schedule, which may be established either by a contract, or by the deadlines dictated by compulsions of change of model, or by competitors. The design must be *competitive* and *saleable*. However, the factors involved in saleability vary widely and may include *cost*, *special features*, *appearance*, and several other factors.

As far as possible, a designer should employ proven design techniques. When design objectives cannot be met by proven and familiar design practices, the designer is expected to employ new methods, borrow design techniques from other industries, or use available new *state-of-the-art* materials and processes. Since designers are generally supposed to be creative, it is often difficult for them to resist trying something new even though a technique of proven effectiveness and reliability exists. It is the responsibility of management to establish a system that makes it easier for a designer to use proven design than to try unproven design. Also as all system objectives cannot be met to the fullest extent in a design, the designer should be encouraged to attempt a trade-off between the set of important objectives.

By specifying unusually tight tolerances or use of exotic materials, a designer may be able to increase reliability but generally at the expense of producibility. Sometimes, a designer may be tempted to take chances with lowered reliability design without demonstrating its ability to function under the worst scenario of environment and ageing, so that the design is released on schedule. Some of these compromises and trade-offs are unavoidable. The management has the necessary information and responsibility to make decisions in this respect. However, the designer must disclose the fact that trade-offs have been made and the reasons for making these decisions to the reliability section and to the management.

To accomplish a system design, the design management must set clear-cut design objectives. These design objectives may be either imposed by the user or by the general management, or they may be developed within the design organization for submission to and acceptance (with or without modification) by the general management.

The design process necessitates a very high degree of creativeness, technological insight, and flexibility. At the initial stage, several activities like brainstorming, consultations, literature search, interviewing, systems engineering, and so on, are carried out. In the feasibility study, a designer must apply his mind and all his experience and creativity him in proposing a number of plausible solutions. Once the feasibility study has been completed, the

design has advanced to a point where a number of *alternative solutions are available for further study.* This marks the beginning of *the preliminary design phase*.

The first step in the preliminary design phase likewise depends upon the designer, who is to choose for further study the most promising configuration or topology from the feasibility analysis. Having done this, the rest of the preliminary design is carried out without changing the system configuration or topology. The designer has to choose the specifications and component parameters such that the best possible alternative within the limitations of a fixed topology results, duly considering component parameter variations and conditions of use including environmental effects.

The last phase of the design process is the *detailed design phase*, which brings the design to detailed part specifications, assembly drawings, testing of prototypes, *etc*. Following this phase, we come to the point where we may be planning for production and subsequently follow up with other stages such as distribution, utilized servicing, and retirement of the product of system.

2.5 Engineering Design

Basically, there are two main approaches in engineering design, *viz.,* the bottom-up and top-down approaches. In the case of bottom-up design, physical realizability in terms of known elements is assured, whereas the top-down design process ends with the system elements as its functional entities. Their physical realizability may not be guaranteed. In the top-down approach, the requirements are always satisfied at every step of the design process because it is an inherent part of the methodology, whereas in the bottom-up approach the methodology provides no assurance that that finally would happen.

2.5.1 Bottom-up Approach

Traditional engineering design is basically a *bottom-up approach*, where one starts with a set of known elements and creates a product or a system by *synthesizing* a set of specific system elements. It is also very rare that the functional requirements are met right in the first instance unless the system is quite simple. After determining the system's performance and deviations from what is desired, these elements and/or their configuration may be changed again and again till the desired performance is assured and the system objective is met. The process is known as the *bottom-up process* and is iterative in nature. Of course, the number of iterations naturally would depend on the complexity of the system being designed and the experience and creativity of a designer.

2.5.2 Top-down Approach

A more general methodology to engineering design is provided using the systems approach, which is actually based on a *top-down approach* to the design. There are two main features of the top-down process. First, the process is applicable to any part of the system. Starting with the system as a whole, repeated application of this process to various levels of system hierarchy will result in partitioning of the system into smaller and smaller *elements*, better known as *subsystems* and *components*. Second, the process is self-consistent. External properties of the whole system, as described by the inputs and outputs and relations between parts, must be reproduced by the external properties of the set of interacting elements.

The top-down approach also recognizes that general functions are available in transforming inputs into outputs and a designer abstracts from the particular case to the underlying generic case, and represents the genetic case by several interacting functional elements. The use of functional elements is the essential feature of the systems approach compared with systems integration in convention design. A particular functional element is applicable to a whole class of systems. Consequently, only a few such elements are required to realize many real systems.

Lastly, it may be emphasized that a systems approach is not intended to replace bottom-up design totally. Every end product incorporates physical objects working together to meet the desired objective. At any point in the design process there must be a transition from the

functional to the physical. Thus almost all engineering designs may gainfully employ both methodologies. However, the first to be employed is supposed to be the systems approach, which will reduce the system complexity by decomposing it into its constituent elements and then bottom-up design can be used to realize the design elements physically.

2.5.3 Differences Between Two Approaches

The systems approach lays emphasis on the following aspects of engineering design:

1. The systems approach views the system as a whole, whereas conventional engineering designs have always covered the design of various system components but the necessary overview and understanding of how these system components effectively fit together is not outright obvious.
2. Emphasis in the past was primarily placed on the design and system acquisition activities, without considering their impact on production, operations, maintenance, support, and disposal. If one is to adequately identify the risks associated with the upfront decision-making process, these should be based on life-cycle considerations. The systems approach considers a *life-cycle orientation* that views all phases of the system's life, *i.e.,* system design and development, production and/or construction, distribution, operation, maintenance and support, retirement, phase-out, and disposal.
3. In the systems approach, emphasis is put on providing the initial *definition of system requirements* and on the specific design criteria followed by analysis to ensure the effectiveness of early decision making in the entire design process. The actual system requirements are well defined and specified, and the tractability of these requirements right from the system level downwards are transparent. In fact, in earlier designs, this type of early analysis in many new systems was always practically non-existent. The lack of defining such an early "baseline" often resulted in greater design efforts downstream, which subsequently often resulted in expensive system modifications.
4. *The systems approach necessitates an interdisciplinary team approach* throughout the design and development process. This ensures that all design objectives are addressed in an effective and efficient way.

Last but not least, the systems approach involves the use of appropriate technologies and management principles in a synergetic manner and its application requires a focus on the process, along with a *thought process* that should lead to better system designs.

2.6 The System Design Process

To design a system is to synthesize it. This requires selecting known elements and putting them into a new configuration. A design alternative is an arrangement to realize the system objective. Evaluation is a prediction of how good the design alternative would be if it were accepted for implementation. System design evaluation generally precedes the system analysis, which in turn, is preceded by synthesis. In fact analysis, evaluation and synthesis are followed in a cyclic order till the objective of system design is met. In order to make system design cost-effective and competitive, system design evaluation should be carried out as an essential technical activity within the design process. However, it should not be pursued in isolation. System design evaluation should necessarily be carried out regularly as an assurance of continuous design improvement. As one proceeds from the top-down approach in the early phases of system design and development, there is also a follow-on "bottom-up" procedure at the same time. During the latter phases of the preliminary and detail design and development phase, subsystems or components are combined, assembled, and integrated into the specified system configuration. This, in turn, leads to the iterative process of system evaluation. Inherent within the systems engineering process is always a provision for constant feedback and necessary corrective action.

2.6.1 Main Steps of Design Process

The designer's approach to design is basically the same whether it is design of a component or a part, a subsystem, or a system, and the difference lies only in in the degree with which the task is carried out. The following is the sequence of steps that are commonly executed during the design:

1. Develop one or more design concepts that satisfy the design objective.
2. Carry out the feasibility analysis of the various possible design concepts using personal experience or by theoretical analysis and simulation, or by experimentation and testing, or by combinations of these.
3. Choose the design concept that meets all of the design objectives. Apportion reliability or any other performance goal requirements at all levels down to the part level of system hierarchy.
4. Prepare preliminary specifications and drawings.
5. Based on preliminary drawings and specifications, pass on the design for fabrication and production and procurement of development hardware to be used for feasibility and evaluation testing of the hardware.
6. Plan qualification test requirements and participate in planning production test and inspection requirements.
7. Participate in the preparation of prototype and qualification testing, taking whatever corrective design action is found to be necessary.
8. Prepare the final design. It is at this point that the review of set of designed objectives is necessary.
9. Review and approve those portions of the design that are not created by the design section.
10. Release the completed design, after ensuring that the objectives of design and other required approvals, for manufacturing or fabrication or for the user's disposition as applicable, have been achieved.

The designer has several tasks to perform even after the design is released. Two of these functions, design-configuration control and design-change control, are closely related. All design-change requests must be fully and carefully reviewed for impact on design objectives such as inherent reliability as well as for other impacts. As the design approaches completion, design-change control must come under the direct control of top management, because it is difficult to stop most design organizations from making changes. Design-configuration control relates to the control of requirements for a specific model type of hardware, serial number or production block.

There are two approaches for executing the first two phases of the design, *viz.,* the feasibility study and the preliminary system design and the most common and realistic approach based on the foregoing practice of design is outlined in Figure 2.1(a), where the configuration is fixed at the discretion of the designer and formal optimization is subsequently applied only to this design. While choosing the most promising design from the feasibility study, a designer usually makes some rough calculation of the expected performance of the system. Needless to say, a comparison of designs can only be valid if each design has been optimized according to the same criterion. If the designs are acceptable, there is no point in comparing an optimized design to one that has not been optimized, as there is little to gain by comparing two non-optimized designs.

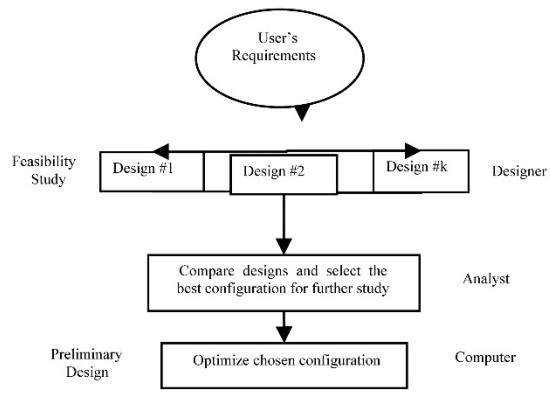

Figure 2.1(a). Common practice for system design

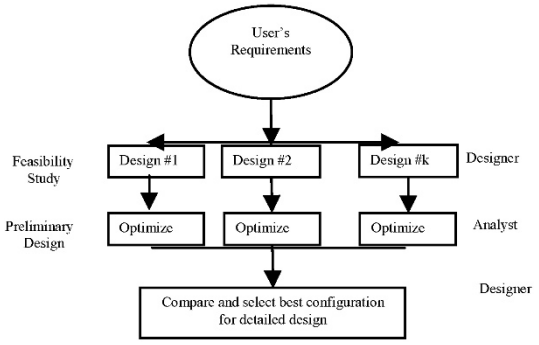

Figure 2.1(b). Ideal process for system design

Figure 2.1(b) shows the idealized structure for the first two phases of the design process. It would be unrealistic to consider this structure at all, if the design were not achieved through a computer optimization. It is, however, necessary to appreciate that the optimization of different design configurations can be quite time consuming; the designer must in each case prepare the specific actions for consideration.

It should be mentioned here that in either case the final design configuration is realized through the interaction of designer and analyst and very often we will need to do some iterations as the results of the preliminary design may sometimes provide ideas for minor changes in the design configuration.

2.6.2 Phases of System Design

Basically, any system design [6] evolves through the following phases of development:

- Conceptual Design
- Preliminary System Design
- Detail Design and Development
- System Test and Evaluation

2.6.2.1 Conceptual Design

This is the first phase in a system design and development process. Conceptual design is the foundation on which the life-cycle phases of the remaining stages of system design, *viz.,* preliminary system design, detail design and development, and system test and evaluation, are based.

Conceptual design evolves from:

- Functional definition of the system based on an identified need of the system and the requirements of the customer.
- Establishment of design criteria.

Therefore, system design is a process that starts with the need and definition of user requirements to a fully developed system configuration that is ready for production and delivery for subsequent use. To identify need, we must identify the deficiencies in the present design involving the customer if necessary; in fact, the customer should be associated with the design team throughout the design from start to end.

Once we have established the need, it is necessary to identify a possible design approach that can be pursued to meet that need and we can assess various approaches in terms of performance, effectiveness, maintenance, logistic support and economic criteria and select the best alternative. At this stage the possible technology can also be selected and the operational requirements of the system in terms of deployment, mission profile, utilization, environment of use and performance and effectiveness related parameters, *etc.,* can be developed. Maintenance and logistic support [7] for the system can also be designed at this stage. Having accomplished this, system specifications can be developed and a review of the conceptual design can be undertaken.

2.6.2.2 Preliminary System Design

This phase of design translates the system level requirements obtained from the conceptual design phase into subsystem level requirements and below for developing a system configuration. It also extends functional analysis and requirements allocation from the baseline, to the depth that is needed to identify specific requirements for hardware, software, man-power, facilities, logistic support, and other related resources. Subsystem functional analysis is basically an iterative process and decomposes requirements from the system level to the subsystem level and if desired to the components level if it is necessary to describe functional interfaces and identifying resource

needs adequately. These resources may be in the form of hardware, software, people, facilities, data, or their combinations. Also allocation of resources along with statement of maximum or minimum specifications of all important parameters is done in this phase. A system design review is again undertaken to ensure that the overall requirements are being met and the results of the functional analysis and allocation process, the trade-off studies, the design approach selected, *etc*., are reviewed for compliance with the initially set requirements. All deviations are recorded, and the necessary corrective measures as considered appropriate are initiated. Results from this phase support detail design and development.

2.6.2.3 Detail Design and Development

The design requirements at this stage are derived from the system specifications and evolve through applicable lower-levels specifications. These specifications include appropriate design-dependent parameters, technical performance measures and associated design-to criteria for characteristics that must be incorporated into the design of system, subsystems and components. This is achieved by the requirements allocation process. Design requirements for each system element are specified through the process of allocation and the identification of detailed performance and effectiveness parameters for each element in the functional analysis *(i.e.,* input–output factors, metrics, *etc*.). Given this information, a designer can decide whether to meet the requirement by an item that is commercially available and for which multiple suppliers are available or by modifying an existing commercially available item off-the-shelf or by designing, developing and producing a new item to meet the specific requirement. Detail design documentation is an essential part of detail design phase and generates a database for the purpose of information processing, storage and retrieval so that it can be used during the testing and is also available for future designs. At this stage, the design may be evaluated through the fabrication of a prototype model or using a physical working model. Detail design review is undertaken generally after the detail design has been completed, but before the release of firm design data to initiate production and/or fabrication. The objective is to establish a good "*product baseline*". Such a review is conducted to verify the adequacy and producibility of the design. The design is then "frozen" at this point, and manufacturing methods, schedules and costs are re-evaluated for final approval and the product or system design may go for testing and evaluation. This baseline design should also be evaluated for environmental impact, social acceptability, *etc*.

2.6.3 Design Evaluation

The objective of design evaluation is to establish the *baseline* against which a particular design configuration can be evaluated. The whole idea of evaluation is that the functions that the system must perform to satisfy a specific user need should be assessed along with the expectations in terms of effectiveness, costs, time, frequency and any other factors. However, the functional requirements starting at the *system level* are ultimately expected to determine the characteristics that should be incorporated within the design of the system and its subsystems and components. The ultimate objective is to assess requirements at each level of system hierarchy in terms of hardware, software, facilities, people and data.

System evaluation is a continuous process and is undertaken starting with the conceptual design, and extends to the operational use and support phase, and concludes only when the system is retired. The objective of system evaluation is to determine (through a combination of prediction, analysis and measurement activities) true system characteristics and to ensure that the system successfully fulfils its intended purpose or mission.

2.6.4 Testing Designs

The test plan for testing a system may vary depending on the system requirements; however, a general outline of test plan is expected to include the following:

- The definition and schedule of all test equipment and details of organization, administration, and control responsibilities.
- The definition of test conditions including maintenance and logistic support.
- The description of test plans for each type of testing.
- A description of the formal test phase.
- The description of conditions and provisions for the retest phase.
- The test documentation.

The basic test plan serves as a valuable reference and indicates what is to be accomplished, the requirements for testing, the schedule for the processing of equipment and materials for test support, and data collection and reporting methods and so on. All this information is useful in developing an information feedback subsystem, in providing historical data that may be useful in the design and development of new systems in future of the same type or having similar function.
Also testing is done at each stage of design to ensure that the design is progressing in the intended direction and goal. For example, *feasibility testing* is done by the designer to prove the design concept and to choose the most promising concept from several possible design concepts. *Evaluation testing* is done to test early hardware in the operating and environmental conditions for which it was designed. Test procedures and test results are documented. Hardware, test equipment, and test procedures can be modified, if conditions require this. *Qualification testing* is done for formal proofing of the design against the design specifications. Corrective design action in the form of hardware redesign is taken if test results indicate the necessity for such design modifications.

2.6.5 Final Design Documentation

As is common with engineering design, the final design documentation usually includes the following:

- *Specifications:* These list the performance requirements, specify environmental conditions, establish system performance goals, and specify the basic logistic requirements.
- *Drawings:* These include coordination drawings, correlation drawings, production drawings procurement drawings, and drawings of special test equipments.
- *Parameters:* These documents detail the functional parameters with their tolerances starting at the operational-use end and working backwards to the supplier. Tolerances are tightened at each major step so that there is room for some functional parameters drift or degradation with time and transportation. These adjusted tolerances are called “funnels of tolerance”, with the small end of the funnel at the suppliers and the large end of the funnel at the users.

The design section usually produces the design documentation in consultation and approval of the product assurance department.

2.7 User Interaction

As we have seen in the earlier sections, the design begins with the specifications of more-or-less well-defined system requirements, and “users require-ments”, which made the basis of a search for acceptable design solutions in a feasibility study acceptable in terms of both physical and economic soundness.

The user must be kept fully informed of the system limitations and the conditions of use for which it was intended. However, these must be agreed upon between the designer and the user. If the user has some special requirements to meet, they must be defined, in the system’s specifications, the exact conditions under which the system is intended to operate. Furthermore, the user must ensure that the system is subsequently operated within those conditions for the sake of the safety of the system. It is also necessary during system operation to invest in a sound user-training program and back it up with the assessment of actual conditions of use. This is expected to assist the designer to anticipate actual environments and adverse conditions during system operation, so that

the designer makes due allowance for them and the possibility of failure is not overlooked. On the other hand, the designer can take the initiative to apprise the user of the conditions and environments of use that the designer expects the system may happen be operated in and the user must be given every opportunity to match this use of the system to the designer's anticipation.

The designer must receive adequate feedback of the in-service behaviour of the system design from the user. This feedback of field experience will let the designer know about the possible deficiencies in the existing design, so that remedial measures can be taken. It will also help designer to remove those deficiencies from future system designs.

In short, matching of the design to the requirements of the user in its intended environment requires intense and good communication between the designer and the user.

2.8 Conclusions

This chapter has discussed the basic design procedure generally followed for engineering systems design. It is observed that the systems approach is convenient and tractable as compared to the bottom-up approach that was commonly followed earlier. This will become more apparent from the subsequent chapters presented in this handbook.

A Practitioner's View of Quality, Reliability and Safety[1]

Patrick D.T. O'Connor

Consultant
62 Whitney Drive, Stevenage, Hertfordshire SG1 4BJ UK

Abstract: The closely related topics of quality, reliability and safety are discussed in the context of modern technology, economics and society. Practical experiences are related to illustrate some of the key points.

3.1 Introduction

If the people involved in design and production of a new product never made mistakes, and there was no variation of any feature (dimensions, parameters, strength, *etc.*) or in the environment that the product would have to endure, then it would be relatively easy to design and manufacture products which would all be correct and which would not fail in use. Of course, engineering reality is seldom like this. Engineering designers must take account of variation, and also of the wear and degradation imposed by use and time. Production people must try to minimize the effects of process variations on quality, yield, reliability and costs. Maintenance people and users must work to keep the products serviceable.

The more that variation can be reduced and quality and reliability improved, the greater will be the benefits to the manufacturer and the user. Fewer failures during development will reduce development costs (redesign, re-test, delays, *etc.*). Less variation and fewer failures in production will reduce production costs (rework, scrap, work in progress, investigations, *etc.*). Finally, the reliability in service will be improved, resulting in enhanced reputation and thus increased sales, lower warranty costs, and greater profit opportunities. Throughout, the managers and engineers who would otherwise be busy dealing with failures would be freed to concentrate on new and improved products.

The modern world demands that products and services are safe. Ensuring the safety of engineering designs, production, use and maintenance presents great challenges to management of all of these functions.

3.1.1 The Costs of Quality, Reliability and Safety

There are two aspects to the quality, reliability and safety cost picture. By far the largest, in nearly all cases, are the costs of failure. Failures generate

[1] This chapter is based in part on the author's book The New Management of Engineering [1]

costs during development, during production and in service.

The further downstream in the process that causes of failures are discovered the greater is the cost impact, both in terms of the effect of the failure and to remove the cause, in nearly all cases.[2] Problems that cause failures or rejection after the product has been delivered add to the costs of warranty or service, and can also influence the product's reputation and sales. These internal and external costs of failures obviously depend upon the rates of occurrence.

Some of these costs, for example the cost of a re-design and re-test to correct a problem, the costs of production rework and scrap, and warranty repair costs are relatively easy to identify and quantify. These can be thought of as the direct failure costs. There are also indirect costs, for example management time involved in dealing with failures, staff morale, factory space needed for repairs, documentation, the extra test and measurement equipment needed for diagnosis and repair, the effects of delays in entering the market, delivery delays, and the effects on product reputation and therefore on future sales. Deming [2] called these the "hidden factory", the cost of which usually exceeds the profit margin on the products concerned. In extreme cases failures can lead to product recalls, and litigation and damages if injury or death is caused. The indirect costs can be difficult to identify and quantify, but they are often much greater than the direct costs. It is important to note that failure costs begin soon after initial design and continue throughout the life of the product, over many accounting periods, and even beyond to future products. For a new product they are impossible to predict with confidence.

Obviously, we should have a strategy for identifying and minimizing these costs and risks. The strategy must be in place at the earliest stages of the project and it must extend through the life cycle. A sensible first step is to make a determined attempt to forecast the likely range of failure costs.

Of course these figures can never be exact, nor can they all be stated with certainty. For example, the cost of the extra testing can be stated precisely, but how can we be sure that it will reduce the failure proportion to 5%? Also, they are based on projections into the future. Therefore they might not be convincing to financial people, particularly if their horizon is this year's figures.

We must overcome these problems by obtaining agreement on the input values and performing the analyses. Modern business software, particularly life cycle cost programs, enable the analysis to be performed in great detail. Company and project management must take the long-term view. Finally, the expected benefits in terms of reduced failures must be taken on trust. They cannot be guaranteed or proven, but overwhelming evidence exists to show that quality and reliability can be improved dramatically with relatively small but carefully managed up-front effort.

3.1.2 Achievement Costs: "Optimum Quality"

In order to create reliable designs and products it is necessary to expend effort and resources. Better final designs are the result of greater care, more effort on training, use of better materials and processes, more effective testing, and use of the results to drive design improvement (product and processes). Better quality products are the result of greater care and skill, and more effective inspection and test. It seems plausible that there is an optimum level of effort that should be expended on quality and reliability, beyond which further effort would be counter-productive.

Ideally, we should seek to optimize the expenditure on preventing causes of failures, in relation to the costs that would arise otherwise. The conventional approach to this problem has been to apply the concept of the "optimum cost of quality". It is argued that, in order to prevent failures, the "prevention costs" would have to be increased. If these rising costs could be compared with the

[2] The "Times Ten Rule" is often quoted: there will be a factor of 10 increase in costs for each further stage that a failure occurs. For example, a failure cause that is found during design might cost $100 to correct. The same failure found during development test might cost $1000 to correct, in production $10,000, and in service $100,000. Several cases show that this factor can be too low, with actual cost multipliers of 40 to 100 times being reported, and sometimes much higher if failures in service have serious consequences, such as product recall or causing injury or death.

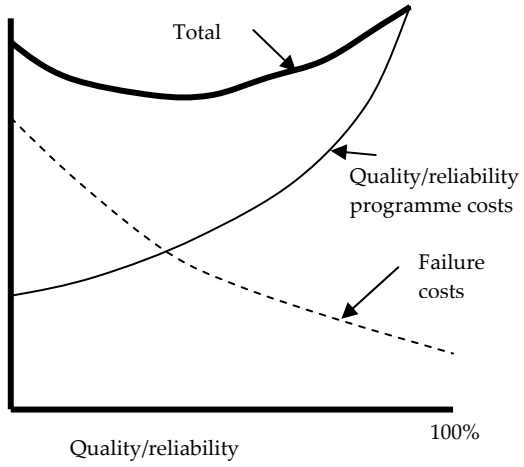

Figure 3.1. Quality and reliability costs – A traditional view

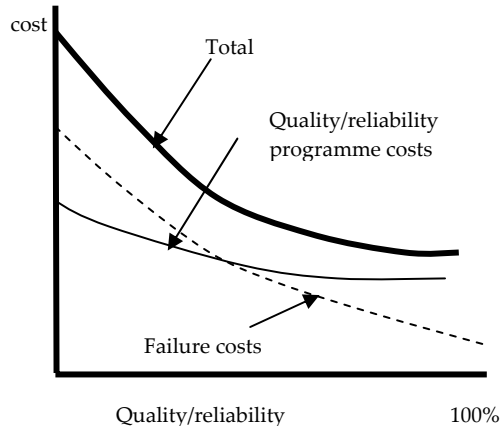

Figure 3.2. Quality and reliability costs – A modern view

falling costs of reduced failures, an optimum point would be found, at which the total "cost of quality" would be minimal (see Figure 3.1). Note that the "quality/reliability" scale of the abscissa is indicative, 100% representing no failures in production or use). The concept of the "optimum cost of quality" or "optimum quality level" at which this changeover occurs is embedded in much teaching and thinking about quality and reliability. Actually identifying the point in quantitative terms is highly uncertain. Nevertheless, the concept has often been used as a justification for sticking with the *status quo*. The idea of an optimum quality somewhat lower than perfection can be a powerful deterrent to improvement. Since the "optimum" point is so uncertain, it is tempting to believe that it is the status quo: what we are achieving now is as good as we can get. For example, on a missile system 90% reliability was accepted as being "optimum" for many years, because this was the specified level, which was eventually achieved.

It was Deming who explained the fallacious nature of the "optimum cost of quality"[3]. The minimum total cost of failures occurs when they approach zero, not at some finite, determinable figure. The argument that achieving high quality necessarily entails high costs is dismissed by considering the causes of individual failures, rather than generalized measures such as reliability or failure rate. At any point on the curve of quality/reliability *versus* cost, certain failures occur. Deming explained that, if action is taken to prevent the recurrence of these, there would nearly always be an overall saving in costs, not an increase. It is difficult to imagine a type of failure whose prevention will cost more than the consequences of doing nothing. Therefore the curve of cost *versus* failures moves downwards as quality is increased, and not upwards (see Figure 3.2). The missile example quoted above provided a striking confirmation of this when it was determined that better control of electronic parts and assembly quality, at no increased cost, resulted in reliability improvement to over 95%.

The truth of the logic taught by Deming has been dramatically exposed by the companies that have taken it to heart. The original title of Deming's book was *Quality, Productivity and Competitive Position*, thus emphasizing the strong positive correlation of all three factors. This realization has been at the core of the success of the Japanese and other companies that have set new standards and expectations for quality and reliability, in markets such as cars, machine tools, electronics and many others, while at the same

[3] Actually, Deming's arguments were presented in the context of production. This insight was probably the most important single idea that drove the Japanese post-war industrial revolution. He did not explicitly include the effects of reliability in service. Of course, if these are included the case is strengthened even more.

time reducing their costs of development and production. The concepts follow inevitably from the principles of management taught by Peter Drucker [3], requiring a completely integrated team approach to the product, rather than the functional approach of "scientific" management. The talents and motivations of everyone on the team must be devoted to improving all aspects of quality. This approach to quality has been called "total quality management" (TQM).

A major problem in this context is the fact that design, development and production costs involved can usually be estimated with reasonable accuracy, and they occur in the near future. However, the savings in failure costs are usually much more uncertain and they arise further ahead in time, often beyond the present financial plans and budgets.

3.1.3 Statistics and Engineering

The "normal" (or Gaussian) distribution is the probability function that most closely describes the great majority of natural variation, such as people's heights and IQs and monthly rainfall. It also describes quite well many variables encountered in engineering, such as dimensions of machined parts, component parameter values, and times to failure due to material fatigue. The "normal" distribution is therefore widely used by statisticians and others and it is taught in all basic statistics courses and textbooks. Therefore it could be a reasonable starting point for application to variation in engineering.

Whilst statistical methods can be very powerful, economic, and effective in engineering applications, they must be used in the knowledge that variation in engineering is in important ways different from variation in most natural processes. The natural processes whose effects are manifested in, for example, people's heights, are numerous and complex. Many different sources of variation contribute to the overall height variation observed. When many distributed variables contribute to an overall effect, the overall effect tends to be normally distributed. If we know the parameters of the underlying distributions (means, standard deviations), and if there are no interactions or we know what the interaction effects are, we can calculate the parameters of the overall distribution. These properties are also true of engineering or other non-natural processes which are continuous and in control: that is, if they are subject only to random variation.

Natural variation rarely changes with time: the distributions of people's heights and life expectancies and of rainfall patterns are much the same today as they were years ago, and we can realistically assume that they will remain so for the foreseeable future. Therefore any statistical analysis of such phenomena can be used to forecast the future, as is done, for example, by insurance actuaries. However, these conditions often do not apply in engineering. For example:

- A component supplier might make a small change in a process, which results in a large change (better or worse) in reliability. Therefore past data cannot be used to forecast future reliability using purely statistical methods. The change might be deliberate or accidental, known or unknown.
- Components might be selected according to criteria such as dimensions or other measured parameters. This can invalidate the normal distribution assumption on which much of the statistical method is based. This might or might not be important in assessing the results.
- A process of parameter might vary in time, continuously or cyclically, so that statistics derived at one time might not be relevant at others.
- Variation is often deterministic by nature, for example spring deflection as a function of force, and it would not always be appropriate to apply statistical techniques to this sort of situation.
- Variation in engineering can arise from factors that defy mathematical treatment. For example, a thermostat might fail causing a process to vary in a different way to that determined by earlier measurements, or an operator or test technician might make a mistake.

- Variation can be non-linear, not only continuous. For example, a parameter such as a voltage level may vary over a range, but could also go to zero, or a system might enter a resonant condition.

These points highlight the fact that variation in engineering is caused to a large extent by people, as designers, makers, operators, and maintainers. The behavior and performance of people is not as amenable to mathematical analysis and forecasting as is, say, the response of an engine to air inlet temperature or even weather patterns to ocean temperatures. Therefore the human element must always be considered, and statistical analysis must not be relied on without appropriate allowance being made for the effects of motivation, training and management, and the many other factors that can influence performance, cost, quality and reliability.

Finally, it is most important to bear in mind, in any application of statistical methods to problems in science and engineering, that ultimately all cause-and-effect relationships have explanations, in scientific theory, engineering design, process or human behavior, *etc.* Statistical techniques can be useful in helping us to understand and control engineering situations. However, they do not by themselves provide explanations. We must always seek to understand causes of variation, since only then can we really be in control.

3.1.4 Process Variation

All engineering processes create variation in their outputs. These variations are the results of all of the separate variables that influence the process, such as backlash and wear in machine tool gears and bearings, tool wear, material properties, vibration and temperatures. A simple electrical resistor trimming process will produce variation due to measurement inaccuracy, probe contact resistance variation, *etc.* In any manufacturing process it is obviously desirable to minimize variation of the product. There are two basic ways in which this can be achieved: we can operate the process, measure the output, and reject (or re-process if possible) all items that fall outside the allowed tolerance. Alternatively, we can reduce the variation of the process so that it produces only good products. In practice both methods are used, but it must be preferable to make only good products if possible. We will discuss the economic and management implications of these two approaches later, but let us assume that we will try to make all products within tolerance.

First of all, we must ensure that the process is inherently capable of maintaining the accuracy and precision required. "Accuracy" is the ability to keep the process on target: it determines the average, or mean, value of the output. "Precision" relates to the ability to make every product as close to target as possible: it determines the spread, or standard deviation, of the process. Having selected or designed a process that is capable of achieving the accuracy and precision required, we must then control it so that variation does not exceed the capability. A process is considered to be "in control" if the only variation is that which occurs randomly within the capability of the process. There must be no non-random trends or fluctuations, and the mean and spread must remain constant. If a process is capable and it is kept in control, in principle no out-of-tolerance products should result. This is the basic principle of "statistical process control" (SPC).

The assumption of statistical normality in engineering applications was discussed earlier. No manufacturing process can be truly "normal" in this sense for the simple reason that there are always practical limits to the process. By contrast, the mathematical normal distribution function extends to plus and minus infinity, which is clearly absurd for any real process, even natural ones. Therefore it makes little sense to extrapolate far either way beyond the mean. Also, even if engineering processes seem to follow the normal distribution close to either side of the mean, say to plus or minus 1 or 2 standard deviations (90% to 95% of the population), the pattern of variation at the extremes does not usually follow the normal distribution, due to the effects of process limits, measurements, *etc.* There is little point, therefore, in applying conventional statistical methods to analyze and forecast at these extremes.

The principles of SPC were first explained by W.A. Shewhart in 1931. He explained the nature of

variation in engineering processes and how it should be controlled. Shewhart divided variation into two categories. "Special cause" or "assignable" variation is any variation whose cause can be identified, and therefore reduced or eliminated. "Common cause" or "random" variation is that which remains after all special causes have been identified and removed: it is the economically irreducible variation left in the process.

Control charts can be used to monitor any production process once the process is in control, and if the numbers being produced are large enough to justify using the method. Many modern production tools, such as machining centers and gauges, include software that automatically generates control charts. They are one of the most important and effective tools for monitoring and improving production quality, and they should always be used, at the workplace, by the people running the process.

Shewhart pointed out the importance of control charts for process improvement. However, in much of industry they have been used mainly for monitoring, and not as part of an active improvement process. Also, an undue amount of attention has been given to the statistical aspects, so that books and teaching have tended to emphasize statistical refinement at the expense of practical utility, and the method is often perceived as being a specialists' tool rather than an aid to the process.

It was Deming, who had worked with Shewhart, who explained to Japanese industrialists the power of control charts for process improvement. This went together with his teaching that productivity and competitiveness are continuously enhanced as quality is improved, in contrast the traditional view that an "optimum" quality level existed beyond which further improvement was not cost effective. Later, Taguchi also took up this point in relation to design and used it as one of the justifications for the application of statistical experiments to optimize product and process designs. Statistical experiments, performed as part of an integrated approach to product and process design, can provide the most rational and most cost-effective basis for selecting initial control limits. In particular, the Taguchi method is compatible with modern concepts of statistical process control in production since it points the way to minimizing the variation of responses, rather than just optimizing the mean value. The explicit treatment of control and noise factors is an effective way of achieving this, and is a realistic approach for most engineering applications.

The control chart's use for process improvement is not based upon statistics. Instead, operators are taught to look for patterns that indicate "special causes" of variation. All process variation is caused by something, and the distinction between "common cause" and "special cause" lies only in the attitude to improvement. Any perceived trend or regular fluctuation can be further investigated to determine whether it represents a cause that can be eliminated or reduced.

Deming and Ishikawa taught Japanese production managers, supervisors, and workers how to interpret control charts and use them for process improvement. They also taught the use of other simple methods, such as Pareto charts and other graphical techniques, and Ishikawa developed the cause-and-effect diagram, an effective method for structuring and recording the efforts to determine causes of problems and variation. All of these methods (the "seven tools of quality") are used by the "quality circles", small groups of workers meeting during working time to determine and recommend ways of improving the processes they work on. Quality circles are the best known manifestation of Drucker's emphasis on people at the workplace being the most effective at generating improvements. The truth and effectiveness of these ideas have been dramatically demonstrated by many modern companies in highly competitive industries. Survival and growth in manufacturing industries depends as much on the fluent application of modern production quality management and methods as on product innovation and design.

3.2 Reliability

If quality can be thought of as the excellence of a product at the time it is delivered to the customer,

reliability is used in the engineering context to describe the ability of a product to work without failure during its expected time in use. A product's reliability therefore depends upon how well it is designed to withstand the conditions under which it will be used, the quality of manufacture, and, if appropriate, how well it is used and maintained.

Engineering products can fail in service for many reasons. These include:

- Variation of parameters and dimensions, leading to weakening, component mismatch, incorrect fits, vibration, *etc.* Design and manufacturing to minimize variation and its effects have been discussed earlier.
- Overstress, when an applied stress exceeds the strength of a component. Examples are mechanical overstress leading to fracture or bending of a beam or electrical overstress leading to local melting of an integrated circuit transistor or breakdown of the dielectric of a capacitor.
- Wear out, which is the result of time-dependent mechanisms such as material fatigue, wear, corrosion, insulation deterioration, *etc.*, which progressively reduce the strength of the component so that it can no longer withstand the stress applied.

There are of course many other causes of failure, such as electromagnetic interference in electronic systems, backlash in mechanical drives, stiction and friction leading to incorrect operation of mechanisms, leaks, excessive vibration, and intermittent electrical connections. Failures are not always unambiguous, like a light bulb failure, but may be open to subjective interpretation, such as a noisy gearbox, a fluctuating pressure regulator or an incorrectly diagnosed symptom in an electronic system.

Designers can in principle, and should in practice, ensure that their product designs will not fail under any expected conditions of variation, stress, wear out or for any other reason. The designers do not control variation in production, but, as explained earlier, they can ensure, together with the production people, that the effects of variations on performance and reliability are minimized and that appropriate tolerances and controls are designed into the production processes. Designers can prevent overstress failure if they understand the stresses that can be applied and ensure that adequate safety margins and protection are provided. They can protect against wear out failures by understanding the mechanisms and environments involved and by ensuring that the time to failure exceeds the expected life of the product by providing protection and, when appropriate, by designing a suitable inspection and maintenance plan. Finally, they can protect against all of the other causes of failure by knowing how they occur and by attention to detail to prevent them.

3.2.1 Quantifying Reliability

Since reliability is often expressed as a probability, the subject has attracted the attention of statisticians. Reliability can be expressed in other ways, for example as the mean time between failures (MTBF) for a repairable system, or mean time to failure (MTTF) for a non-repairable item, or the inverse of these, the failure rate or hazard rate. (Note that these measures imply that failures occur at a constant average rate: this is a convenient assumption that simplifies the mathematics, but which might bear little relation to reality).

Statistical methods for measuring, analyzing and predicting reliability have been developed and taught to the extent that many engineers view reliability engineering as being a specialist topic, based largely on statistics. This is also manifest in the fact that most books, articles and conference papers on the subject relate to the statistical aspects and that nearly all university teaching of reliability is performed by mathematics, not by engineering faculties.

As we have discussed earlier, the application of statistics to engineering is subject to practical aspects that seriously limit the extent to which statistical models can credibly represent the practical engineering situation, and particularly as a basis for forecasting the future. Since the cause of nearly every failure of a product in service is ultimately traceable to a person making a mistake, it is quite wrong and misleading to associate

reliability with the design or the product, as though reliability were a physical characteristic like mass or power. The mass and power of an engineering product are determined by physical and chemical laws, which limit what a particular design can achieve. Every product built to that design would have the same mass and power, subject of course to small variations due to production variation. However, nature places no such constraints on reliability. We can make any product as reliable as we want or need to, and the only constraints are our knowledge, skill and effort. It therefore follows that a measurement of reliability is only a statement of history. However, any attempt to use this information to predict future reliability must be conditioned by the answers to questions like these:

- What were the causes of the failures? Were the causes poor quality of some components, poor assembly control, or design features that led to their being overstressed? (Note that if the first two causes predominate, repair should lead to fewer failures in future, but if the problem is mainly due to design, repair will not improve reliability.)
- When the components failed and were replaced, were the new ones better than the ones that failed? Were the repairs performed correctly?
- Will future production of the same design use the same quality of components and of assembly? (Of course if failures have occurred action should have been taken to prevent recurrence).
- If the information on reliability is to be used to predict the reliability of another system that uses similar components, do we know that the application will be identical in terms of stress, duty cycles, environment, test, *etc.* and, if not, do we know how to relate the old data to the new application?

These are not the only relevant questions, but they illustrate the problem of quantifying reliability. In the great majority of cases the questions cannot be answered or the answers are negative. Yet we can confidently say that every 280 KΩ 1% resistor will have a resistance of 280 KΩ, plus or minus 2.8 KΩ, and will handle up to its rated power in watts. The difference is that reliability measurements and predictions are based on perceptions, human performance and a huge range of variables, whilst parameter measurements and predictions are based on science.

To most engineers these comments might seem obvious and superfluous. However, measurements and predictions of reliability are made using just such approaches and the methods are described in standards and stipulated in contracts, particularly in fields such as military and telecommunication systems. For example, the U.S. Military Handbook for predicting the reliability of electronic systems (Military Handbook 217) provides detailed mathematical "models" for electronic component failure rates, so that one can "predict" the failure rate contribution per million hours of, say, a chip capacitor while being launched from a cannon, to an accuracy of four significant figures! Other organizations have published similar "data", and similar sources exist for non-electronic items. The ISO standards on dependability and safety stipulate the use of these methods. Reliability prediction "models" have even been proposed for software, for which there are no time-related phenomena that can cause failure. These methods are all in conflict with the fundamental principle that engineering must be based on logic (*i.e.,* commonsense) and on science.

Statistical inference methods have also been applied to reliability "demonstration". The concept seems simple: test the product under representative conditions, for a suitable length of time, count the failures and calculate the reliability (*e.g.,* MTBF). Then apply standard statistical tests to determine if the reliability demonstrated meets the requirement, to a specified level of statistical confidence. However, statistical "sequential" reliability demonstration tests do not reflect practical reality. For example, if a product is tested and fails 10 times in 10 000 hours its demonstrated "best estimate" of MTBF would be 1000 hours. However, if five of the causes can be corrected, is the MTBF now 2000 hours? What about the failures that might occur in future, or to different units, that did not occur in the tests? Will the product be more or less reliable as it becomes older? Is it considered more

reliable if it has few failures but the effects of the failures are very expensive or catastrophic?

The correct way to deal with failures is not merely to count them, but to determine the causes and correct them. The correct way to predict reliability is to decide what level is necessary and the extent of the commitment to achieving it. For example, a manufacturer of TV sets discovered that competitors' equivalent sets were about four times as reliable, measured as average repairs per warranty year. They realized that to compete they had to, at least, match the competitors' performance, so that became the reliability prediction for their new product. Note that the prediction is then top down, not from component level upwards. This is much more realistic, since it takes account of all possible causes of failure, not just failures of components. The prediction is top down also in the sense that it is management-driven, which is of course necessary because failures are generated primarily by people, not by components.

Reliability engineering methods and management are described in detail in my book *Practical Reliability Engineering* [4], which has been updated to take account of technology changes, new methods and other developments.

3.3 Testing

Testing is usually the most expensive and time-consuming part of engineering development programs. Paradoxically, most development testing should in principle be unnecessary, since it is performed primarily to confirm that the design works as intended, or to show up what features need to be changed in order to make it work. If we could have complete faith in the design process we could greatly reduce the need for testing. There are some products where in fact no testing is carried out: civil engineering structures and buildings are not tested (though many such designs are now analyzed using CAE simulations) partly because of the impracticability of building and testing prototypes, but also because the designs are relatively simple and conservative. However, nearly all engineering designs must be tested. Unfortunately, this is seldom done as effectively as it could be. Here are some examples from my experience:

- A project director, managing the development of a military system that involved novel technologies and high risk of failure, stated that there would be no environmental testing because "our engineers are paid to get their designs right".
- Railway systems, particularly new locomotives and trains, were subjected to minimal development testing in comparison with systems of equivalent complexity and risk in other industries, such as cars, aircraft, and military systems. The reasons were not based upon any logic, but entirely on tradition. For most of its history, rail vehicle engineering has consisted of relatively proven technology, applied by a small number of famous designers. Also, there was nowhere to test a new train except on the rails with all the other traffic. This limited testing tradition suddenly came unstuck from about the 1980's when rail vehicle design belatedly but rapidly included a range of advanced technologies, such as AC electric traction, air conditioning, digital system controls, passenger information systems, *etc.* Some rail vehicle suppliers are now building test tracks and environmental test facilities
- A large diesel engine was selected to power a new diesel-electric freight locomotive. The engine was a well-proven machine, with previous applications in ship propulsion, power generation, *etc.* To provide assurance for the rail application, one engine was subjected to a "standard type test", involving 150 hours continuous running at maximum rated power. It passed the test. However, in rail service it proved to be very unreliable, suffering from severe cracking of the cylinder block. The problem was that the previous experience involved long duration running under steady and mostly low-stress conditions, which are totally different to the very variable, often high-stress, rail application. Also, in the previous applications,

and in the "type test", the coolant supply was large enough to ensure that it was always cool on entry to the engine, but the locomotive coolant tank was much smaller, so that the inlet temperature was very variable. The combination of variable duty cycles and variable coolant temperature led to early fatigue induced cracking of the block.

- A contract for the development of a complex new military system included a requirement that the reliability be demonstrated in a formal test before the design could be approved for production. The test criterion was that no more than 26 failures were to occur in 500 test hours, in the specified test conditions. When questioned, the customer "reliability expert" accepted that the test criterion would not be achieved if 27 minor failures occurred, but would be achieved with 25 major failures.
- A new airline passenger entertainment system was developed and sold, for installation in a fleet of new aircraft. Reliability was considered to be a critical performance requirement, since failure of any seat installations would lead to passenger complaints. A test program was implemented. However, cost and time constraints resulted in inadequate testing and problems detected not being corrected. Reliability was so poor when the system was installed and put into service that it eventually had to be removed, and the project terminated.
- A manufacturer of electronics systems submitted samples of all production batches to long-duration test at 40 °C. When asked why, the Quality Manager replied "to measure the reliability". Further questioning revealed that the systems had been in world wide service for some time, that in-service reliability performance was well known from maintenance and utilization records, and that the testing had not generated any problems that were not already known. So I said: "but you know the reliability, this test is very expensive and delays delivery, so why not stop doing it?" Months later they were still doing it. Apparently the reason was that their written company procedures said it had to be done, and changing the procedures was too difficult!
- The US Military Standard for testing microcircuits (MIL-STD-883) required that components must be tested at high temperature (125 °C) for 168 hours. This requirement was later copied into other national and international standards. The reason for choosing this unnecessarily long and expensive test time? There are 168 hours in a week!
- Among the sparse examples of recent books on aspects of testing, one makes no mention of accelerated tests and another actually condemns the idea of testing production electronics hardware at stresses higher than might be experienced in service.
- Some "experts" argued that systems that relied on software for safety-critical functions such as aircraft flight controls could never be considered to be safe, because it is not possible to prove by mathematical analysis or testing that failures will *never* occur. (We cannot prove that for pilots or mechanical controls either, but software does not make the mistakes humans make, and mechanical controls do break.)
- A military system, in service with different forces, displayed much worse reliability in army than in air force use. Investigation of the causes revealed that the army were following their traditional procedure of testing the whole system every day, whilst the air force's procedure was to test only if problems were reported. (How often do you test your TV?)
- No one seems to be able to report a completed engineering development project where too much testing had been performed. Nearly all engineering projects could have benefited from more testing, and wiser testing.

The main reason for insufficient or inappropriate testing seems to be that engineers have not developed a consistent philosophy and methodology for this essential activity. Testing is not taught as part of most engineering curricula, and academics seem to be unaware of the importance of testing, or even sometimes of its existence as a project activity.

Specialist areas are taught, for example fatigue testing to mechanical engineers and digital circuit testing to electronics engineers. However, a wide range is untaught, particularly multidisciplinary, systems and management aspects. Engineering training tends to emphasize design. Testing (and manufacturing) are topics that attract less attention, and they do not have the "glamour" of research and design. This is reflected in the generally lower esteem, status and salaries of engineers working in test and manufacturing. In some countries the near-disappearance of technician and apprentice training as routes to recognized engineering qualification has greatly reinforced this unfortunate trend. Engineering industry suffers shortages of talented engineers in these key areas. As a result, designs are often inadequately tested in development and products are inadequately tested in manufacture and maintenance. This creates high costs throughout the product cycle, damages competitiveness, and can lead to hazards.

If the design team possesses all the knowledge and resources (CAE, time, *etc.*) necessary to create correct designs, and the project leader has faith in this knowledge, then the need for testing can be reduced. Furthermore, what testing is performed will be less likely to show design errors, so the total design effort will be reduced. The point to be stressed here is that the potential improvements in engineering productivity that can in principle be achieved by harnessing the innate ability of people to learn, and then to use their knowledge to reduce the need for product test and redesign is enormous. Nevertheless, despite the most determined attempts to minimize the need for test by team organization, training, analysis and simulation, most engineering product development must involve considerable testing. Design, test, redesign and re-test proceed iteratively and in parallel, at different levels and in different locations.

Therefore development testing must be managed as an integral aspect of the whole product process. Design and test must be closely integrated from the earliest stages, and designers should be active participants in the analysis and testing of their designs. Suppliers' test programs and methods must also be managed as part of the overall project.

Testing is also an integral part of the manufacturing processes, and often of maintenance. Therefore the methods to be applied must be designed and tested during the preceding phases. Design teams should be aware of the relevant technologies and methods.

Whilst development and manufacturing testing is expensive, insufficient or inadequate testing can be far more costly later, often by orders of magnitude. Therefore the test program must be planned and financed as a long-term investment, not merely as a short-term cost. This can be a difficult concept to sell, particularly as so many organizations are driven by short-term financial measures like end-of-year profits, dividends and stock options. Engineering as well as commercial experience and judgment must be applied to the difficult and uncertain business of test. Managers at all levels and in all contributing functions must appreciate the concept that test is an investment which must be planned, and which can generate very large returns. *Test adds value***.**

The New Management of Engineering [1] is the only book on engineering management (to the best of my knowledge) that discusses the subject. My book *Test Engineering* [5] is the only book that provides an overview of test methods, economics and management.

3.4 Safety

Engineering products can cause hazards during operation or maintenance and if they fail. Safety incidents can obviously impact the reputation of a product and of the supplier. They can also generate very high costs, in product recalls, re-design and re-test. More significantly, they can lead to litigation and very high financial penalties.

Design, development, manufacture and maintenance of engineering products must obviously seek to minimize the possibility of hazards. The methods that can be applied are mostly the same as for assuring reliability, so these should be extended as appropriate.

Increasingly, engineers are being required to "prove" the safety of new products and systems, particularly in applications such as public transport and large installations that present potential hazards, *e.g.,* chemical plant and nuclear power stations. These formal, detailed statements are sometimes called "safety cases". The proof must be based on analysis of all potential modes of failure, including human failure, and of their consequences. The techniques used include failure modes, effects and criticality analysis and fault tree analysis, as used for reliability analysis as well as other techniques. The objective is to show that the probability of a single event or of a combination of multiple events that could cause defined hazards is acceptably low. The criteria for acceptability are usually laid down by the regulating authorities, and are typically for a probability not exceeding 10^{-8} per year for an accident causing loss of life. In order to "prove" such probabilities it is necessary to know or to agree what figures should be applied to all of the contributing events. We have discussed the incredibility of predicting reliability. Predicting hazard probabilities of this order is of course quite unrealistic. Any data on past events are likely to be only of historic significance, since action will almost certainly have been taken to prevent recurrence. Applying such probabilities to human actions or errors is similarly of extremely doubtful credibility. Also, accidents, particularly major ones, are usually the result of unforeseen events not considered in the hazard analyses.

It is of course essential that the hazard potentials of such systems are fully analyzed and minimized. However, it is equally important to apply commonsense to reduce the tendency to over-complicate the analysis. There is no value to be gained by attempting to quantify an analysis beyond the precision and credibility of the inputs. If the expected probability range of expected events is considered to be known to within an order of magnitude, it is absurd to present analyses that show the combined probability to a precision of several significant figures. It is also absurd to perform highly complex analyses when the causes and consequences can be sufficiently accurately estimated by much simpler methods. Such analyses can generate misguided trust in their thoroughness and accuracy, when in fact their complexity and implied precision can result in oversights and make them difficult to interpret or query. The KISS principle ("*keep it simple, stupid"*) applies to safety analysis just as much as it does to design.

3.5 Quality, Reliability and Safety Standards

3.5.1 Quality: ISO9000

The international standard for quality systems, IS09000, has been developed to provide a framework for assessing the extent to which an organization (a company, business unit or provider of goods or services) meets criteria related to the system for assuring quality of the goods or services provided. The concept was developed from the US. Military Standard for quality, MIL-Q-9858, which was introduced in the 1950s as a means of assuring the quality of products built for the U.S. military services. Most industrial nations have adopted ISO9000 in place of their previous quality standards.

The original aim of supplier certification was to provide assurance that the suppliers of equipment operated documented systems, and maintained and complied with written procedures for aspects such as fault detection and correction, calibration, control of subcontractors and segregation of defective items. They had to maintain a "Quality Manual", to describe the organization and responsibilities for quality. It is relatively easy to appreciate the motivation of large government procurement agencies to impose such standards on their suppliers. However, the approach has not been effective, despite the very high costs involved.

The major difference between the ISO standards and their defense-related predecessors is not in their content, but in the way that they are

applied. The suppliers of defense equipment were assessed against the standards by their customers, and successful assessment was necessary in order for a company to be entitled to be considered for contracts. By contrast, the IS09000 approach relies on "third-party" assessment: certain organizations are "accredited" by their national quality accreditation body, entitling them to assess companies and other organizations and to issue registration certificates. The justification given for third-party assessment is that it removes the need for every customer to perform his own assessment of suppliers. A supplier's registration indicates to all his customers that his quality system complies with the standard, and he is relieved of the burden of being subjected to separate assessments ("audits") by all of his customers, who might furthermore have varying requirements. To an increasing extent, purchasing organizations such as companies, government bodies and national and local government agencies are demanding that their suppliers must be registered[4]. Many organizations perceive the need to obtain registration in order to comply with these requirements when stipulated by their customers. They also perceive that registration will be helpful in presenting a quality image and in improving their quality systems.

IS09000 does not specifically address the quality of products and services. It describes, in very general and rather vague terms, the "system" that should be in place to assure quality. In principle, there is nothing in the standard to prevent an organization from producing poor quality goods or services, so long as procedures are followed and problems are documented. Obviously an organization with an effective quality system would normally be more likely to take corrective action and improve processes and service than would one that is disorganized. However, the fact of registration cannot be taken as assurance of quality. It is often stated that registered organizations can, and sometimes do, produce "well-documented rubbish". An alarming number of purchasing and quality managers, in industry and in the public sector, seem to be unaware of this fundamental limitation of the standards.

The effort and expense that must be expended to obtain and maintain registration tend to engender the attitude that the optimal standards of quality have been achieved. The publicity that typically goes with initial registration supports this. The objectives of the organization, and particularly of the staff directly involved in registration, are directed at the maintenance of procedures and audits to ensure that people work to them. It becomes more important to work to procedures than to develop better ways of doing things. Third-party assessment is at the heart of the IS09000 approach, but the total quality philosophy demands close partnership between the purchaser and his suppliers. A matter as essential as quality cannot be safely left to be assessed by third parties, who are unlikely to have the appropriate specialist knowledge and who cannot be members of the joint supplier-purchaser team.

Defenders of IS09000 say that the total quality approach is too severe for most organizations, and that IS09000 can provide a "foundation" for a total quality effort. However, the foremost teachers of modern quality management all argue against this view. They point out that any organization can adopt the total quality philosophy, that it will lead to far greater benefits than registration to the standards and at much lower costs. The IS09000 approach, and the whole system of accreditation, assessment and registration, together with the attendant bureaucracy and growth of a sub-industry of consultants and others who live parasitically on the system, is fundamentally at variance with the principles of the new management. It shows how easily the discredited "scientific" approach to management can be re-asserted by people and organizations with inappropriate motivation and understanding, especially when vested interests are involved.

ISO9000 has always been controversial, generating heated arguments in quality management circles. In an effort to cater for much of the criticism, ISO9000:2000 was issued. However, whilst this mitigates some of the weaknesses of the earlier version (for example, it includes a requirement for improvements to be pursued), the

[4] The European Community "CE Mark" regulations encourage registration. However, it is not true, as is sometimes claimed, that having ISO9000 registration is a necessary condition for affixing a CE Mark.

fundamental problems remain. Special versions of the standard have been developed by some industry sectors, notably automotive (ISO/TS16949:2002, replacing QS9000), commercial aviation (AS9000) and telecommunications (TL9000).

It is notable that the ISO9000 approach is very little used in Japan or by many of the best performing engineering companies elsewhere in the world, all of whom set far higher standards, related to the actual quality of the products and services provided and to continual improvement. They do not rely on "third-party" assessment of suppliers.

The correct response to IS09000 and related industry standards is to ignore them, either as the basis for internal quality management or for assessing or selecting suppliers, unless they are mandated by customers whose importance justifies the expense and management distraction involved. If registration is considered to be necessary it is important that a total quality approach is put in place first. Compliance with the IS09000 requirements will then be straightforward and the tendency to consider achievement of registration as the final goal will be avoided.

3.5.2 Reliability

U.S. Military Standard 785 is the original standard on reliability programs. It described the tasks that should be performed and the management of reliability programs. It referred to several other military standards that cover, for example, reliability prediction, reliability testing, *etc.*[5] U.K. Defence Standards 00-40 and 00-41 are similar to MIL-STD-785, but include details of methods. Non-military standards for reliability include British Standard BS5760 and the range of international standards in the IS0603000 family. Whilst these do include varying amounts of practical guidance, much of the material over-emphasizes quantitative aspects such as reliability prediction and demonstration and "systems" approaches similar to those of IS09000.

3.5.3 Safety

International, national and industry regulations and standards have been created for general and for specific aspects of safety of engineering products. Managers must be aware of what regulations and standards are applicable to the projects for which they carry responsibility and they must ensure compliance. For example, the European CE Mark Directive is primarily related to safety, medical equipment must comply with US FDA regulations, and there are strict regulations for aviation equipment, high voltage electrical equipment, *etc.*

A recent development has been the "safety case", which is a document that must be prepared by the supplier and accepted by the customer. The safety case describes the hazards that might be presented and the ways by which they will be avoided or mitigated. The approach is applied in fields such as rail, power, process plant, *etc.*, particularly when government approval is required. The safety case approach tends to be bureaucratic and "systems" based, rather like the ISO9000 approach to quality, and its effect on the safety of the UK railway system has not been encouraging.

An important new standard as far as engineering management is concerned is ISO/IEC61508, which is concerned with the safety of systems that include electronics and software. Nowadays, not many do not. The standard is without any practical value or merit. The methods described are inconsistent with accepted industry practices, and many of them are known only to specialist academics, presumably including the members of the drafting committee. The issuing of the standard is leading to a growth of bureaucracy, auditors and consultants, and increased costs. It is unlikely to generate any improvements in safety, for the same reasons that ISO9000 does not improve quality. Nevertheless, managers need to be aware of its applicability and how best to deal with it. It must not be ignored.

[5] The US DoD withdrew nearly all of these standards in 1995.

3.6 Managing Quality, Reliability and Safety

3.6.1 Total Quality Management

Engineering project managers must take the lead on quality, reliability and safety, since all aspects of design, development, production and support are links that determine the levels achieved. Quality and reliability are critical contributors to development time and costs, production costs and project success. Safety hazards can present very high business risks. By delegating responsibility for these aspects the project manager hands over control of some of the most significant determinants of success or failure. He must therefore manage quality, reliability and safety, at the same time making the best use of specialists assigned to the project. The project manager must understand the full effects, in particular the relationships to competitiveness and costs. He must ensure that all engineers on the project are dedicated to excellence, and that they are trained and supported so that failures and hazards are avoided whenever practicable and corrected whenever found.

All engineers are quality, reliability and safety engineers. However, not all are trained and experienced in design analysis methods like failure modes and effects analysis, the relevant statistical and other analysis techniques, test methods, *etc.* Therefore some specialization is often appropriate. A small specialist group can also provide the focus for development of methods, internal support and consultancy and training. However, it is essential that the engineers performing quality, reliability and safety work on projects are integrated into the project teams, just like all the other contributors. It is unfortunate that, partly because of the perception that quality and reliability use statistical methods that most engineers find unfamiliar, and partly because many of the people (engineers and statisticians) engaged in this work have exaggerated the statistical aspects, quality and reliability effort is often sidelined and given low priority.

Depending upon the type of project, the hazard risks involved and the contract or regulatory requirements, safety aspects could be managed separately from quality and reliability. However, there should be close collaboration, since many of the analysis and test methods are complementary.

Management of the quality and reliability function should be combined to ensure that the product benefits from an integrated approach to all of the factors discussed earlier. The combination of quality and reliability responsibilities should be applied centrally, as well as on projects. However, some companies separate the roles of quality and reliability. They consider reliability to be related to design and development, and quality to production. This separation of functions can be justified in organizations and in projects in which design and development work predominates, or when production is undertaken elsewhere, for example by "outsource" subcontractors. However, it is nearly always preferable to combine the functions. A combined approach can be a powerful glue to encourage cooperation between design and production engineers, whereas separation can foster uncoordinated attitudes and approaches. A combined approach can also foster an integrated approach to training, of both quality and reliability specialists and of other engineers in quality and reliability topics. Since quality of design and of production are so integrally related to productivity, costs and reliability, many of the world's most competitive engineering companies combine the functions, and many use the term "quality" to encompass the integrated function. Sometimes the expression "off-line quality" is used to describe all of the work related to quality and reliability before production starts, and "on-line quality" to refer to related work after the start of production. This top-down, integrated approach to managing quality has been called total quality management (TQM).

3.6.2 "Six Sigma"

The "six sigma" approach was originally developed in the USA by the Motorola company. It has spread to many other companies, mainly in the USA, particularly after its much-publicized application by GE under Jack Welch. It is based on the idea that if a process that is variable can be controlled so that all of its output that is within

plus or minus six standard deviations of the statistical distribution will be within specification, then only about one in a million times will it produce a "defective" output. This assumes that the output is statistically "normally" distributed, as discussed earlier; this is of course, highly unlikely, especially at such extremes. The approach is supported by the use of statistical analysis tools to identify causes of variation and to implement improvements.

The main differences between six sigma and the quality circles approach is that six sigma is run by specialists, not by the people running the processes. Some of the analytical methods used are more advanced, including ANOVA and Taguchi. The trained six sigma people are given titles like "black belts", and it is their job to find problems and generate solutions. The whole operation is driven from the top, and is directed at achieving stated targets for measurable cost savings. External consultants are often involved in training and in execution.

Six Sigma has been credited with generating significant improvements and savings. However, it is expensive. The management approach is "scientific", so it is arguable that the quality circles approach is a more effective philosophy.

3.7 Conclusions

Proper care and attention to quality, reliability and safety in design, development, production and maintenance, far from being unrealistic and expensive, are in nearly all cases practicable and highly cost effective. Reliability is a major determinant of a product's reputation and cost in service, and small differences in the reliability of competing products can greatly influence market share and profitability. If the reliability of a new product is perceived to be below expectations, or less than required by contract, serious losses or cancellation can result. Just as Deming pointed out the fallacy of an "optimum" level of production quality less than perfection, so design and development for any level of reliability less than 100% is wasteful and uncompetitive.

Note that we are discussing the probability of no failures within the expected life and environment. The designer is not expected to cater for gross overstress or inadequate maintenance, though of course the design must include margins of safety related to the criticality of failure and the likely variations in stress and strength. The creation of a reliable design is nearly always more economical than creating a design that fails in service. Furthermore, it is usually extremely difficult and expensive to improve the reliability of a product after it has been delivered, particularly if the failures are due to design shortcomings.

Designing, developing, and manufacturing modern products and systems to be reliable is therefore crucially important. The principles of reliability engineering are, however, inherently simple. Good engineering leads to good products.

Finally, it must be emphasized: well-managed effort and expenditure on quality, reliability and safety will always prove to be an excellent investment.

Product Design Optimization

Masataka Yoshimura

Optimum System Design Engineering Laboratory
Graduate School of Engineering, Mechanical Engineering Division
Kyoto University, Kyoto, Japan

Abstract: This chapter describes product design processes in product manufacturing from a technological point of view pertaining to optimization. The importance of optimization techniques for present and future product manufacturing is clarified and fundamental strategies for product design optimization are discussed, based on concurrent engineering concepts. The details of advanced optimization methodologies using hierarchical multiobjective optimizations are then explained, and a comprehensive applied example of a machine-tool optimization is provided.

4.1 Introduction

The product-manufacturing paradigm has seen profound changes during the past 100 years, as the mass production of a relatively small range of products was replaced by a job-shop type of production capable of manufacturing a large variety of products. Currently, job-shop manufacturing, in which customers select the most preferable products from a variety of products that makers prepare in advance, is giving way to a manufacturing paradigm that supports making products to order. Prompt response to customer needs is required, spurring the development of methods capable of delivering products that offer high performance, high quality and low cost, produced within a product development time that is as short as possible.

Relatively new is an increasing public awareness of the consequences of widespread product manufacturing. Its potential for causing serious harm to natural environments and the depletion of precious natural resources has made it mandatory to consider product life-cycle issues, the recycling of parts or raw materials, and manufacturing operations at all levels. Furthermore, leading product manufacturers must now also consider the mental and physical satisfaction of their customers as they live and work with their products, so design methodologies that can more closely tailor product characteristics to suit the emotional and mental requirements of particular people are necessary.

The foregoing product environments and pressures imply that product manufacturing is increasingly competitive, and the difference between business success and failure often depends on what would seem to be small design or manufacturing details. To satisfy and balance all of the foregoing factors as much as possible during the design and development of various products,

the use of sophisticated optimization techniques is indispensable, despite the complexity of the task and the difficulties encountered when dealing with requirements that include numerous characteristics having conflicting interrelationships.

In what follows, product design circumstances are first clarified, and practical methodologies for obtaining the most preferable design solutions are then presented.

4.2 Progressive Product Design Circumstances

The primary goals of advanced product manufacturing are to develop and manufacture essential products that fulfill lifestyle needs to the highest degree possible, and auxiliary products that make our living more comfortable, efficient and satisfying. Figure 4.1 illustrates examples of products associated with high standards of living. The manufacturing of all products depends on various levels of technologies. In the Stone Age, early people crafted spears and stone tools so that they could kill and process game, gather edible plants, and live as securely as they were able. Such items were developed to fit human hands and operated at a correspondingly human scale.

Over centuries and millennia of gradual human progress, innumerable kinds of products have been manufactured. The most advanced products of today are associated with high standards of living,

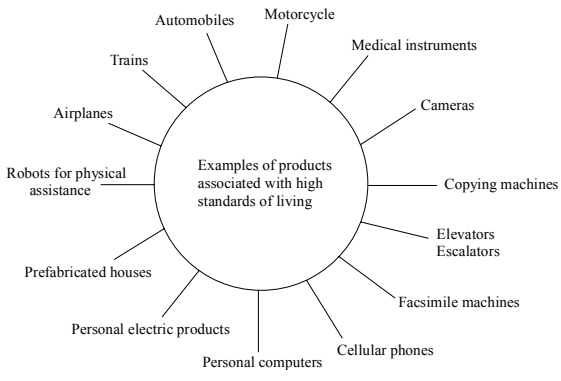

Figure 4.1. Examples of products associated with high standards of living

such as vehicles for transportation, electronic equipment for communication, business and leisure, and products for recreation and amusement. This tremendous variety of products and their associated technologies encompass a wide range of scales, from manipulation on an atomic scale, exploiting quantum effects, to monumental enterprises such as the creation of dams or a megalopolis, with the scale of the human body roughly at the center. In the course of progress, more efficient airplanes and trains are designed and built to transport increasing numbers of people to their destinations in shorter times, advanced power plants aim to provide a more stable infrastructure, and buildings of increasing scale that incorporate more sophisticated control of materials and climate aim to provide higher levels of comfort.

When considering the impact of human activity upon the natural environment and planet as a whole, it is clear that such extremely large scales really should be included in product development and design processes. On the other hand, it seems that an unbalanced degree of attention is focused on smaller scales, as shown by products for personal use that are increasingly miniaturized to provide greater convenience, utility and comfort. The realm of nanotechnology is receiving increasing publicity, as research uncovers ways to incorporate features at the scale of billionths of a meter in practical, everyday products that aim to satisfy requirements for lighter weight, superior function, and higher density of parts. Moreover, some areas of research focus on atomic and molecular scales, where certain discoveries have already lead to important breakthroughs that soon have profound social impact.

Thus, the scale of current product manufacturing covers a range from atoms and molecules, to household products, cars, trains and planes, skyscrapers, space stations, and even monumental earthworks. Since the design, manufacturing, sale and use over time of consumer products is almost always associated with rising standards of living, it is vital to preserve a strong awareness of human scales, which lie approximately at the center between the very large and the very small. Product manufacturing that ignores human needs and

desires, that is, manufacturing that concentrates too strongly on one particular scale at the expense of the human scale, may turn out to be uncomfortable or even harmful. The design and production of successful products almost always requires an astute examination of the relationships of scale between such objects, the surroundings in which they will be used, and the people who make them a part of their lives.

There are two major kinds of products, as follows:

(1) Products that ordinary customers buy and use.
(2) Industrial products used to manufacture products categorized in (1) above.

Figure 4.2 shows the relationship between customers and the manufacturers of consumer products and the industrial machines used to produce the products. The behavior of customers as they "vote with their wallets" naturally influences the demand for certain products, which in turn affects product manufacturers and supporting industries. As retail sales increase, certain manufacturers flourish and business activity radiates to other manufacturers and business sectors according to the specifics required for the production of the given products. The need to design and develop increasingly useful, attractive and sophisticated consumer products provides a fundamental stimulus for development and improvement in the manufacturing realm.

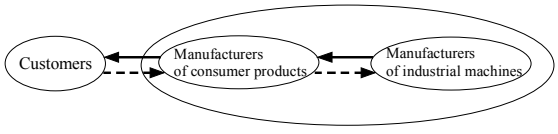

Figure 4.2. Relationship between customers and manufacturers of consumer products and industrial machines

Figure 4.3 shows a generalized manufacturing flow, which is usually the same for both consumer products and industrial machines.

Generalized manufacturing flow begins with market research and proceeds through product development, product design, product manufacturing, and ultimate sale of the goods.

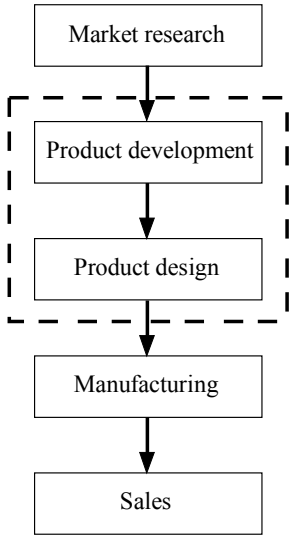

Figure 4.3. Conventional product manufacturing flow

4.3 Evaluation Criteria for Product Designs

In order to obtain optimum product design solutions, criteria for product manufacturing should first be defined, with the specifics depending on the particular nature of the product. The most fundamental criteria are described below.

4.3.1 Product Quality and Product Performance

The aim of product manufacturing is to produce products that fulfill their functions, required performances, qualities, and characteristics. The criteria first described below pertain to product qualities, which can be classified into two types: design qualities and manufacturing qualities. Design qualities correspond to values that customers require for the product, and in the case of industrial machines such as machine-tools and industrial robots, these are the accuracies, efficiency, operational energy requirements and similar performance aspects. In the case of automobiles, drivability, acceleration and braking performance, fuel economy, comfort, versatility, aesthetic value, and so on, would be considered.

On the other hand, manufacturing qualities pertain to the manufacturing processes used when producing products that incorporate desired design qualities. In the case of machine-tools, such qualities would correspond to dimensional variances, surface roughness, processing accuracy, and so on. To ensure a satisfactory level of product quality, manufacturers must evaluate whether or not their products achieve designated design specifications. Here, variations during manufacturing processes are therefore the principal evaluation factors.

Qualities that customers require in the products they seek to acquire are often labeled as being aspects of product performance. For example, accuracies when considered as a product performance correspond to certain levels of precision when the product is used for work or to accomplish its objective. Efficiencies are often evaluated by the time required to complete an objective task or sequence of operations, and a product that can accomplish work more quickly is said to have higher efficiency.

4.3.2 Manufacturing Cost

The next important criterion in product design is the total manufacturing cost, the sum of the various costs required to actually manufacture the product. The material cost of structural members and components, machining costs, casting and forging costs, powder metallurgy costs, the cost of welding, assembly, and so on, are all included in the manufacturing cost. Examples of other costs that are included in the total product cost include labor expenses, and overhead, advertising, and so on.

4.3.3 Process Capability

Process capability pertains to the maintenance of uniform qualities during the manufacturing process, and is evaluated by measuring variations in the attributes of manufactured work-pieces.

4.3.4 Reliability and Safety

The reliability and safety of products are extremely important criteria in product designs. Whenever a product fails significantly, much effort is devoted to determining the causes and how to prevent future occurrences of similar trouble. The need to adequately consider such issues when products are designed would seem to be common sense, but this is not always the case. Safety evaluations place utmost stress on the prevention of harm or injury to human beings. On the other hand, evaluations of reliability mostly focus on the regular accomplishment of product functions.

4.3.5 Natural Environment and Natural Resources

Product manufacturing has a tremendous influence on natural environments and has led to a number of catastrophes as well as shortages or exhaustion of natural resources. In response to these concerns, consideration of product life-cycles and the recycling of products and material have become indispensable aspects of responsible product designs.

One of the criteria in product life-cycle designs is given as follows:

$$\Phi = \frac{Satisfaction\ \ level\ for\ society\ as\ a\ whole}{Total\ damage\ to\ global\ environments} \tag{4.1}$$

That is, the ratio of satisfaction levels due to the successful realization of product functions over the consequential impact and damage to natural environments should be maximized to preserve the long-term viability of economical societies and establish truly sustainable lifestyles.

4.3.6 Mental Satisfaction Level

Currently, products offering high performances and qualities at reasonable costs are the norm rather than the exception. Given this situation, qualities related to mental factors such as aesthetic characteristics are becoming distinguishing factors that both encourage and respond to customer discrimination.

4.4 Fundamentals of Product Design Optimization

A basic optimization problem is formulated by including evaluation characteristics for product

designs in an objective function f, and constraint functions $g_j(j=1,2,...,m)$ and $h_k(k=1,2,...,p)$,as follows:

$f \rightarrow$ minimize or maximize

$g_j \le 0, \quad j=1,2,...,m$,

$h_k = 0, \quad k=1,2,...,p$,

f , $g_j(j=1,2,...,m)$ and $h_k(k=1,2,...,p)$ are functions of design variables $d_i(i=1,2,...,n)$. The design variables are determined by solving the foregoing optimization problem.

For the objective function f , an evaluation factor is selected from among those pertaining to the generation profits or conditions having business value, or an evaluation factor that is particularly important in terms of competition with other companies. The evaluation factors that have to be satisfied without fail are set as the constraints. Objective function f can be expressed as either a maximization or minimization problem, as desired, by expressing f as $-f$ or $1/f$.

Problems aiming to obtain values of characteristics, performances, costs, *etc*., after setting design variable values are called forward problems, while those seeking to obtain design variable values that satisfy the requirements of set characteristics, performances, costs, and the like, are called inverse problems. Design optimization problems are of the inverse type.

In any case, product designs always require that the product manufacturing cost be minimized, and methods for reducing this cost in most practical scenarios inevitably result in degradation of the product performances. There are cases where a specific product performance must be as high as possible, and to realize this requirement, the product manufacturing cost is forced upward. Furthermore, when the upper or lower bounds of the constraints are set, their values determine the result of the optimum solution, but in practical scenarios, setting specific upper or lower bounds is often problematic when certain factors are unclear. In these cases, formulating optimization problems with a number of objective functions that include such characteristics is effective, and design optimization problems of this type are generally called multiobjective optimization problems [1].

When there are two objective functions and smaller values of each objective function is more preferable, the objective of the multiobjective function is expressed as follows:

$$f=[f_1, f_2] \rightarrow \text{minimize.} \qquad (4.2)$$

As an example, consider a scenario where product designers are seeking a design solution that has a higher product performance while process designers engaged in practical manufacturing desire solutions that have lower product manufacturing costs. These two requirements naturally have conflicting interrelationships. Figure 4.4 shows the relationships between a product performance that must be maximized and the product manufacturing cost that always needs to be minimized. When the product performance and the product manufacturing cost are respectively expressed by f_1 and f_2 , the foregoing multiobjective formulation is changed as follows:

$$f=[-f_1, f_2] \rightarrow \text{minimize.} \qquad (4.3)$$

The shaded area in Figure 4.4 corresponds to the region that is feasible using presently available knowledge and technology. The line PQ corresponds to a Pareto optimum solution set for the two objective functions of the product performance and the product manufacturing cost.

The Pareto optimum solution set is defined as a set consisting of feasible solutions in each of which there exist no other feasible solutions that will yield an improvement in one objective without causing degradation in at least one other objective. The Pareto optimum solution set such as shown in Figure 4.4 is a set of candidate solutions from which the optimum solution is selected. The line (or, when there are three objective functions, the curved surface) is useful because it clearly shows the features of the solutions from a broad point of view [2–5]. Designers usually seek solutions in the direction of the large arrow located in the feasible region.

Looking at the design solutions at points A, B, and C on the Pareto optimum solution line PQ, we see that the design solution at point A provides excellent product performance, but at a very high manufacturing cost. The design solution at point C has a low manufacturing cost, but inferior product

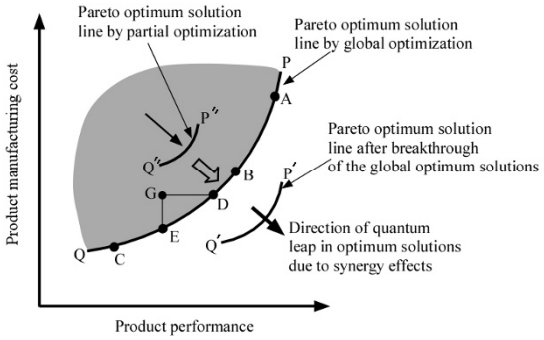

Figure 4.4. Conflicting relationships between a product performance characteristic and manufacturing cost

performance, and the design solution at point B offers rather good product performance and also a reasonable manufacturing cost. The solution actually used will be selected according to the customer's preference and priorities.

Designers generally look for practical design solutions on the Pareto optimum solution line. A global solution on the PQ line is difficult to obtain by the accumulation of partial optimizations that, for example, would yield solutions on the P"Q" line located within the feasible region, but rather far from the Pareto optimum solution line where the best solutions are located. For example, solution point G inside the feasible design region is inferior to any solution on solution line DE, and thus should not be selected as a design solution.

The foregoing discussion illustrates that searching for design solutions that lie on the global Pareto optimum solution line is an important part of practical product design and manufacturing. Given the competitive nature of the marketplace, it is obvious that companies making more preferable products that offer better value will usually gain market share. Obtaining Pareto optimum solutions that are superior in the global sense is therefore often of crucial importance in the development of successful product designs.

The display of a Pareto optimum solution set such as shown in Figure 4.4 is useful not only because it displays specific solutions, but also because a range of candidate optimum solutions on the PQ line can be visually and quantitatively understood. By looking at the whole Pareto optimum line, the relationships between the conflicting objective functions can be clearly recognized and compared. While accurately judging the worth of a single solution in isolation is impossible, the quality of specific available solutions can be judged and verified by the relative comparison of a set of candidate solutions.

In optimizations for product manufacturing, the initial focus is on obtaining solutions such those lying on the PQ line shown in Figure 4.4, which are termed the global optimum solutions. After such solutions are obtained, it is usually necessary to search for even better solutions, such as those lying on the P'Q' line, which represent important breakthroughs, beyond the PQ line. Given marketplace competition, there is significant pressure driving the evolution of product design solutions and product manufacturing techniques, and a currently successful product may rapidly lose its appeal due to the introduction of more sophisticated products that offer better customer value. The satisfaction levels of increasingly knowledgeable and sophisticated customers can only be met by continual improvements in product design and manufacturing.

4.5 Strategies of Advanced Product Design Optimization

Optimization methods and related technologies have been applied to many stages of product manufacturing. The levels at which such techniques can be applied have become increasingly broad, as shown in Figure 4.5. The accumulation of incremental improvements of parts, which can yield progressively better products over time, can now be augmented by optimizations of wider scope that extend beyond individual fields, or set of multidisciplinary fields, all the way to global optimizations.

Prior to the development of optimization techniques, incremental improvements were discovered through trial and error, and implemented at various stages of the design and manufacturing process. The accumulation of partial improvements over time ultimately led to quite profound advancements in the efficiency and quality of product designs and manufacturing.

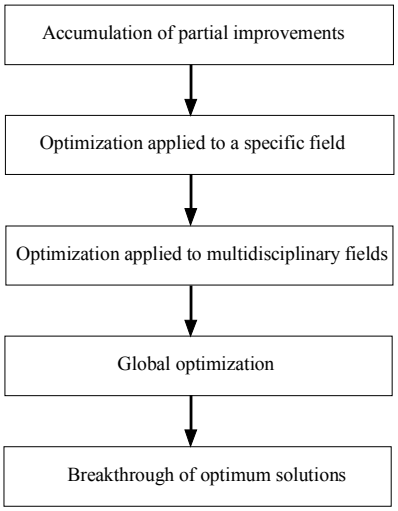

Figure 4.5. Developmental progress in optimization techniques applied to industrial activities

However, it became obvious that accumulations of partial improvements, and the results of trial and error processes, were inefficient and unlikely to bring about the best design solutions. The need to find more preferable schemes for the design and production of consumer products, and the industrial machines that manufacture them, made the utility of optimization techniques increasingly attractive. Thus, optimization techniques were partially applied in manufacturing areas under the direction and control of individual engineers.

As optimization techniques evolved, it became clear that decision-making factors in a specific field often affect, and are affected by, other fields, which gradually lead to the adoption of optimization techniques capable of handling broader scenarios, such as those that include a number of related fields. This type of optimization is generally called multidisciplinary optimization. Recently, it has been recognized that even optimum solutions for a set of multidisciplinary fields are not broad enough, so the importance of global optimization techniques is frequently discussed.

Multidisciplinary optimization (MDO) research has been carried out since the beginning of the 1980s, most notably with numerous applications for complex aeronautical design problems having a large number of design variables and criteria. In 1982, Sobieski [6], one of the pioneer MDO researchers, presented a method in which a complex design problem was decomposed into simpler sub-problems, each having a smaller number of design variables. This is assumed to mark the start of MDO research, and subsequent research efforts have focused on methods for decomposing large-scale systems and hierarchically expressing the resulting sub-problems.

Bloebaum *et al.* [7] decomposed large-scale systems by using a design structure matrix (DSM) that Steward [8] had proposed in 1981. In 1987, Kusiak *et al*. [9] proposed an optimization method whereby a system is decomposed by applying group technology to MDO, and the relationship between the design variables and criteria is expressed via a matrix [10].

Papalambros *et al.* [11] decomposed a large-scale system using Kusiak's research concepts, expressing the relations between the design variables and criteria via an overall matrix, and then extracting design variables common to the global problem. Papalambros' optimization method was later improved so that the system could be decomposed using graphical representations [12].

Recently, a variety of advanced decomposition methods for efficiently obtaining design solutions have been presented. The target cascading method for product development proposed by Papalambros [13] is a systematic means for consistently and efficiently propagating the desired top-level system design targets to appropriate subsystem and component specifications. The bi-level integrated system synthesis (BLISS) method proposed by Sobieski applies decomposition to the optimization of engineering systems, where system level optimization, which has relatively few design variables, is separated from potentially numerous subsystem optimizations that may each have a large number of local design variables [14].

Collaborative optimization is also a two-level optimization method specifically created for large-scale distributed-analysis applications [15]. Braun presented a collaborative architecture in a multi-disciplinary design environment, using a launch vehicle as an example [16].

Another useful method incorporating decomposition for optimization of machine product designs having hierarchical design variables is the hierarchical genetic algorithm proposed by Yoshimura and Izui [17, 18]. The decomposition-based assembly synthesis method proposed by Saitou also uses a systematic decomposition process as a tool [19]. A hierarchical multi-objective optimization method based on decomposition of characteristics and extraction of simpler characteristics has been proposed to address the importance of clarifying the conflicting relationships occurring between related characteristics in complex product design optimization problems [20].

4.5.1 Significance of Concurrent Optimization

Products are conventionally put on the market using the following manufacturing sequence: (1) research and development, (2) product design, (3) manufacturing, and then (4) marketing. Within a company, each of these operations usually corresponds to a single division, and within each division, particular decisions are made according to information received from upstream divisions. The decisions taken in upper divisions to implement various requirements and details therefore become constraints with respect to decision-making in downstream divisions. For example, attempting to reduce manufacturing costs after the details of a product design have already been decided will likely prove ineffective since it is the product design itself that largely determines the manufacturing cost. In a rigidly sequential manufacturing flow, cost reductions can seldom be implemented after the product design phase, such as at the process design stage when manufacturing methods and details are determined. Conflicting requirements may exist among divisions but these cannot be resolved due to the sequential manufacturing flow. Furthermore, a strictly chronological approach to product design and production is especially ill-suited to current merchandising trends where rapid product turnover and time to market are cardinal concerns.

When concurrent engineering principles are applied, the decision-making pertaining to product design and manufacturing factors is cooperatively performed, simultaneously and concurrently [21]. Concurrent engineering therefore means that all divisions work together cooperatively and at the same time, to make decisions concerning a range of factors before determining product details, a task that is facilitated by the use of computer networks. Competitive requirements, conflicting factors pertaining to different divisions, and trade-off relationships among product characteristics can all be appropriately resolved, and an enterprise atmosphere of mutual understanding and improved cooperation can be realized. Concurrent engineering has philosophical similarities with CIM (computer-integrated manufacturing) [22] from the standpoint of "integration" but the former emphasizes simultaneous and concurrent decision making in the early production stage.

To realize the potential benefits of concurrent engineering, the use of various optimization technologies is indispensable. Figure 4.6 shows the fundamental flow used when applying the concept of concurrent engineering to product designs. First, a wide range of evaluative factors and decision/design variables are gathered, according to experience. Next, the relationships between the evaluative factors are systematically analyzed and then suitable optimization procedures for obtaining the global optimum solution are constructed. Optimization based on the concept of concurrent engineering is here called concurrent optimization.

The products manufactured by various makers are bought by consumers who then use and maintain them when necessary, until they cease to

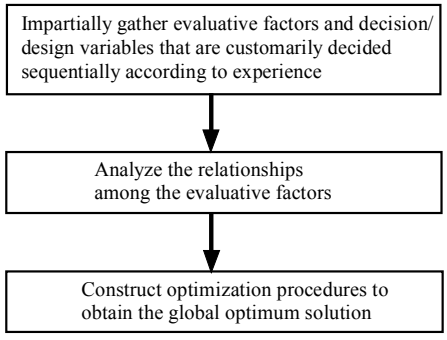

Figure 4.6. Fundamental flow in preparation for executing concurrent optimization

be useful. At that time, certain product parts and materials can, in certain cases, be reused or recycled, while the remainder is disposed of. This flow of products from creation, through use, repair, reuse, recycling and disposal, forms what is called a product's lifecycle. To achieve optimal product designs, all factors and items pertaining to a product's lifecycle should be fully considered at the earliest possible product design stage. That is, as the concept is shown in Figure 4.7, the full range of factors concerning a product's lifecycle, such as the manufacturing and purchase of machine components, the assembly, use, maintenance, disassembly, disposal, material recycling, and reuse of parts and materials, should all be concurrently considered and optimized from the initial design proposal stage.

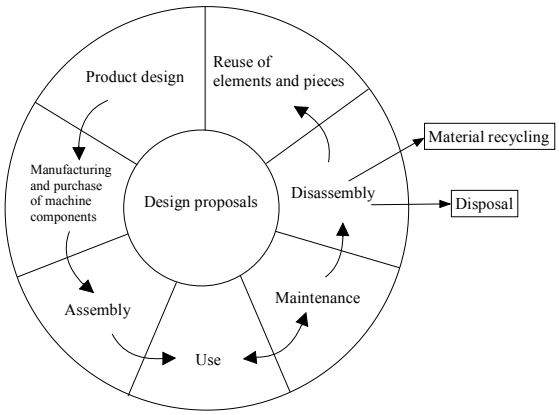

Figure 4.7. Conceptual diagram of lifecycle design

During the course of a product's lifecycle, many kinds of inconvenience may occur. Some of these undesirable outcomes affect the consumer's ability to use the product or derive the expected degree of satisfaction from it, while others may affect the environment in which the product is used, or the environment at large. If the steps required to mitigate these unwelcome circumstances are considered only when they occur, the potential for implementing the best possible solution or improvement will be clearly inferior to the outcome if such scenarios were considered at the early design stage of the product.

4.5.2 Fundamental Strategies of Design Optimization

Optimization methods based on mathematical programming methods and genetic algorithms have been widely developed and employed [23]. However, even though obtaining solutions for problems formulated as an optimization problem is often easy, judging the quality of the results in practical contexts is often difficult. In studies of practical methods for obtaining solutions to complex optimization problems, the response surface method based on the design of experiments has received much recent attention.

One of the troublesome aspects of current complex optimizations for product designs is that many local optimum solutions exist in the feasible design space. In many cases, obtaining the global optimum solution remains quite difficult, and optimization methods that simply and mechanically apply common optimization procedures seldom yield useful results for practical problems. However, by concentrating on the formulation of the optimization problem and by developing specific strategies to solve complex problems, practical optimization techniques and truly optimal results can be achieved, as will be explained below.

One of the most important points in the practical application of useful optimization methods is to formulate the problem being regarded while comprehensively including all available engineering knowledge and experiences, and to then carefully evaluate the obtained results.

The essential features that advanced and effective product design optimization methods should incorporate are as follows:

(1) Support design decision-making from the conceptual design stage.
(2) Facilitate detailed understanding and evaluation of exactly how the global optimum solution was obtained.
(3) Enable precise judgment concerning the validity of the obtained optimum solution.
(4) Support generation of novel and especially relevant ideas that lead to more preferable solutions.

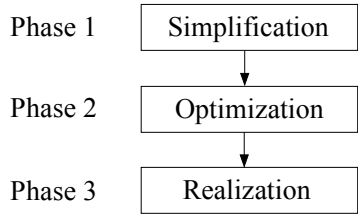

Figure 4.8. Multiphase design optimization procedures based on simplification of design models

Optimum design methods are often applied to the improvement of detailed designs, but this implies that the optimization starts from states where the most of the important design decisions have been already been made. In order to obtain more preferable design solutions, optimization methods should begin from a state where the range of design possibilities is as broad as possible, namely from the conceptual design stage. A method focusing on the fulfillment of requirement (1) above uses multiphase design optimization procedures based on the simplification of structural models, as shown in Figure 4.8 [24, 25].

In the first phase, the simplification process, a simplified mathematical or simulation model is constructed that has structural characteristics equivalent to the practical machine structure being considered. A complete, but simplified structural model that includes simplified structural models of parts and joints is constructed. In the second phase, an optimization procedure is conducted for the entire structural model. In the third and last phase, realization, practical detailed designs for each structural member and joint are determined from a wide range of possible alternatives, to most closely meet the specifications obtained in the second phase.

Solutions to goals (2), (3), and (4) above can be obtained by using a hierarchical multiobjective optimization method. In general, when requirements for a given performance characteristic can be realized without the presence of trade-off relationships with the other characteristics, the optimization problem is a simple one where the optimum solution can be easily obtained. The obtained solution is, in such cases, often quite similar to what can be achieved when relying on the experience and intuition of a decision maker. However, when conflicting relationships exist among the performance characteristics, and those characteristics have complex interrelationships, optimization problems become complicated and finding the optimum solution is far from easy. Optimizations for product designs are almost always of this type, where there are conflicting relationships among characteristics, but multiobjective optimization methods can be successfully applied to such problems.

4.6 Methodologies and Procedures for Product Design Optimization

Machine products have functions that are designed to accomplish specific tasks, jobs that are performed by the movement and operation of certain parts of the machine. During design, the operational accuracies and the time taken to complete specific jobs are evaluated so that the overall product efficiency can be considered. Here, the accuracy and efficiency are concurrently evaluated and higher values of both are generally more preferable, while it is desirable to minimize the operational energy used to accomplish the desired jobs that the product is designed to carry out. The product manufacturing cost is always to be minimized in actual manufacturing.

Each original performance characteristic is usually very complicated, since it is expressed as compounds or additions of various other component characteristics. The optimum design solutions for each of the original performance characteristics are generally different from each other, meaning that such performance characteristics have conflicting interrelationships, which is a proximate cause of the difficulty of obtaining globally optimal solutions.

To clarify the interrelationships among characteristics, they are examined so that their expression and composition, as well as their dynamic behavior and mathematical expression, can all be succinctly expressed in the context of the optimization problem at hand. For example, machine accuracies are often expressed by static and/or dynamic displacements at specific points that are determined according to the objective of

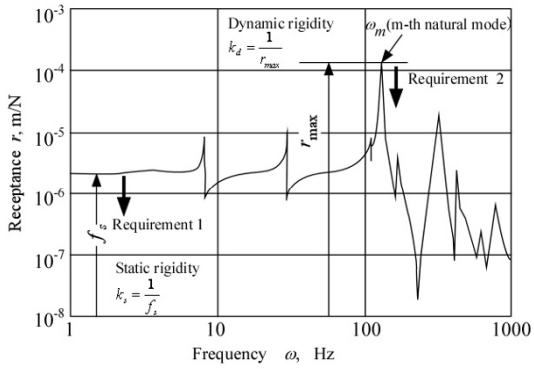

Figure 4.9. An example of frequency response at the cutting point of a machine-tool structure

specific jobs. Similarly, static rigidities can be used to evaluate the static displacements, and dynamic rigidities are used when evaluating the dynamic displacements. In general, machine products can be classified into those for which static rigidities alone are evaluated, and those for which dynamic rigidities are also evaluated. Since machine products carry out their jobs by the movement and operation of various parts, it is usually necessary to evaluate and optimize dynamic rigidities as well as static rigidities.

Figure 4.9 shows an example of the frequency response at a specific point of the machine (the cutting point in the case of machine tools, the end-effector point in the case of industrial robots, *etc*.). The receptance frequency response is expressed as follows:

$$r(\omega) = \frac{X}{F}(\omega) = \sum_{m=1}^{\infty} \left[\frac{f_m}{1 - (\frac{\omega}{\omega_m})^2 + 2j(\frac{\omega}{\omega_m})\varsigma_m} \right] \quad (4.4)$$

The static rigidity k_s is obtained using the reciprocal of the static compliance f_s, while the dynamic rigidity k_d is obtained using the reciprocal of the maximum receptance value $r_{\max}$ over the whole frequency range.

When the frequency ω is set to 0 in (4.4), the following simple relationship between f_s and modal flexibility f_m is established [26, 27].

$$f_S = \sum_{m=1}^{\infty} f_m \quad . \quad (4.5)$$

Both f_s and f_m have positive values. The modal flexibility f_m $(m = 1,2,...,\infty)$ expresses the distributed magnitude of the static compliance f_s for each natural mode. Equation (4.5) indicates that minimizing the static compliance f_s, which is equivalent to maximizing the static rigidity, reduces the modal flexibility at the natural mode where the modal flexibility value is highest.

In machine structures, vibration damping is most pronounced at joint interfaces, be they bolted or sliding. The consequences of damping effects can generally be controlled by carrying out detailed adjustments of joint parameters during the detailed design stage. When structural member rigidities are maximized, increasing the damping effects at the joints becomes easier [27]. The damping ratio ζ_m has a different value at each natural mode. The material damping ratios and the damping ratios for machine elements or parts vary according to the material properties, shapes and other parameters, however the damping ratio for the machine structure as a whole, despite the inclusion of many joints, often has a specific value or lies within a rather narrow range of values. Such values are often defined by experimental studies, and here the damping ratio is given as a specific constant value of ς for the initial stages of the design optimization.

The dynamic rigidity k_d is approximately expressed by the static rigidity k_s and the damping ratio ς as follows:

$$k_d = \frac{1}{r_{\max}} \cong \frac{2\zeta}{af_s} = \frac{2k_s\zeta}{a} \quad , \quad (4.6)$$

where a is assumed to be a constant value, such as 0.7. Examination of the related characteristics yields the result that increasing the static rigidity k_s increases the dynamic rigidity k_d.

In light of the above, it is clear that optimization of the static rigidity should have priority over optimization of the dynamic rigidity.

Practical procedures are explained with applied examples. Figure 4.10 shows a framework model of a machine tool composed of structural members and joints. The performance characteristics to be considered are the static and dynamic rigidities at the cutting point and the manufacturing cost of the

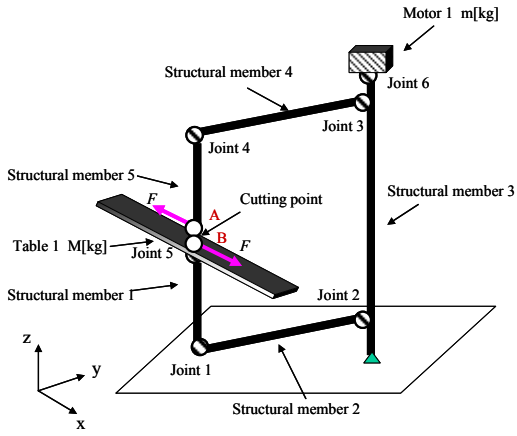

Figure 4.10. Framework model of a milling machine

machine tool. The static rigidity k_s is the reciprocal of the static compliance f_s between points A and B at the cutting point, which is obtained as X/F where X is the relative displacement between A and B, and F is the cutting force at points A and B. The dynamic rigidity k_d, *i.e.*, the reciprocal of the maximum receptance value $r_{\max}$ of the frequency response curve, is obtained from the frequency response curve.

The objective functions are the maximum receptance value and the machine's manufacturing cost C_T, each of which should be minimized. The formulation of $r_{\max}$ is simplified as shown in (4.6). Then, the characteristic of the maximum receptance value $r_{\max}$ is decomposed into two characteristics, namely the static compliance f_s and the damping ratio ς. The manufacturing cost C_T is decomposed into the material cost C_M of the structural members and the machining cost C_J of the joints

The optimization procedures carried out during the hierarchical multiobjective optimization [20] are as follows:

Step 1: The multiobjective optimization problem for the static rigidity k_M and the total structural weight W_s of the structural members on the static force loop is solved and a Pareto optimum solution set of cross-sectional dimensions is obtained. The structural model used for the structural analysis is shown in Figure 4.11, where only structural members on the static force loop are indicated, and each joint is treated as a rigid joint for the purposes of simplicity. The design variables are the cross-sectional dimensions of each structural member.

Step 2: The Pareto optimum solution line between the static rigidity k_M of the structural members and the material cost C_M of the structural members is obtained. The material cost C_M is calculated by multiplying the material cost per unit weight by W_s.

Step 3: The multiobjective optimization problem is solved for the total joint rigidities k_J on the static force loop and the machining cost C_J of the joints. The structural model used for the structural analysis is shown in Figure 4.11, where each joint is now treated as a flexible joint modeled as a spring, and the maximum surface roughness of the contact surface is included in the design variables. The results of the cross-sectional dimensions obtained in Step 1 are used as initial design variables. In this optimization, the relationships between the surface roughness $R_{\max}$ and the machining cost C_u per unit contact surface, shown in Figure 4.12, are used, where three kinds of machining methods, namely, milling, grinding, and super finishing, are considered. The joint rigidities are calculated according to their surface roughness values and contact surface areas [25].

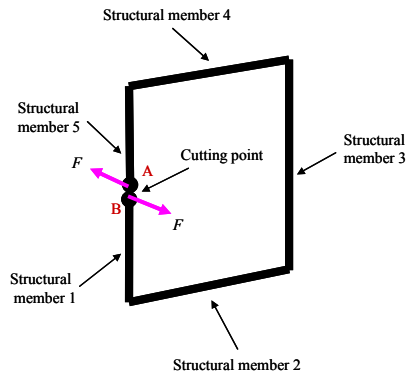

Figure 4.11. Structural model of the static force loop

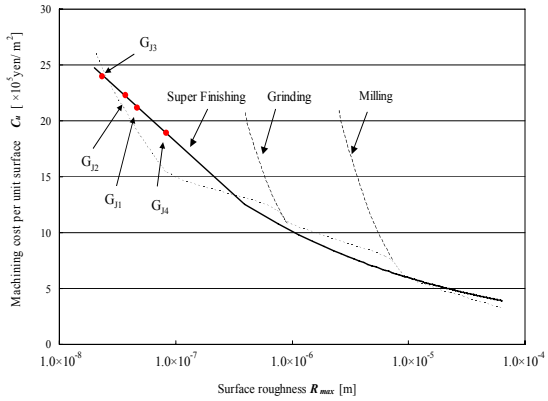

Figure 4.12. Relations between surface roughness and machining cost per unit contact area

Step 4: The multiobjective optimization problem is solved for the static compliance f_s (the reciprocal of the static rigidity k_s) and the total manufacturing cost C_T of the structural members on the static force loop, which is the sum of the material cost C_M and the machining cost C_J of the joints, and a Pareto optimum solution set is obtained.

Step 5: The multiobjective optimization problem for the maximum receptance value $r_{\max}$ and the total manufacturing cost C_T is solved and a Pareto optimum solution set is obtained. The structural model now used is shown in Figure 4.10, where each joint is modeled as a flexible joint and the maximum surface roughness of the contact surface is included in the design variables. The results of the cross-sectional dimensions and spring stiffnesses obtained in Step 2 are used as initial design variables.

Figure 4.13, the Step 1 result, shows the Pareto optimum solution set line between the static rigidity k_M and the total structural weight W_s of the structural members on the static force loop. Figure 4.14, the Step 4 result, shows the Pareto optimum solution set line between the static compliance f_s and the total manufacturing cost C_T .

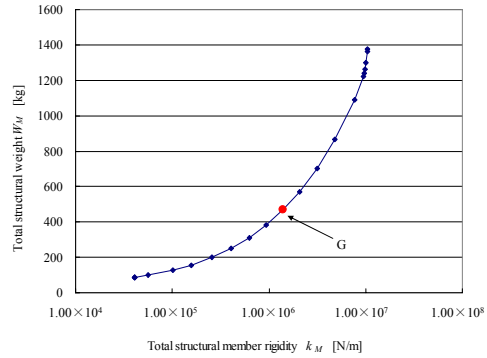

Figure 4.13. Pareto optimum solution line for Step1

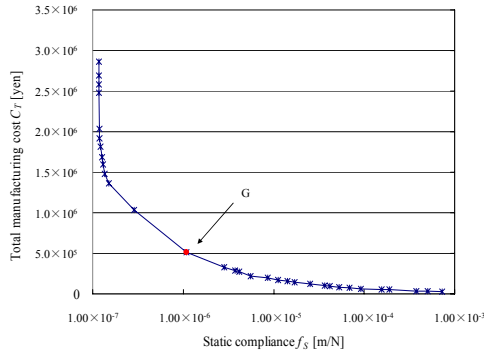

Figure 4.14. Pareto optimum solution line for Step 4

Figure 4.15, the Step 5 result, shows the Pareto optimum solution set line between the maximum receptance $r_{\max}$ and the total manufacturing cost C_T . To demonstrate the effectiveness of the proposed method, the obtained results are compared with those achieved by a conventional method, where the performance characteristics (objective functions at Step 5) are directly optimized using the feasible direction method but without using the proposed hierarchical optimization procedures. These are shown with ◆ symbols in Figure 4.15, while the results obtained by the proposed method are shown with ∗ symbols. The Pareto optimum solution line is shown by the thin line, which indicates the optimum solution frontier. The results show that proposed method obtains more preferable solutions, and does so more reliably.

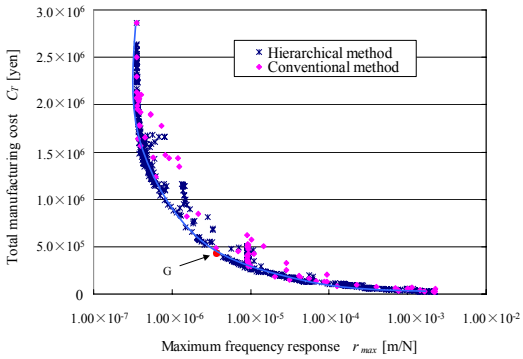

Figure 4.15. Pareto optimum solutions for Step 5

In the method explained above, the final global optimum solution can be analyzed and understood in terms of the interrelationships between correlated solution points existing in the final and first hierarchical levels, or in intermediate levels. The validity of the obtained design solutions, and their fitness for particular purposes, can therefore be more effectively evaluated. With point G selected on the Pareto optimum solution line in Figure 4.15, corresponding solution points on the Pareto optimum solution lines in Figures 4.13 and 4.14 are also indicated by points labeled G. At each corresponding point, the detailed values of the design variables and the characteristics can be examined, enabling a deeper understanding of the solution contents. For example, points G_{Jx}, with x corresponding to the joint number, are shown in Figure 4.12 and they indicate the solution's recommended machining method. The design solution corresponding to points G_{J1}, G_{J2}, G_{J3} and G_{J4} for joints 1, 2, 3 and 4, respectively, are illustrated, and it can be seen that super finishing machining is indicated for these particular joints. Furthermore, useful comparisons of several design solutions on the Pareto optimum solution line at the final stage can be conducted by going back to earlier optimization stages, enabling more detailed examinations of the optimum solutions.

Because the relationships between the optimum solution at the final hierarchical level and solutions at the topmost level are exposed and can be easily understood, examination of the features of characteristics at the lowest level, which are usually very simple, can often lead to further effective ways of improving these characteristics and, ultimately, the overall fitness of the final product design. That is, the techniques listed in Section 4.5.2 above more effectively support the generation of further ideas for improving tentative design solutions, and facilitate more rapid examination of the resulting improvement levels. For example, it may be advantageous to use a new material for a structural member, and the validity and utility of doing so can be readily evaluated using the Pareto optimum solutions obtained during earlier optimization stages.

4.7 Design Optimization for Creativity and Balance in Product Manufacturing

An important goal of product manufacturing is to design and manufacture products that, as far as possible, are in harmony with the environment, climate, nature, and culture where the products are used, in addition to satisfying personal preferences and tastes. This, and other goals, can be achieved by systematically considering a range of evaluative factors. Many industries are starting to realize that their long-term success depends on addressing factors beyond the design of products that merely satisfy minimum requirements in isolation. As shown in Figure 4.16, for industries to truly flourish, product manufacturers must be aware of the cultural impact of their products, and strive to achieve balanced approaches that address broader issues pertaining to natural environments, climate, and the personality of those who purchase and use

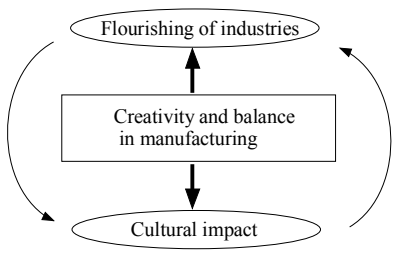

Figure 4.16. Conceptual diagram of the relationship between creativity and balance in manufacturing, and cultural impact and flourishing of industries

their products, so that customer satisfaction can be truly maximized.

Diversification in product manufacturing can increase the personal satisfaction of customers, and drive the creation of new products that better cope with a variety of local environments. The application of optimization techniques to product designs is important not simply from the standpoint of obtaining a single superior design solution, but because such techniques can provide a useful variety of design solutions. Using this variety, the most appropriate global solution can be selected from a number of alternative solutions, according to detailed requirements pertaining to specific products in specific locations and times. Thus, optimization techniques can potentially play important roles in both creating products that deliver greater satisfaction levels, and in manufacturing products that achieve greater harmony with their surroundings, by skillfully considering a broader range of factors.

4.8 Conclusions

Since a great deal of human activity is related in some way to product manufacturing, it directly affects the growth and survival of economic entities at all scales, while offering potential improvements in the satisfaction levels of people around the world. To achieve truly sustainable product manufacturing, its impact on gobal environments and ecologies, as well as the depletion of natural resources, must be given the attention that these pressing concerns deserve. Also of primary concern is the psychology of the people whose lives are affected by the manufacturing and use of mainstream as well as novel and improved products that aim to make our lives easier, more comfortable or more worthwhile. The use of advanced optimization technologies during product design processes is practically indispensable if these goals are to be met.

In the beginning of this chapter, progressive product design circumstances were explained, and the importance of clarifying product design criteria when seeking to develop more preferable product designs was emphasized. Next, the principal criteria for product designs were described, along with the problem of related criteria that often have complicated conflicting interrelationships. Then, to cope with the multitude of features that needs to be addressed, product optimization details and the use of multiobjective Pareto optimum solutions were explained. Concurrent engineering concepts for obtaining superior product designs were discussed next, and then fundamental strategies of product design optimizations were described. Product design optimization methodologies were explained using a practical machine-tool example. Product manufacturing is directly related to the flourishing of a wide range of industries. Since these industries also exercise considerable cultural impact, finally, their flourishing, as they recognize and respond to the global and interrelated nature of their environmental and cultural impact, was mentioned in terms of the need for increasingly sophisticated and practical product design optimization methods and strategies.

Constructing a Product Design for the Environment Process

Daniel P. Fitzgerald[1], Jeffrey W. Herrmann[1], Peter A. Sandborn[1], Linda C. Schmidt[1] and Thornton H. Gogoll[2]

[1]University of Maryland in College Park, Maryland, USA
[2]Black & Decker in Towson, Maryland, USA

Abstract: The greatest opportunity to reduce the environmental impact of a new product occurs during the design phase of its life cycle. Design for environment (DfE) tools, when implemented, become part of the product development process. Often, however, the DfE tools are isolated from the other activities that comprise the product development process. To avoid this problem, tools must be situated in a DfE process that describes how the DfE tools will be used and links DfE activities with the rest of the product development process. This paper presents an innovative DfE process that is being incorporated into an existing product development process at a leading power tool manufacturing company, The Black & Decker Corporation. The DfE process includes DfE tools and activities that are specifically designed to help Black & Decker achieve their environmental objectives.

5.1 Introduction

Environmentally responsible product development (ERPD), also known as environmentally benign manufacturing, considers both environmental impacts and economic objectives during the numerous and diverse activities of product development and manufacturing. ERPD seeks to develop energy-efficient and environmentally benign products. Products generate environmental impacts throughout all stages (*i.e.* raw material extraction, manufacturing, assembly, distribution, and end of life) of their life cycle. There are many ways to minimize these environmental impacts. Studies demonstrate the greatest opportunity for ERPD occurs during the product design phases [1]. The decisions that are made during these phases determine most of the product's environmental impact. Although ERPD requires extra effort, it not only protects the environment but also provides a channel for the application of environmental policies determined at the corporate level.

Consequently, manufacturing companies have spent a great deal of effort developing tools to help designers create environmentally benign products. The two major classes of tools are life cycle assessment (LCA) [2] and design for environment (DfE) tools [3]. LCA provides a fundamental methodology that evaluates the environmental impact associated with a product during its complete life cycle. DfE tools are design decision support tools that help a designer reduce these impacts by improving the product design. DfE incorporates the consideration of national

regulations, human health and safety, hazardous material minimization, disassembly, recovery, recycling, and disposal into the design process.

Many obstacles to the effective use of LCA and DfE tools have been noted [1]. Two of the most significant obstacles are the difficulties acquiring the needed data and the challenges developing realistic, appropriate metrics of environmental impact. Consequently, LCA and DfE tools are, generally, not integrated with the other activities and tools used in the product development process. That is, the information flow and decision-making required for existing LCA and DfE tools to be effective is inconsistent with the information flow and decision-making present in product development organizations. The result is often a post-design, standalone, environmental review of a product.

However, manufacturing firms need a tool to consider environmental objectives during the design of new products. Especially urgent is the need to comply with an ever-increasing number of environmental regulations and customer demands. To overcome the limitations of standalone DfE tools, manufacturing firms need to consider important environmental objectives in a systematic way during the design process. This chapter describes such a DfE process for a leading worldwide power tool manufacturer, The Black & Decker Corporation. In close collaboration with Black & Decker, the authors have developed this DfE process. Black & Decker is now working to implement this process.

The development of this DfE process was advanced by considering the product development process as a decision-making system. The next section of this chapter elaborates on this perspective and desscribes a methodology for improving product development, which can be used to enhance any type of performability engineering. Section 5.3 presents an overview of Black & Decker's environmental objectives. Section 5.4 presents the specific product-level metrics that product development teams can evaluate and describes how they are relevant to Black & Decker's environmental objectives. Section 5.5 makes recommendations about the product development milestones when these metrics should be complete. Section 5.6 describes compares this innovative DfE process to traditional DfE and LCA tools. Section 5.7 concludes the chapter.

5.2 A Decision-making View of Product Development Processes

Product development is a complex and lengthy process of identifying a need, designing, manufacturing and delivering a solution, often in the form of a physical object, to the end-user. Product development is a difficult task made more difficult by the challenges inherent in complex, open-ended, and ill-defined tasks. A successful product development process incorporates information inputs from seemingly unrelated and remote areas of an organization into the decision-making process [4].

Due to their complexity, it is not surprising that a variety of perspectives is needed to understand product development processes. The task-based perspective view product development as a project of related tasks and emphasizes project management guidelines. Smith and Reinertsen [5] present an economic view of product development and stress the relationships between development time, development cost, unit cost, and product performance and the product's overall profitability.

5.2.1 Decision Production Systems

Building on both the decision-based perspective of engineering design and the decision-making paradigm of organizational design, Herrmann and Schmidt [6] argued that product development organizations are decision production systems and describe product development as an information flow governed by decision-makers who operate under time and budget constraints to produce new information. The term is relevant because a product development organization creates new product designs and other information that are the accumulated results of complex sequences of decisions. Herrmann and Schmidt [7] present a methodology for improving a product development organization. Herrmann [8] further explores the

concepts on which this view depends and considers their implications for designing product development processes.

The decision production system (DPS) perspective looks at the organization in which the product development process exists and considers the decision-makers and their information processing tools (like databases) as units of a manufacturing system that can be viewed separately from the organization structure. By viewing organizations in this manner, one can understand how information flows and who is making the key decisions. As a result the hierarchical view and decision production system view of a product development organization are quite different. Similarly, Simon [4] noted that an organization's "anatomy" for information processing and decision-making is naturally different than the departmentalization displayed in an organization chart. The greater the interdependence between decision-makers, the less the DPS will resemble an organization chart.

The DPS perspective is an overarching framework to map product development activities (with an emphasis on decisions) within an organization in such a way as to illustrate current decision-making practices. The DPS representation of a product development organization provides a meta-level view of the actual decision-making processes taking place in an organization, which are not necessarily the processes that management may have prescribed. The DPS perspective enables problem identification in decision-making practices that will lead to a more effective deployment of resources including decision support tools.

The DPS perspective enables a deeper understanding of the organization than typical hierarchical organization charts of a firm or Gantt charts of product development projects. Understanding the real process (as opposed to the corporate guide for the design process) is a key step in improving product development. Furthermore, recognizing design as a "knowledge agent" and the designing activity as a crucial organizational knowledge process can improve an organization's ability to innovate within their competitive environment [9]. The need for research on new work practices [10] and the need for developing new representation schemes for product development [11] are additional motivations for considering the DPS perspective.

5.2.2 Improving Product Development Processes

Simon [4] argues that systematic analysis of the decision-making in a product development process would be useful for implementing changes to the product development organization in a timely and profitable manner, and he proposes the following technique for designing an organization:

- Examine the decisions that are actually made, including the goals, knowledge, skills, and information needed to make those decisions.
- Create an organization pattern for the tasks that provide information for these decisions.
- Establish (or change) the pattern of who talks to whom, how often, and about what.

Of course, this must be repeated for the more specific decisions that form the more general decisions.

Viewing a product development organization as a decision-making system leads to a systems-level approach to improving product development. In particular, this perspective is not concerned primarily with formulating and solving a design optimization problem. Moreover, the problem is not viewed only as helping a single design engineer make better decisions (though this remains important). Instead, the problem is one of organizing the entire system of decision-making and information flow to improve the performability of the new products that are being developed.

As with other efforts to improve manufacturing operations or business processes, improving product development benefits from a systematic improvement methodology. The methodology presented here includes the following steps in a cycle of continuous improvement, which is based in part on ideas from Checkland [12].

1. Study the product development decision-making system.
2. Build, validate, and analyze one or more models of this decision-making system.
3. Identify feasible, desirable changes.
4. Implement the changes, evaluate them, and return to Step 1.

The important features of the decision-making system are the persons who participate in it, the decisions that are actually made, including the goals, knowledge, skills, and information needed to make those decisions. Also relevant are the processes used to gather and disseminate information. It will also be useful to study other processes that interact with product development, including marketing, regulatory compliance, manufacturing planning, and customer service.

An especially important part of studying product development is determining the sources that provide information to those making decisions. If they are not documented, changes to the system may eliminate access to these sources, which leads to worse decision-making. In addition, like any group of tools accumulated over time, it is critical to review how and when each decision support tool is applied to the product development process. This requires a meta-level understanding of decision-making during all phases of product development.

Modeling is a key feature of this methodology. Creating a model of the as-is product development organization has many benefits. Though it may be based on pre-existing descriptions of the formal product development process, it is not limited to describing the "should be" activities. The process of creating the model begins a conversation among those responsible for improving the organization. Each person involved has an incomplete view of the system, uses a different terminology, and brings different assumptions to the table. Through the modeling process, these persons develop a common language and a complete picture. Validation activities give other stakeholders an opportunity to give input and also to begin learning more about the system. Even those that are directly involved in product development benefit from the "you are here" information that a model provides. For more details about possible models, see Herrmann and Schmidt [7].

5.3 Environmental Objectives

Based on discussions with Black & Decker staff, such as the Director of Engineering Standards and the Senior Manager of Environmental Affairs, and documents provided by Black & Decker, we identified six primary environmental objectives based on the corporation's environmental policy:

1. Practice environmental stewardship.
2. Comply with environmental regulations.
3. Address customer concerns.
4. Mitigate environmental risks.
5. Limit financial liability.
6. Report environmental performance.

This section describes these in more detail.

5.3.1 Practice Environmental Stewardship

Black & Decker seeks to demonstrate environmental awareness through creating an environmental policy and publishing it on their website, including information about recycled content on packaging, and its Design for Environment program. In addition, Black & Decker belongs to environmental organizations such as the World Environmental Center, which contributes to sustainable development worldwide by strengthening industrial and urban environment, health, and safety policy and practices. It is also member of the Rechargeable Battery Recycling Corporation (RBRC) and RECHARGE which promote the recycling of rechargeable batteries.

5.3.2 Comply with Environmental Regulations

As a global corporation that manufactures, purchases, and sells goods, Black & Decker must comply with all applicable regulations of countries where its products are manufactured or sold. Currently, the European Union exerts significant influence on addressing environmental issues through regulations and directives. Listed below are examples of important US and European environmental regulations.

There are many regulations that apply to US and European workers and these are set by both

federal and state agencies. The Occupational Safety & Health Administration (OSHA) limits the concentration of certain chemicals to which workers may be exposed. The Environmental Protection Agency (EPA) regulates management of waste and emissions to the environment. Black & Decker provides employees with training on handling hazardous wastes, which is required by the Resource Conservation and Recovery Act and the Hazardous Materials Transportation Act [13]. California's Proposition 65 requires a warning before potentially exposing a consumer to chemicals known to the State of California to cause cancer or reproductive toxicity. The legislation explicitly lists chemicals known to cause cancer and reproductive toxicity.

The EU Battery Directive (91/157/EEC) places restrictions on the use of certain batteries. The EU Packaging Directive [14] seeks to prevent packaging waste by requiring packaging re-use and recycling. In the future, countries in the European Union will require Black & Decker to adhere to certain laws so that the state achieves the goals of the EU Packaging Directive. Thus, Black & Decker will be interested in increasing the recyclability of its packaging.

Black & Decker has also implemented procedures to comply with the Waste Electrical and Electronic Equipment Directive (WEEE). The following excerpt describing this directive is from the UK's Environmental Agency [15]: "The Directive is one of a series of 'producer responsibility' directives that makes producers of new equipment responsible for paying for the treatment and recycling of products at the end of their life. It affects any business that manufactures, brands or imports [electrical and electronic equipment (EEE)] as well as businesses that sell EEE or store, treat or dismantle WEEE within the EU. It will affect businesses that have WEEE to dispose of and the public who will have more opportunities to reuse, recycle and recover these products."

This regulation requires appropriate marking on EEE, sets targets for household WEEE collection, requires EU member states to register EEE producers, requires procedures to enable take-back and treatment, and sets targets for recycling and recovery.

5.3.3 Address Customer Concerns

Black & Decker's retail customers are concerned about the environmental impacts of the products they sell. Examples of customer concerns are: ensuring timber comes from appropriate forests, increasing the recyclability and recycled content in packaging, using cadmium in batteries, and using lead in printed wiring boards and electrical cords. More specifically, some retailers require that Black & Decker's products be free of lead-based surface coatings.

5.3.4 Mitigate Environmental Risks

An activity's environmental risk is the potential that the activity will adversely affect living organisms through its effluents, emissions, wastes, accidental chemical releases, energy use, and resource consumption [16]. Black & Decker seeks to mitigate environmental risks through monitoring chemical emissions from manufacturing plants, reducing waste produced by its operations, ensuring safe use of chemicals in the workplace, and ensuring proper off-site waste management.

5.3.5 Reduce Financial Liability

There are different types of environmental liabilities [17]:

- Compliance obligations are the costs of coming into compliance with laws and regulations.
- Remediation obligations are the costs of cleaning up pollution posing a risk to human health and the environment.
- Fines and penalties are the costs of being non-compliant.
- Compensation obligations are the costs of compensating "damages" suffered by individuals, their property, and businesses due to use or release of toxic substances or other pollutants.

- Punitive damages are the costs of environmental negligence.
- Natural resource damages are the costs of compensating damages to federal, state, local, foreign, or tribal land.

Some of these may be a concern to Black & Decker.

5.3.6 Reporting Environmental Performance

Black & Decker reports environmental performance to many different organizations with local, national or global influence and authority. An example of an organization is the Investor Responsibility Research Center (IRRC).

Consistent with its policy, Black & Decker's environmental objectives will evolve. New regulations will be promulgated in the years to come. Stakeholders will ask for additional environmental information. Black & Decker must be flexible enough to comply. The need for a DfE process that is robust and can adapt to the constantly changing nature of environmental regulations and requirements is great.

5.4 Product-level Environmental Metrics

Incorporating a DfE process that fits into the existing product development process has significant potential to help manufacturing firms achieve their environmental objectives. This section briefly describes eight product-level environmental metrics developed by the authors and Black & Decker staff that product development teams can evaluate during the product development process. These metrics were chosen because they relate directly to a particular product (they are not plant or corporate metrics). In addition, the measures concern attributes that are relevant to Black & Decker's primary environmental objectives, as described below.

5.4.1 Description of the Metrics

There are eight product-level environmental metrics, which the following paragraphs describe:

1. Flagged material use in product
2. Total product mass
3. Flagged material generated in the manufacturing process
4. Recyclability/disassembly rating
5. Disassembly time
6. Energy use
7. Innovation statement
8. Application of the DfE approach

Flagged Material Use in Product

This measures the mass of each flagged material contained in the product. A material is considered flagged if it is banned, restricted or being watched with respect to regulations or customers. A consulting firm has provided Black & Decker with a list of materials that are banned, restricted and being watched. This metric addresses the following corporate environmental objectives:

- Comply with environmental regulations.
- Address customer concerns.
- Limit financial liability.
- Report environmental performance.

Total Product/Packaging Mass

This measures the mass of the product and packaging separately. This metric addresses the following corporate environmental objectives:

- Comply with environmental regulations.
- Address customer concerns.
- Report environmental performance.

Flagged Material Generated in the Manufacturing Process

This is a list of each flagged material generated during the manufacturing process. A material is considered flagged if it is banned, restricted or being watched with respect to regulations or customers. This metric addresses the following corporate environmental objectives:

- Comply with environmental regulations.
- Address customer concerns.
- Mitigate environmental risks.
- Limit financial liability.
- Report environmental performance.

Recyclability/Disassembly Rating

This metric is the degree to which each component and subassembly in the product is recyclable. Recyclability and separability ratings can be calculated for each component based on qualitative rankings. Design engineers are provided with a list of statements that describe the degree to which a component is recyclable or separable and a value from 1 to 6 is associated with each statement. Low ratings for both recyclability and separability facilitate disassembly and recycling. The design engineer rates the recyclability and separability of each component, subassembly, and final assembly. If both ratings for an item are less than "3", than the item is recyclable [18].

This metric addresses the following corporate environmental objectives:

- Practice environmental stewardship.
- Comply with environmental regulations.
- Address customer concerns.
- Mitigate environmental risks.
- Report environmental performance.

Disassembly Time

A measure of the time it will take to disassemble the product. Research has been conducted on how long it typically takes to perform certain actions. Charts with estimates for typical disassembly actions are provided to the design engineers who can then estimate how long it would take to disassemble a product [18].

This metric addresses the following corporate environmental objectives:

- Practice environmental stewardship,
- Mitigate environmental risks.

Energy Consumption

The total expected energy usage of a product during its lifetime. This metric can be calculated by multiplying the total expected lifetime hours by the energy use per hour the product consumes. This metric need to be calculated only for large energy consumers such as compressors, generators, and battery chargers.

This metric addresses the following corporate environmental objectives:

- Practice environmental stewardship.
- Comply with environmental regulations.
- Address customer concerns.
- Mitigate environmental risks.
- Limit financial liability.

Innovation Statement

A brief paragraph describing the ways a product development team reduced the negative environmental impact of their product. The product development team should write this after the product is launched. All environmental aspects considered should be included as well.

This metric addresses the following corporate environmental objectives:

- Practice environmental stewardship.
- Report environmental performance.

Application of DfE approach

This binary measure (yes or no) is the answer to the following question: Did the product development team follow the DfE approach during the product development process? Following the DfE approach requires the team to review the DfE guidelines and evaluate the product-level environmental metrics.

This metric addresses the following corporate environmental objectives:

- Practice environmental stewardship.
- Report environmental performance.

While this list of metrics cannot completely measure every environmental impact, the metrics provide designers with a simple way to compare different designs on an environmental level. Black & Decker plans to track the trends of these metrics as the products advance through future redesigns. Furthermore, each product will have environmental targets set at the beginning of the project, and the metrics provide a way to track how well the product development team performed with respect

to attaining the targets. The Corporate Environmental Affairs group will also use the metrics to respond to retailers requests for environmental information.

5.4.2 Scorecard Model

A scorecard was created in Microsoft Excel in order to ensure that the metrics above could be used more effectively during the product development process. There is a single worksheet with inputs and outputs specifically related to most of the aforementioned metrics. Calculations for each metric are carried out on a hidden calculations worksheet. Separate worksheets contain the most important outputs from each metric and appropriate graphs. The following paragraphs list the specific inputs and outputs for each metric.

Flagged Material Use in Product:

Inputs: The components containing flagged material, mass of each component, flagged material contained within each component, percent of each component that is hazardous.
Outputs: The mass of each flagged material in each component, and the total mass of each flagged material within each product.

Total Product and Packaging Mass:

Inputs: Product weight and packaging weight.
Outputs: Product mass and packaging mass.

Flagged Material Generated in Manufacturing Process:

Inputs: Flagged material generated, manufacturing process, component being made.
Outputs: List of flagged materials generated for product.

Recyclability/Disassembly Rating:

Inputs: Assembly name, component name, quantity, material the component is made of, total mass, recyclability rating, separability rating.
Outputs: Total mass of product for each recyclability rating, total mass of product for each disassembly rating, pie charts for both sets of outputs, percent of the product that is recyclable, whether a particular component is recyclable.

Disassembly Time:

Inputs: Disassembly step, fastener used, removal method, time per fastener, number of jobs.
Outputs: Total time for each step, total time for disassembly.

Energy Consumption:

Inputs: Expected lifetime of the product, total power rating.
Outputs: Total energy used by product over lifetime.
The innovation statement and application of DfE approach metrics are not included in the spreadsheet because they do not involve numbers or calculations. The final output page highlights key environmental metrics and is calculated with the spreadsheet based on the designer inputs listed above. The key environmental metrics are: Amount of flagged material in product (g), total product mass and (g), number of manufacturing processes that generate flagged materials, percent product recyclable, total disassembly time (s), and total energy consumed (kJ).

5.4.3 Guidelines and Checklist Document

To ensure that design teams at Black & Decker address appropriate environmental concerns during the product development process, a guidelines and checklist document has been created. The checklist portion of the document lists items that must be addressed before the product is released to the market. The document contains references which are links to additional information about the requirements and guidelines. The guidelines section of the document lists issues that engineers should try to address to make the product more environmentally friendly. Not addressing an item in the guideline section would not prevent a product from going to the market however.

The Checklist of Regulatory and Policy Requirements contains the following requirements:

- No material restricted by Black & Decker is used in the product or manufacturing process.
- All materials restricted in the RoHS directive are under the respective threshold limit within the product.

- All special lead applications are under the respective threshold limit within the product.
- Product manual contains appropriate Proposition 65 warning if necessary.
- Packaging of product adheres to the European Packaging Directive.
- Batteries contain no materials banned in the European Union's battery directive.
- Product and manual contain appropriate markings for products with batteries.
- Product and manual contain appropriate markings for products with respect to the WEEE directive.
- Prohibited manufactured processes are not used.

The following are the Design for Environment Guidelines:

- Reduce the amount of flagged materials in the product by using materials not included on Black & Decker's should not use list.
- Reduce raw material used in product by eliminating or reducing components.
- Reduce the amount of flagged material released in manufacturing by choosing materials and processes that are less harmful.
- Increase the recyclability and separability of the product's components.
- Reduce the product's disassembly time.
- Reduce the amount of energy the product uses.

Samples of these documents can be found in Fitzgerald *et al*. [19].

5.5 The New DfE Process

Ideally, every product and process design decision should consider environmental concerns. However, this is not feasible because some designers are unfamiliar with DfE principles. Therefore, we defined a DfE process that naturally integrates environmental issues into the existing product development process with little extra effort or time. Black & Decker uses a stage-gate product development process that has eight stages. Every stage requires certain tasks to be completed before management signs off giving permission to proceed to the next stage. This signoff procedure is known as the gate.

Currently, Black & Decker has safety reviews during stages 2, 3, 4, and 6. Safety reviews are meetings intended for reviewers to evaluate the assessment, actions, and process of the design team in addressing product safety. The DfE process adds an environmental review to the agenda of the safety reviews held during Stages 2, 4, and 6. A separate environmental review will be held during Stage 3, an important design stage, in order to focus specifically on the environmental issues for the particular product. The environmental reviews will require design teams to review the checklist of key requirements and to consider guidelines for reducing environmental impact. When the DfE process is first implemented, design teams will have to fill out the Environmental Scorecard only during Stage 6 after the product design is complete. Doing this begins the process of recording environmental data and allows design teams to adapt gradually to the new process. When design teams become more familiar with the process, the scorecard will be completed two or more times during the stage-gate process in order to track design changes that effect environmental metrics during the development process.

In addition to the environmental reviews, environmental targets will be set during Stage 1 as goals for the new product. The design team will write a lessons learned summary during Stage 8 to highlight innovative environmental design changes. The lessons learned summary will provide the innovation statement metric. Figure 5.1 shows the Safety Review Process and Environmental Review Process running in parallel. The sections below discuss the aforementioned environmental activities in more detail. Note that, throughout this process, many other product development activities occur, causing changes to the product design.

5.5.1 Product Initiation Document

The Product Initiation document is a document that Black & Decker uses to benchmark competitors, define performance targets, and predict

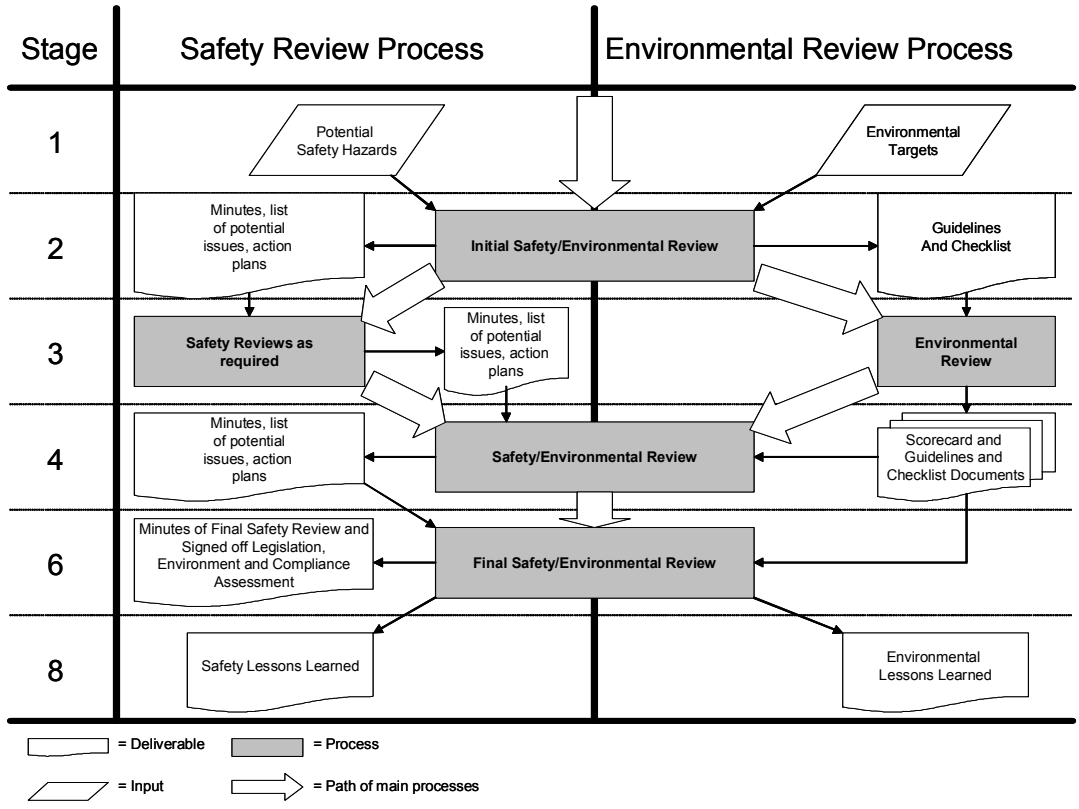

Figure 5.1. Combined safety and environmental review process [19]

profitability and market share. In addition to these issues, the product initiation document will also address environmental regulations and trends and opportunities to create environmental advantage. Targets for environmental improvement will also be included.

5.5.2 Conceptual Design Environmental Review

The second environmental review is held separately from the safety hazard review. During this meeting, the project team will check compliance regulations, fill in the guidelines and checklist document, discuss the metrics in the guidelines and checklist document and write the minutes.

The lead engineer will update the scorecard and review opportunities and additional environmental issues for the next meeting.

The result of this meeting is an updated guidelines and checklist document and meeting minutes. The reliability representative will update.

5.5.3 Detailed Design Environmental Review

The third environmental review is coupled with a safety review. During this meeting, the project team should ensure that all environmental compliance issues are resolved. There should be no further changes to the design due to environmental reasons after this meeting. The result of the meeting is an updated guidelines and checklist document and meeting minutes. The reliability representative will update the guidelines and

checklist document and write the minutes. The lead engineer will update the scorecard for the next meeting.

5.5.4 Final Environmental Review

The fourth and final environmental review is coupled with a safety review. During this meeting, all environmental compliance issues must be resolved. Optimally, no design changes due to environmental reasons would have been made between the last meeting and this meeting. The result of the meeting is a final guidelines and checklist document and meeting minutes. The reliability representative will finalize the guidelines and checklist document and write the minutes. The lead engineer will finalize the scorecard and create a material declaration statement (MDS) packet for the product.

5.5.5 Post-launch Review

Black & Decker includes a lessons learned summary in their product development process. This document discusses what went well with the project, what did not go well with the project, and reasons why the product did not meet targets set in the trigger document. The lessons learned summary will include environmental design innovations realized during the product development process for publicity and customer questionnaires. An example of an item to be included in the lessons learned summary is a materials selection decision. Details should include what materials were considered and the rationale of the decision. The lessons learned summary is a very important part of the DfE process because it provides future design teams with the environmental knowledge gained by the previous designers.

5.5.6 Feedback Loop

The completed checklist and guidelines documents and lessons learned summaries create a feedback loop for the DfE process. Design engineers working on similar products can use this information to make better decisions immediately and the information is also valuable when the next generation of the product is designed years down the road. Design engineers will record what environmental decisions were made and why they were made. The decision information, scorecards and comments on the guideline document will be archived permanently. The goal is to save the right things so the information is there in the future when more feedback activities, such as a product tear-down to verify scorecard metrics, can be introduced.

5.6 Analysis of the DfE Process

Black & Decker's new DfE process described above is innovative and has many advantages compared to traditional DfE tools. There are many standalone DfE tools available to designers. Otto and Wood [18] provide an overview of some of the DfE tools currently used. Two examples cited are general guideline/checklist documents and life cycle assessments (LCAs).

A general guideline/checklist document is a simple DfE tool that forces designers to consider environmental issues when designing products. Integrating a guideline/checklist within a new DfE process is simple and effective way to highlight environmental concerns. However, it should be noted that the guideline/checklist document needs to be company specific and integrated systematically into the product development process. Using an existing generic, standalone guideline/checklist document will most likely be ineffective. First, the point of a guideline/checklist document is to ensure that designers are taking the proper steps towards achieving environmental objectives. Another organization's guidelines /checklist document was designed to obtain their own objectives which may not coincide with another company's objectives. Second, obtaining a guideline/checklist document and simply handing it to designers will lead to confusion as to when and how to use the list. Specific procedures need to be implemented to ensure the designers are exposed to the guideline/checklist document early in the product development process to promote environmental design decisions.

LCAs are time-consuming projects that research a product's environmental impacts and conducts tests to produce environmental impact quantities. The problem with LCAs is that they take a long time, are very expensive, and provide information only after the design is complete. LCAs do not help designers improve a current product's environmental impact. Our DfE process, however, provides guidelines that help achieve Black & Decker's environmental objectives, and it contains a lessons learned summaries that provide a design engineer with helpful information about previously used decisions and techniques.

Klein and Sorra [20] argue that successfully implementing an innovation depends upon "the extent to which targeted users perceive that use of the innovation will foster the fulfilment of their values." The DfE process contains values that coincide with the organization's values. Within the Corporation's Code of Ethics and Standards of Conduct [21], there is a section titled Environmental Matters which "places responsibility on every business unit for compliance with applicable laws of the country in which it is located, and…expects all of its employees to abide by established environmental policies and procedures." Black & Decker's environmental objectives were taken into account and consequently the DfE process requires designers to track related metrics. The process leverages existing processes hence minimizing time-to-market and requiring little extra effort from the designers. Black & Decker's product development process was studied to ensure information availability. A DfE process that is customized for Black & Decker is much more likely to be implemented than standalone tools. By researching any organization's product development process and understanding the decision-making processes, information flow, and organizational and group values, it is possible to construct a DfE process that is customized and easy to implement.

5.7 Conclusions

This chapter describes an innovative DfE process in which a design team repeatedly considers key product-level environmental metrics. These metrics are directly related to the corporation's environmental objectives. These metrics do not require excessive time or effort. The iterative nature of the DfE process means that design teams consider different aspects of DfE at the most appropriate time, when information is available and key decisions must be made.

The DfE process was created specifically for Black & Decker through studying their product development process and incorporating DfE activities with similar existing activities. Environmental regulations are treated in a systematic and formal way so that the design teams can document the new product's compliance. Finally, this report includes guidelines and an environmental scorecard that the product development teams can use to improve the product's environmental performance.

The research team is now assisting with the implementation and planning assessment activities such as material declaration forms and upgrading service bill of material lists to include material identification for recycling. The assessment of this approach remains for future work. Such an assessment would need to involve performance metrics such as: the time required for DfE reviews, the number of additional tasks required, the improvement in product environmental metrics, and the percentage of questions that can be accurately answered in customer questionnaires. Further research using this methodology will establish its usefulness for improving product development.

Dependability Considerations in the Design of a System

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: For better system performance, attributes such as quality, reliability, maintainability, safety, and risk that are closely related and govern the dependability of the system, must be considered. It is also necessary to understand the inter-relationship between these factors so that one not only minimizes the chances of occurrence of any untoward incident at the design and fabrication stage but also minimizes the chances of occurrences and the consequences of such an event during the system operation and use phase.

6.1 Introduction

As systems become more and more complex, their chance of failure-free operation also decreases and we cannot possibly altogether eliminate a failure within a system but we can certainly attempt to contain its impact. High-risk systems particularly require a thorough investigation or analysis to ensure high level of performance and safety as an accident can cause havoc in the surrounding environment and may be economically disastrous if it occurs.

We have seen in Chapter 1 that to ensure that a system or product is dependable, we must ensure that its survivability is high and that it is safe during its operation and use. Obviously, ensuring high performance levels in design and operation of the system in question can avert accidents. Prevention of an accident requires excellence in performance, which leads to high plant dependability and reduces the chances of failure and the associated risk. Consequently, the safety of the plant should be high. In other words, high system dependability helps prevent accidents. However, there is a balance to be struck between the safety and the cost of achieving it. On the other hand, although a plant may be safe, the standards from ecological and stringent environmental protection may require serious consideration of the consequences that would follow from a probable accident.

6.2 Survivability

The ultimate worth of any product or system is judged by its performance, either expected or specified. In order to define the desired performance of a product or system, it is important to consider the following aspects:

- Definition or objective of a product or a system
- Criteria of acceptable performance
- Definition of failure or malfunctioning
- Expected time of operation
- Operating conditions
- Maintenance conditions
- Tests and sampling procedures

How well a product or a system meets its performance requirements depends on its various characteristics, such as quality, reliability, availability and efficiency. A product or a system having these attributes is usually expected to perform well over its lifetime incurring minimum life-cycle costs, which include design and development, manufacturing, and maintenance costs.

No one can ever dispute the necessity for a product or a system to survive its expected life; however, this survivability depends on attributes like quality, reliability and maintainability or availability. Therefore, to ensure higher survivability of a product or a system, it is essential that all the above attributes be ensured, not just one of them.

Often the only concern of a manufacturer appears to be the *product quality* and the customer is happy to accept the product as long as it is supported with a warranty. At best the customer may also have some protection in law, so that he may claim redress for failures occurring within a reasonable time, usually the warranty period. However, this approach provides no guarantee of performance over a period of time, particularly outside the warranty period. Even within a warranty period, the customer usually has no grounds for further action if the product fails once, twice or several times, provided that the manufacturer repairs the product as promised each time. If it fails often, the manufacturer will suffer high warranty costs, and the customers will suffer inconvenience. However, outside the warranty period, it is only the customer who is left to suffer the consequences of failures. Of course, the manufacturer may also probably incur a loss of reputation and possibly future business.

Therefore, we have the requirement of a time-based concept of quality. The inspectors' concept is not time-dependent nor does it ensure that the product will be able to function satisfactorily under the actual conditions of environment of use. The quality tests either pass a product or fail it. In other words we must not only have high quality but also higher reliability, since reliability is usually concerned with failures in the time domain of the use of a product or a system. This distinction also highlights the difference between traditional quality control efforts and pursuing reliability engineering programs. Moreover, whether or not failures occur and the times of their occurrence, can never be forecast accurately. Therefore, reliability implies an aspect of engineering uncertainty, which is often reflected in its probabilistic definition, *viz.*, *it is the probability that a product or a system will perform the intended function without failure under stated conditions of use over a stated period of time*. However, to produce reliable products or systems, we may have to incur increased costs of design and manufacturing.

Besides *one-shot equipment/devices* like ICs, electric components, bulbs, rockets, missiles, *etc*., there are products or systems whose survivability can be improved considerably and these can be maintained in a functional state over a long period of time by carrying out necessary maintenance, whether it is *preventive* or *corrective*. Preventive maintenance consists of routine maintenance at predetermined points of time during the operation phase to reduce the chances of failure of a unit, whereas corrective maintenance or repair is carried out only after a failure has occurred. Sometimes maintenance may be carried out based on the condition of a unit based on the signature analysis of certain parameters like vibration, noise, *etc*. Such maintenance is known as *predictive* maintenance.

Maintenance also has a significant influence on the life of a product or system and consequently on the reliability. In addition to maintenance, the supply function also has a considerable effect on reliability. The supply function is concerned with providing of the necessary personnel, material, parts and equipment to support operation in the field. Collectively, maintenance and supply efforts, materials, facilities and manpower form the logistics support. The logistics costs over the lifetime of a product or system may exceed considerably the initial cost of the product or system. In fact, maintenance includes all actions necessary to keep the unit in a usable condition through preventive measures, which include check-out, testing, overhaul, repair, instructions, operational schedules, spares and last but not least personnel.

Maintainability and reliability are the two most important design parameters in establishing the availability of a product. Availability is defined as the probability of a product working satisfactorily at any given point of time when used under given conditions. Obviously, availability depends on the time during which the product is available. Time is of basic importance in this concept. The available time or uptime and is the time during which the product is working. The unavailable time or downtime is the time during which the maintenance is being done. Obviously, availability becomes a more important parameter of performance of the maintained product or system than reliability. However, reliability and maintainability are both related to availability.

Maintainability is determined by the design of the product or system and can be greatly enhanced if fault detection, isolation and repair procedures are worked out during the design stage itself. Maintenance procedure charts and diagrams can also help considerably during repair and should include all pertinent tests points and a description of what should be measured and observed at each test point. In documenting these repair procedures, due consideration must be given to personnel skill levels, tools, facilities and the time that will be available under field conditions for the repairs.

Poor or deficient performance attributes not only affect the life-cycle costs but also have effects in terms of environmental consequences. Degraded performance attributes reflect more on the material and energy requirement and wastes and cause more environmental pollution when reckoned over a given period of time. Obviously, a product with poor quality, reliability, maintainability, availability, or efficiency will incur more life-cycle costs and would be uneconomical to use. Generally, these costs are also inter-dependent on the attributes of performance. For example, a highly reliable product will have lower maintenance costs.

6.3 System Effectiveness

The *system effectiveness* relates to that property of system output, which was the reason for having that system. Obviously, if the system is effective, it should carry out this function very well otherwise efforts can be made to improve the chosen system attributes in which the system is deficient. Effectiveness is influenced not only by the way the system/equipment is designed and built, but also the way in which the system/equipment is used and maintained. In other words, the design engineer, the production engineer, the operator and the maintenance man can materially influence system effectiveness. It can also be influenced by the logistic system that supports the operation, and by the administration through personnel policy, rules governing equipment use, fiscal control, and many other administrative policy decisions.

The term *system effectiveness* is defined in several ways. A formal definition is:

1. *System effectiveness is the probability that the system would successfully meet an operational demand within a given time when operated under specified conditions*.

An alternative definition of system effectiveness is given as:

2. *System effectiveness is the probability that the system will operate successfully when called upon to do so under specified conditions.*

The major difference between these two definitions lies in the fact that, in definition 2 (which is basically for one-shot devices or non-maintained systems such as missiles, *etc*.), time is relatively unimportant. The first definition is more general and the operating time is a critical element, and effectiveness is expressed as a function of time. Another difference is that the first definition provides for the repair of failures, both at the beginning of the time interval (if the system is inoperable then) and also during the operating interval (if a failure occurs after a successful start); the second definition assumes no repairs.

However, both the definitions imply that the system fails if:

(1) It is an inoperable condition when needed, or,
(2) It is operable when needed but fails to complete the assigned mission successfully.

The expression "*specified conditions*" implies that system effectiveness must be stated in terms of the requirements placed upon the system, indicating that failure and use conditions are related. As the operational stress increases, the failure frequency may also be expected to increase.

6.4 Attributes of System Effectiveness

There are several attributes of system effectiveness and it would be worthwhile to discuss these here. Various definitions of terms used shall also be provided. The following is an outline, not necessarily a complete and perfect enumeration, of the factors, which must be considered while designing a system:

(i) Design Adequacy

The system should satisfy the following attributes:

1. Technical capabilities
   - Operational simplicity
   - Accuracy
   - Range
   - Invulnerability to countermeasures
2. Specifications
   - Space and weight requirements
   - Input power requirements
   - Input information requirements
   - Requirements for special protection against shock, vibration, low pressure, and other environmental influences

(ii) Operational Readiness

In order that the system fulfills operational requirements adequately over the intended period of time, the system must be designed for:

- Reliability, which means, the system has
  - failure-free operation
  - redundancy or provision for alternative modes of operation
- Maintainability
  - Time to restore the failed system to operating state
  - Technical manpower requirements for maintenance
  - Effects of use cycle on maintenance
  - Logistic support

(iii) System Cost

The system must be developed with minimum cost.

- Development cost, and particularly development time, from inception to operational capability
- Production cost
- Operating and operational support costs

The optimization of *system effectiveness* by judiciously balancing the conflicting requirements or specifications in the above list is an extremely difficult task, as there is a high degree of interaction among the factors involved in the problem. It is not always practicable to maximize all the desirable properties of a system simultaneously. Naturally, there would be some *trade-offs* between system cost and the achievable levels of reliability and maintainability and many other parameters of design. In the following sections, we will define these parameters one by one and also discuss the implications of choosing one or more parameters of system design.

6.4.1 Reliability and Mission Reliability

The definition of reliability is generally given as:

> *Reliability is the probability that a system will perform satisfactorily for at least a given period of time under stated conditions of use.*

However, *mission reliability* is defined as:

> *The probability that a system will operate in the mode for which it was designed for the duration of a mission, given that it was operating in this mode at the beginning of the mission*.

Mission reliability thus defines the probability that no system failure takes place during the *mission time, i.e.*, the period of time required to complete a mission. All possible redundant modes of operation must be considered while describing reliability, mission reliability, and system effectiveness.

6.4.2 Operational Readiness and Availability

The capability of a system to perform its intended function when called upon to do so is often referred to by either of the two terms, namely, *operational readiness* and *availability*. System effectiveness includes the built-in capability of the system, its accuracy, power, *etc*. Operational readiness excludes the ability of the system to do the intended job but includes only its readiness to do it at a particular time.

It would be worthwhile to mention the distinction between the terms-operational readiness and availability. Availability is defined in terms of operating time and downtime, where the downtime includes active repair time, administrative time, and logistic time. On the other hand, operational readiness is defined in terms of all of these times, and, in addition, includes both free time and storage time, *i.e.*, all calendar time. Therefore, availability and operational readiness are defined as follows:

Availability of a system or equipment is the probability that it is operating satisfactorily at any given point in time when used under stated conditions, where the total time considered includes operating time, active repair time, administrative time, and logistic time.

Operational readiness of a system or equipment is the probability that at any point in time it is either operating satisfactorily or is ready to be placed in operation on demand when used under stated conditions, including stated allowable warning time. Thus, total calendar time is the basis for computation of operational readiness.

6.4.3 Design Adequacy

System design adequacy is the probability that a system will successfully accomplish its mission, given that the system is operating within design specifications.

The design may include alternative modes of operation, which are equivalent to built-in automatic repair, usually with allowable degradation in performance. These alternative modes of operation are included in the definition of system design adequacy.

6.4.4 Repairability

Repairability is defined as the probability that a failed system will be restored to operable condition in a specified active repair time.

6.4.5 Maintainability

Obviously, this attribute refers to only those systems that can be repaired or maintained. *Maintainability* is defined as the probability that a failed system is restored to operable condition in a specified downtime. Actually downtime consists of *administrative*, *logistic*, and *actual repair times*. In reality, preparation time, fault location time, part procurement time, actual repair time and testing time after repair all add up to increase the total downtime. Maintainability [4] is primarily determined by the design of the product or system and can be greatly enhanced if the fault detection, isolation, and repair procedures are worked out during the design stage itself. In documenting the repair procedure, due consideration should be given to personal skill levels, tools, facilities, and the time that will be available under the field operating conditions.

This attribute is quite analogous to repairability. The difference is merely that while maintainability is based on the *total downtime* (which includes active repair time, logistic time, and administrative time), repairability is restricted to include active repair time only.

6.4.6 Serviceability

Intuitively, it would seem that some term should be used to present the degree of difficulty with which equipment can be repaired. The term serviceability has been selected for this concept. Serviceability has a strong influence on reparability, but the two are essentially different concepts. *Serviceability* is an equipment design characteristic while reparability is a probability involving certain categories of time.

Although the definition of serviceability is stated in a manner that suggests a quantitative concept, it is often necessary to accept a qualitative evaluation of the serviceability of a system or

equipment. When we say that equipment A is more serviceable than equipment B, we mean that the better the serviceability, the shorter the active repair time. Hence, reparability is a reflection of serviceability even though the two concepts are quite distinct.

Serviceability is dependent on many hardware characteristics, such as engineering design, complexity, and the number and accessibility of test points. These characteristics are under engineering control, and poor serviceability traceable to such items is the responsibility of design engineers. However, many other characteristics, which can cause poor serviceability, are not directly under the control of a design engineer. These include lack of proper tools and testing facilities, shortage of workspace in the maintenance shop, poorly trained maintenance personnel, shortage of repair parts, and other factors that can increase the difficulties of maintenance.

6.4.7 Availability

Availability is defined as: the probability of a product or system working satisfactorily at any given point of time when used under the given conditions of use.

Thus availability signifies the probability that the system is available and is working satisfactorily at a given point of time. Availability is a more meaningful parameter of performance of a maintained system than reliability. However, reliability and maintainability are related to availability and are two important design parameters in establishing the availability of equipment.

6.4.8 Intrinsic Availability

The intrinsic availability of a system or equipment is the probability that it is operating satisfactorily at any given point in time when used under stated conditions, where the time considered is operating time and active repair time. Thus, intrinsic availability excludes from consideration all *free time*, *storage time*, *administrative time*, and *logistic time*. As the name indicates, intrinsic availability refers to the built-in capability of the system or equipment to operate satisfactorily under stated conditions.

6.4.9 Elements of Time

Time is of basic importance in the concept of corrective maintenance. The unavailable time or downtime is the time in which the maintenance is being done. This includes waiting time, which is the time lost for administrative or logistic reasons. There are other classifications of time such as free time and storage time. This time may or may not be the downtime depending on whether the product is in operable condition or not. Uptime is the time during which the product is available for use by an intended user. In order to use the probability definitions discussed in the previous sections, the following definitions are given for the time elements, which must be considered in the evaluation of system effectiveness.

6.4.9.1 Operating Time

Operating time is the time during which the system is operating in a manner acceptable to the operator.

6.4.9.2 Downtime

Downtime is the total time during which the system is not in an acceptable operating condition.

Since downtime is subdivided into *active repair time*, *administrative time* and *logistic time*, it is appropriate here to discuss these elements in a little more detail.

6.4.9.3 Active Repair Time

Active repair time is that portion of downtime where the repair crew is working on the system to affect a repair. This time includes preparation time, fault-location time, fault-correction time, and final checkout time for the system.

Both the active repair time and operating time are determined by the inherent characteristics of the equipment, and hence are primarily the responsibility of the manufacturer. Improvement in this area requires action to reduce the frequency of failure or to facilitate the ease of repair, or both. In fact, operating time and active repair time are representative of reliability and reparability and are related through the concept of intrinsic availability.

6.4.9.4 Logistic Time

Logistic time is that portion of downtime during which a repair is held up because of procurement or replacement of a failed part or parts.

Logistic time is the time consumed by delays in repair due to the unavailability of replacement parts. This is a matter largely under the control of administration, although the requirements for replacements are determined by operating conditions and the built-in ability of the equipment to withstand operating stress levels. Policies determined by management and procurement personnel can, if properly developed, minimize logistic time. Therefore, the responsible administrative officials in this area are likely to be different from those who most directly influence the other time categories.

6.4.9.5 Administrative Time

Administrative time is that portion of the total downtime that is not included under active repair time and logistic time. This is the time lost on account of necessary administrative activities and unnecessarily wasted time in organizing a system repair.

The administrative time category is almost entirely determined by administrative decisions concerning the processing of records and the personnel policies governing maintenance engineers, technicians, and those engaged in associated clerical activities. Establishing efficient methods of monitoring processing, and analyzing repair activities is the responsibility of administration. In addition, administration time has been defined to include time wasted due to bottlenecks in executing the responsibility of administration. It is independent of engineering activities as such, and is also does not concern the manufacturer of equipment.

6.4.9.6 Free Time

Free time is the time during which the system is idle and is not operational. This time may or may not be downtime, depending on whether or not the system is in an operable condition.

6.4.9.7 Storage Time

Storage time is the time during which the system is presumed to be in good condition (and can be put to use), but is being held as a spare for emergency.

It may be noted here that while the system effectiveness is dependent upon all of the time elements, the design adequacy does not involve any of them.

6.5 Life-cycle Costs (LCC)

All expected costs incurred during the entire life of a product discounted to obtain the present value at a given level of reliability forms the part of life-cycle cost (LCC) analysis. It is well known that we can engineer survivability into a product at the design stage, if adequate resources are available. Generally, survivability costs, which include quality and reliability costs, can be split into two parts, *viz.*, c*ontrollable costs* and r*esultant costs*.

The controllable costs are the costs that are incurred on planned activities that are necessary to ensure quality and reliability, inspection and testing costs being included in these costs. The remaining costs are unplanned costs on account of not achieving the desired levels of quality and reliability. These include *internal failures* costs and *external failures* costs. External failures costs result from failures after the product is delivered to the customer, whereas the internal costs are the costs incurred on account of failures before the shipment of a product. If the manufacturer intends to stay in business, not only he is required to optimize LCC and profits but also customer satisfaction.

Usually, manufacturer costs consist of reliability design costs (including, planning, inspection and life testing training and management cost, and research and development costs), internal failure costs (including yield loss scrap and wastage, diagnostic costs, repair and rework operations, and loss of time and wages), and the external costs (including after-scale service and repair costs, replacement, warrantee costs and costs of loss of reputation). It may be observed that any effort to increase the reliability of a product will increase

quality and reliability costs, however the internal-failure costs would increase. The external costs would also decrease with an increase in the reliability of a product.

On the other hand, customer satisfaction depends on initial cost, operating cost, maintenance cost, failure and associated costs, and depreciation cost. The sum total of the above costs is called the *life-cycle cost* of a product and is often several times greater than the basic purchase cost of a product. One way of expressing customer product satisfaction can be in terms of the benefit/cost ratio, also known as the product value, is given by

$$Product Value = \frac{performance\ and\ /\ or\ service}{total\ life - cycle\ costs},$$

where the performance of the product can be assessed in terms of the reliability or one or more of its allied characteristics, such as quality, availability, MTTF, *etc*.

6.6 System Worth

In designing a system, the economics of building that system must always be considered. Every system has certain intended functions to perform at minimum cost. The total cost of ownership (including initial and operating costs for the service life of the equipment) can be substantially reduced if proper attention is given to factors like reliability and maintainability right at the early design stage of the system. These considerations, therefore, lead to the concept of *system worth*, and relate system effectiveness to total cost, scheduling, and personnel requirements. To optimize system worth, program managers face a difficult task of striking balances in maximizing system effectiveness while minimizing the total cost, development time, and personnel requirements.

6.7 Safety

The general definition of *safety* is the condition of being protected against physical, social, spiritual, financial, political, emotional, occupational, psychological, educational or any other types of consequences arising from failure, damage, error, accidents, harm or any other event that could be considered *undesirable*. This can take the form of being protected from an event or from exposure to something that can cause health or economical losses. It can include protection of people or of possessions. There are also two slightly different notions of *safety*, namely, a *safety home* may indicate its ability to protect against any external harmful events, and the second that its internal installations are safe (not dangerous/harmful) for its habitants or users. Safety is generally interpreted as implying a real and significant impact on the risk of death, injury or damage to property. In response to perceived risks many interventions may be proposed, with engineering responses and regulation being two of the most common.

It is important to distinguish between products that meet standards that are safe and those that merely feel safe.

Normative safety is a term used to describe products or designs that meet applicable design standards.

Substantive safety means that the real-world safety history is favorable, whether or not standards are met.

Perceived safety refers to the level of comfort of users. For example, traffic signals are perceived as safe, yet under some circumstances they can increase traffic crashes at an intersection. Probably the most common individual response to perceived safety issues is insurance, which compensates for or provides restitution in the case of damage or loss of property.

6.7.1 Plant Accidents

A complex system or a plant constitutes several kinds of subsystems. It is usually a failure of some small part somewhere in a system or a plant that leads to an accident of enormous consequences. In reality a wide variety of failures, errors and events can occur in complex and potentially hazardous plants and these usually occur on account of logical interactions between human operators and

the system or plant. Some of these interactions can be listed by arguing "why", "how", "when", and "where" of failures. In fact, these interactions can occur at any instant or time during the plant life; *viz.*, during sitting, design, manufacturing, construction, commissioning, and operation. It is generally believed that accidents occur as a result of failures during plant operations but this is too narrow a view. Failures can occur at any stage of system acquisition and operation or use. Broadly speaking, an accident may occur due to any of the following reasons:

New Technology: New technologies improve system functioning but may sometimes introduce some snags during the initial burn-in period or during the technology maturing period.

Location: The physical location of the system or plant including natural factors, such as geological and seismological conditions and potential for hydrological and meteorological disturbances, may affect plant safety. The release of toxic and flammable gases from chemical plants, and aircraft impact (if located in the air corridor) can also influence plant safety. In the case of such a release, air, food chains, ground water and water supplies provide pathways for the possible transport of hazardous materials to humans.

External Events: External events such as fire, floods, lightening, and earthquakes may also be responsible for major accidents. In such cases, the design of a system should be such that consequences of such an external event are minimized and cause minimal fatalities or loss of property.

Design: Accidents can also be caused by errors committed during research, development and demonstration phases, and while commercializing a design for an actual use. Design errors may be caused by short research, development and monitoring periods. A system deficiency can prove to be very costly once the design has been released for production and is manufactured and deployed, since the costs may not only include replacement and redesign costs, due to modifications but also include liability costs, and loss of user faith.

Manufacturing, Construction and Commissioning: Defects can be introduced when a system or a plant is being fabricated and constructed with deviations from the original design specifications and from fabrication/construction procedures or due to inadequate quality checks. Defects in design, manufacturing and construction stages may show up after commissioning and during the demonstration before it is made operational. A bug in the software package can also be an example of commissioning failures.

Operation: A system or plant operation can be categorized as *normal*, *operation during anticipated abnormal occurrences*, operation *during complex events below design basis*, and *operation during complex events beyond design basis*. Generally, physical barriers, normal control systems, emergency safety systems, and in-site and off-site emergency counter-measures protect all plants. For example, an emergency safety system in a nuclear reactor [1] operates when the plant state reaches a trip set point below the safety limit but above the operating range. The safety system can fail in two modes, *viz.*, *fail-safe* and *fail-dangerous*. Accident causation mechanisms can also be split into an *event layer* and *a likelihood layer*. Usually, event and fault trees analyses deal with the event layer. Recently, emphasis has been placed on the likelihood layer where management plays crucial role in managing occurrence probabilities, dependence of event and uncertainties associated with the events.

System safety [2] is constrained by physical containments and stabilization of an unstable phenomenon. In fact, accidents can be caused either by hardware failure, human error or external events. Generally, accidents are caused by any of the following reasons:

Failure of Physical Containment: All systems have built-in physical barriers or containment to prevent the release of hazardous materials or to prevent hazardous effects. As long as these containments do not fail, an accident of high consequence cannot take place. It is only when the containment fails that an accident occurs.

Failure of Safety Systems: All systems have adequate control systems during their normal

operations and safety systems and in-site and off-site emergency measures during an emergency. If anything goes wrong with the normal control system, incidents occur and if emergency safety systems fail to cope up with these incidents, a plant accident may occur. Finally, if in-site emergency measures fail to contain an accident, it invades into the environment and when off-site emergency measures fail to cope up with the invasion, this may cause serious consequences for the public and the environment.

Human Errors: Human errors constitute the vast majority of causes of major accidents. Sometimes hardware failure induces human errors, which may eventually lead to an accident. For example, a faulty indicator may cause wrong human intervention to cause an accident. Sometimes, system induced failures occur due to improper management caused by human and hardware failures.

Dependent Failures: A chain of failure events can be caused by dependency of failures due to sharing of a common environment or location.

6.7.2 Design for Safety

Safety engineers work on the early design of a system, analyze it to find what faults can occur, and then propose safety requirements in design specifications up front and changes to existing systems to make the system safer. In the early design stage, a fail-safe system can often be made acceptably safe with a few sensors and some software to read them. Probabilistic fault-tolerant systems can often be made by using more, but smaller and less expensive pieces of equipment. Far too often, rather than actually influencing the design, safety engineers are assigned to prove that an existing, completed design is safe. If a safety engineer then discovers significant safety problems late in the design process, correcting them can be very expensive.

Through safe design and better performance of systems, one can minimize the ecological impacts and associated losses. This also does not mean that we do not build these systems at all to avoid such accidents or hazards. We have work out the advantages accruing from these systems *vis-à-vis* the risk involved. Of course this opens up the question of an acceptable risk *vis-à-vis* employing the technologies that build the systems [3].

Safety has been considered important in the following cases:

- Design of the end product for safety
- Design of the manufacturing process for safety
- Design of the safety system

A safety system is defined as the total set of men, equipment and procedures specifically designed for the purpose of ensuring safety.

Safety and reliability are related engineering disciplines [4, 5] with many common statistical techniques. In fact safety has lot of mathematical techniques common with reliability, like fault trees, events trees, *etc*. Here we are concerned with statistical safety, which is one of the attributes of dependability related to other attributes like quality, reliability, availability, maintainability or in short survivability. These issues tend to determine the performance of any product, system or service, and a deficiency in any of these attributes is considered to result in lower dependability and higher cost. Besides the cost of addressing the problem, good management is also expected to minimize total cost.

Designing Engineering Systems for Sustainability

Peter Sandborn and Jessica Myers

CALCE, Department of Mechanical Engineering, University of Maryland, USA

Abstract: Sustainability means keeping an existing system operational and maintaining the ability to manufacture and field versions of the system that satisfy the original requirements. Sustainability also includes manufacturing and fielding revised versions of the system that satisfy evolving requirements, which often requires the replacement of technologies used in the original system with newer technologies. Technology sustainment analysis encompasses the ramifications of reliability on system management and costs via sparing, availability and warranty. Sustainability also requires the management of technology obsolescence (forecasting, mitigation and strategic planning) and addresses roadmapping, surveillance, and value metrics associated with technology insertion planning.

7.1 Introduction

The word "sustain"" comes from the Latin *sustenare* meaning "to hold up" or to support, which has evolved to mean keeping something going or extending its duration [1]. The most common non-specialized synonym for sustain is "maintain". Although maintain and sustain are sometimes used interchangeably, maintenance usually refers to activities targeted at correcting problems, and sustainment is a more general term referring to the management of system evolution.

Sustainability can mean static equilibrium (the absence of change) or dynamic equilibrium (constant, predictable or manageable change) [2]. The most widely circulated definition of sustainability (or more accurately sustainable development) is attributed to the Brundtland Report [3], which is often stated as "development that meets the needs of present generations without compromising the ability of future generations to meet their own needs." This definition was created in the context of environmental sustainability, however, it is useful for defining all types of sustainability. Although the concept of sustainability appears throughout nearly all disciplines, we will only mention the most prevalent usages here.

Environmental Sustainability is the ability of an ecosystem to maintain ecological processes and functions, biological diversity, and productivity over time [4]. The objective of environmental sustainability is to increase energy and material efficiencies, preserve ecosystem integrity, and promote human health and happiness by merging design, economics, manufacturing and policy.

Business or Corporate Sustainability refers to the increase in productivity and/or reduction of consumed resources without compromising

product or service quality, competitiveness, or profitability. Business sustainability is often described as the triple bottom line (3BL) [5]: financial (profit), social (people) and environmental (planet). A closely related endeavor is "sustainable operations management", which integrates profit and efficiency with the company's stakeholders and the resulting environmental impacts [6].

Technology Sustainment refers to all activities necessary to a) keep an existing system operational (able to successfully complete its intended purpose), b) continue to manufacture and field versions of the system that satisfy the original requirements, and c) manufacture and field revised versions of the system that satisfy evolving requirements. The term "sustainment engineering" is sometimes applied to technology sustainment activities and is the process of assessing and improving a system's ability to be sustained by determining, selecting and implementing feasible and economically viable alternatives [7]. For technology sustainment, "present and future generations" in the Brundtland definition can be interpreted as the users and maintainers of a system.

This chapter focuses on the specific and unique activities associated with technology sustainability.

7.1.1 Sustainment-dominated Systems

In the normal course of product development, it often becomes necessary to change the design of products and systems consistent with shifts in demand and with changes in the availability of the materials and components from which they are manufactured. When the content of the system is technological in nature, the short product life cycle associated with fast moving technology changes becomes both a problem and an opportunity for manufacturers and systems integrators.

For most high-volume, consumer oriented products and systems, the rapid rate of technology change translates into a critical need to stay on the leading edge of technology. These product sectors must adapt the newest materials, components, and processes in order to prevent loss of their market share to competitors. For leading-edge products, updating the design of a product or system is a question of balancing the risks of investing resources in new, potentially immature technologies against potential functional or performance gains that could differentiate them from their competitors in the market. Examples of leading-edge products that race to adapt to the newest technology are high-volume consumer electronics, *e.g.*, mobile phones and PDAs.

There are, however, significant product sectors that find it difficult to adopt leading-edge technology. Examples include airplanes, ships, computer networks for air traffic control and power grid management, industrial equipment, and medical equipment. These product sectors often "lag" the technology wave because of the high costs and/or long times associated with technology insertion and design refresh. Many of these product sectors involve "safety critical" systems where lengthy and expensive qualification/ certification cycles may be required even for minor design changes and where systems are fielded (and must be maintained) for long periods of time (often 20 years or more). Because of these attributes, many of these product sectors also share the common attribute of being "sustainment-dominated", *i.e.*, their long-term sustainment (life cycle) costs exceed the original procurement costs for the system.

Some types of sustainment-dominated systems are obvious, *e.g.*, Figure 7.1 shows the life cycle cost breakdown for an F-16 military aircraft where only 22% of the life cycle cost of the system is associated with design, development and manufacturing (this 22% also includes deployment,

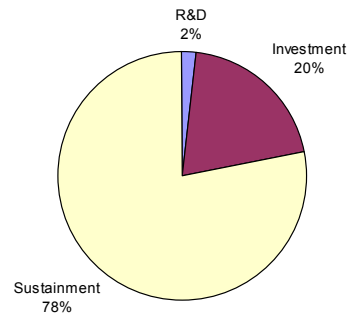

Figure 7.1. Cost breakdown for an F-16, [8]

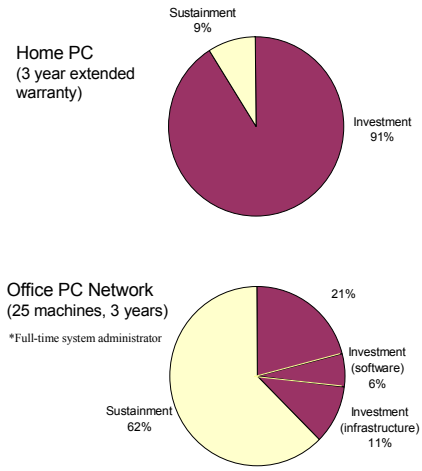

Figure 7.2. Life cycle cost breakdown of PCs, [9, 10]

training, and initial spares). The other 78% is operation and support and includes all costs of operating, maintaining, and supporting, *i.e.*, costs for personnel, consumable and repairable materials, organizational, intermediate and depot maintenance, facilities, and sustaining investment.

Sustainment-dominated systems are not necessarily confined to just the military or other exotic technology systems. Consider the systems shown in Figure 7.2. Obviously, a home PC is not sustainment-dominated, however, an office network of PCs (once you account for system administration) can quickly become a sustainment-dominated system. In fact, when one considers the cyclical "upgrade trap" that is often forced upon PC users (Figure 7.3), the effective sustainment cost of an individual PC and an office PC network may be even larger.

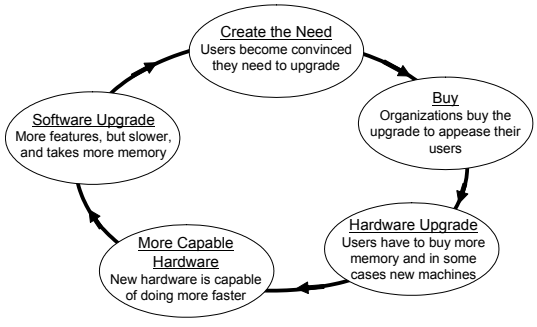

Figure 7.3. Cyclical upgrade trap commonly experienced by PCs and PC networks

The upgrade trap is indiscriminant, even users who derive no actually benefit from higher performance hardware or greater functionality software, are forced to "keep up" whether they want to or not. Even systems that are seemingly disconnected from commercial interests such as weapons systems are impacted, *e.g.*, if these systems contain COTS (commercial off-the-shelf) application software, the application may require the operating system to be upgraded, *etc*.

The one thing that is worse than being caught in the upgrade trap, is not being caught in the upgrade trap, *i.e.*, many sustainment-dominated systems get caught in the "sustainment vicious circle" (also called the DoD death spiral) – Figure 7.4. In this case, more money is going into sustainment at the determent of new investment, which causes the systems to age, which in turn causes more money to be required for sustainment, which leaves less money for new investment, *etc.* The sustainment vicious circle is a reality for militaries of many of the world's countries. On a smaller scale, individuals might face this dilemma with their automobile – fixing your existing car is expensive, but it is less expensive than buying a new car; after several such repairs one is left to wonder if purchasing a new car would have been less expensive, but there is no turning back, too much has been invested in repairing the old car.

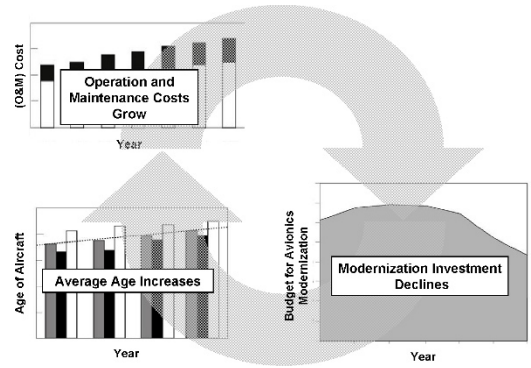

Figure 7.4. Sustainment vicious circle, a.k.a., the DoD death spiral for aircraft avionics [11]

7.1.2 Technology Sustainment Activities

Technology sustainment activities range from automobile oil changes every 3,000 miles and timing belt replacement in a car after 60,000 miles, to warranty repair of a television and scheduled maintenance of a commercial aircraft engine. There are also less obvious sustainment activities that include time spent with technical support provided by a PC manufacturer via telephone or email, installation of an operating system upgrade, or addition of memory to an existing PC to support a new version of application software. The various elements involved in sustainment include:

- Reliability
- Testability
- Diagnosability
- Repairability
- Maintainability
- Spares
- Availability
- Cross-Platform Applicability
- Obsolescence
- Warranty/guarantee
- Qualification/ certification
- Configuration control
- Regression testing
- Upgradability
- Total cost of ownership
- Technology infusion/insertion

Obviously, the relevancy of sustainment activities varies depending on the type of system. For "throw-away" products such as a computer mouse or keyboard, sustainment primarily translates into warranty replacement. For consumer electronics, such as televisions, sustainment is dominated by repair or warranty replacement upon failure. Demand-critical electronics (availability sensitive systems), such as ATM machines and servers, include some preventative maintenance, upgrades, repair upon failure, and sparing. Long field life electronics, such as avionics and military systems, are aggressively maintained, have extensive built in test and diagnosis, are repaired at several different levels, and are continuously upgraded.

This chapter cannot practically cover all the topics that make up technology sustainment. We will not focus on reliability (reliability is the topic of many books and addressed in several other chapters within this book). Neither will we focus on testability or diagnosability since these are also the topics of other books and journals. Rather, we will concentrate on the ramifications of reliability on system management and costs via sparing, availability and warranty (Section 7.2). Section 7.3 treats technology obsolescence and discusses forecasting, mitigation and strategic planning. Section 7.4 addresses technology insertion.

7.2 Sparing and Availability

Reliability is possibly the most important attribute of a system. Without reliability, the value derived from performance, functionality, or low cost cannot be realized. The ramifications of reliability on the system life cycle management are linked to life cycle cost through sparing requirements and warranty return rates, and measured by system availability.

Reliability is the probability that an item will not fail. Maintainability is the probability that the item can be successfully restored to operation after failure; and availability provides information about how efficiently the system is managed and is a function of reliability and maintainability.

7.2.1 Item-level Sparing Analysis

When a system encounters a failure, one of the following things happens:

- Nothing – a workaround for the failure is implemented and operation continues or the system is disposed of and the functionality or role that the system performed is accomplished another way or deleted.
- The system is repaired – if your car has a flat tire, you do not dispose of the car, and you may not dispose of the tire either, you fix the tire.
- The system is replaced – at some level, repair is impractical and the failing portion of the system is replaced; if an IC in your laptop computer fails, you cannot repair a problem inside the IC, you have to replace the IC.

If a tire on your car blows out on the highway and is damaged to such an extent that it cannot be repaired, you have to replace it. What do you replace the flat tire with? If you have a replacement (spare) in your trunk, you can change the tire and be on your way quickly. If you do not have a replacement you have to either have a replacement brought to the car or you have to have the car towed to some place that has a replacement. If no one has a replacement, someone has to manufacture one for you.

Spare tires exist and are carried in cars because the "availability" of a car is important to the car's driver, *i.e.*, having your car unavailable to you because no spare tire exists is a problem, you cannot get to work, you cannot take the children to school, *etc*. If you are an airline, having an airplane unavailable to carry passengers (thus not earning revenue) because a spare part does not exist or is in the wrong location can be a very costly problem. Therefore, *spares* are manufactured and available for use for many types of systems.

There are several issues with spares that make sparing analysis challenging:

- How many spares do you need to have? I do not want to manufacture 1000 spares if I will only need 200 to keep the system operational (available) at the required rate.
- When are you going to need the spares? The number of spares I need is a function of time (or miles, or other accumulated environmental stresses), *i.e.*, as systems *age,* the number of spares needed may increase. When should I manufacture the spares (with the original production or later)? What if I run out and have to manufacture more spares?
- Where the spares should be kept? Spares need to be available where systems fail, not 3000 miles away. When I have a flat tire, is a spare tire more useful in my garage or in the trunk of my car?
- What level (in a system) do you want to spare at? It makes sense to carry a spare tire in my trunk, but it does not make sense to carry a spare transmission in the trunk, why? Because transmissions do not fail as frequently as tires, transmissions are large and heavy to carry, and one may not have the tools, or expertise to install a new transmission on the side of the road.

Spare part quantities are a function of demand rates and are expected to [12]:

- cover actual item replacements occurring as a result of corrective and preventative maintenance actions,
- compensate for repairable items in the process of undergoing maintenance,
- compensate for the procurement lead times required for replacement item acquisition, and
- compensate for the condemnation or scrappage of repairable items.

In order to explore how spare quantities are determined, we first need to review simple reliability calculations. Reliability is given in terms of time (t) by,

$$R(t) = 1 - \int_0^t f(t)dt . \qquad (7.1)$$

The reliability, R(t), is the probability of no failures in time t. If the time to failure, f(t), follows an exponential distribution,

$$f(t) = \lambda e^{-\lambda t}, \qquad (7.2)$$

where λ is the failure rate (λ = 1/MTBF, MTBF = mean time between failure), then the reliability becomes,

$$R(t) = 1 - \int_0^t \lambda e^{-\lambda t} dt = 1 + e^{-\lambda t}\Big|_0^t = e^{-\lambda t} . \qquad (7.3)$$

Equation (7.3) is the probability of exactly 0 failures in time t. This result can be generalized to give the probability of exactly x failures in time t,

$$P(x) = \frac{(\lambda t)^x e^{-\lambda t}}{x!} . \qquad (7.4)$$

So, for x = 0, $P(0) = e^{-\lambda t}$ (the result in Equation (7.3)), for x = 1, $P(1) = \lambda t e^{-\lambda t}$, *etc*. For a unique system with no spares, the probability of surviving to time t is P (0). For a unique system with exactly

one spare available, the probability of surviving to time t is given by,

$$P(0) + P(1) = e^{-\lambda t} + \lambda t e^{-\lambda t}, \qquad (7.5)$$

or in general,

$$P(x \le k) = \sum_{x=0}^{k} \frac{(\lambda t)^x e^{-\lambda t}}{x!}. \qquad (7.6)$$

Equation (7.6) is the cumulative Poisson probability, *i.e.*, the probability of k or fewer failures in time t. This is the probability of surviving to time t with k spares, or, k is the minimum number of spares needed in order to have a confidence level of $P(x \le k)$ that the system will survive to time t.

The derivation of (7.6) assumes that there is only one instance of the spared item in service, if there are n instances in service, then (7.6) becomes [13],

$$P(x \le k) = \sum_{x=0}^{k} \frac{(n\lambda t)^x e^{-n\lambda t}}{x!}, \qquad (7.7)$$

where,

k = number of spares
n = number of unduplicated (in series, not redundant) units in service
λ = constant failure rate (exponential distribution of time to failure) of the unit *or* the average number of maintenance events expected to occur in time t
t = given time interval
$P(x \le k)$ = probability that k is enough spares *or* the probability that a spare will be available when needed
nλt = system unavailability.

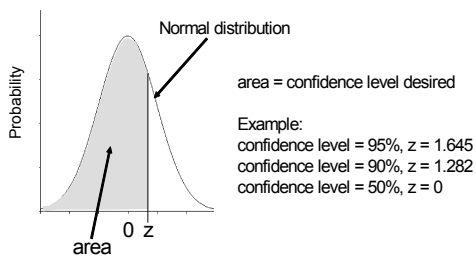

Figure 7.5. Relationship between z and confidence level

When k is large, the Poisson distribution can be approximated by the normal distribution and k can be approximately calculated in closed form,

$$k \cong \left\lceil n\lambda t + z\sqrt{n\lambda t} \right\rceil, \qquad (7.8)$$

where z is the number of standard deviations from the mean of a standard normal distribution, Figure 7.5. Equation (7.8) is only applicable when times between failures are exponentially distributed, and the recovery/repair times are independent and exponentially distributed.

Figure 7.6 shows a simple example sparing calculation performed using (7.7) and (7.8). For the example data shown in Figure 7.6 a simple approximation for the number of required spares is: the MTBF = $1/\lambda = 2\text{x}10^6$ hours and the unit has to be supported for t = 1500 hours; $1500/2\text{x}10^6$ = 0.0008 spares per unit; therefore, for n = 25,000 units, the total number of spares needed is (25000)(0.0008) = 18.75. Rounding up to19 spares, Figure 7.6 indicates that for the simple approximation, there is a 58% confidence that 19 are enough spares to last 1500 hours.

There are several costs associated with carrying spares:

- Cost of manufacturing spares.
- Cost of money tied up in manufactured spares for future use – spares for the future may have to be made now before the required components become obsolete (see Section 7.3).

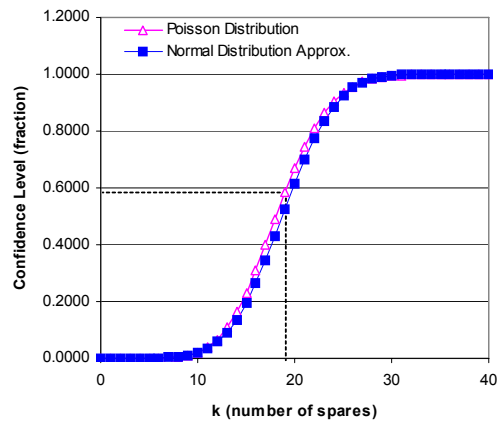

Figure 7.6. Sparing calculation for n = 25000, t = 1500 hours, and λ = 0.5 failures/million hours

- Cost of transporting spares to where they are needed (or conversely the cost of transporting the system to the location where the spares are kept).Cost of storing spares until needed.
- Cost of replenishing spares if they run out.
- Cost of system availability impacts due to spares not being in the right place at the right time.

The simple "item-level availability method" performed in this section ((7.7) and (7.8)) determines recommended quantities of spares based on only demand rates and the confidence in having a spare item available. The difficulty with the item-level availability approach is the following: if I have a 95% confidence that each item within a system has a spare available when needed, what is the availability of a system containing 100 different items? In other words, the calculation so far only determines the number of required spares one item at a time, and ignores interactions between multiple items that make up a system, *i.e.*, it assumes that all the items that make up a system can be spared independently. In order to address system-level sparing, we must first consider availability.

7.2.2 Availability

Availability is the probability that system will be able to function (*i.e.*, not failed or undergoing repair) when called upon to do so. Availability is a function of a system's reliability (how quickly it fails) and its maintainability (how quickly it can be replaced or repaired when it does fail). Availability is closely tied to many of the issues associated with sparing.

Many types of systems care about availability. For example, bank ATM machines, communications systems such as 911 systems, airlines, and military systems. Recently, a large customer claimed the cost of downtime on their point-of-sale verification systems was on the order of $5M/minute [14] – obviously in this case, the availability of the point-of-sale verification system is probably a more important characteristic than the system's price. The United States Department of Defense is adopting a new approach for the management and acquisition of systems. "Performance based logistics" (PBL) is the purchase of support as an integrated, affordable, performance package designed to optimize system readiness and meet performance goals for a system through long-term support arrangements with clear lines of authority and responsibility. Simply put, performance-based strategies would be "buy outcomes, not products or services" [15]. Although PBL implies many things, at its core it is essentially a shift from purchasing systems and then separately purchasing their support, to purchasing the availability of systems.

There are several different types of availability that can be evaluated. Generally, availability is classified either according to the time interval considered, or the type of down time [16]. Time-interval availabilities are characterized as the probability that the system will be available at a time t (instantaneous or point availability), proportion of time available within a specified interval of time (average up-time availability), or the limit as $t\to\infty$ of the average up-time availability (steady-state availability). Alternatively, down-time classified availability includes: only corrective maintenance (inherent availability), corrective and preventative maintenance (achieved availability), and operational availability. In operational availability, down time includes contributions from a broader set of sources than other types of availability,

$$\begin{aligned}\text{Availability}_{\text{operational}} &= \frac{\text{Up time}}{\text{Total time}} = \frac{\text{Up time}}{\text{Up time} + \text{Down time}} \\ &= \frac{\text{Average up time}}{\text{Average up time} + \text{Average down time}}, \\ &= \frac{\text{MTBM}}{\text{MTBM} + \text{MDT}}\end{aligned} \tag{7.9}$$

where

MTBM = mean time between maintenance actions (corrective and preventative)

MDT = mean down time.

Figure 7.7 shows a summary of the elements that could be included within an operational availability calculation.

There are potentially significant life cycle costs associated directly with availability including: loss sales (point-of-sale systems), loss of capacity (in a

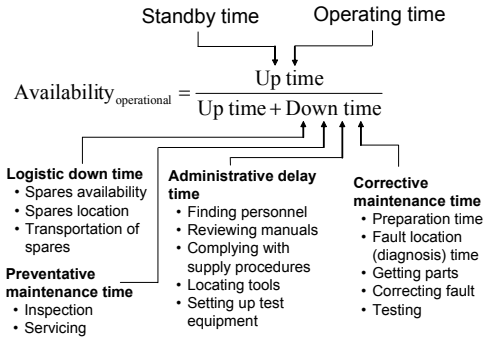

Figure 7.7. Elements included within an operational availability calculation (after [17])

manufacturing operation), loss of customer confidence (*e.g.*, airlines), and loss of mission/assets (military). In addition, many military contracts are now written with availability clauses in them, *e.g.*, the fraction of the contract price paid to the supplier is a function of the availability of the product that the customer actually experiences.

7.2.3 System-level Sparing Analysis

In order to perform a system-level sparing analysis, the number of spares is minimized subject to a required minimum operational availability (alternatively, the availability can be maximized for a fixed set of spares). This type of minimization has been performed numerous ways (*e.g.*, [18–20]). One approach is to compute the number of backorders (expected number of demands that cannot be filled because of lack of spares) [20]. The number of backorders is inversely related to the system availability. It has been shown that if the number of backorders is minimized, the system availability will be maximized [20]. The number of backorders, BO, for exactly x failures with k spares available is given by,

$$BO(x|k) = (x - k). \qquad (7.10)$$

The expected (mean) number of backorders (EBO) for k spares is then given by,

$$EBO(k) = \sum_{x=k+1}^{\infty} (x - k) P(x). \qquad (7.11)$$

Operational availability is the expected fraction of systems that are operational, *i.e.*, not waiting for a spare; and a particular version of operational availability is supply availability, which is computed by approximating MDT as MSD (mean supply delay time) in Equation 7.9. The supply availability can be computed as a function of the expected number of backorders [20],

$$\text{Availability}_{\text{supply}} = \prod_{i=1}^{I} \left(1 - \frac{EBO_i(k_i)}{NZ_i}\right)^{Z_i}, \qquad (7.12)$$

where

$EBO_i(k_i)$ = expected number of backorders for item i with k_i spares
N = number of systems
Z_i = number of instances of item i in the system
I = number of different items in the system.

In Equation 7.12, there are NZ_i instances of item i installed, the probability that one of those fails is $EBO_i(k_i)/NZ_i$, a system is available only if there are no failures (1-…) in all of the Z_i instances of item i in the system (the Z_i exponent), or for any other items (the product of I items).

Consider the example provided in Figure 7.6: λ = 0.5 failures/million hours, if there are k = 0 spares and t = 6 million hours, (7.11) predicts EBO(0) = 3 (3 = (0.5)(6)). If k = 1, then EBO(1) = 2.05 (note, as the number of spares increases, EBO decreases but never gets to zero because the time to failure follows an exponential distribution, (7.2), *i.e.*, it is not exactly 2 million hours ($1/\lambda$) for every instance of every item in every system). If N = 1000, I = 100, and Z_i = 2 (assuming that all the different items in the system have the same reliability and number of instances), then equation (7.12) predicts a supply availability of 81.4%. Conversely, for a minimum required availability, the number of spares, k_i, of ith items in the system can be varied until availability greater than the minimum is obtained.

7.2.4 Warranty Analysis

A warranty is a manufacturer's assurance to a buyer that a product or service is or shall be as represented. A warranty is considered a contractual

agreement between the buyer and the manufacturer entered into upon sale of the product or service. In broad terms, the purpose of a warranty is to establish liability among two parties (manufacturer and buyer) in the event that an item fails. This contract specifies both the performance that is to be expected and the redress available to the buyer if a failure occurs [21].

Warranty cost analysis is performed to estimate the cost of servicing a warranty (so that it can be properly accounted for in the sales price or maintenance contract for the system). Similar to sparing analysis, warranty analysis is focused on determining the number of expected system failures during some period of operation (the warranty period) that will result in a warranty action. Unlike, sparing analysis, warranty analysis does not base its sparing needs on maintaining a specific value for system availability, but only servicing all the warranty claims.

Warranties do not assume that failed items need to be replaced (they may be repairable). Those items that are not repairable need replacement and therefore need spares. Spares may also be needed as "loaners" during system repair.

Warranty analysis differs from sparing in two basic ways. First, warranty analysis usually aims to determine a warranty reserve cost (the total amount of money that has to be reserved to cover the warranty on a product). The cost of servicing an individual warranty claim may vary depending on the type of warranty provided. The simplest case is an unlimited free replacement warranty in which every failure prior to the end of the warranty period is replaced or repaired to its original condition at no charge to the customer. In this case, the warranty reserve fund (ignoring the cost of money) is given by,

$$C_{wr} = C_{fr} + nkC_c, \tag{7.13}$$

where,

- n = quantity of product sold
- C_{fr} = fixed cost of providing warranty coverage
- C_c = recurring replacement/repair cost per produce instance
- k = number of warranty actions, *i.e.*, $\cong \lambda T_w$ or determined from Equations (7.7) or (7.8)
- T_w = length of the warranty.

Other types of warranties also exist. For example some warranties are *pro-rata* – whenever a product fails prior to the end of the warranty period, it is replaced at a cost that is a function of the item's age at the time of failure. If θ is the product price including the warranty then (following a linear depreciation with time), $\theta\left(1-\frac{t}{T_w}\right)$ is the amount of money rebated to a customer for a failure at time t. In this case, the total cost of servicing the warranty assuming a constant failure rate is given by,

$$C_{wr} = \int_0^{T_w} \theta\left(1-\frac{t}{T_w}\right) n\lambda e^{-\lambda t} dt = n\theta\left(1-\frac{1}{\lambda T_w}\left(1-e^{-\lambda T_w}\right)\right). \tag{7.14}$$

Consider a manufacturer of television sets who is going to provide a 12 month *pro-rata* warranty. The failure rate of the televisions is $\lambda = 0.004$ failures per month, n = 500,000, the desired profit margin is 8%, and the recurring cost per television is $112; what warranty reserve fund should be put in place? From Equation (7.14), $C_{wr}/\theta = 11{,}800$. Assuming that the profit margin is on the recurring cost of the television and its effective warranty cost, θ is given by,

$$\theta = (\text{profit margin} + 1)\left(\text{recurring cost} + \frac{C_{wr}}{n}\right), \tag{7.15}$$

and solving for C_{wr} gives $1,464,659, or $2.93/television to cover warranty costs.

The warranty reserve funds computed in Equations (7.13) and (7.14) assume that every warranty action is solved by replacement of the defective product with a new item. If the defective product can be repaired, than other variations on simple warranties can be derived, see [22].

A second way that warranties differ from sparing analysis is that the period of performance (the period in which expected failures need to be counted) can be defined in a more complex way. For example, two-dimensional warranties are common in the automotive industry – 3 years or 36,000 miles, whichever comes first. A common way to represent a two-dimensional warranty is shown in Figure 7.8. Note, many other more

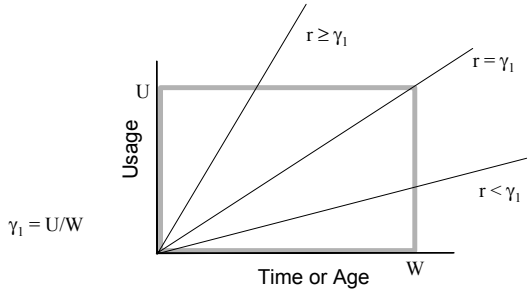

Figure 7.8. A representation of a two-dimensional free-replacement warranty policy

complexly shaped two-dimensional warranty schemes are possible, see [23]. In Figure 7.8, W is the warranty period and U is the usage limit, *i.e.*, unlimited free replacement up to time W or usage U, whichever occurs first from the time of initial purchase. r is called the usage rate (usage per unit time). The warranty ends at U (if r ≥ γ1) or W (if r < γ1). Every failure that falls within the rectangle defined by U and W requires a warranty action. As a result, modeling the number of failures that require warranty actions involves either a bivariate failure model (*e.g.*, [23]), or a univariate model that incorporates the usage rate appropriately (*e.g.*, [24]).

7.3 Technology Obsolescence

A significant problem facing many "high-tech" sustainment-dominated systems is technology obsolescence, and no technology typifies the problem more than electronic part obsolescence, where electronic parts refers to integrated circuits and discrete passive components. In the past several decades, electronic technology has advanced rapidly causing electronic components to have a shortened procurement life span, *e.g.*, Figure 7.9. QTEC estimates that approximately 3% of the global pool of electronic components goes obsolete every month, [26]. Driven by the consumer electronics product sector, newer and better electronic components are being introduced frequently, rendering older components obsolete. Yet, sustainment-dominated systems such as aircraft avionics are often produced for many years

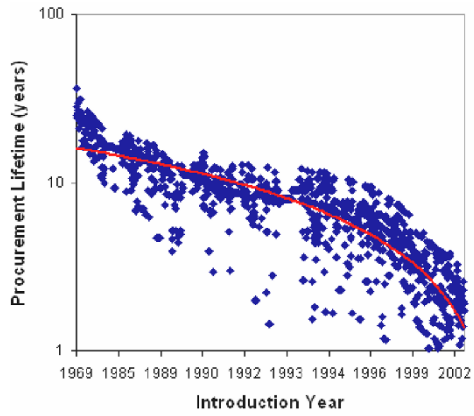

Figure 7.9. Decreasing procurement lifetime for operational amplifiers, [25]. The procurement life is the number of years the part can be procured from its original manufacturer

and sustained for decades. In particular, sustainment-dominated products suffer the consequences of electronic part obsolescence because they have no control over their electronic part supply chain due to their low production volumes. The obsolescence problem for sustainment-dominated systems is particularly troublesome since they are often subject to significant qualification/certification requirements that can make even simple changes to a system prohibitively expensive. This problem is especially prevalent in avionics and military systems, where systems often encounter obsolescence problems before they are fielded and always during their support life, *e.g.*, Figure 7.10.

Obsolescence, also called DMSMS (diminishing manufacturing sources and material shortages), is defined as the loss or impending loss of original manufacturers of items or suppliers of items or raw materials. The key defining characteristic of obsolescence problems is that the products are forced to change (even though they may not need to or want to change) by circumstances that are beyond their control. The type of obsolescence addressed here is caused by the unavailability of technologies (parts) that are needed to manufacture or sustain a product. A different type of obsolescence called "sudden obsolescence" or "inventory obsolescence" refers

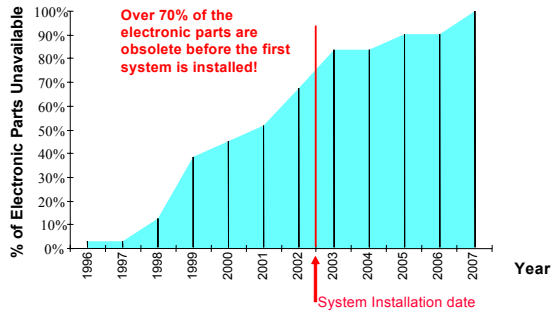

Figure 7.10. Percent of commercial off-the-shelf (COTS) parts that are un-procurable versus the first ten years of a surface ship sonar system's life cycle (courtesy of NAVSURFWARCENDIV Crane)

to the opposite problem in which inventories of parts become obsolete because the system they were being saved for changes so that the inventories are no longer required, see, *e.g.*, [27].

7.3.1 Electronic Part Obsolescence

Electronic part obsolescence began to emerge as a problem in the 1980s when the end of the Cold War accelerated pressure to reduce military outlays and lead to an effort in the United States military called *acquisition reform*. Acquisition reform included a reversal of the traditional reliance on military specifications ("mil-specs") in favor of commercial standards and performance specifications [28]. One of the consequences of the shift away from mil-specs was that mil-spec parts that were qualified to more stringent environmental specifications than commercial parts and manufactured over longer periods of time were no longer available, creating the necessity to use commercial off-the-shelf (COTS) parts that are manufactured for non-military applications and, by virtue of their supply chains being controlled by commercial and consumer products, are usually procurable for much shorter periods of time. Although this history is associated with the military, the problem it has created reaches much further, since many non-military applications depended on mil-spec parts, *e.g.*, commercial avionics, oil well drilling, and industrial equipment.

Most of the emphasis associated with methodology, tool and database development targeted at the management of electronic part obsolescence has been focused on tracking and managing the availability of parts, forecasting the risk of parts becoming obsolete, and enabling the application of mitigation approaches when parts do become obsolete. Most electronic part obsolescence forecasting is based on the development of models for the part's life cycle. Traditional methods of life cycle forecasting utilized in commercially available tools and services are ordinal scale based approaches, in which the life cycle stage of the part is determined from an array of technological attributes, *e.g.*, [29, 30], and are available in commercial tools such as TACTRAC™, Total Parts Plus™, and Q-Star™. More general models based on technology trends have also appeared including a methodology based on forecasting part sales curves [31], leading-indicator approaches [32], and data mining based solutions [33]. The OMIS tool, [34], consolidates demand and inventory, and combines it with obsolescence risk forecasting. A few efforts have also appeared that address non-electronic part obsolescence forecasting, *e.g.*, [35, 36].

7.3.2 Managing Electronic Part Obsolescence

Many mitigation strategies exist for managing obsolescence once it occurs [37]. Replacement of parts with non-obsolete substitute or alternative parts can be done as long as the burden of system re-qualification is not unreasonable. There are also a plethora of aftermarket electronic part sources ranging from original manufacturer authorized aftermarket sources that fill part needs with a mixture of stored devices (manufactured by the original manufacturer) and new fabrication in original manufacturer qualified facilities (*e.g.*, Rochester Electronics and Lansdale Semiconductor) to brokers and even eBay. Obviously buying obsolete parts on the secondary market from non-authorized sources carries its own set of risks [38]. David Sarnoff Laboratories operate GEM and AME, [39], which are electronic part emulation foundries that fabricate obsolete parts that meet original part qualification standards using newer technologies (BiCMOS gate arrays).

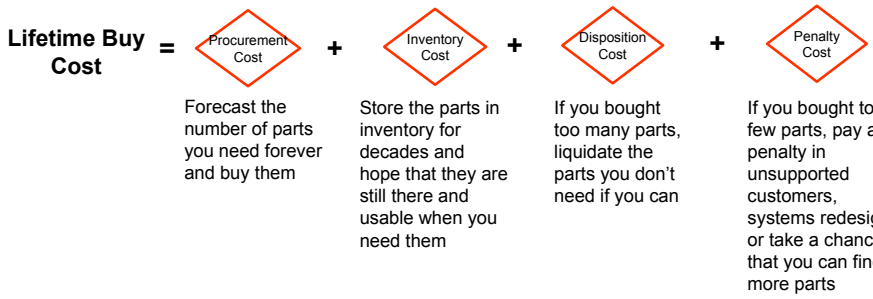

Figure 7.11. Lifetime buys made when parts are discontinued are a popular electronic part obsolescence mitigation approach, but are also plagued by uncertainties in demand forecasting and fraught with hidden costs

Thermal uprating of commercial parts to meet the extended temperature range requirements of an obsolete mil-spec part is also a possible obsolescence mitigation approach [40].

Most semiconductor manufactures notify customers and distributors when a part is about to be discontinued providing customers 6–12 months of warning and giving them the opportunity to place a final order for parts, *i.e.*, a "lifetime buy". Ideally, users of the part determine how many parts will be needed to satisfy manufacturing and sustainment of the system until the end of the system's life and place a last order for parts. The tricky problem with lifetime buys of electronic parts is determining the right number of parts to purchase. For inexpensive parts, lifetime buys are likely to be well in excess of forecasted demand requirements because the cost of buying too many is small and minimum purchase requirements associated with the part delivery format. However, for more expensive parts, buying excess inventory can become prohibitively expensive. Unfortunately, forecasting demand and sparing requirements for potentially 10–20 years or longer into the future is not an exact science, and predicting the end of the product life is difficult. Stockpiling parts for the future may also incur significant inventory and financial expenses. In addition, the risk of parts being lost, un-usable when needed, or used by another product group (pilfered), are all very real occurrences for electronic part lifetime buys that may need to reside in inventory for decades. Figure 7.11 shows lifetime buy cost drivers. A method of optimizing lifetime buys is presented in [41].

The obsolescence mitigation approaches discussed in the preceding paragraph are *reactive* in nature, focused on minimizing the costs of obsolescence mitigation, *i.e.*, minimizing the cost of resolving the problem after it has occurred. While reactive solutions will always play a major role in obsolescence management, ultimately, higher payoff (larger sustainment cost avoidance) will be possible through *strategic* oriented methodology/tool development efforts [42].

If information regarding the expected production lifetimes of parts (with appropriate uncertainties considered) is available during a system's design phase, then more strategic approaches that enable the estimation of lifetime sustainment costs should be possible, and even with data that is incomplete and/or uncertain, the opportunity for sustainment cost savings is still potentially significant with the application of the appropriate decision making methods.

Two types of strategic planning approaches exist: material risk indices and design refresh planning. Material risk index (MRI) approaches analyze a product's bill of materials and scores a supplier-specific part within the context of the enterprise using the part, *e.g.*, [43]. MRIs are used to combine the risk prediction from obsolescence forecasting with organization-specific usage and supply chain knowledge in order to estimate the magnitude of sustainment dollars put at risk within a customer's organization by the part's obsolescence. The other type of strategic planning approach is design refresh planning, which is discussed in the next section.

7.3.3 Strategic Planning – Design Refresh Planning

Because of the long manufacturing and field lives associated with sustainment-dominated systems, they are usually refreshed or redesigned one or more times during their lives to update functionality and manage obsolescence. Unlike high-volume commercial products in which redesign is driven by improvements in manufacturing, equipment or technology, for sustainment-dominated systems, design refresh is often driven by technology obsolescence that would otherwise render the product un-producible and/or un-sustainable.

Ideally, a methodology that determines the best dates for design refreshes, and the optimum mixture of actions to take at those design refreshes is needed. The goal of refresh planning is to determine:

- When to design refresh
- What obsolete system components should be replaced at a specific design refresh (*versus* continuing with some other obsolescence mitigation strategy)
- What non-obsolete system components should be replaced at a design refresh

Numerous research efforts have worked on the generation of suggestions for redesign in order to improve manufacturability. Redesign planning has also been addressed outside the manufacturing area, *e.g.*, general strategic replacement modeling, re-engineering of software, capacity expansion, and equipment replacement strategies. All of this work represents redesign driven by improvements in manufacturing, equipment or technology (*i.e.*, strategies followed by leading-edge products), not design refresh driven by technology obsolescence that would otherwise render the product un-producible and/or un-sustainable. It should also be noted that manufacturers and customers of sustainment-dominated systems have as much interested in "design refresh" as "redesign".[1]

The simplest model for performing life cycle planning associated with technology obsolescence (explicitly electronic part obsolescence) was developed by Porter [45]. Porter's approach focuses on calculating the net present value (NPV) of last time buys[2] and design refreshes as a function of future date. As a design refresh is delayed, its NPV decreases and the quantity (and thereby cost) of parts that must be purchased in the last time buy required to sustain the system until the design refresh takes place increases. Alternatively, if design refresh is scheduled relatively early, then last time buy cost is lower, but the NPV of the design refresh is higher. In the simplest form of a Porter model, the cost of the last time buy (C_{LTB}) is given by,

$$C_{LTB} = P_0 \sum_{i=0}^{Y_R} N_i \,, \tag{7.16}$$

where

P_0 = price of the obsolete part in the year of the lifetime buy (year 0)
Y_R = year of the design refresh (0 = present year, 1 = 1 year from now, *etc*.)
N_i = number of parts needed in year i.

Equation (7.16) assumes that the part becomes obsolete in year 0 and that the last time buy is made in year 0.

The design refresh cost for a refresh in year Y_R (in year 0 dollars), C_{DR}, is given by,

$$C_{DR} = \frac{C_{DRI_{Y_R}}}{(1+d)^{Y_R}} \,, \tag{7.17}$$

where

$C_{DRI_{Y_R}}$ = inflation adjusted design refresh cost in year Y_R
d = discount rate.

The total cost for managing the obsolescence with a year Y_R refresh is given by,

$$C_{Total} = C_{LTB} + C_{DR} \,. \tag{7.18}$$

[1] Technology refresh refers to changes that "have To be done" in order for the system functionality to remain useable. Redesign or technology insertion means "want to be done" system changes, which include new technologies to accommodate system functional growth and new technologies to replace and improve the existing functionality of the system, see [44].

[2] A last time buy (also called a bridge buy) means procuring and storing enough parts to sustain manufacturing and fielded units until the next design refresh.

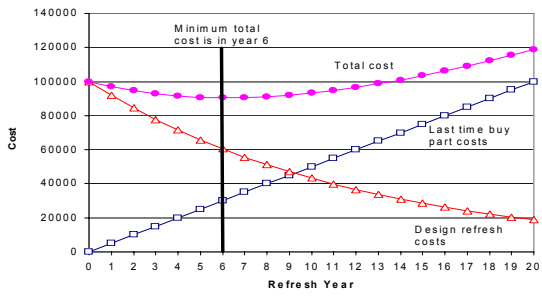

Figure 7.12. Example application of Porter's refresh costing model

Figure 7.12 shows a simple example using the Porter model. In this case C_{DRI_0} = \$100,000, d = 12%, N_i = 500 (for all i), P_0 = \$10 and an inflation rate of 3% was assumed. In this simple example, the model suggests that the optimum design refresh point is in year 6.

The Porter model performs its tradeoff of last time buy costs and design refresh costs on a part-by-part basis. While the simple Porter approach can be extended to treat multiple parts, and a version of Porter's model has been used to plan refreshes in conjunction with lifetime buy quantity optimization in [46], it only considers a single design refresh at a time. In order to treat multiple refreshes in a product's lifetime, Porter's analysis can be reapplied after a design refresh to predict the next design refresh, effectively optimizing each individual design refresh, but the coupled effects of multiple design refreshes (coupling of decisions about multiple parts *and* coupling of multiple refreshes) in the lifetime of a product are not accounted for, which is a significant limitation of the Porter approach.

A more complete optimization approach to refresh planning called MOCA has been developed that optimizes over multiple refreshes and multiple obsolescence mitigation approaches (the Porter model only considers last time buys) [47]. Using a detailed cost analysis model, the MOCA methodology determines the optimum design refresh plan during the field-support-life of the product. The design refresh plan consists of the number of design refresh activities, their content and respective calendar dates that minimize the life cycle sustainment cost of the product.

Figure 7.13 shows the MOCA design refresh planning timeline. Fundamentally, the model supports a design through periods of time when no parts are obsolete, followed by multiple part-specific obsolescence events. When a part becomes obsolete, some type of mitigation approach must take effect immediately: If sufficient inventory exists, a lifetime buy of the part is made or some other short-term mitigation strategy that only applies until the next design refresh. Next there are periods of time when one or more parts are

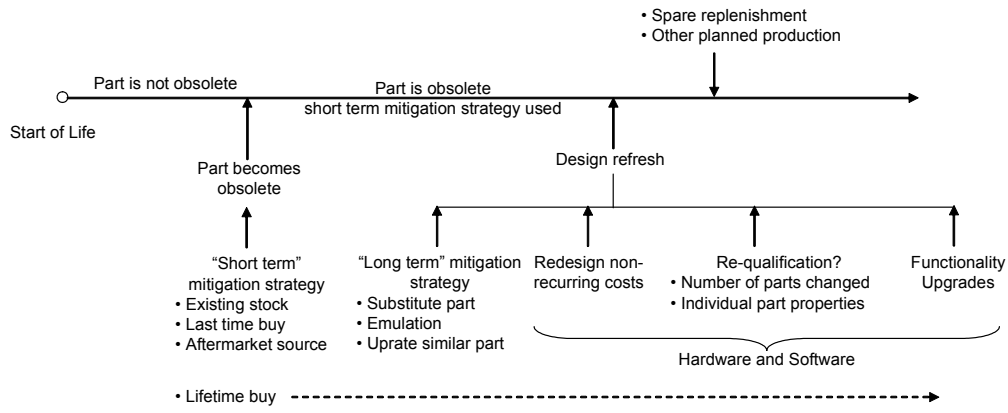

Figure 7.13. Design refresh planning analysis timeline (presented for one part only, for simplicity, however in reality, there are coupled parallel timelines for many parts, and design refreshes and production events can occur multiple times and in any order)

obsolete, and short-term mitigation approaches are in place on a part-specific basis. When design refreshes are encountered the change in the design at the refresh must be determined and the costs associated with performing the design refresh are computed. At a design refresh, a long-term obsolescence mitigation solution is applied (until the end of the product life or possibly until some future design refresh), and non-recurring, recurring, and re-qualification costs are computed. Re-qualification may be required depending on the impact of the design change on the application – the necessity for re-qualification depends on the role that the particular part(s) play and/or the quantity of non-critical changes made. The last activity appearing on the timeline is production. Systems often have to be produced after parts begin to go obsolete due to the length of the initial design/manufacturing process, additional orders for the system, and replenishment of spares.

The MOCA methodology can be used during either a) the original product design process, or b) to make decisions during system sustainment, *i.e.*, when a design refresh is underway, determine what the best set of changes to make given an existing history of the product and forecasted future obsolescence and future design refreshes. See [47], for refreshing planning analyses using MOCA.

7.3.4 Software Obsolescence [48]

In most complex systems, software life cycle costs contribute as much or more to the total life cycle cost as the hardware, and the hardware and software must be co-sustained. Software obsolescence is usually caused by one of the following:

1. Functional obsolescence: Hardware, requirements, or other software changes to the system, obsolete the functionality of the software (includes hardware obsolescence precipitated software obsolescence; *and* software that obsoletes software).
2. Technological obsolescence: The sales and/or support for COTS software terminates:
   - The original supplier no longer sells the software as new
   - The inability to expand or renew licensing agreements (legally unprocurable)
   - Software maintenance terminates – the original supplier and third parties no longer support the software
3. Logistical obsolescence: Digital media obsolescence, formatting, or degradation limits or terminates access to software.

Analogously, hardware obsolescence can be categorized similarly to software obsolescence: functional obsolescence in hardware is driven by software upgrades that will not execute correctly on the hardware (*e.g.*, Microsoft Office 2005 will not function on a 80486 processor based PC); technological obsolescence for hardware means that more technologically advanced hardware is available; and logistical obsolescence means that you can no longer procure a part.

Although some proactive measures can be taken to reduce the obsolescence mitigation footprint of software including: making codes more portable, using open-source software, and third-party escrow where possible; these measures fall short of solving the problem and it is not practical to think that software obsolescence can somehow be avoided. Just like hardware, military and avionics systems have little or no control over the supply chain for COTS software or much of the software development infrastructure they may depend upon for developing and supporting organic software. Need proof? Consider the following quote from Bill Gates [49]: "The only big companies that succeed will be those that obsolete their own products before someone else does." Obviously, Microsoft's business plan is driven by motivations that do not include minimizing the sustainment footprint of military and avionics systems.

In the COTS world, hardware and software have developed a symbiotic supply chain relationship where hardware improvements drive software manufactures to obsolete software, which in turn cause older hardware to become obsolete – from Dell and Microsoft's viewpoint, this is a win-win strategy. Besides COTS software (hardware specific and non-hardware specific), system sustainment depends on organic application software, software that provides infrastructure for

hardware and software development and testing, and software that exists at the interfaces between system components (enabling interoperability. While hardware obsolescence precipitated software obsolescence is becoming primarily an exercise in finding new COTS software (and more often COTS software and new hardware are bundled together), the more challenging software obsolescence management problem is often found at the interfaces between applications, applications and the operating system, and drivers. One particular class of functional obsolescence of software that is becoming increasingly troublesome for many systems is security holes.

In reality, obsolescence management is a hardware/software co-sustainment problem, not just a hardware sustainment problem. Software obsolescence (and its connection to hardware obsolescence) is not well defined and current obsolescence management strategic planning tools are not generally capable of capturing the connection between hardware and software. For additional information on various aspects of software obsolescence, readers are encouraged to refer to [50, 51].

7.4 Technology Insertion

Each technology used in the implementation of a system (*i.e.*, hardware, software, the technologies used to manufacture and support the system, information, and intellectual property) can be characterized by a life cycle that begins with introduction and maturing of the technology, and ends in some type of unavailability (obsolescence). The developers of sustainment-dominated systems must determine when to get off one technology's life cycle curve and onto another's in order to continue supporting existing systems and accommodate evolving system requirements, (Figure 7.14).

In order to manage the insertion of new technologies into a system, organizations need to maintain an understanding of technology evolution and maturity ("technology monitoring and forecasting"), measure the value of technology changes to their systems ("value metrics"), and build strategic plans for technology changes they wish to incorporate ("roadmapping").

7.4.1 Technology Monitoring and Forecasting

Attempts to predict the future of technology and to characterize its affects have been undertaken by many different organizations, which use many different terms to describe their forward-looking actions.

These terms include "technological intelligence", "technology foresight", "technology opportunities analysis (TOA)" [53], "competitive technological intelligence", and "technology assessment" [54]. These terms fall under two, more general umbrella terms: "technology monitoring" and "technology forecasting". To monitor is "to watch, observe, check and keep up with developments, usually in a well-defined area of interest for a very specific purpose" [55]. Technology monitoring is the process of observing new technology developments and following up on the

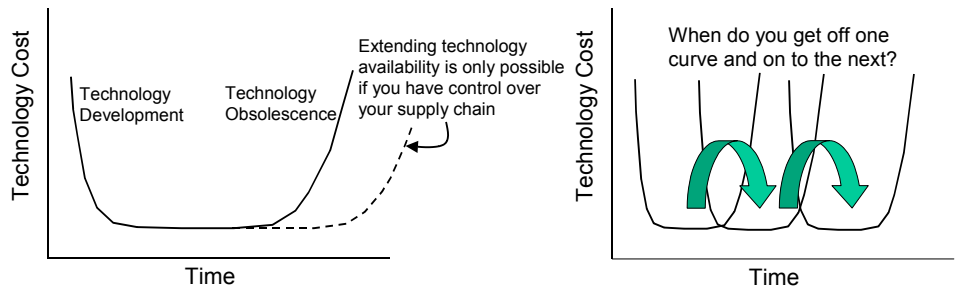

Figure 7.14. Supporting systems and evolving requirements [52]

developments that are relevant to an organization's goals and objectives. Technology forecasting, like technology monitoring, takes stock of current technological developments, but takes the observation of technology a step further by projecting the future of these technologies and by developing plans for utilizing and accommodating them.

For high-volume consumer oriented products, there are many reasons for organizations to monitor and forecast technological advances. First, when the organization's products are technologically-based, a good understanding of a nascent technology is needed as early as possible in order to take advantage of it. Additionally, monitoring and forecasting technology allows organizations to find applications for new technology [54], manage the technologies that are seen as threats, prioritize research and development, plan new product development, and make strategic decisions [56]. For manufacturers of sustainment-dominated products, monitoring and forecasting technology is of interest for the reasons listed above and also to enable prediction of obsolescence of the currently used technologies. The primary method for locating and evaluating materials relevant to technology monitoring is a combination of text mining and bibliometric analysis. These methods monitor the amount of activity in databases on certain specified topics and categorize the information found into graphical groupings. Because of the amount of literature available on a given technology, much of the text mining process has been automated and computerized. Software is used to monitor data bases of projects, research opportunities, publications, abstracts, citations, patents, and patent disclosures [56]. The general methodology for the automated text mining process is summarized in Figure 7.15.

The monitoring process involves identifying relevant literature by searching text that has been converted into numerical data [57]. Often there are previously defined search criteria and search bins where results can be placed. After literature has been found it must be clustered [58] with similar findings and categorized into trends. The data is categorized using decision trees, decision rules, k-nearest neighbors, Bayesian approaches, neural networks, regression models and vector-based models [57]. This categorization allows hidden relationships and links between data sets to be determined, and helps locate gaps in the data, [58]. Once the data has been grouped, it is organized graphically in a scatter-plot form. Each point on the scatter plot can represent either a publication or an author. These points can be linked or grouped together to show the relationships and similarities between points.

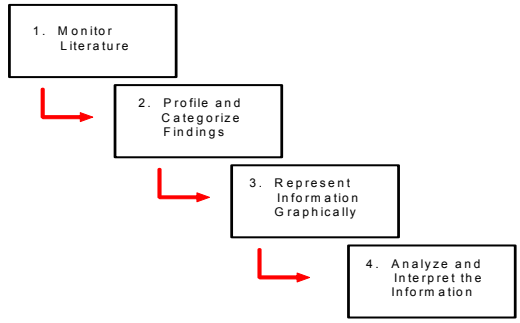

Figure 7.15. Steps in the technology monitoring process

The monitored data must then be interpreted and analyzed to determine which new technologies are viable and relevant. To do this, many organizations network with experts in related fields, and they employ surveys and other review techniques similar to the Delphi method [59] to force consensus among the experts. Expert opinion allows organizations to assess the implications of a new technology, and it is the first step in planning and taking action to cope with the benefits and risks associated with a new technology [53].

Technology monitoring and forecasting methods are still relatively new and untested, especially for larger databases of documents. Automated methods of forecasting and monitoring need to be refined and improved upon before they truly perform as they are intended to. Additionally, these tools will need to operate on a larger scale and in a more diverse environment. Also, many organizations will begin to seek customer and client input when monitoring and forecasting. Finally, forecasts will eventually be evaluated against global, political, environmental, and social trends [54], placing them in a broader context, and expanding their uses beyond single organizations.

7.4.2 Value Metrics and Viability

Value is used to refer to the relative usefulness of an object, technology, process, or service. In the case of a system, value is the relative benefit of some or all of the following: acquiring, operating, sustaining, and disposing of the system. One way to represent value is shown in Figure 7.16 [60]. The "attributes" axis includes measures of the application-specific direct product value. The "conditions" axis includes details of the product usage and support environment. In simplified models, the conditions axis provides the weights and constraints that govern how the attributes are combined together. The "time" axis is the "instantaneous time value", *i.e.*, value at a particular instant in time. Particular attributes may be weighted more than other attributes and their relative weightings are functions of time. For example, the value attributes during the final 20 seconds of a torpedo's life are weighted differently than the value attributes during its prior ten year storage life. All three axes in Figure 7.16 can be integrated. For example, if you integrate over the time (instantaneous time value) axis, you get "sustainability value". Integrating over the time axis tells you things about value attributes like "total cost of ownership" and availability. You could also integrate over the conditions axis, which would give you a measure how you are balancing multiple stockholder's conflicting requirements. Integration along the attributes axis builds composite value metrics.

A special case of Figure 7.16 is viability that addresses the application-specific impact of technology decisions on the life cycle of a system [52]. The objective of evaluating viability is to enable a holistic view of how the technology (and specific product) decisions made early in the design process impact the life cycle affordability of a system solution.

We define viability as a monetary and non-monetary quantification of application-specific risks and benefits in a design/support environment that is highly uncertain. The definition of viability used in this discussion is a combination of economics and technical "value", but assumes that technical feasibility has already been achieved. Traditional "value" metrics go part of the way

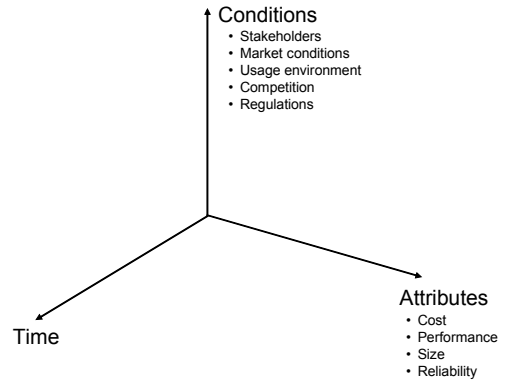

Figure 7.16. Three-dimensional value proposition [60]

toward defining viability by providing a coupled view of performance, reliability and acquisition cost, but is generally ignorant of how product sustainment may be impacted. We require a viability metric that measures both the value of the technology refreshment and insertion, *and* the degree to which the proposed change impacts the system's current and future affordability and capability needs. This viability assessment must include hardware, software, information and intellectual property aspects of the product design. Viability therefore goes beyond just an assessment of the immediate or near-term impacts of a technology insertion, in that it evaluates the candidate design (or candidate architecture) over its entire lifetime.

Although *viability* can be defined in many ways, its underlying premise is that economic well-being is inextricably linked to the sustainability of the system. According to studies conducted for the United States Air Force Engineering Directorate [11] viability assessment must include:

- *Producibility* – The ability to produce the system in the future based upon the "current" architecture and design implementation. (production and initial spares, not replenishment spares).
- *Supportability* – The ability to sustain the system and meet the required operational capability rates. This includes repair and re-supply as well as non-recurring redesign for supportability of the "as is" design implementation and performance.

- *Evolvability (Future Requirements Growth)* – The ability of the system to support projected capability requirements with the "current" design. This includes capability implemented by hardware *and* software updates.

The critical steps to making use of viability concepts in decision making are:

1) Identifying practical and measurable indicators of viability
2) Understanding how the indicators can be measured as a function of decisions made (*and* time passed)
3) Managing the necessary qualitative and quantitative information (with associated uncertainty) needed to evaluate the indicators
4) Performing the evaluation (possibly linked to other analyses/tools that are used early in the design process).

The viability of each technology decision made, whether during the initial design of a product or during a redesign activity, should be evaluated. Viability is formulated from a mix of many things including the following two critical elements:

- *Technology life cycle* – the life cycle of various technology components (for example electronic parts) has been modeled and can be represented, *e.g.*, technical life cycle maturity, life codes and obsolescence dates. The life cycle forecast may be dynamic and change (with time) in response to some form of technology surveillance program. In general, this metric is not application specific (and only hardware-part specific at this time). This concept, however, could be extended in two ways: 1) for a "technology group", *i.e.*, computers, memory, bus architectures, sensors, databases, middleware, operating systems, *etc*. A "scaled-up" version of life cycle forecasting could provide a maturity metric for a technology grouping versus a specific application that uses one (or a combination of) technology groups; and 2) for non-hardware components such as software, information and intellectual property.[3] No present methodologies or tools are capable of assessing a particular technology category and mapping evolutions against the 30, 40 or 50 year life cycles that military systems and platforms are expected to perform.
- *Associativity* – the second element is the impact of a particular technology's modification on the specific application. As an example, one technology may be late in its life cycle, but the impact of changing it on the application is low (making it a candidate for consideration), *i.e.*, it is not in the critical path for qualification or certification, it does not precipitate any other changes to the application, or it is modularized in such a way as to isolate its impact on the rest of the system, *i.e.*, a timing module that provides synchronization can be easily changed without impacting on any other part in the system and thus no associativity. On the other hand, other technologies (at the same point in their life cycle) may be central to everything (such as an operating system or bus architecture) and therefore have high associativity.[4]

When formulating the indicators of viability, the methodology must accommodate the fact that there

[3] For example, electronic part obsolescence forecasting benefits from the commonality of parts in many systems, non-electronic part obsolescence cannot take advantage of this situation, and therefore, common commercial approaches that depend on subjective supply chain information will likely be less useful for general non-electronic and non-hardware obsolescence forecasting.

[4] This is important as we begin to consider the affordability of a technology refresh or insertion. It is also important to identify the "critical system elements"; one way to do this is by using acquisition cost multiplied by the quantity needed in a system. But an operating system is relatively inexpensive and yet very critical. Thus the "value" of the operating system is *not* just its acquisition cost multiplied by its quantity, but should also sum all of the acquisition costs (multiplied by quantities) of all effected parts of the system refreshment. This would be done for each element in the system bill of materials, and thus a new sorting of the bill of materials would highlight the "system critical elements" by their impact to change. System critical really refers to "difficulty to change based on affordability". This is also important because technology management represents a cost, and thus must focus on the system elements that drive cost.

are many stakeholders who all possess different portions of the knowledge necessary to accurately evaluate the viability of a specific choice or decision. Another difficulty is that the information necessary to make the decision is generally incomplete, and consists of qualitative and quantitative content and their associated uncertainties. Thus viability evaluation represents an information fusion problem.[5]

7.4.3 Roadmapping

Technology roadmapping is a step in the strategic planning process that allows organizations to systematically compare the many paths toward a given goal or result while aiding in selecting the best path to that goal.

Many organizations have been forced to increase their focus on technology as the driver behind their product lines and business goals. This is different from the focus on customer wants and needs and the competitive demands that have previously determined the path of an industry. Technology roadmaps are seen as a way to combine customer needs, future technologies, and market demands in a way that is specific to the organization, and enables mapping a specific plan for technologies and the products and product lines they will affect.

Physically, the nodes and links depicted in roadmaps contain quantitative and qualitative information regarding how science, technology, and business will come together in a new or novel way to solve problems and reach the organization's end goal [61]. The time domain factors into the roadmap because it takes time for new technologies to be discovered, become mature, and be incorporated into a product, and for market share to grow to encompass new products, or for new possibilities to arise. In essence, technology roadmaps are graphical representations of the complex process of "identifying, selecting, and developing technology alternatives to satisfy a set of product needs" [62].

It is important to note that, like their real world counterparts, technology roadmaps are not just needs driven documents (as in, "I need to get somewhere, what direction do I go?") but can also be based on current position (as in, "where could we go from here?"). It should also be stressed that roadmapping is an iterative process and that roadmaps must be continually maintained and kept up to date [63]. This is because the information contained in the roadmaps will change as time passes and new paths emerge or old paths disappear, and because an iterative roadmapping process will lead to a mature roadmap with clear requirements and fewer unknowns [64]. An iterative roadmapping process also leads to better understanding and standardization of the process, allowing roadmaps to be created more quickly, and the information in them to be more valuable.

Regardless of the type of roadmap and the information it contains, all roadmaps seek to answer three basic questions [64]:

1) Where are we going?
2) Where are we now?
3) How can we get there?

The process of creating a roadmap should answer these questions by listing and evaluating the possible paths to an end goal, and result in the selection of a single path to focus funding and resources on. Despite selecting a 'final path', companies should remain open minded and keep alternative paths open in case a poor decision has been made. This is yet another reason to continually update the roadmap, since it serves as a mechanism to correct previous bad decisions.

Developing strategies and roadmaps that leverage technology evolution has been of interest for some time. The difficulty with historic roadmapping-based strategies is that they are 1) inherently not application-specific and 2) tend to focus more on accurately forecasting the start of the technology life (when the technology becomes available and mature) and ignore the end of the technology life (obsolescence). While this roadmapping approach may be acceptable for those

[5] Information fusion is the seamless integration of information from disparate sources that results in an entity that has more value (and less uncertainty) than the individual sources of information used to create it. Fused information is information that has been integrated across multiple data collection "platforms" (soft and hard) and physical boundaries, then blended thematically, so that the differences in resolution and coverage, treatment of a theme, character and artifacts of data collection methods are eliminated.

product sectors where there is no requirement for long-term sustainment (*e.g.*, consumer electronics), it is not acceptable to sustainment-dominated product sectors. Thus the process of roadmapping will need to grow and develop if it is to be used by the sustainment industry. Since product roadmapping is still a relatively new process it will gradually become more application specific and more defined as time passes.

The design refresh planning tool discussed in Section 7.4, MOCA, has been extended to include technology roadmapping constraints [65]. MOCA maps technology roadmap constraints into 1) timing constraints on its timeline, *i.e.*, periods of time when one or more refreshes (redesigns) must take place in order to satisfy technology insertion requirements; and 2) constraints on which parts or groups of parts must be addressed at certain refreshes (redesigns); and 3) additional costs for redesign activities.

7.5 Concluding Comments

Over the past 20 years, the use of the term sustainability has been expanded and applied to the management of environmental, business, and technology issues. In the case of environmental and business, sustainability often refers to balancing or integration of issues [1], while for technology its meaning is much closer to the root definition meaning to maintain or continue.

For many systems the largest single expenditure is for operation and support. Sustainment of military equipment was recognized as early as the 6th century BC as a significant cost driver by Sun-tzu in the Art of War [66]: "Government expenses for broken chariots, worn-out horses, breast-plates and helmets, bows and arrows, spears and shields, protective mantles, draught oxen and heavy wagons, will amount to four-tenths of its total revenue." Today it is not just military systems but many other systems ranging from avionics to traffic lights and the technology content in rides at amusement parks.

Failure to proactively sustain the technological content of systems is no longer an option for many types of systems. System evolution is not free and also cannot be avoided, proactive solutions are required in order to maintain market share and/or affordably provide continued system support and operation.

The Management of Engineering

Patrick D.T. O'Connor

Consultant
62 Whitney Drive, Stevenage, Hertfordshire SG1 4BJ, UK

Abstract: Managing engineering is more difficult, more demanding and more important than managing any other human activity in modern society. The article explains how, by adhering to the principles taught by Peter F. Drucker in his landmark book *The Practice of Management*, managers can exploit the full potentials of their peoples' talents and of changing technologies, methods and markets. The chapter is extracted from parts of the book [1] by the author.

8.1 Introduction

Peter Drucker's landmark book *The Practice of Management* [2] was published in 1955. In this book are to be found all of the profound ideas that have shaped the way that the world's best-managed companies and other excellent organizations work. Drucker exposed the poverty of so-called "scientific" management, which held that managers were the people who knew how all levels of enterprises should be run, and who should therefore provide detailed instructions to the "workers", who were assumed not to have the knowledge and skills necessary for managing their own work. They then had to manage the workers to ensure that they performed as required. "Scientific" management was the term used by the American engineer F.W. Taylor [3] to define the doctrines he proposed during the early years of 20th century industrialisation. This management approach called for detailed controls and disciplines, and it inspired the production line, the division of labor, and emphasis on specialisation. Drucker showed that there is no level at which management stops: every worker is a manager, and every manager a worker. Modern workers have knowledge and skills that can be applied to the management of their work. Freeing these talents generates improvements in motivation and productivity that can greatly exceed "planned" levels. It follows that work involving high levels of knowledge and skill are particularly suited to the management philosophy presented by Drucker.

Drucker taught that work should be performed by teams of people who share the same motivations. Management's role, at all levels, is to set objectives, organize, motivate, measure performance and to develop the people in the teams. Drucker initiated management concepts which today seem new and revolutionary to many engineers, such as "simultaneous engineering", involving all the skills of design, production, marketing, *etc*., in an integrated development team from the start of a project. The "quality circles" movement, in which production workers are

encouraged to generate ideas for improvement, is entirely in keeping with Drucker's teaching.

Drucker's teaching on management is universal. Drucker wrote that the people are "the only resource that really differs between competing businesses". Each business can buy the best machines, and their performance will not vary significantly between users. However, the performance of people, particularly as managers, can be greatly enhanced by applying the new first principles of management. He forecast that countries whose managers understood and practised the approaches he described would become the world's economic leaders. Japanese managers quickly adopted them across nearly all industries.

In the West the ideas received patchy recognition and application: many leading companies owe their success to the application of Drucker's teaching, but other companies and organizations fall far short of their potential because their managers do not appreciate or apply the principles.

Ironically, engineers often have difficulty in applying Drucker's principles, yet the principles of "scientific" management, that managers manage and workers do what they are told, is fundamentally inappropriate to even the simplest engineering tasks. In fact, because of the pace of technological change, it is common for engineering managers to be less knowledgeable than many of their subordinates in important aspects of modern product and process development, so making a philosophy based on trust and teamwork even more necessary.

The main reason why engineers have tended to gravitate towards the "scientific" approach to management is that they are normally, and have been taught to be, rational, numerate and logical. Engineering is the application of science to the design, manufacture and support of useful products, and scientific education is rational, numerate, and logical. Therefore the ideas of "scientific" management were welcomed by engineers, and they have difficulty in giving them up in favor of methods that seem vague, subjective, and not amenable to quantification and control. This attitude is reinforced by the fact that few engineers receive training in the new management principles, and in fact much current management training and literature is tinged with Taylorism. However, all engineering work is based on knowledge, teamwork and the application of skills. Applying "scientific" plans and controls to such work takes Taylor's original concept far beyond its original intent of managing manual labor. "Scientific" management, and related forms of organization and project control so often observed in engineering are inappropriate, wasteful and destructive of morale, both within enterprises and in the societies in which such principles are applied.

8.1.1 Engineering is Different

Managing engineering is different to managing most other activities, due to the fact that engineering is based on science. It is a first principle of management that the managers must understand the processes they are managing. Most non-scientific endeavors, such as retailing, financial services and transport planning can be learned fairly quickly by people with basic knowledge and reasonable intelligence. However, engineering requires proficiency in relevant science and mathematics and their application, and this can be obtained only by years of specialist study and practice.

Every engineering job is different to every other, even within a design team or on (most) production lines. Every one requires skill and training and there is always scope for improvement in the way they are performed. Nearly all involve individual effort as well as teamwork. These aspects also apply in different degrees to many other jobs, but engineering is unique in the extent to which they are relevant and combined.

Engineering is also different due to the reality that engineering products must proceed through the phases of design, development testing, manufacture and support. This is also true in part for some other fields of endeavor: for example, a building or a civil engineering structure like a dam or a bridge must be designed and built. However, these projects do not share some of the greatest challenges of most engineering creations: the first

design is usually correct, so there is little or no need to test it. They are seldom made in quantity, so design for production, managing production and item-to-item variation do not present problems. They are simple to support: they rarely fail in service and maintenance is simple.

8.1.2 Engineering in a Changing World

Engineering is a profession subject to continual and rapid change, due to developments in science and technology, components, materials, processes and customer demands. It is also subject to economic and market forces and often to pressures of competition, so costs and timing are crucial. In particular, there are few engineering products that do not face worldwide competition, whether they are produced for specialists or for the public. Engineering managers must take account of all of these factors, scientific, engineering, economic, markets and human, in an integrated and balanced way. They must also balance short term objectives with long term possibilities, so they must be able to weigh the advantages and risks of new technologies.

No other field of management operates over such a wide range or in the face of so much change and risk. It is not surprising that many organizations have made the mistake of separating the management of people from that of technology, instead of facing the challenge posed by the new management.

The philosophy will not guarantee success, particularly in competitive situations. As in sport, the best are more likely to win. As in sport, there is also an element of luck: a good project can fail due to external forces such as politics or global economic changes, or a simple idea might be fortuitously timed to coincide with a market trend or fashion. However, again as in sport, there is little chance of success if the approach to the business and its practice is not of the best in every way. There are no minor leagues or second divisions in engineering business, and no amateurs. Survival depends on being able to play at the top. The philosophy and methods taught by Drucker have been proven to provide the basis for winning.

8.2 From Science to Engineering

The art of engineering is the application of scientific principles to the creation of products and systems that are useful to mankind. Without the insights provided by scientific thinkers like Newton, Rutherford, Faraday, Maxwell and many others, engineering would be an entirely empirical art, based on trial and error and experience, and many of the products we take for granted today would not be conceivable. Knowledge and a deepening understanding of the underlying scientific principles, often as a result of scientists and engineers working as teams, drives further development and optimization across the whole range of engineering. By themselves, theories have no practical utility, until they are transformed into a product or system that fills a need. Engineers provide the imagination, inventiveness, and other skills required to perceive the need and the opportunity, and to create the product.

In its early days, engineering was a relatively simple application of the science that was known at the time. There was little distinction between science and its engineering application. The products were also easily understandable by most people: anyone of reasonable intelligence could see how a steam engine or electric telegraph worked, and they were described in children's encyclopedias. Today, however, most products of engineering effort involve multi-disciplinary effort, advanced technology related to materials, processes, and scientific application, and considerable refinement and complexity. Most people cannot understand the electronic control system of an electric power tool, the principles of a laser disc recording system, or the stress calculations for a turbine blade. This complexity and refinement have been driven by advances in science and in its application, and by the ceaseless human motive to improve on what has been achieved before.

As in pure science, engineering ideas must be based on knowledge and logic. To be useful they must also take account of several other factors from which scientists can remain aloof, such as economics, production, markets and timing. We can create both revolutionary and evolutionary

change, with the objective of creating products perfectly adapted to the preferences and constraints of their markets. The only limitations are those imposed by the laws of physics and by the extent of our imagination and ingenuity.

8.2.1 Determinism

Applying mathematical principles to problems of science and engineering enables us to predict cause-and-effect relationships, to select dimensions and parameter values and to optimize designs. Scientists take for granted the determinism provided by mathematics, and scientific theory is often derived directly by mathematical deduction. However, not all problems in engineering can be quantified in ways that are realistic or helpful. Lord Kelvin wrote:

"When you can measure what you are speaking about and express it in numbers, you know something about it; when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind".

Of course, the knowledge we need in engineering is often of a "meagre and unsatisfactory kind". This does not mean that we must avoid quantification of such information or beliefs. However, it is essential that we take full account of the extent of uncertainty entailed. Kelvin's aphorism has led many engineers and managers into uncritical and dubious quantifications, which then often appear in analyses of costs, benefits, risks, or other parameters. Analyses and "models" that are based on dubious inputs, particularly those that pretend to levels of precision incompatible with the level of understanding of causes and effects, are common manifestations of the "garbage in, garbage out" principle.

There are situations in which attempts at quantification, in a predictive sense, can actually confuse and mislead. This is particularly the case in problems of quality, reliability and safety. For example, the yield of a process, such as electronic or mechanical assembly, is influenced by many factors, including component and process tolerances, machine settings, operator performance and measurement variability, any of which can make large differences to the process output. Any prediction of future yield or reliability based on past performance or on empirical evidence is subject to very large uncertainty: the yield or reliability might suddenly become zero, or be greatly reduced, because of one change. When this is corrected, yield or reliability might improve slightly, or by a large amount, depending on what other factors are involved. Yield, reliability, and factors that are dependent on them, can be predicted only for processes that are known to be fully under control. "Fully under control" is a condition that is rare in engineering, though of course we often strive to attain it. However, the more tightly a process is controlled, the greater is the divergence if perturbations occur and are not detected and corrected. In cases such as these, predictions should be based on intentions, and not merely on empirical models or past data, which can give a spurious and misleading impression that causes and effects are all understood and controlled.

8.2.2 Variation

There is a further aspect of uncertainty that affects engineering design and manufacture, but which is not a problem in science, and that is variation. Products and components must operate in variable environments of temperature, humidity, mechanical stress, *etc*. The processes of manufacture, assembly, test, and measurement used to make and verify the product will all be variable. The extent and nature of the variations will in turn be variable, and often uncertain. For example, resistor values might be specified to be within ±5%, but a batch might arrive wrongly marked and be of a different tolerance, or even a different nominal value, and a machining process might be subject to a cyclical disturbance due to temperature change.

Variation exists in the behavior and performance of people, such as machine and process operators, as well as in the machines themselves. Variation in human behavior can be particularly difficult to understand, predict, and control, but might be the critical factor in a production operation.

Whereas variation that occurs in nature is passive and random, and improvement is based entirely on selection, the variations that affect engineering can be systematic, and we must control and minimize them by active means. Understanding, prediction, and control require knowledge of the methods of statistics, as well as the nature of the processes and of the people involved.

Statistical methods are used to analyze the nature, causes, and effects of variation. However, most statistical teaching covers only rather idealized situations, seldom typical of real engineering problems. Also, many engineers receive little or no training in statistics, or they are taught statistics without engineering applications. Since variation is so crucial to much modern product performance, this lack of understanding and application can have severe consequences. Conversely, proper understanding and application can lead to impressive gains in performance and productivity.

8.3 Engineering in Society

The business of engineering exists within the framework of society at large, at all levels from local to international. Engineering contributes enormously to society: nearly every product and service used by modern society depends upon engineering. Even non-engineering products and services such as food and banking depend upon engineering: engineering products are needed for food production, processing, packaging and retailing, and banks rely upon computers and telecommunications. At the same time, engineering depends upon the supply of the right kind of people and on the attitudes of society. Despite the benefits that engineering has bestowed, these attitudes are not universally favorable. Many people perceive engineering as being not entirely honorable, or as a profession that lacks the esteem and rewards of others such as entertainment, medicine, law and finance. Partly this is due to the fact that engineering is so wide ranging, from making electric toasters to designing spacecraft. Engineering is often perceived as being associated with militarism and with damage to the natural environment. These attitudes become reinforced by people such as teachers, journalists and politicians who influence others, particularly young people, when their future directions are being determined.

Engineering is hard work, both to learn and to practice. Many other professions seem to be easier, and this is a further reason why people turn away.

The future of engineering therefore depends upon how it is managed within society. Engineering managers should attend not only to the internal affairs of their organizations, but must be conscious of the local, national and international social pressures that influence the effects of their decisions. They should in turn work to shape these influences so that they develop favorably towards engineering, and to society as a whole.

8.3.1 Education

Education is the lifeblood of engineering. Future engineers are formed by the early exposure of children to science and mathematics. Their directions are influenced by their aptitudes, so those with average or above-average abilities in these subjects are potential engineers.

Teachers of mathematics and science are mostly qualified in these disciplines, so they must be expected to teach them well and to generate interest among their students. They are not in general expected to be good teachers of other subjects in which they are not qualified, even if the subjects are in some way related. Very few teachers are engineers. School curricula have in the past not normally included engineering as a subject, so there is little tradition of engineering education or experience in primary and secondary education in modern society.

Since modern economies depend to such a large extent on the supply of engineers, it has been fashionable in many advanced countries to try to stimulate this by introducing engineering, or "technology", into schools. This has generally been a flawed approach, for three reasons. First, teachers have been expected to teach topics in which they are not qualified or experienced. Second, and probably more significant, is that since engineering is based on science and mathematics, these basics

must be mastered before they can be applied to the learning of engineering. Of course there are overlaps between what can be called science and what can be called engineering, but the practical content of schoolwork should be planned to illustrate principles and demonstrate basic applications, and not to be premature exercises in engineering design. Third, all time spent on "technology" must be taken away from teaching of basic principles. In Britain, for example, all school children are required to study "technology"[1], regardless of their aptitudes or inclinations and despite the fact that few teachers are competent to teach the subject. This combination of unqualified teachers and misguided teaching has had the opposite effect to that intended: not surprisingly, young people are dissuaded from taking up an engineering career, and for those that do their formal engineering training begins with less knowledge of the fundamentals than they would have had under the traditional teaching regime.

Of course, it is appropriate for schools to encourage an interest in engineering, as they should for all later courses of study. However, this effort should not be part of the mainstream curriculum. If engineering topics are taught they should be dealt with separately, for example as voluntary activities. The fact that modern economies need engineers is not a rational justification for teaching children engineering. We also need doctors, architects and hotel managers, but we do not teach these professions in schools.

The effect of social pressures and inappropriate school teaching, as well as of recent "progressive" trends in school education, has led to a decline in the entry of young people, particularly the most able, into engineering. Engineering colleges and universities have had to reduce their entrance standards. They have had to expend more initial effort and time on teaching the basics of science and mathematics to make up for the deficiencies in school education. This leaves less time for teaching what should properly be taught at this level, thus inevitably reducing the knowledge on graduation.[2]

There is a need for a spread of engineering graduate knowledge, from those who will work at the frontiers between science and engineering in research and in new applications to those who will be mainly involved in the practical business of design, development, test, production and maintenance. Engineering also covers a wide range of topics, specializations and depths of specialization. Higher education must therefore provide this spectrum of output, whilst ensuring that there is no general difference in the esteem and status of the different courses and of the institutions providing them. However, there has been a trend in many countries, particularly in the United Kingdom, to place greater emphasis on academic aspects. The policy-makers and teaching staff perceive practical courses, and the institutions that offer them, as being somehow of lower status than those offering academic degrees and a research programme. These institutions then attract the more talented students, many of whom then find that their courses offer less in the way of practical engineering than they would have expected. Few university engineering courses include more than fleeting training or experience in manufacturing methods such as workshop skills. Practically none teach testing or maintenance.

Stability is a critically important factor at all levels of education. Students, parents, teachers, and employers can be disorientated and disaffected if they are not familiar with the education system. Instability and rapid change make it difficult to guide young people and to compare standards. As a result standards fall, even when the changes are supposed to improve them, and students and employers lose faith in them. It is far better to encourage progressive improvements in existing systems than to impose dramatic changes, yet governments have imposed sweeping changes and continue to do so in countries in the West. The results have almost always been a general

[1] The term has come to be associated almost entirely with "information technology" (IT). Children are taught how to use PCs, but not much else that is technological.

[2] In the UK this trend has continued steadily downwards during the 10 years since these words were written. Stupidity at work?

depression in standards, morale and respect for education, particularly in science and engineering.[3]

Teachers, at all levels, are the developers of the future talents needed by society. Sadly, in some of the most advanced Western countries, particularly in Britain and the United States, the status and rewards for teachers do not attract the best[4]. Teachers have a more fundamental impact on the future well being of advanced societies, and of their relative competitiveness, than any other profession. Doctors, accountants and lawyers, and even engineers, do not influence the long-term quality of society to anything like the extent that teachers do. Teachers should enjoy the same status and rewards as other professions, and this is the only way to guarantee that teaching will attract the necessary share of the most talented. This is particularly important for teachers of science, mathematics and engineering, for whom prospects in industry are usually better than for those with qualifications in subjects such as languages or history. The common practice of remunerating teachers at a standard rate, regardless of specialization and usually regardless of performance, is an appropriate ingredient in a policy of industrial decline, which no government intentionally supports but some nevertheless have managed to achieve.

It should be possible for professional people such as scientists and engineers to move between other employment and teaching in order to bring experience to the classroom and the lecture hall. This is particularly important for training young engineers, because of the practical nature of the subject and to keep pace with the change. Unfortunately this flexibility is reduced because few good engineers are attracted by the lower rewards for teachers, particularly in schools and non-degree-level training institutes. The formal pedagogical qualifications demanded for working as a teacher, particularly in schools, is also a barrier to easier movement of experienced engineers into teaching.

The proper role of government in engineering is to ensure the provision of educated, motivated people. Education, starting from primary school and continuing through various forms of adult education, particularly vocational training and university, cannot be managed by industry. Engineering managers can obtain capital, plant and materials, limited only by their finances, so long as they operate successfully in a commercial economy. However, they cannot ensure the provision of the talents they need, except by competing for the supply available. If the supply is limited it imposes long term but intangible constraints on all aspects of performance.

The constraints are long term for the simple reason that it takes a generation to influence the quality of education. They are intangible because even if managers can find the numbers of people they need, if the quality of their education has not developed their knowledge, skills and attitudes to their full potentials, the shortfalls cannot be measured in terms of inventiveness, productivity, and effectiveness of management. Their employers can and should continue to develop them, since there is no end to an individual's potential to learn, but industry cannot make up for widespread, long-term inadequacy in a nation's educational provision. Individual companies can ensure that they select and develop the best, but the burden on industry as a whole can seriously restrict national competitiveness. The relative decline of the UK and US engineering economies over the last 30 years or so has been due largely to the reduction in educational standards, particularly in relation to science and engineering.

More so than in any other profession, engineering education is never complete. Every engineer requires continual updating as methods, materials, technologies and processes change, as systems become more complex, and as multi-disciplined approaches become increasingly necessary. Therefore engineering education should always emphasize the need for continuation and should stimulate further development. Employers should ensure that their people are given the opportunities and motivation to continue to learn,

[3] The 10 years since this was written show that this self-destruction continues, with lessons unlearnt. More stupidity at work?

[4] UK government interference in how and what schoolteachers teach, and the loss of classroom discipline, have made teaching an unenviable career choice.

for example by linking advancement to training. Many universities and other institutions provide excellent short courses as well as post-graduate degree courses. Engineering managers should be aware of which courses are most appropriate to their work and should make use of them and help to develop them.

Of all the issues in engineering management, education is the one with the longest time-scale. It also has the widest impact, since it affects the whole supplier chain. Employers have a duty to promote continuing education, but they should not be expected to teach people what they should have learned at school or college, and they should be able to expect that the people they employ will be numerate, literate and motivated to learn more. Companies operating where engineering education is excellent will enjoy the effects for a generation. Those working in countries in which standards of education have been allowed to fall will carry an extra burden until long after improvements are made.

8.3.2 "Green" Engineering

Protecting and improving the natural environment is a concern of many engineers and engineering companies. This concern is now also expressed in politics and in legislation. In many countries environmental pressure groups such as Greenpeace make life interesting for engineers involved with products and processes that are noisy, noxious, non-biodegradable, or nuclear. There is no doubt that the pressure groups have benefited society, but, like most pioneering movements, their targets and methods sometimes appear irrational to engineers.

The most notable achievements of the environmental movement as far as engineering is concerned, and which have involved enormous engineering effort and cost, have been the noise reduction of aircraft jet engines, the reduction of lead and other emissions from vehicle engines, and the cleaning of rivers and emissions from coal- and oil-fired power stations.[5] They have secured many other less dramatic improvements on behalf of society, and they have forced the legislation that governs environmental issues. They have also had a negative impact in frightening society and politicians concerning the safety of nuclear power, although even here they have forced the nuclear power industry to banish complacency in their operations.

We are on the verge of an environmental explosion similar to the quality "systems" explosion described earlier. Standards are being written[6] and armies of consultants, inspectors and auditors are being formed. Engineers and the bodies that represent them must be sympathetic to public anxiety, and must help to educate legislators, the media and the public without appearing to be defending vested interests or covering up problems.

8.3.3 Safety

Public perceptions of risk are not always as rational as engineers would like. When the risks are difficult to understand or quantify the gap in understanding is increased. For example, public fears of nuclear and electromagnetic radiation are based, to a large extent inevitably, on ignorance and on the invisibility of the radiation. These fears are reinforced by the fact that even the specialists are uncertain about the long-term effects of radiation exposure. To a lesser extent there is also fear of software. Engineers know that software is intrinsically safer than people or hardware performing the same function, since software cannot degrade or wear out and it is not subject to variation: every copy is identical. Software can contain errors, but properly managed design and tests can ensure that it is correct in relation to safety-critical functions, if not in every possible but remote eventuality.[7]

The employers of engineers must ensure that safety liabilities are minimized by providing

[5] In 2006 we can add CO2 and ozone-depleting emissions that influence global warming, and lead-free solder. In other respects the "greens" have generated fears that are less well grounded, such as about the effects of electromagnetic radiation from power lines and telephones.

[6] ISO14000 was published in 1996.

[7] As pointed out earlier, software has not been the cause of any recent disasters.

training and a system that works to eliminate all foreseeable risks from products, processes and operations. For most engineering companies it is now essential that a manager is appointed to coordinate safety issues.

8.3.4 Business Trends

One of the major features of modern business that influences the task of managers is the continuing pace of company acquisitions, mergers and disposals. These often occur across national borders, as business becomes more multinational. They nearly always lead to displacement of people and force changes in organizations and methods. They present opportunities for some, but uncertainty and loss for others. Since the main justification for the moves is usually financial, changes are often forced down by new managers in order to generate quick savings.

Another important trend is the transfer of manufacturing work overseas in order to reduce costs. This is an understandable move, but it can be unsettling to the important interface between design and production.

Much of modern business is driven by short term pressures, and this seems to be an increasing trend. Companies feel threatened by competitors, possible acquirers and shareholders if they do not generate profits and share price growth. Some of the reward contracts for CEOs and other board level people motivate them towards short term greed rather than the long term good of the business. As a consequence of these pressures, companies shed staff and cut investments in training and research. Of course it is necessary to seek to operate the business as economically as possible, but, as Drucker emphasized, the main duty of top management is to ensure survival of the business, and this means taking account of the long term. Short term economies, especially when driven as campaigns with defined targets ("reduce staff across the board by 5%"; "cut capital spending by 20%"; "cut indirect expenses (training, travel, *etc*.) by 50%", *etc*.), are often applied, but they can be very damaging and expensive in ways that accountants might not appreciate. The financial benefits soon appear on the balance sheet, but the damage to the business in the longer term is less apparent.

There is an unfortunately "macho" attitude to much of modern management, largely driven by these pressures and trends. This seems to have been fostered by books and articles on management by fashionable "gurus", presenting panaceas and "paradigms". The contributions from the management training schools have not resisted this trend. Maybe this is tolerable in enterprises that are not critically dependent on skill, training, teamwork and long-term effort and investment. However, "macho" management of engineering is counterproductive and damaging.

8.4 Conclusions

Science is difficult. Scientific work requires intelligence, knowledge, powers of induction and deduction, and patient effort. Engineering is even more difficult. There are greater problems in terms of resources and time. Variations in human performance and design parameters make outcomes more uncertain and difficult to predict. Aspects such as production, market appeal, competition and maintenance must be considered. Several technologies might be involved, and the development teams must be multi-disciplined. Technologies, in materials, components, and methods, are continually changing, and the team must keep abreast of these. Engineers must be aware of the scientific principles and mathematical methods that are the foundations of their work. They must also be aware of the limitations of applying these to the real world of engineering, which involves variation, uncertainty, and people. Naive application of basic principles is the mark of the novice. Appreciating the complexities of the real world is the mark of experience. It is often the application of new ideas, regardless of how simple they might at first appear, that causes the greatest problems in engineering development.

However, in spite of these difficulties, or maybe more accurately because of them, engineering is often performed very well. People respond to challenges, and we see the results in the remarkable new products that flow from

engineering teams, particularly in competitive markets.

The principles of management, on the other hand, are basically very simple and unvarying. No difficult theories are involved. Perversely, management is often performed very badly, or at least in ways that fall far short of releasing the full power of people and the teams they form. Sub-optimal management is commonplace in engineering.

Successful engineering depends holistically on the blend of scientific application, empirical and mathematical optimization, inventiveness and design of the product and of its manufacturing processes, and the leadership of the project. There is no other field of human enterprise that requires such a wide range of skills; skills that can be developed and maintained only by a combination of education and continual training and experience.

Managers of creative people need to understand and abide by the simple principles in the performance of their difficult task of leadership. Carl von Clausewitz, writing in his classic book **"***On War", stated: "*the principles of war are very simple. Wars are lost by those who forget them*".

8.4.1 In Conclusion: Is Scientific Management Dead?

Despite the wisdom of Drucker's teaching and the dramatic positive effects of its application, "scientific" attitudes to management still persist widely in Western industrial society. This is reflected in much of the modern literature and teaching on management and in the emergence of bureaucratic procedures, regulations and standards. Many managers, it seems, are unaware of the new management or are inhibited from applying it by the pressures and constraints of their work situation.

Engineering is the epitome of modern civilization. Like science and most art, it is truly universal. Like art, engineering is creative, and it can even create beauty. More than science and art it influences and changes all lives. However, not all of the results of engineering have been beautiful or beneficial, and the people engaged in its many forms are as human as the rest. Also, engineering is so widespread a discipline, and so much of it is perceived to be routine and unglamorous, or hardly perceived at all by the wider public, that its profession is often undervalued. Very few engineers achieve national or international recognition outside their profession. Even fewer have attained the kinds of reputations enjoyed by great writers, artists or scientists[8]. To a large extent this reflects the fact that few engineers work alone. In a world-class engineering product such as a high-speed train or a mobile telephone, every electronic component, plastic molding and fastener is the product of engineering teamwork, as is every subsystem and the complete train system or telephone network. No credits are published, so the engineers' names are not listed as are, for example, the directors, producers, makeup artists, gaffers, focus pullers, sound recorders and others who contribute to the making of a movie or a TV film.

Engineering is therefore largely anonymous and the satisfactions are more personal, to the individual and to the team. Though engineers' names do not appear in lights they have the satisfaction that, in well managed teams and organizations, they can all influence the products and services in ways that are more fundamental than are allowed to gaffers and focus pullers.

Engineering and engineering management are not governed by any particular codes of ethics, as for example the Hippocratic Oath taken by the medical profession. All professions are governed by law and by normally accepted standards of ethics. In addition, many engineering societies and institutions issue codes of practice, but these are not enforceable or supported by disciplinary frameworks. The profession of engineering has served society well without such additional regulation, and there is no reason why it should not continue to do so and to improve its contributions. Since engineering management is a continuous, long-term activity, high ethical standards are essential for successful leadership and competitive progress.

All work should provide satisfaction to those engaged in it and to those who will benefit from it.

[8] Or writers and "artists" who create pretentious nonsense, or entertainers, or the generality of the modern "celebrity" class.

However, mere satisfaction is barely sufficient. Work and its results should provide satisfaction beyond expectation, and happiness and fulfillment to those most directly involved. As Deming himself has stated, his famous 8th point for managers ("*drive out fear*"), needs now to be re-stated as "*create joy in work*". Striving for happiness in work is not a naive or merely altruistic objective. It is the logical culmination of the most influential teaching of management. It is also the common observation of people at work, including the managers who make it happen, that the correlation between happiness and performance is very intense, yet subtle and fragile.

Happiness can generate quality, inventiveness, teamwork and continuous improvements that transcend "scientific" plans and expectations. Happiness at work must be based on shared objectives and challenges, not on self-satisfaction or fear.

It must be tempered by efficiency and discipline, and reinforced by learning and by the freedom and duty to contribute to the common effort. It must be of a quality that inspires and encourages effort, but not adulation or blind subservience.

Generating and strengthening happiness at work of such quality, and maintaining it in the whole of the organization despite the problems and changes that human enterprises must encounter, is the most difficult but most satisfying and rewarding task of managers.

This is the fundamental challenge for modern managers. In free societies, from which the fear of tyranny and global war has hopefully been removed, human creativity and productivity can be developed to their fullest when the work of individuals and of teams creates and increases happiness.[9]

[9] More than ten years since I first wrote this sentence, this message still seems apt. History has not ended, and the world still faces real and imagined dangers. I would merely add the words of advice: "Creating happiness is the first role of statesmen". I would also quote the words of the American Declaration of Independence about peoples' "unalienable rights" to "life, liberty, and the pursuit of happiness." Creating happiness is the first role of managers, at all levels.

Engineering *Versus* Marketing: An Appraisal in a Global Economic Environment

Hwy-Chang Moon

Graduate School of International Studies, Seoul National University, Seoul, Korea

Abstract: The global manager should consider engineering first before marketing because optimal engineering efficiency creates more values than customized marketing efficiency. Although the debate over the global standardization continues in the area of global strategic management, global firms need to conduct this new type of global strategy. Foreign consumers actually prefer global products to locally customized products in many industries such as automobiles, electronics, food, and others in which engineering applications are important. Therefore, the most important task of the global firm is to change local products to global products through enhanced engineering.

9.1 Introduction

Innovation telecommunications is growing faster than ever before. Michael Armstrong [1], Chairman and CEO of AT&T, said, "*It took radio 30 years to reach 50 million people; it took 13 years for TV to do the same; but the World Wide Web reached twice as many users in half the time*." The number of Internet users will soon reach a "critical mass" and the Internet will be treated as a valuable business platform. The future will move even faster. Bill Gates [8], Chairman and CEO of Microsoft Corporation, said, "Business *is going to change more in the next 10 years than it has in the last 50 years*." We have witnessed that all these predictions are becoming true.

Globalization has been accelerating with these rapid developments in telecommunication technology. Telecommunications break down national trade barriers and create seamless global trading, global shopping, and global manufacturing. The environment of international business has thus been dramatically changed. In this globalizing business environment, there have been debates on what the global standards are and whether business people should follow the global standards. There are basically three approaches to global standards: international organization-driven, government-driven, and corporate-driven standards. International organizations such as the World Trade Organization set new rules on global standards in such areas as E-commerce. Rules and principles formulated by international organizations are sometimes mandatory, but are advisory in many cases. Governments set new standards in product specifications, safety rules, and so on.

[1] This chapter, in parts, is based on Moon [21] and is has been adapted with permission.

These standards are often mandatory and necessary rather than advisory. Global firms pursue management strategies and techniques that can be regarded as global benchmarking or global standards by other firms.

This study focuses on corporate-driven standards. In particular, this chapter addresses strategic issues concerning global standardization and local responsiveness. A corporate-driven global standard can be defined as the standardization of the best product and management in a competitive global market. Firms usually prefer a standardization strategy that minimizes production and management costs but may also prefer a customization strategy that responds to local differences, thereby increasing the local market share. Standardization and customization are thus two conflicting forces or trade-offs that firms must consider simultaneously.

The standardization of market strategies has been a continuing topic of debate and research since Levitt's [13] article. Debates on the standardization *vs*. customization (or segmentation) strategy in the world market are documented well in scores of articles (*e.g.*, Levitt [13], Douglas and Wind [6], Bartlett and Ghoshal [3], Varadarahan, Clark and Pride [30], McCutcheon, Raturi and Meredith [16], Gupta and Govindarajan [11], Chen and Paliwoda [5], Capar and Kotabe [4], Gabrielsson and Gabrielsson [7], London and Hart [14]).

In theory and practice, the opportunity cost of a standardization strategy may be lost sales, while a customization strategy may sacrifice the firm's production and/or marketing efficiencies. However, the debate itself is often pedagogical. In addition, most scholars have chosen examples selectively and interpreted subjectively in order to support one of the two extreme arguments. On the other hand, by recognizing that the world market is neither extremely homogenous nor heterogeneous, a compromising strategy has been introduced. For example, a word that captures the global and local perspective is “glocal”, a new concept for a new globally competitive world [10]. However, this study argues that the most challenging issue is not to choose one of the two extremes, nor to compromise the two, but how to increase the degree of standardization by enhancing the product values.

In the next section, the standardization issue for value creation will be revisited, including an attempt to clearly explore its assumptions and criticisms. Counter-arguments will also be provided. In the section that follows, strategic implication of global standardization and new challenging issues will be discussed. A new model for dynamic globalization will then be introduced. Finally, the new organization of global firms will be discussed to pursue this new global strategy.

9. 2 Creating Product Values with Low Cost and High Quality

According to Levitt [13], companies must learn to operate as if the world were one large market, ignoring regional and national differences. Historical differences in national tastes or modes of doing business will disappear. An emerging similarity of global customer preferences will be triggered by developments in both production technology and in communication and transportation networks. Such conditions in turn will lead to standardization strategies for product and other marketing mix elements, as well as manufacturing. Companies which are able to push costs and prices down while pulling quality and reliability up will inevitably attract customers to the firm's globally available and standardized products. Levitt believes that multinational corporations will have minimal needs for local adaptation in the evolving “global village”.

In contrast, Quelch and Hoff [27], for example, challenged the “standardization imperative” for global managers. Despite the promised economies and efficiencies to be gained with standardization strategies, many managers appear reluctant to take the global marketing plunge. These managers see customers and competitive conditions as differing significantly across national boundaries. This perception (and some bad experiences) represents the basis for much of the skepticism about standardized strategies.

Levitt's argument was further criticized by Douglas and Wind [6]. They questioned three of Levitt's assumptions: (1) that consumer tastes are becoming homogenous worldwide; (2) that

consumers are willing to sacrifice personal preferences in return for lower prices; and (3) that economies of scale (EOS) are significant with standardization. It is useful to examine Douglas and Wind's criticisms on Levitt's assumptions. Counterarguments will then be discussed.

9.2.1 "Consumer Tastes Are Becoming Homogenous"

Douglas and Wind claimed that evidence is lacking to show that consumer tastes are becoming more similar globally. Indeed, they contended that the world market is probably becoming more diverse. For example, Coca-Cola markets Georgia Coffee, a canned coffee drink, in Japan, but the product is not accepted by U.S. and other buyers around the globe. However, this is one of a few examples of customization. Many other products are easily transferable across countries. Keegan, Still and Hill [12] reported that multinational firms selling consumer packaged goods perceived few problems in transferring products between markets as dissimilar as the U.S. and less developed countries (LDCs). They found that about 1200 (54.4%) of the 2200 products sold by 61 subsidiaries had been transferred from home-country markets (U.S. or U.K.) into LDCs. This means that over half the items in LDC lines are "international products", that is, their commercial appeal extends over multiple markets.

While there may be a lack of substantive evidence of movement towards a more homogenous global market, the same is true in support of an increasingly heterogeneous global market. Despite the lack of empirical data, more scholars seem to agree with the homogenization trend. Sheth [28], for instance, argued that there is evidence of increasing international standardization of both product quality and product safety standards. Porter [25] also noted a change towards more homogenization of needs internationally.

9.2.2 "Consumers Are Willing to Sacrifice Personal Preference in Return for Lower Prices"

A low price appeal resulting from standardization offers no long-term competitive advantage to the firm, according to Douglas and Wind. They saw the inevitable vulnerability of this pricing strategy as stemming from these factors: a) new technological developments that lower costs; b) attacks from competitors with lower overhead and lower operating or labor costs, and c) frequent government subsidies paid for emerging country competitors. Any or all of these, they claimed, may undermine the effectiveness of low price strategy.

What they did not consider, however, is that a low price strategy linked to reduced average cost which results from a firm's technological advantage *does* endure. Standardization, thereby, offers a long-term competitive advantage. In fact, Levitt emphasized both low price and high quality. He suggested that if a company could push costs and prices down and at the same time pull quality and reliability up—thereby maintaining reasonable concern for buyer suitability—customers would prefer its world-standardized products.

Whether a firm can pursue more than one generic strategy is an important issue in the area of strategic management. Porter [25] classified two basic types of competitive advantage that a firm could possess: low cost and differentiation. These two basic types of competitive advantage combined with the scope of activities (broad target or narrow target) lead to three generic strategies: cost leadership, differentiation, and focus. The focus strategy has two variants, cost focus and differentiation focus [24]. According to Porter [23, 24], the underlying implication of generic strategies is that a firm has to make a choice about the type of competitive advantage that it seeks to gain. A firm could choose a cost leadership or differentiation in a broad competitive scope; a cost or differentiation focus in a narrow target scope. Porter argued strongly that businesses should compete on the basis of just one (not the combination) of the four generic strategies in order to be successful.

However, there are some criticisms of Porter's framework. As a matter of fact, cost leadership and differentiation are not mutually exclusive, but often complementary. Differentiation, which increases demand and market share by satisfying consumers, may produce economies of scale and speed up the descent along the cost curve [17]. On the other

hand, many cost-reducing skills may also enhance the quality, design, and other differentiated features of the product. Global players are concerned about both cost leadership and differentiation [18]. An important issue of standardization is not to give up quality, but to serve the global market with a recognized and branded product at a reasonable price.

9.2.3 "Economies of Scale Are Significant with Standardization"

Douglas and Wind pointed out three weaknesses in Levitt's Economies of Scale (hereafter EOS) justification for standardization: a) flexible factory and automation enable EOS to be achieved at lower as well as higher levels of output; b) the cost of production is only one and often not the critical component in determining the total product cost; and c) strategy should be not only product-driven but should take into account other components of the marketing mix.

The arguments of Douglas and Wind are true in particular industries. However, there are still many industries where the benefits of EOS are significant with standardization. An example of the magnitude of EOS is found in the paper industry. In the production of uncoated paper for printing, an expansion from 60,000 to 120,000 tons brings with it a 28% drop in fixed costs per ton. For this same expansion, labor costs can be reduced by 32% as new technical opportunities for production open up (Oster [22]). Prolonged benefits from EOS are significant in many mature industries such as steel and automobiles.

9.3 Strategic Implications of Global Standardization

In evaluating the standardization strategy, Levitt focused on perceived and real similarities, while Douglas and Wind stressed the perceived and real dissimilarities. The correct strategy for any particular firm appears to be highly empirical and circumstantial in determination. The more challenging issue is whether we can predict which of the two strategies, standardization or segmentation, would be appropriate, given stated conditions and industries.

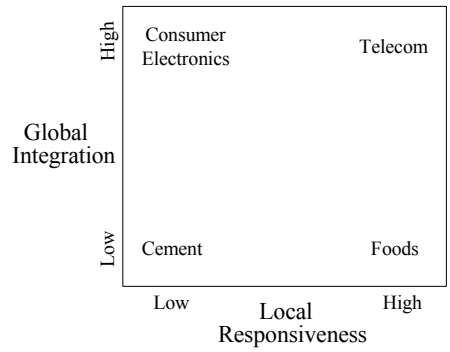

Figure 9.1. I-R framework

The preference for a standardization strategy identified by previous research is determined mainly by the type of product or industry. Bartlett [2], for example, offered a model as shown in Figure 9.1 to illustrate how forces for global integration strategy versus national responsiveness strategy may vary from one industry to the next. Bartlett [2] and also Ghoshal [9] suggested that the consumer electronics industry (radio and TV) is characterized by low responsiveness benefits and high integration benefits. The reasoning is that EOS in electronics product development and manufacturing are important sources of competitive advantage. In contrast, for branded packaged foods, firms may experience variations in local (foreign) tastes, buying habits, distribution channels, and promotional media. Food industry firms would, as a result, possibly benefit by the use of country-differentiated strategies. Douglas and Wind [6] also pointed out that standardization may be more appropriate for industrial rather than consumer goods, and for consumer durables rather than nondurables.

However, there are several problems with these traditional views. Firstly, Bartlett's model, for example, is not clear in distinguishing product standardization from the standardization of the other marketing mix elements, *i.e.*, distribution, promotion, and pricing. The distribution and promotion strategies of Coca-Cola Co. may differ across national borders, but the basic product is standardized. From this viewpoint, at the least,

product strategy can often be efficiently standardized over multiple markets. Simon-Miller [28] also argued that where the product itself is standardized or sold with only minor modifications globally, its branding, positioning, and promotion may reflect local conditions.

Secondly, what is more important is the firm's strategy, not the industry condition. Bartlett [2] argued that within any industry companies can and do respond in many different ways to diverse and often conflicting pressures to coordinate some activities globally, and to differentiate others locally. In his example of the auto industry, Toyota had a world-oriented strategy with a standardized product, while Fiat built its international operations on various governments' interest in developing national auto industries. If this is true, *i.e.*, if different firms have different strategies in a single industry, then an industry-based framework such as the one shown in Figure 9.1 may not be very useful. Therefore, a new framework is needed to explain why and how a firm (not industry) pursues a standardization strategy, while others in the same industry may not. Why, for example, is Kentucky Fried Chicken more standardized and globally accepted than other competing products in the "same" (fast foods) industry?

Finally, the strategic recommendations of previous researchers are based on static rather than dynamic conditions, whether these are either for the choice of the two strategies of standardization or customization, or a compromise of the two. Bartlett and Ghoshal [3] found that managers in most worldwide companies recognize the need for simultaneously achieving global efficiency, national responsiveness, and the ability to develop and exploit knowledge on a worldwide basis. To achieve these multiple goals, they suggested the transnational strategy. However, it is doubtful whether this strategy is really optimal and desirable. Would not more astute managers seek to implement a global strategy, focusing on transnational similarities rather than differences? The global strategist, recognizing the risks but being aware of the trade-offs, would seek to offset consumer resistance with his or her extended product package, rather than customize the product to precisely meet the local consumer needs. In the next section, a new model will be developed to explain the dynamic behavior of global firms, which improve country-specific products to global products.

9.4 The Dynamic Nature of the Global Strategy

Products can be classified into two categories: global and country-specific. The global product is output efficiency-based, more easily standardized, and universally offered, and accepted by consumers worldwide. Examples are industrial products and consumer durables. The country-specific product is quite sensitive to environmental factors. Sales are more closely tied to political, economic and cultural forces, meaning that localized or national strategies seem preferable. Processed food and clothing items are examples.

In a dynamic setting, even country-specific products may become candidates for global

products as shown in Figure 9.2.

This is where both industry and firm are driven by the search for higher technological content and stricter quality control. Coca-Cola, McDonald's, Kentucky Fried Chicken, and Levi Strauss, for example, all offer products that are more globally acceptable than parallel products with country-of-origin other than the U.S. However, note that these products—food and clothes—are all ethnic products that may be positioned in the lower right-hand corner in Figure 9.1 where forces for national responsiveness are high.

Let us take a closer look at the food industry, for instance, in which strategic positioning can be

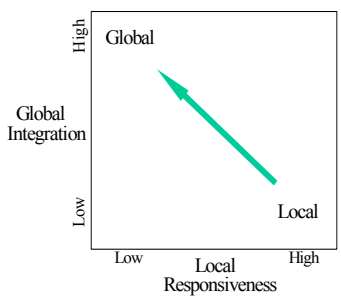

Figure 9.2. Dynamic globalization strategy

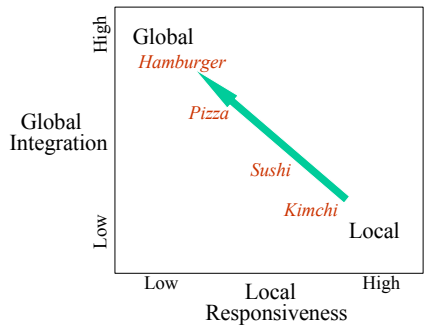

Figure 9.3. Different strategic positioning

diverse. There are several foods along the dynamic globalization arrow in Figure 9.3, ranging from kimchi that is the most localized food to the hamburger that is the most globalized food. It is important to note how a firm can enhance the local product to global product.

Kimchi is a spicy, fermented pickle that invariably accompanies a Korean meal. The vegetables most commonly used in its preparation are celery cabbage, Chinese turnip, and cucumber. The prepared vegetables are sliced, highly seasoned with red pepper, onion, and garlic, and fermented in brine in large earthenware jars. Dried and salted shrimp, anchovy paste, and oysters are sometimes used as additional seasonings. During fermentation, which takes approximately one month depending on weather conditions, the kimchi jars are stored totally or partially underground in cellars or sheds built expressly for this purpose. Kimchi is very unique in taste and thus country-specific to Korea.

Sushi is a Japanese food, consisting of cooked rice flavored with vinegar and a variety of vegetables, eggs, and raw fish. Sushi began centuries ago in Japan as a method of preserving fish. It is told that the origins of sushi came from countries of Southeast Asia. Cleaned raw fish was pressed between layers of rice and salt and weighted with a stone. After a few weeks, the stone was removed and replaced with a light cover, and a few months after that, the fermented fish and rice were considered ready to eat. It was not until the 18th century that a clever chef named Yohei decided to forego the fermentation and serve sushi in something resembling its present form. Anyhow, raw fish is a major ingredient of sushi. Still, many people think sushi means raw fish, but the literal translation means “with rice.” So, sushi used to be very unique and country-specific to Japan. However, when sushi is introduced in other countries, the ingredients are significantly changed. In particular, raw fish is often replaced with other ingredients such as avocado. Sushi has been evolved from a country-specific food into a globally accepted product.

Pizza is a dish of Neapolitan origin consisting of a flattened disk of bread dough topped with olive oil, tomatoes, and mozzarella cheese. Pizza is baked quickly and served hot. The popularity of pizza in the United States began with the Italian community in New York City; the first pizzeria appearing there in 1905. After World War II the pizza industry boomed. In the United States, sausage, bacon, or ground beef, mushrooms, peppers, shrimps, and even oysters are sometimes added. Thus, pizza originated in Italy but is now well accepted in the global market.

The hamburger is customarily eaten as a sandwich. Between two halves of a round bun, mustard, mayonnaise, catsup, and other condiments, along with garnishes of lettuce, onion, tomato, and pickle, constitute the classic dressing. In the variation known as the cheeseburger, a slice of cheese is melted over the patty. The patty itself is often seasoned or augmented with chopped onions, spices, or bread crumbs before being cooked. The hamburger is probably the most global food, but it too used to be a local product. The hamburger is named due to the city of its origin, Hamburg, Germany. In the 1850s it was brought by German immigrants to the United States, where in a matter of decades it came to be considered an archetypal American food.

How can the hamburger become a global food? First of all, the hamburger is probably the most efficient food in terms of the function as a food. It contains almost all the ingredients for the nutritional requirements of food in a small, convenient size. This function as a near complete food is well accomplished with reliable quality and at an affordable price by global firms such as McDonald’s. The company’s strategy is to maintain rigorous, standardized specifications for

its products, raw ingredients, and store management worldwide. The company has standardized recipes for its products. Menus in international markets are a little diverse, but most of the products are quite standardized in terms of ingredients and even the temperature of the food. When McDonald's entered Russia, the company found that local suppliers lacked the capability to produce quality products. To solve this problem, McDonald's built the world's largest food-processing plant in Moscow at a cost of $40 million. McDonald's also tightly controls the operating procedures of stores around the world. Therefore, the most important strategy of McDonald's is to enhance the economic values (*i.e.*, reliable quality and affordable price) of the product by effectively maintaining the standardized, strict specifications of the product engineering.

The above examples show that successful global firms can move the country-specific strategy in a more global direction if they can make the perceived benefits of better quality and reasonable price outweigh the need for buyers to satisfy their specific localized preferences. Therefore, the most important strategic implication is that the real issue of globalization is not the forced choice between the two extremes, nor a compromise of these two, but rather how to increase the degree of engineering efficiency through standardization. A high level of technology and quality control may redirect the firm's strategic choice away from national responsiveness towards higher global standardization.

One more important thing is that a global firm can pursue a strategy of product diversity only if the introduction of a new or customized product does not hurt the overall efficiency. An example is the product lines of Coca-Cola: Coke, Diet Coke, Classic Coke, New Coke, and so on. The product strategy of Coca-Cola is not completely segmented, since the formulas for Coca-Cola products are not without overlap or similarity. The firm makes only slight changes in the basic ingredients for all. The availability of flexible manufacturing enables the firm to produce and market slightly differentiated products to different target market groups, without sacrificing the benefits of global EOS. Coca-Cola would not have introduced New Coke or Classic Coke if the development of this product were to significantly impede the company from achieving its engineering efficiency. Benefits from efficiently engineering the product and principal business functions should be emphasized first for a successful global firm.

Levitt [13] suggested that although the earth is round, marketers should view it as flat. However, one further step can be suggested: "Do not just treat it as flat, but make it flat". Many multinational marketers may still insist on viewing the world through the lens of localized tastes and unique buying habits. Correct understanding of the behavioral context in foreign markets is at first very important for the global manager. However, really successful global managers may have to be able to inform and persuade local consumers through communications. Some consumers in LDCs, for example, enjoy American-type soft drinks, but they prefer them at room temperature and sweeter in comparison with North American taste. They might be persuaded to prefer less sweet drinks through education that excess sugar is not good for their teeth or general health. They might also be persuaded to prefer colder soft drinks, as refrigerators become more common in their households.

Coming up as fast as communication tools are supra-national electronic media, which transcend country boundaries. These media will permit the use of standardized and simultaneous promotional strategies across vast regions and multiple markets. These developments in global telecommunications, together with parallel innovations in transportation and an expansion of international advertising agency services will facilitate media and message access to some unfamiliar markets. With these tools the most important task of global managers is to find the common need of global consumers and to develop global products, rather than to customize their product to the local markets.

9.5 A New Strategy for Dynamic Globalization

In the integration-responsiveness (I-R) framework, several different strategies can be contrasted as shown in Figure 9.4.

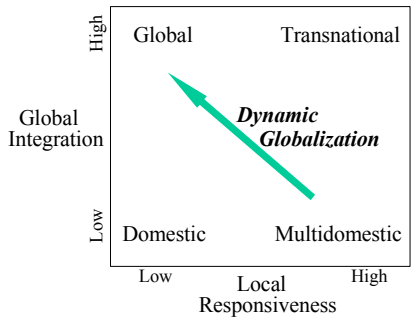

Figure 9.4. Types of international strategies

Type 1: Centralized Organization: Standardized Strategy

Levitt [13] argued that there is a new commercial reality: the emergence of global markets for standardized products. According to him, the global corporation operates at relatively low cost as if the entire world were a single entity; it sells the same things in the same way everywhere. Levitt's global strategy is thus located in the upper left corner (high integration and low responsiveness) of the I-R model.

Type 2: Decentralized Organization: Customized Strategy

Douglas and Wind [6] critically examined the key assumptions underlying the philosophy of the integration strategy, and the conditions under which it is likely to be effective. Based on this analysis, they proposed that the responsiveness strategy is more common than the integration strategy because international markets are more heterogeneous than homogenous. Their strategy is thus located in the lower right corner (low integration and high responsiveness) of the I-R model. This type of firm can be called a multinational [6] or multidomestic firm [26, 19].

Type 3: Mixed Organization: Transnational Strategy

According to Bartlett and Ghoshal [3], each of the above two approaches is partially true and has its own merits, but none represents the whole truly. They suggested the need for simultaneously achieving global integration and local responsiveness. To achieve global competitive advantage, costs and revenues have to be managed simultaneously, efficiency and innovation are both important, and innovations can arise in many different parts of the organization. Therefore, instead of centralizing or decentralizing assets, the transnational firm makes selective decisions. They call this the transnational solution, which can be located in the upper right (high integration and high responsiveness) of the I-R model.

Type 4: Flexible Organization: Dynamic Globalization

However, none of these strategies adequately explain the dynamic nature of global firms that improve country-specific products to global products by recognizing global needs and persuading global consumers with value-added products. This strategy implies the dynamic shift from a multidomestic firm to a global firm as the arrow indicates in Figure 9.4. The new paradigm should be a flexible organization that enables the firm to educate or persuade local consumers, through enhanced engineering efficiency.

It is important to understand the relation between the exploration of new possibilities and the exploitation of old certainties. This complementary aspect of firm's asset portfolio is particularly important in understanding the entry modes of multinational firms [20]. March [15] argued that adaptive processes, by refining exploitation more rapidly than exploration, are likely to become effective in the short run but self-destructive in the long run. The static global strategy of deciding whether the international market is homogeneous or heterogeneous, in order to most effectively exploit a firm's existing products or capabilities, is related to the exploitation of old certainties. However, the dynamic global strategy of introducing new global products or improving country-specific products to global products is related to the exploration of new possibilities.

The truly global firm can achieve this exploration goal by enhancing the product's economic values, such as price and differentiation, so that local consumers give up their local

preferences for the increased economic value of the product. In other words, the most important task of global managers and organizations is not to decide whether the international consumer is global, local, or even glocal, but to change local consumers to global consumers by providing products in which product values outweigh local tastes.

The debate on standardization versus customization is an important subject in the international marketing field and thus related examples and cases are primarily consumer products. However, very important implications can also be derived for engineering products and engineering applications to consumer products. In today's global economy, the need for customization in the foreign market is often overstated with an overemphasis on differences in consumer tastes across nations. However, the introduction of a customized product is costly and sometimes risky when the customized product is deviated from engineering efficiency. Foreign consumers actually prefer global products to locally customized products in many market segments such as automobiles, electronics, and other products in which engineering applications are important. The global manager should consider engineering efficiency first before marketing efficiency because optimal engineering efficiency creates more values than customized marketing efficiency.

9.6 Conclusions

Despite numerous articles on this issue, the debate over international standardization continues. This is partly because there is a lack of empirical data, but mainly because most scholars merely deal with selective examples for their particular purposes. The main problem with existing studies is that they are static rather than dynamic. Their strategic recommendations are mostly based on the perceived and static dissimilarities or similarities of international markets. This chapter argues not that the global market is homogenous or heterogeneous, but that the most successful global firm should be able to change more heterogeneous local consumers to more homogenous global consumers through enhanced engineering.

The global market place is not purely homogenous. Managers are frequently urged "to tailor for fit" in each different country environment. If they focus too much on the differences, however, the global screening process may undervalue the available markets. In many cases, environmental differences among national markets can be dealt with over time through appropriate strategies. This chapter suggested a new strategic guideline for global firms to pursue this new task of dynamic globalization.

In today's globalized and also localized economy, international managers selectively choose globalization and customization to maximize profits. However, the most important role of the global manager is not just to find profits but to add value to product and management by reducing local differences and unnecessary waste. Therefore, the debate on global standardization should focus on how to shift local product to global product, rather than on whether global standardization is good or not. This study has demonstrated that a preferred strategy is dynamic globalization and engineering efficiency is often more important than marketing efficiency in creating values. Further empirical studies would be necessary to establish whether the ideas presented in this study will make an impact on the success of global firms.

The Performance Economy: Business Models for the Functional Service Economy

Walter R. Stahel

The Geneva Association, Route de Malagnou 53
CH-1208 Genève, Switzerland

Abstract: The industrial economy creates wealth through the optimization of production processes and related material flows up to the point of sale; more growth means a higher resource throughput; a decoupling of growth and resource consumption is not possible. The shift to a more sustainable economy, to create wealth with substantially reduced flows of materials and energy, needs new business models. This chapter shows new business models to achieve the EU Lisbon objectives for 2010 – more growth and more jobs – while simultaneously reducing the resource consumption of industrialized countries. The new business models are grouped under the name of the performance economy, there common denominator is that they enable entrepreneurs to achieve a higher competitiveness with greatly reduced resource consumption and without an externalization of the costs of waste and of risk. The change from an industrial to a performance economy is full of opportunities but also obstacles. This chapter summarizes some of the major issues involved in such a shift; many others depend on the economic sector concerned and the national framework conditions in place. It also proposes two new metrics to measure the path towards the sustainability of corporations and to give sustainable investors a reliable guide for historic analysis and future projections.

10.1 Introduction

The dominating industrial economy is focused on the optimization of production and related material flows up to the point of sale (POS) as its principal means to create wealth. More resource throughput means more wealth – a situation which is still valid in situations of a scarcity of goods and services. Highly industrialized countries, however, need to develop economic models in which wealth creation and resource consumption are decoupled, and which achieve this economic optimization over the full life cycle of goods – production, utilization and re-marketing of goods and molecules.

One such economic model is the performance economy [4]) (see Figure 10.1), which bridges the gap between the 2010 Lisbon Objectives of the European Union – higher growth and more jobs – and the sustainability objective to considerably reduce the resource consumption – energy and materials – especially of industrialized countries:

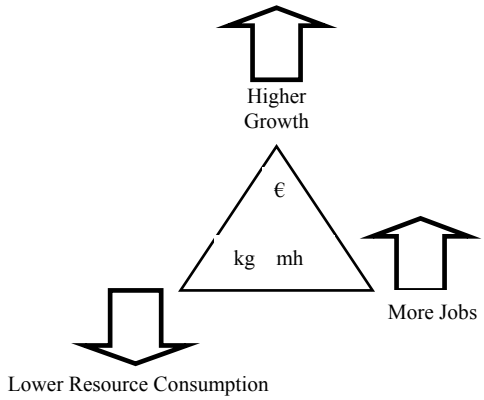

Figure 10.1. The objectives of the performance economy

By thinking "smart", companies and governments can economically profit from technological progress and at the same time contribute to sustainable development. But in order to measure the success of the performance economy, new metrics in the form of decoupling indicators are needed linked to:

- producing performance: **'$**-per-kg' ratio to measure wealth creation in relation to resource consumption, by using business models focused on intellectual asset management;
- managing performance over time: "man-hour-per-kg" ratio to measure job creation in relation to resource consumption, by using business models focused on phasical asset management;
- selling performance: business models that enable entrepreneurs to achieve a higher competitiveness without externalizing the costs of waste and risk.

A functional service economy that optimizes the use (or function) of goods and services and thus the management of existing wealth (knowledge, physical goods and nature) is an integral part of the performance economy. The economic objective of the functional service economy – to create the highest possible use value for the longest possible time while consuming as few material resources and energy as possible – means shifting from a production-oriented industrial economy toward a performance economy.

Sustainability

Sustainability depends on several interrelated systems. Each is essential for the survival of humans on Earth. This means that priorities cannot be argued over nor can there be speculation about which of these systems humankind can afford to lose first. In fact, humans cannot risk losing ground in any of these areas:

- The eco-support system for life on the planet (*e.g.,* biodiversity), a factor of the regional carrying capacity of nature with regard to human populations and human life styles.
- The toxicology system (qualitative, sometimes accumulative), a direct danger to man and increasingly the result of humankind's own economic activities.
- The flows-of-matter system (quantitative), a factor of planetary change (toward a re-acidification) and thus a danger to human life on Earth.
- Social ecology – the system of societal and economic structures, factors contributing to our quality of life.
- Cultural ecology – the system that defines cultural values and attitudes of producers and consumers.

The last two areas carry the idea of a sustainable society [1]. They encompass the broader objective of the longevity and sustainability of our civic and economic structures.

This insight was at the basis of the movement that coined the English term "sustainability" anew in the early 1970s. The emergence of the "green" movement and its use of the term sustainability missed the wider perspective of a sustainable society because they were based on the original term "sustainability" coined by Prussian gentleman foresters 200 years ago, a concept well known to the foresters of the early USA. The broader perspective includes considerations such as full and meaningful employment and quality of life. That perspective is necessary for understanding the importance of the social, cultural, and

organizational changes needed to create a more sustainable economy.

10.2 The Consequences of Traditional Linear Thought

Current economic systems are the result of linear thinking. For example, the terms "added value," relating exclusively to production, and "waste" to the end of the first (and often only) use phase of goods, are notions of a linear industrial economy. Similarly, manufacturers' liability for quality stops shortly after the point of sale (POS), at the end of the warranty period. At the POS, the buyer becomes responsible for the utilization and disposal of the goods purchased without knowing what materials are incorporated in the goods and without the operation and maintenance skills necessary to exploit the full technical product-life of the goods.

In contrast, cycles, lakes and loops have no beginning or end. In a true loop economy there is thus no added value or waste in the linear sense. A loop economy is similar to natural systems, such as the water cycle, but in contrast to nature has to search for the highest conservation of economic value. Moreover, quality has to be guaranteed and maintained over the full life cycle of goods.

Present national accounting systems and the use of the gross national product (GNP) as a measure of success is again an inheritance of the linear industrial economy. Adding income and expenses together is an indication of activity, not of wealth and well-being: waste management, car accidents, pollution control, and remediation costs all constitute positive contributions to the GNP at the same level as the manufacturing of goods. This shows a basic deficiency of national accounts. In this old frame of reference, sufficiency and (waste) prevention corresponds to a loss of income which is economically undesirable. From a sustainability and performance economy view, waste and loss prevention (*e.g.*, accidents) is a reduction of costs that contributes to substantial national savings. For instance, waste management in Germany costs the economy (but contributes to GNP) in excess of US $545 billion per year. Waste prevention could reduce the need for this management cost and contribute to national wealth through sufficiency.

When discussing the benefits of moving toward a more sustainable society and searching for metrics to gauge such change, it is important to keep the inability of the non-sustainable national accounting systems in mind to measure, *e.g.*, the contributions of sufficiency strategies.

10.3 Resource-use Policies Are Industrial Policies

The choice of the best waste-management strategy is often a self-fulfilling prophecy. The promotion of recycling strategies – closing the material loops – conserves the existing economic structures and is thus easy to implement. Unfortunately, an increase in the amount of secondary resources can cause an oversupply of materials and depress the prices of virgin and recycled resources alike. The result is a problem of oversupply and sinking resource prices that jeopardize the economics of recycling. Future technical innovation in recycling will include improvements in design for the recyclability of goods and new recycling technologies, both of which cannot overcome the basic price squeeze mentioned [3]. Increased recycling does not reduce the flow of material and energy through the economy but it does reduce resource depletion and waste volumes, that is the beginning and end of the linear economy.

In contrast to recycling, strategies for higher resource efficiency reduce the volume and speed of the resource flows through the economy. One of the keys to resource efficiency is the take-back strategy: closing the (product and material) *responsibility loops*. However, strategies of higher resource efficiency counter the validity of the present calculus of economic optimization that ends at the point of sale. At first sight, closed responsibility loops even seem to violate traditional task definition in the economy: Industry produces efficiently, consumers use quickly, and the state disposes efficiently.

Strategies to close the product responsibility loops, such as the voluntary or mandatory take-back of consumer goods, impose structural changes

and new business models and are thus more difficult to implement than the recycling of materials. These strategies are driven by innovative corporate approaches, such as Xerox's asset management programme, as they are more competitive as well as more sustainable. These strategies will become even more competitive as the functional service economy develops, energy and resource prices rise and framework conditions change accordingly [9]. Future technical innovations that can be expected in this field are those that enable the use of remanufactured and technologically upgraded components and goods as well as commercial innovations to keep goods in use as long as possible.

Coming changes in framework conditions may include increased taxes on the consumption of non-renewable resources, and/or bonuses on resource consumption reductions, such as tradable CO_2-emission rights on non-manufacturing activities, such as remanufacturing and other utilization optimization services.

Higher resource efficiency through an optimization of the use of goods can be measured as "resource input per unit of use" over long periods of time and will cause substantial structural change within the economy. Again, the change will be helped by the fact that these strategies increase competitiveness. An early adoption may thus give a considerable long-term advantage to companies that dare to change first (first mover advantage). Among the strategies for higher resource efficiency are those for a longer and more intensive use of goods, those for dematerialized goods and those for innovative system solutions (Table 10.1). Among the innovations to emerge from a promotion of higher resource efficiency are both new technical and new commercial strategies to improve use.

A reduction in the flows of matter through the economy can be achieved by decreasing the volume of flow (through innovative multi-functional products and a more intensive use of products and system solutions) or by slowing the speed of flow (*e.g.*, through the remanufacturing and remarketing of goods to extend their service life).

The biggest potential is hidden in innovations at system level, to redesign components, goods, and systems that reduce material use in manufacturing and in reducing the costs of operating and maintaining the goods in use (see Figure 10.2).

10.4 The Problem of Oversupply

The economies of industrialized countries are characterized by several key factors [2]:

- Their populations account for only 20% of the world population but for 80% of world resource consumption.
- Their markets for goods are saturated and the stocks of goods represent a huge storage of resources. For built infrastructures, there is also an increasing financial burden with regard to operation and maintenance costs of ageing infrastructures.
- Their economies suffer from oversupply, which indicates that the old remedy of a higher economy of scale (centralization of production to reduce manufacturing costs) can no longer solve the economic problems or the sustainability issue. The reason for this is that the costs of the services that are instrumental for production are a multiple of the pure manufacturing costs; a further optimization of production therefore does not make economic sense.
- Incremental technical progress is faster than product development: substituting new products for existing ones will increasingly restrain technological progress compared with the alternative of a fast technological upgrading of existing goods.

The situation for the economies of many developing countries, however, is radically different. These countries will continue to experience a strong demand for basic materials for the construction of their infrastructures and will continuously suffer from a shortage of affordable resources and mass-produced goods, including food, shelter, as well as infrastructure and services

Table 10.1. Resource efficiency and business strategies in the service economy

Resource efficiency objectives	**Implementation of strategies**	
	Closing material loops (technical strategies)	**Closing liability loops** (commercial/marketing strategies)
Reduce the volume of the resource flow	**Ecoproducts** • dematerialized goods • multifunctional goods	**Ecomarketing** • shared utilization of goods • selling *utilization instead*
Reduce the speed of the resource flow	**Remanufacturing** • long-life goods • product-life goods • cascading, cannibalizing	**Remarketing** • de-curement services • away-grading of goods and components • new products *from waste*
Reduce the volume and the speed of the resource flow	**System solutions** • Krauss-Maffei plane transport system	**Systemic solutions** • lighthouses • selling results instead of goods • selling *services instead of goods*

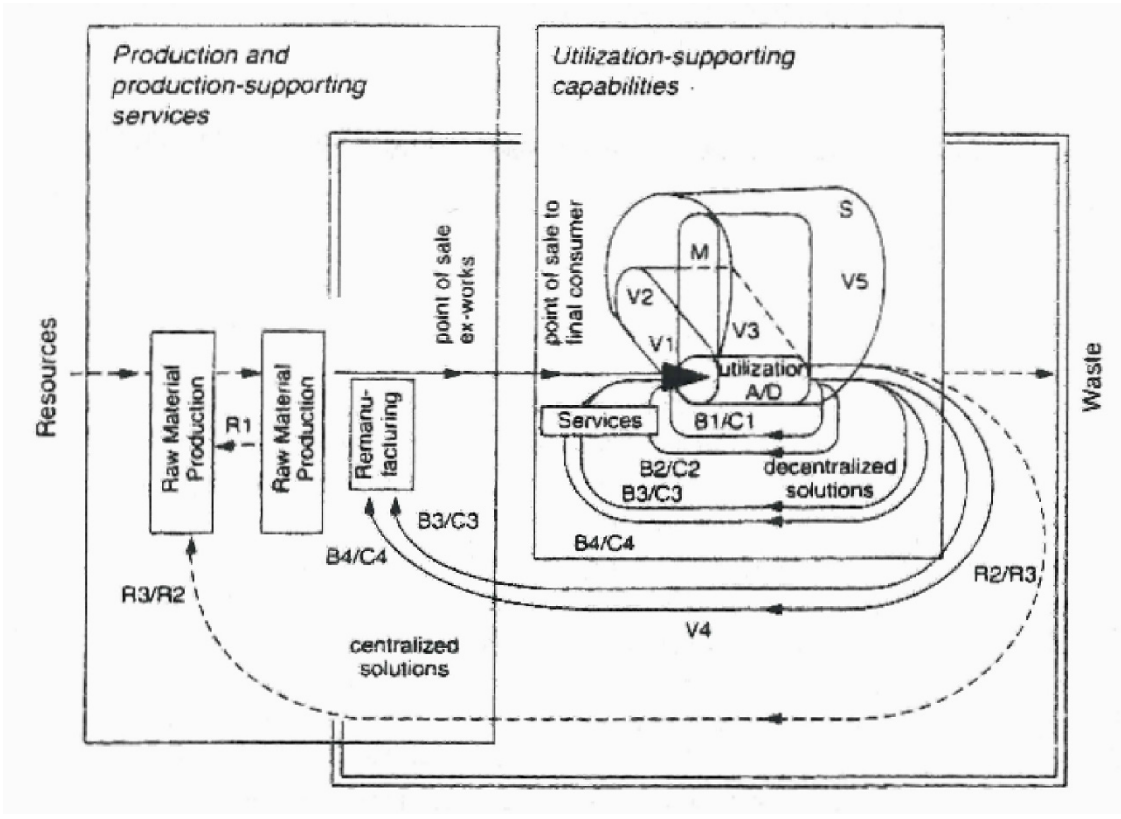

Figure 10.2. Strategies for higher resource efficiency (adapted from [11])

for health and education. Resource efficiency in industrialized countries will ease World market pressure on the prices of resources.

10.5 The Genesis of a Sustainable Cycle

A great deal of change in how we think about economics is necessary for understanding a "life after waste" industrialized society. A critical change is to shift to a service economy in loops detailed in Figure 10.2 [2]. Cycles have no beginning and no end. Economically, the most interesting part of the cycle and new focal point is the physical management of the stock of existing goods in the market. Economic well-being is then no longer measured by exchange value and GNP but by the use-value of a product and the wealth presented by the stock of existing goods. This is not only true for durable goods but equally for areas such as health and education, where the yardstick must be a better health of the population and a higher qualification of children, not the expenses to achieve this.

Long-term ownership of physical assets becomes the key to the long-term (rental) income of successful companies, and with that ownership comes unlimited product responsibility that includes the cost of risk and cost of waste. Strategies of selling the use of goods instead of the goods themselves (*e.g.*, Xerox selling customer satisfaction) and business models that provide incentives to customers to return goods to manufacturers become keys to long-term corporate success. The adaptability of existing and future goods to changes in users' needs and to technological progress (to keep them current with technological progress) becomes the new challenge for designers and engineers. The economic structure must maximize the return from these new resources: a fleet of existing goods in a dispersed market. An adaptation of today's economic, legal, and tax structures to these new requirements may become a decisive competitive advantage for countries to attract and breed successful economic players for a sustainable functional performance-focused service economy.

Several multinational companies such as Schindler, Caterpillar and Xerox have already started to successfully implement these new strategies. Schindler sells "carefree vertical transport" instead of elevators, a strategy that provides all the services needed by customers (*i.e.*, maintenance, remanufacturing, and technological updating of elevators). In addition, there is a telephone connection linking every elevator 24 hours a day to an emergency service center. In collaboration with the decentralized maintenance crews of the manufacturer, this system ensures that no person ever gets stuck for more than a few minutes in an elevator that has stopped functioning for technical reasons.

Xerox's asset management program is focused on selling customer satisfaction that is photocopying services instead of photocopiers. Asset recovery is now part of a new business process that includes an asset re-uses management organization. Xerox has decoupled manufacturing volume from turnover and profits, regionalized activities, and changed its skill pool and employee responsibilities accordingly.

I. Strategies for slowing down the flow of matter through the economy
   - A. Long-life goods: Philips induction lamp, Ecosys printer
   - B. Product-life extension of goods:
     - B1. Reuse: re-useable glass bottles
     - B2. Repair: car windscreen, flat tire
     - B3. Remanufacture: re-treaded tires, renovated buildings
     - B4. Technology upgrading: Xerox copier '5088, mainframe computers
   - C. Product-life extension of components:
     - C1. Reuse: refill printer cartridges, roof tiles
     - C2. Repair: welding of broken machine parts, re-vacuum insulating windows
     - C3. Remanufacture: remanufacturing engines and automotive parts
     - C4. Technology upgrading: upgrading of (jet) engines to new noise and emission standards
   - D. Remarketing new products from waste (product-life extension into new fields)

II. Strategies for reducing the volume of matter through the economy
  M. Multifunctional goods: fax-scanner-printer-copier all-in-one, Swiss Army knife, adaptable spanner
  S. System solutions: micro cogeneration of cold or heat and power, road railers
III. Strategies for a cradle-to-cradle product responsibility
IV. Commercial or marketing strategies
  IV1. Selling use instead of goods: operational leasing of cars, aircraft, trucks, construction equipment, medical equipment, photocopiers, rental apartments
  IV2. Selling shared-use services: Laundromats, hotels (beds),
  IV3. Selling services instead of products: lubrication quality instead of engine oil
  IV4. Selling results instead of products: pest-free and weed-free fields instead of agro chemicals, individual transport instead of cars
  IV5. Monetary bring-back rewards: 10-year cash-back guarantee

10.6 The Factor Time – Creating Jobs at Home

How will this shift to a loop economy impact the factor inputs into the economy? The following Figure 10.3 shows the development of the life cycle costs for operating an automobile over 50 years.[1] This analysis is representative for the life-cycle costs of most durable goods.

At the POS, the producer-distributor in an industrial economy sells a durable good to the user-consumer, the sales price being equal to the exchange value. The value embedded in the product is represented mostly by the nonrenewable (depletable) ENERGY + MATERIALS used in the manufacturing and distribution processes; making up nearly 100%. Labor is a small part of the manufacturing input.[2] The sales price remains constant throughout the utilization period, so its relative weight will decrease over time. It is represented by the left upper triangle in Figure 10.3.

During the utilization period, the main resources employed are renewable, mainly in the form of human labour for such service activities as maintenance and repairs. These MANPOWER costs accumulate over the years, up to a ceiling of about 75%, and are represented by the lower right triangle in Figure 10.2.

Spare parts and components make up a relatively stable 20% of life-cycle costs (the dark wedge). These parts have a high potential to be remanufactured in the loop economy, adding up to 15 additional percentage points to the pure manpower input shown in Figure 10.3.

With increasing service-life (years of utilization), the cost share of depletable resources diminishes rapidly, while renewable resources (manpower) increases. A strategy of service-life extension for durable goods – such as infrastructure, buildings, ships, aircraft, equipment and cars – is thus equivalent to a substitution of manpower for energy and materials.[3] This strategy creates jobs at home while at the same time reducing resource throughput in the economy. It also has a much higher value-per-weight ratio than manufacturing, as will be shown later. In addition, it preserves energy investments (also called gray energy) and reduces CO_2 emissions.

Skilled and experienced craftsmen are needed in repair and remanufacturing activities, which can be undertaken in comparatively small workshops, scattered widely throughout the country where there is a need for product renovation and customers for them, as is the case with car-repair workshops. These enterprises can be located in any rural or urban area with high unemployment, making product-life extension a doubly attractive proposition for job creation.

[1] The figures are based on the Life-Cycle Costs of the author's car, a 1969 Toyota Corona Mk II

[2] According to a press communication by Wofgang Bernhard, Head of VW division at Vokswagen AG Wolfsburg, workers at VW need 50 hours to build a car, while the industry average is 25 hours

[3] See also [7]

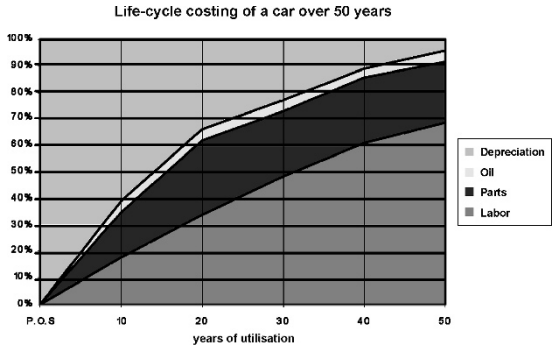

Figure 10.3. Evolution of the life cycle costs for goods in the Lake Economy

10.7 Strategic and Organizational Changes

In contrast to the manufacturing economy, economic success in the sustainable service economy does not arise from mass production but from good husbandry, caring attitudes and stewardship. Economic rewards come from minimizing tasks needed to transfer a product from one user to the next. Local reuse after a quality check or repair by the manager's representative is the smallest possible cycle in Figure 10.2 and the most profitable strategy. A product that can no longer be commercialized (*i.e.*, rented or used) will be remanufactured and upgraded or, in the worst case, be dismantled with the aim of reusing its components for new products. If there is no re-use possibility, the materials can be recycled and used to manufacture new components.

To achieve the smallest cycles, a different economic and organizational mindset is necessary in several areas:

- The industrial structure for manufacturing and remanufacturing activities will have to be regionalized in order to be closer to the market assets. This proximity demands the capability to handle smaller remanufacturing volumes more efficiently. Appropriate methods for such purposes will have to be developed and skilled labor trained. The cost for such a change is offset by dramatic reductions in the purchase of materials and the virtual elimination of disposal costs.
  - Products will have to be designed as technical systems that are part of pre-designed modular master plans. Such plans will facilitate ease of maintenance and ease of out-of-sequence disassembly by workers or robots.
- Components will have to be designed for remanufacturing and technological upgrading according to the commonality principle. This principle was first used by Brown Boveri Company in the 1920s to design its revolutionary turbo compressors. It has been perfected by Xerox in the 1990s in the design of its copiers. The commonality principle promotes standardized multi-product function-specific components that are interchangeable among different product lines.
  - Goods and standardized components will increasingly be designed to be maintenance free, self-protecting and fault tolerant, which greatly reduces operating costs (such as service interventions, repairman training and spare-parts management).
- New technologies aimed at optimizing the resource efficiency and safety of products and components over long periods of time will have to be developed. These include spare less repair methods, in situ quality-of-function monitoring systems, and memory chips to register life-cycle data.
  - Business models to sell performance instead of goods (Table 10.2 explains the differences), such as the "pay by the hour" for jet engines of GE and Pratt & Witney, integrate many of the above issues into the economy.

- New professions and job qualifications will emerge, such as operation and maintenance engineers. The salesperson of the past will have to become customer advisor able to optimize generic products for the needs of specific users, and to upgrade existing products according to the wishes of the user as technology advances. For the first time since the beginning of the Industrial Revolution, the economy will offer workplace mobility rather than rely on worker mobility. The more immaterial goods that are transported, the greater the feasibility of telecommuting. Flexible work periods and part-time work are compatible with and even a necessity for, providing services and results around the clock.

Table 10.2. Selling performance *versus* selling products

Efficiency strategy **Sale of a product** [industrial economy]	**Sufficiency strategy** **Sale of a performance** [functional service economy]
The object of the sale is a product	The object of the sale is performance, customer satisfaction is the result
Liability of the seller for the manufacturing quality [defects]	Liability of the seller for the quality of the performance [usefulness]
Payment is due for and at the transfer of the property rights ['as is where is'-principle]	Payment is due pro rata if and when the performance is delivered ["no fun no money" principle]
Work can be produced centrally/ globally [production], products can be stored, re-sold, exchanged	Work has to be produced in situ [service], around the clock, no storage or exchange possible
Property rights and liability are transferred to the buyer	Property rights and liability remain with the fleet manager
Advantages for buyer: • right to a possible increase in value • status value as when buying performance	Advantages for the user: • high flexibility in utilization • little own knowledge necessary • lost guarantee per unit of performance zero risk • status symbol as when buying product
Disadvantages for buyer: • zero flexibility in utilization • own knowledge necessary [driver licence] • no cost guarantee • full risk for operation and disposal	Disadvantages for user: • no right to a possible increase in value
Marketing strategy = publicity, sponsoring	Marketing strategy = customer service
Central notion of value: high short-term exchange value at the point of sale.	Central notion of value: constant utilization value over long-term utilization period.

- Users (ex-consumers) will have to learn to take care of the rented or leased products as if they owned them, to enjoy the new flexibility in product-use offered by a use-focused service economy. Whereas in the industrial economy, misuse and abuse of products lead to a financial punishment inthe form of increased maintenance cost for the owner-user, in the service economy they may lead to the exclusion of a user from the use-focused system.

10.8 Obstacles, Opportunities, and Trends

Many of the obstacles that need to be overcome on the way to an economy optimizing multiple service-lives or use-cycles are embodied in the logic of the present linear industrial economy. The definition of quality, for example, is based on the absence of manufacturing defects only (limited to 6 or 12 months) and on the newness of components in new goods. The logic framework of a functional economy requires a demand-side definition of quality based on unlimited customer satisfaction and the guarantee of a system functioning over longer periods of time.

The definition of "quality" in the performance economy integrates

- technology management (efficiency),
- risk management (preventive engineering) and
- the factor time (sustainability management),

and redefines quality as the three-dimensional vector of a long-term optimization of system functioning, which is a synonym for performance (Figure 10.4).

A functional service economy needs an appropriate structure. The characteristics include a regionalization of jobs and skills, such as mini-mills for material recycling, remanufacturing workshops for products, decentralized production of services (*e.g.*, rental outlets), local upgrading and take-back, supplemented by centralized design, research, and management centers. Such an economy will consume fewer resources and have higher resource efficiency, and its production will be characterized by smaller regionalized units with a higher and more skilled labor input. Transport volumes of material goods will diminish and be replaced by transports of immaterial goods such as recipes instead of food products, software instead of spare parts.

The signs on the horizon clearly point to a use-focused economy:

- The European Community-directives on product liability and more recently on product safety and the draft directive on service liability all stipulate a 10-year liability period, or impose a manufacturers disposal liability (end of life vehicles, WEEE).
- Some car manufacturers offer a total cost guarantee over three or five years, which includes all costs except tire wear and fuel.
- Industry shows an increasing willingness to accept unlimited product responsibility and to use it aggressively in advertising, through money-back guarantees, exchange offers, and other forms of voluntary product take-back and is learning to make product retake and remarketing a viable business division.
- Out-sourcing has rapidly become a generally accepted form of selling results instead of (capital) goods or services.

Companies and regions that initiate the change toward a sustainable society rather than suffering the consequences of it through the actions of their competitors will have a head start and be able to position themselves strategically. An old, but in the age of market research somewhat forgotten, truth of economies will play its heavy hand again: Real innovation is always supply driven – the role of demand is one of selection [2].

10.9 New Metrics to Measure Success in the Performance Economy

To measure shift from an industrial to a performance economy, we need new metrics in the sense of decoupling indicators, which can be used for individual goods by the customer at the POS,

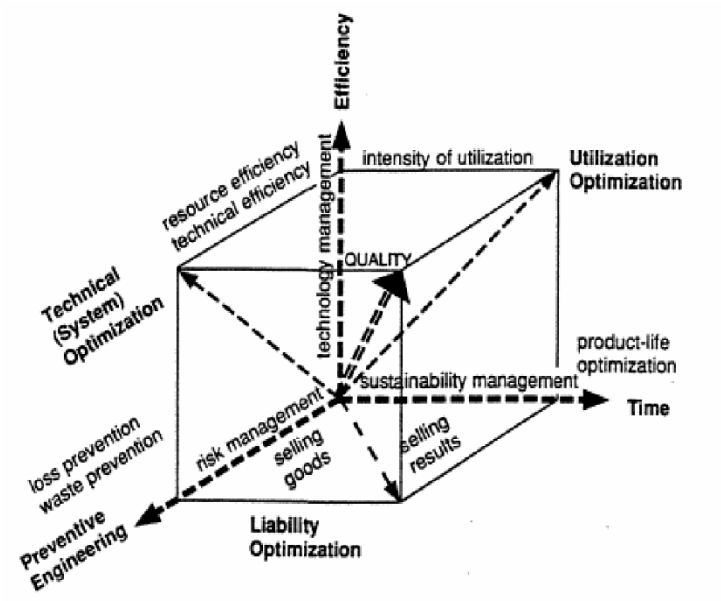

Figure 10.4. The quality cube of the performance economy (adapted from from [6])

but also calculated on an annual basis for plants, corporations, economic sectors or nation states.

These new metrics in the form of decoupling sustainability indicators were already mentioned in the Introduction:

- producing performance: "$-per-kg" ratio to measure wealth creation in relation to resource consumption;
- managing performance over time: "man-hour-per-kg" ratio to measure job creation in relation to resource consumption;
- selling performance: new business models that enable entrepreneurs to achieve a higher competitiveness without externalizing the costs of waste and risk.

OECD coined the term DEI – decoupling environmental indicator. The term decoupling refers to breaking the link between *environmental bads* and *economic goods.* It refers to the relative growth rates of a direct pressure on the environment and of an economically relevant variable to which it is causally linked. Decoupling occurs when the growth rate of the environmental pressure (EP) is less than that of its economic driving force (DF) over a given period. One distinguishes between *absolute and relative decoupling.* Decoupling is said to be absolute when the environmental variable is stable or decreasing while the economic variable is growing. Decoupling is relative when the environmental variable is increasing, but at a lower rate than the economic variable.

The decoupling indicators of the Performance Economy go beyond the OECD's DEIs, which are environmental and ecological, as they also include the social pillar of sustainability.

10.10 Regionalization of the Economy

The performance economy will lead to a regionalization of economic activities for a number of reasons.

Producing performance through, *e.g.*, nano- and life-sciences means in some cases to localize production for technical reasons, such as

- lab-on-a-chip – micro high-tech production units that can produce small quantities of the desired substances much more efficiently than a big production unit;
- some nano-products, such as nano carbon tubes (NCT), cannot be transported and have to be produced at the place of their integration in other goods;
- the leasing of smart materials imposes the leasing of the final goods in the performance economy as well as a loop economy (take-back guarantees).

Maintaining performance over time through, *e.g.*, remanufacturing and remarketing is under the axiom of the loop economy, which says that the smaller the loop, the higher the profitability is cheaper remanufacturing services are best done regionally

Business models of selling performance instead of goods are based on locally available services. As services cannot be produced in advance and stored but have to be delivered at the location of the client when needed, a decentralized service structure available 24 hours 346 days a year are necessary in many cases.

In addition, these business models mean sustainable profits without an externalization of the cost of risk. Business interruptions in the global economy will become more frequent through the criticality of transport systems and networks, be it for physical goods, energy or data. Terrorism and pandemics are just two reasons that can lead to a shut-down of the world economy for a few days or weeks. Just-in-time production and delivery chains can then no longer be guaranteed.

10.11 Conclusions

The shift in the economy towards a more sustainable society and a functional service economy has begun some time ago. However, most experts are unaware of the fundamental change, probably because they interpret the signs on the horizon in terms of the old industrial economic thinking. A performance economy will not solve all the problems of this world, and especially not the inherited problems from the past (*e.g.*, pollution cleanup and unemployment of overspecialized production workers); nor will it make the manufacturing sector superfluous. However, the industrial sector could well be split into high-volume producers of global standardized components and regionalized assemblers (*e.g.*, computer components and DELL) and regional remanufacturers and remarketeers of products active in the physical asset management of industrialized regions.

Cleaner Production and Industrial Ecology: A Dire Need for 21st Century Manufacturing

Leo Baas

Erasmus University Rotterdam,
Room M7-16, P.O. Box 1738, 3000DR Rotterdam,
The Netherlands

Abstract: The chapter discusses the dissemination of the concepts of cleaner production and industrial ecology as an operationalization within the framework of *sustainability systems* in the industrial practice. Experiences in cleaner production and industrial ecology projects show that an open, reflective and on-going dialogue must be designed to develop trust, transparency and confidence to ensure real involvement of diverse stakeholders in charting the future of their organizations and regions as part of the transition to sustainable societies. The integration of ecological, economic, social and cultural dimensions of corporate activities become a dire need for a sound use of scarce resources in the 21st century.

11.1 Introduction

Cleaner production and industrial ecology are known concepts worldwide, however, their dissemination is not an easy process. The concepts of *cleaner production* can be described as "the continuous application of an integrated, preventive environmental strategy to both processes and products to reduce risks to humans and the environment [1]". *Industrial ecology* is described as "an integrated system, in which the consumption of energy and materials is optimized and the effluents of one process serve as the raw material(s) or energy for another process [2]".

As a process of dissemination of new concepts, the cleaner production paradigm was introduced to industrial leaders as a prevention-oriented paradigm for achieving cleaner industry and more sustainable communities; this was viewed as an important way to supplant or supplement the old paradigm of pollution control. In the cleaner production paradigm, the conceptual approach was to catalyse the transition from *waste management policies and approaches at the end-of-the-pipe,* to *"environment included"* in *industrial innovation policies for waste prevention* and *waste minimization* at the sources of the problems [3]. Industrial routines are embedded in unsustainable practices that are difficult to change. The complexity and uncertainties of new concepts are often approached with ignorance and mis-perception. Nevertheless the integration of economic, environmental and social dimensions in industrial activities is increasingly perceived as a necessary condition for a sustainable society.

This chapter discusses the dissemination of the concepts of cleaner production and industrial ecology as an operationalisation within the framework of *sustainability systems* in the industrial practice. At first in Section 11.1.1, some reflection is given to climate change as new environmental policy incentive in the context of global trends and their local adaptation processes. In Section 11.2 the dissemination of new preventive concepts is reflected upon at the macro, meso and micro levels in societies. The practical experiences with the dissemination of cleaner production and industrial ecology concepts are connected to the theoretical notions of embeddedness in Section 11.3. For insight in the challenges of the introduction of industrial ecology concepts, the results of industrial ecology programs in the Rotterdam harbor and industry complex are described in Section 11.4. This section is followed by an analysis of the lessons learned on the introduction and dissemination of the concepts of cleaner production and industrial ecology as interaction between theory and practice in Section 11.5. Finally, conclusions and recommendations for a dire need for manufacturing sustainability systems are formulated in Section 11.6.

Climate Change as Environmental Policy Incentive

Climate change worries many persons in the world, because direct effects are also seen all over the world: from the melting ice in Greenland to the vanished snow at the top of the Kilimanjaro in Tanzania [4]. Nevertheless, the responsibility at the environmental policy level is still diffuse. Both at the public and private policy levels much depends on the sense of emergency [4] of responsible managers in combination with the emerging elaboration of social responsibility.

In the past decade, global trends in environment related issues within multi-national corporations have incorporated different dimensions in the concepts of environmental management (ecology), cleaner production (ecology, economy), industrial ecology (ecology, economy) and corporate social responsibility (ecology, economy, social aspects).

The trends in production facilities have been:

- Outsourcing of (mass) production by the northern corporations: to China, Vietnam.
- Near-sourcing of production: USA to Mexico; Western Europe to Central Europe.
- Emerging national mass production facilities: such as in China, India, Vietnam.

These trends involve that working with preventive concepts needs to estimate the context of their embeddedness in the society and the involvement of relevant partners.

At a global environmental policy level implementation processes are related to agreements and strategies such as:

- Johannesburg Declaration on Sustainable Development [5].
- United Nations Millennium Declaration [7].
- UNIDO's Corporate Strategy with focus on Environmentally Sound Technologies and CP market mechanisms [8].
- UNEP's incorporation of Human Development through the Market [8].

It has also to be taken into account that the world population urbanization trend is expected to grow to 60% of the world population living in urban areas in 2040 (developing countries are expected to grow to an urbanization grade of 50% in 2020) [10].

Worldwide the urban problems are concentrated upon: water management, energy, air pollution, and mobility. A recent publication [11] concludes the fact that the following activities and product groups cause 70% to 80% of the total environmental impacts in society:

- Mobility: automobile and air transport.
- Food: meat and dairy, followed by other types of food; and
- The home, and related energy use: buildings, and heating-, cooling-, and other energy using appliances.

In the meantime, tourism, including many aspects of the above mentioned activities, has become the biggest economic sector in the world [4].

The environmental impacts of urban problems can be covered by cleaner production system approaches. Experiences with the dynamic aspects

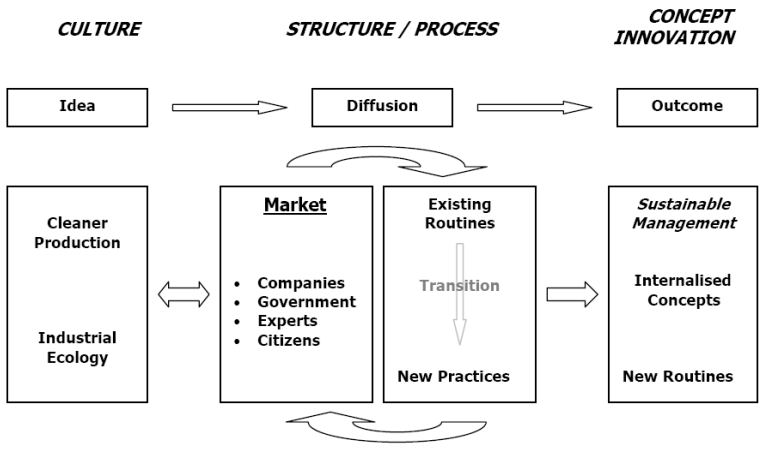

Figure 11.1. The arena of transition processes of new concepts

of the introduction and dissemination of cleaner production and industrial ecology reflect several theoretical notions that are worthwhile to consider in discussing future trends (n*othing is more practical than a good theory*) [11].

11.2 Different Levels of the Dissemination of Preventive Concepts

All considerations about the introduction of (new) concepts such as cleaner production and industrial ecology face an institutionalized arena with routines on environmental performance that challenge *changes in routines* in the competition to achieve better market positions. As the preventive approach is presented as a better business practice, the cleaner production concept provides *prevention as vision* as a label, the *cleaner production assessment* in an organization as instrument for problem analysis, the *cleaner production options* and the integral approach of *continuous improvement* as solutions, and the *cleaner production demonstration projects* as part of a *cleaner production dissemination infrastructure* as the applications of successes.

The *arena* of transition processes of new concepts is visualized in the following model shown in Figure 11.1 [3].

It is assumed that a representative of one of the four societal categories in the market of concept transition processes figure will explore a new concept such as cleaner production and industrial ecology knowledge dissemination. Committed to the new concept, the introducing actor(s) will approach organizations to explore it. After the introduction, acknowledgement and acceptance of the concept, learning (explicit or implicit) and change processes connected to the new concept affect expertise at the individual and organizational levels. In this thesis, the concepts of cleaner production, industrial ecology and sustainability are connected to the micro, meso and macro levels. The different levels are used in relation to system boundaries such as single organizations, organizations located in regions or as members of an industrial sector, and society. There are also levels within an organization that affect the dissemination of a new concept. For instance, for the introduction of cleaner production, the focus is on single organizations; outside actors can introduce the concept and the translation by internal actors might affect the routines. The introduction of industrial ecology goes beyond single organizations, which means that actors outside the companies will influence the overall processes in a dependent manner in relation to the individual company managers.

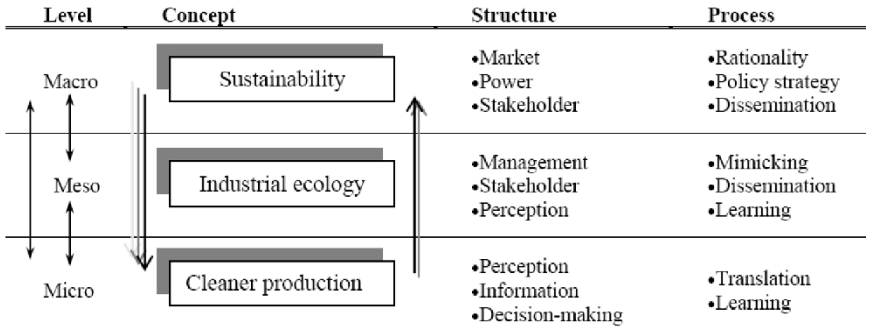

Figure 11.2. The multi-level concept innovation model

The different levels of preventive concepts involve the issue of system boundary. Although one might analyze cleaner production at the micro level of companies and industrial ecology at the meso level of industrial estates, [3] a systems approach of the concept of cleaner production involves the interconnection to industrial ecology and sustainability can be labeled by c*leaner production systems* or s*ustainable consumption and production systems* (see Figure 11.2).

The capacity and capability to break through existing routines is part of an eventual organizational change. Learning processes related to the new cleaner production concept face the techno-structure based on an engineering perspective at the micro level that dominates its translation. The learning processes for industrial ecology face a (plant) management perspective that is limited to the system boundary of their organisation. At first glance, the translation of the new concept is mainly based on mimicking. Both mimicking and dissemination include learning processes. Mimicking involves above all the reception or passive translation of knowledge, while dissemination includes a process of knowledge transfer. At the macro level policy strategy development, both at the private and public organizational levels, is subjected to the influence of translation processes of stakeholders.

Normative concepts – such as the *prevention is better than cure* approach of cleaner production projects – assume implicitly the involvement of all members of the organization in identifying and implementing both non-technical and technical improvements. The following individual and organizational learning processes are experienced according to different dimensions such as:

- Individual learning by members of an organization to look after and cope with incremental (first order) and radical (second order) changes in their organizations [13].
- Different levels at the individual and organizational learning level with single-loop, double-loop, and triple-loop learning processes [14].
- Different types of learning effects: *Learning by doing*, *learning by interaction*, *learning by using*, and *learning by learning* [15].
- Different ways of learning: Strategic or tactical learning [16].

11.3 Practical Experiences and Types of Embeddedness

Several conclusions can be drawn from the shift from environmental technology towards cleaner production [3]. Industrial environmental protection started on a pollution control basis with control technologies. The 1970s can be characterized as a pure technology engineering approach to control pollution. In the 1980s, public policy development included the emergence of integrated environmental policies and new economic and voluntary instruments.

During the cleaner production emergence phase, university experts set up cleaner production

research projects, whilst during the growth phase consulting firms mediated the dissemination of results. This process has been repeated in many countries in Europe. UNEP and UNIDO organizations also mimicked the dissemination of the concepts through demonstration projects, instruction manuals and in a later phase dissemination policies with stakeholder involvement. Another aspect of the institutionalization process is professionalization, in the shape of specialized expertise, national, regional and global expertise networks and expert and scientific journals.

In general, during the emergent phase of a new approach, there is space to reflect about further development. However, the status of the *cleaner production assessment method* meant that the label embodied an encoded knowledge approach that became the basis for preventive developments. As a result, it created a trade-mark that was not open to further dialogue. Although the cleaner production assessment was designed with several feedback loops, in practice the assessment developed as a one-loop learning process, ending with a *cleaner production plan* after the feasibility phase. The engineering approach, based on encoded knowledge, largely dominated the characteristics of the cleaner production concept. Furthermore, demonstration projects had to show practical results. All these activities developed in the direction of a mature phase of institutionalization and stronger internationalization. Also, professionalization and specialization are characteristics of a mature phase. However, societal dissemination processes ask for more ingredients in continuous social change processes and this has been hardly the case [3].

The year 1989 can be regarded as a starting point because of the re-emergence on the environmental agenda of industrial ecology in the wake of an article by Frosch and Gallopoulos [2]. The U.S. Academy of Engineering promoted the concept very much. Also a link with the Japanese Ministry of Trade and Industry was established and strengthened in the course of several workshops in the period 1993–1994 [17].

The most famous reference in the field of applied industrial ecology is the *Industrial Symbiosis*[1] project in Kalundborg in Denmark [18]. Every book (including this book), numerous articles and conferences about industrial ecology make repeated reference to the Kalundborg industrial area. The Kalundborg situation has been copied all over the world since the mid-1990s. In discussions of, and references to, the Kalundborg system it is seldom reported that that Industrial Symbiosis program grew organically on a social-economic basis in a small community where plant managers knew and met each other in a local community atmosphere.

In the last 30 years of the community's evolution, a partnership grew between several industrial plants, farmers and the municipality of Kalundborg. This partnership led to huge improvements in the environmental and economic performances of the Kalundborg region [19]. The core partners in Kalundborg are a power station, an oil refinery, a plasterboard factory, an international biotechnological company, farmers and the municipality. These partners voluntarily developed a series of bilateral exchanges such as:

- The refinery provides the plasterboard company with excess gas.
- The power station supplies the city with steam for the district heating system.
- The hot cooling water from the power plant is partly redirected to a fish farm.
- The power plant uses surplus gas from the refinery in place of coal.
- The sludge from the biotechnological company is used as fertilizer in nearby farms.
- A cement company uses the power plant's desulphurized fly ash.
- The refinery's desulphurization operation produces sulphur, which is used as a raw material in the sulphuric acid production plant.
- The surplus yeast from the biotechnological company is used by farmers as pig feed.

[1] The Industrial Symbiosis label was introduced by the spouse of a plant manager in Kalundborg in Autumn 1989 (According to Jørgen Christensen in New Haven, 8 January 2004).

In practice the concept of eco-industrial parks evolved from waste exchange between companies towards integrated regional ecosystems. The implementation of industrial ecosystems was considered on existing (*brown fields*) and new (*green fields*) industrial areas. An industrial ecosystem must be designed in relationship with the characteristics of the local and regional *ecosystem* but its development must also match the resources and needs of the local and regional *economy*. According to Lowe [19], these dual meanings reinforced the need for working in an inquiry mode: learning from the experiences of other communities developing industrial ecosystems is important.

A compressed air pilot study in an industrial symbiosis project in the Rotterdam harbor and industry complex (INES project) [3] presented instructive challenges. A feasibility study showed that the usage of compressed air was lower than expected (7,000 Nm^3/hr instead of the presumed 12,000–15,000 Nm^3/hr). The results meant that the economy of scale needed for cost reduction was insufficient. Compounding the problem of diminished economies of scale, the supplier was very busy with the installation of a larger system for the delivery of compressed air to the largest refinery in the region. As a result, they gave less priority to the INES compressed air sub-project. In addition, not all of the potential users were enthusiastic about the INES sub-project, although they did not reject participation completely. Another compressed air supplier, however, learned about this project. This company was able to start a new project by building the trust required for the exchange of knowledge with four other firms and by reducing the scale of the investment needed for the installation. The supplier invested in the installation and the pipelines, and now runs the process, maintains the system and is responsible for a continuous supply. This central installation for four companies has been in operation since January 2000.

Preliminary results show savings of 20% in both costs and energy, and a reduction of CO_2 emissions (as a result of the reduction in energy use) of 4,150 metric tons each year. In 2002 another three plants and in 2003 seven plants more, joined that system. This construction provided new business opportunities for the utility provider. They designed a new utility infrastructure for compressed air and nitrogen for 10 companies in the Delfzijl industrial park in the north of the Netherlands (aluminum, chemical and metal-working companies) that opened under the management of the utility provider in 2004 [21].

It can be concluded that the industrial ecology concept is increasingly becoming widely accepted. Also, institutionalization – as with the initiation of a scientific Journal on Industrial Ecology in 1997 and the start of the International Society on Industrial Ecology in 2001 – draws attention to the issue of industrial ecology. The complex system of eco-industrial parks involving different companies and actors (including their different activities and targets) that is required for the existence of industrial ecology in a region is an important, but time-consuming variable. In the Netherlands, several local authorities were encouraged to set up successful eco-industrial parks through a deliberate policy-making process; the consulting firms involved developed various planning methods with several functions. However, the vision of sustainability was scarcely explicitly defined, the categories *symbiosis* and *utility sharing* were not sufficiently considered, the companies were not sufficiently involved in the development process, and the steering instruments could only enforce options with a limited environmental benefit [3].

Considering the practical experiences of the introduction and dissemination of cleaner production and industrial ecology from a systemic perspective, the concepts are addressing material and energy streams as they result from human activities. These activities do not occur in a vacuum, they are embedded, *i.e.*, they are shaped by the context in which they occur. The following five dimensions can be described [21]:

11.3.1 Cognitive Embeddedness

The manner in which individuals and organizations collect and use information, the cognitive maps they employ in making sense of their environment, the mental disposition of individuals. Themes that can be derived from this are:

Bounded rationality: following economic approaches, we often assume individuals and organizations to behave according to a rational actor model. A more realistic view is that action is that rationality is bounded, in the sense that individuals and organizations have limited capacities for information processing and decision-making. It has consequences for our ability to deal with complex, multi-value problems such as sustainable development. In the cleaner production and industrial ecology concepts, boundaries of departments, hierarchical decision-making, and between companies have to be faced.

Systems thinking: individuals have different strategies for problem solving. Some of these are more suited to systemic problems than others. It is difficult and often neglected to what extent such strategies can be identified in participants in cleaner production and industrial ecology initiatives.

Characteristics of change agents: cleaner production and industrial ecology deal with social change processes. Individuals that act as change agents within or between organizations have special backgrounds and capabilities [23]. The knowledge about the ways in which these characteristics emerge, and how they can be successfully employed within cleaner production and industrial ecology networks, is still limited.

11.3.2 Cultural Embeddedness

This dimension addresses the influence of collective norms and values in guiding economic behavior, such as the shaping of preferences, and the influence of ideologies in shaping future visions. A tendency to externalize normative issues, or to take normative positions for granted, both in our scientific activities and in the subject matter s often experienced. Referring to the latter, some interesting topics are:

Collective cognitive maps: social groups (industrial sectors, regions, national societies, product chains) tend to develop a collective view on the world and ways in which problem should be addressed (both cleaner production as well as industrial ecology itself are such a map). This narrows the search for innovations and solutions for social and ecological problems with respect to the development of maps, and how do they restrain or enhance the development of cleaner production and industrial ecology. Although the concept of industrial ecology was new in the area, the traditional waste exchange results in the INES project 1994–1997 were disappointing in the view of the researchers [3].

Industrial systems fulfil and help define consumer preferences. These preferences are to a great extent culturally determined. How preferences have developed over time, and in what ways has industry influenced them to increase material consumption, is another issue for further research in the 21st century.

Defining what is *legitimate*; the definition of what is acceptable industrial behavior is a social construction, as is the definition of what constitutes acceptable government intervention in industrial activities. This helps to explain why legitimate behavior differs from country to country. Consequently, it is difficult to copy successful practices of cleaner production and industrial ecology from one country (or even region) to another.

Defining what sustainable, cultural embeddedness is directly implies that sustainability cannot be defined objectively. The major consequence of this is that it needs to be defined in local contexts. What are processes to do so, and what mechanisms make existing definitions difficult to change?

11.3.3 Structural Embeddedness

Structural embeddedness emphasizes the way in which relationships between actors influence their actions. This dimension is the one which has gotten most attention as organizational contribution to the field of cleaner production and industrial ecology. Industrial networks have been analysed [24], and co-ordination mechanisms have been discussed [25]. However, linking these structural features to other dimensions of embeddedness remains a relatively unexplored territory.

11.3.4 Political Embeddedness

Political embeddedness is acknowledging the fact that processes of power influence economic actions. This includes the role of the state in the economic process. The role of power is hardly discussed systematically. This maybe has to do with the fact that it is one of the more difficult concepts of sociology in terms of empirical analysis. Nevertheless, actors are not equally able to influence each other's actions and system outcomes, and this has to be taken into account. In relation to the industry-government relationship the *new institutionalism* paradigm formulated by Jordan and O'Riordan [26] is interesting. They cluster various definitions of *institution* as a conglomerate of types of policy networks, standard operating procedures and barriers to rational decision-making, structures of political power and legitimacy, national policy styles, international regimes, and pre-determined social commitments. This means that many stakeholders influence developments in this conglomerate of positions and approaches on the basis of their power (the ability to get what one wants, usually at the expense of the interests of others [27] and/or status.

State promotion of cleaner production and industrial ecology: Although research indicates the importance of spontaneity and emergence in successful examples of cleaner production and industrial ecology, many governmental actors have sought to promote cleaner production and industrial ecology. For the dissemination of new concepts, this means first that standard operating procedures and other routines [28] have important consequences for decision-making processes regarding cleaner production and industrial ecology – by regulating the access of participants and the patterns of negotiation and consultation. Regulation can entail affecting the participants' allocation of attention, their standards of evaluation, priorities and perceptions, identities, and resources. Secondly, in this process, the individual's motivations and perceptions are determined by their own preferences, but also by the importance of the role given to them by the company ("…where you stand depends upon where you sit…" [29]). Thirdly, standard operating procedures can become reifications into specific ideologies or worldviews within entire departments.

Market power: Relationships between firms are asymmetrical. This has effects in terms of their abilities to start or raise barriers to changes in product chains. In eco-industrial parks it is often observed that certain companies such as electricity works, refineries, chemical and food processing companies are in the core of industrial symbiosis activities.

Exit, voice and loyalty: Industrial actors often have an economic/rational management approach [30] to operational organizations. Their approach determines the economic conditions for environmental projects and outcomes. Their function is described within the system boundary of their organization. Their position (responsibility for decision-making), scope (compliance and mandate), perspective (value of the project or concept), commitment and the authority that the actors draw from this, influence the outcomes and the intensity of changes at the aggregated level of industrial ecology. Contrarily to cleaner production demonstration projects, were employees of different organizational were involved, participants in industrial symbiosis are limited per company. When the environmental awareness that many people have cannot be deployed in the work environment, an external compensation will be sought, for instance through membership of an environmental advocacy organization [31].

11.3.5 Spatial and Temporal Embeddedness

Spatial and temporal embeddedness cover the way in which geographical proximity and time influence economic action. The dimensions of space and time are implicit in many accounts of industrial ecology in peculiar, yet it is believed that they deserve explicit treatment. Physical proximity has been identified as crucial in, for instance, complex forms of learning and the building of trust. Porter [24] points to four issues on the strategic agenda for a breakthrough of cluster management: the choice of location, local commitment, the upgrading of a cluster, and working collectively. Time is important as the

evolution of industrial systems typically involves long time periods [31].

11.4 Industrial Ecology Programs in the Rotterdam Harbor Area

In this section, the perspective of sustainability embeddedness issues will be applied to the Rotterdam Harbor and Industry Complex. The Rotterdam Harbor and Industry Complex (HIC) has been an environmental sanitation area in the period 1968–1998. The regional Environmental Protection Agency and Water Authority regulate all companies in the area. Many, but not all,[2] companies are involved in different covenants,[3] concerning environmental performance targets, such as covenants on the reduction of hydrocarbons, the chloro-fluorocarbon reduction program, the implementation of environmental management systems, and the four-year environmental management plan of a company. The INES project in the Rotterdam harbor industrial area started with the participation of 69 industrial firms in 1994 [25]. The project was initiated by an industrial association Deltalinqs, active in the joint interests of industrial companies in the Europoort/ Botlek harbor area near Rotterdam.

Originally, the Deltalinqs approach to environmental problems was very defensive. Later, a more constructive attitude was developed through the stimulation of environmental management in companies. The development from environmental management systems to sustainability projects can be characterized in four phases in the period 1989–2007.

11.4.1 Phase I: The Development of Environmental Management Systems

Following the national trend of self-regulation, Deltalinqs in 1989 started to develop an approach to promote environmental management systems in 70 member companies. During the period 1991–1994 it stimulated the companies' own responsibility through separate meeting groups for six branches of industry. Facilitated by a consultant, companies exchanged information and experiences on the implementation of environmental management systems. In a co-ordinating group, experiences were exchanged among these groups. This structure was evaluated positively by the participating environmental co-ordinators of the firms. Deltalinqs started to search for funds, which led to the start of the Industrial Ecosystem program (INES project) in 1994.

11.4.2 Phase II: INES Project (1994-1997)

Based on assessments of the resources, products and waste streams of companies 15 industrial ecology projects were defined and pre-feasibility studies were performed. Although the projects had a limited scope in terms of the product chain links and preventive approaches, sharing of utilities was found to be a first possibility for developing alliances within the region. After a complex decision-making process within the INES-project team (consisting of the two university researchers, the Deltalinqs project leader, a consultant, and a company representative) three projects were selected for further development. They were seen as good prospects for development within the INES-framework due to their economic potential, environmental relevance, and company participation potential. The projects were:

- *Joint systems for compressed air:* The use of compressed air systems constituted a significant (7% to 15%) part of electricity use of companies. The companies participating in the pilot project were an air supplier, an organic chemical company, an inorganic chemical company, an aluminum-processing company and a cement company. It was assumed that the companies in the pilot project could achieve the following results in the economic and environmental spheres: the price of compressed air can be lowered by approximately 30% and energy consumption could be reduced by approximately 20%.

[2] An USA multinational corporation perceives the covenant as a risk for unexpected liabilities; they prefer to participate in separate projects of the covenant that are within the management policy of their organization

[3] Voluntary agreements between the government and industry

When the real use of compressed air was measured, it was found that it was much lower than expected (7,000 Nm^3/hr instead of the anticipated 12,000 to 15,000 Nm^3/hr) [33]. Another finding was that the total energy consumption could be reduced in two ways. Firstly, by lowering pressure, preventing or reducing leaks, and by a re-design of the existing pipeline system, companies could save approximately 20%. Secondly, by installing a central supply through a ring pipeline system, companies could save approximately another 20%.

- *Waste water circulation*: The reduction of diffuse sources had high priority for the Water Authority, and was consequently of interest to companies. The project increased the awareness that water management improvement can facilitate a remarkable reduction in water emissions and the use of clean water. The use of the so-called pinch technology[4] showed how it is possible to use a certain water quality at the highest level of need of the company's production process or an industrial ecology cluster of companies. By doing this, re-use of several wastewater streams could result in a 10% reduction of total water use.
- *Bio-sludge reduction system*: The total, annual amount of waste bio-sludge produced by 12 companies was about 57,000 tons, including a 3% dry component of 1,900 tons. The actual logistics and treatment costs were approximately €1,200 per ton of dry component. Due to the implementation of primary waste minimization within the companies, a bio-sludge reduction of between 10% and 20% was expected, which could result in annual savings worth between €250,000 and €500,000.

In this phase, these projects did not result in immediate innovations; the projects mirrored political demands and were to a great extent end-of-pipe oriented. However, they created awareness for efficiency improvements at the company level (waste water cascading, compressed air). In the latter case, this actually decreased the necessary economies of scale for a collaborative system. In at least one case, an identified sub-project was commercialized. This concerned the flaring of natural gas that occurred as a by-product of oil drilling in the Rotterdam harbor. Through the INES project, a contract for utilizing this natural gas was made with a company within one week.

11.4.3 Phase III: INES-Mainport Project (1999-2002)

In 1998, the results from the INES program were evaluated by the Board of Deltalinqs, which took time given their meeting only twice every year [33]. Nevertheless, Deltalinqs used this period to acquire new funding, and thus the insights from the first INES program and the learning process that arose from it, led to a second INES program, called the INES Mainport project 1999–2002.

The INES Main port project was a four-year program focused on initiating and supporting industrial ecology initiatives, coordinated again by Deltalinqs. The INES Main port project took the feasibility studies of the INES 1994–1997 program and focused on the following themes: water, CO_2/energy, utility sharing, rest products/waste management, soil, and logistics. At the same time, a more strategic process was initiated. The project initiated a strategic decision-making platform, in which the following societal actors were involved: Deltalinqs – supervising the projects; representatives from major companies in the area; the Dutch National Industry Association; the Dutch National Ministries of Economic Affairs (EZ), and Environment & Spatial Planning (VROM); Province of Zuid-Holland; Municipal Port Authority; Regional Environmental Agency (DCMR); Regional Water Management Agency (RWS/directory Zuid-Holland); Provincial Environmental Association (MFZH); and the Erasmus University.

[4] The functional specification of the wastewater was researched for re-use at the highest level in production processes.

11.4.4 Phase IV: Inclusion in the Sustainable Rijnmond Program

Starting on 1 January 2003, the industrial ecology programs were included under the label of *Sustainable Enterprises in the Rotterdam Harbor and Industry Complex* (HIC) on the ROM-Rijnmond program.[5] The project (which is to run until 2010) aims to strengthen the Rotterdam harbor and industrial area as international gateway and to improve the living quality of the residential areas by integrating the environment in the physical planning of the Rijnmond region. This project, which includes a strategic discussion platform made up of relevant stakeholders, was intended to be part of the driving mechanisms towards a sustainable region. In 2003, it presented its 45 page vision document, [35] based on the concept of transitions, a then emerging theme in the national environmental policy agenda. The vision was summarized in the following statement:

> *"A world striving towards lowering carbon-intensity of the economy provides an attractive perspective for industrial centres that are able to process carbon related streams in a highly efficient, clean, and sustainable way. Rotterdam harbor is ideally suited to be such a centre. It has the ambition to be in 2020 the preferred location in Europe for the haulage and processing of carbon-related fuels and raw materials. It can only make this ambition a reality by being a trendsetter in economically feasible reductions of CO_2 emissions related to these activities, and by acting as a field of experimentation for innovations on themes such as clean fossil fuels, clean energy carriers such as hydrogen, syngas, heat, electricity and biomass as a gateway to a carbon-extensive future."*

The program runs for the period 2003-2010 and is led up by a small ROM Rijnmond staff bureau of a strategic platform that involves representatives of the Ministries of Economics and Environment, the province of Zuid-Holland, the Development Board of Rotterdam, the Port Authority, the industry association Deltalinqs, a plant manager, the Sustainable Mobility Program manager, representatives of the Universities of Delft and Rotterdam, and the representative of an environmental advocacy organization. Thanks to the historical development within several programs the strategic platform could build on the built-up trust between the members of the different organizations and the conditions for successful projects that earlier failed.

A long-term vision *To C or not to* C [35] was developed and established in 2003. The conclusion was that Rotterdam port activities were heavily based on fossil carbon energy sources such as oil and gas. Because of both climate change, dependency on fossil energy sources in political and ecological sensitive regions, as well as the development of new technologies for less or non-fossil carbon based energy supply, the vision is that the Rotterdam Energy Port should anticipate these developments by stimulating innovation, the development of new markets and a transition path towards a sustainable region on the basis of renewable energy, mobility and physical planning. The strategic platform functions as stimulator and *sustainability conscience* of all involved stakeholders in these Rotterdam Energy Port developments. The members of the strategic platform also share the reflective learning processes from projects within and around their own organizations as a basis for the construction of the *ecological concept learning and innovation* transition model of Figure 11.3.

Within this context a large project of the application of the rest heat (in total 2,200 MW in the area) was kept under study, under the condition that coupling the rest industrial heat of Shell Pernis (and later of Esso/Exxon and BP) to the Rotterdam city district heating system should be economically viable and that the responsibility for the coupling between industry and city should be organized clearly. In 2002, the Rotterdam municipality

[5] The ROM-Rijnmond programme (Physical Planning and Environment in the Rijnmond area) is based on a policy covenant signed by all the government bodies and industry in the Rijnmond area on 9 December 1993.

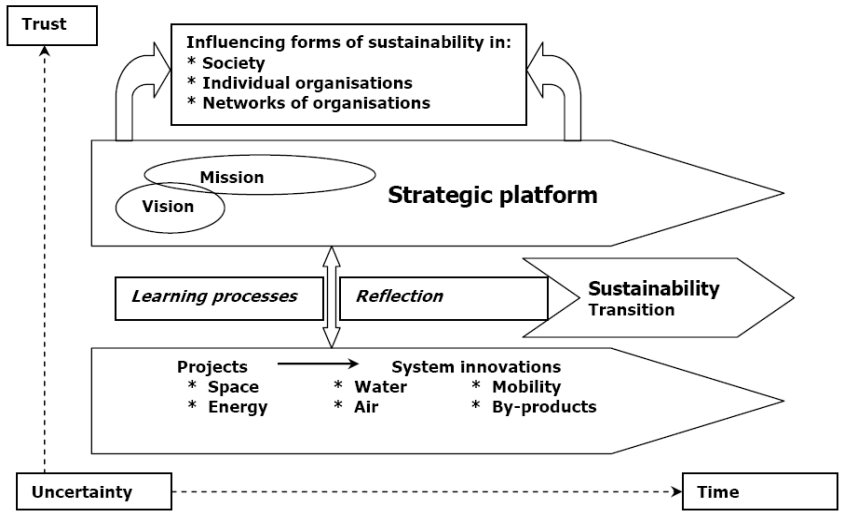

Figure 11.3. Reflective learning in the transition from projects to sustainability system innovations

decided to provide a guarantee for the extra funds that had to be invested in a heating system with temporary equipment in a new residential area nearby the Shell industrial site in Pernis. When all conditions for realization were finally met in 2004 (including liberalization of the Dutch energy market, and reductions of CO_2 demanded by the national government), the coupling of the 6 MW of Shell's rest industrial heat with the city's district heating system would make the temporary equipment redundant; 3,000 houses started to benefit in the Hoogvliet residential area in 2007. The heat supply system will be extended to 100 MW for the application to 50,000 houses[6] [36]. The feasibility study *Grand Design Project* [37] has analyzed that 900 MW can be applied for the heating of 500,000 houses in 2020.

In addition to the planned projects it is experienced that other initiatives are taken. The knowledge of the feasibility study of the compressed air project (see Section 11.4.2) stimulated another company to start compressed air delivery in a joint pipeline system. The air supplier started with the delivery of compressed air to four companies in 2000. Preliminary results showed savings of 20% in both costs and energy, and a reduction of CO_2 emissions (as a result of the reduction in energy use) of 4,150 metric tons each year. In 2002 another three plants, in 2003 seven plants more, and in 2005 three joined that system. [3]. This construction provided new business opportunities for the utility provider.

They designed a new utility infrastructure for compressed air and nitrogen for 10 companies in the Delfzijl industrial park in the north of the Netherlands (aluminum, chemical and metal-working companies) that opened under the management of the utility provider in 2004 [37].

On the basis of sensitivity for the concepts two young professionals at the Rotterdam Port Authority started a private initiative. Their exploration of industrial ecology possibilities resulted in the most well-known industrial symbiosis project in the Rotterdam harbor area. They started the production of fresh king-size shrimps in the *Happy Shrimp Farm* [39], constructed on the basis of rest heat and CO_2 delivery in February 2007.

[6] This is the part of the Hoogvliet/Rotterdam South river border delivery.

11.5 Lessons Learned on the Introduction and Dissemination of Cleaner Production and Industrial Ecology

The cleaner production and industrial ecology concepts are faced with business economics routines of the general *rule of thumb* approach that environmental investments should show a pay back of the investment within a maximum of three years. Although the concepts are being promoted as the *common good* for the economy and ecology of organizations and describe the relationship between the costs of environmental protection and the efficiency of the production process as a *win-win* concept, this usually triggers an *environment* perspective instead of the intended *innovation* perspective.

At the level of single-loop learning, incremental steps such as good housekeeping and regional efficiency improvements have gained credibility as part of these new concepts. In order for radical breakthroughs to sustainability to occur, the approach needs to be different. Continuous learning processes play an important role in this approach, see Table 11.1.

Various experiences demonstrate clearly that the *cleaner production concepts need a broader approach in order to be accepted*: cleaner production involved a radical new perspective, but progress within organizations and their surroundings only took place in small, incremental steps. From this it is clear that various levels of management and the crucial professional educational backgrounds in organizations have different "personal and social clocks" as regards the recognition, acknowledgement and acceptance of new approaches.

At the level of the subject boundary the question can be raised as to whether cleaner production is limited to a system's perspective. As an analogy, the example of a car can be used: one can study the development of cleaner cars, but this does not say much about the sustainability of transportation systems in general. This does not mean that cleaner production concepts are irrelevant, but in a sustainability hierarchy, a holistic approach such as a *cleaner production system* is needed. On the one hand, one can debate whether this is a radical technological process change or a product change; at least it is a breakthrough concerning material substitution, a change that may play a longer term catalytic role. On the other hand, one can debate whether there are ups and downs in continuous improvement. That is to say that continuous improvement is not a straight-line evolutionary process and that sometimes companies seem to move backwards.

The industrial ecology concept is becoming increasingly becoming widely accepted. It is obvious that the Kalundborg Industrial Symbiosis experience is used as the main example worldwide. In the Kalundborg industrial area, [18] company managers developed bilateral links for the shared use of waste and energy; these agreements evolved over several decades. They performed this intentionally in an open economic system of modification and survival. One can say, without labeling this with the metaphor of an industrial ecosystem, that they mimicked elements of the ecosystem. Once environmental problems had been thrust upon the political agenda, it was realized at

Table 11.1. Cleaner production application as result of the type of cleaner production learning processes and their elaboration in organizational change

Learning process	Organizational change: Incremental change	Organizational change: Radical change
One-loop learning process	Cleaner production assessment in demonstration project	Cleaner production innovation
Continuous learning process	Cleaner production assessment implementation and continuous improvement	Cleaner production re-designing

Table 11.2. Industrial ecology application as result of the type of industrial ecology learning processes and their elaboration in organizational change

Learning process	Organizational change: Incremental change	Organizational change: Radical change
One-loop intervention: single lesson given from outside	Industrial ecology assessment in demonstration projects	Industrial ecology innovation
Continuous intervention: learning within a region, as a routine	Industrial ecology implementation	Industrial ecology re-design

one point that all the different links can be labeled an industrial symbiosis, for which Kalundborg is now world famous. However, the human activity system cannot fully mimic an eco-system, because one has to take into account the fact that the various actors in the system have targets and intentions that may not be known to each other. Those targets and intentions can be conflicting and without any knowledge of this, the foundations of an industrial ecology system can be weak from the start. If industrial ecology is viewed as a process, this is the first phase to elaborate. The further dimensions of this type of change can also be applied in the industrial ecology concept, as portrayed in Table 11.2.

In relation to industrial ecology, a similar development can be observed. Despite the fact that industrial ecology is perceived as a normal business practice (waste exchange and energy sharing), the industrial ecology assessments in demonstration projects generated mainly first order changes of knowledge about the concept.

However, the implementation of that knowledge in practice is time-consuming and difficult, and only a few incremental first order changes are usually made. Often the concept is found to be attractive but its operationalization is strongly path-dependent on the originator of the plan. Also, until now, the industrial ecology concept has had a strong engineering focus. The social conditions and organization of the concept have scarcely been explored.

The lack of awareness about and the utilisation of the concepts of change management within both cleaner production and industrial ecology assessments lead most of the assessments to be limited technical approaches that usually do not include the social and psychological dimensions of organisational change. Existing experience and implicit knowledge are almost never utilised in the process of exploration and development of the new cleaner production and industrial ecology pathways. The question is whether industrial ecology on a longer time frame will be an essential part of the sustainability system. The number of companies, their diversity in size and type, and the intensity of their interactions are major variables in the system. Here the links between individual companies and the links between companies and society are to be tested according to the criteria of sustainability. This system demands a holistic approach based on new world views. The production process is an element at the level of individual companies (at the micro level) but the output of by-products is also the function of the *servant of the network* [40] at the meso level (Table 11.3).

The interconnectedness of cleaner production and industrial ecology to sustainable regional development can be linked to regional education and innovation institutes. Also, new employment for the region and informational, social and cultural contributions complete the holistic worldview at the macro level (Table 11.4).

In this triple bottom line approach, government agencies and relations between companies and regulating agencies must also be changed. The integration of environmental management within companies means more self-regulatory responsibility for the companies and as a result, important changes have to take place in the relations between industry and regulatory agencies. Regional learning that involves multi-loop learning processes within and among organizations is

Table 11.3. The type of concept and the involvement of actors and the main characteristics of focus and perspective in business management

Concept / Issue	End-of-pipe technology	Cleaner production	Industrial ecology	Sustainability
Actors	Environmental co-ordinators; Environmental technology specialists	Environmental managers; Plant managers	Eco-industrial park management; Plant managers; Physical planners	CEO; Division Managers; Plant managers
Focus	Pollution control	Pollution prevention	Pollution prevention, Recycling and Utility sharing	Production for needs in balance with socio-economical and eco-system
Perspective	Waste	Production process, Products, Services	Production process, product chain and energy carriers	Re-engineering and innovation of production, products and energy carriers

Table 11.4. The three concepts challenge for sustainability: from weak to strong

Three Concepts Challenge	From WEAK	to STRONG
Cleaner production	*One hit* intervention in EMS	Integration in decision-making
Industrial ecology	Waste exchange	Material flow, logistic & social industrial park management
Sustainable development	Lip service to policy integration; Faint social awareness and little media coverage	*Triple bottom line* performance of all relevant stakeholders

essential. Until now this more integrated approach has scarcely been used in an optimal way anywhere in the world.

11.6 Conclusions and Recommendations

There are many different perceptions of the impact of cleaner production. A simple one is: "The picking of low hanging fruit in new areas and organizations" ("..although it is not as easy a process as is often suggested..") [41]. A more complex one is: "A time consuming process in more advanced phases like business re-engineering or re-structuring" [3].

Because so many actors and organizations are involved, the development of industrial ecosystems is site-specific. An important distinction can be made between existing and new industrial areas. The design of an industrial ecosystem must take into account the characteristics of the local and regional *ecosystem* but its development must also match the resources and needs of the local and regional *economy*. These dual requirements reinforce the need for working in an inquiry mode [19]. In combination with learning processes involving the experiences of other communities, developing industrial ecosystems in an interactive

dialogue with stakeholders is a practical route towards the implementation of sustainability projects in a long-term perspective.

In the life-cycle of dealing with environmental issues, we are for answering the question whether environmental management is needed as an independent concept, beginning to understand that negative impacts on our surroundings are indicators of the inefficiency of industry, due to wastage of materials and energy. So, how can we influence other choices in production, products, services, and logistics in such a way that negative impacts are reduced? In this perspective, can we imagine that the emergence of an advanced clean industry is noticeable? The answers to these questions have evolved to the concepts of *sustainable enterprises* [42] and *corporate social responsibility* [43], [44], and s*ustainable regions and communitie*s [45]. The long-term sustainable development of regions ask for new institutional arrangements and the facilitation of initiatives such as organizational research, information, conferences, think tanks, vocational training providers, specialized training and general education [46].

It is recommended that in order to make more effective progress with cleaner production and industrial ecology in the future, the following should be done:

1. All cleaner production efforts, in the case of application in the design, start-up and growth life-cycle phase need to be made with a comprehensive organizational support and involvement and should also include the stakeholders throughout the life-cycle of the products and services that the organization provides to society.
2. Multi-loop learning processes should be used both within single companies and between clusters of companies. This should also increasingly involve the wider citizen population in sustainable regional development planning and implementation.
3. Cleaner production and industrial ecology concepts and approaches should be integrated vertically and horizontally from the policy and strategic levels down to the detailed operational levels of both individual companies and clusters of companies.
4. The implementation of industrial ecology should be integrated within the regional economy, ecology, technology, culture, and sustainability plans of the region.
5. Trust, transparency and confidence must be developed through an open, reflective and on-going dialogue designed to ensure real involvement of diverse stakeholders in charting the future of their organizations and regions as part of the transition to sustainable societies.
6. On the basis of cleaner production and industrial ecology and conditions of trust, transparency and confidence, the concepts of sustainable enterprises and communities can integrate all social, economic, environmental and cultural dimensions.

In stimulating and facilitating the above recommendations several partnerships create added value:

At the macro level, international policies and agreements, such the United Nations Millennium Declaration, Clean Development Mechanisms, Global Environmental Forum, Environmental Sound Technologies, and Human Development through Markets, must be integrated in an economic, ecological and social regional framework.

At the meso level, municipalities, industry associations, and education institutes/knowledge centers can join in integrated public private partnerships to generate and facilitate sustainability programs. The local situation provides the context whether it be government-driven, such as is the case in several Asian countries for eco-industrial park development, or voluntary partnership-driven. Also regional approaches for cleaner production in partnerships in developing countries can have a broad scope [47].

At the micro level, various disciplinary approaches such as industrial (eco) design, environmental management accounting and sustainable banking must be integrated.

Overall, the emerging education initiatives for initial Master's courses on sustainability subjects

must be strongly stimulated. Where UNESCO initiated the UN Decade on Sustainability in Higher Education 2005–2014, [48] the concepts of cleaner production, industrial ecology and sustainability can be educated within a cleaner production systems approach.

All together, the ecological, economic, social and cultural dimensions of nations and corporate activities are best combined in the label *nations and corporations taking their responsibility for working towards social, economic, environmental and cultural sustainability*.

Quality Engineering and Management

Krishna B. Misra

RAMS Consultants, Jaipur, India

Abstract: All production processes employ materials, men and machines. Each of these elements has some *inherent variability* in addition to *attributable variability*, which can be controlled to an irreducible economic minimum. The subject of quality engineering and management is about reducing the variablity in products and processes, quality costs and to provide maximum satisfaction to the customers through improved product performance. The subject has grown considerably since 1930, when Shewhart first developed his statistical approach to quality. Several developments that have taken place since then are presented in this chapter along with quality planning, control, assurance and improvement, which form the backbone of any quality program.

12.1 Introduction

Quality is a world wide concern of manufacturers. However, the word quality has had different connotations when used by different people. The definition has also undergone changes and its meaning has been extended over time but it can be definitely called an attribute that is generally used to reflect the degree of perfection in manufacturing of a product. It is easy to realize that this degree of perfection is inversely proportional to the variability present in the process. All manufacturing processes involve materials, men and machines and they all have some element of *inherent variability* in addition to *attributable variability*, which can be controlled to an irreducible economic minimum. Reducing variability in production is synonymous with improving the quality of the product.

The reason for material variation can be traced to inadequate care taken in the purchase of material (quality assurance), or on account of poor material specifications or due to urgency of purchase compromising the quality specifications, *etc*.

The source of variation due to machines is the natural limits of capability that every process has, which is also known as *process/machine capability,* and any attempt to reduce this range would cost heavily in terms of money. If the process is incapable of acceptable operation within design limits, then we have the option of separating nonconforming from conforming products, using more precise process or change in the design of the product or system in order to achieve an optimum design at minimum total cost.

The third source of variation is man himself and this is the most important contributor to variability. In fact, man's decisions or actions directly influence the extent of variability to a very large extent.

It is not difficult to realize that quality is inversely proportional to the variability, and one must try to reduce all sources of variability if quality is to be improved.

12.1.2 Definition

The most widely accepted definition of quality is: quality of a product is a measure of the degree of conformance to applicable design specification and workmanship standards. Obviously, this definition concerns itself with the manufacturing phase of a product. Several other definitions of quality have been put forward by several eminent practitioners but the central concept remains the same: the quality of a product is considered satisfactory if the product is able to satisfy the requirements of the consumer. Alternatively, it is an attribute of a product, which if incorporated into a product meant for a specific purpose or use, will satisfy a consumer. However, it is definitely agreed that bad quality affects reliability because inferior workmanship is likely to shorten the life of a product and thus its reliability. Earlier, in western management ensuring quality was left to the quality inspectors. However, it was Deming's work using statistical tools and scientific management philosophies in Japan that gave quality effort an impetus, importance and respectability, it has been acquired over time and quality tends to become all pervasive. Deming's 14 points for management provided the roadmap for quality movement in Japan and elsewhere.

There are others, mostly engineers, who do not quite agree with statisticians and have the notion that it is an engineering design effort, by which the performance of a product can be increased. They may as well be called as proponents of reliability and see quality as a necessary but not sufficient characteristic. There are others (mostly statisticians) who consider reliability effort as a part of the quality program. We will discuss the difference in the definitions of quality and reliability a little later in this paper, but it can be said with certainty that quality professionals themselves have struggled with the definition of quality for quite some time.

Crosby [1] defines quality as conformance to requirements or specifications. Juran [2] provides a simple-looking definition of quality as the fitness for use.

Deming [3] defined two different types of quality, *viz.*, *quality of conformance* and *quality of performance*. Quality of conformance is the extent to which a firm and its suppliers surpass the design specifications required to meet the customer's need. Sometimes, another aspect of quality is added to the definition of quality, *i.e.,* quality of design, which implies that the product must be designed to meet at least the minimal needs of a consumer. *Quality function deployment* is a system of product design based on customer demands with participation from all concerned. The quality of design has an impact on the quality of conformance, since one must be able to produce what was designed.

Quality of performance, on the other hand, is a measure, arrived at through the research and sales/service call analysis, in assessing how well a product has performed when put to use. It signifies the degree to which the product satisfies the customer or the user. This measure, incidentally, is synonymous with the concept of reliability and leads to redesign, new specifications, and to a product improvement program on a continuous basis for any manufacturing concern through interaction with the user or the customer.

Feigenbaum [4] defines quality as: the total composite product and service characteristics of marketing, engineering, manufacture, and maintenance through which the product and service in use will meet the expectations of the customers.

Taguchi [5] defines quality as the loss imparted to the society from the time a product is shipped. He also divides quality control effort into two categories; online and off-line quality control. On-line involves diagnosis and adjustment of the process, forecasting and correction of problems, inspection and disposition of product and follow up on defective shipped to the customer. The off-line quality control is quality and cost control activities carried out at the product and process design stages during the product development cycle. Taguchi's concept of quality, relates to determining the ideal target values (parameter design) and evaluating losses due to variation from the target value. Thus the objective of a quality program is to minimize

total losses to the society, which means both the producer and the consumer.

Therefore, it is not without confusion that one may want to settle for a practical definition of quality. However, whatever definition of quality one might settle for, no one can deny that to ensure the basic objective of high quality, a designer must be able to translate the needs of the consumer into an engineering design, including specifications and tolerances; the production engineer must be able to design a production process that will produce the product meeting these specifications and tolerances; of course while ensuring minimum waste, emissions or pollution of the environment.

12.1.3 Quality and Reliability

Obviously, the widely accepted definition of quality did not concern itself with the element of time and could not say whether a product would retain its quality over a period of time nor did it mention the product's performance under a set of given conditions of use or environment. Neither of these elements form a part of quality but are inherent in the definition of reliability, which is defined as the ability that a product will perform a specified function over a specified time without failure under the specified conditions of use. One proceeds to eliminate or minimize the failures during the product's mission time and their causes and to improve upon the design [6]. Moreover, quality definition does not make itself expressible in terms of a probability figure, which reliability does. However, the quality of performance comes closest to the definition of reliability as far as satisfying the user's requirement is concerned and the concept of quality of design can help build reliability at the design stage. However, whether reliability is a part of the quality effort or whether quality is reliability during the manufacturing phase is a question over which statisticians and engineers often differ.

12.2 Quality Control

Quality control (QC) is the most important activity during manufacturing and aims to provide and maintain a desired level of quality of a product. In fact, QC is the name given to a set of techniques and means [7]: used to manage, monitor, and control all those steps that are necessary in production of a product of desired quality.

Juran [2] provides the definition of control as "The process of measuring quality performance, comparing it requirements, and acting on difference". Feigenbaum [4] defines control as a "process for delegating responsibility and authority for a management activity while retaining the means of assuring satisfactory results". This definition is sufficiently generic to apply to any activity, which may include products or services, and involves four steps of control, *viz.*,

- setting standards
- appraising conformance
- acting when necessary
- planning for improvements

The activities that need control include workmanship, manufacturing processes, materials, storage and issue of parts and materials, engineering design changes and deviations, production and incoming material inspection and tests, vendor control and many related activities. The most important concern in quality control is workmanship, which can be achieved by good manufacturing methods and techniques, and through inspection of manufactured product. If performed during the manufacturing the inspection is called an *in-process* inspection and if it is performed on finished product is called the *final inspection.*

Off-line Quality Control

The procedures involved in off-line quality control deal with measures to select parameters of product and processes in such a way that the deviation between the product or process output and the standard is minimized. This is mainly achieved through product and process design in which the goal is to produce a design within the constraints of resources and environmental parameters.

Experimental design is an important tool for improving the performance of a manufacturing process in the early stage of process development as this can result in improved process yield reduced

variability and closer conformance to target requirement reduced development time and thereby in reduced overall costs. The principles of design of experiments and the Taguchi method [7] help to come up with off-line process control procedures. Chapter 17 of this handbook on robust engineering deals with a certain aspect of the problem and illustrates it through an example.

On-line Quality Control

Instead of taking off-line quality control measures, it may be necessary to take online quality measures to correct the situation. When the output differs from a specified norm, the corrective action is taken in the operational mode on a real time basis for quality control problems. In fact, this forms the basis of online statistical process control methods. The most effective method of controlling the process is the most economic and positive method. It is for this reason that quality control engineers use control charts, as it is always better to control the method of doing things while the process is being performed, than to correct things after the job has been done. Since most processes are dependant on men and machines, inspection becomes a necessity to ensure that the product made is good. Quality control also concerns new design, control and change of specifications. Since QC affects the performance of a product over its lifetime, QC must be stringently implemented.

Classical quality control was achieved by observing important properties of the finished product and accepting/rejecting the finished product. As opposed to this technique, statistical process control uses statistical tools to observe the performance of the production line to predict significant deviations that may result in rejected products.

By using statistical tools, the operator of the production line can judge for himself if a significant change has been made to the production line, by wear and tear or due to other reasons, and even take measures to correct the problem – or even stop production – rather than producing a product outside specifications. The simplest example of such a statistical tool may be the Shewhart control chart.

12.2.1 Chronological Developments

Quality control has evolved constantly during the last century. The period between 1920 and 1940 was called the inspection quality control period by Feigenbaum [4], since the inspectors were designated to check the quality of a product by comparing it with a standard. If discrepancies were noticed, the deficient products were either rejected or reworked. The processes, however, were becoming more and more complex and side by side statistical aspects of quality control were also being developed. Shewhart [8] can be said to have laid down the foundation of using control charts to control the variables of a product. Acceptance sampling plans were developed to replace the 100% inspection and the 1930s saw the extensive use of sampling plans in industries. This gradually laid the foundation of statistical quality control and the period 1940–1960 was called the period of statistical quality control by Feigenbaum [4]. Statistical quality control became further popularized when W. Edwards Deming visited Japan in 1950 and taught Japanese industries the principles of SQC. Japanese were quick to embrace this new discipline and proved that a competitive edge can be achieved in the world market through SQC. J.M. Juran further helped strengthen Japanese management's belief in quality programs when he visited Japan in 1954. Later, in 1980, he wrote his excellent text [2]. The next phase of *total quality control* started in the 1960s. The concept of *zero defects* was spawned during this period when the Martin Company of Orlando delivered a Pershing missile to Cape Canaveral with zero nonconformity. As the people started getting round the idea of the involvement of shop floor workers in the quality improvement programs, the impetus for TQC got a boost. Organizing *quality circles* in industries, an idea that originated in Japan, was keenly pursued the world over during this period. The next phase of implementation of total quality control started in the 1970s, beginning with the concept of involving everyone in the company right from top management to workers in the quality program; this laid the foundation of the concept of the *total quality system* pursued vigorously during 1980s. Taguchi [5, 9] introduced

the concept of parameter and tolerance design and indicated the use of experimental design as a valuable quality improvement tool. Management saw the need and importance of giving training programs in statistical quality control to all levels of workers in the industry. Terms and concepts like quality management system (QMS), total quality management (TQM), total engineering quality management, product life-cycle management, Six Sigma, and ISO 9000 to promote quality consciousness and development of a distinct quality culture flourished between 1980 and the present. Around 2001, the concept of product life-cycle management (PLM) came into being; this is a holistic business activity addressing many things such as products throughout their life-cycles from cradle to grave, organizational structure, working methods, processes, people, information structures, and information systems.

12.2.2 Statistical Quality Control

The quality of a product can be assessed using the performance characteristics. Performance characteristics of a product are the primary quality characteristics that determine the product's performance in satisfying the customer's requirements. Performance variation can be best evaluated when a performance characteristic is measured on a continuous scale. The characteristics having randomness can be represented by statistical distributions. The quality of the product is defined using a target value, and upper and lower specification limits for each characteristic. We can compare the statistical distribution of each characteristic to decide whether the product should be accepted or rejected. This is called *statistical quality control* (SQC). As we have seen earlier, there are mainly two sources of variations in product characteristics, *viz.,* variability of materials and components and the variability of the production process. Statistical quality control can be applied to identify and control both sources of variability. However when SQC is applied to processes, it is referred to as *statistical process control* (SPC). Here online measurements of product performance characteristics can be made and compared with the specification limits. This will not only inform the operators of the off-specification product but should also identify the sources of variability in the process that need to be eliminated.

12.2.3 Statistical Process Control

Statistical process control (SPC) was pioneered by Walter A. Shewhart [8] and created the basis for control charts. Later on it was pursued by Deming [3], who was instrumental in introducing SPC methods to Japanese industry after World War II. A typical control chart is a graphical display of a quality characteristic that has been measured or computed from a sample versus the sample number or time. The chart contains a center line that represents the average value of the quality characteristic corresponding to the in-control state. Two other horizontal lines, called the upper control limit (UCL) and the lower control limit (LCL) are also drawn. These control limits are chosen so that if the process is in control, nearly all of the sample points will fall between them. As long as the points plot within the control limits, the process is assumed to be in control, and no action is necessary. Shewhart [8] concluded that while every process displays variation, some processes display controlled variation that is natural to the process, while others display uncontrolled variation that is not present in the process causal system at all times. However, a point that plots outside of the control limits on the control chart is interpreted as evidence that the process is out of control, and investigation and corrective action are required to find and eliminate the assignable causes responsible for this behavior. The control points are connected with straight line segments for easy visualization. Even if all the points plot inside the control limits, if they behave in a systematic or nonrandom manner, then this is an indication that the process is out of control.

The underlying assumption in the SPC method is that any production process will produce products whose properties vary slightly from their designed values, even when the production line is running normally, and these variances can be analyzed statistically to control the process. Today, we have a wide variety of control charts [11] for controlling

different quality characteristics. In fact, one can find a discussion of several of these control charts and indexes in [11], and in this handbook, Chapter 14 deals with certain aspects of SPC and discusses some of the control charts and indexes.

12.2.4 Engineering Process Control

Engineering process control is a subject of statistics and engineering that deals with architectures, mechanisms, and algorithms for controlling the output of a specific process. Engineering process control (EPC) is used to control the continuous production processes and is a collection of techniques to manipulate the adjustable variables of the process to keep the output of the process close to the targetted value. This objective is achieved by generating an instantaneous response, opposing the changes to balance a process and take corrective action to bring the output as close to the target as possible. The approach involves forecasting the output deviation from the target that would occur if no control action were taken and then to take action to cancel this deviation. The control is achieved by an appropriate feedback or feedforward control that indicate when and by how much the process should be adjusted to achieve the objective.

In Chapter 15 of this handbook, we shall see how EPC can be applied to control the processes in a product industry.

12.2.5 Total Quality Control

In modern practice, QC begins with the design process and continues through manufacturing and product use. The sum of all these efforts is called *total quality control* (TQC). Quality control, therefore, can also be viewed as an aggregation of all activities directed toward discovering and controlling variations in performance.

According to Feigenbaum [4], TQC encompasses the entire product life-cycle, and involves activities such as:

- marketing
- engineering
- purchasing
- manufacturing engineering
- production
- inspection and tests
- shipping
- installation, maintenance and service

In fact, one can plan for quality during all the above activities, even before the product is produced.

12.3 Quality Planning

Quality planning is at the heart of TQC and is an activity aimed at preventing quality problems; it includes:

- establishing quality objectives
- building quality into the design
- procurement for quality
- control of nonconforming material
- ensuring in-process and finished product quality
- inspection and test planning
- handling and follow-up of customer complaints
- education and training for quality.

Quality guidelines are established by knowing the customer requirements and once these are clearly understood and it is determined that the company policies, procedures, and objectives are in conformity with these requirements, one may proceed to develop an effective quality plan. If necessary, these procedures and objectives can be revised. Comparing the proposed design with the customer requirements, including reliability and maintainability considerations, ensures design quality. A design is finally reviewed for *producibility* and *inspectability* since it is always possible to design a product that satisfies the customer's requirements but cannot be manufactured with the existing technologies. Design quality requires establishing specifications for all important quality characteristics and developing formal product standards. Work instruction and detailed procedures also form a part of this activity.

Inspection and test planning is always integrated with the design and production activities as they

directly influence the quality of the product and involve fixing of inspection points, classification of characteristics according to their criticality, design and procurement of inspection and test equipment, and development of inspection, instructions and test procedures. The material control procedures are often incorporated into the purchase order or a contract.

Sampling [12] rather than inspecting 100% of the manufactured products reduces the cost of inspection and involves making decisions based on the results of limited inspection or tests. However, this is at the cost accepting a risk, usually known as the sampling risk. In fact, there are two types of risks and the first one is known as the product risk, and may result in a good product being incorrectly classified as nonconforming although it is not. The other is known as consumer risk, in which a nonconforming product may be incorrectly classified as conforming. For critical characteristics, there is no acceptable level of consumer risk and it is never sampled except to verify a previous 100% inspection. An exception occurs only when the inspection or test is destructive, where there is no option but to sample. Tests can either be classified as destructive or non-destructive depending upon whether or not they cause damage to the product or raw material. The nondestructive test includes eddy current, dye penetrant, magnetic particles, ultrasonic and X-ray tests, and is often used to check properties of a material or product such as cracks and porosity. The other problem in sampling is to resolve the question of how much to sample. All inspection and test activities involve some degrees of error, since no measuring instrument is perfect. However, there are statistical methods of assessing all kinds of inspection and tests errors. The known size is called a standard, and the process of adjustment of gauges is known as calibration. These form the routine activities of any quality planning.

12.4 Quality Assurance

Quality cannot be the concern of one person or one department, such as quality control department in a manufacturing concern; therefore a system has to be evolved that continually reviews the effectiveness of the quality philosophy of the company. All those who are directly or indirectly connected with the production department must be involved in the task. For example, this group may advise market department about the nature and type of information that may be helpful for the design team based on customer requirements. In fact, the quality assurance (QA) group must audit various departments and assist them to accomplish the company's goal of producing a quality product. The quality assurance department will ensure that means exist in terms of physical resources and manpower within the company to execute the quality plans. If any shortcomings are noticed, the quality assurance group may advise the concerned department to affect those changes. The quality assurance department actually acts as a coordinating agency for the quality needs of a company with respect to the products being manufactured. Thus the formal definition of a quality assurance activity involves all those planned actions necessary to provide confidence to the management and the customer that the product will eventually satisfy the given needs of a customer. Quality control is just a part of the quality assurance task. It is also true that all leading manufacturers depend on several vendors for incoming raw material or components and it will be incumbent on the quality assurance department to assist these vendors in maintaining and controlling the quality of parts supplied by them, since the quality of final product depends heavily on the quality of the parts supplied. In such cases, the quality assurance department's responsibility is also extended to include vendor product quality. In fact, vendors must be considered as partners in the quality program.

QA covers all activities from design, development, production, installation, servicing to documentation. It introduced the sayings "fit for purpose" and "do it right the first time". It includes the regulation of the quality of raw materials, assemblies, products and components, services related to production, and management, production, and inspection processes.

12.5 Quality Improvement

Quality improvement [13] is a continual process in any company and should be the objective of everyone in the company for increasing productivity and cost reduction and thereby increasing profitability. Since improvements are possible through reduction of variability of process and production of nonconforming items, quality improvement is possible by detection and elimination of common causes, in contrast with special causes that can be identified and eliminated through process control. Special causes are those having an identifiable reason, such as tool wear, poor raw material or operator fatigue, but common causes are inherent to the system and are always present, such as variability in characteristics caused by the inherent capability of a machine. Special causes can usually be controlled by an operator but common causes necessarily require the attention of the management.

In fact, there are three stages of the quality improvement program, *viz.*, the commitment stage, the consolidation stage, and finally the maturity stage. In the commitment stage, management accepts to undertake the quality improvement program, and plans and policies are drawn including the organizational structure to implement it. This phase usually concerns itself with identifying and eliminating special causes in the first instance. With the training and education of personnel and support from the management the quality improves and the percentage of nonconformities drops appreciably during this phase. In the consolidation stage, the main objective is to improve the quality of conformance and efforts are made to identify and eliminate common causes by improving process capabilities and investment is made to prevent defects. The causes of all defects must be traced to their origins and adequate measures be taken to prevent them in future. This exercise is likely to minimize the number of items for rework or scrapping, resulting in reduction of total cost. However, the percentage drop of nonconforming items is not as high as in the first stage of implementation. In the maturity stage, the processes are considered to have matured and process parameters are adjusted to create optimal operating conditions and the total cost reduces further as the number of scraps and reworked items reduces, but the rate is slower. The process of improvement continues and the quality improves asymptotically to a zero defect paradigm if the process performance keeps improving. However, one must bear in mind that the quality improvement program pays off only in the long run but the cost of improvement is immediate. This should not detract management or personnel engaged in the improvement program.

12.6 Quality Costs

Quality cost comprises four major components, *viz.*, prevention cost, appraisal cost, internal failure cost and external failure costs. Prevention costs are costs incurred in planning, implementing and maintaining a quality system, which include all the costs of making a product right the first time, such as the development costs of product design, process design and control techniques and salaries. Appraisal costs are the costs of measuring, evaluating and auditing products, components, incoming raw materials to determine the degree of conformance, as well as product inspection and testing and cost of calibration etcat the stage of final acceptance. Internal failure costs are all those costs incurred when products, components, materials fail to meet the quality requirements. These costs also includes the cost of rework, scraps, labour and other overheads associated with nonconformities, including loss of production and revenues. The external failure costs are the costs incurred when the product does not perform satisfactorily after it is delivered to the customer. Warranty and product liability costs are included in this component of the total cost. A quality system in place should reduce the total cost.

12.7 Quality Management System

A quality management system (QMS) is achieved by having an organizational structure, resources, procedure and programs, and processes to implement quality management. The major

objective of QMS is to integrate all processes and functional units to meet the quality goal of a company. Planning is absolutely necessary for the success of a quality program. A strategic plan must be clearly defined. Quality policy and procedural manuals help in guiding the entire quality activity. An organizational structure should be created to establish a line of authority and responsibility.

Several companies are developing their quality systems to:

- reduce the first time failure,
- reduce the costs of customer claims,
- get things right the first time,
- improve service to the customer and to increase competitiveness.

Today, we need to pursue these goals more vigorously in order to minimize environmental pollution and wastes, besides affecting energy savings and conserving material resources.

In this handbook, Chapter 18 discusses how to build a quality management system.

12.8 Total Quality Management

Tobin [14] defines *total quality management* (TQM) as totally integrated effort for gaining competitive advantage by continuously improving every facet of organizational culture. Witcher [15] highlights important aspects of TQM using the following explanation:

Total signifies that every person in the firm must be involved (possibly even customers and suppliers)

Quality indicates the customer requirements are met fully.

Management represents that the senior executives are fully committed.

Feigenbaum [4] defines TQM as the organization-wide impact of TQC. The Department of Defense (DOD) of the US defines TQM as a philosophy and a set of guiding principles of a continuously improving organization. In fact, TQM [16, 17, 18, 19] entails the application of management techniques, quantitative methods and human resources to improve the material services supplied to an organization, all the processes within the organization, and the degree to which the requirements of its customers are met, now and in future. It stresses on optimal life-cycle cost and applies management methodologies to target improvements. A sound quality policy together with organization and facilities is a fundamental requirement for implementing TQM. The important elements of TQM philosophy are the prevention of defects and an emphasis on quality in design, elimination of losses and reduction of variability. It also stresses the development of relationships between employees, suppliers and customers.

TQM starts at the top and top management should demonstrate their commitment to quality and communicate it down to every one in the company through the middle level management. Developing and publishing clear corporate beliefs and objectives or mission statement helps motivating people. Every employee must be able to participate in making the company successful in its mission. This flows from empowerment of people at all levels to act for quality improvement and the efforts of all those who contributed to achieve good results must be recognized and publicized. The management should strive to remove barriers between the departments of the organization. Instead they should inculcate the spirit of team work and establish perfect communication between them. It often requires a mindset to change to breakdown the existing barriers. In fact, implementing TQM is like growing a new culture in the organization. The role of training and education cannot be underestimated and should back up the efforts of implementing TQM so that all employees clearly know what is at stake.

It is often believed that TQM is perhaps the only way of assuring customers what they want first time, each and every time. There is enough evidence to show that this is so. If it were not leading firms like American Express, IBM, Xerox, 3M, Toyota, Ricoh, Cannon, Hewlett-Packard, Nissan and many others may not be so successful. TQM is not just to meet customer requirements but to provide them satisfaction. Some companies, like Rover Cars, have extraordinary customer satisfaction as their corporate mission. Among other features, customer requirement may include

delivery, availability, maintainability, reliability and cost effectiveness. While dealing with a supplier–customer relationship, the supplier must establish marketing activity charged with this task. The marketers must, of course, not only understand the requirement of the customer completely, but also their own ability to meet customer demands. Within organizations, and between customers and suppliers, the transfer of information regarding requirements is often very poor and sometimes totally absent. Therefore a continual examination of the customers' requirements and our ability to meet them is the price of maintaining quality. In fact, TQM philosophy very much relies on using the knowledge base as an asset in an organization. Everybody needs to be educated and trained to do a better job.

12.9 ISO Certification

The objective of International Organization for Standardization (ISO), which consists of representatives from several countries, comprised of more than 180 technical committees, covering many industry sectors and products, is to promote the development of standards, testing, and certification in order to encourage the trade of goods and services. Usually a standards body represents each country. There are two types of standards introduced by ISO, *viz.*, ISO 9000 for quality and ISO 14000 for environment.

ISO 9000 came into being in 1987 followed nearly by 10 years later by ISO 14000. ISO 9001 initially developed four standards (ISO 9000-9004) for different types of industries but in 1995 ISOs were revised and finally in the year 2000, there was only one standard, *i.e.*, ISO 9000-2000, which is the main stay of quality management system for all types of industries and organizations. Likewise, there is ISO 14000 for environment system management. ISO by itself does not audit or assess the management system of organizations to verify that they have been implemented in conformity with the requirements of the standards nor does ISO issue certifications. However, the auditing and certification done by ISO has approved more than 750 certification bodies active around the world.

The basic objective of the ISO 9000 quality standards is for a company to be able to establish quality systems, maintain product integrity, and satisfy customers.

ISO 9000 has become an international reference for quality management requirements in business-to-business dealings, which helps organizations to fulfil:

- customer quality requirements, and is
- applicable regulatory requirements, while aiming to
- enhance customer satisfaction, and
- achieve continual improvement of its performance in pursuit of these objectives.

ISO 14000 is primarily concerned with *environmental management*. This means what the organization does to:

- minimize the harmful effects on the environment caused by its activities, and to
- achieve continual improvement of its environmental performance.

For some firms, the first step in creating a total quality environment begins with the establishment of a quality management system such as enunciated by ISO 9000. For others, it is always debatable whether it is better to implement TQM or ISO 9000 first. However, if one views ISO 9000 as a route to TQM, they are complementary to each another. For companies already on TQM, installing ISO 9000 is comparatively straightforward. However, for companies planning towards TQM, the use of ISO 9000 can act as an instrument to achieve TQM. Nonetheless, it is true that, even with ISO 9000 certification, it cannot be guaranteed that the products and services are of high quality. To produce quality products and services, a company needs TQM to meet expectations.

12.10 Six Sigma

The term Six Sigma [20] was coined by Bill Smith, an engineer at Motorola, in 1986 and is actually a trademark of Motorola that resulted in a saving of US $17 billions by January 2006. It is a measure

of process capability and is related to the defect rate and complexity of a process/ product. Six Sigma is a standard of excellence that allows less than four (or precisely 3.4) defects per million opportunities.

Some of the top companies that have embraced Six Sigma [21] as their company's strategy for quality improvement are: General Electric (GE), Honeywell International, Raytheon, Sony, Honda, Texas Instruments, Hitachi, Canon, Asian Brown Bovery, *etc*. In fact, GE is said to have made a gross annual profit of US $6.6 billion in the year 2000, which was 5.5% of their sales [22].

Six Sigma offers a proven management framework of processes, techniques and training that satisfies ISO 9000:2000 requirements with respect to:

- demonstrating top management commitment to continually improving the effectiveness of the quality management system;
- competence, awareness and training in statistical techniques and quality management;
- continual improvement of the quality management system;
- monitoring and measurement of customer satisfaction;
- monitoring, measurement and improvement of processes and products;
- analysis of data.

In fact, Six Sigma capitalizes on the good points of TQM with a sharp focus on customer satisfaction and thus combines good features of all earlier quality initiatives for quality improvement and does not have very many tools of its own. It is asking tougher and tougher questions until quantifiable answers are received. Through Six Sigma companies question every process, every number, every step along the way to creating a final product.

Six Sigma is a data-driven, systematic approach to problem solving, with a focus on customer impact. Statistical tools and analysis are often useful in the process. However, the Six Sigma project can be started with only rudimentary statistical tools.

For successful implementation of Six Sigma, a company requires the active role of the following:

- *Executive leadership* empowers the other role holders with the freedom and resources to explore new ideas for breakthrough improvements.
- *Champions* are responsible for the Six Sigma implementation in the company and are drawn from the upper management. Champions also act as mentor to black belts.
- *Master black belts* act as full time in-house expert coaches for Six Sigma and ensure integrated implementation of Six Sigma across various departments in the company.
- *Black belts* operate under master black belts to apply the Six Sigma methodology to specific projects.
- *Green belts* are common employees who help black belts implement Six Sigma along with their normal job responsibilities.

When 50% or more employees of a company embrace Six Sigma, the profitability of the company is bound to increase dramatically.

Design for Six Sigma (DFSS) is an important step in designing new products and/or processes and uses Six Sigma as a strategy. It is a way to implement the Six Sigma methodology as early in the product or service cycle as possible. It is a pathway to exceed customer expectations and a means to gain market share. It results in high ROI (return on investment) and reduces warranty costs.

Further, for services, a fusion of Lean and Six Sigma improvement methods is required. Lean Six Sigma is a business improvement methodology that maximizes shareholder value by achieving the fastest rate of improvement in customer satisfaction, cost, quality, process speed, and invested capital. The need for Lean Six Sigma arose from the fact that one cannot just have quality or speed, one needs a balanced process that can help an organization to focus on improving service quality, as defined by the customer within a set time limit.

Recent Six Sigma trends are in the development of a methodology by integrating it with TRIZ for inventive problem solving and product design. It was developed by the Russian engineer Genrich Altshuller [23] and his colleagues in 1946. TRIZ (the Russian acronym for the theory of inventive problem solving) is basically a collage of concepts

and tools to solve manufacturing problems and create new products and has been used by companies like Procter & Gamble, Ford Motor Company, Boeing, Philips Semiconductors, LG Electronics, Samsung and many others.

In order to familiarize the reader with Six Sigma and to explore the future trends, Chapter 16 on Six Sigma has been included in this handbook.

12.11 Product Life-cycle Management

Product life-cycle management (PLM) is the activity of managing a company's products most effectively all through their life-cycles. This allows a company to take control of its products. With products becoming increasingly complex, customers becoming more demanding, the need to have shorter product development times, and the competitive product environment in the market, on-going globalization, outsourcing of product development, mass customization to meet customer requirements, end of life issues, product support over its long life, WEEE-like directives about disposal and recycling would make this job still more difficult. Losing control can have disastrous effects for a company. PLM [24] helps bring better products in the shortest possible time to the market, provides better customer support and reduces the cost of a product. In fact, PLM helps maximize the value of a product over its life-cycle. All companies need to manage communications and information with its customers through customer relationship management (CRM) and its suppliers through supply chain management (SCM)) and the resources within the enterprise through enterprise resource planning (ERP). In addition, a manufacturing engineering company should develop, describe, manage and communicate information about their products through PLM. PLM helps reduce the time to market, improves product quality, reduces prototyping costs, affects savings through the re-use of original data, reduces waste, and results in savings through the complete integration of engineering workflows and thereby provides a framework for product optimization.

The product life-cycle goes though many phases, involves many professional disciplines, and requires many skills, tools and processes. Product life-cycle management (PLM) is more to do with managing descriptions and properties of a product through its development and useful life, mainly from a business/engineering point of view; whereas product life-cycle management (PLC) is to do with the life of a product in the market with respect to business/commercial costs and sales measures.

Within PLM there are two primary areas:

- product data management (PDM)
- product and portfolio management

PDM is focused on capturing and maintaining information on products and/or services through its development and useful life. This is the activity that has the major influence on the time taken to get the product to market and on the cost of the product. Since the quality of the product delivered to the customer is in many ways a function of the quality defined during product development, it is here that major improvements in product quality must be made.

On the other hand, product and portfolio management focuses on managing resource allocation, tracking progress *vs*. plan for projects in the new product development projects that are in process (or in a holding status). Portfolio management is a tool that assists management in tracking progress on new products and making trade-off decisions when allocating scarce resources.

The core of PLM is in the creation and central management of all product data and the technology used to access this information and knowledge. PLM as a discipline emerged from tools such as CAD, CAM and PDM [25], but can be viewed as the integration of these tools with methods, people and the processes through all stages of a product's life. It is not just about software technology but is also a business strategy.

12.12 Other Quality Related Initiatives

There are several other initiatives related to quality improvement that have been introduced from time to time with the basic objective of improving quality of products, and productivity and profitability of the company.

Concurrent Engineering

Concurrent engineering can be defined as a strategy of employing a multi-disciplinary team consisting of specialists from business, engineering, production and customer support to conceptually conceive a product and to carry out its design and production planning all at one time. Inputs from all departments concerned, such as materials, purchase, marketing, finance, engineering design, production, quality, suppliers and customers, *etc*., are available simultaneously through brainstorming sessions to arrive at an agreed design. That is why sometimes it is also known as simultaneous engineering or parallel engineering. This is done to prevent problems with quality and productivity from occurring and eliminates the possibility of engineering changes at a later stage, which helps decrease the lead time and costs. This practice is at variance from sequential engineering followed earlier. Concurrent engineering designs the product within production capabilities so that statistical process control is effective and rework costs decrease. The main advantages of concurrent engineering are a substantial decrease in lead time to market, faster product development, better quality, and increased productivity. For example, the Chrysler Corporation used concurrent engineering to develop the Viper model from the concept stage to full production in less than three years with a budget of US $50 million. General Motors eliminated 900 parts from the 1995 Chevrolet Lumina model in comparison to its 1994 model and reduced assembly time by 33%. Westinghouse Electronic Systems decreased development lead times from 20 months to 9.

Kaizen

Kaizen is the Japanese term for *continuous improvement*. "Zen" in the word Kaizen emphasizes the learning-by-doing aspect of improving production. The Kaizen concept was pioneered by in Japan by Toyota as a daily challenge to all its employees to improve their processes and working environment little by little over time. Kaizen refers to a "quality" strategy and is related to various quality-control systems, including methods of W. Edwards Deming. Kaizen aims to eliminate waste or activities that add to the cost but do not add to the value. It is a rigorous and scientific method of using SQC and an adaptive framework of organizational values and beliefs that keeps workers and management focused on the objective of zero defects.

The Kaizen cycle has four steps:

- Establish a plan to change whatever needs to be improved.
- Carrying out changes on a small scale.
- Observe the results,
- Evaluate both the results and the process and determine what has been learned.

Masaaki Imai made the term famous in his book on Kaizen [26]. Kaizen methodology includes making changes and monitoring results, then adjusting. Large-scale pre-planning and extensive project scheduling are replaced by smaller experiments, which can be rapidly adapted as new improvements are suggested.

Quality Circles

One of the most publicized aspects of Japanese management is the *quality circles* or *Kaizen teams*. The quality circles concept first originated in the 1960s and became very popular around the world, partly due to the phenomenal Japanese success in improving the quality of their products. A quality circle is a voluntary group of workers doing a similar job, who meet regularly during the working hours under the leadership of their supervisor to identify, analyze and solve shop floor problems and possibly recommend solutions to management. These circles were successful in some countries but failed in others, partly due to a lack of enthusiasm in inculcating quality consciousness and understanding on the part of senior management and partly due to different cultural backgrounds.

Just in Time

Just in time (JIT) is an inventory strategy implemented to improve the return on investment of a business by reducing in-process inventory and its associated costs. The process is driven by a series of signals, or *Kanban* that tell production processes when to make the next part. Kanban are called "tickets" but can be simple visual signals, such as the presence or absence of a part on a shelf.

JIT [27] can lead to dramatic improvements in a manufacturing organization's return on investment, quality, and efficiency if implemented correctly.

Actually, the JIT inventory systems have a whole philosophy that the company must follow in order to avoid its downsides. The ideas in this philosophy come from many different disciplines including statistics, industrial engineering, production management and behavioral science. Inventory is seen as incurring costs, or waste, instead of adding value, contrary to traditional thinking. Under the JIT philosophy, businesses are encouraged to eliminate inventory that does not compensate for manufacturing issues and to constantly improve processes so that inventory can be removed. Secondly, by allowing any stock, management may be tempted to keep stock to hide problems within the production system, which include backups at work centers, machine reliability, process variability, lack of flexibility of employees and equipment, and inadequate capacity, among other things.

In short, the just-in-time is an inventory system that allows one to have the right material, at the right time, at the right place, and in the exact amount.

Quality Engineering: Control, Design and Optimization

Qianmei Feng[1] and Kailash C. Kapur[2]

[1]University of Houston, Houston, Texas, USA
[2]University of Washington, Seattle, Washington, USA

Abstract: This chapter reviews the present status and new trends in quality engineering for control, design, and optimization of product and manufacturing processes as well as other processes/systems. Reviews of quality management strategies and programs are presented including principle-centered quality improvement, quality function deployment, Six Sigma process improvement, and Design for Six Sigma. Techniques for off-line quality engineering are presented with emphasis on robust design, signal-to-noise ratios, and experimental design. Approaches for on-line quality engineering are described including acceptance sampling, 100% inspection, statistical process control, control charts, and process adjustment with feedback control.

13.1 Introduction

In the current competitive global market, organizations are under increasing pressure to improve quality of products or services by reducing variation. The application of quality programs, tools and techniques has been expanded beyond the traditional manufacturing industry to healthcare, service, finance, retail, transportation, military defense and many other areas. The traditional quality tools are no longer sufficient to handle emerging challenges due to customized products, low production runs, automated processing, and real-time diagnosing [1]. With the recent advancement in technologies along with more involvement of statistical techniques, quality tools, techniques, and methodologies have been enhanced to meet new challenges. Over the last 30 years, a lot of progress has been made in the field of quality engineering based on research in statistical quality control (SQC), engineering process control (EPC), statistical experimental design, robust design, and optimization methods. The purpose of this chapter is to provide a review on the current status and future trends of quality engineering in terms of control, design and optimization.

The chapter starts with definitions of quality and quality engineering, followed by an overview of quality management strategies and programs including principle-centered quality improvement, quality function deployment, and Six Sigma methodology. The current status and advances in off-line quality engineering are presented with emphasis on robust design. The techniques for on-line quality engineering are then described including acceptance sampling, 100% inspection, statistical process control, and process adjustment with feedback control.

13.2 Quality and Quality Engineering

13.2.1 Quality

Quality has been defined in different ways by various experts and the operational definition has even changed over time. The best way is to start from the original meaning of the word. Quality, in Latin, *qualitas*, comes from the word *quails,* meaning "how constituted" and signifying "such as the thing really is" [2–4]. Merriam-Webster dictionary defines quality as "*….peculiar and essential character…a distinguishing attribute….*"

A product typically has several or infinite qualities. Juran and Gryna considered multiple elements of fitness of use based on various quality characteristics (or qualities), such as technological characteristics (*e.g*., strength, dimensions, current, weight, and ph values), psychological characteristics (*e.g*., beauty, taste, and many other sensory characteristics), time-oriented characteristics (*e.g*., reliability, availability, maintainability, safety, and security), cost (*e.g*., purchase price, and life cycle cost), and product development cycle [5].

Deming also discussed the three corners of quality, which relate to various quality characteristics, and focused on the evaluation of quality from the viewpoint of the customer [6]. The American Society for Quality defines quality as the "*the characteristics of a product or service that bear on its ability to satisfy stated or implied needs*" [7]. Thus, quality of products or services is defined and evaluated by the customer.

Dynamic competition in the global market is forcing organizations to provide products and services with less variation than their competitors. A product must be designed for manufacturability and must be insensitive to variability presented in the production environment and in the field when used by the customer. Montgomery provided a definition of quality related to variability as: "*quality is inversely proportional to variability*" [8]. This concept is also related to an evaluation of quality using quality loss function promoted by Taguchi, which will be discussed in this chapter. Reduced variation translates into greater repeatability, reliability, and ultimately cost savings to both the producer and the consumer and thus the whole society.

It is obvious from the definitions of quality that the emphasis of any quality programs or processes is to meet and exceed customers' needs and expectations, and focus on delight and enthusiasm of the customer.

13.2.2 Quality Engineering

Quality engineering is a series of operational, managerial, and engineering approaches to ensure that quality characteristics of a product are delivered at the required levels from the viewpoint of the customer for the duration of the designed product life. To achieve high quality of a product, quality engineering approaches must be applied over each phase of the product life cycle. Figure 13.1 shows how the cost to fix or solve problems increases as we move downstream in the product life cycle. The early and proactive activities should be taken to prevent problems, because approximately 90% of the life cycle cost is determined by the concept and development phases of the life cycle for many systems.

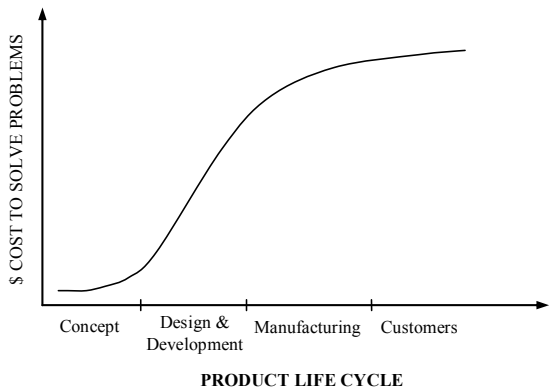

Figure 13.1. Cost to solve problems vs. product life cycle

Various quality engineering approaches can be utilized at different phases of product life cycle [3]. It results in two areas of quality engineering: (1) *off-line quality engineering* that is implemented as part of the research, design and development

phases, and (2) *on-line quality engineering* that is typically applied during production.

As the most efficient and cost-effective quality improvement activity, off-line quality engineering is a systematic methodology to improve the design of products and processes. Three design phases: system design, parameter design, and tolerance design are implemented for off-line quality engineering to make product or process performance insensitive (robust) to uncontrollable variables, which are noise factors. The optimal values of the mean (related to nominal value) and standard deviation (related to tolerance) of quality characteristic are determined by minimizing the variability of the quality characteristic through experimental design and process adjustment techniques. The three design phases were originally developed by Genichi Taguchi, and introduced to American industries in the 1980s [9, 10]. Since then, a lot of research has improved the related statistical techniques of quality engineering proposed by Taguchi and clarified many underlying assumptions and principles.

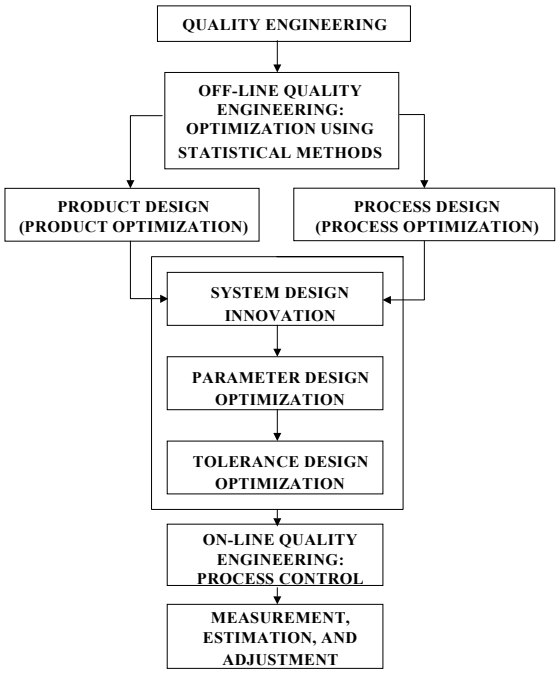

Figure 13.2. Quality engineering

As opposed to off-line quality engineering (Figure 13.2), on-line quality engineering refers to techniques employed to maintain quality during the manufacturing process. Statistical quality control (SQC) or statistical process control (SPC) is a primary on-line control technique for monitoring the manufacturing process or any other process with key quality characteristics of interest. The major goal of SQC (or SPC) is to monitor the manufacturing process, keep the values of mean and standard deviation stable, and finally reduce variability. Some additional quality techniques for on-line quality engineering include acceptance sampling and other quality inspection methods. Acceptance sampling is defined as the inspection and classification of samples chosen from a lot randomly and decision about disposition of the lot.

13.3 Quality Management Strategies and Programs

Off-line and on-line quality engineering provides the technical basis for problem solving in quality improvement, while quality management ensures the effective implementation of such techniques within an organization. In many organizations, the product development process is often based on trial and error and many activities have conflicting goals and objectives. The needs of the customer are not clearly understood. The purpose of quality management is to transform an organization to an integrated and distributed system as shown in Figure 13.3 [11].

There have been many quality management programs devoted to quality improvement and management, including total quality management (TQM), ISO 9000 series, Six Sigma, Lean Sigma, *etc.* The successful implementation of these programs requires that the supportive management system of an organization supervise the overall quality improvement effort, including quality planning, quality assurance, and quality control and improvement [8].

Quality planning (QP) is a strategic process to identify external and internal customers, clarify voice of customers, and develop plans to meet or exceed customers' expectations. Quality function

deployment (QFD) is a very important technique for the strategic quality planning, and the details of QFD will be discussed later.

Quality assurance (QA) contains systematic activities implemented within the quality system that can be demonstrated to provide confidence that a product or service will fulfill requirements for quality [7]. The ISO 9000 series provide generic standards that are applicable to any type of organization to perform quality assurance activities. Also available from the International Standards Organization is the ISO 14000 family, which is primarily concerned with "environmental management."

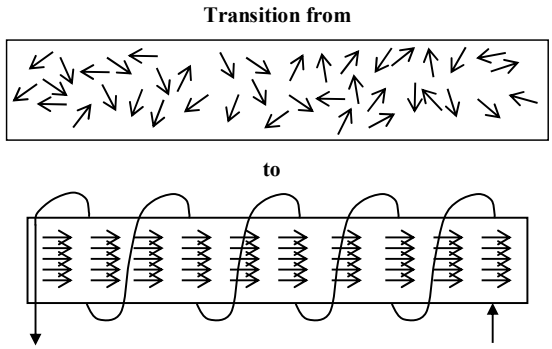

Figure 13.3. Integrated and distributed process

Quality control and improvement involves the activities of quality engineering that are implemented through projects. Six Sigma is a project-by-project approach that integrates the philosophy of quality management and techniques of quality engineering. Six Sigma methodology will be introduced later in this section. Before the emergence of Six Sigma, the implementation of total quality management (TQM) in many organizations enhanced people's awareness of the importance of quality. TQM emphasizes managing quality improvement activities on an organization-wide basis, and integrating the quality system with other organizational activities around the quality improvement goal. However, the importance of technical tools is not very well promoted in TQM.

In this section, the principle-centered quality management strategies will be elaborated by comparing traditional practices and new trends. Several recent quality improvement tools and programs will be reviewed including quality function deployment, Six Sigma, and Design for Six Sigma (DFSS).

13.3.1 Principle-centered Quality Management

Various quality programs stress the importance of quality for management in an organization. To develop consistent ideas for research and development that are useful for the 21st century and beyond, the constancy of purpose for quality and productivity improvement should be emphasized based on these principles. Such principles for quality improvement include [12]:

1. Customer focus and constancy of purpose
2. System focus
3. Process focus
4. Understanding the hierarchical structure and causation
5. Future focus and ideals for quality
6. Continuous improvement
7. Prevention and proactive strategies
8. Scientific approach
9. Integration

Table 13.1 presents the traditional practices versus new trends for each of the principles [12]. In general, the trend for quality management is to integrate organizational culture, values and beliefs, habits, technology, and strategic operations, as shown in Figure 13.4 [12].

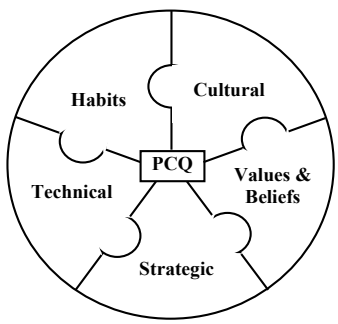

Figure 13.4. Integration for principle-centered quality (PCQ)

Table 13.1. Principle-centered quality: traditional practices versus new trends

	Traditional or past practices	Ideals or new trends
Customer focus	Fads, Trends	Constancy of purpose, Principle-centered
	Internal	External, Customer focus
System focus	Independence or dependence	Interdependence
	Competition	Teamwork, Collaboration
	Focus on control and centralization	Distributed but integrated by enterprise processes
	Quality & Reliability – subsystem optimization	Systems approach and system integration – holistic & synergistic
Process focus	Feedback	Feed forward
	Sequential	Simultaneous
	Ends	Means to achieve higher customer satisfaction
Hierarchical structure	Effect, Ends, Results/objectives	Cause, Means, Process focused
Future focus	Short term thinking	Infinite horizon
	Measurement (statistical estimation)	Improvement and growth, future perfect
Continuous Improvement	Binary	multi-state, continuous
	Specifications or tolerances or limits	Targets or ideals
	Six Sigma	Infinite sigma
	Achievable metrics	Ideals, never ending, perfection, continuous, improvement
	Failure or defect, nonconformance	Transition of the system from one state to another
Prevention and proactive	Inspection/audit /detection	Prevention /proactive
	Burn-in	Reduce process, variation
Scientific approach	Follow or copy other's success stories	Scientific and not anecdotal
	Eliminate/minimize cause	Reduce the effect of the cause
	Accept time as a noise	Achieve robustness
Integration	Fragmented-jump from tool to tool	Integration based on values and beliefs
	Probability models	Utility, customer satisfaction, probability as a basis for action

13.3.2 Quality Function Deployment

A process may have many processes before it, which are typically called the suppliers, and has many processes after it, which are its customers. Therefore, anything that the present process affects is its customer, such as the next process, environment, the end user, *etc*. One of the most important tasks in a quality program is to understand and evaluate the needs or expectations of the customer, and then provide products and services that meet or exceed those expectations. Shewhart states this as follows [13]: "*The first step of the engineer in trying to satisfy these wants is, therefore, that of translating as nearly as possible these wants into the physical characteristics of the thing manufactured to satisfy these wants. In taking this step, intuition and judgment play an important role as well as the broad knowledge of human element involved in the wants of individuals. The second step of the engineer is to set up ways and means of obtaining a product which will differ from the arbitrary set standards for these quality characteristics by no more than may be left to chance.*"

Mizuno and Akao developed a technique called quality function deployment (QFD) that contains the necessary philosophy, system, and methodology to achieve the first step proposed by Shewhart [14]. As presented in Figure 13.5, QFD is a means to translate the "voice of the customer" into substitute quality characteristics, design

configurations, design parameters, and technological characteristics that can be deployed (horizontally) through the whole organization: marketing, product planning, design, engineering, purchasing, manufacturing, assembly, sales, and service [14, 15]. Products have several characteristics and an "ideal" state or value of these characteristics must be determined from the customer's viewpoint. This ideal state is called the target value. Using QFD methodology, target values can be developed for substitute quality characteristics, which satisfy the requirements of the customer. The second step mentioned by Shewhart is accomplished by statistical process control, which is given in his pioneering book [13].

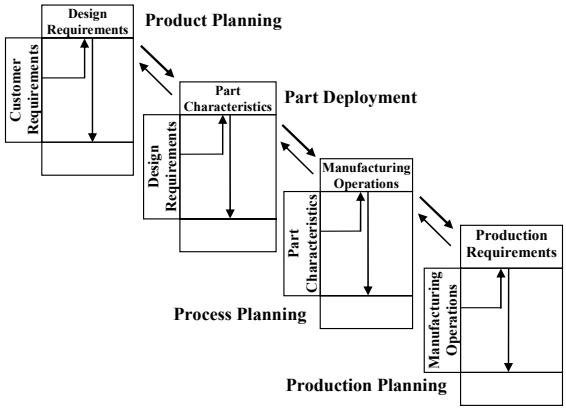

Figure 13.5. Phases for quality function deployment

13.3.3 Six Sigma Process Improvement

Based on the ideal or target value of the quality characteristic from the viewpoint of the customer, the traditional evaluation of quality is based on average measures of the process/product and their deviation from the target value. However, customers judge the quality of process/product not only based on the average, but also by the variance in each transaction with the process or use of the product. Customers want consistent, reliable and predictable processes that deliver or exceed the best-in-class level of quality. This is what the Six Sigma process strives to achieve. Six Sigma has been applied to many manufacturing companies and service industries such as healthcare systems, financial systems, *etc*.

Six Sigma is a customer-focused, data driven and robust methodology, which is well rooted in mathematics and statistics [16–18]. A typical process for Six Sigma process improvement has six phases: Define, Measure, Analyze, Improve, Control and Technology Transfer, denoted by (D)MAIC(T). Traditionally, a five-phase process, DMAIC is often referred in the literature [19]. We extend it to the six-phase process, (D)MAIC(T), because we want to emphasis the importance of the technology transfer (T) as the never-ending phase for continuous applications of the Six Sigma technology to other parts of the organization to maximize the rate of return on the investment in developing this technology [20, 21].

The process of (D)MAIC(T) stays on track by establishing deliverables at each phase, and by creating engineering models over time to reduce the process variation. In each phase, several steps need to be implemented. For each step, many quality improvement methods, tools and techniques are used. Interested readers are referred to Kapur and Feng for further details [20, 21].

The primary reason for the success of Six Sigma is that it provides an overall approach for quality and process improvement, and it is not just a collection of tools. During most quality training in academia, industry and government, students and professionals usually are taught a number of individual tools such as DOE, SPC, FMECA, FTA, QFD, *etc*., and leave the course without a mental big picture about how all these tools fit together. Six Sigma provides an overall process of improvement, (D)MAIC(T), that clearly shows how to link and sequence individual tools. With Six Sigma, students and professionals know what to do when faced to a real problem.

Six Sigma focuses on reducing process variation and thus on improving the process capability [22, 23]. The typical definition for process capability index, C_{pk}, is: $C_{pk} = \min\left\{\frac{USL-\hat{\mu}}{3\hat{\sigma}}, \frac{\hat{\mu}-LSL}{3\hat{\sigma}}\right\}$, where USL is the upper specification limit, LSL is the lower specification limit, $\hat{\mu}$ is the point estimator of the mean, and $\hat{\sigma}$ is the point estimator of the standard deviation. If the process is centered at the middle

of the specifications, which is also interpreted as the target value, i.e. $\hat{\mu} = \frac{USL + LSL}{2} = y_0$, then the Six Sigma process means that C_{pk} =2. In literature, it is typically mentioned that the Six Sigma process results in 3.4 defects per million opportunities (DPMO). For this statement, it is assumed that the process shifts by 1.5σ over time from the target (which is assumed to be the middle point of the specifications). It implies that the realized C_{pk} is 1.5 for the Six Sigma process over time. It is obvious that 6σ requirements or C_{pk} of 1.5 is not the goal; the ideal objective is to continuously improve the process based on some economic or other higher-level objectives for the system.

13.3.4 Design for Six Sigma (DFSS)

While Six Sigma process improvement approach leaves the fundamental structure of a process unchanged, Design for Six Sigma (DFSS) involves changing or redesigning the process at the early stage of product/process life cycle. DFSS becomes necessary when [18]

- An organization or designer chooses to replace, rather than repair, the current process;
- Improving an existing process cannot achieve the required quality level; or
- An opportunity is identified to offer a new process.

Although DFSS takes more effort at the beginning, it will benefit the system in the long run by designing Six Sigma quality into product/process. There are several methodologies for DFSS, such as DMADV, IDOV or ICOV. DMADV is a popular methodology since it has the same number of letters as the DMAIC acronym. The five phases of DMADV are defined as: Define, Measure, Analyze, Design and Verify. IDOV or ICOV is a well-known design methodology, especially in the manufacturing world. The IDOV (or ICOV) acronym is defined as Identify, Design (Characterize the design), Optimize and Validate. Interested readers are referred to the details in an article by Simon [24].

13.4 Off-line Quality Engineering

13.4.1 Engineering Design Activities

The engineering activity of designing and optimizing a product or process is complex. Off-line quality engineering methods are conducted at the product development cycle with the overall aim to improve product manufacturability and reliability, and reduce product development and lifetime costs [25]. As part of the delivery of these activities, three essential elements have to be specified: (1) system architecture including design of the overall system, subsystems and components, (2) nominal values of parameters in the system, and (3) tolerances of parameters. These three elements are accomplished through three steps of engineering design: system design, parameter design, and tolerance design [9].

1. *System design:* During this step, a variety of system architectures and technologies are examined, and the most suitable one is selected for achieving the desired function of the product or process. This step requires the experience, skills, and creativity of the design team. Quality function deployment (QFD) discussed in Section 3 can be used to translate the "voice of the customer" into design configurations, design parameters, and technological characteristics. After system design, it is often that the theoretical model is not available to describe the functional relationship between output variables and input variables. Statistical design of experiments, orthogonal polynomials, and regression analysis are important tools to derive the empirical model for the system transfer function.
2. *Parameter design*: In this step, the optimal settings of input variables are selected to optimize output variables by reducing the influence and effect of noise factors. The best settings should improve the quality level without increasing manufacturing cost. This is achieved by using low-grade components and materials with wide tolerances on noise factors, while the best settings of input variables are insensitive or robust to the variability. This step makes effective use of experimental design and response surface methods. Parameter design is the central focus of robust

design that is to improve the quality of a product or process by minimizing the effect of the causes of variation without eliminating the causes. Robust design is introduced in the next section of this chapter.

3. *Tolerance design*: In practice, when parameter design cannot achieve the desired results from the viewpoint of the customer, the quality of a product can be further improved using tolerance design. In this step, tolerances or variances of input variables are set to minimize the variance of output response by directly removing causes of variation. Usually, a narrower tolerance corresponds to a higher grade of material or component that leads to higher manufacturing costs. Therefore, design and manufacturing costs and quality losses due to variability to the customer have to be carefully evaluated and balanced (optimized) to determine the variances of input variables.

13.4.2 Robust Design and Quality Engineering

Robust design is a systematic approach that uses statistical experimental design to improve the performance of products and processes. It was originally developed by Taguchi and introduced to several major American companies in the 1980s, which resulted in significant quality improvements. Bendal *et al*. provided a collection of case studies covering the applications in automotive, electronics, plastics, and process industries [26].

The fundamental principle of robust design is to improve the quality of a product by minimizing the effect of variation without eliminating the causes [9, 10, 27, 28]. Robust design improves product quality while working on product design and manufacturing processes simultaneously by making product and process performance insensitive (robust) to hard-to-control noises [29]. Parameter design and tolerance design are very important to achieve this objective. Robust design and its associated methodology typically focus on the parameter design phase. The following are the two important tasks in robust design [27]:

1. *Performance measures* are used as an indicator to evaluate the effect of design on the product's performance in order to achieve the desired optimization goal. Taguchi introduced a family of performance measures called *signal-to-noise (S/N)* ratios.

2. *Effective experimental design* is used to determine the dependable information about control factors and their values to achieve robustness. Taguchi popularized orthogonal arrays (which have been known since the 1940s) to study many control factors simultaneously. Further information on statistical design of experiments can be found in [30–34].

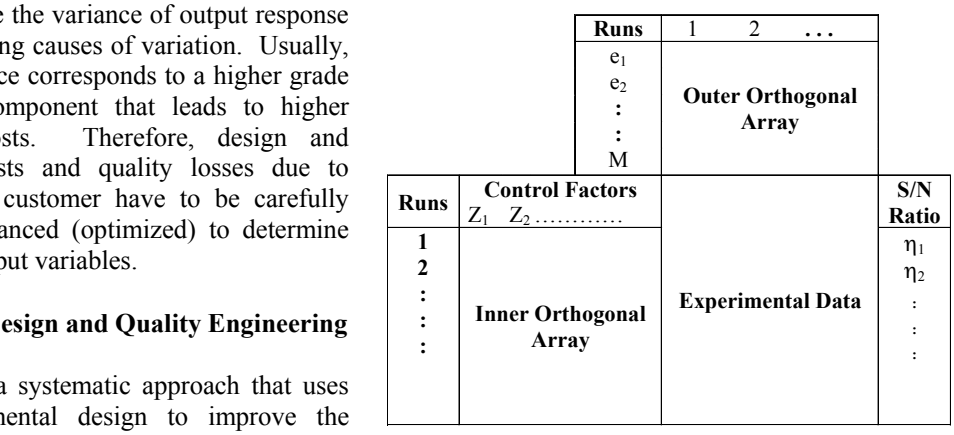

Figure 13.6. The inner and the outer orthogonal arrays

13.4.2.1 Experimentation

The goal of robust design is to reduce performance variation of a system by choosing the setting of its control factors to make it less sensitive to noise factors. Here, control factors and noise factors are two broad categories of input variables. A cross array or an inner-outer array design is often used as an experimental layout for robust design as shown in Figure 13.6. A cross array consists of a control array (or inner array) and a noise array (or outer array). For many dynamic characteristics, the inner array also has indicative factors and the outer array has signal factors (M) [10]. Each level combination in the control array is crossed with all the level combinations in the noise array. Usually, orthogonal arrays are chosen for the control array and the noise array. If some of the noise factors have more than three levels, the run size of the orthogonal array for the noise factors may be too large. Alternative plans include Latin hypercube sampling [35] and "uniform" designs based on number-theoretic methods [36].

When the run size of a cross array is too large, an alternative is to use a single array for both control and noise factors, which requires a much smaller run size. Wu and Hamada discussed the selection of cross arrays and single arrays, as well as the approaches for modeling and analyzing the data from experiments [32].

13.4.2.2 Quality Loss Function

Quality loss relates to cost or "loss" in dollars (or other measures), not just to the manufacturer at the time of production, but also to the next consumer. The intangible losses (customer dissatisfaction, loss of customer loyalty, and eventual loss of market share), along with other tangible losses (rework, defects, down time, *etc*.), make up some of the components of the quality loss. The quality loss function is a way to measure losses due to variability from the target values and transform them to economic values. The greater the deviation from target is, the greater is the economic loss.

A good quality evaluation system should measure the quality of all the items within and outside specifications. The concept of quality loss function provides a quantitative evaluation of loss caused by variation for "smaller the better", "larger the better" and "target the best" quality characteristics.

"Smaller the better" quality characteristics

The objective is to reduce the value of the quality characteristic. Usually the smallest possible value for such characteristics is zero, which is the "ideal" or target value. Some examples are wear, degradation, deterioration, shrinkage, noise level, harmful effects, level of pollutants, *etc*. Such characteristics generally have an upper specification limit (*USL*). A good approximation of the quality loss function, $L(y)$, is $L(y) = ky^2$, $y \geq 0$. The constant k depends on the natural of quality loss function $L(y)$, which reflects requirements of the customer.

"Larger the better" quality characteristics

For such quality characteristics, we want to increase their values as much as possible (within a given frame of reference). Some examples are strength, life of a system (a measure of reliability), fuel efficiency, *etc*. An ideal value may be infinity, though impossible to achieve. Such characteristics generally have a lower specification limit (*LSL*). A good approximation of $L(y)$ is $L(y) = k/y^2$, $y \geq 0$.

"Target the best" quality characteristics

An ideal or target value is specified for such a quality characteristic. The performance of the product deteriorates as the characteristic moves away from either side of the target value. Some examples are dimensional characteristics, voltage, viscosity of a fluid, shift pressure, clearance, and so on. Such characteristics generally have both *LSL* and *USL*. An approximation of the quality loss function is $L(y) = k(y - y_0)^2$.

13.4.2.3 Performance Measure: S/N Ratio

Taguchi introduced a family of performance measures called signal-to-noise (S/N) ratios. Based on the concept of quality loss function, the S/N ratio is a measure of quality loss due to noise factors and thus is used to achieve robustness and high quality. The form of S/N ratio is closely related to the form of the quality loss function that depends on the characteristic of the output response.

"Smaller the better" quality characteristics

The expected quality loss of a "smaller the better" quality characteristic is $E[L(Y)] = kE[Y^2]$. The signal to noise (S/N) ratio is a measure of the quality loss due to the effect of noise factors. Taguchi recommended using the logarithmic transformation for $E[Y^2]$ to calculate the signal to noise ratio, η:

$$\eta = -10 \log E\left[Y^2\right].$$

In order to decrease quality losses, we must increase the value of η. Let $y_1, y_2, .., y_n$ be a random sample from the distribution of Y. Then, S/N ratio (a measure of performance) can be estimated by

$$\eta = -10 \log\left(\frac{1}{n}\sum {y_i}^2\right).$$

"Larger the better" quality characteristics

The quality characteristic is continuous and nonnegative, and the target value is infinity. The expected quality loss of the "larger the better" quality characteristic is $E[L(Y)]=kE[1/Y^2]$. Again, we can develop a performance measure or S/N ratio, which minimizes the expected quality loss:

$$\eta = -10\log E\left[\frac{1}{Y^2}\right],$$

which can be estimated by the statistic:

$$\eta = -10\log\left\{\frac{1}{n}\sum\frac{1}{y_i^2}\right\}.$$

"Target the best" quality characteristics

For a "target the best" quality characteristic with the target value of y_0, an approximation for the expected loss is $E[L(Y)] = k\left[(\mu - y_0)^2 + \sigma^2\right]$. If the variance is not linked to the mean, we can use a monotone function of σ^2 and the performance measure or S/N ratio is given by

$$\eta = -10\log\sigma^2,$$

and this can be estimated by the statistic

$$\eta = -10\log\left\{\frac{\sum(y_i - \bar{y})^2}{n-1}\right\}.$$

If variance changes linearly with mean, we can minimize the coefficient of variation σ/μ to reduce quality losses. Since S/N ratio is always defined so that we maximize it, Taguchi suggested the following measure:

$$\eta = 10\log\frac{\mu^2}{\sigma^2}.$$

This can be estimated by the statistic

$$\eta = 10\log\left\{\frac{n\bar{y}^2 - s^2}{ns^2}\right\} = 10\log\left\{\frac{\bar{y}^2}{s^2} - \frac{1}{n}\right\}.$$

This performance statistics (S/N ratio) minimizes the coefficient of variation.

For "target the best" quality characteristics, Taguchi recommended a two-step procedure: (1) select the levels of the control factors to maximize the S/N ratio, and (2) select the level of adjustment factors to bring the location on target.

A summary of opinions and research directions of robust design are given in [37]. For the performance measure or the S/N ratio, Wu and Hamada described that the S/N ratio requires the system be a linear input-output system, and it lacks a strong physical justification in most practical situations [32]. A two-step procedure for the "target the best" quality characteristics was developed based on the quadratic loss function. Usually, parameter design is followed by a tolerance design, and it is called a sequential two-stage design. An economical alternative is to perform parameter design and tolerance design simultaneously [38–40]. A comprehensive review of operating window experiments and the performance measure independent of adjustment (PerMIA) for operating window experiments were given in [41].

Although Taguchi's robust design has drawn some criticism, it is broadly applicable due to its inherently sound philosophy and easier-to-implement design of experiments methods. Taguchi's robust design has promoted the use of statistical experimental design for product design improvement, and stimulated a wider application of existing statistical methods.

13.5 On-line Quality Engineering

On-line quality engineering methods are used for monitoring process and inspecting products in order to further reduce variation and improve quality. Techniques aimed at on-line quality improvement should be implemented after actions have been taken for off-line quality engineering. Since no process is free of variation, on-line process control techniques are always required to prevent, detect and reduce variations. Such techniques include acceptance sampling, inspection strategies, statistical process control, and process adjustment using feedback control.

13.5.1 Acceptance Sampling and its Limitations

As one of the earliest methods of quality control, acceptance sampling is closely related to

inspection of output of a process, or testing of product. Acceptance sampling is defined as the inspection and classification of samples from a lot randomly and decision about disposition of the lot. At the beginning of the concept of quality conformance back to the 1930s, the acceptance sample was taking the whole of the quality improvement effort. The most widely used plans are given by the Military Standard tables (MIL STD 105A), which were developed during World War II. The last revision (MIL STD 105E) was issued in 1989, but canceled in 1991. The American Society adopted the standard for Quality as ANSI/ASQ A1.4.

Due to its less proactive nature in terms of quality improvement, acceptance sampling is less emphasized in current quality control systems. Usually, methods of lot sentencing include no inspection, 100% inspection, and acceptance sampling. Some of the problems with acceptance sampling were articulated by W. Edwards Deming [6], who pointed out that this procedure, while minimizing the inspection cost, does not minimize the total cost to the producer. In order to minimize the total cost to the producer, Deming indicated that inspection should be performed either 100% or not at all, which is called Deming's "all or none rule". In addition, acceptance sampling has several disadvantages compared to 100% inspection [8]:

- There are risks of accepting "bad" lots and rejecting "good" lots.
- Less information is usually generated about the product or process.
- Acceptance sampling requires planning and documentation of the sampling procedure.

13.5.2 Inspection and Decisions on Optimum Specifications

Recent development of automated inspection technologies, such as optical sensors, thermal detectors, gas sensors, and CT scanners, makes it possible to perform 100% inspection on all items with low operating cost. 100% inspection, or screening, plays an important role in many processes, such as automobile assembly, semi-conductor manufacturing, airport baggage screening or other decision-making processes where the consequences of excessive deviations from target values are very high.

Variability means some kind of waste, yet it is impossible to have zero variability even after off-line quality engineering. The common wisdom is to set, not only a target performance value, but also a tolerance or specification about the target, which represents "acceptable" performance. The quality characteristic is regarded as acceptable only if the measurement falls within the specifications. The specification limits have to be determined in order to decide if a quality characteristic is acceptable or not. Feng and Kapur considered the specifications from the whole-system viewpoint of both the customer and the producer [42, 43]. They proposed an inspection strategy that is used to decide when to do 100% inspection, as well as to determine specifications for the 100% inspection. Two questions are to be answered after off-line engineering actions have been taken:

Question 1: Should 100% inspection be performed before output products are shipped to the next or downstream customer?

Question 2: If 100% inspection is to be performed, how to determine the optimal specification limits that minimize the total cost to the system including both the producer and the consumer?

By answering the above two questions, the decision maker has to choose between the following two decisions:

Decision 1: No inspection is done, and thus all the output products are shipped to the next customer. One economic interpretation of cost to the downstream customers is the expected quality loss.

Decision 2: Do 100% inspection. It is clear that we will do the inspection and truncate the tails of the distribution only if it reduces total cost to both the producer and the consumer. When we truncate the distribution by using certain specification limits, some additional costs will incur, such as the measurement or inspection cost (to evaluate if units meet the specifications), the rework cost, and the scrap cost. The general optimization model is

$$\text{Minimize } ETC = EQL + ESC + IC$$

where ETC = Expected total cost per produced unit
EQL = Expected quality loss per unit
ESC = Expected scrap cost per unit
IC = Inspection cost per unit.

Based on this general optimization model, several models have been formulated under different assumptions for different quality characteristics, quality loss functions, and inspection errors [2, 42–44].

13.5.3 Statistical Process Control

As traditional approaches of on-line quality engineering, acceptance sampling and inspection strategies control the final product and screen out items that do not meet the requirements of the next customer. This detection strategy related to after-the-fact inspection is mostly uneconomical, as the wasteful production has already been produced. A better strategy is to avoid waste by not producing the unacceptable output at the first place and focus more on prevention. Statistical process control (SPC) is an effective prevention strategy for monitoring the manufacturing process or any other process with key quality characteristics of interests [8, 13, 45–47].

13.5.3.1 Benefits of Using Control Charts

Statistical process control plays a very important role during the effort for process improvement. When we try to control a process, analysis and improvement are naturally resulted in; and when we try to make an improvement, we naturally come to understand the importance of control. We can only make breakthrough when we have achieved control. Without process control, we do not know where to improve, and we cannot have standards to use control charts. Some of the important benefits that come from using control charts include:

- Control charts are simple and effective tools to achieve statistical control. They can be maintained at the job station by the operator, and give the operator reliable information on when action should/should not be taken.
- When a process is in statistical control, its performance to specification will be predictable. In this way, both the producer and the customer can rely on consistent quality levels and stable costs of achieving that quality level.
- After a process is in statistical control, its performance can be further improved to reduce variation. The expected effect of proposed improvements in the system can be anticipated, and the actual effect of even relatively subtle changes can be identified through the control chart data. Such process improvements will:
  - Increase the percentage of output that meets customer expectations (improve quality),
  - decrease the percentage of scrap or rework (reduce cost per good unit produced), and
  - increase the total yield of acceptable output through the process (improve effective capacity).
- Control charts provide a common language for communications about the performance of a process between
  - two or three shifts that operate a process;
  - line production (operator, supervisor) and support activities (maintenance, material control, process engineering, and quality control);
  - different stations in the process,
  - supplier and user, or
  - the manufacturing/assembly plant and the design engineering activity.
- Control charts, by distinguishing special causes from common causes of variation, give a good indication of whether any problems are likely to be correctable locally or will require management action. This minimizes the confusion, frustration, and excessive cost of misdirected problem-solving efforts.

13.5.3.2 Trends of SPC Applications

SPC has a broad application in the manufacturing industry, and it has recently expanded to non-manufacturing sectors such as health care, education, banking, and other industries. For instance, standard control charts are recommended for use in the monitoring and improvement of hospital performance [48]. Woodall *et al*. provided an excellent review of current uses of control charts and issues in healthcare monitoring, primarily focused on public-health surveillance, and cumulative sum and related methods [49].

Standard control charts originated by Shewhart in the 1930s have been improved in many ways due to the expansion of SPC applications recently. New methodologies are developed to provide tools that are more suitable for specific applications, such as short-run SPC, SPC with autocorrelated process data, multivariate process control, and process adjustment with feedback control.

13.5.3.3 Advanced Control Charts

Major disadvantage of standard control chart is that it uses the information in the last plotted point and ignores information given by the sequence of points. This makes it insensitive to small shifts. Two effective control charts to detect small process shifts are [8]

- Cumulative sum (CUSUM) control charts, and
- exponentially weighted moving average (EWMA) control charts.

The competitive global market expects lower defect rate and higher quality level that requires 100% inspection of output products. The recent advancement of sensing techniques and computer capacity makes 100% inspection more feasible. Due to the reduced intervals between sampling of the 100% inspection, the complete observations will be correlated over time. However, one of the assumptions for Shewhart control charts is the independence between observations over time. When the observations are autocorrelated, Shewhart control charts will give misleading results in the form of many false alarms. Time series models, such as an autoregressive integrated moving average (ARIMA) model, are used to remove autocorrelation from data and control charts are then applied to the residuals. Further discussion on SPC with autocorrelated process data can be found in [8, 50, 51].

It is often necessary to simultaneously monitor or control two or more related quality characteristics. Using individual control charts to monitor the independent variables separately can be very misleading. Hotelling developed multivariate SPC control charts based on multivariate normal distribution [52]. Multivariate methods are particularly important today, as automatic inspection systems make it relatively easy to measure many parameters simultaneously. The recent development of multivariate SPC can be found in [8, 53, 54].

The use of control charts requires the selection of sample size, sampling frequency or interval between samples, and control limits for the charts. The selection of these parameters has economic consequences in that the cost of sampling, the cost of false alarms, and the cost of removing assignable causes will affect the choice of parameters. Therefore, economic design of control charts has called attention in research and practice [8, 55–57]. Other research issues and ideas in SPC can be found in review papers [58, 59].

13.5.4 Process Adjustment with Feedback Control

Processes frequently need to be adjusted due to unavoidable disturbances. The SPC monitoring techniques such as Shewhart control charts are inappropriate and inefficient for this purpose. Engineering process control (EPC) or automatic process control (APC) can be readily used to adjust processes [60, 61]. The principle idea of EPC or APC is the feedback control technique, which has become an important resource for quality engineers [51]. A variety of techniques for process adjustment have been studied, such as run-to-run process control in the semiconductor industry [62], and a unified view of process adjustment procedures for setting up a machine based on a Kalman filter approach [63].

13.6 Conclusions

In this chapter, we reviewed the status and new trends in quality engineering for the control, design, and optimization of product and manufacturing processes as well as other systems. Quality management strategies and programs are overviewed including principle-centered quality improvement, quality function deployment, and Six Sigma methodology. The techniques for off-line quality engineering are presented with emphasis on robust design, followed by approaches for on-line quality engineering including

acceptance sampling, 100% inspection, statistical process control, and process adjustment with feedback control.

With the advancement of technology, quality practitioners need more advanced quality tools, techniques, and methodologies in order to meet new challenges. The following new trends in quality engineering have been identified:

- Principle-centered quality improvement is emphasized based on the constancy of purpose in order to develop consistent ideas for research and development that are useful for the 21st century and beyond. Comparison of traditional or old methods with new methods and trends as well as ideals is given in Table 13.1.
- Integrated or unified methods are becoming more prevalent, such as the unified method of parameter design and tolerance design, and the integration of SPC and EPC, *etc*. This also applies to integration of all quality characteristics including reliability, safety, security, life cycle cost as well as the total product development cycle [4].
- Application of quality engineering has been expanded to non-manufacturing sectors, such as healthcare systems, banking, and biomedical systems.

Statistical Process Control

V.N.A. Naikan

Reliability Engineering Center, Indian Institute of Technology, Kharagpur – 721302, India

Abstract: Statistical process control (SPC) is a tool used for on-line quality control in mass production. Statistical sampling theory is effectively used for this purpose in the form of control charts. Various types of control charts have been developed in industry for controlling different types of quality characteristics. The basic principles of development, design and application of various types of control charts are discussed in this chapter. The state of the art and recent developments in SPC tools are included with references for further research. A separate section on process capability studies is also included.

14.1 Introduction

The concepts of quality are as old as human civilization. It has been a constant endeavor of any society or culture to design and develop finest pieces of quality in all walks of life. This is visible in many of the human made world wonders such as the Taj Mahal of India, the pyramids of Egypt, the high roads and sculptures of the Roman Empire, the finest paintings of Renaissance Europe, or the latest developments such as space shuttles, super computers, or atomic power generation. However, quality as a science or as a formal discipline has developed only during the 20th century. Quality has evolved through a number of stages such as inspection, quality control, quality assurance, and total quality control.

The concepts of specialization, standardization, and interchangeability resulted in mass production during the Second World War. This also changed the traditional concepts of inspection of individual products for quality control. It was found that applications of statistical principles are much more practical and beneficial in mass production. Statistical sampling theory, for instance, helped to minimize the need of resources for quality control with acceptable levels of accuracy and risk. The concept of statistical process control (SPC) has now been accepted as the most efficient tool for on-line quality control in mass production systems. SPC uses control charts as the main tool for process control. The control chart is one of the seven tools for quality control. Fishbone diagrams or Ishikawa diagrams check sheets, histograms, Pareto-diagrams, scatter diagrams, and stem and leaf plots are other tools. They are discussed in detail in [1]. This chapter focuses on SPC using control charts.

14.2 Control Charts

The control chart is a graphical tool for monitoring the activities of a manufacturing process. The

numerical value of a quality characteristic is plotted on the *Y*-axis against the sample number on the *X*-axis. There are two types of quality characteristics, namely variables and attributes. The diameter of shafts, the strength of steel structures, service times, and the capacitance value of capacitors are examples of variable characteristics. The number of deformities in a unit, and the number of nonconformities in a sample are examples of attribute quality characteristics. A typical control chart is shown in Figure 14.1.

As shown in this figure, there is a centerline to represent the average value of the quality characteristic. It shows where the process is cantered. The upper control limit (UCC) and the lower control limit (LCL) on the control chart are used to control the process. The process is said to be in statistical control if all sample points plot inside these limits. Apart from this, for a process to be in control the control chart should not have any trend or nonrandom pattern.

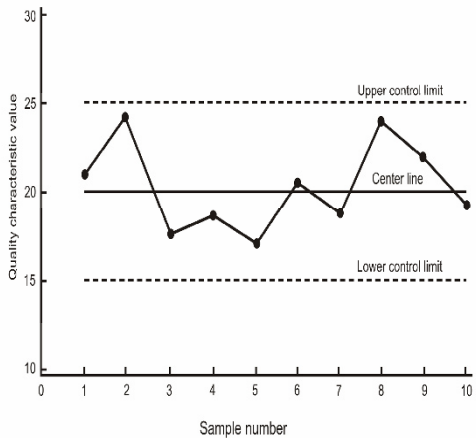

Figure 14.1. A typical control chart

14.2.1 Causes of Process Variation

Many factors influence the manufacturing process, resulting in variability. For example, variation in raw materials, skills of operators, capabilities of machines, methods, management policies, and many other factors including environmental variations affect the performance of a process. The causes of process variability can be broadly classified into two categories, *viz.*, assignable causes and chance causes.

Assignable Causes

If the basic reason for the occurrence of a cause of process variation can be found, then we list it under the category of assignable causes. Improper raw materials, usage of inappropriate cutting tools, carelessness of machine operators, *etc*., are examples of this. Such causes are also known as special causes. The basic purpose of using control charts is to identify the presence of assignable causes in the process and to eliminate these so as to bring back the process to statistical control.

Chance Causes

These are natural causes inherent in any process. The basic reasons for the occurrence of such causes cannot be correctly established. Elimination of such causes is also not possible in actual practice. A process is said to be out of control if any assignable cause is present in the process. Inherent material variations, operator skills, environmental conditions, and machine vibration are examples of chance causes. These are also known as common or random causes.

It is found that the assignable causes result in large variations in the process parameters whereas chance causes bring only small variations. It is reported that about 15% of the causes of variation are due to assignable causes and the remainder are due to chance causes for which only the management is accountable [2]. It is very important to remember that a process under statistical control will have some variations due to chance causes. In fact, the control limits are designed based on this principle.

Statistical Basis

Control charts are formulated based on the properties of the normal distribution [3]. The central limit theorem [1] states that if we plot the sample average of a process parameter, it will tend to have a normal distribution. The normal distribution is described by its parameters mean

(μ) and standard deviations (σ). For a normal distribution it can be shown that 99.74% of all points fall within the 3σ limits on either side of the mean. The upper and lower control limits of the control chart are determined based on this principle. This means that almost all the data points will fall within 3σ control limits if the process is free from assignable causes.

Errors in Control Charts

Two types of errors are associated with using the control charts. These are type I error and type II error. Type I error is the result of concluding that a process is out of control (based on actual data plotted on the chart) when it is actually in control. For a 3σ control chart this chance (α) is very small (about 0.0026). Type II error is the result of concluding that a process is in control (based on actual data plotted on the chart) when it is actually out of control. This may happen under many situations, such as the process mean changes from its initial setup, but all sample points fall within the control limits. The probability of type II error is generally represented by β and it is evaluated based on the amount of process change and the control limits. A plot of β *versus* the shifting process parameter is known as the operating characteristic (OC) curve of a control chart. The OC curve is a measure of the ability of a control chart to detect the changes in process parameters. A good control chart should have an OC curve as shown in Figure 14.2. For small changes in the process parameter, the probability of nondetection (β) by the control charts is high. For large changes in the process parameter, β should be small so that it is detected and corrected by the control chart.

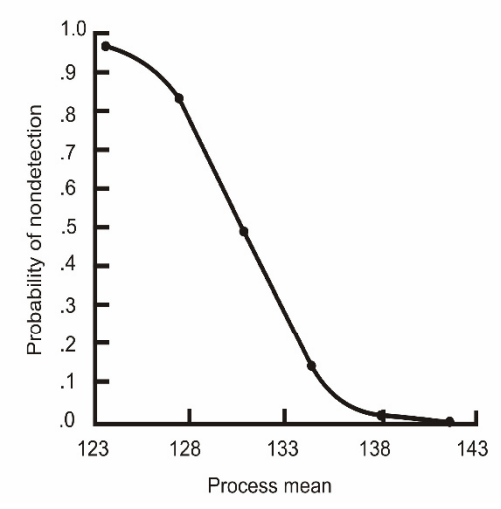

Figure 14.2. Typical OC curve for control charts

Average Run Length (ARL)

The average run length (ARL) is another measure of the performance of a control chart. It is the number of samples required to detect an out-of-control by a control chart. It is measured as reciprocal of type I error α.

$$ARL = \frac{1}{\alpha}.$$

For a 3σ control chart, $ARL = \left(\frac{1}{0.0026}\right) = 385$.

This shows that on an average one sample point is expected to fall out of 385 sample points outside the control limits. A large ARL is preferred since it produces fewer false alarms in a control chart.

Other Considerations

As mentioned earlier, control charts are plotted by taking small samples from the manufacturing process on a regular basis. Therefore, selection of sample size is very important in using the control charts.

Sample Size

It can be shown that a larger sample size results in narrow control limits. Decreasing the sample size makes the control limits wider. A larger sample size is needed if the small shift in the process parameter needs to be detected early. Apart from these factors the selection of sample size is influenced by the availability of resources, the types of tests used for sample evaluation, production rate, *etc*.

14.2.1.8 Frequency of Sampling

Theoretically it is most beneficial if we have more frequent large sample sizes. The type of inspection and the resource constraints are the main factors influencing the selection of these. In most practical situations a small sample size at frequent intervals is preferred.

Decision Rules for Control Charts

Five rules are used to detect when a process is going out of statistical control. These are briefly discussed below:

Rule 1: A process is going out of control if a single point plots outside the control limits.

Rule 2: A process is going out of control if two out of three consecutive points fall outside the 2σ warning limits on the same side of the centerline.

Rule 3: A process is going out of control if four out of five consecutive sample points fall outside the 1σ limits on the same side of the centerline.

Rule 4: A process is going out of control if nine or more consecutive points fall to one side of the centerline.

Rule 5: A process is going out of control if six or more consecutive sample points run up or down.

Applications of Control Charts

Control charts have several applications. This helps us in the following decision making:

1. To decide when to take corrective actions and when to leave the process as it is.
2. They give indications of type of remedial actions necessary to bring the process to control.
3. They help us to estimate the capability of our process to meet certain customer demands or orders.
4. They help us to improve quality.
5. They help us to take decisions such as the need for machine or technology replacement to meet quality standards.

Quality control and improvement are ongoing activities and, therefore, control charts must be maintained or revised as and when changes occur in the process. Installation of a new machine or application of a new technology necessitates the development of new control charts.

As mentioned earlier, the quality characteristics are broadly of two types. These are variables and attributes. Variable characteristics are continuous in their range where as attributes are discrete. Therefore, control charts are broadly classified into two categories, *viz.*, control charts for variables and for attributes.

14.3 Control Charts for Variables

Quality characteristics that can be measured on a numerical scale such as diameter of a shaft, length of a component, strength of a material and weight of a part are known as variables. Process control means controlling the mean as well as the variability of the characteristic. The mean of the variable indicates the central tendency and variability indicates the dispersion of the process. Variability is measured in terms of the range or standard deviation. Various types of control charts are discussed in the following sections.

14.3.1 Control Charts for Mean and Range

These charts are used to control the process mean and its variations. This is because the process control is ensured only if its mean is located correctly and its spread is kept within its natural limits. Therefore, these charts are used in pairs. The following steps are generally used for designing these control charts:

Step I: Decide the sampling scheme (sample size, number of samples, and frequency of sampling) and the quality characteristic to be controlled.

Step II: Collect the samples randomly from the process, measure the quality characteristic, and enter it into a data sheet. Let n be the sample size and X_i be the i-th observation, $i = 1...n$.

Step III: For each sample (j) calculate mean and range using the following equations ($j = 1...g$).

$$\overline{X}_j = \frac{\sum_{i=1}^{n} X_i}{n} \quad , \tag{14.1}$$

$$R_j = X_{j\max} - X_{j\min} \quad . \tag{14.2}$$

Step IV: Estimate the centerline (CL) and trial control limits for both mean and range charts using the following equations:

$$CL_{\overline{X}} = \overline{\overline{X}} = \frac{\sum_{j=1}^{g} \overline{X}_j}{g} \quad , \tag{14.3}$$

$$CL_R = \overline{R} = \frac{\sum_{j=1}^{g} R_j}{g} \quad , \tag{14.4}$$

$$\left(UCL_{\overline{X}}, LCL_{\overline{X}}\right) = \overline{\overline{X}} \pm A_2 \overline{R} \quad , \tag{14.5}$$

$$\left(UCL_R\right) = D_4 \overline{R} \quad , \tag{14.6}$$

$$LCL_R = D_3 \overline{R} \quad . \tag{14.7}$$

The values of A_2, D_3, D_4 depend on the sample size and can be taken from Appendix A-7 of [1].

Step V: Plot $\overline{X}_j$ and R_j on the control charts developed as per Step III. Check whether the process is in control as per the decision rules discussed earlier. If so, the control limits in Step III are final. Else revision of control limits by elimination of the out of control points is required. Repeat these steps for revision of control limits until final charts are obtained. The principle of development of other control charts is similar to the above methodology.

If the sample size is not constant from sample to sample, a standardized control chart can be used. The reader is referred to [4] and [5] for more details. Sometimes control charts are to be developed for specified standard or target values of mean and standard deviation. The reader is referred to [1] for the complete procedure for this. If a process is out of control assignable causes are present, which can be identified from the pattern of the control chart. AT & T [6] explains different types of control chart patterns that can be compared with the actual pattern to get an idea about "what" action is to be taken "when".

The effect of measurement error on the performance of $\overline{X}$ and S^2 charts is frequently quantified using gage capability studies [7], which are further investigated using a linear covariate [8]. Their study also identifies conditions under which multiple measurements are desirable and suggests a cost model for selection of an optimal mean. They also suggest taking multiple measurements per item to increase the statistical power of control charts in such cases.

14.3.2 Control Charts for Mean and Standard Deviation $\left(\overline{X}, S\right)$

Both range and standard deviation is used for measuring the variability. Standard deviation is preferred if the sample size is large (say $n > 10$). The procedure for construction of $\overline{X}$ and S charts is similar to that for $\overline{X}$ and R chart. The following formulas are used:

$$CL_s = \overline{S} = \frac{\sum_{j=1}^{g} S_j}{g} \quad , \tag{14.8}$$

$$UCL_s = B_4 \overline{S} \quad , \tag{14.9}$$

$$LCL_s = B_3 \overline{S} \quad . \tag{14.10}$$

The reader is referred to Appendix A-7 of [1] for the values of B_3 and B_4. $\overline{X}$ and S charts are sometimes also developed for given standard values [1].

14.3.3 Control Charts for Single Units (X chart)

In many practical situations we are required to limit the sample size to as low as unity. In such cases we use an X chart in association with a moving range (MR) chart. The moving range is the absolute value of the difference between successive observations. The assumption of normal distribution may not hold well in many cases of X and MR charts. The following formulas shown in Table 14.1 are used for developing the charts.

Table 14.1. Control limits for X and MR charts

Chart	CL	UCL	LCL
X	$\overline{X}$	$\overline{X} + 3\overline{MR}/d_2$	$\overline{X} - 3\overline{MR}/d_2$
MR	$\overline{MR}$	$D_4\overline{MR}$	$D_3\overline{MR}$

The values of d_2 depend on the sample size and can be taken from Appendix A-7 of [1]. These charts can also be developed for given standard values.

The control charts discussed so far are initially developed by Walter A Shewhart. Therefore, these charts are also known as Shewhart control charts [9]. Shewhart control charts are very easy to use and are very effective for detecting magnitudes of shifts from 1.5σ to 2σ or larger. However, a major limitation of these charts is their insensitivity to small shifts in process parameters, say about 1.5σ or less. To alleviate this problem a number of special charts have been developed. These are discussed in the following sections.

14.3.4 Cumulative Sum Control Chart (CUSUM)

These control charts are used when information from all previous samples need to be used for controlling the process. CUSUM charts are more effective in detecting small changes in the process mean compared to other charts discussed earlier.

The cumulative sum for a sample m is calculated by

$$S_m = \sum_{j=1}^{m} \left(\overline{X}_i - \mu_o\right) , \tag{14.11}$$

where μ_o is the target mean of the process. In this case CUSUM is plotted on the y-axis. The details of development and implementation of CUSUM charts are discussed in [10]. A V-mark is designed and developed for taking the decision on the process control while using these charts. A methodology to use CUSUM charts for detecting larger changes in process parameters is also available in this reference.

A comparative study of the performance based on the ARL of a moving range chart, a cumulative sum (CUSUM) chart based on moving ranges, a CUSUM chart based on an approximate normalizing transformation, a self-starting CUSUM chart, and an exponentially weighted moving chart based on subgroup variance is discussed in [11, 12]. The CUSUM chart is again compared with several of its alternatives that are based on the likelihood ratio test and on transformations of standardized recursive residual [13]. The authors conclude that the CUSUM chart is not only superior in the detection of linear trend out-of-control conditions, but also in the detection of other out-of-control situations. For an excellent overview of the CUSUM chart techniques the reader is referred to [14].

The adaptive CUSUM (ACUSUM) chart was proposed to detect a broader range of shifts on process mean [15]. A two-dimensional Markov chain model has also been developed to analyze the performance of ACUSUM charts [16]. This improves on the theoretical understanding of the ACUSUM schemes and also allows the analysis without running exclusive simulations. Moreover, a simplified operating function is derived based on an ARL approximation of CUSUM charts [16].

14.3.5 Moving Average Control Charts

These charts are also developed to detect small changes in process parameters. The moving average of width w for a sample number r is defined as:

$$M_r = \frac{\overline{X}_r + \overline{X}_{r-1} + \cdots\cdots + \overline{X}_{r-w+1}}{w} . \tag{14.12}$$

That means M_r is an average of latest w samples starting from the r-th sample. The control limits for this chart will be wider during the initial period and stabilize to the following limits after the first (w-1) samples:

$$CL = \overline{\overline{X}} , \tag{14.13}$$

$$\left(UCL, LCL\right) = \overline{\overline{X}} \pm \frac{3\sigma}{\sqrt{nw}} . \tag{14.14}$$

The initial control limits can be calculated by substituting r in place of w in these equations. Larger values of w should be chosen to detect shifts of small magnitudes. These charts can also be used when the sample size is unity.

14.3.6 EWMA Control Charts

The exponentially weighed moving average (EWMA) control chart was introduced in 1959 [17]. EWMA charts are also used for detecting shifts of small magnitudes in the process characteristics. These are very effective when the sample size is unity. Therefore, these are very useful for controlling chemical and process industries, in discrete part manufacturing with automatic measurement of each part, and in automatic on-line control using micro computers. EWMA is similar to MA, except that it gives higher weighting to the most recent observations. Therefore, the chances of detecting small shifts in process are better compared to the MA chart. These charts are discussed in details in [18–20], and [1]. The control limits of the EWMA chart are

$$CL = \overline{\overline{X}}\ , \tag{14.15}$$

$$(UCL, LCL) = \overline{\overline{X}} \pm 3\sigma \sqrt{\frac{p}{n(2-p)}\left[1-(1-p)^{2r}\right.} \tag{14.16}$$

where p is the weighing constant $(0 < p \le 1)$, and r is the sample number.

It may be noted that if p = 1, EWMA chart reduces to Shewhart chart and for $p = 2/(w+1)$, it reduces to MA chart. Selecting a small value of p (say 0.05) ensures faster detection of small shifts in process. These charts are also known as geometric moving average control charts.

As discussed earlier, violation of the assumption of independent data results in increased number of false alarms and trends on both sides on the centerline. A typical approach followed in the literature to study this phenomenon is to model the autocorrelated structure of the data and use a traditional control chart method to monitor the residuals. See [21–25], for more details. An alternative approach is the exponentially weighted moving average (MCEWMA) chart proposed in [26]. The literature also explores the shift detection capability of the moving centerline exponentially weighted moving average (MCEWMA) chart and recommends enhancements for quicker detection of small process upsets [27].

14.3.7 Trend Charts

In many processes the process average may continuously run either upward or downward after production of every unit of product. This is a natural phenomenon and therefore, it is an acceptable trend. Examples are effects of wearing of the punch, die, cutting tools or drill bits. However, such a trend in the process mean is acceptable only within some upper and lower limits (in most cases the specification limits). The trend charts are developed to monitor and control these types of processes. The centerline of the trend chart will have an upward or downward trend, and the upper and lower control limits will be parallel to the centerline. The intersection of centerline a and the slope b can be evaluated from the observations collected from the process [1]. The equations for the control limits are

$$CL = a + b_i\ , \tag{14.17}$$

$$UCL = (a + b_i) + A_2 \overline{R}\ , \tag{14.18}$$

$$LCL = (a + b_i) - A_2 \overline{R}\ . \tag{14.19}$$

These charts are useful for detecting changes in the process and also to decide whether or not a tool change is required. These charts are also known as regression control charts and are very helpful in controlling processes in machine shops and other production machines.

14.3.8 Specification Limits on Control Charts

If we want to include specification limits on the control charts, we require modification of the control limits. This is because the specification limits are defined on individual units where as most control charts are developed for sample average values. A simple methodology for finding the modified control limits is discussed in [1].

14.3.9 Multivariate Control Charts

The quality of a product is a function of many characteristics. For example, the length, diameter, strength, and surface finish among others contribute to the quality of a shaft. Therefore

controlling of all these variables is required to control the quality of the product. Multivariate control charts are developed to simultaneously control several quality characteristics. The procedure for development and application of multivariate control charts are discussed in detail in [1]. The T^2 distribution is used to develop the control chart and the F-distribution is used for finding the upper control limit [28]. The lower control limit is zero. The probability of type I error for this type of chart is very difficult to establish if the variables are dependent. If all the variables are independent then we can calculate this probability by the equation:

$$\alpha^* = 1-(1-\alpha)^p \quad , \tag{14.20}$$

where p is the number of independent variables.

Two phases in constructing multivariate control charts are defined, with phase I divided into two stages [29]. In stage I of phase I, historical observations are studied for determining whether the process was in control and to estimate the in-control parameters of the process. The T^2 chart of Hotelling is used in this stage as proposed in [30], and [31]. Control charts are used in stage II with future observations for detecting possible departures from the parameters estimated in the first stage. In the phase II charts are used for detecting any departures from the parameter estimates, which are considered the true in-control process parameters. A T^2 control chart based on robust estimators of location and dispersion is proposed in [32]. Using simulation studies the author shows that the T^2 control chart using the minimum volume ellipsoid (MVE) estimators is effective in detecting any reasonable number of outliers (multiple outliers).

Multiway principal components analysis (MPCA), a multivariate projection method, has been widely used for monitoring the batch process. A new method is proposed in [33] for predicting the future observation of the batch that is currently being operated (called the new batch). The proposed method, unlike the existing prediction methods, makes extensive use of the past batch trajectories.

The effect of measurement error on the performance of the T^2 chart is studied in [34]. For some multivariate nonnormal distributions, the T^2 chart based on known in-control parameters has an excessive false alarm rate as well as a reduced probability of detecting shifts in the mean vector [35]. The process conditions that lead to the occurrence of certain nonrandom patterns in a T^2 control chart are discussed in [36]. Examples resulting from cycles, mixtures, trends, process shifts, and auto correlated data are identified and presented. Results are applicable to a phase I operation or phase II operation where the T^2 statistics is based on the most common covariance matrix estimator. The authors also discuss the cyclic and trend patterns, effects of mixture of populations, process shifts and autocorrelated data on the performance of the T^2 chart.

A strategy for performing phase I analysis (of the multivariate control charts) for high-dimensional nonlinear profiles is proposed in [37]. This consists of two major components: a data reduction component that projects the original data into a lower dimension subspaces while preserving the data-clustering structure and a data-separation technique that can detect single and multiple shifts as well as outliers in the data. Simulated data sets as well as nonlinear profile signals from a forging process are used to illustrate the effectiveness of the proposed strategy.

Excellent reviews on the T^2 chart are presented in [38, 39]. Several useful properties of the T^2 statistics based on the successive difference estimator which give a more accurate approximate distribution for calculating the upper control limit individual observation in a phase I analysis are demonstrated in [40].The author discusses how to accurately determine the upper control limit for a T^2 control chart based on successive difference of multivariate individual observations.

A multivariate extension of the EWMA chart was proposed in [41]. This chart, known as MEWMA chart, is based on sample means and on the sum of squared deviations from the target. The performance of many of these control charts depends on the direction of the shifts in the mean vector or covariance matrix [42].

14.4 Control Charts for Attributes

Attribute characteristics resemble binary data, which can take only one of two given alternatives. In quality control, the most common attribute characteristics used are "conforming" or "not conforming", "good" or "bad". Attribute data need to be transformed into discrete data to be meaningful.

The types of charts used for attribute data are:

- Control chart for proportion nonconforming items (*p* chart)
- Control chart for number of nonconforming items (*np* chart)
- Control chart for nonconformities (*c* chart)
- Control chart for nonconformities per unit (*u* chart)
- Control chart for demerits per unit (*U* chart)

A comprehensive review of the attribute control charts is presented in [43]. The relative merits of the *c* chart compared to the X chart for the Katz family covering equi-, under-, and over-dispersed distributions relative to the Poisson distribution are investigated in [44]. The Katz family of distributions is discussed in [45]. The need to use an X chart rather than a *c* chart depends upon whether or not the ratio of the in control mean is close to unity. The X chart, which incorporates the information on this ratio, can lead to significant improvements under certain circumstances. The c chart has proven to be useful for monitoring count data in a wide range of application. The idea of using the Katz family of distribution in the robustness study of control charts for count data can be extended to the cumulative sum (CUSUM) and exponentially weighted moving average (EWMA) chart.

The *p* and *np* charts are developed based on binomial distribution, the *c*, *u*, and *U* charts are based on Poisson distribution. These charts are briefly discussed in this section.

14.4.1 The *p* chart

The *p* chart is used when dealing with ratios, proportions or percentages of nonconforming parts in a sample. Inspection of products from a production line is a good example for application of this chart. This fulfils all the properties of binomial distribution. The first step for developing a *p* chart is to calculate the proportion of nonconformity for each sample. If *n* and *m* represent the sample size and number of nonconforming items in the sample, then the fraction of nonconforming items *p* is given by:

$$p = \frac{m}{n}. \tag{14.21}$$

If we take g such samples, then the mean proportion nonconforming $\overline{p}$ is given by:

$$\overline{p} = \frac{p_1 + p_2 + ... + p_g}{g}. \tag{14.22}$$

The centerline and the 3σ limits of this chart are as follows:

$$CL = \overline{p}\ , \tag{14.23}$$

$$UCL = \overline{p} + 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n}}\ , \tag{14.24}$$

$$LCL = \overline{p} - 3\sqrt{\frac{\overline{p}(1-\overline{p})}{n}}\ . \tag{14.25}$$

In many situations we may require to develop p-charts with variable sample size. In such situations control charts can be developed either for individual samples or for a few representative sample sizes. A more practical approach is to develop a standardized chart. For this a standardized value z of p for each sample is calculated as follows:

$$z_i = \frac{p_i - \overline{p}}{\sqrt{\overline{p}(1-\overline{p})/n_i}}\ . \tag{14.26}$$

z_i is then plotted on the chart. This chart will have its centerline at zero and the control limits of 3 on either side. A number of rules are developed for decision making on the out-of-control situations. Different types of p-charts and the decision rules are discussed in more detail in [1] and [5]. A p chart has the capability to combine information from many departments, product lines, and work centers and provide an overall rate of product nonconformance.

14.4.2 The *np* chart

The *np* chart is similar to the *p* chart. It plots the number of nonconforming items per sample. Therefore it is easier to develop and use compared to the *p* chart. While the *p* chart tracks the proportion of nonconformities per sample, the *np* chart counts the number of defectives in a sample. The binomial distribution can be used to develop this chart. The mean number of nonconformities in a sample is *np*.

The centerline and the control limits for an *np*-chart are as follows:

$$CL = n\bar{p}, \tag{14.27}$$

$$UCL = n\bar{p} + 3\sqrt{n\bar{p}(1-\bar{p})}, \tag{14.28}$$

$$LCL = n\bar{p} - 3\sqrt{n\bar{p}(1-\bar{p})}. \tag{14.29}$$

np charts are not used when the sample size changes from sample to sample. This is because the centerline as well as the control limits are affected by the sample size. Using and making inferences in such cases are very difficult.

14.4.3 The *c* chart

The *c* chart monitors the total number of nonconformities (or defects) in samples of constant size taken from the process. Here, nonconformance must be distinguished from defective items since there can be several nonconformances on a single defective item. For example a casting may have many defects such as foreign material inclusion, blow holes, hairline cracks, *etc*. Other examples are the number of defects in a given length of cable, or in a given area of fabric. Poisson distribution is used to develop this chart. If the sample size does not change and the defects on the items are fairly easy to count, the *c* chart becomes an effective tool to monitor the quality of the production process.

If $\bar{c}$ is the average number of nonconformities per sample, then the centerline and the 3σ control limits of the *c* chart are:

$$CL = \bar{c}, \tag{14.30}$$

$$UCL = \bar{c} + 3\sqrt{\bar{c}}, \tag{14.31}$$

$$LCL = \bar{c} - 3\sqrt{\bar{c}}, \tag{14.32}$$

14.4.4 The *u* chart

One of the limitations of the *c* chart is that it can be used only when the sample size remains constant. The *u* chart can be used in other cases. It can be effectively used for constant as well as for variable sample size. The first step in creating a *u* chart is to calculate the number of defects per unit for each sample,

$$u_i = \frac{c_i}{n_i}, \tag{14.33}$$

where *u* represents the average defect per sample, *c* is the total number of defects, *n* is the sample size and *i* is the index for sample number. Once all the averages are determined, a distribution of the means is created and the next step will be to find the mean of the distribution, in other words, the grand mean.

$$\bar{u} = \frac{\sum_{i=1}^{g} c_i}{\sum_{i=1}^{g} n_i}, \tag{14.34}$$

where *g* is the number of samples. The control limits are determined based on $\bar{u}$ and the mean of the samples *n,*

$$UCL = \bar{u} + 3\sqrt{\bar{u}/n_i}, \tag{14.35}$$

$$LCL = \bar{u} - 3\sqrt{\bar{u}/n_i}. \tag{14.36}$$

Furthermore, for a *p* chart or an *np* chart the number of nonconformances cannot exceed the number of items on a sample, but for a *u* chart, it is conceivable since what is being addressed is not the number of defective items but the number of defects in the sample.

14.4.5 Control Chart for Demerits *per* Unit (*U* chart)

One of the deficiencies of the *c* and *u* charts is that all types of nonconformities are treated equally. In actual practice there are different types of nonconformities with varying degrees of severity. ANSI/ASQC Standard A3 classifies the nonconformities into four classes, *viz.*, very serious, serious, major, and minor, and proposes a

weighing system of 100, 50, 10, and 1, respectively. The total number of demerits (D) for a sample is therefore calculated as the weighed sum of nonconformities of all types as follows:

$$D = w_1 c_1 + w_2 c_2 + w_3 c_3 + w_4 c_4 \ . \qquad (14.37)$$

The demerits per sample (U) is defined as $U = D/n$ where n is the sample size. The center line of the control chart is given by:

$$CL = \overline{U} = w_1 \overline{u_1} + w_2 \overline{u_2} + w_3 \overline{u_3} + w_4 \overline{u_4} \ , \qquad (14.38)$$

where $\overline{u_i}$ represent the average number of nonconformities per unit in the i-th class. The control limits of the chart are:

$$UCL = \overline{U} + 3\sigma_U \ , \qquad (14.39)$$

$$LCL = \overline{U} - 3\sigma_U \ , \qquad (14.40)$$

where

$$\sigma_U = \sqrt{\left(w_1^2 \overline{u_1} + w_2^2 \overline{u_2} + w_3^2 \overline{u_3} + w_4^2 \overline{u_4}\right)/n} \ . \qquad (14.41)$$

For a detailed discussion on the U hart the reader is referred to [1].

As mentioned earlier, the success of using control charts for process control depends to a great extent on the observed data. Data must be independent of one another to ensure the random phenomenon. If this is not strictly ensured, the data will be autocorrelated and the inferences on process control based on the control charts will be misleading. In actual practice there is a chance of some level of autocorrelation of the data. Therefore, dealing with autocorrelated data has been a research problem in SPC. Many useful ideas have been developed and published on this topic.

A model for correlated quality variables with measurement error is presented in [46]. It is shown that the performance of multivariate control charting methods based on measured covariates is not directionally invariant to shifts in the mean vector of the underlying process variables, even though it may be directionally invariant when no measurement error exists. For further information on the directional invariance of multivariate control charts the reader is referred to [41, 47, 48], and [49].

The traditional control charts become unreliable when the data are autocorrelated [50]. In the literature the reverse moving average control chart is proposed as a new forecast-based monitoring scheme, compare the new control chart to traditional methods applied to various ARMA(1,1), AR(1), MA(1) processes, and make recommendations concerning the most appropriate control chart to use in a variety of situations when charting autocorrected processes [51].

Many new types of control charts have been proposed in the recent literature to handle different types of data. The proportional integral derivative (PID) chart for monitoring autocorrelated processes based on PID predictors and corresponding residuals is introduced in [52]. The PID charting parameter design, the mean shift pattern analysis, and the relationship between the average run length performance and PID parameter selection are also discussed extensively in the literature. Improved design schemes are suggested for different scenarios of autocorrelated processes and verified with Monte Carlo simulation. This study provides useful information for practitioners to effectively apply PID charts. See [53–56] for further discussions on autocorrelation of data in control charts.

The cumulative conformance count (CCC) chart was introduced as a Six Sigma tool to deal with controlling high-yield processes (see [57]). CCC chart was first introduced in [58] and became popular through [59]. It is primarily designed for processes with sequential inspection carried out automatically one at a time. A control scheme that is effective in detecting changes in nonconforming fractions for high yield processes with correlation within each inspection group is followed in [60]. A Markov model is used to analyze the characteristics of the proposed schemes in terms of which the average run length (ARL) and average time signal (ATS) are obtained. The performance of the proposed schemes in terms of ATS is presented along with the comparison with the traditional cumulative conformance count (CCC) chart. Moreover, the effects of correlation and group size are also investigated by the authors. The authors also have proposed a control scheme, the C^4-chart for monitoring high-yield high volume

production/process under group inspection with consideration of correlation within each group. Circumstances that lead to group inspection include a slower inspection rate than the production rate, economy of scale in group inspection, and strong correlation in the output characteristics.

Many applications and research opportunities available in the use of control charts for health-care related monitoring are reported in [61]. The advantage and disadvantage of the charting methods proposed in health care and public health areas are considered. Some additional contribution in the industrial statistical process control literature relevant to this area are given. Several useful references in the related areas are listed in this paper. This shows that the application of SPC for health care systems has become increasingly popular in recent times.

14.5 Engineering Process Control (EPC)

In recent times EPC has been used to control the continuous processes manufacturing discrete parts. It is also known as automatic process control (APC) in which an appropriate feedback or feedforward control is used to decide when and by how much the process should be adjusted to achieve the quality target. It is an integrated approach in which the concepts of design of experiments and robust design are also effectively used for designing control charts. EPC has been developed to provide an instantaneous response, counteracting changes in the balance of a process and to apply corrective action to bring the output close to the desired target. The approach is to forecast the output deviation from target that would occur if no control action were taken and then to act so as to cancel out this deviation [62].

14.6 Process Capability Analysis

Process capability represents the performance of a process when it is in a state of statistical control. It is measured as the total process variability when only common causes are present in the system. The process spread 6σ is generally taken as a measure of the process capability. 99.74% of all products will be within this spread if the normality assumption is valid. In many situations we are required to check if our existing process is capable of meeting certain product specifications. Such decisions are taken based on the process capability indices (PCI). The following PCI are generally used.

14.6.1 Process Capability Indices

This relates the process spread to the specification spread as follows:

$$C_p = \frac{USL - LSL}{6\sigma}. \qquad (14.42)$$

where *USL* and *LSL* are the upper and lower specification limits. From the above equation it can be seen that the process is capable when $C_p > 1$. However, C_p is not a good measure since it does not take care of the location of the center of the process. C_p represents only the process potential. Therefore other PCI such as upper capability index (*CPU*), lower capability index (*CPL*), C_{pk} and C_{pm} are also developed for such studies. They are defined as follows:

$$CPU = \frac{USL - \mu}{3\sigma}, \quad CPL = \frac{\mu - LSL}{3\sigma}, \quad \text{and}$$

$$C_{pk} = Min\{CPU, CPL\}. \qquad (14.43)$$

Since C_{pk} also takes into account the position of the centerline of the process (μ), it represents the actual process capability of the process with the present parameter values. Taguchi proposed and used another index, *viz.*, C_{pm} [63, 64]. The author emphasizes the need to reduce the process variability around a target value *T*. C_{pm} is defined as follows.

$$C_{pm} = \frac{USL - LSL}{6\tau}, \qquad (14.44)$$

where τ is the standard deviation from the target value and is calculated by

$$\tau^2 = E\left[(X - T)^2\right] . \quad (14.45)$$

Combining the merits of these indices, a more advanced index, C_{pmk}, is proposed that takes into account process variation, process centering, and the proximity to the target value, and has been shown to be a very useful index for manufacturing processes with two-sided specification limits. The behavior of C_{pmk} as a function of process mean and variation is discussed in [65]. If the variation of the process increases, the maximum value of C_{pmk} moves from near the target value to the midpoint of the specification. If the process mean varies inside the specification, C_{pmk} decreases as the variation increases. It is argued that these properties may constitute a sensible behavior of the process capability index. For an extensive study on process capability the reader is referred to [66–68].

In many situations we may require to compare several processes based on process capability. If there are two processes, the classical hypothesis testing theory can be applied as suggested in [69, 70]. A bootstrap method for similar studies is proposed in [71]. When there are more than two processes, the best subset selection method proposed in [72–76] can be effectively used. A solutions to this problem based on permutation testing methodology is proposed in [77]. In the case of two processes, the methodology is based on a simple permutation test of the null hypothesis that the two processes have equal capability. In the case of more than two processes, multiple-comparison techniques are used in conjunction with the proposed permutation test. The advantage of using the permutation methods is that the significance levels of the permutation tests are exact regardless of the distribution of the process data. The methodology is demonstrated using several examples, and the potential performance of the methods are investigated empirically.

Engineering Process Control: A Review

V.K. Butte and L.C. Tang

Department of Industrial & Systems Engineering
National University of Singapore
1, Engineering Drive 2, Singapore 117576

Abstract: The chapter provides an overview of engineering process control (EPC). The need for EPC and earlier misconceptions about process adjustments are discussed. A brief overview of time series is provided to model process disturbances. Optimal feedback controllers considering the various costs involved such as off-target costs, adjustment costs and sampling costs are discussed. Further, optimal control strategies in the case of short production runs and adjustment errors are also discussed. This is followed by an overview of run-to-run control in the semiconductor industry. First the most widely used single-EWMA controllers are detailed and then their weakness and the need for double EWMA controllers are discussed. Double-EWMA is detailed and its transient and steady state performances are also discussed. Further, the need for variable EWMA and initial intercept iteratively adjusted (IIIA) controllers are pointed out and elaborated on. The chapter then addresses some criticism of EPC and responses to it. Finally the integration of SPC and EPC for greater benefits is discussed.

15.1 Introduction

15.1.1 Process Control in Product and Process Industries

In product based industries the objective is to keep the quality characteristics as close as possible to the desired target. The exact conformance to the target value is not achievable since there are many factors affecting the manufacturing process and causing deviation from target. The objective is achieved by statistical process control (SPC), which involves the plotting and interpretation of control charts. The quality characteristics of the process such as the mean of a continuous process, nonconformities or percent nonconformities are monitored on a chart sampling of the process over time. A centerline and control limits are established using the process measurements. As long as the measurement falls within the control limits, no action is taken. Whenever the process measurement exceeds the control limits, a search for the assignable causes begins. SPC takes a binary view of the condition of a process; the process is either running satisfactorily or not. The purpose is to differentiate between inevitable random causes and assignable causes in the process. If random causes alone are at work, the process is continued. If assignable causes are present, the process is stopped to detect and eliminate them. SPC tools such as Shewhart

control charts, exponential weighted moving average (EWMA) charts and cumulative sum (CUSUM) charts are employed for this purpose.

EPC is used in process control of continuous production processes. EPC is a collection of techniques to manipulate the adjustable variables of the process to keep the output of the process as close to the target as possible. The aim of engineering process control is to provide an instantaneous response, counteracting changes in the balance of a process and to apply corrective action to bring the output close to the desired target. The approach is to forecast the output deviation from target, which would occur if no control action were taken and then to act so as to cancel out this deviation. The control is achieved in EPC by an appropriate feedback or feedforward control that indicates when and by how much the process should be adjusted to achieve the objective.

In this chapter we shall study EPC for product industries. The quality objective of the process is met by systematic application of the feedback process adjustment. The first step in feedback adjustment is to build a predictive model for the process determining how process output and input are related. This is an important task as it provides the basis for a good adjustment policy. Design of experiment (DOE) and response surface methedology are initially used offline to construct the process predictive model. In this chapter control variables are assumed to be available and responsive processes are considered, in which the dynamic behavior of the output is only due to disturbance dynamics and the control excercised comes into full effect immediately. In such descrete part manufacturing problems, the control factor will typically be the machine set point. The change in steady state output that will be obtained by unit change in input is called gain. The value of the gain is obtained offline after conducting designed experiments and regression techniques before proceeding to process adjustment. The literature available on process adjustment can be broadly classified according to the problems addressed:

- Feedback adjustment for machine tool problems
- Setup adjustment problems
- Run-to-run process control in application to the semiconductor industry

Machine tool problems address the processes that are affected by disturbances, the setup problems address processes that are offset during initial setting up, while run-to-run problems address the processes affected by process disturbance and are also offset.

15.1.2 The Need for Complementing EPC-SPC

Though SPC and EPC have been developed in different fields for respective objectives, they can be a good compliment to each other as both share the objective of reduction of variability. The following points highlight the need for process adjustment in the product manufacturing industry:

1. Practical production environments are nonstationary and the process is subject to occasional shifts. Though the causes of the shifts are known, it may be either impossible or uneconomical to remove them. A few examples are raw material variability, change of process behavior due to maintenance, variation in ambient temperature and humidity, *etc*. Such sources of variability are unavoidable and cannot be eliminated from process monitoring alone. Process adjustment can be applied to minimize process variability in such circumstances.
2. A process may undergo slow drift. The drift might be due to known causes such as build up of deposition inside a reactor, ageing of components, *etc.*, which cannot be precisely identified. SPC alone is not well suited to control a process with slow drift. With no interference in control process, the process must drift a certain distance before a control action is taken in response to an alarm. If the product's off-target cost is high or the adjustments are inexpensive, there is no need to wait for a long time to observe out of limit points and take control action.

3. In few processes the state of statistical control may be an ideal case and difficult to achieve or it is difficult to tell if the process is in statistical control. In these cases it is beneficial to have mild control with process adjustment.
4. Process adjustment alone is not suited to eliminate special causes that may affect the process. When special causes occur, such as a sudden change in environment conditions or mistakes in readings, *etc.*, process adjustment alone will not handle such situations. It will result in off-target bias and increase variability of output. Process monitoring may be utilized to detect assignable causes.

Hence the objective on quality requirement can be better realized by integrating SPC and EPC. This is especially true in these contemporary times where the hitherto border line between product and process based industries have faded. There are several industries where a combination of product and process manufacturing techniques are employed. The semiconductor manufacturing industry is one such industry. High quality products are required for technical and market reasons. Process monitoring coupled with process adjustment will form a better tool to achieve process control and high quality.

The control steps are as follows:

1. Detect the process performance from a stable process.
2. Identify the assignable cause of variation with the help of control charts and remove them.
3. If all the assignable causes cannot be removed economically, find a variable to adjust the process so as to maintain quality characteristics as close to the target as possible.

15.1.3 Early Arguments Against Process Adjustments and Contradictions

In the past statisticians and process engineers adhered to the notions of "do not interfere with the process that is in statistical control". They shunned the idea of process adjustment. Such a notion was also advocated by Deming through what is popularly known as Deming's funnel experiment [1]. The experiment was conducted by monitoring a funnel over a target bull's eye placed on a flat surface. The marbles were continuously dropped through a funnel and their position with respect to the target was measured. The aim was to keep the balls on target with minimum variance. The position of the funnel relative to target can be adjusted from drop to drop. Deming studied the effect of no adjustments to adjustments on the variance of the process. He found that the strategy of no adjustment produced minimum variance and the process remained on target. Deeper insights on the experiment can be obtained by understanding the assumptions made in the experiment, which were as follows:

1. The process producing deviation from target is in statistical control.
2. The process is initially on target.
3. It is possible to aim the funnel at the target.

The same experiment was further analyzed and useful information was obtained [2]. The process on target and statistical control should not be adjusted. However, if the uncontrolled process exhibits autocorrelation the feedback control rules would prove beneficial. For a nonstationary process the mean itself is moving, if left uncontrolled the mean will move away from the target, hence feedback control is needed. This case is analogous to the moving bull's eye in the funnel experiment, keeping the funnel fixed is not the best alternative.

The process variance would double if we apply full adjustment equal to deviation on a process that is in statistical control. Policy of adjustment would be better if the process is slightly nonstationary. Introduction of mild control would greatly reduce the variance of output. Implementing mild control on process under statistical control would increase the variance slightly [3].

EPC uses the feedback controller for process control; deviations from the target are usually autocorrelated and this information is used to forecast the future deviation from target. The time

series model is fitted to the autocorrelated output and model is identified and then the model parameters are estimated. This model is used to get the minimum mean square error forecast of future disturbance and the controller is set in such a way that the deviation from the target is cancelled out. However, an efficient process adjustment strategy has to take into account the economical aspects of process adjustment. In the following sections, we shall review the above mentioned steps.

15.2 Notation

The notation with terms used in this chapter is given below.

T : Process target
y_t : Process quality characteristics at period t
z_t : Deviation of quality characteristic from target T
x_t : Control variable (input)
G : Damping factor
a_t : White noise $N(0,\sigma_a^2)$
ϕ : Autoregressive parameter
θ : Moving average parameter
λ : Discount factor
(V_m) : Variance of values m steps apart
β : Process gain.
m: Sampling interval
C_T : Cost of being off- target by an amount σ_a
C_M : Fixed cost incurred each time the process is observed
C_A : Fixed cost incurred each time the process is adjusted
AAI: Average interval between adjustments-measured in terms of unit interval
MSD: Mean squared deviation
ISD: Increase in standard deviation
L : Bound length
σ_e^2 : Variance of scheme
η_t : Process disturbance
α : Intercept or offset of the process.
p_t : Estimate of intercept
b: Estimate of gain
w : Discount factor
δ : Deterministic drift rate
w_1 : Discount factor to estimate mean
w_2 : Discount factor to estimate trend
ξ : Gain estimate bias

15.3 Stochastic Models

The important need for process adjustment is to model the stochastic disturbances accurately. It is necessary to understand the behavior of disturbances and their effect on the quality characteristics of interest. The most valuable contributions to model dynamic behavior of process are due to from Box and Jenkins [4–7]. In their contributions stochastic time series modeling was adopted. The disturbances were envisaged as the result of a sequence of independent random shocks entering the system.

15.3.1 Time Series Modeling for Process Disturbances

Stochastic disturbances are most conveniently modeled as a time series. We shall briefly revise time series analysis; an in-depth analysis can be obtained from references [4–13].

The simplest time series is a sequence of values of $a_t, a_{t-1} \ldots a_1$, which are normally independently distributed with mean zero and standard deviation σ_a. Such a series is called white noise. Let us define disturbance as $z_t = y_t - T$, where y_t is the quality characteristics to be maintained on target *T*. The time series model is an equation that relates the sequence of disturbance values z_t to white noise a_t.

Time series models are broadly classified into two classes (see Figure 15.1):

1. Stationary time series models
2. Nonstationary time series models

Stationary time series are the time series that oscillate around a fixed mean while nonstationary time series do not stay around a fixed mean but gradually move away from the mean.

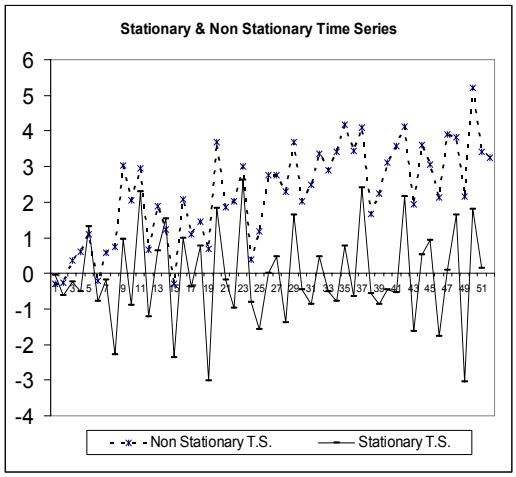

Figure 15.1. Stationary and nonstationary time series

Stationary Time Series Models

Stationary time series models assume that the process is in equilibrium and oscillates about a constant mean. The three stationary models are autoregressive models, moving average models and autoregressive moving average models.

In autoregressive AR(p) models the current value of the process is expressed as function of p previous values of the process. The AR(p) model is represented as

$$\begin{aligned} &\phi(B)z_t = a_t \\ &where \\ &\phi(B) = 1 - \phi_1 B - \phi_2 B^2 ... \phi_p B^p \\ &B^m z_t = z_{t-m} \end{aligned} \tag{15.1}$$

In moving average MA(q) models z_t is a linear function of finite number (q) of previous a_t's. The MA(q) model is represented as

$$\begin{aligned} &z_t = \theta(B)a_t \\ &\theta(B) = 1 - \theta_1 B - \theta_2 B^2 ... \theta_q B^q \end{aligned} \tag{15.2}$$

In autoregressive moving average ARMA(p, q) models include both AR and MA terms in the model. It is represented as

$$\phi(B)z_t = \theta(B)a_t \tag{15.3}$$

Nonstationary Time Series Models

Many series come across in practice in various fields exhibit nonstationarity, *i.e.*, they do not oscillate around a fixed mean but drift. Stock prices, bacterial growth, and process disturbance are few of such series. So most commonly assumed disturbances are of the nonstationary time series family, where once the time series makes the excursion from the mean it does not return unless control action is taken.

Autoregressive integrated moving average ARIMA(p, d, q) models are nonstationary time series models and are of great help in representing nonstationary time series. ARIMA has AR, MA and an integrating operator.

It is represented as

$$\begin{aligned} &\phi(B)\nabla^d z_t = \theta(B)a_t \\ &\nabla = 1 - B \\ &\varphi(B)z_t = \theta(B)a_t \\ &\varphi(B) = \phi(B)\nabla^d \end{aligned} \tag{15.4}$$

ARIMA can be regarded as a device transforming the highly dependent and possibly nonstationary process z_t to a sequence white noise a_t.

15.3.2 Stochastic Model Building

Box and Jenkins proposed three-stage iterative procedures to build model to data. The three steps are identification, estimation, and diagnostic checking of model

1. Use the data efficiently to *identify* the promising subclass of parsimonious models.
2. Use the data effectively to *estimate* the parameters of the identified model
3. Carry out a *diagnostic check* on the fitted model and its relation with the data to find the model inadequacies and analyze the need for model improvement.

Model Identification

The task at the model identification is to estimate parameters p d q. It is most convenient to estimate model parameters based on autocorrelation

functions and partial autocorrelation function graphs.

The first step is to check for the time series stationarity. If the time series is not stationary, reduce it to a stationary time series by differencing to appropriate degree. The stationarity of the time series can be inferred by looking at the time series plot. However, a statistical way may also be adopted. If the estimated autocorrelation function of the time series does not die out rapidly, this suggests that the underlying stochastic process is nonstationary. If the time series is found to be nonstationary the differencing is done *d* times until the estimated autocorrelation of differenced series dies out quickly. The reduced time series is of the form

$$\varphi(B)z_t = \theta(B)a_t \,.$$

The next step is to identify the resultant stationary ARMA process. The various subclasses of the time series model have the following autocorrelation and partial autocorrelation properties:

- For an AR(*p*) process,

The autocorrelation function of an AR(*p*) process tails off and the partial autocorrelation function of an AR(*p*) process cuts off after lag *p*.

- For an MA(*q*) process,

The autocorrelation function of an MA(*q*) process cuts off after lag *q,* and the partial autocorrelation function of an MA (*p*) process tails off.

- For an ARMA(*p q*) process,

both the autocorrelation function and the partial autocorrelation function tail off.

As can be noted, AR(*p*) parameter *p* and MA*(q)* parameters *q* are easier to identify than ARMA(*p q*) parameters *p* and *q*. In practice the ARMA model is fixed after trying with the pure AR and MA processes. Most time series encountered in practice have parameters *p, d, q* less than or equal to 2.

Model Parameter Estimation

The parameters of the identified model are to be estimated. If the estimation is carried out using an historical data set it is called offline estimation. The parameters are estimated by maximum likelihood estimates.

Diagnostic Checking

If the model fitted is appropriate, the residuals should not have any information concealed in them. If the autocorrelation is completely captured, the residuals should be white noise. In diagnostic checking the autocorrelation function of residuals is checked. The Ljung–Box–Pierce statistic is used to test the null hypothesis of no autocorrelation for any lag. If the residuals show significant autocorrelation then the model must be refit and all the three steps should be repeated until a satisfactory model is fit.

15.3.3 ARIMA (0 1 1): Integrated Moving Average

IMA (0 1 1) is a special class of the ARIMA(*p d q*) model. It is capable of representing a wide range of time series encountered in practice, such as, stock prices and chemical process characteristics (temperature, viscosity, concentration). It is also most suitable for modeling disturbances occurring in a process. With the AR parameter 0 and I and MA parameters 1 each, the ARIMA becomes

$$\nabla z_t = a_t - \theta a_{t-1} \tag{15.5}$$

The model has two parameters θ and σ_a^2. It may be convenient to represent IMA (0 1 1) in following forms:

$$\begin{aligned} \nabla z_t &= (1-\theta B)a_t \\ z_t &= z_{t-1} + a_t - \theta a_{t-1} \\ z_t &= \text{constant} + a_t + \lambda \sum_{i=1}^{t-1} a_i \end{aligned} \tag{15.6}$$

Intuitively z_t is a mixture of current random shocks and sum of previous shocks

The obtained model is used to forecast the disturbances and characterize the transfer function of the dynamic process. It is easy to show that EWMA provides the minimum mean square error forecast for IMA (0 1 1). They are used in feedback control in engineering process control.

Justification for IMA (0 1 1) Model

The nonstationary time series model IMA (0 1 1) is most commonly used to model industrial disturbances. As can be noted, most of the literature assumes that the disturbances are IMA (0 1 1). Here we shall justify the use of IMA (0 1 1) disturbance assumptions in deriving control actions to be used in practical cases.

A good way to explain the nonstationary model and to justify its adoption is by a variogram. The variogram tells us how much bigger the variance is for values *m* steps apart (V_m) than for values one step apart (V_1). The plot of (V_m / V_1) against *m* is called a variogram [14]. For a white noise the (V_m / V_1) ratio is equal to unity for any value of *m* as data are uncorrelated. For a stationary series the ratio (V_m / V_1) increases rapidly initially and then flattens out. This implies that the variance for initial *m* values differs but for further values, the ratio reaches a steady value. This is practically not justifiable because once the process goes out of control the variance keeps on increasing. For example, if a crack appears on a shaft the crack goes on increasing until the shaft breaks down. For nonstationary models the (V_m / V_1) ratio keeps on increasing as *m* increases and this represents a more practical case [15]. Stationarity implies that once a process goes out of control, it just wanders about the mean value. A nonstationary model implies that once the process goes out of control, it keeps on drifting away from the mean unless a control action is taken.

Study on ARMA and IMA models for a discrete adjustment scheme has shown that a) the IMA model leads to a much easier analysis, b) almost exactly the same average adjustment interval (AAI) and mean square deviation (MSD) are obtained under both disturbance models in the region of interest of the action limits, c) for wider action limits the ARMA disturbances overestimate the AAI and MSD with respect to the results provided by IMA disturbances, and d) the IMA model is robust against model misspecification but the ARMA is not [16]. Hence the IMA (0, 1, 1) model is adopted to represent the process disturbance.

15.4 Optimal Feedback Controllers

The objective of EPC is to minimize the variance of quality characteristics around the target. It is assumed that a control variable that can be adjusted to compensate for the disturbances is available. In this chapter no process dynamics is considered. The effect of a change in control variables is observed fully in the next period on quality characteristics. Such responsive systems are common in discrete parts manufacturing. The expected deviation from the target for the next period is forecasted at the end of every period and the control variable is set so as to cancel out the deviation. Similar to any intuitive controllers, the adjustment is made proportional to the deviation. A typical adjustment equation may be represented as

$$\beta x_t = \hat{z}_{t+1} \tag{15.7}$$

β is called the process gain. It is similar to the regression coefficient showing the relative effect of change in input on output. The value of β may be determined from classical design of experiments and response surface methodology [17]. In the machine tool setting gain is usually assumed to be unity.

$\hat{z}_{t+1}$ is the minimum mean square error forecast of next deviation from target. The controller is known as the minimum mean square error controller.

Example 1

Consider the hypothetical industrial process shown in Figure 15.2 (Table 15.3), whose quality characteristics have to be maintained on target = 0. The process is affected by disturbances from various sources and the quality characteristics drift away from the target. The graph shown in figure depicts the process. We shall demonstrate EPC methodologies in industrial scenarios through the data set in this chapter.

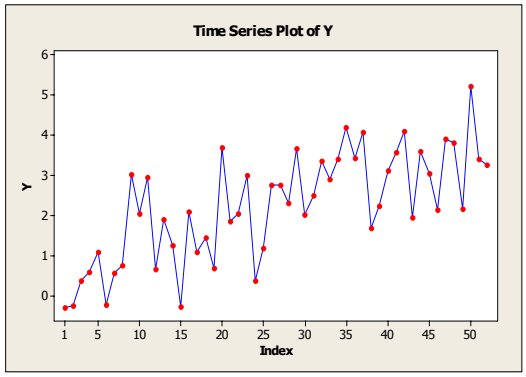

Figure 15.2. Uncontrolled process

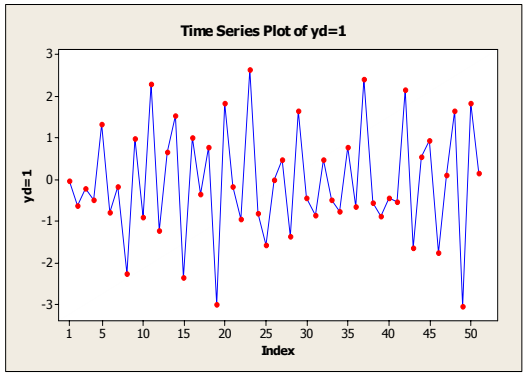

Figure 15.3. Differenced time series

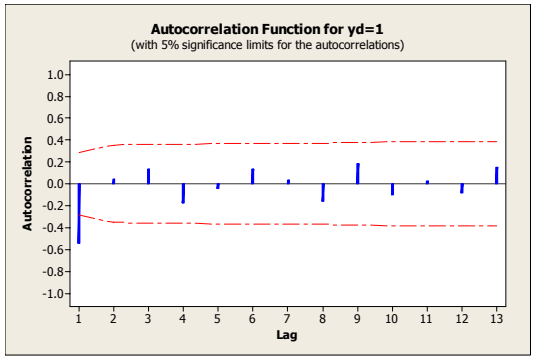

Figure 15.4. Autocorrelation function (5% significance limits)

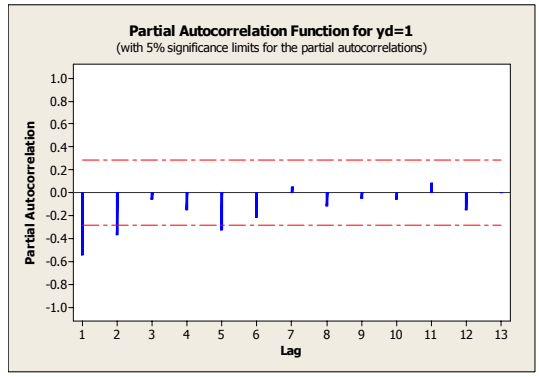

Figure 15.5. Partial autocorrelation function (5% significance limits)

Model Identification

The first step is to identify and estimate the time series model for the process disturbances.

From the graph in Figure 15.2 it can be seen that the process is nonstationary, as the process drifts away from target. The first differencing operation is carried out on the data. The graph of the differenced series shows that the series is reduced to a stationary time series (Figure 15.3). To identify the time series model further, the autocorrelation and partial autocorrelation graphs are plotted as shown in Figures 15.4 and 15.5. The following observations are made

1. The autocorrelation function cuts off after lag 1.
2. The partial autocorrelation function tails off.

These are the characteristics of the MA (q) model and the order of the MA series is 1 ($q = 1$).
The parameter of this MA(1) series is $\theta = 0.75$.

Minimum Mean Squares Error Control

In minimum mean squares error control (MMSE), at the end of each period the next period disturbance (deviation from target) is forecasted and the control is applied against the forecasted disturbance. Figure 15.6 shows the MMSE controlled process. The deviations from the target in an MMSE controlled process are forecast errors.

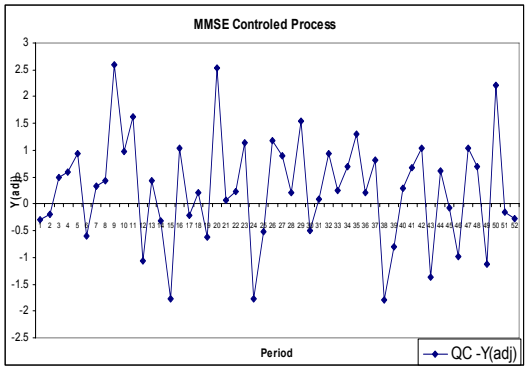

Figure 15.6. MMSE controlled process

Robustness Against Suboptimal Model Parameter Estimation

Most industrial disturbances follow IMA (0 1 1). The optimal value of smoothing constant, which produces minimum mean square error at the output is $G = \lambda = 1 - \theta$.

In industrial settings estimates from the available data set may not be accurate due to a lack of data set. Minimum mean square error control is robust against the use of inaccuracy of the damping factor [18]. The sum of the square curve tends to be flat in the neighborhood of the theoretical minimum. So a moderate departure from the theoretical optimal damping factor would produce a relatively lower increase in the mean square error. The control applied using these estimates will produce an output variance very close to the theoretical minimum.

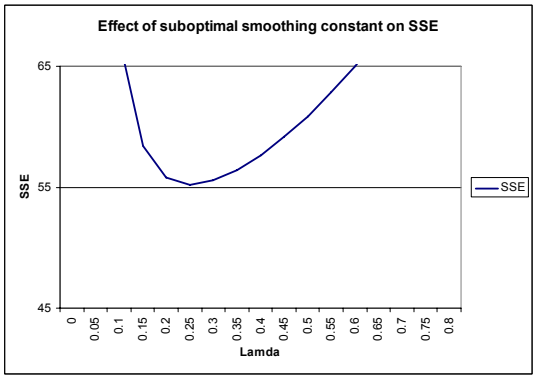

Figure 15.7. MMSE robustness against a suboptimal smoothing constant

The graph in Figure 15.7 illustrates the sum of squared errors (SSE) forecast for the assumed process data; it should be noted that the minimum is not a sharp point but a smooth flat curve near the optimal value of $\lambda = 0.25$. Even if we would have chosen any value in the most general interval of industrial disturbance $\lambda \sim [0.2, 0.4]$ the increase in SSE from the minimum possible SSE would have been just 4.47%.

Further the robustness is well explained as follows [3]. Consider an IMA (0 1 1) disturbance model with the true value of smoothing constant θ_T . Let the value of G used in the control scheme be a suboptimal value different from $\lambda_T = 1 - \theta_T$. The variance of the control scheme is inflated by the following factor

$$\frac{\sigma_e^2}{\sigma_a^2} = 1 + \frac{(G - \lambda_T)^2}{G(2 - G)} \tag{15.8}$$

The equation depicts the inflation in the process variance as a consequence of using a suboptimal smoothing constant. Two important points can be noted from the analysis:

1. If the process in the state of statistical control $\lambda_T = 0$ is adjusted equal to the deviation G = 1. The variance of the process is inflated by a factor of 2. This point is a reaffirmation of Deming's funnel experiment. The process already in a state of statistical control should not be tampered with.
2. If the process is slightly nonstationary $\lambda_T > 0$ the use of mild control (*G = 02~0.4)* greatly reduces the process variance when compared with the no control strategy. In fact, several times in practice a state of statistical control is difficult to maintain. Manufacturing environments are not static and the quality engineer cannot be sure if the process is under a state of statistical control. In these cases process adjustment is a better strategy.

15.4.1 Economic Aspects of EPC

The aim of EPC is to adjust the process to keep the quality characteristics on target. In practice, there

are various costs incurred. These costs have to be taken into account to make a rational decision. The major cost parameters involved in engineering process control are as follows

Off-target Costs

Off-target costs are costs incurred when quality characteristics deviate from the target. These costs are proportional to the deviation from the target; they are linear functions. Off-target costs are usually assumed to be quadratic. The cost function is symmetric. The costs of deviation above and below target by same amount are the same. However, it is not rare to come across cases where the loss function is not symmetric about the target.

Adjustment Costs

Adjusting a process may incur significant costs in real-life processes. The adjustments may require the process to be stopped and some costly manipulations to be made. This consumes monitory resources as well as valuable time. Frequent adjustments are hence not encouraged. It may be noted that adjustment is also shunned because it may induce additional variability in the process. The adjustment costs in EPC are assumed to be fixed and independent of the magnitude of adjustment.

Sampling Costs

Sampling costs are those costs incurred in obtaining the final numerical value of the quality characteristics. They include the costs incurred in sampling the process and making physical and chemical analyses to obtain accurate readings from high precision measurements. When the sampling costs are significant it may be desirable to reduce the sampling rate.

These costs are highly situation and case dependent. While producing a costly product the off-target costs may dominate the adjustment and sampling costs. In some processes the sampling costs may be high, while in others the required output data may be easily available from digital display. Similarly, some process adjustment costs may be high, requiring the process to be stopped or some costly repairs to be done, while in others the adjustment may only involve turning a knob, making the adjustment costs insignificant. The rational decision, whether to adjust the process and how often to sample the process should be based on the off-target costs, adjustment costs, and sampling costs.

15.4.2 Bounded Feedback Adjustment

If there are no adjustment costs and sampling costs, and the adjustment is accurate, it is advisable to adjust the process at every period. In such cases, the minimum variance controllers will be appropriate and effective in keeping the process on target. In several practical cases it is undesirable to adjust and sample the process often due to the respective costs. A controller operating on the sole objective of minimizing the variability of quality characteristics around the target while neglecting other costs may not be of significant practical value.

To accommodate cost parameters into feedback adjustment, bounded feedback adjustment is proposed. In bounded feedback adjustment a deadband is placed around the target. The process is adjusted only if the forecasted deviation from the target exceeds the bound length. This bound length is a function of off-target costs, adjustment costs, and sampling costs.

Example 2

The bounded feedback control is applied to the process (Figure 15.8). Let the bound length of 1

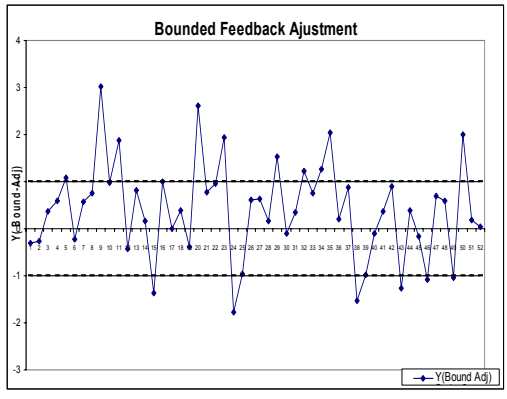

Figure 15.8. Bounded feedback adjusted process

Table 15.1. Comparison of **r**esults

		MSD about Target	No. of adjust-ments	Out-put std dev
Feed-back Adjust-ed	Un-bounded	1.06	51	1
	Bounded $L = 1$	1.86	3	1.02
Unadjusted		6.8		1.8

unit be placed around the target. The process is not adjusted if the forecasted deviation from the target falls within this deadband. If forecasted deviation from the target falls beyond the deadband, the process is stopped and the control is applied to nullify the forecasted deviation from the process. The process is carried out further in the same way.

Table 15.1 gives the relative comparison on performance of the bounded and unbounded feedback control.

It can be seen that though mean squared deviation (MSD) about the target for bounded adjusted process has increased, the number of adjustment has decreased in greater proportion.

Decision on Deadband Limits

Under the assumption of the responsive adjustment system the uncontrolled disturbance is adequately modeled by the IMA (0 1 1) model with parameters λ and σ_a. The average adjustment interval (AAI) and increase in standard deviation (ISD) considering quadratic off-target cost, fixed adjustment costs, and fixed sampling costs for various values of λ and σ_a are determined as follows [19, 20]:

The following assumptions are made regarding the process:

1. Process disturbance is adequately modeled by IMA (*0 1 1*)
2. Quadratic off-target costs
3. Fixed adjustment costs
4. Fixed sampling costs
5. Infinite production length

A process that was initially sampled at unit intervals, considering the possibility of sampling at interval *m* units apart where *m* is an integer, the sampled process is still an IMA (0, 1, 1) time series but with parameters λ_m and σ_m [9].

Here,

$\lambda^2{}_m\sigma^2{}_m = m\lambda^2\sigma^2{}_a$ and $\theta\ {}_m\sigma^2{}_m = \theta\ \ \sigma^2{}_a$

The overall expected cost *C* per unit interval is

$$C = \frac{C_A}{AAI} + \frac{C_M}{m} + \frac{C_T(MSD)}{\sigma_a{}^2} \tag{15.9}$$

where

C_T: cost of being off target by an amount σ_a

C_M: observed fixed cost incurred each time process is sampled

C_A: Fixed cost incurred each time process is adjusted

AAI: Average interval between adjustments measured in terms of unit interval

MSD: Mean squared deviation

MSD is defined by

$$MSD = \frac{1}{AAI} E\left[\sum_{J=0}^{n-1}\sum_{K=1}^{m} \varepsilon_{mj+k}{}^2\right] \tag{15.10}$$

Finally the overall cost function arrived at is

$$C = \frac{C_A}{mh[L/(\lambda_m\sigma_m)]} + \frac{C_M}{m} + C_T\left\{\frac{\theta}{\theta_m} + m\lambda^2 g[L/(\lambda_m\sigma_m)] - \frac{(m-1)\lambda^2}{2}\right\} \tag{15.11}$$

where *h(.)* and *g(.)* are both solely functions of $L/(\lambda_m\sigma_m)$ that relate *AAI* and *MSD*. These functions are exactly characterized by integral equations. These equations can be approximated by the following functions, which have been checked by extensive simulations [21]:

$$h(B) = (1 + 1.1B + B^2) \times \{1 - 0.115 \exp[-9.2(B^{.3} - .88)^2]\} \quad (15.12)$$

and

$$g(B) = \frac{1 + .06B^2}{1 - .647\Phi\{1.35[\ln(B) - .67]\}} - 1 \quad (15.13)$$

Where $\Phi(.)$ is the standard normal *cdf*. The optimal bound length is obtained by minimizing the above overall cost C with respect to bound length L.

15.4.3 Bounded Feedback Adjustment Short Production Runs

The current market life of several products is short. Products become outdated with the entry of better quality products at reasonable costs. In such cases, it is not reasonable to assume infinite production length. The rapid development of technology, product innovation, use of just-in-time manufacturing, *etc*., have made production run lengths short. To control such processes, applying the bound lengths obtained based on infinite production run length may prove to be suboptimal. There is a need to solve this under finite production length assumption. It is shown that the length of production significantly influences adjustment strategy. The use of control limits based on the assumption of an infinite run process can significantly inflate the expected costs. The short run limits were computed using dynamic programming and an algorithm was developed. It has been shown that the optimal deadband limits funnel out as the end of production run approaches. It is less attractive to adjust if the end of run is close [22]. Owing to the lack of data available on the short production run model, the parameters are estimated adaptively and recursively.

The same cost function [22] was further studied with inclusion of adjustment errors [23]. The effects of adjustment costs, adjustment variance, and drift rate on the obtained optimal policy have been studied. The following two important results were given in the study. Firstly, in the case of nonzero adjustment error there will be a deadband in the optimal policy even when there is no fixed adjustment cost. It is advantageous not to make adjustments if the adjustment is imprecise even if there is no fixed adjustment cost. Secondly, for relatively small nonzero deterministic drifts the optimal policy calls for a certain amount of over compensation with each ordered process adjustment to anticipate drift that will occur in future time periods.

15.5 Setup Adjustment Problem

In manufacturing process it is crucial to accurately set up the machine at the beginning of production run. An incorrect setup can result in sever consequences on the part produced in the run. The effect of set-up error is to induce a mean shift in the output. It is necessary to adjust and correct the process that has set-up error induced at the beginning of the run.

Consider a process where a machine is set up before the production run and this set-up is subject to set-up errors. The so induced set-up error will induce step deviation in the output quality characteristics (y_t) and deviates it from the desired target T. The objective is to adjust the process to eliminate the offset induced in output. Suppose that a control variable x is available that has a direct effect on the output and control exercised comes into effect immediately without delay. In set-up adjustment the objective is to bring the process on target quickly by estimating the offset accurately. The magnitude of offset is estimated from the observed data. The observations are subject to inherent process variation and measurement errors. The accuracy of the offset estimate can be improved with increase in the available observation. Waiting for a long time to collect data, conflicts with the objective of bringing the process on target as soon as possible. An optimal strategy for this situation is to sequentially estimate the offset and adjust the process accordingly. Grubbs proposed an elegant sequential adjustment rule to solve the set-up error adjustment problem;

this is popularly known as Grubb's harmonic rule [24]. The proposed adjustment strategy is to adjust the process according to following equation,

$$x_{t+1} - x_t = \frac{-(y_t - T)}{t} \qquad t = 1, 2, 3, \ldots$$

The expected value of the process quality characteristics of every next period will have the mean as target value and the variance is minimum around the target.

The adjustment rule implies that, after producing the first part, the machine is adjusted against the full observed deviation. After the second part is produced, the machine is adjusted against half the observed deviation and so on. The adjustment follows a harmonic series $\left[1, \frac{1}{2}, \frac{1}{3}, \ldots\right]$, thus called as Grubb's harmonic rule.

The following assumptions were made:

1. The process is stable with no autocorrelation or drift in the mean.
2. Adjustments modify the process mean
3. Adjustments are exact and implemented on every part.

Sullo and Vandevan [25] studied optimal adjustment strategies for a process with run-to-run variation and 0-1 quality loss function for a short run manufacturing process. They considered a set-up error induced at the beginning of each run and remaining fixed through the run. They developed a single adjustment strategy based on taking a sample of fixed size from the process. The strategy depends on the actual process parameters such as adjustment error, run size, and adjustment and sampling costs. They specified both the time and magnitude of adjustment for 0-1 quality loss function and a short run manufacturing environment.

Pan and Del Castillo [26] studied the set-up adjustment problem and presented scheduling methods to determine the optimal time instants for adjusting a process. They compared the three scheduling methods in terms of the expected manufacturing cost and computational effort of each method. The adjustment methods were based on estimates of process variance and size of the offset. The robustness of these methods with respect to biased estimates of process variance and of the set-up error was discussed. They recommended the silver-meal heuristic used in inventory control based on performance analysis.

15.6 Run-to-run Process Control

Run-to-run control is also a discrete form of feedback control in which control action is exercised between runs or batches to minimize deviation from target and process variability. It is mostly referred to in the context of semiconductor manufacturing. Run-to-run control has some characteristic differences from the machine tool control problem discussed in the preceding sections. Reviews on run-to-run control can be found in [27, 28].

The main difference between machine tool problems and the run-to-run (R2R) control problem lies in adjustment costs. In the machine tool problem the adjustment costs are assumed to be significant and adjustments are performed manually. In R2R problems the adjustment costs are insignificant because adjustment may involve simply turning a knob. Machine tool problems often assume long production runs. The parameters of disturbance are assumed to be determined to a satisfactory degree of accuracy offline. In R2R problems production runs are short. There is no luxury of large historical data set to accurately estimate the model parameters. The parameters are roughly estimated offline with a limited data set and are updated online. The differences between the R2R and machine tool problems are summarized in Table 15.2. The differences are not a strict demarcation between the two but a rough classification is provided.

R2R control has found several successful applications in semiconductor manufacturing, such as photolithography, reactive ion etching and chemical mechanical polishing.

Table 15.2. Machine tool and R2R problem comparison

	Machine tool problem	Run-to-run problem
1	Adjustment costs are significant	Adjustment costs are not significant
2	Production length is large	Production length is small
3	Trend in the process is assumed to be stochastic	Trend in the process is assumed to be deterministic

15.6.1 EWMA Controllers

Single EWMA controllers are the most widely used controllers in the semiconductor manufacturing industry. These controllers are simple and yet highly effective in keeping the process on target and reducing variability. The procedure of adjusting the process by using EWMA controllers is as follows [29].

Consider a process that is offset and interfered with by process disturbance. Let the process be described by following equation:

$$y_t = \alpha + \beta x_{t-1} + \eta_t \tag{15.14}$$

where

y_t: Value of process quality characteristics (output) for batch number *t*

x_{t-1}: Control variable (input) chosen at the end of the run

η_t: Process disturbance

α: Intercept or offset of the process

β: Slope or gain.

α and β are assumed to be constant over time. They are unknown and are to be estimated from available data.

Process gain is similar to a regression coefficient depicting the amount of change in output for the corresponding change in input. Process gain is estimated through design of experiments, regression analysis and response surface methodology [17].

Let p_0 and b denote initial estimates of α and β. p_0 and b are typically chosen to be least square estimates of α and β based on historical data. Like in any other controller, in run-to-run control the control variable is set to nullify the deviation from target. Thus,

$$x_0 = \frac{T - p_0}{b} \tag{15.15}$$

where T is the desired target value of output.

In the proposed EWMA controller, the unknown parameter α (intercept or offset) is recursively estimated and updated and the input variable is determined at the end of each run. The equation for estimation is as follows:

$$p_t = w(y_t - bx_{t-1}) + (1-w)p_{t-1} \tag{15.16}$$

where $0 \le w \le 1$ is called the discount factor.

The estimated intercept is substituted into the following equation to determine the value of control variable:

$$x_t = \frac{T - p_t}{b}$$

As it can be noted, the key idea in the EWMA controller is that for a predetermined process gain, the intercept and input variables are updated recursively. The expected value will then asymptotically converge to the desired target.

If the process disturbances follow the nonstationary IMA (0 1 1) model

$$\eta_t = \eta_{t-1} + a_t - \theta_1 a_{t-1}$$
$$a_t \sim N(0, \sigma_a^2) \quad t = 1, 2, \ldots$$

and the gain estimate bias be represented as $\xi = \frac{\beta}{b}$ under the condition that $0 < \frac{\beta}{b} < 2$, *i.e.*, the gain estimation is biased not more than twice the original value, the optimal discount factor is given by

$$w_0 = \frac{b(1-\theta_1)}{\beta}$$

However, an inaccurate estimation of unknown parameters α and β leads to a large value of the initial bias

$$\frac{\alpha + \beta(T - p_0)}{b}$$

and it will take several runs for the EWMA controller to bring the process back to target.

Example 3

Consider the process given in Table 15.3. In addition to being interfered with by IMA (0,1 1) process disturbance let the process be offset $\alpha = 2$. Suppose that the gain estimate is determined and found to be unity $\beta = 1$. The objective is to bring the process on target by process adjustment. A single-EWMA controller with $w = 0.25$ is employed to control the process and keep it near target. The control is started with the initial estimate of offset $p_0 = 0$ and is recursively updated in subsequent steps. Figure 15.9 shows the uncontrolled and single EWMA controlled process.

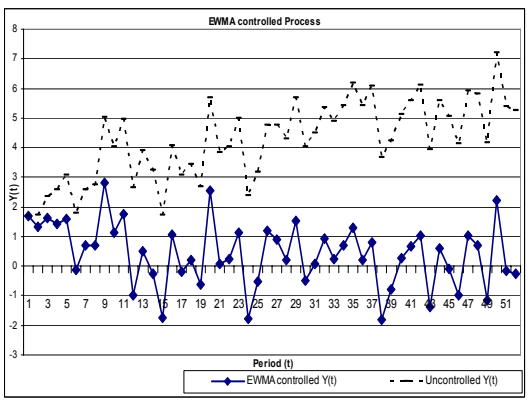

Figure 15.9. Uncontrolled and EWMA controlled process

15.6.2 Double EWMA Controllers

The manufacturing process may experience deterministic drifts with time and trend away from the target. Such a phenomenon may be due to ageing machines or deterioration of ideal manufacturing conditions with time. The goal of feedback control is to adjust control variables so that the output will be as close to the target as possible. Use of single-EWMA in this case would not be optimal because it cannot compensate for a deterministic trend. Hence, such processes are not efficiently controlled using single-EWMA controllers.

Consider a process that is offset and interfered with by process disturbance and is drifting with runs. Let the process be described by the following equation:

$$y_t = \alpha + \beta x_{t-1} + \delta t + \eta_t \qquad (15.17)$$

as defined earlier $y_t, \alpha, \beta, \eta_t, x_{t-1}$ denote output, intercept, slope, process disturbance and the input recipe determined at the end of *(t-1)*th run, respectively. δ denotes the deterministic drift rate. The following double-EWMA controllers are applied for such linear drifting manufacturing processes [30]:

$$x_t = \frac{T - p_t - D_t}{b} \qquad (15.18)$$

$$p_t = w_1(y_t - bx_{t-1}) + (1 - w_1)p_{t-1} \qquad 0<w_1 \le 1$$
$$D_t = w_2(y_t - bx_{t-1} - p_{t-1}) + (1 - w_2)p_{t-1} \qquad 0<w_2 \le 1$$

(15.19)

A double-EWMA controller consists of a filter to estimate the true output mean as well as a filter to estimate the trend. The forecast is equal to the smoothed value plus the smoothed trend.

It may also be represented in following way:

Current smoothed value =

$(1-\alpha)$data at time t+(α)best previous estimate

Current smoothed trend= (1-β)Estimated trend value at time t

+ (β)previous trend estimate

Forecast=Current smoothed value+Current smoothed trend

Example 4

Consider the process given in Table 15.3. In addition to being interfered with by IMA (0,1,1) process disturbance, let the process be offset by $\alpha = 3$ and also be experiencing a deterministic trend of $\delta = 0.5$ per period, Suppose that the gain estimate is determined and found to be unity $\beta = 1$. The objective is to bring the process on target by process adjustment. First, a single-EWMA controller with $w = 0.25$ is employed to control the process and keep it near target. The control is started with an initial estimate of offset $p_0 = 0$ and is recursively updated in subsequent steps. It can be observed in Figure 15.10 that single-EWMA control leaves the process with considerable offset. This is because unlike double-EWMA controllers, single-EWMA is not equipped to control processes with high deterministic drift. A double-EWMA controller with $w_1 = 0.25$ and $w_2 = 0.05$ is employed to control the process. The control is started with the initial estimate of $p_0 = 0$ and $D_t = 0$. They are recursively updated in subsequent steps. The graph in Figure 15.10 shows the single-EWMA controlled and double-EWMA controlled process.

Weights in the double-EWMA controller are selected considering transient and long term stability conditions [31, 32]. The process given by $y_t = \alpha + \beta x_{t-1} + \delta t + a_t$ and regulated by double-EWMA will be asymptotically stable if and only if,

$$|1 - 0.5\xi(w_1 + w_2) + 0.5\kappa| < 1$$

and

$$|1 - 0.5\xi(w_1 + w_2) - 0.5\kappa| < 1$$

where

$$\kappa = \sqrt{\xi(\xi((w_1 + w_2)^2 - 4w_1 w_2}$$

The no oscillation and stability conditions for different ranges of values of ξ are given as follows [31]:

$$\xi \in \begin{cases} (-\infty, 0] & \text{System is unstable} \\ \left(0, \dfrac{4w_1 w_2}{(w_1 + w_2)^2}\right) & \text{System is stable but oscilates} \\ \left[\dfrac{4w_1 w_2}{(w_1 + w_2)^2}, \dfrac{1}{(w_1 + w_2 - w_1 w_2)}\right] & \text{System is stable and does not oscilate} \\ \left(\dfrac{1}{(w_1 + w_2 - w_1 w_2)}, \dfrac{2}{(w_1 + w_2)}\right] & \text{System is stable and oscilates} \\ \left(\dfrac{2}{(w_1 + w_2)}, +\infty\right) & \text{System oscilates and is unstable} \end{cases}$$

For the general class of ARIMA (*p,d,q*) process disturbances, the exact expression for process output under double-EWMA control, stability conditions and feasibility region have been obtained by Tseng *et al*. [33]. They derived the optimal discount factor by minimizing the rework rate of the process output instead of minimizing the mean square error criteria used in [32].

In the case of the double-EWMA control scheme, the predicted model is constructed by a random sample to input-output variables, the strength of the linear relationship between input output plays an important role in determining the validation of the stability conditions. Tseng and Hsu [34] derived a formula for an adequate sample size required to construct the predicted model in the case of single input single output, and multiple input single output systems. They demonstrated the effectiveness of the covariance structure of input output variables in determining the sample size. The stability conditions of single and double-EWMA feedback controllers are invariant with

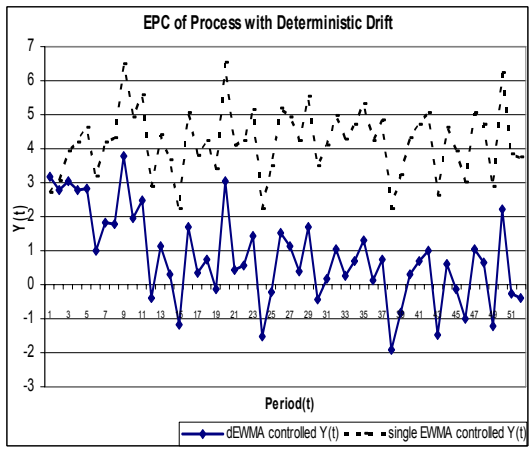

Figure 15.10. Single-EWMA and double-EWMA controlled process with deterministic drift

respect to the large class of process disturbances that model the drift. However, the use of double-EWMA in place of single-EWMA is justified only if the drift rate is severe [35].

15.6.3 Run-to-run Control for Short Production Runs

Single-EWMA controllers and double-EWMA controllers presented above long term stability under suitable discount factors but it may take a large number of runs to bring the process output to meet its target. This will have severe consequences in short production runs, frequently encountered in the semiconductor industry. In this section internal intercept iteratively adjusted (IIIA) controllers and variable EWMA controllers, which overcome this shortcoming and reduce the high rework rate during initial runs, are briefly discussed..

Internal Intercept Iteratively Adjusted (IIIA) Controllers

Double-EWMA guarantees long term stability under suitable fixed discount factors but it takes a large number of runs to bring the process output to meet its target. The quality characteristics may be out of specification limit in the first few runs. This makes double-EWMA controllers inefficient for short production runs. This weakness is overcome by adopting internal intercept iteratively adjusted (IIIA) controllers [36]. IIIA controllers further reduce the off-target or nonrandom bias of the process output. The equation is similar to double-EWMA controllers. The IIIA controller updates the double-EWMA filter to remove initial nonrandom bias for short production runs. It is found that the mean square error of IIIA controllers is less than the mean square error of double-EWMA controllers.

Variable EWMA Controllers

The EWMA controller with a small discount factor can guarantee long term stability under fairly regular conditions but it usually requires a large number of runs to bring the process output to its target. Variable EWMA controllers overcome this weakness [37]. In variable EWMA instead of using a fixed discount factor, a variable discount factor is used. To accelerate convergence, a larger discount factor is used in first few runs of R2R control. An optimal variable discount factor is obtained by minimizing the total mean square error within the first few runs.

15.6.4 Related Research

Paterson *et al*. [38] addressed the challenge of selecting the variable to feedback for applying feedback control to the semiconductor manufacturing process. They proposed an empirical methodology for selecting the best process variable for feedback in order to minimize variation in product variables. Paterson *et al.* [39] illustrated the practical aspects of utilizing the Paterson *et al.* [38] methodology to the self-aligned gate etch process.

Firth *et al.* [40] presented just-in-time adaptive disturbance estimation, which uses recursive least square parameter estimation to identify the contributions to variation that depend on the manufacturing context.

Chen and Guo [41] analyzed that controllers based on the EWMA statistic are not sufficient for controlling a wearing out process. They proposed a predictor corrector controller (PCC) to enhance the run-to-run control capability.

The topic of run-to-run control for multiple inputs and multiple output process has not received the deserved attention. Some notable work is listed here. Del Castillo [32] showed that double-EWMA controllers for single output and single input can be extended to multiple input single output models. Tseng *et al.* [42] proposed multivariate EWMA for linear MIMO models. They obtained the stability conditions and feasible region of its discount factor.

15.7 SPC and EPC as Complementary Tools

Greater benefits are obtained when SPC and EPC are used as complementary tools. This combination helps to verify adequacy of adjustment and also to identify assignable causes of change in performance.

It is criticized that EPC implementation deprives us of the opportunity of improving a process by identifying the assignable cause and removing it. EPC has even been described as a bandage to cover the wound not to cure it. The implementation of EPC and feedback control may conceal the true nature of the disturbance affecting the process. This may be avoided by monitoring the control variable and the deviation from the target. Any out of control points in the controller variable corresponding to an unusual large compensation for a disturbance may alarm the engineer that there is a special cause in the system. Similarly, any unusual errors will be seen through the charts monitoring deviation from the target. Another criticism is that the implementation of EPC may result in suboptimal compensation. This may happen if the disturbance models are wrongly chosen or parameter estimate is inaccurate. In most cases the disturbance is assumed to be the integrated moving average, and EWMA is used to forecast the next disturbance to apply control to. The EWMA smoothing constant used for industrial disturbances is often less than 0.3. Hence the inflation of process variance due to a wrong model and inaccurate parameter estimates is not severe. In addition, EWMA provides a good estimate even if the process model is not precise IMA.

Suitability of EPC and SPC for a process depends on following factors [43]:

1. When adjustment costs and/or adjustment errors are high it is better not to implement EPC.
2. When the measurement errors are high it is not advisable to implement EPC.
3. Finally, when the sampling is slow relative to the process dynamics (the rate at which quality characteristics react to a change in controllable factor), the process observed will be uncorrelated and SPC alone will be sufficient.

It should be noted that reducing sampling frequency for SPC purposes may be useful only if the original process is stationary. Reducing sampling frequency of a nonstationary process still produces nonstationary processes; an adjustment strategy of EPC based on prediction is advisable in such cases [44].

SPC charts can be effective in reducing process variation when assignable causes exist in EPC controlled processes. Algorithmic statistical process control (ASPC) is a framework that unifies EPC and SPC. Its is a control system that employs EPC to regulate the processes and then uses SPC methods to monitor the EPC controlled processes to detect any departure from the assumed system model and revise it if necessary [45, 46, 47]. There are two methods used to integrate SPC and EPC: the first one is to monitor the output of the EPC controlled process. The second one is to monitor the EPC control action. One of the issues with monitoring output of EPC controlled process is that, when assignable causes exist, outputs are contaminated by control action and are autocorrelated. This results in a small window of opportunity for detection of assignable causes. However, monitoring control action can be more efficient in some autocorrelated processes, while monitoring output can be more efficient in others [48]. The performance of monitoring an EPC controlled process depends on:

1. Monitoring data stream-controlled output or control action.
2. EPC control scheme employed-MMSE control of PID control.
3. Underlying autocorrelation structure.

Standard schemes such as Shewhart control charts, CUSUM charts, EWMA charts, proportional-integral feedback control and various feedforward schemes are appropriate or inappropriate, depending on the choice of parameters in the model, the objective about assignable cause, the nature of noise, process dynamics, off-target costs, adjustment costs and observation costs of the process [49].

Joint monitoring schemes using either Hotelling's approach or Bonferroni's approach can overcome the shortcomings of conventional SPC for controlled processes and both are quite efficient over a wide region of parameter space [50]. Among the various multivariate procedures for joint monitoring of process output and control actions combined $U_o - U_\infty$ charts [51, 52] show good performance followed by T^2 [50] and M [53] charts [52].

Six Sigma – Status and Trends

U. Dinesh Kumar

QMIS Group, Indian Institute of Management, Bannerghatta Road, Bangalore 560076, India

Abstract: Six Sigma originated from Motorola as a simple statistical technique to reduce defects in manufacturing in the 1980s with an objective to improve quality by improving manufacturing processes. Today, Six Sigma is an important corporate strategy used by many companies to improve their business processes, create a competitive advantage, and to increase market share and profitability. A recent study conducted by DynCorp, USA, has revealed that the effectiveness of Six Sigma as a tool for process improvement is the highest compared to other process improvement tools such as total quality management (TQM) and ISO 9000. The main objective of this chapter is to provide an overview of Six Sigma and discuss emerging trends in Six Sigma such as Design for Six Sigma (DFSS) and Lean Six Sigma (LSS).

16.1 Introduction

Quality has been an important discriminating factor for many centuries now. Many strategies have evolved over the last several decades to improve the quality of manufacturing and service organizations. Six Sigma as a method to reduce manufacturing defects was introduced more than 20 years ago by William Smith of Motorola. Motorola was the first company to win the Malcom Baldridge National Quality Award in 1988 for developing what later became to known as the Six Sigma methodology. The Six Sigma methodology tries to achieve a process capability index value of 2, whereas in the past a process capability index value of 1 was an acceptable quality standard. In the past (prior to Six Sigma), the upper and lower specification limits for a process were set at the three sigma level ($\mu + 3\sigma$ and $\mu - 3\sigma$), whereas the corresponding limits in a Six Sigma processes are set at $\mu + 6\sigma$ and $\mu - 6\sigma$, respectively, where μ is the process mean and σ is the standard deviation of the process.

Six Sigma is an extension of other quality initiatives such as Deming's statistical quality control and total quality management (TQM). Most management strategies on quality improvement are customer focused and Six Sigma is also focused around meeting the customer expectations as the main objective. It is difficult to define a methodology like Six Sigma, since it is a combination of several tools and techniques. Kwak and Anbari [1] define Six Sigma as a combination of TQM with strong customer focused additional data analysis plus financial results and project management. That is:

Six Sigma = TQM + stronger customer focus + additional data analysis tools + financial results + project management

Six Sigma evolved by synergizing most of the earlier quality improvement tools and created very few tools of its own. While Six Sigma was being developed as a technique to reduce defects in manufacturing, the world of business was witnessing the rise of the service industry. Currently, the growth of the service industry is much higher than that of the manufacturing industry in most developed nations. Service quality plays a crucial role in the profitability of a business, since customer defections can significantly reduce the profit of the service industry [2]. From an operational strategy Six Sigma has evolved as a competitive corporate strategy and a new mantra of the corporate world. Even traditional companies that adhere to conventional management methods have started embracing Six Sigma and believe that Six Sigma is a method of substance that will increase market share and profitability [3].

Although Six Sigma originated within the manufacturing industry to reduce the wastes due to manufacturing process deficiencies, it is now used by almost all industries including service industries such as healthcare management, banking, *etc.* [4–8] None of the previous quality improvement initiatives has received such wide applications outside the manufacturing industry.

The term Six Sigma was coined by William Smith, a reliability engineer at Motorola, and is a registered trade mark of Motorola. Smith pioneered the concept of Six Sigma to deal with the failure rate experienced by systems developed by Motorola. Smith proposed the Six Sigma process as a goal to improve the reliability and quality of the product. The initial days of Six Sigma were focused at reducing defects by improving manufacturing processes. Six Sigma uses five macro phases for process improvement called the DMAIC (define, measure, analyze, improve and control) procedure. DMAIC cycle is a standardized methodology used by Six Sigma to achieve process improvement iteratively. However, the DMAIC cycle itself has many similarities with Deming's "plan-do-check-act" (PDCA) cycle. A differentiating factor between TQM and Six Sigma is that Six Sigma provides a well defined target for quality that the process defect rate should not be more than 3.4 defects per million opportunities. This focused target along with the well defined DMAIC procedure probably resulted in a higher success rate for Six Sigma compared to TQM. Another important difference between Six Sigma and TQM is that Six Sigma is mostly a business results oriented model compared to the return on investment orientation of TQM [9].

Six Sigma can be used as an operational strategy to reduce the number of defects or as a business strategy to improve business processes and evolve new business models. Many proponents of Six Sigma stress that its power lies in the fact that it can be used as a business strategy to improve market share and profitability. The Design for Six Sigma (DFSS) concept uses Six Sigma to as a strategy to design and develop new products compared to the traditional Six Sigma, which aims to reduce the defects. A survey conducted by DynCorp revealed that the concept of Six Sigma is rated highly compared to many other process improvement techniques [10]. Table 16.1 shows the ratings of Six Sigma and other process improvement techniques based on the survey conducted by the DynCorp to determine the most successful process improvement tool.

For manufacturing companies the benefit of Six Sigma results from reduction in the number of

Table 16.1. Rating of Six Sigma and other process improvement techniques [10]

Process improvement tool	Impact
Six Sigma	53.6 %
Process mapping	35.3 %
Root cause analysis	33.5 %
Cause and effect analysis	31.3 %
Lean thinking and manufacturing	26.3 %
ISO 9001	21.0 %
Statistical process control	20.1 %
Design of experiments	17.4 %
Total quality management	10.3 %
Malcolm Baldridge criteria	9.8 %
Knowledge management	5.8 %

defects due to improved manufacturing processes. However, the direct benefit of Six Sigma decreases as the sigma quality level increases. The sigma quality level is a measure of process defect rate. A higher sigma level indicates that the process results in fewer defects, whereas a lower sigma means higher defect rate. The sigma quality level can be used for benchmarking purposes and helps to measure quality of the process. The sigma quality level also helps to set a realistic target for improvement of process quality during the DMAIC cycle of process improvement. Improving a process from sigma level 3 to sigma level 4 reduces the number of defects per million opportunities (DPMO) from 66,811 to 6,210, whereas improving the sigma level from 5 sigma to 6 sigma reduces the DPMO from 233 to 3.4. However, more effort may be required to improve a process from sigma level 5 to 6 compared to improving a process from sigma level 3 to 4. Thus, any process improvement using Six Sigma requires careful analysis. That is, Six Sigma implementation may not always result in financial benefit. Dinesh Kumar *et al.* [11] developed a mathematical programming model to select various improvement opportunities in an optimal way.

Any improvement in the sigma level is likely to reduce the cost of poor quality (COPQ). The cost of poor quality as a result of manufacturing defects is a function of rework cost, excessive use of material, warranty related costs, and excessive use of resources. Assuming that COPQ is linearly related to the number of defects produced by the process, the benefit of a relative increase in the sigma level decreases [11]. The improving process may involve replacing the existing process with a new technology. Gowen and Tallon [12] point out that Six Sigma programs must take into consideration the level of technological intensity of the organization to determine the impact of Six Sigma. Replacing existing process with a new technology can be costly and if the resulting new process does not improve the sigma level significantly, the investment required to improve the process may not result in significant returns. Like any other process improvement technique, Six Sigma would also fail to deliver if the management fails to understand the cost of implementing Six Sigma and its effectiveness.

The objective of this chapter is to review the current status of Six Sigma and recent trends. In Section 16.2, the metrics used by Six Sigma is presented. Selection of projects for implementation of Six Sigma plays a crucial role in the success of Six Sigma implementation. Section 16.3 discusses issues in Six Sigma project selection. Section 16.4 deals with DMAIC methodology and an example is used to illustrate the DMAIC cycle. The trends in Six Sigma such as Design for Six Sigma and Lean Six Sigma are discussed in Section 16.5. Conclusions are presented in Section 16.6.

16.2 Management by Metrics

Six Sigma is without any doubt an important strategies used by companies irrespective of their business. Six Sigma is very popular among manufacturing companies and is equally, if not more, popular among service organizations. One of the reasons for the success of Six Sigma can be attributed to its metrics. Other than sigma level quality, all other measures in Six Sigma can be traced to concepts such as statistical process control and total quality management. In this section we will define and establish the relationship between the following fundamental Six Sigma metrics:

1. yield
2. defects per million opportunities (DPMO)
3. sigma quality level

16.2.1 Yield

Yield, Y, is an important measure of process capability and is defined as the ratio of the total number of defect free units to the total number of units produced (or opportunities):

$$Yield = Y = \frac{\text{Number of defect free units}}{\text{Number of opportunites}} \times 100\% \tag{16.1}$$

At Six Sigma quality, the yield is 99.99966%. This value of course assumes that the process mean may

shift up to 1.5σ, where σ denotes the process standard deviation. In the absence of any shift in the process mean, the yield at Six Sigma quality will be 99.9999998%. That is, two defects per billion opportunities.

16.2.2 Defects *per* Million Opportunities (DPMO)

Defects per million opportunities (DPMO) measures the number of defects in a process in terms of million opportunities. It is also known as ppm (defects counted in parts per million). However, it is very difficult to get the complete data of defects in one million opportunities for most processes. Usually DPMO is estimated from a sample of units produced. DPMO is calculated from estimating the defects per unit (DPU) using the following expression:

$$DPMO = DPU \times \mathbf{10^6}. \qquad (16.2)$$

The above equation can be written as:

$$DPMO = \frac{\text{Number of defects}}{\text{Number of opportunities}} \times \mathbf{10^6}. \qquad (16.3)$$

16.2.3 The Sigma Quality Level

The sigma quality level is a measure of quality of the output produced by an organization. The higher the sigma level, the better the quality. In other words, a process with a high sigma level will result in fewer defects. The sigma level or sigma quality level can be understood as the Z value of the standard normal distribution under the assumption that there is no shift in the process mean. Several polynomial approximations [13] are available to calculate the value of Z. Similarly, when there is a shift in the process mean (say as much as Λσ), then the following mathematical relationship [14] can be used to approximate the value of Z (sigma level):

$$Z = \Lambda + \left(Q - \frac{C_0 + C_1 Q + C_2 Q^2}{\mathbf{1} + d_1 Q + d_2 Q^2 + d_3 Q^3} \right), \qquad (16.4)$$

where C_0 = 2.515517, C_1 = 0.802853, C_2 = 0.010328, d_1 = 1.432788, d_2 = 0.189269, d_3 = 0.001308 and,

$$Q = \sqrt{\ln\left(\left(\mathbf{1} - \frac{Y}{\mathbf{100}}\right)^{-2}\right)}, \qquad (16.5)$$

where Y is the process yield. In Excel® spreadsheet, the Sigma quality level can be calculated using the function NORMINV(Y, Λ, 1). Here, Λσ is the shift in the process mean over a long period of time. Six Sigma uses several context specific measures and a few of them are listed below:

1. Time to market.
2. Percentage of sales from new product.
3. Ratio of units returned over units sold.

16.3 Six Sigma Project Selection

Six Sigma is a project based problem solving methodology. In Six Sigma, each process improvement opportunity is treated as a project. Thus it is important to choose a project that would result in maximum benefit. Several Six Sigma project selection methodologies have been reported in the literature [14]. The chosen project should align with the strategic objectives of the organization. Pande *et al.* [15] classify Six Sigma project selection criteria into three categories: 1) business benefits criteria, 2) feasibility criteria, and 3) organization impact criteria. Business benefits criteria include issues such as the *impact on customers*, the *impact on business strategy*, and the *impact on core competencies*, *financial impact* and *urgency*. Feasibility criteria for Six Sigma project selection include criteria such as *resources needed, expertise available, complexity* and *probability of success*. Learning benefits and cross-functional benefits are listed under organizational impact criteria. Harry and Schroeder [16] propose the following criteria for Six Sigma project selection: 1) DPMO, 2) net cost savings, 3) cost of poor quality, 4) cycle time, 5) customer satisfaction, 6) capacity, and 7) internal performance. Banuelas *et al.* [17] list the following six criteria as critical for Six Sigma project selection.

1. Customer impact.
2. Financial impact.
3. Top management commitment.
4. Measurable and feasible.
5. Learning and growth.
6. Connected to business strategy and core competence.

The most frequently used methodology for project selection is the analytic hierarchy process (AHP). AHP is a multi-criteria decision making tool, which selects a best solution to a problem from a set of alternatives by assigning weights to multiple criteria. For Six Sigma projects, the following criteria are considered in AHP:

1. Duration (time required to complete the Six Sigma project).
2. Project cost.
3. Probability of success.
4. Strategic fit of the project.
5. Increase in customer satisfaction.
6. Increase in Sigma quality level.
7. Reduction in cost of poor quality (CoPQ)
8. Manpower requirement (Six Sigma green belts and Six Sigma black belts).

The above list of criteria is only representative and not exhaustive. AHP identifies the strength with which one alternative (alternative Six Sigma project) dominates the other and comes out with an overall priority list. This task is achieved by normalizing the pair-wise comparison matrices. For more details about Six Sigma project selection using AHP the reader may refer to Dinesh Kumar *et al.* [14]. Once a project is chosen for Six Sigma implementation, it goes through the DMAIC methodology, which implements Six Sigma solution systematically.

16.4 DMAIC Methodology

DMAIC (pronounced De-MAY-ick) is at the center of every Six Sigma project. DMAIC stands for five stages of Six Sigma methodology, namely, define, measure, analyze, improve and control. The tasks performed during these five stages of DMAIC are described in the following paragraphs:

Define

The main focus of the *define* stage is to identify the problem in terms of critical to quality (CTQ) parameters. The problem is defined in terms of some deficiency in CTQ parameters. In other words, in the define stage the problem with respect to one or more CTQ parameters is identified.

Measure

During the m*easure* stage an appropriate metric is used to measure the current process capability. The main objective during this stage is to establish the current performance of the process and measure the gap in the process performance and set target for improvement.

Analyze

In this stage, the cause and effect relationship between process performance and the process inputs are identified. The causes for performance gap measured in terms of CTQs are identified and solutions to the problems are generated. The best solution is then chosen to improve the process performance.

Improve

The main focus during this stage is to implement the solution to the problem identified during the define stage and target set during the Measure stage. Several optimization techniques are used to solve the problem in an optimal way.

Control

Sustaining the improvement obtained is equally important as achieving the improvement itself. In the control stage of the DMAIC cycle several statistical tools are used to sustain the quality improvement achieved using the previous four stages. The strength of DMAIC lies in its tool box. The methodology uses several mathematical and statistical tools and techniques to identify and solve the problem. A few of the tools and techniques used during various stages of DMAIC cycle is shown in Table 16.2. It should be noted that a particular tool may be used in more than one stage of the DMAIC cycle, since the most tools are context specific.

Table 16.2. DMAIC tool box

16.4.1 DMAIC Case: Engineer Tank

In this section we demonstrate the DAMIC procedure using an engineer tank case. The data used in this case example are for demonstration purposes only. Engineer tanks are used on the battlefield to undertake engineering tasks. This vehicle's primary task on the battlefield is to open routes. Its tasks include providing a route across short gaps, countering mines by clearing routes across mine fields and obstacle breaching and clearance (by digging and bulldozing). The functional elements for the armored vehicle are: mobility, surveillance, and communications, Lethality and survivability. During the development of the engineer tank engine, reliability targets were set and these targets are shown in Table 16.3.

The failure data collected from 70 engines are shown in Table 16.4. These failures have resulted in unscheduled maintenance of the engine. The time to failure data given in Table 16.4 is analyzed using a statistical software package MINITAB to find the best fit probability distribution. The best fit in this case is a Weibull distribution with scale parameter $\eta = 246.361$ and shape parameter $\beta = 1.286$. The corresponding mean time between failures, MTBF, value is 228.05 hours.

The analysis of in-service data shows that the achieved MTBF is much less than the target value of 420 hours. Improvement of reliability in this case is a good candidate for Six Sigma project and the DMAIC methodology. The DMAIC procedure for the reliability improvement in this case is discussed in the following example.

Table 16.3. Target reliability measures for engineer tank engine

Metric	Target: engine hours
Mean time between failure (MTBF)	420
Mean time between mission critical failures (MTBMCF)	3500
Mean time between routine overhaul	13500

Table 16.4. Failure data (failures resulting in unscheduled maintenance)

215	114	247	122	91	291	194	315	241	9
95	378	425	252	22	153	195	165	130	451
456	350	105	275	294	232	441	94	360	202
18	50	68	244	126	557	168	64	99	323
42	560	232	198	27	947	239	89	325	273
178	33	997	75	126	23	416	247	292	216
210	36	46	223	284	52	223	454	151	88

The define stage, as mentioned earlier, basically identifies the problem.

Poor reliability of the engineer tank engine is a major concern and thus reliability improvement forms the basis for remaining four stages of DMAIC cycle. The measure stage of the DMAIC cycle identifies the gap in the target and achieved reliability of the tank engine. The reliability of the engine is measured using the engine hours and based on the analysis of the in-service data it is found that the actual reliability of the engine is 228.05 hours against the target of 420 hours. To achieve the target MTBF of 420 hours, an almost 85% increase in reliability is required from the current level of 228.05 hours MTBF.

During the analyze stage the actual causes of reliability problems are analyzed. Figure 16.1 shows failure cause Pareto for engine failures. It is evident from Figure 16.1 that dust ingestion is a major cause of failure followed by mechanical failures and overheat. Since armored vehicles work in an environment hostile to air filters, it is expected that dust ingestion is a major cause for failure of engines.

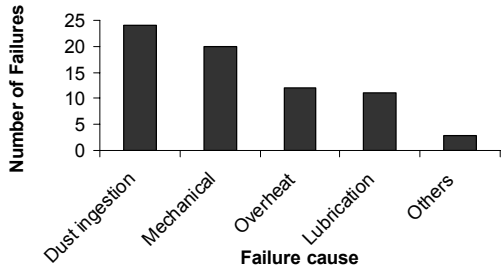

Figure 16.1. Failure cause Pareto

During the improve stage, the objective is to generate solutions to solve the reliability problem; in this case, it would be to design an air-filter that can reduce the engine failures due to dust ingestion. However, one should also look at alternative ways of improving the reliability since re-designing the air-filter may not be the optimal solution to the problem (that is, either it may not be feasible or cost effective). It may easier to eliminate other failure causes than dust ingestion, such as providing a better cooling system to reduce failures due to overheat. Once the optimal solution has been identified, one should go ahead and implement the solution. Strategies to sustain the reliability improvement would be objective of the control stage. Control charts and online health monitoring systems can be used to meet the objective of the control stage.

16.5 Trends in Six Sigma

Six Sigma has gone through a dramatic change over the last decade. Although it started as a tool to reduce waste it is now used as a strategy to run businesses. In this section, we shall discuss Design for Six Sigma (DFSS) and Lean Six Sigma (LSS), two of the most powerful tools used by industries to improve profitability.

16.5.1 Design for Six Sigma

Six Sigma is not just a technique to reduce defects. It has evolved into a successful strategy deployed by many companies to improve the design of products and services. For many companies, an important business objective is to improve profitability and Six Sigma is successfully applied to achieve this by using the Design for Six Sigma (DFSS) approach [18, 19].

In DFSS, design engineers interpret and design the functionality of customer requirements by optimizing both customer needs and organizational objectives. DFSS consists of five stages, namely (i) define, (ii) measure, (iii) analyze, (iv) design, and (v) verify, and is popularly known as DMADV methodology. DMADV is appropriate for new product development where the product and processes do not exist. The activities during various stages in DMADV are given below:

- *Define*: Develop new product development (NPD) strategy, scope of the NPD project.
- *Measure:* Understand the customer requirements and critical to quality parameters.
- *Analyze:* Develop conceptual design after analyzing various design options.

- *Design:* Develop detailed design of the product and processes.
- *Verify:* Develop prototype to verify the effectiveness of the design and check whether the product has met all the goals set during the previous stages of product development.

It is believed that Six Sigma is more effective when it is used for designing new products and processes rather than improving existing processes, since in many cases replacing existing processes may not be an easy task. Thus, the maximum benefit of Six Sigma is realized when it is used for design and development of new products.

16.5.2 Lean Six Sigma

Lean Six Sigma (LSS) combines the lean concepts along with Six Sigma to achieve higher performance. Lean management originated from Toyoto production systems (TPS). TPS is also credited with creating just-in-time (JIT) methodology, a key method in lean management [20]. Lean concepts try to improve efficiency of a process by eliminating the waste in the process/system, whereas Six Sigma makes a process effective by reducing process variation and improving process capability. Combining lean and Six Sigma results in an efficient and effective process improvement tool. That is, lean Six Sigma synergies the speed of lean with accuracy of Six Sigma.

The principle of lean Six Sigma [21] is that the activities, which cause the customers' critical quality issues creating longest delays in any process, offer greatest opportunity for improvement. The current trend in Six Sigma is to apply lean concepts first and then apply Six Sigma. That is, first make the process efficient by eliminating process waste and then effective by eliminating process variation. Here process waste refers to overproduction, inventory lead time, process cycle time. *etc*. George [21] has reported several applications of LSS in various fields including manufacturing, finance, logistics and supply chain management.

16.6 Conclusions

Six Sigma has become a new corporate mantra. Since its beginning in late the 1980s, Six Sigma has evolved into the most powerful tool of the 21st century so far. Kwak and Anbari [1] compiled the benefits of Six Sigma across various industries. Table 16.5 shows the benefits of Six Sigma as reported by them. It should be noted that Six Sigma is not just a tool for quality improvement but an organizational culture to achieve excellence in business processes. However, like any other process improvement tool, Six Sigma should be used with caution. Six Sigma is not a one stop solution to all problems. Before any company wishes to embrace Six Sigma, it should realize that achieving Six Sigma quality is not possible with the existing knowledge in most cases. In fact, in most cases, achieving even five sigma quality itself is impossible. However, this does not in anyway reduce the power of the Six Sigma concept. It is probably the best methodology currently available for continuous process improvement. Any company that would like to embrace Six Sigma should set a realistic target for quality improvement measured in terms of the sigma quality level. For example, if a company at present is a 3 sigma company, then a realistic improvement target would be a 3.5 sigma level rather than a 5 or 6 sigma level.

Any tool comes with its own limitations. For small and medium size (SMEs) companies, a large scale Six Sigma implementation may not be financially feasible. SMEs should target small process improvement, which in many cases tends to improve the quality and profitability of the company. Six Sigma is without any doubt a champion tool among all the process improvement tools.

Table 16.5. Reported benefits of Six Sigma [1, 11, 22–26]

Company	Metrics/Measures	Benefits/Savings
Motorola (1992)	In-process defect levels	150 time reduction
Raytheon aircraft integration system	Depot maintenance inspection time	Reduced 88% as measured in days
GE (Railcar leasing business)	Turnaround time at repair shops	62% reduction
Allied Signal (Honeywell) – Lamination plant in South Carolina	Capacity, Cycle Time Inventory, and On time delivery	Up 50%, Down 50%, Down 50% and increased to near 100%
Huges aircraft's missile system group / wave soldering operations	Quality / productivity	Improved 1000% and Improved 500%
Continental Teves/ Brake and axle assemblies	Failure rate	More than 50% reduction in failure rate
Borg Warner Turbo Systems	Financial	$ 1.5 million annually since 2002
General Electric	Financial	$ 2 billion in 1999
Motorola	Financial	$15 billion over 11 years
Dow Chemical – Rail delivery project	Financial	Savings of $2.45 million in capital expenditures
DuPont/Yerkes plant in New York	Financial	Savings of more than $ 25 million
Telefonica de Espana (2001)	Financial	Savings and increase in revenue 30 million Euro in first 10 months
Texas Instruments	Financial	$ 600 Million
Johnson and Johnson	Financial	$ 150 Million
Honeywell	Financial	$ 1.2 Billion
Ford Motor Company / Exterior Surface defects	Financial	$500,000

Computer Based Robust Engineering

Rajesh Jugulum[1] and Jagmeet Singh[2]

[1]MIT and Bank of America, Boston, Massachusetts, USA
[2]GE Energy, Greenville, South Carolina, USA

Abstract: In this chapter, new trends in robust engineering (RE) are discussed. The chapter discusses use of robust engineering principles in simulation based experiments and in software testing with illustrative examples.

17.1 Introduction

Robustness can be defined as designing a product in such a way that the level of its performance in various customer usage conditions is same as that in the nominal conditions. Robust engineering methods (also known as Taguchi methods) are intended as cost-effective methods to improve the performance of a product by reducing its variability in the customer usage conditions. Because they are intended to improve companies' competitive positions in the market, these methods have attracted the attention of many industries and academic community across the globe. The methods of robust engineering are the result of research effort led by Genichi Taguchi.

Quality, in the context of robust engineering can be classified into two types:

1. customer driven quality
2. engineered quality

Customer quality leads to the size of the market segment. It includes product features such as color, size, appearance and function. The market size becomes bigger as the customer quality gets better. Customer quality is addressed during the product planning stage. Customer quality is extremely important to create the new market. On the other hand, engineered quality includes defects, failures, noise, vibrations, pollution, *etc*. While the customer quality defines the market size, the engineered quality helps in winning the market share within the segment.

All problems of engineered quality are caused by three types of uncontrollable factors (called noise factors).

I. Various usage conditions
   - environmental conditions

II. Deterioration and wear
   - degradation over time

III. Individual difference
   - manufacturing imperfection robust engineering (RE) methods or Taguchi methods (TM) aim at improving the engineered quality.

While designing a new product optimization for robustness can be achieved in the following three stages:

1. concept design
2. parameter design
3. toleranced design

Although there are three stages, most of the RE applications focus on parameter design optimization and tolerance design. It is widely acknowledged that the gains in terms of robustness will be much higher if a design process is started with a robust concept selected in the concept stage. Techniques like Pugh concept selection, the theory of inventive problem solving (TRIZ), and axiomatic design and P-diagram strategies developed for conceptual robustness through Ford-MIT collaboration by [1] can be used to achieve robustness at the concept level.

The methods of robust engineering are developed based on the following five principles:

1. Measurement of function using energy transformation.
2. Take advantage of interactions between control and noise factors.
3. Use of orthogonal arrays and signal-to-noise ratios.
4. Two-step optimization.
5. Tolerance design using quality loss functions and on-line quality engineering.

Taguchi [2] and Phadke [3] provide a detailed discussion on the principles of TM. These principles have been successfully applied in many engineering applications to improve the performance of the product/process. They are proved to be extremely useful and cost effective. A brief illustration of these principles is given below:

1. *Measurement of Function Using Energy Transformation*
   The most important aspect of Taguchi methods (TM) is to find a suitable function (called the ideal function) that governs the energy transformation in the system from input signal to output response. It is important to maximize the energy transformation by minimizing the effect of uncontrollable or noise factors. In the Taguchi approach measure the functionality of the system to improve the product performance (quality). The energy transformation is measured in terms of signal to noise (S/N) ratios. A higher S/N ratio means better energy transformation and hence functionality of the system.
2. *Take Advantage of Interactions Between Control and Noise Factors*
   In TM, we are not interested in measuring the interaction between the control factors, but rather in the interaction between the control and noise factors, since the objective is to make the design robust against the noise factors.
3. *Use of Orthogonal Arrays (OA's) and Signal-to-noise Ratios (S/N Ratios)*
   OAs are used to minimize the number of runs (or combinations) needed for the experiment. Usually, many people are of the opinion that the application of OA is TM. However, it should be noted that the application of OAs is only a part of TM. S/N ratios are used as a measure of the functionality of the system.
4. *Two-Step Optimization*
   After conducting the experiment, the factor-level combination for the optimal design is selected with the help of two-step optimization. In two-step optimization, the first step is to minimize the variability (maximize S/N ratios). In the second step, the sensitivity (mean) is adjusted to the desired level. It is easier to adjust the mean after minimizing the variability.
5. *Tolerance Design Using Quality Loss Function and On-line Quality Engineering*
   While the first four principles are related to parameter design, the fifth principle is related to the tolerance design and on-line quality engineering. Having determined the best settings using parameter design, the tolerancing is done with the help of quality loss function. If the performance deviates from the target there is a loss associated with the deviation. This loss is termed as the loss

to the society. It is proportional to the square of the deviation. It is recommended to design the safety factors using this approach. On-line QE is used to monitor the process performance and detect the changes in the process.

17.1.1 Concepts of Robust Engineering

17.1.1.1 Parameter Diagram (P-diagram)

This is a block diagram, which is often quite helpful to represent a product or process or a system. In Figure 17.1, the energy transformation takes place between input signal (**M**) and the output response (**y**). The goal is to maximize energy transformation by adjusting control factors (**C**) settings in the presence of noise factors (**N**).

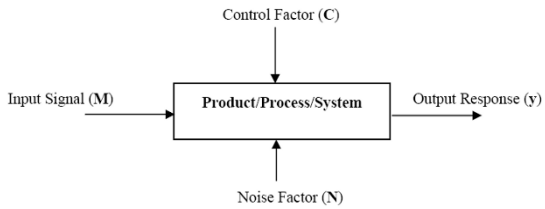

Figure 17.1. Parameter diagram or p-diagram

1. *Signal Factors (M)*
   These are the factors that are set by the user/operator to attain the target performance or to express the intended output. For example, the steering angle is a signal factor because the steering angle is a signal factor for the steering mechanism of an automobile. The signal factors are selected by the engineer based on the engineering knowledge. Sometimes even more than one signal factor is used in combination, for example, one signal factor may be used for coarse tuning and one for fine-tuning.
2. *Control Factors (C)*
   These are the product parameters specification whose values are the responsibility of the designer. Each of the control factors can take more than one value, which will be referred to as levels. It is the objective of the design activity to determine the best levels of these factors that will make product insensitive to noise factors or robust against noise factors. Robustness is the insensitivity to the noise factors.
3. *Noise Factors (N)*
   Noise factors are the uncontrollable factors. They influence the output **y** and their levels change from one unit of the product to another, from one environment to another and from time to time. As mentioned before noise factors can be one of or a combination of the following three types: 1) Various usage conditions, 2) deterioration and wear, and 3) individual difference.

17.1.1.2 Experimental Design

Experimental design is a subject with a set of techniques and a body of knowledge to help the investigator to conduct experiments in a better way, analyze results of experiments and find the optimal parameter combination for design to achieve intended objectives. In experimental design, various factors affecting the product/ process performance are varied (by changing their values called levels) in a systematic fashion to estimate their effects on product/ process variability to find the optimal factor combination for a robust design. There is an extensive literature on this subject. A typical experimental design cycle is shown in Figure 17.2.

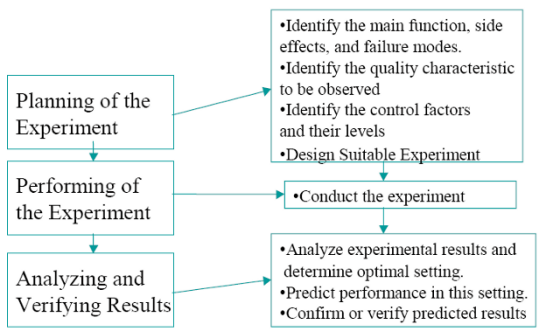

Figure 17.2. Experimental design cycle

Types of Experiments

There are typically two types of experiments, full factorial experiments and fractional factorial experiments. In full factorial experiments, all combinations of factors are studied. All main effects and interaction effects can be estimated with the results of such an experiment. In fractional factorial experiments, a fraction of the total number of experiments is studied. This is done to reduce cost, material and time. Main effects and selected interactions can be estimated with such experimental results. The orthogonal array is an example of this type. In robust engineering, the main role of OAs is to permit engineers to evaluate a product design with respect to robustness against noise, and cost involved by changing settings of control factors. OA is an inspection device to prevent a "poor design" from going "down stream".

17.1.1.3 Signal to noise (S/N) Ratios

The term S/N ratio means signal to noise ratio. S/N ratio tries to capture the magnitude of true information (*i.e.*, signals) after making some adjustment for uncontrollable variation (*i.e.*, noise). From Figure 17.1, we can say that a system consists of a set of activities or functions that are designed to perform a specific operation and produce an intended or desired result by minimizing functional variations due to noise factors. In engineering systems the input energy is converted into an intended output through laws of physics.

These engineered systems are designed to deliver specific results as required by customers. All engineered systems are governed by an ideal relationship between the input and the output. This relationship is referred to as the ideal function. The robust engineering approach uses this relation and brings the system closer to the ideal state (Figure 17.3).

If the all input energy is converted into output, then there will be no energy losses. As a result there would be no squeaks, rattles, noise, scrap, rework, quality control personnel, customer service agents, complaint departments, warranty claims, *etc*. Unfortunately it does not happen because reality is much different from ideal situations.

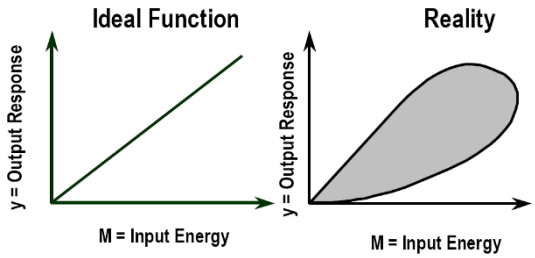

Figure 17.3. Ideal function and reality

In reality there is energy loss when input is transformed to output. This loss occurs because of variability and noise factors. This energy loss will create unintended functions. Further, the bigger the energy loss, the bigger the problems.

The S/N ratio is a measure of robustness as it measures energy transformation that occurs within a design. The S/N ratio is expressed as:

S/N ratio = ratio of energy (or power) that is transformed into intended output and energy (or power) that is transformed into unintended output;

= ratio of useful energy and harmful energy

= ratio of work done by signal and work done by the noise

A higher S/N ratio is more robust than the system's function.

17.1.2 Simulation Based Experiments

Earlier the experiments are performed as hardware experiments. However, the present day trend is towards simulated based experiments. Computer simulations are quite important in robust engineering because:

- Simulated experiments play a significant role in reducing product development time because there is no need to conduct all hardware experiments.
- Simulated based robust engineering can serve as a key strategy for research and development.
- They help to conduct functionality based analysis.

- Simulated experiments are typically inexpensive, less time consuming, more informative and many control factors can be studied.

Once a simulation method is available, it is extremely important to optimize the concept for its robustness. The results of simulated experiments are analyzed by calculating S/N ratios and sensitivities. However, the optimal combination is tried using hardware experimentation to confirm the results. This book focuses only on simulation based experiments. While using simulated based experiments, it is important to select suitable signals, noise factors and output response.

The example given Section 17.1.2.1 explains how to conduct simulation based experiments. This example also explains the differences between Taguchi methods of robust engineering with other methods of design of experiments.

17.1.2.1 Example

Consider a circuit stability design as a simple example with a theoretical equation.

The output current, **y** in amperes of an alternating-current circuit with resistance, *R*, and self-inductance, *L*, is given by Equation 17.1 below,

$$\mathbf{y} = \frac{V}{\sqrt{R^2 + (2\pi f L)^2}}, \qquad (17.1)$$

where:

V: input alternating–current voltage (V)
R: resistance (Ω)
f: frequency of input alternating current (Hz)
L: self-inductance (H) and, $\omega = 2\pi f$.

The target value of output current y is 10 amps. If there is a shift of at least 4 amps during use by the consumer, the circuit no longer functions. The target value of **y** is 10 amps and the tolerance is 10 $\pm$ 4 amps.

The purpose of parameter design is to determine the parameter levels (normal values and types) of a system of elements. For example, it determines whether the nominal value of resistance, *R*, in the circuit is to be 1 or 9. The purpose of tolerance design is to determine the tolerance around the nominal value of the parameter.

Classification of Factors: Control Factors and Noise Factor:

Those variables in the equation whose central values and levels the designer can select and control are the control factors.

The input voltage is 100 volts AC in the case of a household source, and because the designer cannot alter this, it is not a control factor. Neither is the frequency, *f*, a control factor.

Only *R* and *L* are control factors. The designer sets the resistance value at 1Ω, 3Ω, or 9Ω. The same is true with regard to self-inductance, *L*. It is obvious that since the target value of the output current is given as 10 amps, in this case, once one decides on the central value of the resistance, *R*, the central value of the inductance, *L*, will be determined by the equation.

When there are three or more control factors, it is best not to consider such limiting conditions. The reason for this is that it is more advantageous to adjust the output to the target value by changing the levels of those control factors that have little influence on stability after an optimum design for stability has been determined. Factors that are favorable for adjustment are factors that can be used to change the output to the target value. These factors are sometimes termed signal factors. We can perform parallel analyses for the S/N ratio, and for the mean, which are measures of stability and sensitivity, and adjusts the mean after variability has been reduced. In the present case, we choose three levels of *R* and L independently, as follows:

$R_1 = 0.5$ (Ω), $R_2 = 5.0$ (Ω), $R_3 = 9.5$ (Ω),
$L_1 = 0.010$ (H), $L_2 = 0.020$ (H), $L_3 = 0.030$ (H).

An orthogonal array is used if the control factors are more numerous, but since there are only two here, we can use a two-way layout with full factorial experiment. An orthogonal array to which control factors have been assigned is termed an inner orthogonal array or control orthogonal array.

One should use as many control factors as possible, take a wide range of levels and assign only the main effects.

Next, let us examine noise factors. As described earlier, noise factor is a general term for a cause that disperses the target characteristic from the ideal value.

Dispersion by the environment consists of the following two factors in this example, and their levels are taken as follows:

Voltage of input source (V)	90	100 110
Frequency f (Hz)	50	60

The environmental temperature, *etc*., also changes the value of the resistance, R, and the coil inductance, L, although only slightly. However, changes due to deterioration of the resistance and coil are greater than the effects of environmental changes. After having considered changes due to dispersion of the initial-period value, deterioration, and environment, let us decide that the resistance, R, and coil inductance, L, are to have the following three levels:

First level	normal value x 0.9
Second level	nominal value
Third level	nominal value x 1.1

The levels of the noise factors are as given in Table 17.1. It should be noted that a prime has been affixed to symbols for the noise factors, R and L. In this instance, it means there is no error with respect to the noise factors V, R', and L' when they are at the second level. Frequency f is 50 Hz or 60 Hz, depending on the location in Japan. If one wishes to develop a product that can be used in both conditions, it is best to design it so that the output meets the target when the frequency is at 55 Hz, midway between the two. Sometimes one uses an intermediate value that has been weighted by the population ration.

Table 17.1. Noise factors and levels

Noise factor levels			
	First level	Second level	Third level
V	90	100	110 (V)
R'	-10	0	+10 (%)
f	50	55	60 (Hz)
L'	-10	0	+10 (%)

However, now, as is evident from Equation 17.1, the output becomes minimum with $V_1R_3'f_3L_3'$ and maximum with $V_3R_1'f_1L_1'$. If the direction of output changes is known when the noise factor levels are changed, all the noise factors can be compounded into a single factor. If the compound factor is expressed as N, it has two levels. In this case:

$N_1 =$ $V_1R_3'f_3L_3'$ minus side minimum value,
$N_2 =$ $V_3R_1'f_1L_1'$ plus side maximum value.

When we know which noise factor levels cause the output to become large, it is a good strategy to compound them so as to obtain one factor with two levels, or one factor with three levels, including the central level. When we do this, our noise factor becomes a single compounded factor, no matter how many factors are involved. Since one can determine the tendencies of all four noise factors in this example, they have been converted essentially into a single compounded noise factor, N, with two levels. Thus, we need merely investigate the value of the outgoing current for these two levels.

Compounding of noise factors is even more important when there is no theoretical equation. This is because with a theoretical equation, the calculation time is short, usually no more than several seconds. Even if noise factors are assigned to the columns of a separate orthogonal array, there is little improvement in the efficiency of calculation even with compounded noise factors of two levels as in our example. Compounding was necessary in the past when computers were not available. However, when there are too many noise factors, the orthogonal array becomes large and much time and expense is required, even with a

computer. In such case, it is still useful either to reduce the number of noise factors to a few important ones or to compound noise factors.

Parameter Design

Design calculations are performed (experiments are performed when there is no theoretical equation) for all combinations of the inner orthogonal array to which control factors *R* and *L* have been assigned (two-way layout, here) and the noise factor assignment (two-level noise factor here). This is the logical method for parameter design. The assignment is shown in the left half of Table 17.2.

Table 17.2. Calculations of S/N ratios and sensitivities

Assignment of Factors						
No.	*R*	*L*	Compound noise		S/N ratio η	Sensitivity S
			N_1	N_2		
1	1	1	21.5	38.5	7.6	29.2
2	1	2	10.8	19.4	7.5	23.2
3	1	3	7.2	13.0	7.4	19.7
4	2	1	13.1	20.7	9.7	24.3
5	2	2	9.0	15.2	8.5	21.4
6	2	3	6.6	11.5	8.0	18.8
7	3	1	8.0	12.2	10.4	20.0
8	3	2	6.8	10.7	9.6	18.6
9	3	3	5.5	9.1	8.9	17.0

The S/N ratio is the reciprocal of the square of the relative error (also termed the coefficient of variation, $\frac{\sigma}{m}$). Although the equation for the S/N ratio varies, depending on the type of quality characteristic, all S/N ratios have the same properties. When the S/N ratio becomes 10 times larger, the loss due to dispersion decreases to one-tenth.

The S/N ratio, η, is a measure for optimum design, and sensitivity, **S**, is used to select one (sometimes two or more) factor(s) by which to later adjust the mean value of the output is adjusted to the target value, if necessary.

To compare the levels of control factors, we construct a table of mean values for the S/N ration, η, and sensitivity, **S**. For example, in the case of R_1, $\boldsymbol{\eta}$ = 7.5 and **S** = 24.0.

In Table 17.3 the mean values are given for the other control factor levels.

Directing our attention to the measure of stability, the S/N Ratio, in Table 17.3, we can see that the optimum level of *R* is R_3, and the optimum level of *L* is L_1. Therefore, the optimum design is R_3L_1. This combination gives a mean value of 10.1 which is very close to the target value. If there is no difference between the mean value and the target value, we might consider this as an optimal design and therefore, we do not have to adjust control factors based on sensitivities. If there is a difference, it is required to compare the influence of the factors on the S/N ratio and on the sensitivity, and use a control factor or two whose effect on sensitivity is great compared with its effect on the S/N ratio in order to adjust the output to the target.

Table 17.3. Average factorial effects

	η	S
R_1	7.5	24.0
R_2	8.7	21.5
R_3	9.6	18.5

	η	S
L1	9.2	24.5
L2	8.5	21.1
L3	8.1	18.5

17.2 Robust Software Testing

17.2.1 Introduction

A good software [4] should perform its intended function under all combinations of the user conditions. These user conditions are referred to as

active signals and they are used to get the desired output. Examples of the active signals are: inserting the card, punching the personal identification number (PIN) and selecting the desired transaction in case of ATM machine; typing the web-site address, movement of mouse or use of key board for selecting the flight schedules, giving desired price information, *etc*., in the case of airline ticket booking using internet. For the given software the user conditions are unique and they may be very large in number. Usually, the designer tests the software performance under the user conditions separately (like one factor at a time experiments). Even after such tests, the software fails because of the presence of combination effects between the active signals. Therefore, the software designer must study all these effects and take appropriate corrective actions before the release of the software. To estimate these effects, the software should be tested under various combinations of the signals.

The different states of the signal are referred to as the different levels. For a given signal the number of levels may be very high. In the case of the ATM transaction example, the levels for the PIN number may be from 0001 to 9999. If the number such signals is very high, then the number of possible combinations will be in billions. Since it is not feasible to test the software under all the combinations, a procedure is necessary to minimize the number of combinations. This procedure should also be adequate for finding the effects of the signals and their combinations. Here we describe such a method that is developed by using the principles of robust engineering. The objective of this procedure is to obtain all possible two- factor effects by conducting all most the same number of experiments as in the case of one- factor at a time experiments. Since in most cases higher order effects (higher than the second order) are not important, it is sufficient to test only the two-factor effects.

17.2.2 Robust Engineering Methods for Software Testing

In this section, we will explain how the robust engineering methods [4] can be used for testing a software. This method of testing considers all the active signals. The important principles of robust engineering for software testing are as follows:

1. Measurement of the performance of the software under different combinations of the user conditions/active signals.
2. Use of orthogonal arrays to study two factor combinations.

Since there will be several levels of usage conditions, it is adequate to limit the number of levels to two or three. These levels should be selected in such a way that the entire spectrum of usage conditions is covered. Usually, the levels can be selected as low, middle, and high. Figure 17.4 is a *p*-diagram that shows the typical software testing arrangement used this approach. In Figure 17.4, the noise factors correspond to the hardware conditions for the software. For the ATM example, the noise factor is the condition of the ATM machine (old or new). Noise factors are not necessary for all software testing applications and hence this is shown in dotted box.

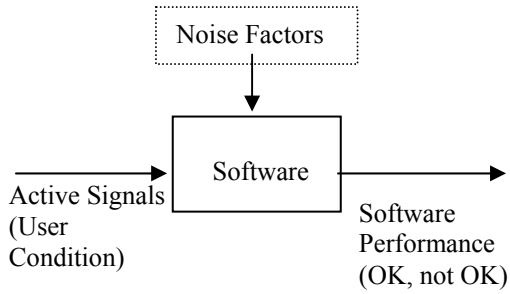

Figure 17.4. p-diagram for software testing

17.2.2.1 Role of Orthogonal Arrays

The purpose of using orthogonal arrays in the robust design or the design of experiments is to estimate the effects of several factors and required combination effects by minimizing the number of experiments. In the case of software testing, the purpose of using the OAs is to study all two-factor interactions with a minimum number of experiments. In fact the number of combinations with OAs is almost equal to the number of experiments to be conducted with one-factor-at-a time.

Let us suppose that there are 23 active signals, 11 with two levels and the remaining 12 with three levels. If we want to study all the two-factor combinations, the total number of experiments in this case would be the following.

The number of two level factor combinations = 4 x $({}^{11}C_2)$ = 220.

The number of three level factor combinations = 9 x $({}^{12}C_2)$ = 594.

The number of two-level and three-level factor combinations = 6 x 11 x 12 = 792

Total	1606

Depending on the number of signal factors and their levels, a suitable OA is selected. For this example, if a suitable OA is used the number of combinations to be run would be 36. The OAs are typically denoted as L_a (2^bX3^c). Where L denotes the Latin square design, a is the number of runs (combinations), b is the number of two-level signal factors and c is the number of three-level signal factors. The array to be used for this example is L_{36} ($2^{11}X3^{12}$).

17.2.3 Case Study

This method of software testing can be best explained with the help of following study conducted by Masahiko Suginuwa and Kazuya Inoue of Omron Company in Japan.

The software performance was required to be analyzed with 23 signals. These signals were numbered as A, B, C, U, V, W. For these factors suitable levels were selected. Table 17.4 shows some of the signal factors with chosen levels.

Table 17.4. Signal factors and number of levels

Signal	A	L	M	N	O	P	B	.....	W	K
#of levels	2	3	3	3	3	3	2	.....	3	2

The factors A, B, C, ..., U, V, W were assigned to the different columns of an L_{36} orthogonal array as described before. The results of the 36 combinations are shown in Table 17.5.

Table 17.5. Results of the different combinations of L_{36} array

Expt.no	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
Response	1	0	0	0	1	1	0	1	0	0	1	1	0	0	0	0	0	0

Response	0	0	0	1	0	1	0	0	0	0	1	0	1	0	0	0	0	0

0: Performance OK
1: Performance not OK

17.2.3.1 Analysis of Results

With the help of the results of Table 17.5, the two-way combination tables were constructed. As mentioned before, for the signals in the L_{36} array, the total number of two-way tables is 253. Out of all two-factor combinations, only two combinations were considered important, as these had 100% errors. These combinations are K2W1 and $Q1S1$. These combinations are shown with arrows in Table 17.6. The combinations of K and W and Q and S are shown separately in Tables 17.7 and Table 17.8.

Table 17.6. Two-factor combinations

	B 1	B 2	..	C 1	C 2	..	D 1	D 2	..	S 1	S 2	S 3	..	W 1	W 2	W 3

Q3	1	1	2	4
Total	6	2	2	10

17.2.3.2 Debugging of Software

After identifying the significant combination effects, suitable corrective actions were taken. After taking the corrective actions again 36 runs of the L_{36} array were conducted. It was found that in these runs all the responses were 0's indicating that there were no bugs in the software

From the above discussions, the steps required to test software can be summarized as follows:

1. Identification of active signals and their levels.
2. Selection of a suitable OA for testing.
3. Conducting the test for different combinations of an OA.
4. Constructing the interaction tables.
5. Identification of significant interactions (by counting the number of 1's).

It should be noted that this method helps in reducing most of the bugs in given software. In some cases, even after applying this method the software may still have a few bugs because of the presence of higher order effects. Even if the number of active signals is very high, orthogonal arrays of higher size can be constructed to accommodate the signals.

Acknowledgements

The authors would like to thank Genichi Taguchi for allowing them to use his case studies in this chapter. They also would like to thank him for his tireless efforts to train industry people and explain the importance of robust engineering concepts.

Integrating a Continual Improvement Process with the Product Development Program

Vivek "Vic" Nanda

Motorola Inc, 101 Tournament Drive, Horsham, PA 19044, USA

Abstract: The focus of this chapter is on the definition of a quality management system, deployment of the system, and continual quality improvement. The chapter describes a step-by-step process for defining a quality management system from scratch, provides guidance on training and facilitating deployment of the quality management system, and provides an overview of various mechanisms that can be leveraged for continual improvement of the quality management system after deployment.

18.1 Introduction

In recent times, while much work has been done and reported in the literature for developing process management infrastructures [1], defining product improvement mechanisms [2], and describing quality assurance engineering activities in a project [3], there appears to be a lack of succinct overview literature providing guidance on the establishment of a self-improving project based continual improvement process. Such a continual improvement process is one which leverages the standard product development process of an organization, tailors it for a project, monitors execution of the process in the project and then leads to empirically driven improvements in the organization's standard product development process. The focus of this chapter is on the definition of a quality management system, deployment of the system, and continual quality improvement.

18.2 Define a Quality Management System

18.2.1 Establish Management Commitment

First and foremost at the beginning of any improvement effort in a quality "conscious" organization is the establishment of management commitment, perhaps best exemplified by the identification of an executive sponsor who is accountable for providing the resources and establishing a vehicle to champion the establishment and continual improvement of the corporate quality management system (typically, the quality steering committee). It is not coincidence that "management responsibility" figures as the first element of the ISO-9001 quality standard [4] or as the first common feature: "commitment to perform" of all CMMi key process areas [5]. Sustained management commitment is key if any quality improvement initiative in an organization is to bear fruit.

18.2.2 Prepare a "Project" Plan

While the usage and continual improvement of an organization's quality infrastructure is an "ongoing" activity and becomes an inherent part of the product development process, the initial effort though is best implemented as an identified capability initiative. This means, launching a project with clearly identified objective(s) and scope, committed resources, identification of roles, and finally, specification of project phases (high level as a minimum) with associated milestones. Equally important is agreement on a "vision" for the quality system and its communication through the project plan. This predominantly relies on the selection of a quality model for usage by the organization, *e.g.*, ISO 9000 [4], CMMi [5]. The organization may also choose to select one model to set up the essentials of a sound quality management system and then graduate to a more rigorous model for increased maturity. A discussion on the relative strengths/weaknesses of one model relative to the others is beyond the scope of this chapter.

18.2.3 Define the Quality Policy

The definition of the system starts at the very top, by documenting the organization's quality commitment in the form of a "quality policy": the statement against which the quality management system is eventually assessed for adequacy and effectiveness.

18.2.4 Establish a Process Baseline

Establishing a process baseline, descriptive as opposed to prescriptive, is a fundamental activity at this stage. This involves mapping the overall product development process as a prerequisite. The task is simplified if the process is bounded as an end-to-end process (commencing at requirements from customer and ending at product delivery) and considering how the organization functional groups (and underlying processes) interact at this macro level [6]. It is also helpful to logically group and map the processes as per their "type":

- management processes,
- operative processes, and
- support processes.

This process map, preferably just a single chart, should identify the standard critical milestones (on phase completion, *e.g.*, end of project planning and definition phase) and the decision points for senior management review of the program and authorization of product release (typically, alpha release, beta release and final release [7]). The process map should also generally respect the time frames when a process starts or ends, although accurate time scaling is not required and not possible (because the standard process would have to be tailored for individual projects as per their unique characteristics [8]). The importance of defining this high-level process map should not be overlooked, it is to serve later as the process "containers" that are populated in the process baselining exercise when the processes are logically grouped and anchored in the appropriate process containers.

Process baselining is best accomplished by involving the practitioners in a "participative" project phase as opposed to processes being defined by a "process expert" in isolation. This is the time for demonstrating the previously pledged cross-functional commitment to the quality improvement initiative. Moreover, cross-functional participation in process definitions and reviews helps secure the buy-in by the various stakeholders and reduces "resistance to change" barriers in the deployment phase. Notice the use of the word "change", it was earlier recommended in this chapter to document descriptive (what is done) as opposed to prescriptive (what should be done) processes. At the same time, it is very likely and appropriate that the practitioners would like to incorporate minor incremental improvements to the processes due to observed deficiencies from their own work experiences. Also, the existing process may have to be updated to comply with the organization's chosen quality model's requirements. However, major rework of the processes is discouraged and unexpected at this stage, that would fall in the ambit of business process re-engineering and is beyond the scope of this chapter. Care should be taken to avoid creating

unnecessary "fat" (in terms of number of process definitions) and instead, focus on identifying and documenting key business processes and their interfaces, examples include (but are not limited to): software analysis, design and construction; test process; external and internal change request process; project planning, tracking and risk management process; configuration management; release management; customer call management and emergency provisioning of bug fixes.

Process ownership should be assigned as per the functional group in which most of the process activities are performed and process owner responsibilities for defining, monitoring and continually improving the process should be specified. The documentation of process definitions should be done using a common template containing pertinent process information. It should also be ensured that the documented processes are consistent in regards to deliverable "handshaking" and use of terminology.

Once all the processes have been identified and defined, the initially defined process map can be enhanced to map out all the individual processes and their interfaces to show the detailed process architecture. This detailed map can also serve as an excellent tool during subsequent process analysis and determining process bottlenecks.

18.2.5 Capture Process Assets

Although defining the business process involves much of the work during this stage of the development of the quality management system, there are other equally important elements that need to be defined as well: the organization's process assets [5]. For example, deliverable templates, quality glossary, best example documents, user guides, guideline documents, checklists and others.

These need to be readily accessible and centralized process assets library, as for instance required by CMMi maturity level 3 key process areas. A very relevant, but still evolving, approach that may be adopted is that of knowledge management. Knowledge management may be defined as the collective knowledge (including experience, skills, data and information) of an organization. It includes knowledge that resides internally as well as knowledge selectively acquired from external sources for improvement of the organization [9]. Thanks to the internet age, today the "corporate intranet" is a very good candidate to be used as a vehicle for knowledge management.

18.2.6 Establish a Metrics Program

Last but not least, a metrics program needs to be established for project, process and product measurements, preferably based on the goal-question-metrics (GQM) methodology [10]. Metrics are not only essential to monitor (define-measure-correct/control) and improve (define-measure-analyze-improve) a quality system but also help substantiate claims of quality improvement by quantifying benefits and help ensure continued senior management support. A discussion on the essentials of a sound measurement system is beyond the scope of this chapter, however, Daskalantonakis's reported work on the software measurement initiative at Motorola is recommended [11].

18.2.7 Define the Continual Improvement Process

With all the essential components of the quality management system defined, the key to deploying the infrastructure is the identification of the continual improvement process[1] of the organization. While this may not be a process definition *per se*, yet it is central to the success of the quality management system because it specifies how the various elements of the quality system interact to form a comprehensive support process. Note that the formality and rigorousness of an organization's continual improvement process varies depending on the duration of the product release cycle and nature of application: applications with longer lead time (say, greater

[1] The underlying fundamentals of quality process are based on measuring, analyzing, controlling/stabilizing and/or improving a process, and they can thus be substituted by other similar activities, as for example in the Six Sigma approach [12].

than nine months) and/or high degree of complexity (*e.g.*, mission critical software) typically lie at the higher end of the continual improvement process maturity spectrum. A recommended example of an organization's continual improvement process is as follows:

At the start of a project, the project team needs to proactively identify the planned deviations (and rationale) from the quality system processes and standards (process assets) and mechanism for requesting and approving process deviations after the start of the project. This exercise, called process tailoring, is based on the premise that "the one process fits all" approach to software engineering does not work, and an organization's standard software development process must be tailored to accommodate the unique characteristics and requirements of individual projects, after all no two projects are alike. Benefits of performing process tailoring and a recommended method are described in [8].

Once the project specific process has been defined as a result of this exercise, the project's software quality assurance plan can now be produced to describe: the planned quality assurance, control and management activities for the project. These include, specifying:

a) Quality objectives for each product release (alpha, beta and final release)[2], *e.g.*, product capability criteria in terms of number and severity of latent defects allowed at release; quality of product documentation at release; performance, reliability, and installability criteria for release, and confirmation of organizational preparedness to support the product after release.
b) Types of reviews planned for various project deliverables.
c) Types of testing planned (unit, system, independent, certification, performance testing).
d) Project metrics;.
e) Project and product audits planned, and so on.

A good example to refer to is the IEEE standard for software quality plans [13][3].

Once the project quality plan has been prepared and other project plans based on the project specific process have been defined, project execution is initiated. From a quality management standpoint, it involves ensuring project team peer reviews of project deliverables (degree of formality may depend on deliverable being review), capturing project metrics at key points (*e.g.*, defect fault density at alpha, beta, final release), ensuring project teams are on-track to achieve quality objectives defined for a release, product quality review (against predefined objectives) at release by project management team[4], auditing project teams to follow up that defined project plans (*e.g.*, test plans, development plan, *etc*.) are being faithfully implemented and finally performing a post-mortem on project completion to identify lessons learned and opportunities for improvement. These opportunities for improvement need to be reviewed to isolate vital few process change requests from trivial many. The metrics gathered need to be reviewed against the target values that were envisioned for the project and taking appropriate corrective action to address failures. The identified process changes need to be then assigned ownership and piloted in the next project as "capability initiatives". A successful pilot then typically leads to the acceptance of the original process change request as a "process improvement" and updating of the corporate process assets library to incorporate the change.

The continual improvement process described above is pictorially depicted in Figure 18.1.

[2] Obviously, to align with the maturity of the product during its development, stringency of criteria increases from alpha to beta to final release.

[3] Other disciplines of software engineering closely related to the quality management function – configuration management and software testing are excluded from this chapter. A look at the relevant IEEE standards is strongly recommended [14, 15].

[4] Recommended: release authorization by senior management only (typically, "director" level employees).

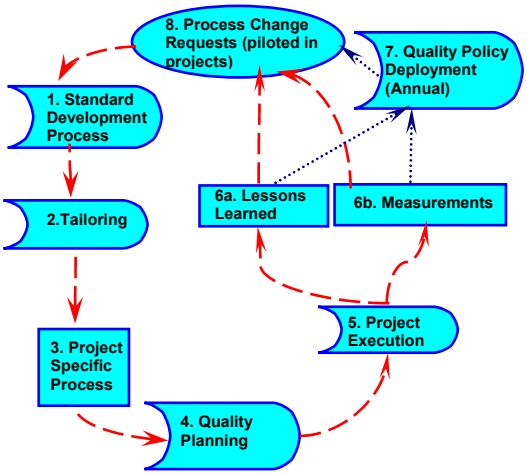

Figure 18.1. The continual improvement process

A word about quality manuals: A documented quality management system without a high level document describing its key elements is incomplete. Typical content of such a manual is: the organization's quality policy, management structure (including steering committee and process owner responsibilities), business processes, continual improvement process, continual improvement mechanisms, and traceability to the chosen quality model. The quality manual provides a brief yet sufficiently detailed overview of an organization's quality management system and is invaluable for both an organization's employees or for registrars, customer audits, and review by potential customers.

18.3 Deploy the Quality Management System

Deployment of a defined quality management system, in the form of formal training for the employees is essential to ensure faithful usage and improvement of the developed system. The training has to be not a one time exercise but ongoing, so as to account for new employees joining the organization or transfers/promotions within the organization and for communicating refinements to the quality management system. While key elements of the quality management system can be delivered as a common set of courses for all employees, much of the training has to be tailored for the employees as per their role within the organization. It is helpful to organize the training primarily on three tracks: management only (line management and process owners), practitioners by functional group (organizational departments) or all employees. The recommended content for the three training tracks is as follows (but not limited to):

a) *Management track*

How does the quality management system satisfy the chosen quality model's requirements; detailed training on the continual improvement process and communication of the organization's continual improvement mechanisms (refer to the "Continual Improvement" section of this chapter).

b) *Practitioner training by functional group*

Training on business process (what to do) the practitioner is part of; procedure level training (how to do it) and communicating relevant process assets of the quality management system.

c) *All employees*

Training on the key elements of the quality management system, for instance: quality policy, process map, purpose and scope of various business processes, structure/content of the process assets library and mechanism for providing feedback from experiential usage to process owners (to facilitate continual process improvement).

The initial analysis for determining the training audience can be done by developing a 2-D grid listing the quality management system elements *vs*. the above mentioned audience tracks[5]. The elements can then be logically grouped by

[5] Note that track 2 has to be decomposed into various sub-tracks by each functional group: *e.g.*, software development, software test, documentation (product manuals), customer support, *etc*.

audience and packaged as formal training courses, preferably starting with relatively brief overview course to increasingly detailed courses.

18.4 Continual Improvement

Continual improvement of an organization's defined quality management system cannot be stand-alone or in isolation from the project lifecycle. The continual improvement process was introduced earlier in this chapter for precisely this reason. Supplementary vehicles for continual improvement are identified below:

a) *Quality policy deployment*

The organization needs to formulate quality related goals over the, say, next three to five years and work towards them by means of formal quality policy deployment mechanisms.

b) *Audits*

The organization needs to leverage quality audits for exploring opportunities for improvement as opposed to compliance auditing [16]. While the project and product audits serve to primarily achieve "in-process control", the system audits are more appropriate for system improvements.

c) Employee suggestions

A mechanism facilitating submission, review and implementation of process improvement suggestions from employees during any project is recommended. This mechanism may be very similar to the one used for reviewing a project's lessons learned on completion. It facilitates in-process control and corrective action and may thus sometimes be advantageous over a post-mortem review.

18.5 Conclusions

This chapter outlines the essential steps for an organization to define and deploy a quality management system and to set up an infrastructure for continual improvement. It integrates the concept of a "continual improvement process" which includes practices to measure, analyze, improve and stabilize a process. The key steps and recommendations described in this chapter to establish a robust quality management system are summarized below for quick reference:

18.5.1 Key Steps and Recommendations

1. Establish management commitment for the company's quality management program and its continual improvement.
2. Execute the quality management system development as a project with set objectives, defined milestones and committed resources.
3. Define overall vision for the quality system with the selection of the guiding model and documentation of the quality policy.
4. Prepare a high-level process map to pictorially depict the business process of the organization along with the critical milestones.
5. Once a high-level process map has been developed and deployed, a finer grained process architecture map should be developed to map out all the processes of the organization. Such a mapping helps to better understand the interplay and relevance of the various business processes and also helps with focus for various quality initiatives, such as, TTM (time-to-market) improvements.
6. Prepare descriptive as opposed to prescriptive process descriptions with minor incremental improvements, if required.
7. Capture organization process assets to complement the defined processes and provide readily accessible "process support" during product development and maintenance. Further, leverage knowledge management concepts for implementing a process assets library.
8. Define a continual improvement process for the organization, *i.e.*, a process with the ultimate objective of driving continual

quality improvements in the development process.

9. Deploy the quality management system by means of executing a formal quality-training program. Such a training qualifies the practitioners to perform their work activities by using the quality management system elements and the QMS can be officially considered "switched on" once this training is complete, in other words, the system is now auditable.
10. Leverage other vehicles for continual quality improvement, such as: quality policy deployment, system audits, and employee suggestions.

Reliability Engineering: A Perspective

Krishna B. Misra

RAMS Consultants, India

Abstract: The most important attribute of performance is reliability and this is defined as the probability of failure free operation over a specified duration of time under a given set of conditions, which depend on location and the kind of application the item is put to. In designing for reliability, the objective must be to maximize inherent and operational reliability such that occurrences of failures are considerably reduced. Component or system reliability goals can be achieved through design and testing. Failures and consequently accidents can be avoided if their causes of can be traced and taken care of during the design process.

19.1 Introduction

The most important characteristic of product performance is reliability and there are several reasons why reliability is more important than before:

- Products are becoming more and more complex and unless reliability is improved, the performance may become inadequate.
- There exists a tough competition between the industrialized nations and only products with high reliability will eventually survive.
- There is a compulsion to minimize waste as the world population grows and the resources keep on shrinking.
- Product longevity implies less world pollution.

19.1.1 Definition

According to IEC definition, reliability is the capability of a product (or a system or a service) to perform its expected job under the specified conditions of use over an intended period of time. Obviously, this definition raises questions like:

- Can this capability be quantified?
- Can this quantification be used with all kinds of products and systems without resorting to any redefinition or modification on a case to case basis?
- Can this capability be used to compare the performance of different engineering designs and technologies for a product or a system and assess their suitability?

As an answer to all the above questions, we can say that if the capability is quantified through probability of satisfactory performance this provides us a very general approach to evaluate

relatively the performance of products and systems. The next important question then arises is: can this capability be engineered into products or systems? The answer is again affirmative and in fact our main concern in reliability engineering is to engineer reliability into products, equipment and systems.

Implicit in the IEC definition of reliability are three components, *viz.*, *probability* of *adequate operation,* over a *specified time* and under the *specified conditions of use.* These components need an explanation.

Adequate operation signifies that a failure of a product (or a system) does not necessarily constitute complete cessation of its operation, but it only represents that the product or the unit is not functioning within the intended bounds of performance or is not *operating satisfactorily*.

Mission time: is the *specified time* in the definition and can also be called *mission time.* Without specifying mission time, a figure of reliability has no meaning since reliability is dependent on mission time and decreases with the increase in length of mission time. The duration of mission time depends on the design objectives of a system and it is this length of time over which the system should not have any failures at all so that the desired mission of the system can be carried out successfully without being impaired or aborted. The choice of mission time exclusively depends upon the objective of the system.

Conditions of use basically refer to the *environmental conditions* under which the product or the system has to operate. In fact, the performance of a product can be adversely affected by these environmental conditions. Thus reliability is always dependent on specified environmental conditions. If there is a departure from the specified conditions; the intended level of performance of the product or system cannot be ensured and there is a risk that the product might even transit to a degraded performance level or even to a failure.

Further, the conditions of use render reliability engineering a challenging task. It can aptly be handled through indigenous know-how, experience and experimentation as the conditions of environment may vary considerably from place to place depending upon the geographical location.

A checklist of environmental factors that the reliability engineer may be face while designing his system is given in Table 19.1. There are two types of factors, *viz.*, *natural* and *induced*.

Table 19.1. Environmental factors that influence reliability

Natural	Induced
Electromagnetic-radiation	Acceleration
Electrostatic-discharge	Chemicals
Frost	Corona
Fungus	Electromagnetic-radiation
Gravity	Electrostatic-discharge
Humidity	Explosion
Lightning	Moisture
Pollution, air	Nuclear radiation
Pressure, high, low,	Shock, thermal
Vacuum	Space debris
Radiation, cosmic,	Temperature: high,
Rain	low,
Salt spray	Turbulence
Sand and dust	Vapour trails
Snow	Vibration:
Temperature	Mechanical ,
Wind	Vibration: acoustic

Each environmental factor requires determination of its impact on the operational and reliability characteristics of materials and parts comprising the system. This includes operational and maintenance environments as well as preoperational environments, when stresses imposed on parts during manufacturing assembly, inspection, testing, shipping and installation may have a significant impact on equipment reliability. Very often more than one environmental factor may be acting on parts or equipment. These combined or concurrent environments may be more detrimental to reliability than the effects of these single environments separately. For example, equipment may be exposed to a combination such as temperature, humidity, altitude, shock, and vibration, while it is being transported. Moreover, the superposition of effects of individual

environmental factors cannot predict the resulting influence that a combination of environmental factors will have on the reliability or performance of the equipment. In fact, the severity of the combination may be much more than individual effects added together. For example, the percentage of failures caused by temperature may be (40% of all failures) vibration (24%) and humidity (19%). Sand and dust (6%) and salinity (4%) but humidity combined with temperature can cause 75% of all failures. Humidity with a salty air environment (as may be common with coastal regions) can be a major cause of degradation of equipment performance since they promote corrosion effects in metallic components besides leading to the formation of surface films on non-metallic parts. Moisture absorption by insulating material can also induce conductivity and a dissipation factor of these materials. As pointed out earlier, the effects cannot be linearly extrapolated if two environments act simultaneously upon a product or a system. Sometimes, sudden changes of temperature may also induce a large amount of internal mechanical stresses in structural elements, particularly, when dissimilar materials are involved. The effect of thermal shock-induced stresses include cracking of seams, delamination, loss of hermeticity, leakage of fill gases, separation of encapsulating materials from components, and enclosure. Natural frequencies of items comprising equipment must also be considered in the design phase, since a resonant condition may greatly amplify subsystem deflection and may increase stresses beyond safe limits. A vibration environment can create relative motion between members and when combined with other environmental stresses, this motion can produce fret corrosion.

Therefore, in order to ensure reliability, environmental testing should form an integral part of performance demonstration. In fact, experimentation on the basis of actual environments envisaged acting upon a product or a system must be carried out or investigated into before finalizing a product design. An environmental stress test is commonly employed during the product design and development stage. For products that are in use over a long period of time, an accelerated life test is usually done in by shortening the time-to-failure by increasing the severity of loading that the product is supposed to bear under normal conditions in order to obtain meaningful results on reliability characteristics. For instance, electronic components may be tested at elevated temperatures in order to hasten the incidence of failures. Likewise, steel pipes used in nuclear power plants may be exposed to neutron irradiation that can increase the brittleness of steel causing brittle failure. However, overstressing is done to the extent that it does not change the product failure mode and mechanisms.

19.1.2 Some Hard Facts About Reliability

There are, however, certain notions that need to be clarified to a beginner in this area.

19.1.2.1 Death Is a Certain Event

Birth and death are certain events of life. This also applies to all man-made objects. It is a universal fact that anything that is born must die some day. Certainly in reliability, we do not or cannot eliminate natural death. A natural death is not considered as an undesired event in reliability but cessation of activity or function during the mission time is certainly an undesired event and is what we call a *failure* in reliability terminology. Our prime concern in reliability engineering is, therefore, to prevent failure of an item during its mission time and not outside it.

19.1.2.2 Failures Are Inevitable

Since, as mentioned earlier, it is not possible to eliminate failures completely, in reliability engineering we aim to prevent them as far as possible and to contain their influence on the functioning of system, if they do occur.

19.1.2.3 100% Reliability Is Impossible

A 100% reliability is possible only when a product or unit never ever fails. Whatever be the mission time, reliability can never be 100%. (Except theoretically, if mission time is zero, *i.e.*, we do not use it at all.) It can approach asymptotically to

unity and can be close to unity, *i.e.,* 0.999…9 but it can never be unity. Until there is a single chance of failure (or death, which is a certainty), reliability can never be unity.

19.1.2.4 The Instant of Failure Is Unpredictable

The instant of failure cannot be predicted. No mathematical equation or theory exists that can do this. The occurrence is just a chance or a random event. Therefore, it should be clear in our minds that the theory of reliability cannot predict the exact instant when a product or a system will fail. One should not hurriedly infer from this statement that reliability theory is imprecise but rahter only supports the statement that failures can occur any time and are random in nature.

19.1.2.5 Uncertainty of Results

Statistical and probabilistic methods are used for analyzing failure data, quantifying reliability during the prediction, measurement and testing phases. However, on account of the high level of uncertainty involved at various levels in the process, these can hardly be applied with the kind of precision and credibility that engineers are accustomed to when dealing with most other engineering problems. However, the mathematical and statistical methods in reliability analysis in fact allow us to have an idea of the uncertainty present.

19.1.3 Strategy in Reliability Engineering

The prioritized objectives of reliability engineering are:

- To apply engineering knowledge to understand and anticipate the possible causes of product or system failures and to take adequate measures to prevent them from occurring.
- To identify and check the failure mechanisms, which eventually lead to failures.
- Explore the ways of reducing the likelihood or frequency of failures despite the efforts to prevent them.
- To apply methods for estimating the reliability of new designs, and for analyzing reliability data with a view to improve future designs.

Basically, reliability engineering is the first and foremost application of good engineering, in the widest sense, during design, development, manufacture, and use.

19.1.4 Failure-related Terminology

There are several terms in vogue in reliability engineering, which should be defined to avoid confusion and for clarity of understanding.

Defect: A defect is the departure of a characteristic of an item from requirement.

Fault: A fault is the state of an item characterized by its inability to perform a required function.

Error: An error is a discrepancy between a computed, observed or measured value or condition and the true, specified or theoretically correct value or condition.

Human error: This is a human action that produces an undesired result or consequence.

Bug: A bug is a software defect.

Failure: A failure is the cessation of the ability of an item to perform a required function.

However, a failure, in reliability engineering, has a wider connotation, which not only includes death but also the inability of an item to perform adequately over the mission time. Thus the definition of failure has been related to the level or quality of the desired performance. For example, if an electric power company guarantees that the voltage within the premises of a consumer shall be within ± 5% of the rated supply voltage, its failure to keep the supply voltage within these limits shall be construed as a failure of power supply. A failure here not only implies that no electric power is available but also an inadequate level of supply voltage. This broad definition of failure permits us to quantify the performance of a product vis-à-vis the expected level of performance.

Failure mechanism: A failure mechanism is a physical, chemical, thermal or metallurgical process that causes component characteristics to change beyond tolerance, which eventually leads to

a certain mode of component failure. Typical failure mechanisms can be electromigration, thermal instability, electrostatic field, corrosion, fatigue, *etc*.

Failure mode: A failure mode is the visible or observable effect by which a component failure is identified. A component can fail in more than one failure mode.

The examples are short circuit or open circuit mode of failure or degraded performance of electronic devices such as capacitors, diodes, *etc*., or valves stuck open or stuck closed in mechanical devices.

Several failure mechanisms may exist simultaneously at a point of time, eventually leading to a failure of a component in a particular mode. Two or more same failure mechanisms can lead different failure modes. All failure modes are known as *primary failures*.

Dependent Failures: When the failure of a component changes the operating stress on other components of a system, dependency exits and this increases the failure probability of other components.

Common mode of failure: This is a single failure mode that results into simultaneous failure of several components.

19.1.4.1 Types of Electrical Failures

Electronic or electrical components may fail in any of the following modes [54]:

- *Short circuit:* Diodes, transistors, capacitors may often fail in this mode.
- *Open circuit*: Resistors, crystals, *etc*. may often fail in this mode.
- *Degraded performance:* SCRs and capacitor aluminium may fail in this mode.
- *Functional failure:* Coils and relays may often fail in this mode.

In fact the relative frequency of occurrences of these failure modes can be different for different component types and these failure modes and their relative frequencies should be considered for a particular type of application of a component during the design of a system using these components. This makes reliability design a challenging task.

19.1.4.2 Types of Mechanical Failures

Depending upon the type of stress, the usual modes of failure in mechanical components [75, 88] can be enumerated as follows:

Material failures: This type of failure mainly occurs due to poor quality checks, fatigue cracks, weld defects, and small cracks and flaws. These defects actually reduce the allowable material strength and consequently lead to premature failure at the flawed spots.

Metallurgical failure: This failure is the result of extreme oxidation or operation in corrosive environment. Environmental factors such as heat, nuclear radiation, erosion, and corrosive media accelerate the occurrence of metallurgical failures. These are also referred as material failures.

Stress concentration failure: This type of failure occurs when uneven stress "flow" through a mechanical member. Usually, the concentration of stress occurs at sudden transitions from thick to thin gauges, at sudden variations in loading along a structure, at right-angle joints or at various attachment conditions.

Compressive failure: This failure occurs under compressive loads. The compressive failure often results in permanent deformation/cracking/ rupturing.

Bearing failure: This type of failure is similar in nature to the compressive failure and it usually occurs due to a round cylindrical surface bearing on either a flat or a concave surface like roller bearings in a race. The repeated loading may cause fatigue failures.

Tensile-yield-strength failure: This failure occurs under pure tensile stress, especially, when the applied stress exceeds the yield strength of member. Usually, it results in permanent deformation in the structure or a permanent set and is rarely catastrophic. The value of safety factors for this kind of failure could be as low as 1 (*i.e.,* design to yield) or 4 or 5 for pressure vessels and bridges.

Ultimate tensile-strength failure: This leads to a complete failure of the structure at a cross-section

and occurs only when the applied stress is greater than the ultimate tensile strength. The values of safety factors for this kind of failure may be as low as unity (*i.e.,* design to fail) or 5 or 6 for pressure vessels and bridges.

Bending failure: This failure occurs when one outer surface is in tension and the other surface is under compression and may therefore be referred as *combined failure.* The tensile rupture of the outer material is a representative of the bending failure.

Fatigue failures: Repeated cycling of the load causes metal fatigue. It is a progressive localized damage due to fluctuating stresses and strains on the material occurs mainly due to repeated loading or unloading (or partial unloading) of an item. The process consists of three stages, *viz.*, crack initiation, progressive crack growth, and finally sudden fracture of the remaining cross section.

Instability failure: This type of failure occurs in structural members such as columns and beams, particularly those manufactured using material where the loading is usually in compression. However, instability failure may also result because or torsion or by combined loading, *i.e.,* including bending and compression. Usually this type of failure is crippling or leads to a total failure of the structure. Experience indicates that a safety factor value of 2 is usually sufficient but a factor of less than 1.5 should not be used.

Shear loading failure: The occurrence of ultimate and yield failure takes place when the shear stress becomes greater than the strength of the material when applying high torsion or shear loads. Usually, these failures occur along 45^0 axis in relation to the principal axis.

Creep failures: Usually, long-term loads make elastic materials stretch even when they are stressed less than the normal yield strength of the material. The material stretches (creeps), if the load is maintained continuously and ultimately results in a rupture. Working at high temperatures accelerates creep.

Corrosion failures: Corrosion is a chemically induced damage to a material that results in deterioration of the material and its properties. This may result in failure of the component. Several factors should be considered during a failure analysis to determine the effect corrosion has played in a failure. For example, the type of corrosion, the corrosion rate, the extent of the corrosion, and the interaction between corrosion and other failure mechanisms.

Multiple failure modes: In fact, a single mechanical member can fail in various different modes of failures. For example, the gear is one of of the important and common components in mechanical equipment and the experience shows that amongst the various causes of gear failure**,** breakage (61.2%), surface fatigue (20.3%), wear (13.2%), and plastic flow (5.3%) are quite common.

19.1.5 Genesis of Failures

There can be several reasons why a product fails. Knowing the potential causes of failures is essential to prevent them. It is rarely possible to anticipate all causes of failures; therefore it is necessary to concentrate on the uncertainties involved in the reliability engineering effort during design, development, manufacture, and use. All the anticipated and possibly unanticipated causes of failure should be addressed to ensure that their occurrence is prevented or minimized. Broadly speaking, failures can occur if:

- The design is inherently weak. The list of possible reasons is endless, and every design problem presents the potential for errors, omissions, and commissions. The more complex the design, the greater is this potential!
- The stress applied exceeds the strength. Overstress failures can occur in spite of designers having provided some margin of safety. Electronic component specifications prescribe the maximum rated conditions of application, and circuit designers ensure that these rated values are not exceeded. In other words, they derate the component by ensuring that the stresses in worst conditions of use remain below the rated stress values. In the same way, mechanical designers know the properties of the materials being used (*e.g.,* ultimate tensile strength) and they ensure that there is an adequate margin of

safety between the strength of the component and the maximum applied stress. However, it is not possible to provide protection against every possible stress application, because failures in most cases can also be caused by variation in stress and strength values; there always exists some uncertainty about them. In fact, this allows us to define reliability in terms of the stress and strength distributions considering that they are random variables. To illustrate how the probability of failure can be computed from the knowledge of distributions of stress and strength, let us assume that the stress applied to a member is normally distributed with a density function $f_{\mathbf{s}}(\mathbf{S})$ with mean and variance given by $\mu_{\mathbf{S}}$ and $\sigma_{\mathbf{S}}$, respectively, and for the sake of simplicity, let us further assume that the strength of this member is determined from some non-destructive test and is determined to be S_1 – a fixed value. Obviously, the member can fail only if the stress is greater than the given strength, *i.e.,* S_1. This would mean that the probability of failure, Q is given by

$$Q \equiv P(\mathbf{s}>S_1) = \int_{S_1}^{\infty} f_{\mathbf{s}}(\mathbf{s})\, \mathrm{d}s, \qquad (19.1)$$

or the reliability of this member or unit would be:

$$R \equiv 1 - Q = 1 - \int_{S_1}^{\infty} f_{\mathbf{s}}(\mathbf{s})\mathrm{d}s = \int_{-\infty}^{S_1} f_{\mathbf{s}}(\mathbf{s})\, \mathrm{d}s = P(\mathbf{s} \le S_1)$$

The definition (19.1) provides unreliability of a component when the component has a known value of strength S_1 and is invariant. However when the variability of both stress and strength is considered, the probability of failure of the component is dependent on the area of overlap between the stress and strength distributions. Larger the area of overlap, higher is the probability of failure of the member. Now let us assume both stress and strength are variable and **s** and **S** represent the stress and strength random variables, respectively. Also the location parameters for their distributions are s_1 and S_1 for stress and strength, respectively. Therefore, the probability density functions for the stress would be given by:

$$f_{\mathbf{s}}(\mathbf{s}) = \frac{\alpha_{\mathbf{s}}}{\beta_{\mathbf{s}}}\left(\frac{\mathbf{s}-s_1}{\beta_{\mathbf{s}}}\right)^{\alpha_s - 1} \exp\left[-\left(\frac{\mathbf{s}-s_1}{\beta_{\mathbf{s}}}\right)^{\alpha_{\mathbf{s}}}\right],$$

where, s_1 is the location parameter and $\alpha_{\mathbf{s}}$, $\beta_{\mathbf{s}}$ are the shape and scale parameters for the stress distribution.

Similarly, the probability density function for strength can be

$$f_S(S) = \frac{\alpha_S}{\beta_S}\left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S - 1} \exp\left[-\left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S}\right], \quad S_1 \le S < \infty$$

where S_1 is the location parameter and $\alpha_s \beta_s$ are the shape and scale parameters for the strength distribution. Therefore, the probability of failure Q would be given by:

$$Q = P\{S < s\} = \int_{-\infty}^{\infty} [1 - F_s(S)] f_S(S) dS \qquad (19.2)$$

$$= \int_{S_1}^{\infty} \exp\left[-\left(\frac{S-s_1}{\beta_s}\right)^{\alpha_s}\right] \frac{\alpha_S}{\beta_S}\left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S - 1} \exp\left[-\left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S}\right] ds$$

If we substitute

$$\delta = \left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S}, \text{ then } d\delta = \frac{\alpha_S}{\beta_S}\left(\frac{S-S_1}{\beta_S}\right)^{\alpha_S - 1} dS$$

and $S = \delta^{\frac{1}{\alpha}} S\beta_S + S_1$, we obtain $R = 1 - Q$, where

$$Q = P\{S < s\} = \int_0^{\infty} e^{-\delta} \exp\left[-\left\{\frac{\beta_S}{\beta_s}\delta^{\frac{1}{\alpha_S}} + \left(\frac{S_1 - s_1}{\beta_s}\right)\right\}^{\alpha_S}\right] d\delta$$

The integral in the above expression can be computed through numerical integration for various combinations of the parameters of stress and strength as suggested in [103]. Also, it is easy to realize that one can compute Q for various combinations of distributions for stress and strength (other than Gaussian) such as exponential, Weibull, lognormal or extreme value distributions following the same procedure. This approach, which may provide closed form expressions in some cases whereas in other cases numerical integration may have to be carried out, is generally used for

computing probability of failure of mechanical and structural members. For a more detailed discussion of the various cases, the reader is referred to Chapter 4 of [103]. Some other approaches such as that in [132] have also been proposed.

- The actual strength of any population of components varies and there are bound to be some that are relatively strong, others that are relatively weak, however a majority of them will have average strength. The applied loads can also vary. Here again the failure will not occur as long as the applied load does not exceed the strength or in other words, a high value of safety factor is used. However, if there is an overlap between the distributions of load and strength, and a load value in the high tail of the load distribution is applied to an item in the weak tail of the strength distribution so that there is overlap or interference between the distributions, then the failure will definitely occur.
- Failures can also be caused by wear out due to any mechanism or process that causes an item that is sufficiently strong at the start of its life to become weaker with the passage of time. Examples of such processes are material fatigue, wear between relatively moving surfaces that are in contact, corrosion, insulation deterioration, and the wear out mechanisms of light bulbs and fluorescent tubes. Initially the strength is adequate to withstand the applied loads, but as time passes weakening occurs and the strength decreases. In every case the average value falls and the spread of the strength distribution widens. This is also the reason why it is difficult to provide an accurate prediction of the lives of such products.
- Failures can also be caused by time-dependent mechanisms. Examples of such a mechanism are creep caused by simultaneous high temperature and tensile stress, as in turbine discs and fine solder joints, battery run-down, and progressive drift of component parameter values. Again the interested reader is referred to [103] for the time dependent cases.
- Other causes of failure can be sneaks. A sneak is a condition in which the system does not work properly even though every part does. Sneaks also occur in software designs..
- There are many other potential causes of failures, such as they can occur on account of errors, incorrect specifications in designs or software coding, or by faulty assembly or tests, by inadequate or improper maintenance, or by misuse.

Therefore, all failures have some cause and by proper anticipation, analysis and application, an engineer can reduce the chances of their occurrence. It is also true that all failures can in principle be prevented by identifying, studying and analyzing them. The O-ring seals on the space shuttle booster rockets were not classed as failures, until the ill-fated launch of Challenger. It is therefore necessary to know more about the reasons for failures and to anticipate them. A reliability engineer must be a hardcore pessimist when it comes to anticipating what can go wrong in a system and take all precautionary or remedial measures against failure but having done so, he should hope for the best and be an optimist.

19.1.6 Classification of Failures

Failures can be classified very broadly based on the causes of failures over the life span of a product. Figure 19.1 shows a typical characteristic of failures over all the three regions of the life span. If the failures occur during the early-life period or what is known as the *infancy period*, they are known as *early-life failures* or *quality failures*. Any substandard item would surely fail during its early life. The responsibility of quality failures, therefore, rightly rests with the manufacturer, as these failures can be attributed to his failure to use the right type of raw material or to control processes and to maintain high quality. As weak or substandard components fail during early life, the hazard rate of the product decreases rapidly. Early-life failures can be eliminated through debugging processes, which consist of operating the product for quite some time under simulated conditions of actual use. This would cause a vast majority of the substandard products to fail in early life and

product hazard rate reaches its lowest point at the end of this period (0-t_E) as shown in Figure 19.1. Beyond the point t_E, the useful life period of the product begins.

The failures that occur during the useful life period are designated as *catastrophic* or *chance failures* and are unpredictable due to their very nature. However, we can always quantify their likelihood statistically. Their rate of occurrence is generally constant during the entire life of a product. It is actually during this useful period of life that a product is utilized to its maximum. The catastrophic failures cannot be eliminated either through good debugging techniques or by the best maintenance practices, because they are caused by sudden stress accumulation beyond the designed strength of the product and can be minimized only by reliability improvement programs. Usually, the hazard rate in the majority of cases can be approximated to be *constant* and the *mean time to failure* can be computed by its reciprocal. An application of a sudden stress in excess of design strength or maintenance induced failures may also exhibit a constant hazard rate pattern.

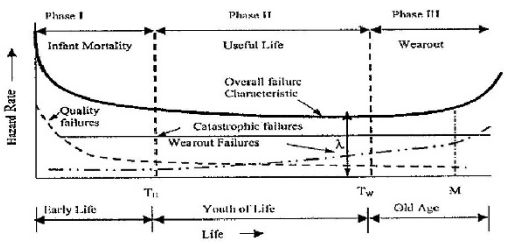

Figure 19.1. Typical bathtub curve

If a product has worked for a sufficiently long period (say 0-t_w in Figure 19.1), wear out sets in due to ageing and the old age effect shows up, causing the hazard rate to increase. Failures during this last phase of life are designated as *wear out failures*. As the time passes, death becomes more and more probable. In products involving mechanical parts, where moving parts are present, the wear out sets in as soon as they are put to use. In fact, the age at which wear out acts depends on the product and the environment under which it is functioning. Wear out failures can be minimized if the product is replaced at an appropriate time. In Figure 19.1, the *mean wear out life* or the *mean life* of product is shown to be (0-M). This, however, should not be confused with the *mean time to failure*, which is the reciprocal of the hazard rate during the useful life period, if the failure distribution is exponential. Moreover, M has to be greater than T_W. The position of M depends on the failure distribution during the wear out period.

19.2 Problems of Concern in Reliability Engineering

In specific terms, the problems that one is concerned about in reliability engineering are:

- How one can extend the useful life of a product?
- How can one minimize the chance failures of a product?
- How can one reduce the initial hazard rate and avoid product failures during its initial period?

The first two problems relate to the design and depend on material selection and the choice of derating and safety factors, with emphasis on prevention, reduction, or complete elimination of chance failures, which considerably improves the reliability in actual use. Here, one is also concerned about the overhauling or preventive replacement of the product during its design life. The third problem concerns the initial or infancy period, which may range from a few minutes to several hundred hours in certain cases. To eliminate the possibility of failures immediately after delivery, manufacturers generally conduct test-runs or debugging tests before delivery to ensure that quality failures have been eliminated and the customer is assured of better product reliability backed by a product warranty.

Since failures can occur any time during the lifetime of a product, reliability [103] can also be called a *birth-to-death* concern. Starting with preproduction activities like procurement of raw material and parts, preparing a conceptual design and detailed engineering design, the product passes through production, test and quality control,

shipment, warehouse storage and finally goes through use and maintenance phase before being discarded at the end of its life.

Quality and maintainability are the activities aimed at improving the reliability of the equipment during manufacture and operation and maintenance phase of product life. Truly, a reliability management program necessarily concerns itself with improving the reliability of a product, right from conception to disposal.

One of the measures of reliability of a product over its entire life period is designated as *operational reliability* (R_o), which can be expressed as a product of *inherent reliability*, (R_i) and the *use reliability* (R_u)*, i.e.,* $R_o = R_i.R_u$. Inherent reliability is what is built into a product during the design and manufacture phases. We cannot expect better reliability of a product than what we build into it during these phases. Within the resources available, a reliable design should use all possible means, such as structural redundancy, derating, safety, environmental factors, *etc.,* for improving product reliability. Having prepared the best possible engineering design, we can still lose on inherent reliability, if we ignore the necessity of stringent quality control during the manufacture. Quality in its simplest interpretation is reliability during the manufacturing phase and it ensures that only proper materials, processes and quality control techniques have been used.

Further, the conditions of use, maintenance and environment often affect the *use-reliability*. In fact, *maintainability* can be considered as reliability during operation and maintenance phases. Unless proper packaging, instructions for storage, shipment and use, operating manuals, maintenance procedures, spare parts, training of maintenance personnel, and conditions of environment are prescribed, it is meaningless to expect a high value of use reliability.

19.2.1 Reliability Is Built During the Design Phase

It has been estimated [144] that 80% of poor quality is caused by design. Over 90% of field failures are the result of poor design, and a high percentage of product recalls have their origin in design. Most law suits are filed on account of improper design and 70–75% of product costs are functions of design. Therefore, if there is any phase in the entire life cycle of a product that has maximum impact on reliability, it is the design phase.

Once a product has been conceived and functionally designed, a designer begins with product design from the performance consideration, which is not a straightforward process. It is an art based on the application of science. Analytical methods help only to select an alternative design or technology; thereafter the process is iterative and repetitive until the specified performance goals have been achieved. Design requires ingenuity and creativeness, and a designer ought to know what has been already tried before and did not work. Generally, a new prototype is not built because the designer knows that it will work better that way, but because he has no reasons why it will not work until it has been tried out.

In order to design reliability into a product, reasons for product failures must be clearly understood. Generally, a product fails prematurely because of inadequate design features, manufacturing and parts defects, abnormal stresses induced during packaging or distribution, human and maintenance errors, or external conditions (environmental or operating) that may exceed the designed values. Usually at the design stage, only rough reliability estimates on components reliabilities are available. The accuracy of these estimates depends upon how much data or information was available to the analyst, and on his ability to use this information or data to improve upon the product. The severity of the environment under which the system is to function must also be considered. As the design progresses, more details usually become available and at that stage it is possible to refine both the apportioned goals and the reliability estimates. In the end, the final estimates are based on the analysis of a detailed design, which incorporates failure rates of all components and parts, and the results of all developmental, qualification, and acceptance tests. The failure rates used in the estimates should be the measured failure rates of the components used in the system.

Inadequate attention to the design effort may result in faulty hardware, and retrofits rarely compensate for the original faulty design and may even be quite costly. They may create additional problems if the designer is not thorough in handling them. Therefore, there is no substitute for a good design, and it is one of the major responsibilities of top management to provide a highly competent design team to bring out a reliable product or system.

In fact, reliability should be designed and built into products and the system at the earliest possible stages of product/system development. It is the most economical approach to minimize the life-cycle costs of the product or system. One can achieve better product or system reliability at much lower costs than otherwise because the majority of life-cycle costs are locked in phases other than design and development; one pays later on in the product life for poor reliability effort at the design stage. As an example typical percentage costs in various life-cycle phases are given in Table 19.2.

Table 19.2. Life-cycle costs

Life-cycle phases	**Percentage costs**
Concept/feasibility	3
Design/ development	12
Manufacture	35
Operation/use	50

Therefore, a sincere effort at the design stage offers theadvantages that it:

- ensures that the product meets the performance goals;
- identifies potential failure mechanisms during product design;
- provides an estimation of the product warranty costs and allows life-cycle and warranty cost analyses;
- optimizes benefits accruing from design alternatives;
- finds the best reliability allocation to meet system reliability goals; and
- permits prediction of product reliability prior to finalization of changes.

For the reliability engineer, reliability during the product design and manufacturing phases should be of primary concern. Several options, such as parts and material selection, derating, stress–strength analysis, use of technology, simplification, and redundancy, are available to him to accomplish this. Very often, combinations of these options may be exercised in the actual design process because trade-offs are made between performance and costs. Each of these options shall be discussed in the following sections.

*Reducing complexity***:** The number of parts in a system is a measure of system complexity. For better performance the complexity should be reduced as far as is possible. Simpler designs are invariably more reliable. Very often the parts are serially related with respect to the system reliability; each part is required to have a very high reliability. Any alternative design that helps reduce the number of parts definitely leads to a significant improvement in reliability. Thus, consideration of simplicity should be exercised throughout all phases of the design process. The necessity of all parts should be questioned and design simplifications should be employed wherever possible. A function that can be achieved by assembling few parts with proven reliability is considered more reliable than a design that uses host of components to achieve more automated operation. Designing parts to serve more than one function or use may also reduce part counts.

In addition to parts minimization, a designer must explore the possibility of minimizing part variation. The use of common parts and components can better control material quality and manufacturing tolerances. Also, as component parameters are known to drift over time, the designer must ensure that different tolerances do not combine in such a way that is likely to degrade system functionality.

Derating: Derating consists of stressing a component significantly below its rated or designed value of stress and provides a very effective method of improving the reliability of a product. This is commonly used practice for electronic equipment and, in fact, is synonymous with the concept of the safety factor in mechanical or structural designs. Voltage and temperature are

common derating stresses for electrical components. However, derating may be applied in the case of current or power as well. One can have derating of temperature and effort should be made to keep the operating temperature as low as possible. This can be accomplished by using product heat transfer models such as reducing power, providing heat sinks and thermal conduction, and radiators, providing packaging with optimum airflow and specifying the operating environment. Stress derating can also be resorted to in the case of mechanical systems.

Redundancy: If the system reliability goal is higher than the system reliability achieved by the functional design of the system, it is necessary to improve system reliability through system structural redundancy. Also, when it is impossible to achieve the desired component reliability through inherent component design, redundancy may be the only alternative. Redundancy may also help achieve increased product reliability against external environmental stresses. Design trade-off analysis is generally carried out to obtain an optimal configuration due to the increased costs of additional components, the size or weight added to the system, and possibly the increase in repair and preventive maintenance necessary to maintain multiple components due to redundancy rather than just one. Redundant system configurations include both active and standby units or there may be the more general k-out-of-m or partial, fractional or even voting redundancy. Redundancy also provides the possibility of repairing the failed units while the other redundant unit or units are operating.

Safety margins and system compatibility: A designer should provide the highest operating margin possible for product design. He can conduct product preliminary tests at stresses beyond the margin extremes experienced during the operation. Test time constraints require accelerated tests but one should not overlook the fact that highly accelerated tests may sometimes present failure modes that may be present during the normal operation of a product under the specified conditions and thus may not reflect the product's true reliability. It should not be missed that the product user will use the product in an unspecified manner and usually not inform the designer or producer how it was being used when a failure occurred, causing unnecessary improvement expense.

Vendor and component selection: Vendor selection is critical for building reliability into a product and therefore appropriate importance should be given to the purchase of reliable components. Purchasing components from a vendor with a proven reliability history goes a long way to enhancing equipment reliability. Electrical and electronic components should have been environmentally stress screened to achieve a higher (and specified) reliability. High reliability (hi-rel) components usually have a higher price, but they help to significantly reduce the overall failure rate of the product. Sometimes, a designer may have to choose between selecting standard parts and manufacturing specialized parts that perhaps have greater tolerances and reliability.

In the design phase, one has the complete freedom to choose the suppliers according to the options available for the choice of components based on technology or type. One should intelligently trade off between cost and reliability by buying reliable components that will economize the task of designing equipment with high reliability. Generally, trade-off is struck on the basis of cost, but ease of repair, parts availability, energy requirements, weight, and size may also be taken into consideration. Databases can be very helpful in selecting parts with a better reliability value among the competing parts.

Communication with the user: It is helpful and advantageous to be in communication with the customer/consumer to improveg product reliability. This is also required to secure a negotiated value for product reliability instead of producing a design of perfect reliability; but it is costly since the customer/consumer may be satisfied with a lower value of product reliability at a much lower cost than a product of high reliability at a very high cost.

Use of alternate technology: Sometimes, alternative technologies are available and the design engineer must explore the possibility of using an alternate technology that may provide the advantage of better reliability, as he may have

considerable flexibility in meeting the design goals. Typical examples include electromechanical devices *versus* solid state devices and digital display versus analog display, *etc*.

Better design tools andstrategy: In the design of electrical and electronic equipment one can make use of a computer-based circuit layout that will help minimize electronic noise and maximize electronic voltage margins in the circuit physical design. At the design level, one has the choice of using materials that tolerate a higher level of temperature, humidity, and chemical corrosion resistance would definitely provide an improved design. These materials, which can be considered a mechanical factor, are implicit in PCB and component structures. For example, one can use a tantalum capacitor in design rather than an electrolytic capacitor to decrease failure rate and increase operating life.

Similarly, in the design of mechanical equipment, computer aided design (CAD) and computer aided manufacturing (CAM) are being used extensively these days, which facilitates producing innovative and creative systems. Tolerances can be made very tight using CNC machines, thereby helping to improve the quality of the product, and many more advanced manufacturing machines and tools are available to produce high precision products.

19.2.2 Failure Data

In reliability, we try to become wiser from past mistakes and the whole effort is to avoid such failures of which the causes have become known. Therefore, failure information or data is a must for any reliability improvement program. The success of a reliability effort depends on the availability of good failure data that is complete and accurate. This would enable a reliability specialist to estimate and predict reliability accurately, take corrective measures, improve designs, plan the production process, properly operate, or even plan maintenance strategies well in advance. Therefore, the failure data collection and storage is central to the success of any reliability management program.

The scarcity and inaccuracy of reliability data has been one of the basis difficulties in the implementation of reliability improvement programs. Although a number or reliability data banks have been established world over, the quality of reliability data cannot satisfactorily support more sophisticated models than what are being employed today. Three types of data are especially important for evaluating product reliability. These are field (operational) failure data, service life data with or without failure, and data from engineering tests. Field failures constitute a meaningful data source because they represent experience from the real world. However, the exact operational and environmental conditions before and at the time of failure may not be fully and exactly known. Nevertheless, it is helpful to have some data that is reasonably, if possible for each operational failure.

Data on service life is necessary in assessing the time characteristic of reliability. It is helpful to know how many units are in service, for what period of time and under what conditions of use. Moreover, how many units have failed at what time? Certainly, this would help obtain considerable insight into product performance. It is would further be uuseful if the above information were supplemented by results from engineering tests (accelerated life tests), since many of the parameters and test conditions can be controlled, or at least are known. As a result, this data is normally considered to be dependable for analysis purposes.

The problem of acquiring data is not an easy one. Although sufficient failure data has been generated and is available for electronic or electrical components and devices, not much published information is available on the failure of mechanical components and, in fact, this lack of information or extrapolation of the available failure information to actual conditions of use constitutes the greatest deficiency in the field of reliability today.

The fact that failure rate information is not published does not necessarily mean that it does not exist. The reality is that those who possess this information are often reluctant to publish or share it because it was not obtained under controlled conditions of experimentation and can easily be questioned. Where the data exists, the owner may

not like to share it, having spent quite a fortune in creating or developing it.

The situation is highly satisfactory in the electronic industry where a great deal of failure information is available today, yet the published material does not make it more accurate for the reliability estimates of electronic systems. This is primarily on account of the fact that each test laboratory obtains a different rate for the same component depending upon the test environment, test equipment and the procedure. Therefore, it is very common that different part manufacturers publish different failure rates for the same parts. Moreover these published failure rates generally pertain to catastrophic failures and do not include information on out-of-tolerance failures. Moreover, the published failure rates do not include the effect of degradation in reliability during manufacturing storage, or transshipment.

Once the failure data is available and environmental conditions are known, the data must be used to fit in an appropriate failure distribution and parameters of the distributions ascertained to represent the model [108, 109, 122, 123, 124, 133]. The situation for the increasing hazard rate is not that simple, since there can be more than one candidate for fitting in the distribution. There are techniques to do that (see, *e.g.,* [128, 136, 146, 147].

There are situations when we design unique equipment, assembly or redesign a product for a new environment for which no failure rates based on prior experience are available. In all such cases, it is often possible to establish a range for the unknown failure rate by comparison with existing similar systems. The analysis then can be carried out for the limiting the critical failure rates in the range. Often such an analysis can be useful in establishing a design configuration. Depending on the importance of the new component, such estimates may have to be substantiated by laboratory tests. Moreover, some knowledge of the correlation of laboratory failure rates with the actual service experience needs to be available.

19.3 Reliability Prediction Methodology

Reliability prediction is fundamental to system design and involves a quantitative assessment of system reliability prior to system development. In fact, reliability prediction [76] provides baseline values for reliability growth and demonstration testing, maintainability, supportability and logistics costs. Thus, prediction has several objectives:

- Feasibility evaluation
- Comparison of competing designs
- Identification of potential reliability problems.
- Provision of input to other reliability and maintainability tasks.

Feasibility evaluation involves evaluating the compatibility of the proposed design concept with the design requirements. Early in the system design, a feasibility evaluation would typically involve the parts count type of prediction (MIL-HDBK-217 F, Appendix A) to determine the compatibility of feasibility evaluation with required reliability. Feasibility evaluation may also include a detailed parts stress type analysis (MIL-HDBK-217 F, Sections 5–23) for components. Feasibility evaluation is usually critical for totally new system designs where no similar experience exists, as with systems with known reliability characteristics.

Comparing competing designs is similar to feasibility evaluation, but for the fact that it provides one output, the predicted reliability, to be used in making broader system level design trade-off decisions involving factors such as cost, weight, power, performance, *etc*. A parts stress type prediction is typically used to provide a quantitative assessment of relative cost-benefit of systems level trade-off considerations. Reliability predictions also provide a systematic means of checking all components and assemblies for potential reliability problems. It also offers a means of evaluating the reliability improvement in the case of potential problem areas by focusing attention on low quality, over-stressed or misapplied parts. It should be emphasized that the prediction itself does not improve the system reliability; it only provides a means for identifying

potential problems that, if resolved, will lead to improvement of the system reliability. Therefore, predictions provide an excellent ground for reviewing and evaluating the progress of system design ahead of testing.

Reliability predictions also provide key inputs to other R/M tasks such as maintainability analysis, testability evaluation, and failure modes and effects analysis (FMEA). Because prediction identifies weak reliability spots, it provides key inputs to weigh the benefits of adding test points, making locations for maintenance more readily accessible or introducing redundancy to minimize the influence of a particularly critical failure mode. Reliability prediction begins at the lowest level in the system hierarchy, *i.e.*, at the components level and proceeds thorough the intermediate level, which is a subsystem level, until system reliability is obtained. In general, there is a hierarchy of reliability prediction technique available, depending on the depth and knowledge of the design and the availability of collected reliability data on the equipment and any useful information on it.

The general procedure of prediction can be outlined as follows:

- Define the system and its operating conditions.
- Define system performance criteria (in terms of either *success* or *failure*).
- Develop a system model using *reliability block diagrams* (*RBD*) or *fault tree methodology*.
- Compile a parts list for the system.
- Assign failure rates and modify *generic failure rates* using an appropriate procedure.
- Select a *prediction procedure* and perform a *parts count* or *parts stress* method for the system.
- Combine part failure rates.
- Estimate system reliability.

The main effort in the reliability predictive sequence lies in carrying out the following tasks:

- A list of components is prepared for the product. The component reliability data for components is usually obtained from the applicable sources or relevant databanks.
- Reconciliation is often needed between the differing values of the failure data available from various sources. A tentative and eventually accepted value for each component is determined.
- Various operating stresses are usually projected for the preliminary design, and expected operating conditions are projected into the prediction of the failure rate of each component. Stress factors are generated as appropriate multiplying factors for the part failure rates for a specific application. One can improve the reliability of a system by carefully anticipating the intended environment of use. In fact, the system being designed may have to function in the presence of harsh environments like extreme temperatures, humidity, salt spray, moisture, dust, sand, gravel, vibration and shock, and electromagnetic induction (EMI), *etc*.
- Product reliability then can be computed to provide a product level estimation of the reliability. This procedure, when applied repeatedly to new evolving products becomes:
  - an accurate indicator of unreliable components in the new products,
  - an accurate indicator of the total system reliability determined by catastrophic failure of components, and, finally
  - a product reliability document.

In fact, a components' level synthesis of product reliability is recommended for all serious product designs. The process becomes more accurate with repeated use and evolves into the reliability design tool for the system.

19.3.1 Standards for Reliability Prediction

Depending on the nature and type of components, whether electrical, electronic or mechanical, several documents are available for reliability prediction procedure. The engineer can select the model that is best suited to the part types and requirements of the component or product whose

reliability is being predicted. It is important that predictions are made as precise as possible, since if the reliability predictions are made too low then one may arrive at an over design and the design can be costly. On the other hand, if the predicted values are too optimistic and high this may lead to catastrophic consequences. The standards for reliability prediction use a series of models for various categories of electronic, electrical and electro-mechanical components to predict failure rates that are affected by environmental conditions, quality levels, stress conditions, and various other factors. Some of these procedures can be found in the following documents:

MIL-HDBK-217: This standard has been the mainstay of reliability predictions for about 40 years. The most recent revision of MIL-HDBK-217 is *Revision F Notice 2*, which was released in February 1995 and has not been updated since then. This is the most widely used and accepted document for the prediction of electronic components and equipment reliability. Reliability prediction using this procedure in electronic design often results in a reduction in design lag time and savings in lifetime costs. MIL-HDBK-217 can be used for both commercial and military grade components. The handbook includes a series of empirical failure rate models developed using historical piece part failure data for a wide range of components. They predict reliability in terms of failures per million operating hours and assume an exponential distribution, which is justified in the case of electronic and electrical components. MIL-HDBK-217 allows a *parts count* analysis and a *parts stress* analysis to be performed. One can use *parts count* for quick estimates and early design analyses or a *part stress* method covering 14 separate operational environments, such as ground fixed, airborne inhabited, *etc*., for taking actual temperature and stress information into account. It therefore offers relatively an accurate estimate of the failure rate. Typical factors used in determining a part's failure rate include the temperature factor (π_T), the power factor (π_P), the power stress factor π_S, the quality factor (π_Q), and the environmental factor (π_E) in addition to the base failure rate (λ_b).

To improve on some of the handicaps of this standard, one can extend the *parts count* and *parts stress* methods by incorporating the mathematical models from the *Telcordia* procedure, which can also be used for the prediction of reliability of electronic components and equipment and allows the consideration of burn-in as well as laboratory and field data.

There are other standards that are useful in reliability prediction process. They are MIL-STD-1629A, BS 5760 Part 5 for carrying out a *failure mode, effects and criticality analysis (FMECA)*. The *FMECA* module provides interactive graphical aid in constructing block diagrams indicating the logical connection between the system and its subassemblies, and components on the other side. This graphical representation can be extended to relate failure modes at various system levels. For maintained systems, standards such as MIL-STD-472 can be helpful in estimating *mean time to repairs (MTTR*) for subsystems and components.

Telcordia SR-332: The Telcordia method was originally developed by AT&T Bell Labs and modified by Bell Communications Research (*Bellcor*e) to improve upon the representation of mathematical equations of MIL-HDBK-217 in accordance with what their equipment was experiencing in the field. However, the main concepts in MIL-HDBK-217 and Telcordia are very similar, but Telcordia has an added the ability to take into account burn-in, field, and laboratory testing, which makes it quite popular with commercial establishments. The current version of Telcordia is *Issue 1*, which was released in May 2001 and follows *Bellcore Issue 6* in order of release. The Telcordia method also assumes an exponential failure distribution and calculates reliability in terms of failures per billion part operating hours, or FITs.

Telcordia also has the ability to perform a *parts count* or *part stress* analysis and also provides models for predicting the failure rates of units and devices during the first year of operation. In fact, the failure rate during this period is expressed as a multiplying factor (*first year multiplier or FYM)* operating on the predicted steady-state failure rate. The prediction module automatically calculates the

first year multiplier based on the specified system, unit and device burn-in times and temperatures.

The Telcordia standard allows reliability predictions to be performed using three methods. The method I parts count approach applies when there is no field failure data available. Method II provides a modification to Method I to include laboratory test data, and the Method III variation includes field failure tracking. Method I includes a first year multiplier to account for infant mortality. Method II includes a Bayes weighting procedure that covers three approaches depending on the level of previous burn-in that the part or unit has undergone. Method III also includes a Bayes weighting procedure but is based on three different cases depending on how similar the equipment is to the one from which the data was collected. For the most widely used Method I, where the burn-in varies, the steady-state failure rate depends on the basic part steady-state failure rate and the quality, electrical stress and temperature factors as follows:

$$\lambda_{SSi} = \lambda_{Gi}\ \pi_{Qi}\ \pi_{Si}\ \pi_{Ti}\,. \qquad (19.3)$$

Telcordia offers ten different *calculation methods*. Each of these methods is designed to take into account different information relating to stress data, burn-in data, field data, or laboratory test data.

Comparison between MIL-HDBK-217 and Telcordia: Since MIL-HDBK-217 was the original standard for reliability prediction analyses, it is known and accepted worldwide, whereas Telcordia is primarily accepted in the United States Although its popularity is gradually growing internationally, it has not been completely accepted by the international community as yet. Moreover, when AT&T Bell Labs developed Bellcore (now Telcordia), they concentrated primarily on commercial equipment. Telcordia was specifically designed to focus on telecommunications, whereas MIL-HDBK-217 was much more broadly based in scope, is useful to both military and commercial equipment, and had no specific focus.

Although the basis of the Telcordia and MIL-HDBK-217 calculations are very similar, it is often observed that calculations in Telcordia are more optimistic than calculations in MIL-HDBK-217. Moreover, Telcordia calculations require fewer parameters for components. This, however, does not mean that Telcordia failure rates are always better. It simply indicates that, depending on the component types, the difference in failure rates can be predicted.

As stated earlier, the Telcordia model has the additional capability of considering burn-in data, laboratory test data, and field data. This feature is extremely helpful in calculating failure rates that are based on historical data, rather than simply calculating stress data. In addition, burn-in data is used to quantify the *first year multiplier*, which is indicative of infant mortality.

One of the differences is that MIL-HDBK-217 calculates failure rates in *failures per million hours,* whereas the Telcordia model calculates failure rates in *failures in time* (or *FITs*), which is expressed as *failures per billion hours*. MIL-HDBK-217 provides models for printed circuit boards, lasers, SAWS, magnetic bubble memories, and tubes, whereas the Telcordia does not support these parts. Telcordia provides models for gyroscopes, batteries, heaters, coolers, and computer systems. However, these part types are not supported by MIL-HDBK-217. Nevertheless, one can always use MIL-HDBK-217 for the majority of parts in the analysis and use Telcordia for those part types that are not supported by MIL-HDBK-217 (or *vice versa*).

Since Telcordia was initially designed for use in the telecommunications industry, the operating environments that Telcordia supports are very limited. For example, Telcordia only supported three different variations of *ground*-based environments, initially. However, Telcordia is evolving rapidly and in the most recent issue of Telcordia, the additional operating environments of *Airborne, Commercial* and *Space,* and *Commercial* have been made available. MIL-HDBK-217, on the other hand, has always offered a number of different operating environments. Currently, MIL-HDBK-217 supports a variety of ground, sea, air, and space environments.

In MIL-HDBK-217, the quality levels used differ from one part type to another and they are derived from specific data that is component dependent. Therefore, the quality levels for resistors are different than the quality levels for

semiconductors and the quality levels for semiconductors are different from the quality levels for integrated circuits. However, the assignment of quality levels in Telcordia is very simple and it currently supports four standard quality levels. These quality levels are identical for all component types, and are simply based on the origin and screening of components.

PRISM: This procedure was developed at the Reliability Analysis Center (RAC) and was released in 2000. It provides the ability to update predictions based on test data and addresses factors such as development process robustness. PRISM interfaces directly with RAC's automated data-bases and provides methodology to assess the quality of the system development process. It has been incorporated into the Relex Reliability Prediction module for carrying out system reliability analysis and MTBF prediction. It has the ability to model the effects of thermal cycling and dormancy. It allows one to select parts from both the electronic parts reliability data (EPRD) and non-electronic parts reliability data (NPRD-95) documents published by RAC and permits the use of predecessor data and process grading factors in the reliability analyses.

The Bayesian approach has facilitated the use of test and field data at the assembly level to enhance predicted component failure rates with real-life experiences. PRISM includes means to deal with software reliability but is limited by the fact that it does not yet include models for all commonly used devices. The system reliability model presented by PRISM is:

$$\lambda_S = \lambda_{IA}\left(\pi_P\pi_{IM}\pi_E + \pi_D\pi_G + \pi_M\pi_{IM} + \pi_E\pi_G + \pi_S\pi_G + \pi_I\pi_E + \pi_N + \pi_W\pi_E\right) + \lambda_{SW} \tag{19.4}$$

where λ_{IA} is the initial assessment failure rate (based on *RACRates* component failure rate models) for the system and the other factors involved address parts processes (π_P), infant mortality (π_{IM}), environment (π_E), design processes (π_D), reliability growth (π_G), manufacturing processes (π_M), item management processes (π_S), induced processes (π_I), no-defect processes (π_N), and wear out processes (π_W). Also, λ_{SW} is the software failure rate. Quantitative values for the individual factors are determined through an interactive process intended to benchmark the extent that measures known to enhance reliability are used in design, manufacturing and management processes.

NPRD-95: This document provides failure rates for a wide variety of items, which include mechanical and electromechanical parts and assemblies. This document provides detailed failure rate data on over 25,000 parts for numerous part categories grouped by environment and quality level. Because the data does not include time-to-failure, the document is forced to report average failure rates to account for both defects and wear out. Cumulatively, the database represents approximately 2.5 trillion-part hours and 387,000 failures accumulated from the early 1970s through to 1994. The environments addressed include the same ones covered by MIL-HDBK-217; however, data is often very limited for some environments and specific part types.

NSWC-98/LE1: This document is also known as the *Handbook of Reliability Prediction Procedures for Mechanical Equipment* (NSWC-98/LE1) and was primarily developed by the United States Navy. This document uses a series of modules for several categories of mechanical components to predict the failure rates that are affected by stresses, flow rates, temperature, and several other factors. In fact, it provides models for various types of mechanical devices including springs, bearings, seals and gaskets, electric motors including motor windings, brushes, armature shafts, *etc*. It also deals with brakes and clutches, compressors, threaded fasteners, mechanical couplings, and slider-crank mechanisms. This is a relatively new standard and also contains reliability models for solenoids, gears and splines, valves, actuators, pumps, filters, *etc*.

CNET 93: This is a document developed by *France Telecom* and provides reliability models for a wide range of components. CNET 93 is a comprehensive model similar to MIL-HDBK-217, which provides a detailed stress analysis.

RDF 2000: This is a newer version of the CNET UTEC80810 procedure developed by UTE and has not received much attention in the US but has the potential of eventually becoming an international standard. It uses cycling profiles and their applicable phases to provide a completely different basis for failure rate calculations. The models take into account power on/off cycling as well as temperature cycling and are very complex with predictions for integrated circuits requiring information on ambient and print circuit ambient temperatures, type of technology, number of transistors, year of manufacturing, junction temperature, working time ratio, storage time ratio, thermal expansion, number of thermal cycles, thermal amplitude of variation, application of the device, as well as transistor technology related and package related base failure rates.

HRD5: This is a reliability prediction procedure developed by *British Telecommunications plc,* which provides models for a wide range of components. In general, HRD5 is similar to CNET 93, but provides simpler models and requires fewer data parameters for reliability analysis.

Document 299B: This document is based on the Chinese standard *GJB/z 299B*. It has been translated into English by Beijing Yuntong Forever Sci.-Tech. Co. Ltd. Document 299B is very similar to the MIL-HDBK-217 reliability procedure and permits one to take temperature and stress information into consideration.

The Physics-of-Failure Procedure: This has a family of approaches that differ significantly from other empirical methodologies and attempts to identify the *weakest link* of a design to ensure that equipment reliability exceeds the design value, and the methodology ignores the problem of defects escaping the manufacturing process and assumes that the product reliability is constrained by the predicted life of the weakest link. The model addresses problems such as microcircuit die attach fatigue, bond wire flexure fatigue and the die fatigue cracking. The models require detailed device geometry and material properties They are, however, used primarily at the subdevice level during the early design stage in electronic system reliability predictions.

*The IEEE Gold Book: **Viz.**, IEEE STD 493-1997* is available for the design of reliable industrial and commercial power systems and provides data on equipment used in industrial and commercial power distribution systems besides dealing with reliability analysis, probability methods, power system reliability evaluation, economic dispatch, and the cost of power outage data. This document was updated in 1997 although the most recent data is from 1989.

19.3.2 Prediction Procedures

The task of predicting the reliability of a product is straightforward if the reliability data of the product is available either from the field, from testing laboratories or from databanks. However, usually if a product that is being designed is new and there is not be enough information available from either of the above-mentioned sources, then the reliability engineer has to use some alternative procedure. There are a variety of reliability prediction procedures that can be used in such a situation.

The Similar Product Technique: This approach is used to estimate the reliability of a new product based upon the known reliability of an existing product with similar attributes. These attributes can be the type of technology used, digital circuitry, the complexity of the product and the operating environmental conditions, and the quality of the product.

The Similar Complexity Technique: In this approach, the reliability of the product under design is estimated by comparing its relative complexity with a known product of similar complexity.

The Prediction by Function Technique: This approach uses the correlations between function and reliability in order to predict the reliability of a new design. However, there are two basic empirical techniques that are often found useful in the task of product reliability estimation, *viz.*:

- The parts count prediction method.
- The parts stress prediction method.

Failure data for both these methods are available in latest release of MIL-HDBK-217F if the product

belongs to the electrical or electronic category. These methods are also used with modification in the case of mechanical equipment, particularly under certain conditions of use.

19.3.2.1 The Parts Count Method

This method is used for obtaining preliminary design and development and consists of preparing a list of the each generic part type such as capacitors, resistors, and so on in an electronic circuit, and their numbers used in the design of electrical or electronic equipment. It assumes that these components are reasonably fixed and over all design complexity is not expected to change substantially during later stages of design, development and prediction process. The parts count method is generally used in the early design phase as sufficient information is not available then, and a full stress method cannot be used. MIL-HDBK-217 provides a set of default tables, which provide a generic failure rate (λ_g) for each component type based upon the intended operational environment. This component generic failure rate is modified by a quality factor (π_Q), which represents the quality of the components in question, *i.e.*, the components are manufactured and tested to a full military standard or to a lesser commercial standard. In addition to this, a learning factor (π_L) is also used for microelectronic circuits and represents the number of years that the component has been in production. Thus, using the component generic failure rate for a given environment and modifying it for quality and learning factors in the case of microelectronics, a component's final failure rate is established. The summation of the individual component's failure rates will yield the overall failure for the circuit. With this and the summation of the other Circuit Card Assembly, the failure rate of a line replaceable unit can be established.

Finally, following this process an overall failure rate for the system can be established. This approach assumes a constant failure rate of each component, assembly, equipment, and the system. The system/subsystem failure rate can be obtained by summation of part failure rates assuming that all components are in series. In the case where the model consists of non-series components or redundant units, the item reliability can still be determined either by considering only series elements of the model as approximation or by summing part failure rates for the individual elements and calculating an equipment series failure rate for non-series elements of the model.

19.3.2.2 The Parts Stress Method

This is an accurate method of system reliability prediction other than measuring reliability under actual or simulated conditions. This method is usually used when the design is almost completed and a detailed parts list and parts stresses are known. The approach requires a detailed knowledge of all the stresses such as temperature, humidity, vibration, *etc*., and their effect on the parts failure rate, to which each part shall be subjected to under actual conditions of use. The part stress analysis also assumes that all times to failure of parts are exponentially distributed. The data necessary for the parts stress analysis include: specific part types (including device complexity of microelectronics), quantity of parts, part quality levels, environment of use, and part operating stresses.

To enable a full stress analysis to be conducted there must be sufficient details of the systems' design available to the reliability engineer. In short, the design of the system must be such that the electronic and electrical design of the hardware is known down to the components level. There will be detailed parts lists and circuit schematics as this is required to take into consideration the electrical and thermal stresses that may be experienced by various components. With the detailed knowledge of the electrical and electronic design and the specific data pertaining to each component type used within the design the stress analysis can be done. Component information, or data sheets, is usually available from the manufacturer and these days this information can also be obtained over the Web. In the case of a parts stress analysis, the mathematical models are available in MIL-HDBK-217 for each component type, *i.e.,*

microelectronics, resistors, capacitors, and electro/mechanical devices.

The most general approach used by MIL-HDBK-217 is that each generic component type is assigned a base failure rate (λ_b) and is modified by influence factors. These factors, such as $\pi_{E,}$ which is the environmental factor, are based upon the intended operation environment of the equipment or system. The other factor considered is π_Q, which is the quality factor and is a general look up factor that represents the quality of the component in question. There are other factors as well that are used for multiplying the generic failure rate. These factors should all be known or can be determined based upon the state-of-hardware, for which the parts stress method is being applied and assumptions regarding the various factors associated with the failure rates can be justified. Some of the factors will result in a linear degradation of the base failure rate, while others may result in an exponential degradation, in particular, those factors associated with temperature. There are many environmental factors for which the generic failure rate can be modified; however, some of the environments factors used in MIL-HDBK-217 are: Ground Benign (GB), Naval Shelter (NS), Airborne, Uninhabited Cargo (AUC), and Space Flight (SF), the details of which can be found in the MIL Standard.

Therefore, the part failure models may vary with different part types. However, their general form is:

$$\lambda_i = \lambda_B \pi_E \pi_A \pi_Q \cdots \pi_N , \qquad (19.5)$$

where

λ_B = base part failure rate; the value is obtained from the part stress data for each generic part type. The data is generally presented in the form of failure rate against normalized stress and temperature factors. The value of λ_B usually determined by the stress level (current, voltage, *etc.*) at the expected operating temperature.

π_E = environmental factor; this factor accounts for the influence of environment other than temperature and is related to other operating conditions such as vibration, humidity, *etc*.

π_Q= quality factor; this factor accounts for the degree of manufacturing control with which the part was fabricated and tested before shipment to the user.

π_N = additional adjustment factor; this can account for cyclic effects, the construction class and other factors that modify data.

Modification for Mechanical Components: Unfortunately, mechanical parts typically do not follow the exponential failure distribution or constant failure rate. Instead they exhibit wear-out characteristics or have an increasing failure rate with time. The procedure developed by RAC makes it possible to still use the standards for the prediction of reliability for mechanical components. While the actual time-to-failure distribution may be Weibull or lognormal, it may appear to be exponentially distributed over a long period of time. However, this is so only when the components are replaced upon failure. This condition is usually true for the vast majority of mechanical components [75].

19.3.3 Reliability Prediction for Mechanical and Structural Members

Mechanical components wear out due to friction, overload, plastic deformation, fatigue, changes in composition due to excessive heat, corrosion, abuse, *etc*. The traditional method of guarding against stress related failures has been to specify a safety factor greater than 1, where the safety factor is defined as: SF = S/s, SF being the nominal safety factor, S is the nominal strength or allowable stress and s is the maximum principal stress. This definition assumed that the values of stress and strength are known exactly and the difference between them provides the safety margin for overloading and reduction of strength over time due to corrosion, cracking, *etc*. If a high value of the safety factor is chosen, the design tends to become heavy, bulky and costly. Thus a designer needs to make a trade-off and use his experience and judgement in arriving at an adequate value of the safety factor.

There is always uncertainty present in the measurements of strength as well as in stress calculations. Therefore, stress and strength must be

treated as random variables and following the principles of probabilistic design (as against the deterministic approach using safety factors) as introduced in (19.1) and (19.2), one can predict the reliability of a mechanical or structural member.

Probabilistic mechanical or structural component reliability [11, 74, 89, 141, 152] is gaining importance of recent due to the fact that today we have high performance materials due to advances in material technology, but these materials often possess detrimental side effects and the other reason is that the need for higher performance is constantly pushing operating stresses to higher levels. The probabilistic design model consists of four major activities; *viz.*, design process, material production, manufacturing and operations. Output from the design process is the expected operating stress distribution resulting from load spectra. The remaining three activities provide the material strength distributions, determined through Monte Carlo simulation of random variables representing random variation of incoming material strength, manufacturing defects and operational factors. The probability of failure can be computed from (19.2) as the probability of stress exceeding the strength. The integral can be computed numerically using the trapezoidal rule or more refined methods such as the Simpson rule, or methods based on polynomials such as Laguerre–Gauss or Gauss–Hermite quadrature formulae.

Analytical methods such as FORM and SORM are also available to calculate the probability of failure. There are first order second moment (FOSM) and advanced first order second moment (AFOSM) methods. These methods derive their names from the fact that they use the first order Taylor series approximation of the performance function linearized at the mean value of the random variable. In FOSM, the information on the distribution of random variables is ignored whereas in AFOSM, the information on the distribution of random variables is taken into account. FOSM is also known as the mean value first order second moment method (MVFOSM). There are other methods such Hasofer–Lind (H–L) method [9], which is basically an AFOSM approach when the random variables are normally distributed. H–L methods are available for linear and non-linear performance equations or limit state equations. One can determine the reliability index, which in both cases is basically the distance between the origin and the design point on the performance equation.

The second order reliability method (SORM) takes into account the curvature of the limit state equation by considering second order derivative terms in the Taylor series expansion, which were actually neglected in FORM approach. Thus SORM is supposed to be a more accurate approach. SORM was first suggested by Fiessler *et al.* [25], who used quadratic approximation. A simple closed form solution for the probability computation using second order approximation was given by Breitung [50], who used the theory of asymptotic approximations.

The reliability computation when limit states are implicit can be done using the analytical methods described earlier but by using a simple simulation technique it is possible to calculate the probability of failure for explicit or implicit limit state functions. In fact, to evaluate the accuracy of these sophisticated techniques, or to verify a new technique, a simulation technique is routinely used to independently evaluate the probability of failure.

A good description of all these approaches can be found in [55, 58] and also in Chapter 63 in this handbook.

19.4 System Reliability Evaluation

Since system reliability design, as we all know, is basically an iterative process and system reliability computation is repeatedly required at each cycle of iteration of the design procedure; reliability evaluation is a must for any system reliability design. This necessitates the development of efficient and fast procedures for system reliability evaluation in order to economize on the time required for the system design. In fact, a considerable amount of research has been done to develop fast methods of system reliability computation.

System reliability computation basically involves a three-step procedure. In the first step, one develops a logical model for the system, and in

the second step, the system logical relationship is transformed into an algebraic relationship of the system reliability expression in terms of component reliabilities. In the third step, one can substitute for component reliabilities in the algebraic expression available for system reliability. Sometimes, computerized algorithms combine steps 2 and 3 and produce a system reliability value without transforming the logical relationship into an algebraic reliability expression. Reference [6] does exactly that for a series-parallel configuration and is the fastest method for computing system reliability. For non-identical parallel components, an algorithm [16] computes reliability very quickly. If analytical procedures are not used, Monte Carlo methods [103, 150, 155] can be used to estimate the system reliability.

19.4.1 Reliability Modelling

Reliability modelling is the first important step in the system reliability evaluation. In order to model a system, it is always possible to decompose it into its constituent parts. For a complex system, the number of such parts may be quite large and a multi-level approach is always helpful to achieve this decomposition. A component by definition is the system constituent at the lowest level. Therefore, it may be necessary to model this multi-component system at various levels. The system can be maintained (where repairs of failed units are possible) or may just be a non-maintained system. Modelling for these two types is done differently. In reliability modelling, we try to achieve a relationship between individual components, or subsystems failures with the system failures for the known system objective. One can model system failure in two ways, *viz.*, using either the black-box approach or the white box-approach. In black-box approach the state of the system is described either in terms of two states (working/failed) or more than two states (a multi-state model) without linking them to the components of the system. In the white-box approach the state of the system is specified in terms of the states of the various components. In the white-box approach we have a *forward* or *bottom- up* approach, in which one starts with the failure events at the part level and then proceeds to the system level to assess the consequences of such failures. Failure mode and effects analysis (FMEA) belongs to this type of modelling. In the backward (top-down) approach, one starts at system level and proceeds downwards to the component level to link the system performance to the failures at part level. Fault tree analysis belongs to this category.

Linking the system performance to the performance of its constituents can be done qualitatively and quantitatively. In the first case, one builds up the logical relationship, whereas in the latter, one obtains a measure of system performance (which may be the system reliability) to the performance (reliabilities) of components. The logical relationship can be expressed graphically either by what is known as the reliability logic diagram (RLD) in the success frame of reference or in the failure frame of reference through a fault tree diagram, where the failure of the system is related to the failures of system constituents at various levels. Both approaches have their own advantages in system analyses.

Fault tree analysis is a well-documented methodology and is being used extensively for assessing the safety and reliability of high risk systems such as the nuclear, chemical, and aerospace industries. A detailed discussion of this technique can be found in Chapter 38 of this handbook and in Chapter 8 of [103]. Other graphical relationships are possible by which the same task can be achieved, *viz.,* events trees, binary decision diagrams (BDD) (Chapter 25 of this handbook], causal trees or diagraphs (Chapter 8 of 103]) *etc*. Petri nets [22, 38, 39, 66, 117] and even neural nets [99] have been found to be useful in system reliability assessment or fault diagnosis programs. This handbook provides a discussion of some of these topics.

The underlying assumption in reliability modelling is that each component or system can have only two states, which means that it is either good, or in working state, or bad, which means not working. Thus the model is a two-state model.

In fact, three-state models [103] have been widely discussed in the past and the optimal design of these systems has also been discussed widely.

Three-state systems are those systems where two modes of failure, such as short circuit and open circuit failures in electrical passive devices and a valve getting stuck open or stuck closed in mechanical systems, are considered in computing the system reliability.

Recently, considerable attention has been paid to the analysis of multi-state systems [139, 142], where the usual assumption of binary states for components and the system is shed to include multi-state components, which may be useful in considering degraded states in addition to working and failed states. The analysis and design of such systems using conventional methods becomes quite cumbersome particularly when repairs are being considered. Also, reliability modelling of nano-scale devices [154] is also becoming important as nanotechnology is being more widly acceptable. Therefore, new approaches are becoming naturally important; this handbook includes Chapters 28, 29, 30 and 58 on recent research in this direction.

Alternatively, a component can be modelled as a two-terminal passive device, which allows a signal to pass through it from its input terminal to its output terminal if it is good and blocks it if it is bad. In other words, a component can be considered as a directed branch with its reliability as its gain. This modelling criterion helped to model a system as a graph like structure known as the *probabilistic graph* and, in fact, facilitated the use of graph theory for system reliability evaluation. The first two papers using this approach [5, 6] were published in 1970 and were trendsetters for the use of graph theory in system reliability evaluation. Reference [5] was subsequently helpful in developing the topological method [23] of system reliability evaluation.

The application of graph theory [5] also led to the definition of the path set and the cut set. A *path set* is a set of those components whose success leads to system success, and this definition works well with the block diagram approach of system representation. Likewise, a cut set is a set of those components in a system whose failure yield system failure, and this definition works well with the fault tree approach. One also defines *minimal path sets* and *minimal cut sets* as sets having the minimum number of components of the system. There can be very many path sets and cut sets in a system. These definitions and developments led to several competing system reliability evaluation techniques [103, 149].

It is needless to emphasize here that this modelling consideration is found to be particularly useful in the performance evaluation of communication systems [63, 72, 151, 153], transportation systems or water supply systems with or without the capacity of links being specified [33, 41, 103]. One can define the system success and thereby its reliability if the communication system is able to communicate between the two specified terminals of the system. Therefore, this is aptly known as two-terminal reliability (or terminal-pair reliability) of the communication system. This leads us to define *k-terminal* [47, 56, 72] or *n-terminal (or all-terminal)* or *global* reliability of these systems, if it is possible to communicate between specified k-terminals or all the n terminals of the system so that all terminals of the system are able to communicate with each other or remain connected with each other. Imperfect nodes were also considered in several papers including [27].

19.4.2 Structures of Modelling

Based on the modelling procedure, several system structures are obtained, such as series, parallel, series-parallel, parallel-series, standby, non-series-parallel, k-out-of-n. Again k-out-of-n , which has been widely researched [18, 19, 28, 32, 45, 52, 62, 83, 84, 85, 92, 104, 105, 115, 116, 129, 130, 134, 145] has a family of its own such as the consecutive-k-out-of-n model and many other models such as the circular consecutive-k-out-of-n model, the circular m-consecutive-k-out-of-n model, the circular r-within-consecutive-k-out-of-n model based on related definitions and possibilities. A good discussion of the above can be found in [103]. Among all the series-parallel (or reducible networks or not non-series parallel) structures, the most widely used and general model is k-out-of-n:G, which consists of n components in parallel out of which at least k components should be good. Likewise one can define k-out-of-n:B or k-out-of-n:F, where at least k units must fail for the

system to fail. In fact, other models like series, parallel, *etc*., can be derived as special cases of this k-out-of-n model. Therefore, it was considered important to include a discussion of this structure and to provide an indication of the new trends in research in this area. The load-sharing model (see Chapter 20 of this handbook) is another realistic model of a parallel or k-out-of-n system, where the failure of any unit increases the hazard rate of the remaining units in parallel.

There are models [17, 103] that help to compute system reliability with the assumption of dependency of failures to approach realistic situations where the analyst cannot ignore the dependency of failures.

The non-series-parallel system or the non-reducible system is a more general category of models but it is difficult to handle. However, methods are available to compute the reliability of such systems.

Markov chains provide a modelling procedure for the availability or reliability modelling of maintained systems under various assumptions of practical importance. Markov models that are discrete in states but continuous in time have been found to be very useful in analysing systems with repairs under varying repair strategies and support facility considerations. However, the main drawback of these models is the size of Markov models, which grows very rapidly with the number of components in the system and therefore restricts its applicability to large systems. A good discussion of Markov modelling of maintained systems can be found in Chapter 7 of [103], where approaches such as state space, network, and conditional probability approaches for maintained systems have been provided. The three-state Markov model is presented in [12, 103].

Several other reliability models have been developed based on conditions of use and physical design constraints but the basic consideration in developing a model is to provide the means to compute its performance as realistically as possible under the assumptions made.

19.4.3 Obtaining the Reliability Expression

System reliability evaluation methods can be classified into two broad categories, *viz.*, those that employ path sets and cut sets for deriving the system reliability expression and those that use recursive method [7, 8, 59] network reduction [6, 96, 113], decomposition [21, 82, 96, 112] or transformation techniques [29, 34, 36]. A good discussion of these techniques is available in [103]. A comparative assessment of earlier methods and error computation was provided in [13, 14].

Early research on evaluation methods was also oriented towards determining path sets and cut sets of a system economically, because the number of path sets and cut sets can be very large even for a system of moderate size. For example, a 33-element system may give as many as 1681 path sets and unionizing them to obtain the algebraic system reliability expression can be time consuming and sometimes unwieldy on all accounts. In general, if there are m path sets of a system, the union of these path sets should normally yield an expression containing 2^m-1 terms, of which many of course will combine, but one can roughly figure out the number of resulting terms by calculating 2^m-1, which for m = 100 provides approximately a value of 1.27×10^{30}. One can imagine what it will be for m = 1681. One should not forget that it was a system with 33 elements only that yielded the number of path sets as 1681. What will be the number of path sets if the system is large, say with 1000 elements?

To overcome this problem, initial research was focused on obtaining directly the non-cancelling terms of the system reliability expression in uncomplemented terms. This led to the development of topological methods [5, 20, 23] of generating directly the terms of the reliability expression. However, it can be easily visualized that the number of non-cancelling terms would not be small. For example, for a 7-element system [5] with 7 path sets, 29 non-cancelling terms are obtained, whereas 2^7-1 is 127.

This difficulty or handicap led to further research in the development of reduction and transformation techniques for obtaining the system reliability expression. For series-parallel systems

decomposition is straightforward and one may use a computerized system decomposition technique such as that suggested in [6], which incidentally computes the system reliability value without obtaining explicitly an expression for the system reliability and is the fastest method of computing system reliability even today. Also, originally it was suggested for redundant systems with active redundancy but it can consider any type of redundancy (*viz,* standby, active, partial, or voting). However, for non-series parallel systems or non-decomposing systems (which cannot be decomposed into series or parallel structure) Bayes theorem or the factoring theorem [5, 6, 65] has been effectively used to obtain the system reliability expression by factoring out one element at a time from the system, which generates two sets of systems (one, with the element being factored out by open circuiting it and the other with this element short-circuited). The resulting configurations can be further used for decomposition by repeatedly applying the factoring theorem until a series parallel configuration is obtained. Simultaneous factoring of several elements is also possible [6]. Each time an element is factored, two configurations are generated. However, here again the computation time increases exponentially with the number of elements being factored out. Work on directed networks [49, 71, 94] has received considerable attention since the factoring theorem with directed components cannot be applied as with undirected elements.

Another direction of research has focussed on transformation techniques [29, 34, 36], which are basically approximate methods but that have been improved upon to provide reasonably accurate results from an engineering point of view.

Yet another direction that is receiving considerable attention and in which a significant amount of work is being done is the use of parallel processing algorithms [114] to reduce computation time and to develop the capability of handling very large systems.

In order to further improve the reliability evaluation procedure and to obtain a compact form of the system reliability expression involving complemented (unreliability) as well as uncomplemented variables (reliabilities), there were suggestions to generate disjointed path sets so that the reliability expression can be obtained just by summing up the probabilities of the disjointed path sets. This approach yielded far less number of terms in the system reliability expression than were obtained using the methods available at that time, usually in terms of uncomplemented variables representing component reliabilities. In fact, the system reliability expression was often very lengthy even for a moderate size system and required many multiplications, which affected the accuracy of the computation of system reliability.

The first attempt to achieve a minimized system reliability expression using the concept of producing disjointed path sets from simple path sets in a general computerized algorithmic procedure was made in 1975 in [15] and is known as the AMG-algorithm. This was basically a single variable inversion technique. Later, several improvements to the procedure were suggested starting with the Abraham [26] algorithm, and a large number of papers started appearing in the literature [31, 40, 51, 53, 60, 61, 67, 69, 70, 81, 90, 102], each claiming to provide an ever-decreasing number of terms in the system reliability expression.

This concept was further extended to include multi-variable inversion [95, 111, 137] and a highly compact form of the system reliability expression. These procedures offered the advantage of a compact expression, which not only saves computation time but can provide a more accurate numerical value of the system reliability as it involves fewer multiplications and handles less terms.

19.4.4 Special Gadgets and Expert Systems

Another important development in reliability evaluation techniques has been in the area of the development of special electronic gadgets or dedicated desktop systems in determining the path sets or cut sets of a system. We can represent a system by a network of two-terminal components and a signal (generated by a signal generating device) is passed through the system. When the signal is able to pass through the system (where each element is in a particular *on* or *off* state) it

simulates the system up-state and is analogous to creating a path set if we are able to record the state of each component. The digital part of this gadget would take care of the algebraic computation of reliability. This gadget is also useful in demonstrating to reliability beginners the idea of path sets and cut sets. The basic idea of the gadget (called "reliability analyzer") was introduced in [24, 121] and was further developed in [35, 37, 43] using a microprocessor platform. Later, this idea was commercially exploited by Laviron [42] to develop a desk-top aid in the form of ESCAF. Of course these developments came about at a time (around the early 1970s) when digital computer capabilities had not expanded to the limits they now have. Today, we have very fast computers to do any job that in the real time domain.

Another related development was in the direction of developing expert systems [57, 73, 77, 78, 100, 120]. In fact, there are expert systems available to carry out failure mode and effects analysis (FMEA). Several expert systems have been developed for specific reliability programs in organizations and companies. For example, REMM [140] was developed to help examine design decisions in the production of a new product in relation to dependability requirements imposed on the product and for environmental concerns in product operation in addition to the expert's opinion and views on various aspects. Another expert system, ARDA [110], helps analyse reliability data. Yet another expert system, RAMES [101], has been developed to assist a weapon system program in weapon system RAM performance analysis and enhancement and many other considerations.

19.5 Alternative Approaches

The main drawback of the probabilistic approach to performance evaluation of an engineering system is the uncertainty associated with the results, which puts the entire process in question. Specifying uncertainty by specifying mean and variance or confidence levels is not found to be the best way of estimating the quality of results. Although some intuitive methods of accounting, combination and propagation of uncertainty exist, these have not been found satisfactory by engineers. While Bayesian models have been extensively used, primarily as a numerical for representation and inference with uncertainty, this again masks the problem of uncertainty when priors are selected and ignorance remains hidden in the priors. All these shortcomings of the probabilistic approach led researchers to look for alternative approaches to system performance assessment.

The conventional probabilistic approach treats failure events as random occurrences and low *probability* of an event does not necessarily mean low *possibility* or that it will rarely occur. In fact, the worst accidents in human history had very low probability evaluated for their occurrence. Zadeh [3] put forward a fuzzy set theory, which appears to resolve these inconsistencies by offering a *possibilistic* approach to performance evaluation based on the premise that small probability does not always mean low possibility, whereas a low probability necessarily should imply low probability. In fact, a large number of papers has published in this area, which holds the promise of providing an alternative approach to the probabilistic approach. Fuzzy set theory also provides to resolve the gap between the *perceived risk* (subjective) and the *statistical risk* (objective), and in the opinion of the editor of this handbook this is a very appropriate area of application of fuzzy set theory. In fact, fuzzy set theory has the capability of providing models close to human thinking or the brain, which has the asset of inferring and decision making in a fuzzy environment. There have been several papers [30, 46, 68, 79, 80, 91, 97, 98, 107, 118 and 125] on the system analysis and design based on fuzzy set theory and it appears logical that this area will be explored extensively in near future.

Another approach that is being actively pursued is the Dempster–Shafer theory [93, 119], which may offer an interesting alternative approach to system performance assessment. This handbook therefore includes an expository chapter with a long list of references to familiarize the reader with these aspects of performance assessment.

19.6 Reliability Design Procedure

The usual design procedure followed by a system designer is:

- Define system terms of the operational requirements.
- Develop an index of system effectiveness and arrange the system into several non-interacting subsystems.
- Apply mathematical techniques to evaluate alternate system configurations in terms of reliability (or any other system effectiveness index) and constraints on resources,
- Specify a system configuration, maintenance policy and inter-relationship with other factors.
- Allocate failure and repair rates to each individual component so as to meet the specified system reliability goals.

In general, reliability is considered to be a good criterion for system effectiveness. However, depending upon the mission, some other criteria may be selected for design. Some of the other parameters that may be of interest are: availability or maintainability, probability of mission success, mean time to failure, duration of single downtime, or operational readiness, *etc*.

Any one of the above (or more) may form the criterion of optimal system design and, therefore, be traded off with some of the constrained resources such as cost, weight, power consumption, *etc*. For non-maintained systems, generally an index of reliability is sufficient for the system reliability effectiveness. However, for maintained systems, it is not enough to base system design on the reliability criterion. For almost all process systems or energy systems, the basic necessity is to know the percentage of time that the systems are available. This establishes criteria for the design based on the system availability; thus one may be interested in maximizing the system availability. Alternately one may rather be interested in comparing the design alternatives based on the duration of the single downtime or the frequency of failures. Whatever the criterion of assessment of various alternatives for design may be, one should be able to build a mathematical model for the design problem that will fit into the present-day techniques of solution.

The above guidelines are by no means the ultimate rule; the actual design procedure depends entirely upon the system under study. However, it is an established fact that, in order to arrive at an optimal design, the allocation process either of reliability or redundancy forms an integral part of the whole design procedure.

We have already seen in an earlier section that the use of either redundancy or high reliability components is a means of achieving a desired level of system reliability. Therefore, the design includes an allocation of either redundancy or reliability or both in a system. For a maintained system design, usually maximization of availability is desired rather than system reliability. However, if maximization of the system reliability is the objective and the state-of-art permits it, failure and repair rates are allocated to each component of the system in order to maximize its system reliability subject to some specified techno-economic constraints on the system design. Moreover, because we cannot stock any number of spares due to limited resources, it becomes imperative to seek an optimal allocation for spare parts while maximizing system availability or reliability subject to constraints on cost, *etc*., or else one can minimize the cost of spares subject to the specified level of availability.

The subject of optimal system design is discussed in two chapters, *viz.,* Chapters 32 and 33, where various formulations for the system design problem and their solution techniques are discussed in depth.

19.7 Reliability Testing

An important feature of reliability engineering today, as distinct from the past when we could have talked qualitatively only, is that we are in a position to say and demonstrate how reliable a product is. This has been made possible by reliability testing and demonstration. Reliability testing is also a major source of generating reliability data. Testing is also required for design review, *failure mode and effect analysis* (FMEA), trade-off studies, *etc*.

Component testing is an important activity in any reliability improvement program. Here tests are generally carried out to determine design margins and failure modes. Testing is also a must on all unproven components. Although component level testing can provide basic design data and helps weed out weak designs, it is not adequate enough in comparison to product or system testing. System testing comprises testing the complete unit or product and is carried out as far as possible under actual stress and environmental conditions. For thorough effectiveness system testing is done on an iterative basis, *i.e.*, test, fail, fix-retest cycle.

Reliability demonstration is done based on life tests. As such, these tests are time consuming and expensive. It is therefore imperative that tests are planned in such a way so as to give maximum information with the fewest items put to test. It is also important that the items to be tested and the performance of the tests be closely controlled in order to assure their validity. Very often products may be put to *accelerated life tests* and may therefore be tested at higher temperature, pressure or other stresses to reduce the test time. This may not be possible for many types of products, particularly when the failure mode is likely to change with an increase in the stress level.

Usually the following tests are in vogue:

Development tests: These are initiated at the time of first prototype assembly and constitute

- Performance tests conducted in a normal environment.
- Environment tests under the specified environment conditions.
- Endurance tests providing data determining the degree of degradation resulting from operating the item over an extended period of time.

Qualification tests: These tests are primarily designed to subject a product to the various environmental conditions and operating stress levels that it is expected to encounter in use. The details of the tests are actually worked out on a mutual basis between producer and consumer and are witnessed by the agents of the consumer. Generally, the decisions are of failure/success or go, no-go type, with no gradation between the two. For these tests the sample sizes are generally small.

Reliability demonstration tests: These tests are performed to demonstrate the product's ability to perform its functions repeatedly, and therefore the criterion is based on MTBF or MTTF. The purpose of these tests is to determine how long a device will continue to function under the specific environment or loading conditions. The maximum number of samples within the economic limits is subjected to these tests.

Accelerated life test: Traditional "*life data analysis*" involves analyzing the time-to-failure data (of a product, system or component) obtained under "*normal*" operating conditions in order to quantify the life characteristics of the product, system or component. In many situations, and for many reasons, such life data (or time-to-failure data) is very difficult, if not impossible, to obtain. The reasons for this difficulty can include the long life times of today's products, the small time period between design and release, and the challenge of testing products that are used continuously under normal conditions. Given this difficulty, and the need to observe failures of products to better understand their failure modes and their life characteristics, reliability practitioners have attempted to devise methods to force these products to fail more quickly than they would under normal use conditions. In other words, they have attempted to accelerate their failures.

Accelerated tests are necessary for obtaining life data quickly. Life testing of products under higher stress levels, without introducing additional failure modes, can provide significant savings of both time and money. Correct analysis of data gathered via such accelerated life testing can yield parameters and other information for the product's life under use stress conditions.

Types of Accelerated Tests:

Different types of tests, that have been called accelerated tests, provide different information about the product and its failure mechanisms.

Generally, accelerated tests can be divided into three types:

Qualitative tests: in general, qualitative tests are not designed to yield life data that can be used in subsequent analysis or for "accelerated life test analysis." In general, qualitative tests do not quantify the life (or reliability) characteristics of the product under normal use conditions. They are designed to reveal probable failure modes. However, if not designed properly, they may cause the product to fail due to modes that would not be encountered in real life. Qualitative tests have been referred to by many names, including elephant tests, torture tests, HALT (highly accelerated life testing) and shake and bake tests.

Elephant tests: These tests are known by several other names, such as design margin tests, design qualification tests, toture tests, shake and bake tests or killer tests. Generally, the sample is small or just one and the specimen is subjected to a single extreme value of stress or thermal cycling, or to a number of stresses, simultaneously or sequentially. If a product passes this test, the designer is satisfied with the design but if the product fails this test, the deginer has to redesign the product or appropriate measure is taken to improve manufacturing. It is not necessary that an elephant test produce a failure that the product may encounter in actual use. Therefore, it may be necessary to devise different elephant tests, such as a high voltage test to reveal electrical failure modes and vibration tests to reveal mechanical failure modes.

Environmental stress screening (ESS): ESS is a process involving accelerated testing of products in an environment such as random vibration and thermal cycling, and shock and bake. The goal of ESS is twofold. The first is as an elephant test during development; its purpose is to expose design and manufacturing problems. The other is accelerated burn-in during manufacturing to improve reliability. MIL-HDBK-344 for electronic equipment and MIL-STD-883C for microelectronics are used.

Burn-in: Burn-in consists of running items under design or accelerated conditions. Burn-in can be regarded as a special case of ESS. Burn-in is a test performed for the purpose of screening or eliminating freak or marginal devices with inherent defects or defects with manufacturing aberrations before customers receive them. If items fail early, they have manufacturing defects. Burn-in is generally used for electronic components and equipment. Static and dynamic burn-in is used on the devices depending upon the complexity and their failure mechanisms.

ESS and burn-in are performed on the entire population and do not involve sampling. ESS includes burn-in as one of its purposes. Although ESS has evolved from burn-in, it is far more advanced process. ESS is an accelerated process of stressing a product in continuous cycles between predetermined environmental extremes mainly comprising temperature cycling and random vibrations. Burn-in, therefore, is a special case of ESS where the temperature change rate for thermal cycling is zero and vibration is sinusoidal if used. The interested reader is referred to the classical book of Kececioglu and Sun [127] on the subject of burn-in.

Quantitative accelerated life tests: Quantitative accelerated life testing, unlike qualitative testing methods, consists of quantitative tests designed to quantify the life characteristics of a product, component or system under normal use conditions, and thereby provide information on the probability of failure of the product under use conditions, mean life under use conditions, and projected returns and warranty costs. It can also be used to assist in the performance of risk assessments, design comparisons, *etc*.

Accelerated life testing can take the form of "usage rate acceleration" or "overstress acceleration." For all life tests, time-to-failure information for the product is always required

Usage rate acceleration: For products that do not operate continuously under normal conditions, if the test units are operated continuously, failures are encountered earlier than if the units are tested under normal usage. For example, if we assume an average washer use of six hours a week, one could conceivably reduce the testing time 28-fold by testing these washers continuously. Data obtained

through usage acceleration can be analyzed with the same methods used to analyze regular time-to-failure data.

Overstress acceleration: For products with very high or continuous usage, the accelerated life-testing practitioner must stimulate the product to fail in a life test. This is accomplished by applying stress levels that exceed the levels that a product will encounter under normal use. The time-to-failure data obtained under these conditions is then extrapolated to use conditions. Accelerated life tests can be performed at high or low temperatures, humidity, voltage, pressure, vibration, *etc*., and/or combinations of stresses to accelerate or stimulate the failure mechanisms.

Accelerated life test (ALT) stresses and stress levels should be chosen so that they accelerate the failure modes under consideration but do not introduce failure modes that would never occur under use conditions. Normally, these stress levels should fall outside the product specification limits but inside the design limits. Usually it is assumed that intrinsic failures due to wear out may only exist and this assumption may not be quite valid in certain cases particularly in the presence of randomly occurring defects due to the manufacturing process. In those cases one may use the methodology described in [135].

HALT and HASS: HALT and HASS are not meant to simulate the environment in field but their sole purpose is to expose weak links in the design and processes while using only a small sample size and in a very short time. The stresses are stepped up to well beyond the expected environment in actual use until the "fundamental limit of technology" is reached. Each weak link discovered provides an opportunity to improve the product design or the processes that may lead to the improved reliability of a product, reduced costs, and reduced design time. It is basically ruggedization of design as a robust product exhibits higher reliability than a non-robust product.

HASS is a 100% screening of the production of items using stresses that are higher than those met in normal use. In HASS, accelerated stresses are applied to production in order to shorten the time to failure of the defective unit, and to shorten the corrective action time and the number of units built with the same flaw. HASS is generally not possible without comprehensive HALT. Without HALT, fundamental design limits will restrict the acceptable stress levels in the production screens.

The originator of HALT and HASS is Gregg K. Hobbs [131] and he has authored a chapter in this handbook on HALT and HASS.

Multiple Environment Overstress Tests (MEOST)
MEOST claims to provide powerful tools that can predict and correct potential field failures at the design stage of the product, besides claiming that it [144] can reduce the design test cost both in terms of labor and the number of units required to demonstrate reliability, as well as reducing the design cycle times. In MEOST the objective is not to pass a product but to fail it, which will highlight the weakness of the design. A single stress or environment is not sufficient to generate failures. More than one stress applied sequentially is not enough to ferret out the interaction effects. Therefore, several stresses or environments are combined simulating the field conditions as closely as possible to create synergy of interaction effects. The combined overstresses go beyond the design stress level to a maximum possible overstress limit (MPOSL) and the rate of overstress is accelerated to produce failures in the shortest possible time. It is claimed that the Apollo lunar module was the first to be subjected to MEOST methodology. Since 1960, MEOST has been successfully applied to aircraft engines, helicopters, automobiles aerospace equipment, *etc.*

19.8 Reliability Growth

The objective of reliability growth is to improve reliability over time during product development. This is primarily during the design and manufacturing phase of the product and is achieved by following a process of test-fix-test-fix cycle. Reliability tests are conducted on prototypes to ensure that reliability goals have been met. Failure analysis is conducted to identify the high failure modes in case the goal is not met and these modes are then fixed. We try to eliminate these modes or attempt to lessen their effects in order to improve

reliability. This cycle is repeated and failure data generated from the tests are plotted in the form of a growth curve called the *reliability growth curve*. As has been mentioned, this growth curve is obtained through continuous tests, evaluation and redesign activity. The earliest reliability growth model was proposed by Duane [2], who enunciated that a plot of the logarithm of the cumulative number of failures per test time *versus* the logarithm of the test time during growth testing is approximately linear. There are other growth models such as Crow-AMSAA [10]. Crow observed that the Duane model could be stochastically represented as a Weibull process and this stochastic extension became what is known as the Crow-AMSAA model; this model was first developed at the US Army Material System Analysis Activity. It is used with systems when usage is measured on a continuous scale. There are other models as well, such as the Lloyd and Lipow model [1], the Gompertz model [4], the Crow extended model [143], and the logistic [87] model. A good coverage of various other models is provided in [44, 106, 126].

Abstract: Load-sharing systems have several practical applications. In load-sharing systems, the event of a component failure will result in a higher load, therefore inducing a higher failure rate, in each of the surviving components. This introduces failure dependency among the load-sharing components, which in turn increases the complexity in analyzing these systems. In this chapter, we first discuss modeling approaches and existing solution methods for analyzing the reliability of load-sharing systems. We then describe tampered failure rate (TFR) load-sharing systems and their properties. Using these properties, we provide efficient solution methods for solving TFR load-sharing models. Because load-sharing *k*-out-of-*n* systems have several practical applications in reliability engineering, we provide a detailed analysis for various cases of these systems. The solution methods proposed in this chapter are applicable for both identical and non-identical component cases. The proposed methods are not restricted to the exponential failure distributions and are applicable for a wide range of failure time distributions of the components. In most cases, we provide closed-form analytical solutions for the reliability of TFR load-sharing *k*-out-of-*n*:G systems. As a special case, efficient solutions are provided for systems with identical components where all surviving components share the load equally. The efficiencies of the proposed methods are demonstrated through several numerical examples.

20.1 Introduction

In reliability engineering, it is a common practice to use redundancy techniques to improve system reliability [1]. In most cases, when analyzing redundancy, independence is assumed across the components within the system. In other words, it is assumed that the failure of a component does not affect the failure properties (failure rates) of the remaining components. In the real-world, however, many systems are load-sharing, where the assumption of independence is no longer valid. In a load-sharing system, if a component fails, the same workload has to be shared by the remaining components, resulting in an increased load shared by each surviving component. In most circumstances, an increased load induces a higher component failure rate [2]. Many empirical studies of mechanical systems [3] and computer systems [4, 5] have proved that the workload strongly

affects the component failure rate. Applications of load-sharing systems include electric generators sharing an electrical load in a power plant, CPUs in a multiprocessor computer system, cables in a suspension bridge, and valves or pumps in a hydraulic system [6]. Therefore, it is important to develop reliability models that incorporate stochastic dependencies among the system's components.

The stochastic dependency models can be broadly classified as shock models and load-sharing models [7, 8]. In shock models, the system is exposed to shocks that cause random amounts of damage [9]. The shocks themselves can occur according to a random process. The intensity and occurrence frequency of the shocks may vary with time. Generally, the occurrences of shocks are modeled using homogeneous or non-homogeneous Poisson processes. The additional damage to the system at a given shock may depend on the intensity of the shock, damage that already experienced, and the age of the system. The system fails when the cumulative damage exceeds a certain level. An example of a shock model is the failure of a dam due to excessive water in the reservoir after several successive rainfalls [10]. Another class of shock models includes common-cause failures. For example, the bivariate shock model introduced by Marshall and Olkin [11] analyzes component dependencies by incorporating latent variables to allow simultaneous component failures. In load-sharing models, the component failure rates depend on the operating status of the other system components and the effective system structure function. In 1945, Daniels [12] adopted the load-sharing model to describe how the strain on yarn fibers increases as individual fibers within a bundle break. For example, a bundle of fibers can be considered as a parallel system subject to a steady tensile load. In this chapter, we concentrate on load-sharing models.

Load-sharing models have a wide range of engineering applications. They are extensively used in the textile engineering (fibers) [12], material science and testing (fatigue and crack growth) [13], mechanical engineering, and civil and structural engineering (welded joint on large support structures) [8] disciplines. Further, load-sharing models have interesting applications in nuclear reactor safety, software reliability [14], distributed computing [15], population sampling [8], combat modeling [16], modeling the incubation period for the human immunodeficiency virus (HIV) [17], and condition-based maintenance [18]. For a summary of these applications, refer to Kvam and Peña [8].

Even though load-sharing systems have been studied for a long time and have a wide range of applications, the methods that are applicable for studying the time-dependent reliability characteristics of these systems are limited. A majority of research papers related to this topic are published in journals on material science, physics, and applied statistics journals. These papers focus on the statistical properties of materials (strength of materials) subjected to load-sharing rules such as equal load-sharing, local load-sharing, monotone load-sharing. The research publications that consider both time-dependent failures (also failure rates) and the dynamic effects of loads are limited [2]. In this chapter, we present existing methods and their useful extensions for analyzing time-dependent reliability characteristics of load-sharing systems. We focus our attention on a specific class of load-sharing models called tampered failure rate (TFR) load-sharing models [19]. Whenever applicable, we also present simplified results for some special cases that include exponential failure distributions and identically distributed components.

Section 20.2 discusses the background and basic concepts in modeling load-sharing systems. Section 20.3 presents a brief overview of static and dynamic methods. It also discusses the related works that are used for analyzing the time-dependent reliability characteristics of load-sharing systems. Section 20.4 presents the system description, assumptions, and details of the tampered failure rate (TFR) models. Section 20.5 presents the reliability analysis of load-sharing k-out-of-n systems with exponential failure distributions, and Section 20.6 focuses on the general failure distributions. Section 20.7 presents the conclusions and future directions of research.

20.2 The Basics of Load-sharing Systems

In order to analyze the reliability of load-sharing systems, we must consider the pattern of loads acting on the system, load-sharing policies that dictate how a load on the system is distributed among its components, and the relationship between the dynamic load and the failure behavior of the components over a time period.

20.2.4 The Load Pattern

In load-sharing systems, the components of the system are subjected to varying loads due to numerous reasons including changing demands of the system, failure of some components, changes in the operating conditions, *etc*. Therefore, the total load on the system can be categorized as:

- Constant total load: In this case, the total load on the system is constant. However, the components experience different loads due to the unavailability of some components as a result of failure or preventive maintenance. The constant total load assumption is applicable for a wide range of applications. The majority of published works are based on this assumption. In this chapter, we also focus on this assumption.
- Time-varying total load: The total load on the system may vary with time. The variation can be deterministic or random. Therefore, the components can experience varying loads due to the variations in the demand. Hence, the load on a component not only changes when other components fail but also when system demands fluctuate.

20.2.4 The Load-sharing Rule

The most important element of the load-sharing model is the rule that governs how the loads on the working components change after some components in the system fail [20].

- Equal load-sharing rule: A constant system load is distributed equally among the working components. Examples of this kind include yarn bundles and untwisted cables that spread the stresses uniformly after individual failures.
- Local load-sharing rule: A load on a failed component is transferred to adjacent components, and the proportion of the load that the surviving components inherit depends on their "distance" to the failed component. Examples of this kind include cables supporting bridges and other structures, composite materials with bounding matrix joins, and transmission systems that are modeled using consecutive *k*-out-of-*n* systems.
- Monotone load-sharing rule: The load on any individual component is non-decreasing as other components fail. This is a generalization to the previous two load-sharing rules. This load-sharing rule is applicable if we are not redistributing any portion of a load from a good component.

The same rules are also applicable for time-varying loading conditions. It should be noted that for the 1-out-of-2 systems subjected to constant total load, all of these load-sharing rules produce the same effects (or coincide).

A generalization to the above load-sharing rules includes the non-monotone load-sharing rule, where the load on working components may increase or decrease depending on the dynamics in the systems. A simple example of this kind includes load on a processor due to the variations in the demand [15]. The non-monotone load-sharing rule may also be applicable (even if the total load on the system is constant) when the components have discrete load-carrying capacities (power generators). Similarly, a modification to the equal load-sharing rule to analyze twisted fiber bundles is proposed in [21].

20.2.3 Load–life Relationship

In order to analyze the reliability of load-sharing systems, we should consider the relationship between the load and the failure behavior of a component. In general, failure rate of a component increases with the applied load. Accelerated life

testing models play an important role in determining the relationships between load and failure rate. There is a wide range of literature available on the accelerated life testing models [22].

20.2.3.1 Proportional Hazards Model (PHM)

PHM was first introduced by Cox [23] and has recently gained popularity in the engineering field [24–26]. PHM assumes that the hazard (failure) rate of a component is the product of both a baseline hazard rate (which can be a function of time t) and a multiplicative factor based on the values of a set of conditions (loads in this case). In PHM, the component failure rate is expressed as:

$$h(t;z) = h_0(t) \cdot \exp(z\beta), \qquad (20.1)$$

where $z = \{z_1, \ldots, z_m\}$ is a set of conditions (loads) acting on the component, and $h_0(t)$ is the baseline failure rate function for the standard set of conditions (at the baseline load). In fact, $\exp(z\beta)$ can be replaced by any known function $g(z,\beta)$. When there is only one type of load, $z = L$, it reduces to:

$$h(t;L) = h_0(t) \cdot \exp(L\beta). \qquad (20.2)$$

If the failure rate of the component at a fixed load is a constant function of time, then we have: $h_0(t) = \lambda_0 = \lambda(L_0)$. Then, we have:

$$\lambda(t;L) = \lambda(L) = \lambda_0 \cdot \exp(L\beta). \qquad (20.3)$$

When the baseline failure distribution is Weibull or exponential, under certain situations, the PHM model is also equivalent to the accelerated failure time model (AFTM) [27].

20.2.3.2 Accelerated Failure Time Model (AFTM)

AFTM was first proposed by Pike [27] and has been widely applied since then [22]. This model specifies that the effect of the load is multiplicative in time. In AFTM, component reliability is expressed as:

$$R(t;z) = R_0(t \cdot \phi(z)). \qquad (20.4)$$

$R_0(.)$ is a survival function of an arbitrary distribution such as Weibull, Gaussian, lognormal, and gamma. Hence, it follows that

$$\begin{aligned} h(t;z) &= \phi(z) \cdot h_0(t \cdot \phi(z)) \\ H(t;z) &= H_0(t \cdot \phi(z)) \end{aligned}. \qquad (20.5)$$

$h_0(.)$ and $H_0(.)$ are the hazard rate and cumulative hazard rate corresponding to the survival function $R_0(.)$. When there is only one type of load, $z = L$, commonly used forms of $\phi(L)$ include:

- The power law: $\phi(L) = L^{\alpha}$.
- The exponential law: $\phi(L) = e^{L\alpha}$.

If the baseline distribution is Weibull (or exponential) and the multiplicative factor (acceleration factor) follows the power law, then AFTM and PHM coincide. However, in general, there is no direct duality between the models in all cases [28].

If the failure distribution is exponential and the multiplicative factor follows the power law, then

$$\lambda(L) = \lambda(L_0)(L / L_0)^{\alpha}. \qquad (20.6)$$

20.2.4 The Effects of Load History on Life

In the previous section, we discussed how the load effects the failure distribution of a component. These models are applicable when a constant, fixed load is acting on a component. However, in load-sharing systems, a component operates at different loads during different time intervals. Therefore, it is important to consider the effects of load history on the component failure rate. Hence, we should also consider other details that are applicable for step-stress acceleration life testing models, where the component experiences different loads at different time intervals. However, unlike in accelerated life testing, in a load-sharing system, the load varies at random time intervals. Hence, analyzing load-sharing systems is much more complex than analyzing fixed duration step-stress acceleration life testing models.

In this section, we present the step-stress accelerated models that describe the failure rate and the remaining life time of the products for a given loading history.

20.2.4.1 The Tampered Failure Rate (TFR) Model

The TFR model was first proposed by Bhattacharrya and Soejoeti [29] and then generalized by Madi [30]. The acceleration of failure when the stress is raised from a lower level to a higher level is reflected in the hazard rate function. The TFR model is relatively simple and has been studied by several researchers [31]. In this model, the failure rate of a component completely depends on the current applied load and the age of the component. In other words, the failure rate is independent of the history of the load applied on the component. However, the cumulative failure rate and reliability of a component is a function of the load history and the ages at which the loads are applied. As pointed out in [32], it should be noted that the Khamis and Higgins model [33] is a special case of the TFR model where the baseline failure distribution is Weibull.

20.2.4.2 The Cumulative Exposure (CE) Model

The cumulative exposure model was proposed by Nelson [34]. It is also called the cumulative damage model [35]. It suggests that, in calculating cumulative failure rate or reliability, the life-stress model must take into account the cumulative effect of the applied stresses when dealing with data from accelerated tests with step stresses. Alternatively, the cumulative failure rate is calculated using the effective age of the component, where the effective age is the sum over all load durations multiplied by the corresponding acceleration factors.

Consider a component that is subjected to the loads $z_1, z_2, \ldots, z_n$ for the durations $\tau_1, \tau_2, \ldots, \tau_n$. Let the acceleration factor corresponding to the load z_i be α_i. The effective age of the component at the baseline failure rate is then: $T_a = \alpha_1\tau_1 + \alpha_2\tau_2 + \ldots + \alpha_n\tau_n$, whereas the actual age is $T = \tau_1 + \tau_2 + \ldots + \tau_n$.

The disadvantage of this model is that the cumulative failure rate or reliability of a component depends only on the duration of the load, but not on the sequence of loads (no sequence effect) or the ages at which the loads are applied. Further, the cumulative damage is additive, and the remaining life of a component depends only on the current stress and the current cumulative distribution function, regardless of the damage accumulation history. Some studies suggest that it is important to consider the effects of load sequencing on the failure behavior [36].

Some variations and generalizations of these models are presented in [37–39]. When the baseline failure distribution is exponential, all these models coincide. In this chapter, we concentrate on the TFR model while studying load-sharing systems subjected to general failure distributions.

20.3 Load-sharing Models

The majority of work on load-sharing models has studied the failure properties of composite materials using the concept of fiber bundles. In these analyses, the failure model of the individual fibers that make up the fiber bundle is specified. The model can be either static or dynamic (or time-dependent). In the static case, the probability of the failure of a fiber is specified in terms of the stress on the fiber [12, 21]. The static models mainly concentrate on the strength distribution of the system (bundle of fibers) in terms of the strength distribution of individual system elements (fibers). These models generally ignore the time-varying properties of materials, *i.e.*, failure is assumed to occur instantaneously. In the dynamic case the statistical distribution of times to failure for the fibers is specified in terms of stresses on the fibers [40]. Experiments generally favor the dynamic failure fiber bundle models [8, 41].

20.3.1 Static Models

Static models generally focus on the influence of fiber strength, bundle length, bundle size, fiber packing, and interface properties. Most of these models assume that components are arranged in parallel (parallel array of fibers) [12]. These studies are also called parallel bundle theories. On the other hand, twisted bundle theories are used to study the twisted mechanical structures such as yarns, ropes, and cables [21].

The earliest work on static models dates back to 1945. In a seminal paper, Daniels [12] showed through a long and complicated proof that when

the load from fiber breaks is redistributed equally among the remaining intact fibers (equal load sharing), the strength of a large bundle asymptotically approaches a Gaussian distribution. Daniels derived expressions for the asymptotic mean and standard deviation as a function of the underlying strength distribution of the fibers and bundle size in terms of number of fibers. Here, the asymptotic value for mean is independent of n. Smith [42] derived a correction factor for mean that depends on n to improve the accuracy for relatively small bundles. For a discussion of load-sharing schemes, we refer to Harlow and Phoenix [20]. For a recent review on parallel bundle theories, we refer the reader to Phoenix and Beyerlein [43].

20.3.2 Time-dependent Models

Time-dependent analysis can broadly be classified as: (1) finite population analysis, and (2) asymptotic analysis. In this chapter, we concentrate on finite population analysis where the number of elements in the system is finite. Analyses for finite populations are published in the reliability journals [2, 44]. On the other hand, the asymptotic behavior (limiting behavior) is studied by assuming the number of elements in the system approaches infinity (are very large). These studies are published in physics, material science, and applied statistics journals [40, 42–54]. Coleman [45, 46] has shown that under certain conditions, as the number of fibers increases, the asymptotic failure time of the bundle approaches the normal distribution. Similarly, using extreme value theory, Harlow *et al*., [53–55] have shown that the time to failure of a parallel bundle follows the Weibull distribution. However, as pointed out by Borges [55], even for the case of exponential failure time distributions, this approximation is unsuitable from the application standpoint because for each fixed value of t (time), the deviation from its true value increases as n (number of elements) increases. In addition to this, using the large deviation theorem of the Cramer–Petrov type and a ranking limit theorem of Loève [56], Borges proposed a better approximation for failure time distribution. These results are further extended for series-parallel systems [55]. Recently, Newman and Phoenix [57], assuming exponential failure time distribution and a power law relationship between failure rate and applied load, developed asymptotic theories and new computational algorithms for local load-sharing models.

20.3.3 Related Models

In this chapter, we focus on the reliability analysis of load-sharing systems with a limited number of components. These models have a wide range of applications in reliability engineering [1–6, 58–61]. Most approximations and asympotic behaviors that are applicable for systems with a large number of elements (fiber bundles) are not applicable when the number of components (elements) in the system is very small. Therefore, these models require a different treatment as compared to fiber bundle models. In addition, it is important to consider the effects of time-varying failure rates, imperfect switching mechanisms, repair policies, *etc*.

In spite of a wide range of applications for load-sharing systems, the literature on the reliability analysis of load-sharing systems is limited [2]. The main reason for this is due to the inherent complexity of these models that is introduced by the load-sharing mechanisms.

As we have already noted, load-sharing systems introduce dependecies among component lives. Bivariate and multivariate distribution play important roles in modeling these dependencies. However, only a certain class of multivariate distributions is applicable for load-sharing systems [7]. Freund [62] first introduced a bivariate exponential distribution to model a two-unit load-sharing system.

20.3.3.1 Freund's Load-sharing Model

Freund's model is the first bivariate model that is physically motivated [7, 62]. Let X and Y represent the lifetimes of components *C1* and *C2* of a two-component system. Further, assume $X \sim \exp(\lambda_1)$ and $Y \sim \exp(\lambda_2)$. According to the Freund's model, the failure rate of *C2* changes to λ'_2 from λ_2 ($\lambda'_2 > \lambda_2$), upon the failure event of component *C1*

because of extra stress. Similarly, λ_1 changes to λ'_1 in the case where component *C2* fails first, ($\lambda'_1 > \lambda_1$), due to the same reason. Assuming that $\lambda_1 + \lambda_2 - \lambda'_1 \neq 0$ and $\lambda_1 + \lambda_2 - \lambda'_2 \neq 0$, the joint density of (X, Y) is:

$$f(x,y) = \begin{cases} \lambda_1 \lambda'_2 \exp[-\lambda'_2 y - (\lambda_1 + \lambda_2 - \lambda'_2)x], \\ \text{if } 0 < x < y \\ \\ \lambda'_1 \lambda_2 \exp[-\lambda'_1 x - (\lambda_1 + \lambda_2 - \lambda'_1)y], \\ \text{if } 0 < y < x \end{cases} \tag{20.7}$$

It should be noted that the marginal distributions of X and Y are not exponential distributions except for the special cases: $\lambda'_1 = \lambda_1$ and $\lambda'_2 = \lambda_2$. However, the marginal distributions can be shown to be mixtures or weighted averages of exponential distributions [7].

If the system functions as long as one out of two components are functioning, the system failure time is equal to $T = \max(x, y)$. Integrating the density function over the region $t < T$ gives the unreliability of the system. Therefore, the system unreliability is:

$$Q(t) = \frac{\lambda_1}{\lambda_1 + \lambda_2}\left(1 + \frac{\lambda'_2 \cdot e^{-(\lambda_1+\lambda_2)t} - (\lambda_1 + \lambda_2)\cdot e^{-\lambda'_2 t}}{\lambda_1 + \lambda_2 - \lambda'_2}\right) + \frac{\lambda_2}{\lambda_1 + \lambda_2}\left(1 + \frac{\lambda'_1 \cdot e^{-(\lambda_1+\lambda_2)t} - (\lambda_1 + \lambda_2)\cdot e^{-\lambda'_2 t}}{\lambda_1 + \lambda_2 - \lambda'_1}\right) \tag{20.8}$$

Therefore, the system reliability is:

$$R(t) = \frac{\lambda_1}{\lambda_1 + \lambda_2}\left(\frac{(\lambda_1 + \lambda_2)\cdot e^{-\lambda'_2 t} - \lambda'_2 \cdot e^{-(\lambda_1+\lambda_2)t}}{\lambda_1 + \lambda_2 - \lambda'_2}\right) + \frac{\lambda_2}{\lambda_1 + \lambda_2}\left(\frac{(\lambda_1 + \lambda_2)\cdot e^{-\lambda'_2 t} - \lambda'_1 \cdot e^{-(\lambda_1+\lambda_2)t}}{\lambda_1 + \lambda_2 - \lambda'_1}\right) \tag{20.9}$$

The reliability expression can be rearranged as:

$$R(t) = e^{-(\lambda_1+\lambda_2)t}\left(1 - \frac{\lambda_1}{\lambda_1 + \lambda_2 - \lambda'_2} - \frac{\lambda_2}{\lambda_1 + \lambda_2 - \lambda'_1}\right) + \frac{\lambda_1}{\lambda_1 + \lambda_2 - \lambda'_2} e^{-\lambda'_2 t} + \frac{\lambda_2}{\lambda_1 + \lambda_2 - \lambda'_1} e^{-\lambda'_1 t} \tag{20.10}$$

The above system behavior can be modeled using a four-state Markov chain, and the closed-form solution can be obtained using either convolution integrals or Laplace transformations [63, 64]. The above model is applicable for all types of load-sharing rules: equal, local, or monotone load-sharing rules. In fact, this model is independent of the load-sharing rule.

Now assume that $\lambda_1 \neq \lambda_2$, but $\lambda'_1 = \lambda'_2 = \lambda'$. This assumption is valid if both the components are identical and load is distributed unequally when both components are working. However, after a failure, the surviving component carries the full load. Hence, we have:

$$R(t) = e^{-(\lambda_1+\lambda_2)t} + \frac{\lambda_1 + \lambda_2}{\lambda_1 + \lambda_2 - \lambda'}\left(e^{-(\lambda_1+\lambda_2)t} - e^{-\lambda' t}\right) . \tag{20.11}$$

If the two components are equal and the load is distributed equally among these two components, we have: $\lambda_1 = \lambda_2 = \lambda$, and $\lambda'_1 = \lambda'_2 = \lambda'$. Hence, we have:

$$R(t) = e^{-2\lambda t} + \frac{2\lambda}{2\lambda - \lambda'}\left(e^{-2\lambda t} - e^{-\lambda' t}\right) . \tag{20.12}$$

Only a few reliability engineering textbooks that discuss the load-sharing systems cover more than this simple model [1, 6, 59].

Freund's model can be viewed as a simple load-sharing model for a system with two components. As noted above, Freund did not consider the underlying load-sharing rules that dictate how failure rates change after some components in the system fail. Weier [66] was the first to actually analyze the reparametrization of Freund's model. He modeled the post failure hazard rate θ_2 by $\gamma\theta_1$, $\gamma > 0$. Here $\gamma = 1$ implies independence, and $\gamma > 1$ corresponds to an increased work load on the remaining component, while $\gamma < 1$ corresponds to a reduced work load. This parameterization allows researchers to extend the Freund's model for general cases, such as *k*-out-of-*n* systems, and make general statistical inferences on the details of possible dependencies among components in a system [7] .

20.3.3.2 The k-out-of-n System with IID Components

Scheuer [44] studied the reliability of a *k*-out-of-*n*:G system where component failure induces higher failure rates in the survivors. His work assumed that the components are IID with constant failure rates. Although it is not mentioned explicitly, the model inherently assumes the equal load-sharing rule. Scheuer modeled the system failure time as the sum of independent exponential distributions. He identified three cases.

- *Case 1* arises when all these exponential distributions are identical. In this case, the system failure follows the Erlang distribution (a special case of the Gamma distribution).
- *Case 2* arises when all these exponential distributions are distinct. In this case, the system failure time follows the hypo-exponential distribution.
- *Case 3* arises when all these exponential distributions are neither equal nor distinct. This happens when distinct groups of distributions exist. Within each of these groups, all of the distributions are equal. In this case, the system failure time is the sum of Erlangian distributions with different parameters. Scheuer [44] mentioned that there is no convenient closed-form solution for this case. However, recently Amari and Misra [65] provided a closed-form solution to this case. This case has a wide range of applications not only in reliability engineering but also in other fields such as control systems and telecommunications [67, 68].

20.3.3.3 The k-out-of-n System with Repair

Shao and Lamberson [69] provide an analysis of a repairable *k*-out-of-*n*:G system with load-sharing components considering imperfect switching. In this model, all components in the systems are identical and follow exponential failure distributions. As in most cases, it also assumes the equal-load sharing rule. The sensing and switching mechanism is responsible for detection of component failures and the redistribution of the load of the system equally among surviving components. System performance measures such as reliability and availability are analyzed using Markov chains. Unfortunately, several errors exist in the above paper, which are corrected by Akhtar [70]. Newton [71] provides an alternative argument for evaluation of the MTTF and MTBF of such systems. A corrected version of this model is presented in [72]. However, [72] did not provide a complete solution to this model, but provided the differential equations for solving the Markov chains. Recently, Chan [73] discussed availability analysis of a load-sharing system and advocated the combining of performance and reliability analyses within the Markov reward framework.

20.3.3.4 Multivariate Exponential Models

Lin *et al*., [74] extended Freund's bivariate exponential model to the multivariate exponential case. In this model, the system consists of *n* non-identical components. The failure rate of a component depends on the number of failed components, but it is independent of the actual set of components that are failed. For example, when there is only one failed component in the system, the failure rate of component 1 is the same, regardless whether component 2 or component 3 failed. This assumption is applicable for the equal load-sharing rule, where the load on a surviving component is a function of the number of failed components. Even with this assumption, the failure time distribution of a 1-out-of-3 system is too complex, and the equation for the system reliability occupies almost two full columns of that paper. Lin *et al*. [74] also presented a closed-form solution for *k*-out-of-*n* systems with IID components following exponential failure distributions. However, this is equivalent to Case 2 studied by Scheuer [44], where the closed-form solution is well known. Later, Amari [64] provided a compact closed-form solution to *k*-out-of-*n* systems with non-identical components.

20.3.3.5 General Failure Distributions

There is not much published work on the reliability analysis of load-sharing systems with components

subjected to general failure distributions. Even though there are some papers, they do not explicitly mention the underlying assumptions. In modeling load-sharing systems with general distributions, it is important to consider an appropriate model to incorporate the effects of loading history. For details, the reader is referred to Section 20.2.4.

Several researchers have extended Freund's bivariate exponential model to other cases that include the case of non-exponential distributions such as Weibull and gamma [75, 76]. However, only a few of these extensions are useful for modeling load-sharing systems. Lu [76] proposed a bivariate Weibull distribution that can be applied to load-sharing systems. In this model, the failure distribution (parameters) of the surviving component changes after load redistribution due to the failure of other component. However, in this model, it is assumed that the effective age of the component becomes zero after the load redistribution, which is not a realistic assumption.

Kececioglu and Jiang [77] presented a 1-out-of-2 load-sharing system with Weibull failure time distributions. In this analysis, it is assumed that after load redistribution, the component age changes according to an accelerated failure-time model (AFTM) as *per* the cumulative exposure model. This model is also available in [59]. Later Liu *et al*. [26, 78, 79] proposed similar concepts for analyzing 1-out-of-2 parallel systems subjected to variable working conditions. Liu [2] further extended this model for analyzing load-sharing *k*-out-of-*n*:G systems with arbitrary load-dependent component lifetime distributions. However, the solution provided in [2] is too complex. Therefore, as mentioned in [2, 6], the solution can only be applied for simple systems where $n \leq 6$ (even using MatLab). Therefore, more efficient methods for handling arbitrary load-dependent component lifetime distributions are needed.

Recently, Amari *et al*. [19] provided a closed-form analytical solution for the reliability of tampered failure rate (TFR) load-sharing *k*-out-of-*n*:G systems with identical components where all surviving components share the load equally. This model can be considered as a generalization of the 1-out-of-2 load-sharing model presented by Hassett [80], where the solution is provided using a numerical integration technique applicable for semi-Markov chains [81].

20.4 System Description

In this chapter, we provide a detailed treatment of TFR load-sharing systems subjected to exponential and general failure time distributions. Because *k*-out-of-*n* systems have a wide range of applications in reliability engineering, a detailed analysis of these systems is presented in this chapter. The concepts presented here can easily be extended to analyze general system configurations. In this chapter, we also would like to relax the IID assumption used in [19].

General Assumptions

1. After a component failure, the load is equally distributed among all surviving components. This assumption will be relaxed in some cases.
2. The failure rate of a component varies as *per* the TFR model. The baseline failure rate of the TFR model can follow an arbitrary distribution such as Weibull, Gaussian, lognormal, and gamma.
3. The redistribution and reconfiguration mechanisms are perfect.
4. The system and its components are non-repairable.

20.4.1 Load Distribution

In a load-sharing system, on component failure, the load on the failed component is redistributed among the surviving components. In the majority of cases, the load is equally distributed over all surviving components. If the total load is L, and there are m good components, then the load on each component is $z = L/m$.

Let n be the total number of components in the system and z_i be the load on each of the surviving components when i components are failed. Hence,

$$z_0 = L/n; \quad z_i = L/(n-i) = z_0 \cdot \frac{n}{n-i}. \quad (20.13)$$

20.4.2 The TFR Model

In the TFR model, the acceleration of failure when the stress is raised from a lower level to a higher level is reflected in the hazard rate function. In this section, we describe this model in terms of *k*-out-of-*n* systems. Consider a component that is subjected to an ordered sequence of loads, where load z_i ($i = 0,1,\ldots, n-k$) is applied during the time interval $[\tau_i, \tau_{i+1}]$, where $\tau_0 = 0$. In other words, the load changes at times $\tau_1, \tau_2, \ldots, \tau_{n-k}$. According to the TFR model, the hazard rate of the component at time t is:

$$h(t) = h_i(t) = \delta_i \cdot h_0(t) \quad \text{for} \quad \tau_{i-1} \le t < \tau_i \ , \quad (20.14)$$

where $\delta_0 = 1$, $h_0(t)$ is the hazard rate at the lower load z_0, and δ_i is the tampered factor at load level z_i. The tampered factor is a function of the applied stress. Hence, the TFR model can be expressed as:

$$h(t) = \delta(z) \cdot h_0(t), \quad (20.15)$$

where z is the load at time t.

20.4.3 System Configuration

In this chapter, we considered a *k*-out-of-*n* structure, which is a common form of redundancy used in reliability engineering. A system is called called a *k*-out-of-*n* system if at least k out of n components must work for the successful operation of the system [1, 6]. The *k*-out-of-*n*:G structure redundancy finds wide applications in both industrial and military systems. Several examples of *k*-out-of-*n*:G systems are available [1, 6]. Both series systems and parallel systems are special cases of the *k*-out-of-*n* system.

20.5 *k*-out-of-*n* Systems with Identical Components

In this section, we discuss the load-sharing *k*-out-of-*n* systems with identical components. The additional assumptions are:

- There are n IID components in the system.
- The system functions successfully if and only if there are at least k good components.

20.5.1 Exponential Distributions

When the system is put into operation at time zero, all components are working, and they are equally sharing the constant load that the system is supposed to carry. In this case, the failure rate of every component is denoted by λ_0. Because there are n working components in the system, the first failure occurs at rate $\alpha_1 = n.\lambda_0$. When the system experiences the first failure, the remaining $(n-1)$ working components must carry the same load on the system. As a result, the failure rate of each working component becomes λ_1, which is typically higher than λ_0. The second failure occurs at rate $\alpha_2 = (n-1).\lambda_1$. When i components are failed, the failure rate of each of the $(n-i-1)$ working components is represented by λ_i $(0 \le i \le n-k)$. The i_{th} failure occurs at rate $\alpha_i = (n-i+1).\lambda_{i-1}$. The system is failed when more than $(n-k)$ components are failed.

Because all components are IID following the exponential distributions, the inter-arrival times of failures are independent random variables X_i, where X_i follows the exponential distribution with parameter α_i for $1 \le i \le n-k+1$. Hence, the lifetime of the system is equal to the $(n-k+1)$-st failure time. Alternatively, the lifetime of the system is equal to the sum of $(n-k+1)$ independent random variables following exponential distributions with possibly different parameters (rates).

$$\begin{aligned} T &= X_1 + X_2 + \ldots + X_{n-k+1} \\ \text{Hence} \quad R(t) &= \Pr\{T \le t\} \end{aligned} \quad . \quad (20.16)$$

To find the distribution of T and the reliability function of the system, we need to distinguish the following three cases.

Case 1: All α_i are equal (say α) [44].

$$\begin{aligned} R(t) &= \sum_{i=0}^{n-k} \frac{(\alpha t)^i \exp(-\alpha t)}{i!} \\ &= gamfc(\alpha t; n-k+1) \end{aligned} \quad (20.17)$$

where *gamfc*() is the complimentary cumulative distribution of the gamma distribution. This case arises when the failure rate of each surviving

component is directly proportional to the load it carries. Hence, in the TFR model, $\delta(z) \propto z$.

Case 2: All α_I are distinct [44].

$$\begin{aligned} R(t) &= \sum_{i=1}^{n-k+1} A_i \cdot \exp(-\alpha_i t) \\ A_i &= \prod_{j=1; j\neq i}^{n-k+1} \frac{\alpha_j}{\alpha_i + \alpha_j} \end{aligned} \tag{20.18}$$

Case 3: α_I are neither equal nor distinct. Specifically, assume that these α_I take a ($1 < a < n-k+1$) distinct values, β_1, β_2, …, β_a. With possibly some renumbering of these α_i values, assume:

$$\begin{aligned} \alpha_1 = \cdots = \alpha_{r_1} &= \beta_1 \\ \alpha_{r_1+1} = \cdots = \alpha_{r_2+r_2} &= \beta_2 \\ \vdots & \\ \alpha_{r_2+r_2+\cdots+r_{a-1}+1} = \cdots = \alpha_{r_2+r_2+\cdots+r_a} &= \beta_a \end{aligned} \tag{20.19}$$

where the assumptions are:

- $a \geq 1$ and an integer.
- All β_{li} are distinct.
- The sum of r_I is equal to n.
- Each $r_i \geq 1$ and an integer.

Hence, $T = V1 + V_2 + ... + V_a$. V_i is a random variable, which follows the Erlangian distribution. The shape parameter is r_i, and the scale parameter is β_i. From [44], we have:

$$R(t) = B\sum_{j=1}^{a}\sum_{l=1}^{r_j} \frac{\Phi_{jl}(-\beta_j)}{(l-1)!(\beta_j)^{r_j-l+1}} .\text{poif}\,(r_j\text{-}l;\beta_j \cdot t)$$

where

$$\begin{aligned} B &= \prod_{j=1}^{a} (\beta_j)^{r_j} \\ \Phi_{jl}(t) &= D^{l-1}\left(\prod_{i=1; i\neq j}^{a} (\beta_i + t)^{-r_i} \right) \\ \text{poif}\,(r_j - 1; \beta_j \cdot t) &\equiv \sum_{i=0}^{r_j-l} \frac{\exp(-\beta_j t)(\beta_j t)^i}{i!} \end{aligned} \tag{20.20}$$

Scheuer [44] mentioned that there seems to be no closed-form expression for $\Phi_{jl}(t)$. Using a multi-function generalization of the Leibnitz rule, Amari and Misra [65] provided a closed-form solution for $\Phi_{jl}(t)$, which in turn completes the closed-form solution for $R(t)$.

$$\begin{aligned} \Phi_{jl}(t) &= (-1)^l (l-1)! \sum_{\Omega} \prod_{i=1; i\neq j}^{a} \nu(i, m_i, t) \\ \nu(i, m_i, t) &= \binom{r_i + m_i - 1}{m_i} (\beta_j + t)^{-(r_i + m_i)} \\ \Omega &\equiv m_1 + \cdots + m_a = l - 1; \text{ where } m_j = 0; m_{i\neq j} \geq 0 \end{aligned} \tag{20.21}$$

Case 3 arises when $\delta(z)$ in the TFR model is either a piece-wise linear function or an *S*-shared increasing function. Case 3 is also applicable when there are some additional spares in standby. In such cases, the load on the surviving components remains the same until the exhaustion of the standby spares. Hence, the values of some α_I will be the same.

20.5.2 General Distributions

In this section, we show that solving TFR models with arbitrary baseline failure distributions is equivalent to solving TFR models with exponential distributions. The basic idea is that using a time-transformation, a TFR model with an arbitrary baseline distribution can be converted into an equivalent problem with an exponential baseline distribution. This in turn reduces the problem under consideration to a simplified problem: the problem of a *k*-out-of-*n*:G load-sharing system with exponential distributions.

Lemma 1: For any failure distribution $F(t)$:

1. The reliability function is $R(t) = 1 - F(t)$.
2. The cumulative hazard function is $H(t) = \ln[R(t)]$.
3. The function $H(t)$ is a non-decreasing function in t.
4. The random variable $y = H(t)$ follows an exponential distribution with a mean of 1.
5. For any constant "a", the random variable $y = a.H(t)$ follows an exponential distribution with a mean of "$1/a$" and a failure rate of "a".

Proof: Points 1–3 are straightforward, basic reliability engineering concepts. Because $R(t) = e^{-y}$, points 4−5 can easily be proved using transformation of variables (see [1]).

Lemma 2: For a TFR model with a standard exponential (mean = rate = 1) baseline failure time distribution:

$$\begin{aligned} h(t) &= \delta_i \\ H(t) &= H(\tau_{i-1}) + \delta(t - \tau_{i-1}) \\ &\text{for} \quad \tau_{i-1} \le t < \tau_i \end{aligned} \qquad (20.22)$$

Proof: Straightforward from (20.15).

Lemma 3: For a TFR model with a baseline failure rate of $h_0(t)$ and a baseline cumulative failure rate of $H_0(t)$:

1. Under the regular scale t:

$$\begin{aligned} h(t) &= \delta_i \cdot h_0(t) \\ H(t) &= H(\tau_{i-1}) + \delta_i \cdot [H_0(t) - H_0(\tau_{i-1})] \\ &\text{for} \quad \tau_{i-1} \le t < \tau_i \end{aligned} \qquad (20.23)$$

2. Under the transformed scale $y \equiv H_0(t)$:

$$\begin{aligned} &\text{Let} \quad \nu_i = H_0(\tau_i) \\ h_y(y) &= \delta_i \\ H_y(y) &= H_y(\nu_{i-1}) + \delta_i \cdot [y - \nu_{i-1}] \\ &\text{for} \quad \nu_{i-1} \le y < \nu_i \end{aligned} \qquad (20.24)$$

where $H_y(y)$ is the cumulative hazard rate in the transformed scale.

Proof: Point 1 is straightforward from the definition of cumulative hazard rate and the $h(t)$ in (20.15). Because $t = H_0^{-1}(y)$ and $H_0(t) = y$, point 2 follows from point 1.

Theorem 1: If the effects of load variations on the hazard rate of an individual component follow a TFR model with $h(t) = \delta_i.h_0(t)$, the reliability of a load-sharing system at time t is equivalent to the reliability of the corresponding exponential load-sharing model at time $y = H_0(t)$, where the failure rate of a component when i components failed is $\lambda_i = \delta_i$ for $i = 0,\ldots, (n-k)$.

Proof: There is a one-to-one relationship between reliability and cumulative failure rate. For example, if the cumulative failure rates of two components at two different time points are equal, then their reliabilities are also equal at those points. Mathematically, if $H_1(t_1) = H_2(t_2)$, then $R_1(t_1) = R_2(t_2)$. From Lemma 2 and Lemma 3, $H_y(y) = H(t)$, where $Hy(y)$ is the cumulative failure rate of a component with an arbitrary baseline failure rate in the transformed scale y, and $H(t)$ is the cumulative failure rate of a component with a constant baseline failure rate (rate = 1) in the regular scale. Therefore, under the transformed scale, all TFR models are equivalent to their corresponding constant failure rate models. Hence, under the transformed scale, the reliability of a load-sharing system can be calculated using $\lambda_i = \delta_i$, where λ_i is the failure rate of a component when i components are failed.

As long as the baseline failure rate in the TFR model is the same, theorem 1 is also applicable for non-identical component cases where δ_i are different for the non-identical components. It should be noted that the results of Theorem 1 are not restricted to k-out-of-n:G systems. However, in this chapter, we apply these results for solving k-out-of-n:G systems.

20.5.3 Examples

Example 1: Consider a 5-out-of-10:G system with Weibull as the baseline failure distribution.

$$\text{Model}: \quad k = 5; \quad n = 10; \quad t = 1000$$

$$\text{Baseline}: \quad h_0(t) = \frac{\beta}{\eta} \cdot \left(\frac{t}{\eta}\right)^{\beta-1}; \quad H_0(t) = \left(\frac{t}{\eta}\right)^{\beta}$$

$$R_0(t) = \exp[-H_0(t)] = \exp\left[-\left(\frac{t}{\eta}\right)^{\beta}\right]$$

$$\text{Baseline Parameters}: \quad \eta = 2000; \quad \beta = 2$$

$$\text{TFR}: \quad h(t) = \delta(z) \cdot h_0(t)$$

$$\delta(z) = z^{1.5} \Rightarrow \delta_i = \delta(z_i) = \left(\frac{n}{n-i}\right)^{1.5}$$

Solution : $y = H_0(t) = 0.25; \quad \lambda_i = \delta_i$

$$\alpha_i = (n-i)\cdot\lambda_i = 31.623(n-i)^{-0.5}$$

Hence : $\alpha_1 = 10; \quad \alpha_2 = 10.541; \quad \alpha_1 = 11.18;$

$\alpha_4 = 11.952; \quad \alpha_5 = 12.91; \quad \alpha_6 = 14.142$

Here all α_i are distinct. Hence, from (20.18), $R_y(0.25) = 0.92415 \Rightarrow R(t = 1000) = 0.92415$.

Example 2: Same as example 1, except: $\delta(z) = z$.

Solution : $\delta(z) = z \Rightarrow \alpha_1 = \cdots = \alpha_6 = \alpha = 10$

Here all α_i are equal. Hence, from (20.17), $R_y(0.25) = 0.95798 \Rightarrow R(t = 1000) = 0.95798$.

Example 3: Same as example 1, except: $\delta(z)$ is piece-wise linear in z.

$$\text{TFR}: \quad \delta(z) = \begin{cases} z & : \quad z < 1.2 \\ 1.1z & : \quad 1.2 \le z < 1.5 \\ 1.2z & : \quad z \ge 1.5 \end{cases}$$

Solution : $\alpha_1 = \alpha_2 = 10; \alpha_3 = \alpha_4 = 11; \alpha_5 = \alpha_6 = 12$

Here α_i are neither equal nor distinct. Hence, from (20.20) and (20.21), $R_y(0.25) = 0.94005 \Rightarrow R(t = 1000) = 0.94005$.

Example 4: Same as example 2: $\delta(z) = z$. Additionally, it has two spares in standby, which are used to replace the first two failed components. The failure rate of a spare in standby is:

In Standby : $h(t) = \gamma \cdot h_0(t)$; where $\gamma = 0.5$

Solution : $\alpha_1 = 11, \alpha_2 = 10.5; \alpha_3 = \cdots = \alpha_8 = 10$

Here α_i are neither equal nor distinct. Hence, from (20.20) and (20.21), $R_y(0.25) = 0.98433 \Rightarrow R(t = 1000) = 0.98433$.

Example 5: Same as example 4, except the spare are in cold standby where the failure rate is zero, and $\delta(z) = z^{1.5}$.

Solution : $\alpha_1 = \alpha_2 = \alpha_3 = 10; \alpha_4 = 10.541;$

$\alpha_5 = 11.18; \alpha_6 = 11.952; \alpha_7 = 12.91; \alpha_8 = 14.14$

Here α_i are neither equal nor distinct. Hence, from (20.20, 20.21), $R_y(0.25) = 0.97874 \Rightarrow R(t = 1000) = 0.97874$.

20.6 *k*-out-of-*n* Systems with Non-identical Components

In this section, we consider a *k*-out-of-*n* system with non-identical components. We first discuss the exponential distribution case that is considered by Lin *et al*. [74] and later extend this model to the general failure distribution case.

20.6.1 Exponential Distributions

In this model, the system consists of n non-identical components. The failure rate of component i when there are j failures in the system is $\lambda(i,j)$. Because the system reaches a failed state when there are $n-k+1$ failed components, we need to consider the j values in the region: $0 \le j \le n-k$. The existing analysis for this model is too complex even for the 1-out-of-3 systems. In this section, we provide a different approach for solving these systems.

One approach to solve this problem is automatic generation of Markov chains. In this approach, as in dynamic fault tree analysis [82, 83], we generate Markov chain that describe the system behavior and solve the Markov chain using numerical integration methods. The number of states generated is:

$$N = \sum_{i=0}^{n-k+1} \binom{n}{i} \qquad (20.25)$$

If we merge all failed states into one single state, then we have:

$$N = 1 + \sum_{i=0}^{n-k} \binom{n}{i} \qquad (20.26)$$

The number of states increases with both n and $n-k$. For a parallel system, the number of states is equal to 2^n. It should be noted that if the failure rate is dependent on both the number of component failures and the actual set of failed components, then the number of states increases drastically. In the later case, because a failed state with k component failures can be reached in $k!$ ways, a parallel system with 10 components can have as many as 9,864,101 states [83]. The existing Markov chain solvers can handle a maximum of 100,000 states. Hence, $2^n \le 100{,}000$. Therefore, n should be less than or equal to 16. There are

several approaches to improve the efficiency of the computation. They include: (1) eliminating the states that contribute an insignificant portion of probability to the failure, (2) solving the Markov chains while generating the states, and (3) utilizing the bounds. Obviously, another alternative is to use simulation methodology. However, in all these methods, we can only have numerical solutions.

In some cases, we may be interested in the closed-form analytical solutions. We use a method proposed in [64] to obtain the closed-form solutions to this problem. The method is demonstrated using a 2-out-of-3 load-sharing system. In this method, we first generate all sequences of component failures that lead to the system failure. The sequences are mutually exclusive. In this case, we have 6 failure sequences. They are: {1, 2}, {1,3}, {2,1}, {2,3}, {3,1} and {3,2}. The overall system failure probability is the sum of the probability of each failure sequence. The Markov model for this sequence is shown in Figure 20.1. The labels in the Markov chain explain the properties of the states and transitions.

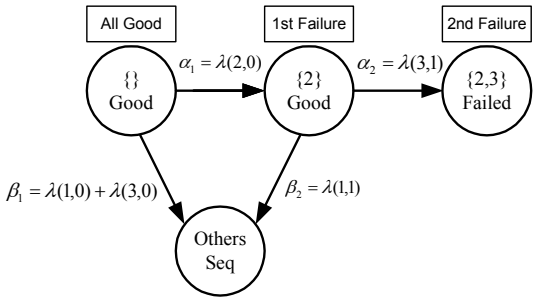

Figure 20.1. Markov chain for sequence {2,3}

The Laplace transform for the failed state is:

$$F(s) = \frac{\alpha_1\alpha_2}{s(s+\alpha_1+\beta_1)(s+\alpha_2+\beta_2)} \quad (20.27)$$

Using [65], the time-dependent failure probability contribution of sequence {2, 3} is:

$$F(t) = A_0 + A_1\exp(-\gamma_1 t) + A_2\exp(-\gamma_2 t) \quad (20.28)$$

where

$$\gamma_i = \alpha_i + \beta_i$$
$$A_0 = \prod_{i=1}^{2}\frac{\alpha_i}{\gamma_i} \quad (20.29)$$
$$A_{j\neq 0} = -\frac{\alpha_j}{\gamma_j}\prod_{i=1;i\neq j}^{2}\frac{\alpha_i}{\gamma_i-\gamma_j}$$

where $n-k+1 = 2$. For the general case, we can replace the *2* with $n-k+1$.

20.6.2 General Distributions

In this model, the system consists of n non-identical components. The failure rate of component i at time t when there are j failed components in the system is $h(i,j,t)$. In addition to this, we also assume that the baseline failure rate of all these components is the same. (or failure rates/are) Hence, we have:

$$h(i,j,t) = \lambda(i,j)\cdot h_0(t) \quad (20.30)$$

Therefore, extending the concepts used for the indentical component case, we can compute the system reliability with general failure distributions using the solutions that are applicable for the exponential failure distributions.

Theorem 2: If the effects of load variations on the hazard rate of an individual component follow a TFR model with $h(i,j,t) = \lambda(i,j).h_0(t)$, the reliability of a load-sharing system at time t is equivalent to the reliability of the corresponding exponential load-sharing model at time $y = H_0(t)$, where the failure rate of a component i when j components are failed is $\lambda(i,j)$.

Proof: This is similar to the proof of *Theorem 1*.

20.6.3 Further Examples

Example 6: Consider a 2-out-of-3:G system with Weibull as the baseline failure distribution.

$$\text{Model}: \quad k=2; \quad n=3; \quad t=1000$$

$$\text{Baseline}: \quad h_0(t) = \frac{\beta}{\eta}\cdot\left(\frac{t}{\eta}\right)^{\beta-1}; \quad H_0(t) = \left(\frac{t}{\eta}\right)^{\beta}$$

$$R_0(t) = \exp\left[-H_0(t)\right] = \exp\left[-\left(\frac{t}{\eta}\right)^{\beta}\right]$$

Baseline Parameters : $\eta = 2000; \quad \beta = 2$

TFR : $h(i, j, t) = \lambda(i, j) \cdot h_0(t)$

$$\lambda(i, j) = \delta_i(z_j)$$

$$z_j = \frac{n}{n-i} \cdot z_0 = \frac{n}{n-i} \text{ (where } z_0 = 1)$$

Hence:

$$\delta_i(z_j) = a_i \cdot (z_i)^{b_i} \Rightarrow \lambda(i, j) = a_i \cdot \left(\frac{n}{n-i}\right)^{b_i}$$

$$a_1 = 1; \quad a_2 = 1.2; \quad a_3 = 1.3;$$

$$b_1 = 1; \quad b_2 = 1.1; \quad b_3 = 1.2;$$

Hence:

$$\lambda(1,0) = 1.0; \quad \lambda(2,0) = 1.2 \quad \lambda(3,0) = 1.3;$$

$$\lambda(1,1) = 1.5; \quad \lambda(2,1) = 1.875 \quad \lambda(3,1) = 2.115;$$

Solution : $y = H_0(t) = 0.25;$

Sequence probabilities at y = 0.25 are:

$$F(1,2) = 0.032195; \quad F(1,3) = 0.036321$$

$$F(2,1) = 0.031808; \quad F(2,3) = 0.044842$$

$$F(3,1) = 0.035101; \quad F(3,2) = 0.043865$$

Hence, the overall failure probability is 0.224131. Therefore, from Theorem 2, $R_y(0.25) = 0.775869$ $\Rightarrow R(t = 1000) = 0.775869$.

It should be noted that as long as the baseline failure rate is the same, this procedure can also be used to compute the reliability of non-equal load-sharing rules.

20.7 Conclusions

In this chapter, various concepts that are important in the modeling and analysis of load-sharing systems, have been presented along with a state-of-the-art review on existing modeling techniques and solution methods. Although load-sharing systems have a wide range of applications, due to the inherent complexity of these systems, the methods available for analyzing these systems are limited.

The existing literature covers only a small portion of these systems that include exponential failure time distributions, equal load-sharing rules, and identically distributed components. Therefore, in order to widen the state-of-the-art, we have proposed efficient methods for computing the reliability of load-sharing *k*-out-of-*n*:G systems with identical and non-identical components where all surviving components share the load equally. The method can be applied for a wide range of failure time distributions including Weibull, lognormal, and gamma distributions. As long as the baseline failure time distribution of all components are the same, the solution proposed in this chapter is also applicable for unequal load-sharing rules. It may be observed here that all TFR models including non-identical baseline failure rate cases can also be solved using semi-Markov chains [64, 80]. However, due to the well-known state space explosion of the Markov chains, the semi-Markov solution approach cannot directly be applied to solving large models. Hence, there is a need for better solutions. Similarly, at present, there are no efficient methods for solving load-sharing cumulative exposure models. In addition to this, it is interesting to study the optimal dynamic load distribution of these systems.

O(*kn*) Algorithms for Analyzing Repairable and Non-repairable *k*-out-of-*n*:G Systems

Suprasad V. Amari[1], Ming J. Zuo[2], and Glenn Dill[1]

[1] Relex Software Corporation, USA
[2] Department of Mechanical Engineering, University of Alberta, Canada

Abstract: The *k*-out-of-*n*:G system has a wide range of applications in reliability engineering. Several efficient algorithms are available for analyzing the reliability of non-repairable systems. However, such efficient algorithms are not readily available for computing other reliability indices such as the failure (hazard) rate, the probability density function, or the mean time to failure (MTTF). Similarly, the methods for computing the steady-state availability measures, such as failure frequency, mean up-time and mean down-time in a failure-repair cycle, and the mean time between failures (MTBF) of repairable *k*-out-of-*n*:G systems are limited. In this chapter, utilizing the concepts of failure frequency, we present efficient algorithms to compute various reliability and availability indices of *k*-out-of-*n*:G systems. The algorithms are applicable for arbitrary general failure and repair distributions. For repairable systems, we also consider a case where components are kept idle during a system failure (suspended animation). Whenever applicable, we also present simplified results for the exponential case. For the non-identical component case, all of these algorithms have at most $O(kn)$ computational complexity. For the identical component case, the computational complexity reduces to $O(n)$.

21.1 Introduction

In reliability engineering, it is a common practice to use redundancy techniques to improve system reliability and availability. A common form of redundancy is the *k*-out-of-*n*:G (F) structure, which was introduced by Birnbaum *et al*. [8] in 1961. The *k*-out-of-*n*:G (F) system consists of *n* components and functions (fails) if and only if at least *k* of the *n* components function (fail). Therefore, a k-out-of-n:G system is equivalent to $(n-k+1)$-out-of-*n*:F system. In research literature, the term "*k*-out-of-*n* system" is often used to indicate either a *k*-out-of-*n*:G system or a *k*-out-of-*n*:F system (or both). However, in practice, most engineers often use the term *k*-out-of-*n* system to represent the *k*-out-of-*n*:G system and are confused by the additional symbols "G" and "F". This is particularly true in the context of reliability block diagrams or any success oriented models. In this chapter, for simplicity, we often omit "G" and refer to a *k*-out-of-*n*:G system as a *k*-out-of-*n* system. Hence, in the context of this chapter, a *k*-out-of-*n* system functions (fails) if and only if at most $n-k$ (at least $n-k+1$) components fail. Thus, the life of a non-repairable *k*-out-of-*n* system can be characterized

by the $(n-k+1)$th order statistic, which represents the $(n-k+1)$th smallest failure time among n possible failure times.

The k-out-of-n:G redundancy finds a wide range of applications in both industrial and military systems. Examples include the cables in a bridge, a data processing system with multiple video displays, communication systems with multiple transmitters, and the multi-engine system in an airplane. Among applications of the k-out-of-n system, the design of electronic circuits such as very large scale integrated (VLSI) circuits and the automatic repairs of faults in an on-line system, would be the most conspicuous [13]. Several examples of k-out-of-n systems are available in [13, 15]. Both series systems and parallel systems are special cases of the k-out-of-n system. The k-out-of-n system has been investigated extensively in the literature. Various related models have been developed and many formulas have been derived, resulting in a large body of literature. For general results, please refer to Singh and Billinton [25], Ravichandran [19], Misra [16], Trivedi [26], and Kuo and Zuo [13], *etc*. Comparisons of various algorithms for computing the reliability of non-repairable systems are provided by Rushdi [24], Dutuit and Rauzy [11], and Kuo and Zuo [13].

Optimal cost-effective design of non-repairable k-out-of-n systems and subsystems is studied in [2]. Load-sharing k-out-of-n systems are studied in [1, 15]. Recently, Koucky [12] derived the exact formula for the reliability of general k-out-of-n systems whose component failures need not be independent and identically distributed (IID). However, there are relatively few publications on repairable k-out-of-n systems. Even for non-repairable k-out-of-n systems, efficient algorithms are not readily available for computing other reliability indices such as failure (hazard) rate, probability density function (pdf), and mean time to failure (MTTF). In this chapter, we provide efficient algorithms to compute various reliability and availability indices of k-out-of-n systems.

Section 21.2 discusses the background of the problem including the general assumptions and motivation. Section 21.3 presents the algorithms to compute the measures of non-repairable systems. Section 21.4 presents the algorithms to compute the steady-state measures of repairable systems. Section 21.5 presents some simplified results for various special cases, including: (1) exponential failure and repair distributions, (2) MTTF of non-repairable systems, (3) mean time to first failure (MTTFF) of repairable systems, (4) systems with suspended animation, and (5) some simple bounds and approximations. Finally, Section 21.6 presents the conclusions and indication to future research.

21.2 Background

21.2.1 General Assumptions

The general assumptions of the model are:

1. The system consists of n statistically independent components. Hence, the life-times and repair-times of the n components of the k-out-of-n system are s-independent.
2. At least k out of n components must work for the successful operation of the system.
3. The failure and repair time distributions of the components can follow any arbitrary general distribution.
   - For the exponential case, the failure and repair time distributions of all components are exponential.
   - For the identical case, all failure time and all repair time distributions are the same.
   - For non-repairable case, the repair time distributions are not applicable.
4. For a repairable system, a component is assigned a repairman as soon as it fails. A repaired component is as good as new, *i.e.*, the repair is perfect. The repair times of failed components are independent.

In addition to these assumptions, specific assumptions that are applicable to various cases will be introduced later in this chapter.

21.2.2 Availability Measures

One of the important measures of a repairable system is its steady-state availability (A). Another important measure of repairable systems is its steady-state failure frequency (ω), which is the

number of failures per unit time in a long run (as time tends to infinity). It should be noted that the steady-state failure frequency is equivalent to the steady-state repair frequency. Other measures, such as mean failure-repair cycle time [also called mean cycle time (MCT) or mean time between failures (MTBF)], mean working time during a failure-repair cycle [also called mean up-time (MUT) or mean time to failure (MTTF)], mean down-time during a failure-repair cycle [also called mean down-time (MDT) or mean time to repair (MTTR)], expected number of system failures/repairs [NSF/NSR] during a specified interval (T), can easily be found from A *and* ω [9].

$$\begin{aligned} MCT &= MTBF = \frac{1}{\omega} \\ MUT &= MTTF = \frac{A}{\omega} \\ MDT &= MTTR = \frac{U}{\omega} \\ NSF &= NSR = \frac{T}{\omega} \end{aligned} \tag{21.1}$$

In some papers [14], MUT and MDT are also referred as expected up-time (EU) and expected down-time (ED), respectively. It should be obvious from (21.1) that once A and ω are found, all other measures can be computed easily with simple formulae that can be evaluated with constant time complexity, *i.e.*, $O(1)$. Therefore, for the repairable case, we provide algorithms only for computing A and ω.

21.2.3 Motivation

There are several algorithms for computing the reliability of a non-repairable *k*-out-of-*n* system with identical or non-identical components. For details, refer to Misra [16], Rushdi [24], Dutuit and Rauzy [11], and Kuo and Zuo [13]. These algorithms are independent of the failure distribution of the components, but they use the independent assumption among the components' failure behavior. However, there are very few algorithms for computing the availability of a repairable *k*-out-of-*n* system. As long as all components are *s*-independent, *i.e.*, failure and repair processes of a component are *s*-independent of the status of other components, we can compute the system availability using the same algorithms (or functions) that are used to compute system reliability. The system reliability (availability) computation uses component reliabilities (availabilities) as inputs. However, it is easy to compute the component reliability, but not the component availability, particularly when the failure and repair distributions are non-exponential. Therefore, even for the *s*-independent case, efficient algorithms are limited to the case of exponential failure and repair distributions. Fortunately, Ross [21] presented an important finding to overcome this difficulty. As long as all components are *s*-independent, according to Ross [21], we can use the same algorithms to compute several steady-state measures of the system including availability and failure frequency using the same algorithms that are used for non-repairable cases. This means that efficient algorithms are available not only for the steady-state availability but also for various other important measures of repairable systems. We believe that most researchers have over looked this important finding. In this chapter, using these basic concepts, we provide efficient algorithms to compute various steady-state availability measures. In most cases, we use or modify the algorithms available for a non-repairable *k*-out-of-*n* system to compute the availability of repairable a *k*-out-of-*n* system. Further, we also use the concepts of failure frequency (used to analyze repairable systems) in computing the failure rate and pdf of non-repairable systems.

21.3 Non-repairable *k*-out-of-*n* Systems

In this section, we assume that the system consists of n independent components. Initially (at time t = 0), all components are working and are all new. It should be noted that the "all new condition" is not required if we know the conditional reliability. The system functions properly as long as there are at least k working components. The failure time of each component can follow any arbitrary distribution. We considered two cases:

- Identical components: all components are identical and follow the same failure distribution.
- Non-identical components: all or some of the components are non-identical and may follow different failure distributions.

21.3.1 Identical Components

Let $p(t)$, $q(t)$, $\lambda(t)$, and $f(t)$ be the reliability, unreliability, failure (hazard) rate, and pdf of each component at time t. For simplicity, we omit t when it is obvious. For any distribution, the following relationships are valid:

$$q(t) = 1 - p(t); \quad f_c(t) = \lambda(t) \cdot p(t). \quad (21.2)$$

It is well-known that the reliability of a k-out-of-n system can be found using binomial distribution.

$$R = \sum_{i=k}^{n} \binom{n}{i} p^i \cdot q^{n-i} = \sum_{i=0}^{n-k} \binom{n}{i} p^{n-i} \cdot q^i. \quad (21.3)$$

The R in (21.3) can be evaluated with $O(n)$ computational complexity as in the following algorithm.

Algorithm 1: Reliability with Identical Components

$x = p^n = \exp\{n \cdot \ln(p)\}$;
for $i = 1$ to $(n-k)$ do
$\quad x = x \cdot y \cdot \dfrac{n-i+1}{i}; \quad \mathrm{Re}l = \mathrm{Re}l + x$
done

At the end of the algorithm, the results for R will be accumulated in Rel. In fact, the computational time of this algorithm depends on both k and n and is proportional to $(n–k)$. Hence, the computational complexity can be considered as $O(n–k)$. If $k < n/2$, in order to reduce computational time, we can compute system reliability from system unreliability.

$$Q = \sum_{i=n-k+1}^{n} \binom{n}{i} q^i \cdot p^{n-1} = \sum_{i=0}^{k-1} \binom{n}{i} p^i \cdot q^{n-i} \quad (21.4)$$
$$R = 1 - Q$$

We can modify Algorithm 1 slightly to compute Q and R in $O(k)$ computational complexity. Therefore, in general, the computational time of R is proportional to $\min\{k, n–k\}$, which is less than $O(n)$. Similar improvements are also applicable for all algorithms discussed in this chapter. However, those improvements are obvious to most reliability analysts; hence, those are not discussed unless special attention to them is required.

The well-known expression for the pdf of the system is:

$$f(t) = \frac{dQ(t)}{dt} = \frac{d[1 - R(t)]}{dt} = \frac{-dR(t)}{dt} \quad (21.5)$$

It is not straightforward to get the closed-form solution for the right-hand side expression in (21.5). However, we can find a closed-form solution to f using the failure frequency concepts applicable for Markov chains. Specifically, the k–out-of-n system fails at time t when the system is in a state where exactly k components are working and one of those k working components fails at time t. Hence, we have:

$$f(t) = p_k(t) \cdot [k \cdot \lambda(t)]$$
$$p_k(t) = \binom{n}{k} p^k \cdot q^{n-k} \quad (21.6)$$

P_k can be calculated using Algorithm 1 with $O(n–k)$ computational complexity. Specifically, the final results accumulated in the variable x in Algorithm 1 is equivalent to P_k (Rel is not required for computing P_k). Therefore, we can find the pdf of a k-out-of-n system with linear time complexity algorithms. Once we know R and f, we can easily find the failure rate of the system: $h = f/R$.

$$h(t) = \frac{f(t)}{R(t)} = \frac{\binom{n}{k}[p(t)]^k \cdot [q(t)]^{n-k}[k \cdot \lambda(t)]}{\sum_{i=k}^{n} \binom{n}{i}[p(t)]^i \cdot [q(t)]^{n-i}} \quad (21.7)$$

Using Algorithm 1 (using only a single pass), we can compute the failure rate with the linear time complexity.

21.3.2 Non-identical Components

Let $p_i(t)$, $q_i(t)$, $\lambda_i(t)$, and $f_i(t)$ be the reliability, unreliability, failure (hazard) rate, and pdf of

component *i* at time *t*. As in the identical component case, irrespective of the failure distribution, the following relationships are valid:

$$q_i(t) = 1 - p_i(t); \quad f_i(t) = \lambda_i(t) \cdot p_i(t) \tag{21.8}$$

In this case, we first select an existing algorithm for computing system reliability with non-identical components. Later, we modify this algorithm without increasing its computational complexity to compute the pdf of the system. Finally, we calculate the failure rate of the system from the calculated system reliability and pdf.

There are several algorithms to compute the reliability of a *k*-out-of-*n* system with non-identical components [13]. In this chapter, we consider a well-known algorithm that was originally proposed by Barlow and Heidtmann [7] and Rushdi [23, 24]. We also utilize the iterative implementation provided in [11]. This algorithm has $O(n \cdot (n-k+1))$ computational complexity and requires less memory than other algorithms [13].

The algorithm is based on the following recursive relationship. Let $H(r,m)$ be the probability of at least *r* components out of the first *m* components are good. Then, we have:

$$\begin{aligned} R &= H(k,n) \\ H(r,m) &= p_m \cdot H(r-1,m-1) + q_m \cdot H(r,m-1) \\ &\qquad \text{for } 1 \le r \le m \\ &= 1 \quad \text{for } r = 0, m \ge 0 \\ &= 0 \quad \text{for } r = m+1 \end{aligned} \tag{21.9}$$

Although $H(r,m)$ is a two-dimensional array, at any given time, we need to store only a few of these values. In the following iterative algorithm, only $k+1$ values of *H* are stored in the one-dimensional array *P*.

Algorithm 2: Reliability with Non-identical Components

$P(0) = 1$; for $i = 1$ to k do $P[i] = 0$; done
for $i = 1$ to n do
  for $j = k$ downto 1 do
    $P[j] = p_i \cdot P[j-1] + q_i \cdot P[j]$
  done
done

At the end of the algorithm, for $1 \le j \le k$, the reliability results for a j-out-of-n system will be accumulated in $P[j]$. Hence, the reliability of a k-out-of-n system is equivalent to $P[k]$.

In order to compute the pdf, we use the concepts of failure frequency [3, 9]. In fact, as mentioned in [4, 5], for non-repairable systems, failure frequency is equivalent to its pdf, *i.e.*, $\omega = f$. There are several algorithms for computing the failure frequency. In this chapter, we use a factorial algorithm that calculates the failure frequency (pdf). Therefore, applying the factorial algorithm to the reliability recursion used in (21.9), we find a recursive relationship for the failure frequency (21.10).

$$\begin{aligned} f &= F(k,n) \\ F(r,m) &= p_m \cdot F(r-1,m-1) + f_m \cdot H(r-1,m-1) \\ &+ q_m \cdot F(r,m-1) - f_m \cdot H(r,m-1) \text{ for } 1 \le r \le m \\ &= 0 \quad \text{for } r = 0; m \ge 0 \\ &= 1 \quad \text{for } r = m+1 \end{aligned} \tag{21.10}$$

The proof of the above recursion is similar to the proof of the failure frequency calculations used in BDD [9]. Integrating the relationships between $H(r,m)$ and $F(r,m)$ shown in (21.9) and (21.10), we propose the following iterative algorithm to compute system pdf.

Algorithm 3: Pdf with Non-identical Components

$P(0) = 1$; $F(0) = 0$;
for $i = 1$ to k do $P[i] = 0$; $F[i] = 0$; done
for $i = 1$ to n do
  for $j = k$ downto 1 do
    $F[j] = f_i \cdot (P[j-1] - P[j]) + p_i \cdot F[j-1] + q_i \cdot F[j]$
    $P[j] = p_i \cdot P[j-1] + q_i \cdot P[j]$
  done
done

At the end of the algorithm, for $1 \le j \le k$, the pdf results for a *j*-out-of-*n* system will be accumulated in $F[j]$. Hence, the pdf of a *k*-out-of-*n* system is equivalent to $F[k]$. Once we know the pdf and reliability, it is straightforward to calculate the failure rate: $h = f/R = F[k]/P[k]$.

21.4 Repairable *k*-out-of-*n* System

In this section, we consider a *k*-out-of-*n* repairable system with the following additional assumptions.

21.4.1 Additional Assumptions

1. Non-failed components continuously operate irrespective of the system state.
2. For each component, the steady-state availability exists. This assumption is mild and can be ignored if both failure and repair distributions are non-deterministic. Specifically, the assumption is satisfied if either failure or repair distribution is non-lattice [21].

A repairable *k*-out-of-*n* system fails only if the total number of failed components at any instant of time reaches (*n*-*k*+1) or more. Assume that all of the system's components are working at time 0. Thus, the system is in the up state at time 0. As components fail, repair work is performed on the failed components. If the number of components simultaneously in the failed state reaches (*n*–*k*+1), the system makes a transition from the up state to the down state. When the system is down, repair work continues on the failed components, and the system will return to the up state as soon as the number of failed components becomes lower than (*n*–*k*+1). For the exponential case, it is obvious that the behavior of the system constitutes a delayed alternating renewal process. However, even with general failure and repair distributions, using the basic concepts presented in Ross [21], we can compute the steady-state measures using combinatorial algorithms [10].

21.4.2 Identical Components

Let ϕ and θ be the MTTF and MTTR of each component. Then, steady-state availability (a), unavailability (u), and failure frequency (ω_c) are:

$$a = \frac{\phi}{\phi+\theta};\quad u = \frac{\theta}{\phi+\theta} = 1-a;\quad \omega_c = \frac{1}{\phi+\theta} \tag{21.11}$$

The system steady-state availability can be found using binomial distribution.

$$A = \sum_{i=k}^{n}\binom{n}{i}a^i \cdot u^{n-1} = \sum_{i=0}^{n-k}\binom{n}{i}a^{n-1}\cdot u^i \tag{21.12}$$

The A in (21.12) can be evaluated with $O(n)$ computational complexity as in the following algorithm.

Algorithm 4: Availability with Identical Components

$$x = a^n = \exp\{n\cdot\ln(a)\};\quad Avail = x;\quad y = \frac{u}{a}$$

for $i = 1$ to $(n-k)$ do

$$x = x\cdot y\cdot\frac{n-i+1}{i};\quad Avail = Avail + x$$

done

At the end of the algorithm, the results for A will be accumulated in *Avail*. The computational complexity is $O(n–k)$.

Further, the steady-state failure frequency of the system is:

$$\omega = P_k \cdot \left\lfloor k/\phi \right\rfloor$$
$$P_k = \binom{n}{k}a^k\cdot u^{n-k} \tag{21.13}$$

The P_k can be calculated using Algorithm 1 with $O(n–k)$ computational complexity. Specifically, the final result accumulated in the variable x in Algorithm 1 is equivalent to P_k. Therefore, we can find the failure frequency of a *k*-out-of-*n* system with linear time complexity algorithms. Once we know A and ω, we can easily find other measures as shown in (21.1).

21.4.3 Non-identical Components

Let ϕ_i and θ_i be the MTTF and MTTR of component i. Then steady-state availability (a_i), unavailability (u_i), and failure frequency (ω_i) of component i are:

$$a_i = \frac{\phi_i}{\phi_i+\theta_i};\ u_i = \frac{\theta_i}{\phi_i} = 1-a_i;\quad \omega_i = \frac{1}{\phi_i+\theta_i} \tag{21.14}$$

Once we know the steady-state measures for individual components, we can compute the system level measures using the following algorithm.

Algorithm 5: Availability with Non-identical Components

$P(0) = 1;$ for $i = 1$ to k do $P[i] = 0;$ done
for $i = 1$ to n do
  for $j = k$ downto 1 do
    $P[j] = a_i \cdot P[j-1] + u_i \cdot P[j]$
  done
done

At the end of the algorithm, for $1 \le j \le k$, the availability results for a j-out-of-n system will be accumulated in $P[j]$. Hence, the availability of a k–out-of-n system is $P[k]$. This algorithm can also be used to get time-specific availability measures of the system provided that the time-specific availability measures of the components are available. However, computing the time-specific availability measures for components with general distributions is difficult. However, for the exponential case, the measures can be found easily.

$$a_i = \frac{\mu_i}{\lambda_i + \mu_i} + \frac{\lambda_i}{\lambda_i + \mu_i} \exp\{-(\lambda_i + \mu_i)t\}$$
$$u_i = 1 - a_i; \quad \omega_i = a_i \cdot \lambda_i \tag{21.15}$$

The algorithm for computing steady-state availability and failure frequency follows. The same algorithm can also be used to compute the time-specific measures for the exponential case.

Algorithm 6: Steady-state A and ω with Non-identical Components

$P(0) = 1;\ F(0) = 0;$
for $i = 1$ to k do $P[i] = 0;\ F[i] = 0;$ done
for $i = 1$ to n do
  for $j = k$ downto 1 do
    $F[j] = \omega_i \cdot (P[j-1] - P[j])$
      $+ a_i \cdot F[j-1] + u_i \cdot F[j]$
    $P[j] = a_i \cdot P[j-1] + u_i \cdot P[j]$
  done
done

At the end of the algorithm, for $1 \le j \le k$, the results for ω and A of a j-out-of-n system will be accumulated in $F[j]$ and $P[j]$, respectively. Hence, the failure frequency of the k-out-of-n system is equivalent to $F[k]$. Once we know A and ω, we can easily find other measures as shown in (21.1).

21.5 Some Special Cases

In this section, we present some results that are specifically applicable for the exponential case.

21.5.1 MTTF

A k-out-of-n system with non-repairable components can fail only once. Therefore, in this case, MTTF is equivalent to MTTFF. The MTTF of any system can be calculated by integrating its reliability over $(0, \infty)$. Hence, we have:

$$\text{MTTF} = \int_0^\infty t \cdot f(t)\,dt = \int_0^\infty R(t)\,dt \tag{21.16}$$

In general, it is difficult to find a computationally efficient closed-form solution for MTTF. It is particularly true for the case of general distributions and non-identical components. However, we can compute MTTF using numerical integration methods [17]. To find MTTF, we should compute $R(t)$ at $t = t_1, t_2, \ldots, t_m$. For any given time t, we can compute $R(t)$ with $O(kn)$ computational complexity. Hence, using the algorithms presented in Section 21.3, we can compute the MTTF with $O(mnk)$ computational complexity, where m is the number of evaluations of $R(t)$. For the identical component case, the complexity reduces to $O(mk)$. To overcome the difficulties with infinite upper limit, we can use the concepts of improper integrals. One such solution is:

$$\text{let } x = e^{-t} \text{ or } t = -\ln(x)$$
$$\text{MTTF} = \int_0^\infty R(t)\,dt = \int_{t=0}^{t=a} R(t)\,dt + \int_{x=0}^{x=e^{-a}} \frac{R(-\ln(x))}{x} dx \tag{21.17}$$

If $a = 1$, we have:

$$\text{MTTF} = \int_{t=0}^{t=1} R(t)\,dt + \int_{x=0}^{x=e^{-1}} \frac{R(-\ln(x))}{x} dx \tag{21.18}$$

In some cases, we can find simple closed-form solutions for MTTF.

1. IID components with exponential failure distribution: $\lambda_i=\lambda$ for all i.

$$\text{MTTF}=\sum_{i=k}^{n}\frac{1}{i\cdot\lambda}=\frac{1}{\lambda}\left[\sum_{i=k}^{n}\frac{1}{i}\right] \tag{21.19}$$

The MTTF in (21.19) can be computed with $O(n–k)$ time complexity. For large n and k, we can compute the MTTF approximation in a constant time using harmonic number approximation.

$$H(n)=\sum_{i=1}^{n}\frac{1}{i}\approx\ln(n)+0.57721$$

$$\text{MTTF}=\frac{1}{\lambda}\left[H(n)-H(k-1)\right]$$

$$\approx\frac{1}{\lambda}\left[\ln(n)-\ln(k-1)\right]=\frac{1}{\lambda}\cdot\ln\left(\frac{n}{k-1}\right) \tag{21.20}$$

2. Some results for IID components with non-exponential failure distribution are presented in [16]. Particularly, closed-form solutions are presented for Weibull and extreme value distributions. Even for the IID case, these formulas are complex, and numerical evaluation of these formulas may not be efficient as compared to the numerical integration used in (21.17). Further, we have:

- If the components follow an increasing failure rate (IFR) distribution, then the system MTTF found with the exponential distribution (21.19), assuming λ is the reciprocal of component MTTF, is the upper bound of the MTTF of the k-out-of-n system.
- Similarly, if the components follow a decreasing failure rate (DFR) distribution, then the system MTTF found with the exponential distribution (21.19), assuming λ is the reciprocal of component MTTF, is the lower bound of the MTTF of the k-out-of-n system.

3. Various MTTF formulas for non-identical components with exponential failure distributions are presented in [16]. For a 2-out-of-3 system, we have:

$$\text{MTTF}=\frac{1}{\lambda_1+\lambda_2}+\frac{1}{\lambda_1+\lambda_3}+\frac{1}{\lambda_2+\lambda_3}-\frac{2}{\lambda_1+\lambda_2+\lambda_3} \tag{21.21}$$

Similarly, we can also find the MTTF using Markov chain solutions.

$$\text{MTTF}=\frac{1}{\lambda_1+\lambda_2+\lambda_3}\left[1+\frac{\lambda_1}{\lambda_2+\lambda_3}+\frac{\lambda_2}{\lambda_1+\lambda_3}+\frac{\lambda_3}{\lambda_1+\lambda_2}\right] \tag{21.22}$$

For large n and small k, *i.e.*, for large n and $n–k$, the direct evaluation of these formulas is very difficult. In fact, computational time increases exponentially, *i.e.*, $O(n^{n-k})$. Therefore, we are not presenting these formulas for general k and n. We recommend numerical integration in (21.17) for computing the MTTF for the non-identical case.

21.5.2 MTTFF

As in the case of any repairable system, the k-out-of-n system with repairable components alternatively visits the up and down states. In a long run, the system reaches a steady-state. The steady-state MTTF, *i.e.*, up-time in a failure-repair cycle, is discussed in Section 21.4. However, in some cases, we are interested in finding the mean time to the first failure (MTTFF). In general, the MTTFF is not equivalent to MTTF. This is because initially all components are considered to be in good condition. In most cases, the first failure time is greater than the steady-state MTTF (also called MUT). Finding the MTTFF for the general case is difficult. For the exponential failure and repair case, the MTTFF can be computed using Markov chains. However, due to the well-known state space explosion problem, this method is computationally expensive for the non-identical case. Therefore, we may wish to find the bounds for MTTFF. When the failure and repair distributions are exponential, we have [5]: MTTFF > MTTF. Therefore, the MTTF calculations presented in (21.1) can be used as an approximation (or a lower

bound) to the MTTFF of the non-identical case. For the identical case, similar to the concepts used in [18], we present an efficient algorithm to compute MTTFF.

The *k*-out-of-*n* has (*n*–*k*+2) states. The state *i* (*i*= 0,···,*n*–*k*+1) has *i* failed components and (*n*–*i*) working components. Let *E(i)* denote the expected time it takes for the system to reach state (*n*–*k*+*1*) from the time it reaches state *i*. Then we have:

$$\begin{aligned}
&\text{MTTFF} = E(0) = \frac{1}{n\cdot\lambda} + E(1)\\
&E(i) = \alpha_i + \beta_i \cdot E(i+1) \quad \text{for } 1 \le i \le n-k\\
&E(n-k+1) = 0\\
&\textit{where}\\
&\alpha_i = \frac{1}{(n-i)\cdot\lambda + i\cdot\mu}\\
&\beta_i = \frac{i\cdot\mu}{(n-i)\cdot\lambda + i\cdot\mu}\\
&\gamma_i = \frac{(n-i)\cdot\lambda}{(n-i)\cdot\lambda + i\cdot\mu}
\end{aligned} \tag{21.23}$$

where α_i, β_i and γ_i are intermediate variables, which are defined as follows:

α_i = expected time per visit spent in state *i*
β_i = Pr{next visit of the system is to state (*i*–1) | system is in state *i*}
γ_i = Pr{ next visit of the system is to state (*i*+1) | system is in state *i*}

From the above recursion, we find that *E*(*i*) depends both on *E*(*i*–1) and *E*(*i*+1). In order to solve this equation, we first remove the dependency of *E*(*i*) on *E*(*i*+1) via back substitution. Hence, using *E*(*n*–*k*+1) = 0, the above recursion can be rewritten as:

$$\begin{aligned}
&E(i) = \frac{x_i + y_i \cdot E(i-1)}{z_i}\\
&z_i = 1 - \frac{\beta_i + 1\cdot\gamma_i}{z_i + 1} \quad \text{for } 1 \le i \le n-k\\
&\text{where } \; x_i = \alpha_i + \frac{x_i + 1\cdot\gamma_i}{z_i + 1}; \quad y_i = \beta_i\\
&x_{n-k} = \alpha_{n-k}; \quad y_{n-k} = \beta_{n-k}; \quad z_{n-k} = 1
\end{aligned} \tag{21.24}$$

The variables x_i, y_i, and z_i define the above recursion, and they themselves can also be found using recursive relations. Finally, the MTTFF of the system is:

$$\text{MTTFF} = E(0) = \frac{z_1}{z_1 - y_1}\left(\frac{1}{n\cdot\lambda}\right) + \frac{x_1}{z_1 - y_1} \tag{21.25}$$

Now we present an iterative algorithm to compute the MTTFF of a *k*-out-of-*n* system with IID components and exponential distributions.

Algorithm 7: MTTFF of a Repairable k-out-of-n System with IID Components and Exponential Distributions

$$\begin{aligned}
&\text{Rate} = k\cdot\lambda + (n-k)\cdot\mu;\\
&x[n-k] = \frac{1}{\text{Rate}};\\
&y[n-k] = (n-k)\cdot\mu\cdot x[n-k];\\
&z[n-k] = 1;\\
&\text{for } i = (n-k-1) \text{ downto } 1 \text{ do}\\
&\quad \text{Rate} = \text{Rate} + \lambda - \mu;\\
&\quad x[i] = \frac{1}{\text{Rate}} + \frac{x[i+1]\cdot(n-1)\cdot\lambda}{\text{Rate}\cdot z[i+1]};\\
&\quad y[i] = \frac{i\cdot\mu}{\text{Rate}};\\
&\quad z[i] = 1 - \frac{y[i+1]\cdot(n-1)\cdot\lambda}{\text{Rate}\cdot z[i+1]};\\
&\text{done}\\
&\text{MTTFF} = \left[\frac{z[1]}{z[1]-y[1]}\right]\left(\frac{1}{n\cdot\lambda}\right) + \frac{x[1]}{z[1]-y[1]};
\end{aligned}$$

The algorithm has linear time complexity, *i.e.*, *O*(*n*–*k*). It should be noted that at any time we need to store only one value of x_i, y_i, and z_i. Hence, to improve the MTTFF algorithm we can eliminate the arrays to reduce the storage requirements.

Algorithm 8: Storage Efficient MTTFF Computation

$$\text{Rate} = k \cdot \lambda + (n-k) \cdot \mu;$$

$$x = \frac{1}{\text{Rate}}; \quad y = (n-k) \cdot \mu \cdot x; \quad z = 1;$$

for $i = (n-k-1)$ downto 1 do

$$\text{Rate} = \text{Rate} + \lambda - \mu;$$

$$x = \frac{1}{\text{Rate}} + \frac{x \cdot (n-1) \cdot \lambda}{\text{Rate} \cdot z};$$

$$z = 1 - \frac{(i+1) \cdot \mu \cdot (n-i) \cdot \lambda}{z};$$

done

$$\text{ymod} = z - \frac{\mu}{\text{Rate}};$$

$$\text{MTTFF} = \frac{z}{y \bmod}\left(\frac{1}{n \cdot \lambda}\right) + \frac{x}{y \bmod};$$

21.5.3 Reliability with Repair

In some cases, we may be interested in finding the reliability and failure rate of a *k*-out-of-*n* system with repairable components. When both failure and repair distributions are exponential, we can find the reliability and failure rate of the system using Markov chain solutions. However, solutions to the Markov chains are computationally expensive. Using the Vesely failure rate [5], we present an efficient approximation to compute the reliability and failure rate of the *k*-out-of-*n* system with repairable components. For exponential failure and repair distributions, the following approximations provide an upper bound on the average failure rate and a lower bound on the system reliability.

$$h(t) \approx \frac{\omega(t)}{A(t)}; \quad R(t) \approx \exp\{-h(\infty) \cdot t\} \qquad (21.26)$$

Using the algorithms presented in Section 21.4, the approximate reliability and failure rate of the system can be found with $O(kn)$ or $O(n)$ algorithms. In [5], it has been shown that the above approximation is efficient as compared to other known approximations.

21.5.4 Suspended Animation

In most practical cases, non-failed components are kept idle to eliminate further damage to the system [14]. This is known as suspended animation (SA) [22]. Suspended animation introduces dependencies among the component states. Angus [6] derived a formula of the steady-state MTBF of the *k*-out-of-*n* system with identical components with exponential failure and repair distributions, assuming that no other failures will occur when the system is down, *i.e.*, to say, all working components are suspended when the system is down. Recently, Li *et al.* [14] presented generalized results for repairable *k*-out-of-*n* system with non-identical components subjected to exponential failure and repair distributions, assuming that no other failures will occur when the number of failures in the system reaches *d*, where $d \geq n-k+1$. Although the formulas in [14] are general and correct, a direct evaluation of these formulas takes a longer time to compute the results. In the worst case, the computational time increases exponentially with the number of components *(n)*. Therefore, in this chapter, we simplify the results presented in [14] and propose an efficient algorithm.

Additional Assumptions:

1. All non-failed components are kept idle once the number of failures reaches a certain limit.
   - Non-failed components are not suspended immediately after the system failure, but after reaching a certain level of failures (say $d \geq n-k+1$ failures). A special case of this model includes $d = n-k+1$, where all non-failed components are suspended immediately after reaching a system failure, i.e,. no failure occurs when the system is down.
2. Both failure and repair distributions of the components are exponential.
3. The components can be identical or non-identical, but are *s*-independent. The only dependency among the component states is due to the suspended animation.

The steady-state availability (A_{sa}) and failure frequency (ω_{sa}) of the *k*-out-of-*n* system subjected to suspended animation can be expressed as [14] follows.

$$A_{sa} = \frac{A(k)}{A(n-d)}; \quad \omega_{sa} = \frac{\omega(k)}{A(n-d)} \qquad (21.27)$$

where $A(k)$ and $v(k)$ are the steady-state availability and failure frequency of the *k*-out-of-*n* system without considering the suspended animation. Similarly, $A(n–d)$ is the steady-state availability of the (*n*–*d*)-out-of-*n* system without suspended animation. Using the algorithms presented in Section 21.4, we compute $A(k)$, $A(n–d)$, and $\omega(k)$, with $O(kn)$ time complexity (using only a single pass). Therefore, we can compute A_{sa} and ω_{sa} with $O(kn)$ time complexity algorithms. For identical cases, the complexity reduces to $O(n)$ or better. Once we know A_{sa} and ω_{sa}, all other measures, including MTBF, MUT, and MDT, can easily be found from (21.1).

21.6 Conclusions and Future Work

In this chapter, we presented efficient algorithms for computing various indices of repairable and non-repairable *k*-out-of-*n* systems. The algorithms presented are not limited to exponential failure and repair distributions. Hence, they can be applied to a wide range of failure and repair distributions, including frequently used distributions such as Weibull, Raleigh, gamma, Erlang, and extreme value. In addition to exact results, we also presented some computationally efficient approximations and bounds. The bounds are particularly important to finding the MTTFF, failure rate, and reliability of *k*-out-of-*n* systems with repairable components. We also discussed the case of suspended animation and its steady-state availability measures. All algorithms presented in this chapter can be computed with $O(kn)$ time complexity. For the identical component case, the time complexity reduces to $O(n)$. All algorithms presented in this chapter, except the suspended animation case, are implemented in Relex RBD [20]. We are currently working on some generalizations to suspended animation that include general failure and repair distributions and general renewal processes (imperfect maintenance).

Abstract: Fault tolerance has been an essential architectural attribute for achieving high reliability in many critical applications of digital systems. Automatic fault detection, location, isolation, recovery, and reconfiguration mechanisms play a crucial role in implementing fault tolerance because a not-covered fault may lead to a system or subsystem failure even when adequate redundancy exists. The probability of successfully recovering from a fault given that the fault has occurred is known as the coverage factor or coverage and this is used to account for the efficiency of fault-tolerant mechanisms. If the fault and error handling mechanisms cannot successfully cover all faults in the system, then the coverage factor becomes less than unity and the system is said to have imperfect coverage. The models that consider the effects of imperfect fault coverage are known as imperfect fault coverage models or simply imperfect coverage models, fault coverage models, or coverage models. For systems with imperfect fault coverage, an excessive level of redundancy may even reduce the system reliability. Therefore, an accurate analysis must account for not only the system structure but also the system fault and error handling behavior, which is often called coverage behavior. The appropriate coverage modeling approach depends on the type of fault tolerant techniques used. In this chapter, we present the status and trends of imperfect coverage models, and associated reliability analysis techniques. We also present the historical developments, modeling approaches, reliability algorithms, optimal design policies, and available software tools.

22.1 Introduction

A system is called fault tolerant if it can tolerate most of the faults that can occur in the system. Therefore, a fault tolerant system functions successfully even in the presence of these faults [54]. In many critical applications of digital systems, fault tolerance has been an essential architectural attribute for achieving high reliability [2]. Fault tolerant designs are particularly important for computer and communication systems that are used in life-critical applications such as flight control, space missions, and data storage systems [9, 46, 54]. Fault tolerance is generally achieved by using redundancy concepts that utilize such techniques as error correcting

codes (ECCs), built-in tests (BITs), replication, and fault masking [54]. Automatic recovery and reconfiguration mechanisms, including fault detection, location, and isolation, play a crucial role in implementing fault tolerance because a not-covered fault may lead to a system or subsystem failure even when adequate redundancy exists [7]. This is because if a faulty unit is not reconfigured out of the system, it can produce incorrect results that contaminate the non-faulty units. For example:

- In computing systems, an undetected fault may affect the subsequent calculations and operations and then operate on incorrect data, possibly leading to overall system failure [63].
- An undetected leak carrying dangerous fluid may lead to a catastrophic failure. Similarly, an undetected fire in a component may affect the whole system. In computing systems, a virus-infected file may corrupt the whole system.

Similar effects can also be found in load-sharing systems [1], power distribution systems [2], communication and transmission systems [33, 37], and data storage systems [40]. Therefore, it is important to consider the effects of not-covered faults on the functionality, safety, and security of fault-tolerant systems.

Systems subject to imperfect fault coverage may fail prior to the exhaustion of spares due to not-covered component failures [24]. In addition, an excessive level of redundancy may reduce the system reliability [4, 30, 60]. Therefore, an accurate reliability analysis of these systems is important. This analysis must consider the fault and error handling behavior in addition to the system structure and its provision of redundancy [10, 24, 29, 59, 61].

The appropriate coverage modeling approach depends on the type of fault tolerant techniques used and the details available on the error handling mechanism. The models can be broadly classified as: (1) component level fault models, and (2) system level reliability/dependability models. The component level fault models are used to describe the behavior of the system in response to a fault in each component. These models are further classified as single-fault models and multi-fault models. The system level reliability models are used to describe the behavior of the entire system, which includes the effects of component level faults on the system structure and its provision for redundancy.

Section 22.2 discusses a brief history of solution methods and related software tools. Section 22.3 presents a general description of component level fault models, which are also known as fault/error handling models (FEHM). Section 22.4 presents specific details of various single-fault coverage models. Similarly, Section 22.5 presents the details of various multi-fault models. Section 22.6 discusses the Markov models for evaluating the system reliability. Sections 22.7 and 22.8 present the combinatorial solutions to compute the system reliability measures using single-fault models and multi-fault models respectively. Section 22.9 briefly describes the policies for optimal design of systems subjected to imperfect fault coverage. Finally, Section 22.10 presents the conclusions and future work.

22.2 A Brief History of Solution Techniques

The seminal paper by Bouricius *et al*. [12] (1969) first defined coverage, also called the coverage factor (CF), as a conditional probability to account for the efficiency of fault-tolerant mechanisms.

$$\text{Coverage} = \Pr\{\text{system recovery} \mid \text{fault occurs}\} \tag{22.1}$$

This concept has been rapidly and widely recognized as a major concern in dependability evaluation studies. Since then a vast amount of work has been devoted to refining the notion of coverage [8, 13] to the identification or estimation of relevant parameters [20] and associated component-level and system-level reliability models [9, 59]. As a result, several modeling tools and techniques have been developed [27, 31].

22.2.1 Early Combinatorial Approaches

Early approaches to reliability analysis of fault tolerant systems were based on a combinatorial method first discussed by Mathur and Avizienis [41], where the reconfiguration mechanism was assumed to be perfect. Bouricius *et al*. [12] extended this model to allow the reconfiguration mechanism to have an imperfect coverage. As an embodiment of this notion, the CARE program was developed at JPL as a computer-aided reliability evaluation package [56].

22.2.2 State-Space Models

In the early approaches, fault coverage was assumed to be a single number, whereas in practice, the times to detect isolate, and recover from a fault are non-zero random variables. Furthermore, these quantities depend on the current state of the system. As a result, combinatorial models, such as static fault trees and reliability block diagrams (RBDs), cannot be used to accurately model the system behavior. Further, combinatorial models cannot adequately model the sequence-dependent failure mechanisms associated with spares management, changing working conditions, and so on. Demands for increased accuracy in reliability estimation quickly forced the development of more elaborate system models without the vastly simplifying independence assumptions [27].

For this reason, many modelers turned to Markov chains for reliability assessment of fault tolerant systems. Markov chains are extremely flexible and they can capture the fault coverage mechanism quite well. As a result, reliability analysis tools, such as ARIES [48] and CAST [19], arose based on Markovian methods, thereby allowing the important first-order dependence.

22.2.3 Behavioral Decomposition

In addition to computational complexity, a major disadvantage of Markov chains (state-space models) is that it is difficult to determine the correct Markov model for a given system. This is because the modeler must specify each operational configuration of the system explicitly and determine the rate at which the system changes from one state to another. However, the relative advantages of combinatorial models (fault trees and RBDs) and Markov models have been exploited by using two key techniques: a) behavioral decomposition [58], and b) automatic conversion of a combinatorial model to an equivalent Markov model [10, 14, 59]. These methods were used in CARE III [56] and are enhanced in HARP [9, 10, 29].

HARP (hybrid automated reliability predictor) offers two classes of fault/error handling models (FEHMs): single-fault models and multi-fault models. In the single-fault model, the uncovered (not-covered) failure may lead to the entire system failure. Hence, this event is called a single-point failure. The HARP multi-fault model is limited to near-coincident (critical-pair) failures where the total system failure occurs as a result of two coexisting (not simultaneously occurring) faults. The near-coincident failure condition occurs when the system has already experienced one fault and is in the process of recovering from it when a second statistically independent fault occurs in another unit that is critically coupled to the unit experiencing the first fault. However, if a second fault occurs during recovery in a unit that is not critically coupled, the second fault is not accounted for in the coverage computation. This second fault is accounted for in the redundancy exhaustion model. An example of critically coupled units is a flight control system in a fly-by-wire aircraft. Two units in a voting triad perform a computation required for survival of the system. While HARP is capable of modeling systems that can tolerate only one critical fault, XHARP [28] removes the critical pair restriction. XHARP is capable of supporting exact multi-fault modeling.

22.2.4 The DDP Algorithm

Although the decomposition technique used in HARP reduces the computational time and the state space, Markov chains are still used for reliability evaluation. Using a combinatorial

solution, imperfect coverage in a combinatorial model of VAXcluster systems was first introduced in [30]. Later, a similar concept for general configurations is proposed in the DDP (Doyle, Dugan, and Patterson) algorithm [22]. According to the DDP algorithm as long as the system failure logic is represented using a combinatorial model (static fault tree or RBD), the inclusion of uncovered (not-covered) single-point failures does not require a complex Markov chain-based solution. Instead, the DDP algorithm combines aspects of behavioral decomposition, sum-of-disjoint products (SDP), and multi-state solution methods.

22.2.5 Simple and Efficient Algorithm (SEA)

SEA [5] further develops and then generalizes the DDP algorithm by eliminating the need for cut-set solution methods and multi-state solution methods. The advantage of SEA is that it can be used with any combinatorial solution technique that ignores fault coverage, such as grouped variable inversion techniques, modular fault tree techniques, solutions of reliability block diagrams (array structures), and the latest algorithms including binary decision diagrams (BDD) [16, 51]. A reliability engineer can use, without modification, any software package that employs a combinatorial model that does not consider imperfect fault coverage, and by simply altering the input and output, produce the reliability of a system with imperfect fault coverage.

Two main advantages of SEA are that: (1) it can convert a fault coverage model into an equivalent perfect coverage model in a linear time, and (2) it can produce simple closed-form solutions for all well-structured systems. As a result, the computational complexity of an imperfect fault-coverage model is reduced to its equivalent perfect fault-coverage model, which in turn proves that it is difficult to find a better algorithm than SEA (if the uncovered failure is caused by single-point failures). The closed-form solutions help one to study the system in detail and find efficient algorithms for finding optimal system designs [4]. The basic idea of SEA has gained the attention of several research groups, and it has been extended and applied for a wide range of systems, applications, and techniques [16, 18, 64, 66, 67]. Most of these research works are included in the Galileo fault tree analysis package [25].

22.2.6 Multi-fault Models

The SEA and DDP algorithms and their extensions only consider single-point uncovered failures (caused by single-fault models), where the coverage probability at a component failure is solely dependent on the properties of the failed component. Little progress has been made in analyzing multi-fault models. HARP and XHARP use Markov chains for solving multi-fault models. Amari [1] proposed a simple combinatorial model to compute the reliability of k-out-of-n systems with identical components subjected to multi-fault (concurrent faults) coverage models. Recently, Myers [44] once again emphasized the need for these multi-fault models, also called fault level coverage (FLC) models, and proposed a combinatorial solution to evaluate the reliability of these systems. It should be noted that the element level coverage (ELC) models in [44] are equivalent to the single-fault coverage models in HARP [9].

Recently, several refinements and approximations to the Myers method have been proposed [6, 45, 46]. Some of these methods are incorporated in the reliability analysis tool Aralia [53]. Further, the concept of multi-fault coverage models are also extended to the multi-state systems and performance dependent coverage models [35–37].

22.3 Fault and Error Handling Models

In order to accurately model the reliability of fault-tolerant systems, it is important to know how the system behaves in response to a fault. The models that describe the system behavior in response to a fault are known as fault/error handling models (FEHM) or the coverage models. In order to describe these models, we borrow some terminology from [8, 23].

A system failure occurs when the delivered service deviates from the specified service. An error is that part of the system state which is liable to lead to failure; the cause of an error is a fault. A fault can be a programmer's error, a short circuit, electromagnetic perturbation, *etc*. Upon occurrence, a fault creates a latent error, which becomes effective when it is activated. When the error affects the delivered service, a failure occurs.

The time constants associated with cycling of the error between the effective and latent states determine if the error is considered permanent, intermittent, or transient. If an error, once activated, remains effective for a long time relative to the time needed to detect and handle it, it may be considered permanent. If the error cycles relatively quickly between the active and latent states, it may be considered intermittent. If the error, once activated, becomes latent and remains latent for a long time, it may be considered a transient. For details on the classification of faults, refer to [23].

The recovery mechanisms periodically monitor the components for the identification of faults and errors. When the faults and errors are identified, depending on the type and status of the fault, the recovery process initiates the sequence of actions that include fault location, isolation, and restoration. The detailed description of this recovery process is specified using an appropriate FEHM. The general behavior of FEHM is described in Figure 22.1. The entry point to the model signifies the occurrence of the fault, and the four exits signify the four possible outcomes.

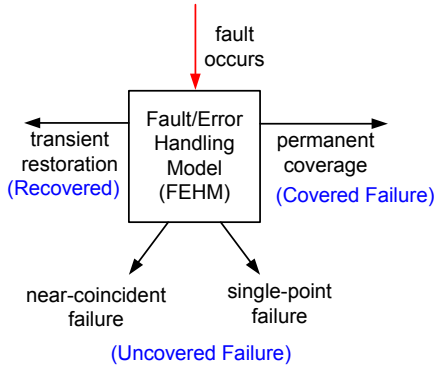

Figure 22.1. General structure of FEHM

If the offending fault is transient, and it can be handled without discarding the component, a transient restoration takes place, and the component returns to its normal working state. If the fault is determined to be permanent, and the offending component is discarded, a permanent fault recovery takes place, and the component is considered to be in the covered failure mode (safe failure mode). If the recovery mechanism is unable to detect, locate, or isolate the fault, the fault may lead to a coverage failure. If the fault by itself causes the system to fail, a single-point failure is said to take place. However, depending on the type of fault-tolerant mechanisms used, some systems can tolerate multiple undetected or non-isolated (non-removed) faults. If the number of such concurrent faults that interfere with the identification and recovery process of each other exceeds the tolerable limit of the system within an identification and recovery window (or simply called recovery window), the system fails in a multi-fault uncovered mode (not-covered mode). If the system can tolerate only one non-isolated fault at a time, the occurrence of a second fault that interferes with the recovery process of the first fault can cause an uncovered failure, which is called a near-coincident failure.

Once the fault occurs, it leads to one of the four possible outcomes or consequences:

- Transient restoration (R)
- Permanent coverage (C)
- Single-point failure (S)
- Near-coincident failure (N)

In the context of FEHM, these consequences are also called exits. In order to analyze the overall system reliability, it is important to calculate these exit probabilities: P_r, P_c, P_s, and P_n [23, 58]. The exit probabilities depend on the fault occurrence rate (λ) and effectiveness of actions that are performed after the occurrence of the fault. Assume that p_r, p_c, p_s, and p_n are the conditional probabilities of exits R, C, S, and N, respectively given that the fault has occurred. These exits are mutually exclusive. Hence, we have:

$$p_r + p_c + p_s + p_n = 1. \qquad (22.2)$$

It should be noted that both the transient restoration (R) and permanent coverage (C) are considered to be the successful actions of the fault-handling mechanisms. Hence, from the definition of coverage factor (CF) in (22.1), we have:

$$CF = p_r + p_c = 1 - (p_s + p_n). \qquad (22.3)$$

Hence, in general, we have: $CF \neq p_c$. However, in order to simplify the analysis, we may ignore the events of fault activations that lead to the R exit. This is because the overall system state is unchanged with these events. Therefore, the effective failure rate of the system becomes $\lambda_{\text{eff}} = (1 - p_r)\lambda$. If we consider only the events that are accounted for the effective fault occurrence rate, the new exit probabilities become: $p_c' = p_c/(1-p_r)$, $p_n' = p_n/(1-p_r)$, and $p_s' = p_s/(1-p_r)$. Hence, in this case, we have: $CF = p_c'$.

Most published papers assume that the conditional exit probabilities are independent of the fault occurrence rate (λ). Therefore, the exit probabilities over a mission time t can be calculated by multiplying these conditional probabilities with the fault occurrence probability: $q = 1 - \exp(-\lambda_{\text{eff}} t)$. Hence, we have: $P_c = q.p_c'$, $P_s = q.p_s'$, and $P_n = q.p_n'$. However, the independence assumption is not valid when near-coincident (or coexisting) failures are present. This is because the occurrence of a near-coincident failure depends on the occurrence rate of another fault in a related component that interfaces with the identification and recovery process of the first fault.

In the majority of research papers on imperfect fault coverage models, the near-coincident faults are not considered [2, 4, 5, 16, 43, 49, 57, 64]. In this case, we have: $p_n = 0$. This assumption is valid only if identification and recovery of a faulty component is independent of the status and information available at any other component. In such cases, the identification and recovery process of a faulty component typically utilizes its built-in test (BIT) capability. Hence, the coverage factor can be considered as a property of that component (element). Therefore, Myers [44] called these models element-level coverage (ELC) models. Because the recovery processes of faults are independent of each other, in HARP these models are known as single-fault coverage models or simply single-fault models. It should be noted that the system subject to single-fault coverage models can perform identification and recovery of multiple faults simultaneously. However, all these recovery processes are assumed to perform independently.

When the identification and recovery process of multiple faults interfere with each other, these models are called multi-fault coverage models or simply multi-fault models [9]. The recovery capabilities of multi-fault models within a recovery and reconfiguration window depend on: (1) the number of known or isolated faults before the recovery window, and (2) the number of new faults occurred in a specific group of components within the recovery window. In these models, the status of each component is compared with the status of other components using predetermined rules (majority voting or mid-value-select voting) to identify the failed components. In some cases, it is possible to correct the faulty components using the information gathered from the existing good components. Examples of this kind include recovery processes used in computer storage and communication applications [54]. Because the recovery capability of a multi-fault coverage model depends on the number of faulty (good) components in a specific group of components, Myers [44] called these models fault-level coverage (FLC) models. The corresponding groups of components are known as FLC groups [6].

When the number of good components within an FLC group is reduced to two, we cannot use majority voting or mid-value-select voting schemes. In this case, the faults in the components may be determined using built-in-tests (BIT). Considering this situation, Myers [44] also proposed a special case of FLC model called the one-on-one level coverage (OLC) model. In this model, the coverage factor is assumed to be unity when the number of good components in a specific FLC group is greater than 2. The rational behind this assumption is that when mid-value-select voting is used, it is almost certain to identify or correct all faulty components as long as the number of good components at the beginning of each recovery window is greater than 2.

At the first glance, we may incorrectly think that single-fault coverage models are efficient as

compared to multi-fault coverage models because the recovery of single-fault models is independent of the co-existing faults in multiple components. As a contradiction to the above intuition, the multi-fault models are efficient, because the identification and recovery of a fault in a component is performed not only using the information of the faulty component but also from the information available in the other good components. In addition to this, the recovery window is generally very small and the probability of multiple fault occurrences within a recovery window is very small. At the same time, in order to accurately analyze the ultra-high reliability systems, we should not ignore the probabilities of multiple faults that defeat the fault-tolerant mechanisms.

22.4 Single-fault Models

In the previous section, we considered a high-level view of FEHM model. In this section, we consider other details that are important to calculate the exit probabilities associated with the FEHM model that are subsequently used to calcuate the coverage probabilities and the overall system reliability measures [53, 57, 58]. Particularly, in this section, we describe the details of various single-fault coverage models proposed in the literature, starting with simplest phase-type models and proceding to complex ones. An appropriate model may depend on the available details on the system behavior. For a system that is still in the design phase, the details of the error handling mechanism may not be known. In such a case, the modeler would be best served by the simple coverage model. As the design progresses, the simple coverage model can be refined. Dugan and Trevedi [23] proposed a methodolgy that allows successive replacement of one coverage model with another within the overall system dependability model, also called the system-level reliability model. In addition to this, the separable method proposed in [5], separates the component-level coverage model (FEHM) from the system-level reliability model and proposes a simple and efficient algorithm (SEA).

As shown in the general structure of FEHM in Figure 22.1, these models have single entry and multiple exits. In addition to this, the FEHM box may contain some internal states. Depending on the details available, the interaction between the states can be modeled using discrete-time Markov models, continuous-time Markov models, semi-Markov models, or non-homogeneous Markov models [57].

22.4.1 Phase Type Discrete Time Models

These models assume that the recovery process takes place in phases and the time spent in each phase is negligible (or not considered). Hence, the FEHM can be represented using discrete-time Markov chains (DTMC). When we consider only the permanent errors, a three phase FEHM with detection, location, and recovery might appear as in Figure 22.2 [57, p. 269]. Each of the three FEHM phases is associated with a probability of success. Hence, the overall probability of successful system recovery is given by the product of success of individual phases (c_d, c_l, and c_r).

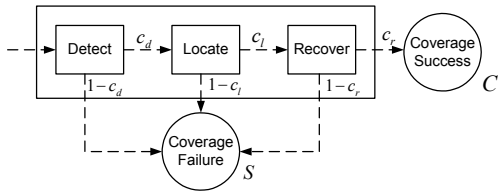

Figure 22.2. Phases of error handling

22.4.2 General Discrete Time Models

In the general discrete models, the recovery process is not restricted to phase type (sequential stages) actions and it may contain loops or backward transitions. Therefore, a state in the FEHM can be revisited. These models are applicable to specify transient restorations, transitions between latent and active fault states, and intermittent errors. Let $P = [p_{ij}]$ be the transition probability matrix of the DTMC. Here, p_{ij} is the probability that the next state will be state j given that the current state is i. Let r_{ij} be the probability of reaching an exit state j from an error

handling state i and let the matrix $R = [r_{ij}]$. Then the matrix of eventual exit probabilities given an entry state is $([I - P]^{-1}R)$ [23].

22.4.3 The CAST Recovery Model

This model is proposed in [19] and it is a DTMC model with a backward transition. This model combines the notion of transient restoration with a permanent recovery model into a single model as shown in Figure 22.3.

The entry to model represents an activation of an error (or a fault) with a total rate of λ (permanent rate) + τ (transient rate). They are detected with probability u.

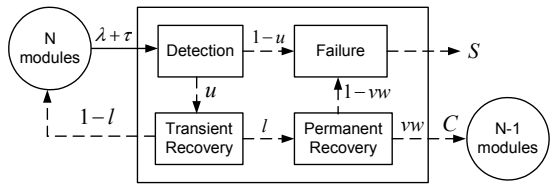

Figure 22.3. CAST recovery model

It conservatively assumes that the failure to detect the error leads to system failure. After detection, transient recovery is attempted and it is successful with probability 1-l (the component returns to its normal working condition). If transient recovery is unsuccessful, a permanent recovery is initiated where the cause of error (fault) is identified with probability v. Once the cause is identified, the system recovers with probability w. The successful permanent recovery removes the faulty component from the system. The unsuccessful permanent recovery leads to system coverage failure (also called uncovered system failure).

22.4.4 CTMC Models

These models assume that the details of FEHM can be represented using continuous-time Markov chains (CTMC). Let the transition matrix $Q = [q_{ij}]$ where q_{ij} is the rate of transition to state j given that the current state is the state i. Let r_{ij} be the rate of transition to an exit state j from an error handling state i and let the matrix $R = [r_{ij}]$. Then the matrix of eventual exit probabilities given an entry state is given by $([- Q]^{-1}R)$ [11, 23, 57]. Several CTMC type FEHM are proposed in the literature. These details are given in the following sections. The dotted lines in these diagrams indicate instantaneous transitions. If there are mutiple outward dotted transitions from a sigle state, then discrete probabilities are used to specify the next state of the FEHM model.

22.4.5 The CARE III Basic Model

This model is proposed in [56] and it is a CTMC model. The model is shown in Figure 22.4. In this model, state A is entered on activation of the fault. The fault is detected with constant rate δ (state D). Once detected the system removes the faulty unit and continues processing (state P). Before detection, the fault can produce an error with constant rate ρ (state E) or can become latent with rate α (state B). The latent fault once again becomes active with rate β. In state E, the error can be detected with probability q and if so the presence of the fault is recognized and recovery can still occur (with rate ε).

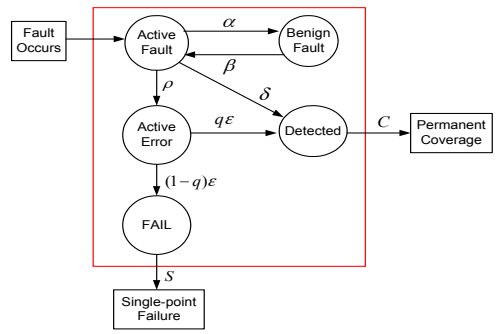

Figure 22.4. CARE III basic model

This model can be used to represent either permanent faults (always effective) or intermittent faults. The permanent faults are represented in this model by setting α and β to zero. To represent intermittent faults both α and β should be positive.

In this model, the probability of taking exit C (reaching state D) is equivalent to the coverage factor. Because state A is the initial state of the model, coverage is equivalent to the exit

probability from state A to the state D. Hence, we have [57]:

$$c = \frac{\delta}{\delta+\rho} + \frac{q\rho}{\delta+\rho} = \frac{\delta+q\rho}{\delta+\rho}. \qquad (22.4)$$

It should be noted that the coverage factor of this model is independent of the parameters: α, β, and ε. As shown [23, 58], in order to compute the system reliability, we need to calculate only the coverage factor from the FEHM. Therefore, the model can be simplified by removing "benign fault state" and setting $\varepsilon = 1$.

22.4.6 The CARE III Transient Fault Model

The CARE III transient model is a generalization to the CARE III basic model and it allows specifying the effects of transient restoration. This model can be used to model transient, intermittent, or permanent faults. In the active state, a fault is both detectable (with rate δ) and capable of producing an error (with rate ρ). Once an error is produced, if it is not detected, it propagates to the erroneous output (with rate ε) and causes system failure. If the fault (error) is detected (with probability q), the faulty element is removed from service with probability P_A when the fault is active or P_B when the fault is benign. With the complementary probabilities, *i.e.*, 1-P_A or 1−P_B, the element is returned to service following the detection of the fault. The model can be specialized to permanent, transient, or intermittent cases. For the permanent model, $\alpha = \beta = 0$, and $P_B = 0$. For the transient model, α is positive and $\beta = 0$. For the intermittent model, both α and β are positive, these rates are fast in relation to the overall model (fault occurrence rates).

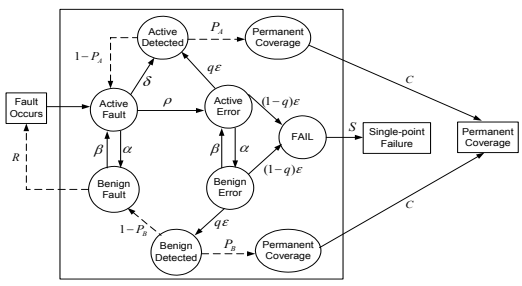

Figure 22.5. CARE III transient model

22.4.7 ARIES Models

The ARIES coverage model was proposed by Makam and Avizienis [48] and it allows the transient restoration. This is a phased recovery model that allows the user to specify how many phases comprise the recovery process. The duration of each phase is constant. The model has three possible eventual exits: system crash (exit S), normal processing (exit R), and permanent fault recovery (exit C). In each phase of the recovery, the system attempts the recovery. If successful, the system returns to the normal processing state without discarding any components. If the recovery in a particular phase is unsuccessful, the next phase attempts to locate and recover from the fault. If all phases are ineffective, the fault is assumed to be permanent. Hence, the component is discarded and system continues its functions with one fewer component provided that redundancy of the system is not exhausted.

22.4.8 HARP Models

HARP supports several single fault models. They include:

1. The no coverage model: This model is used to specify perfect coverage.
2. The value model: In this model, without specifying the detailed behavior of FEHM, the user can specify the probabilities of taking the exits (R, S, and C) directly.
3. The ARIES model.
4. The CARE III model.

In addition to this, HARP also supports the following models.

5. The ESPN model.
6. The probabilities and moments model.
7. The probabilities and distribution model.
8. The probabilities and empirical data model.

The probabilities and distribution model in HARP can be considered as a generalization to the limited

recovery model discussed in [23]. The limited recovery model is applicable for real-time systems, where there may be a time limit within which recovery actions must be completed in order to be considered successful. Assume that the time to perform recovery is exponentially distributed with rate parameter δ, and that recovery is always successful. In the case where there is no limit on the recovery time, the coverage probability is unity. If there is a time limit T on the recovery process, then the coverage probability is given by: $c = \Pr\{\text{recovery time} \leq T\} = 1\text{-}\exp\{\text{-}\delta T\}$. For a more general case, see [57, Section 5.4].

22.5 Multi-fault Models

The need for the multi-fault models arose due to the complex interactions between recovery procedures of multiple faults. In fact, for fly-by-wire aircraft designs such as SIFT and FTMP, it was claimed that all single-point failures were eliminated. Hence, it was thought that near-coincident faults will be the major cause of system failure. The detailed modeling of multiple faults can be computationally expensive and tedious to specify [14, 57]. In addition, the modeling requires the user to input data that are typically unavailable. Therefore, the developers of HARP and other researchers proposed some simple specifications of these models. Although the disadvantage is a reduction in accuracy, published work has demonstrated that the error due to the use of simple models is typically acceptable [9, 42].

22.5.1 HARP Models

HARP supports three simple multi-fault coverage models to automatically incorporate the effects of coexisting faults. All these models are restricted to near-coincident faults.

1. The ALL-inclusive near-Coincident model: In this model, the recovery of a fault is performed as per the single-fault model specified for the individual components. During this recovery process if any other component fails, the system is considered to be failed in the uncovered mode (not-covered mode). In order to include this effect, HARP adds a dummy state between two original states (state i and state j) of the generated Markov model.
2. The SAME-type near-coincident model: This is similar to the ALL-inclusive model, except that the system fails in the uncovered mode only if a similar component fails during the recovery process of the first failure. This model is similar to the model used in [6, 44].
3. USER-defined near-coincident model: This model allows the user to specify, for each component, which other components can interfere with the fault recovery. For example, suppose we have a system consisting of three processors (P1, P2, and P3), a voter V, and a bus B. Suppose further that the processors are connected in a ring network so that processor P1 detects errors and performs recovery for processor P2, processor P2 likewise monitors processor P3, and P3 monitors P1. Thus the failure in processor P1 can interfere with recovery in P2. Similarly, a failure on processor P2 can interfere with recovery in processor P3. Because the processors are connected by the data bus, a bus failure can interfere with recovery on any of the processors. The bus does not relay on any other component for recovery. The voter is self-checking; no faults interfere with recovery from voter faults.

In addition to this, HARP also supports manual specification of exact near-coincident faults.

22.5.2 Exclusive Near-coincident Models

In some cases, we may wish to consider the uncovered (not-covered) failures that are only caused by the occurrence of coexisting faults. In this case, we are ignoring the possibility of single-point failures. This means that the recovery process is perfect as long as there are no coexisting faults within a recovery window. The following approaches can be used to model only near-coincident failures.

1. Exponentially distributed recovery time: In this model, the recovery of a fault is considered to be perfect as long as there is no second fault within a recovery window. The recovery time (window) follows exponential distribution with rate δ. In order to calculate the coverage factors, consider a 1-out-of-3 system subjected to near-coincident faults. The coverage factor at the first fault is calculated as the probability to complete the recovery of that fault before the occurrence of the second fault, which can occur with rate 2λ. Hence, the coverage at the first fault is $c_1 = \delta/(\delta+2\lambda)$. Refer to Fig. 22.6. Similarly, the coverage at the second fault is $c_2 = \delta/(\delta+\lambda)$. This model is discussed in [23, 38, 57].

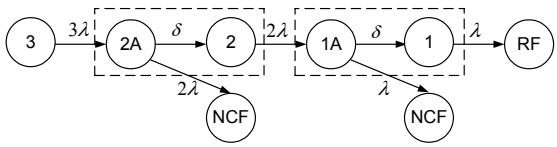

Figure 22.6. Near-coincident model

2. Fixed recovery time: This is the same as the previous model, except that the recovery window time is fixed. Let τ be the recovery window time. During the first failure, any one of the remaining (n-1) components can fail during τ and can cause the system failure. Extending the same logic for other cases, we have:

$$c_i = \exp[-(n-i)\lambda\tau]. \qquad (22.5)$$

   This is exactly the same model used in [1, 44] except for the last two faults where the coverage is calculated using single-fault models associated with built-in-test capabilities.
3. General recovery time: The above models can also be generalized for the general recovery time distribution. Refer to [56, 57] for details. A special case of this model is a phased recovery process discussed below.
4. Phased recovery process: This model is used in CARE [56]. In this model, the recovery of a fault follows a phase-type distribution. For example, consider a 1-out-of-3 system with two phases of recovery for each fault. The Markov model for this system is shown in Figure 22.7. Hence, the coverage factor at the first fault is $c_1 = [\delta/(\delta+2\lambda)]^2$. Similarly, the coverage at the second fault is $c_2 = [\delta/(\delta+\lambda)]^2$.

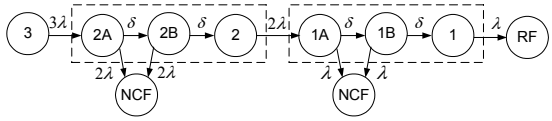

Figure 22.7. Phased recovery near-coincident model

22.5.3 Extended Models

Some generalizations to near-coincident fault models are proposed in [28] and the approach used to analyze these models is called extended behavioral decomposition. In this section, we discuss a specific near-coincident model considered in [28]. In this model, the recovery process attempts to fix the problems in each module (or similar components) at a time. It is assumed that as long as the recovery process is involved in fixing the problems in a specific module, the second or subsequent faults in that module does not lead to the near-coincident failure, but leads to the permanent coverage. However, during a recovery process in a particular module, if another fault occurs in some other module, the recovery process cannot handle that situation and leads to the near-coincident failure.

22.6 Markov Models for System Reliability

Sections 22.4 and 22.5 presented various single-fault and multi-fault models. Now we discuss how to integrate these coverage models into the overall system reliability analysis. For example, consider a 1-out-of-3 system. With perfect coverage, the Markov model of the system is shown in Figure 22.8.

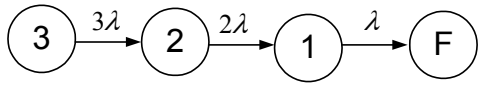

Figure 22.8. A 1-out-of-3 system with perfect coverage

In order to demonstrate the integration of coverage models into the system reliability model, we consider CARE III basic single-fault model. The coverage model will be initiated immediately after occurrence of a fault. Therefore, the coverage model is incorporated after each failure transition in the original Markov model. Hence, the overall system reliability model becomes as shown in Figure 22.9.

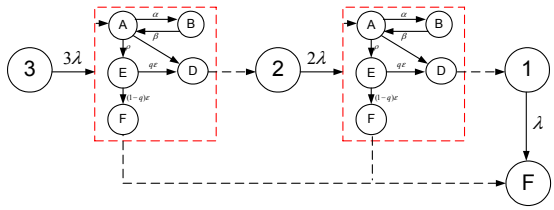

Figure 22.9. 1-out-of-3 system with CARE III basic single-fault model

We can also incorporate the effects of near-coincident faults in the overall system reliability model. For this purpose, assume that any additional failure during the recovery process leads to the near-coincident system failure. Hence, we add a near-coincident failure transition from each state of the recovery process. The procedure is the same for any combination of single-fault and near-coincident models.

The main problem with this approach is stiffness of the resulting Markov chain that contains both fast transition rates (recovery process) and slow transition rates (failure rates). Typically, the mean transition times in the recovery model are in seconds and the mean failure times are in hours. Hence, the difference in the transition rates is in the order of magnitude of 10^6. The numerical solutions of stiff Markov models are very difficult compared to non-stiff Markov models [11, 38, 39, 57]. Another disadvantage of this approach is the state space explosion of the Markov model due to the additional states that describe the details associated with recovery processes. In addition to these difficulties, this approach is inapplicable if the random variables of interest are non-exponentially distributed.

In order to overcome these difficulties, behavioral decomposition has been proposed [58]. This method is based on the fact that time constants of fault-handling processes are several orders of magnitude smaller than those of fault-occurrence events. It is therefore possible to analyze separately the fault-handling behavior of the system (the coverage model) and later incorporate the results of the coverage model, together with the fault-occurrence behavior, in an overall system reliability model. The fast transitions in the fault-handling model are replaced with instantaneous jump transitions. In this method, we first calculate the exit probabilities associated with FEHM [11]. For example, if we consider the CARE III basic single-fault model, we have two exits: C and S. The exit probabilities are:

$$c = \frac{\delta + q\rho}{\delta + \rho}; \qquad s = 1 - c = \frac{(1-q)\rho}{\delta + \rho}. \quad (22.6)$$

Using these exit probabilities as the instantaneous transition probabilities, we can reduce the Markov chain as shown in Figure 22.10.

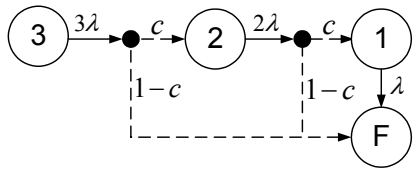

Figure 22.10. 1-out-of-3 system with instantaneous coverage probabilities

Now using the instantaneous jump theorem [28, 58], we can combine the transitions as shown in Figure 22.11.

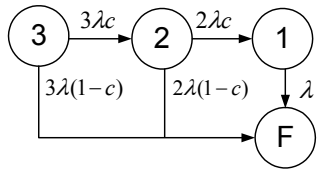

Figure 22.11. Simplified 1-out-of-3 system model with behavioral decomposition

The resulting Markov chain contains the same number of states as in the perfect coverage model

(see Figure 22.8). If we want to distinguish the failures as redundancy exhaustion failures (covered failures) and fault-handling failures (uncovered failures), we can split the failure state accordingly. Similarly, we can also use the behavioral decomposition for analyzing the near-coincident failures [56].

It is important to note that, as shown in [42, 55], the behavioral decomposition always produces conservative results for system reliability, which is a desired property in reliability analysis. In addition to this, the error in the approximation is negligible for any practical purpose. Therefore, this method is used in several software packages including CARE, HARP, and SHARPE [9, 27].

22.7 The Combinatorial Method for System Reliability with Single-fault Models

The decomposition method discussed in Section 22.6 reduces the state-space of a system subjected to imperfect fault coverage to that of a perfect coverage case. However, we still need to use the Markov chains for analyzing the imperfect coverage models even when there are no additional dependencies among the components except the dependencies introduced by the fault-handling processes. Therefore, irrespective of system redundancy mechanisms, the systems subjected to imperfect coverage need to be solved using Markov chains. The main disadvantage of Markov chains is its state-space explosion. Even for a moderate size practical system, the state-space of the Markov chain becomes huge. In order to overcome these difficulties, various approximations and bounds for Markov chains are proposed [15, 42, 57]. In addition to this, some special techniques have been developed to solve the Markov chains associated with the coverage models. They include automatic generation of Markov chains from combinatorial models and solving the Markov chains incrementally while generating them [1, 14, 24].

A major break-through in analyzing the imperfect coverage model came with the publication of the DDP algorithm [22]. According to [22], the system reliability can be computed using combinatorial solution methods when the following conditions are met.

- Component failures (fault occurrence) are statistically independent.
- If manual repair or restoration is applicable, then the restoration process of each component is independent.
- The fault-handling process of each component is independent of the states of other components, *i.e.*, faults do not interfere with each other. This means that there are no near-coincident or multi-fault failures.
- The system failure or success logic is represented using a combinatorial model when we ignore the failures associated with the fault-handling process. This means that when the coverage is perfect, we should be able to represent the system using traditional combinatorial models.

Because there are no near-coincident failures, each component is in one of the following states.

- Good: component is not failed, *i.e.*, working normally.
- Covered failure: component failure is correctly handled, *i.e.*, permanent coverage.
- Uncovered failure (not-covered failure): component failure is not correctly handled, *i.e.*, single-point failure.

Figure 22.12 shows the event space (and corresponding probability) representation of each component.

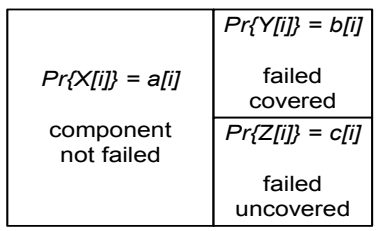

Figure 22.12. Event and probability space of a component

22.7.1 Calculation of Component-state Probabilities

In this method, we first calculate the state probabilities for each component. When there is no manual restoration after a permanent coverage, the state probabilities are calculated from the component reliability and fault coverage probabilities. Refer to [16] for calculating the state probabilities when there are manual restorations. Let $F_i(t)$ be the fault occurrence time distribution that ignores the events associated with transient restoration. It is nothing but component unreliability q_i. Hence, the component reliability is $p_i = 1-q_i = 1-F_i(t)$. Let c_i be the coverage factor of the component. Hence, we have:

$$a[i] = p_i; b[i] = c_i q_i; c[i] = (1-c_i)q_i . \quad (22.7)$$

As discussed in Section 22.3, we can also calculate these probabilities using the exit probabilities associated with FEHM. These calculations are demonstrated using the exponential failure distribution for fault occurrence times. Let λ_i be the combined failure rate (occurrence rate) of transient & permanent faults in component i. Let c_i, s_i, and r_i be the exit probabilities of FEHM corresponding to C, S, and R exits. The effective failure rate of component i is:

$$\gamma_i = (1-r_i)\lambda_i = (c_i + s_i)\lambda_i . \quad (22.8)$$

The failure rates $c_i\lambda_i$, $s_i\lambda_i$ lead to $Y[i]$, $Z[i]$ respectively. From Markov chains, we have:

$$\begin{aligned} a[i] &= \exp(-\gamma_i t) \\ b[i] &= \frac{c_i}{c_i + s_i}[1-\exp(-\gamma_i t)] \\ c[i] &= \frac{s_i}{c_i + s_i}[1-\exp(-\gamma_i t)] \end{aligned} \quad (22.9)$$

This type of equation is used in [24]. However, if $\lambda_i t$ is very small, it is reasonable to assume that at the most one fault can occur in a component during time t. Hence,

$$\begin{aligned} a[i] &= r_i[1-\exp(-\gamma_i t)] + \exp(-\gamma_i t) \\ b[i] &= c_i[1-\exp(-\lambda_i t)] \\ c[i] &= s_i[1-\exp(-\lambda_i t)] \end{aligned} \quad (22.10)$$

This type of equation is used in [22]. If $\lambda_i t \ll 1$, then $\exp(-\lambda_i t) \approx 1-\lambda_i t$, and (22.9) and (22.10) lead to the same results as in (22.11).

$$\begin{aligned} a[i] &= 1-(s_i + c_i)\lambda_i t \\ b[i] &= c_i \lambda_i t \\ c[i] &= s_i \lambda_i t \end{aligned} \quad (22.11)$$

22.7.2 The DDP Algorithm

The system fails in an uncovered mode due to the uncovered failure of any component. Hence, $Z[i]$ is a cut set of the system. Because this cut set contains only one variable (component state), it is also called singleton cut set. If system contains n components, then we have n singleton cut sets corresponding to an uncovered failure of each component.

$$C_i = Z[i] . \quad (22.12)$$

In addition to this, from the system failure logic, we can find the cut sets that represent the exhaustion of redundancy (covered failures). Let there are m such cut sets. These cut sets are represented using the combined events of $Y[i]$ states of different components. We label these cut sets as $C_{n+1},\ldots, C_{n+m}$. Hence, we have a total of $p = n+m$ cut sets. The system unreliability (U) is the probability of union of all these cut sets. Hence, we have:

$$U = \Pr\left\{\bigcup_{i=1}^{p} C_i\right\} \quad (22.13)$$

We cannot add the probability of each cut set to find the unreliability. This is because the cut sets are not disjoint except when $n = 1$. Therefore, [22] proposed a sum of disjoint products (SDP) algorithm to compute the system reliability. The SDP algorithm uses the following identity:

$$\begin{aligned} \bigcup_{i=1}^{p} C_i = C_1 \cup (\neg C_1 C_2) \cup (\neg C_1 \neg C_2 C_3) \cup \\ \ldots \cup (\neg C_1 \neg C_2 \neg C_3 \ldots \neg C_{p-1} C_p) \end{aligned} \quad (22.14)$$

to produce a set of disjoint events whose probabilities can be summed. Here, $\neg C_i$ represents the

negation of C_i and $\neg C_i C_j$ represents intersection of $\neg C_i$ and C_j. Hence, $\neg C_i C_j = (\neg C_i) \cap (C_j)$.

Now the task is reduced to find the probability of each product term in the SDP form. However, we should take a special care while expanding these terms, because each component in the system has three mutually exclusive states, *i.e.*, these are multi-state components. As in the traditional multi-state system (MSS) reliability analysis, we represent each state of the system with a Boolean variable. For example, $Y[i]$ is used to represent the covered failure of component i. The $Y[i]$ is true if the component i is failed in a covered mode; otherwise, it is false. Hence, $Y[i]$ is false if component i is either working ($X[i]$ is true) or failed in an uncovered mode ($Z[i]$ is true). Because the component states are mutually exclusive, exactly one of these variables ($X[i]$, $Y[i]$, and $Z[i]$) is true at a time. Therefore, the SDP terms that contain multiple terms corresponding to a component need to be eliminated. Hence, we use the following identities for simplifying the SDP terms.

$$\begin{aligned} \neg X[i] &= Y[i] \cup Z[i] \\ \neg Y[i] &= X[i] \cup Z[i] \\ \neg Z[i] &= X[i] \cup Y[i] \end{aligned} \tag{22.15}$$

and

$$\begin{aligned} X[i] \cap Y[i] &= \phi \\ X[i] \cap Z[i] &= \phi \\ Y[i] \cap Z[i] &= \phi \\ X[i] \cap Y[i] \cap Z[i] &= \phi \end{aligned} \tag{22.16}$$

To demonstrate this method, we consider a three-unit redundant system that is operational as long as at least one unit is operational, provided that no uncovered failures have occurred. The singleton cut sets that represent uncovered component failures are:

$$\begin{aligned} C_1 &= Z[1] \\ C_2 &= Z[2] \\ C_3 &= Z[3] \end{aligned} \tag{22.17}$$

The system fails in the covered mode if all components fail in the covered mode. Hence, the cut set that represents the redundancy exhaustion is:

$$C_4 = Y[1]Y[2]Y[3] \tag{22.18}$$

Therefore, the system unreliability is:

$$\begin{aligned} U = \Pr\left\{\bigcup_{i=1}^{4} C_i\right\} &= \Pr\{C_1\} + \Pr\{\neg C_1 C_2\} + \\ &\Pr\{\neg C_1 \neg C_2 C_3\} + \Pr\{\neg C_1 \neg C_2 \neg C_3 C_4\} \end{aligned} \tag{22.19}$$

Further, we have:

$$\begin{aligned} &\Pr\{C_1\} = \Pr\{Z[1]\} = c[1] \\ &\Pr\{\neg C_1 C_2\} = \Pr\{(\neg Z[1]) Z[2]\} \\ &= \Pr\{(X[1] \cup Y[1]) Z[2]\} \\ &= \Pr\{X[1] Z[2]\} + \Pr\{Y[1] Z[2]\} \\ &= a[1]c[2] + b[1]c[2] \end{aligned} \tag{22.20}$$

Similarly, we can find that:

$$\begin{aligned} &\Pr\{\neg C_1 \neg C_2 C_3\} = a[1]a[2]c[3] + a[1]b[2]c[3] + \\ &a[2]b[1]c[3] + a[2]b[2]c[3] \\ &\Pr\{\neg C_1 \neg C_2 \neg C_3 C_4\} = b[1]b[2]b[3] \end{aligned} \tag{22.21}$$

Using this approach, we can find the probability of each term in (22.19). The sum of all these probabilities is equivalent to the system reliability.

Although the DDP algorithm reduced the solution complexity from Markov chain based solutions to combinatorial solutions, it is still not suitable for solving large systems. This is because the solution uses cut-set based techniques where finding the cut-sets of a large system itself is a hard problem [43]. Further, expanding the SDP terms needs a complex procedure required for multi-state systems. In addition to this each SDP term contains n variables where the n is the number of components in the system. In order to overcome some of these difficulties, Doyle *et al*., and Zang *et al*. [21, 69] used a latest data-structure called binary decision diagram (BDD). However, unlike in the standard BDD, the variables used in the proposed BDD solution are not independent due to the dependencies among the component states, *i.e.*, the states of a component are mutually exclusive. Hence, the size of the resulting BDD increases, which nullifies the advantages of the BDD technique. Recently, Zing and Dugan [65] proposed a ternary decision diagram (TDD), which is a special type of multi-valued decision diagram (MDD). In the TDD method, a variable can take

three values (branches) that represent the three mutually exclusive states of the component: $X[i]$, $Y[i]$, and $Z[i]$. The advantage of this method is that the TDD contains the same number of nodes as the BDD that is used for the perfect fault coverage case. However, the number of branches in the TDD increases to 3/2 times to that of the BDD for the perfect coverage case. It should be noted that the number of nodes in a BDD is always greater than the number of variables. In most cases, the number of nodes is much greater than the number of variables. Using, the SEA algorithm [5], we can reduce the number of branches to that of the perfect coverage case. However, the TDD approach proposed in [68] solves the phased-mission systems effectively.

22.7.3 SEA

Amari [1] has identified that several computations in the DDP algorithm can be simplified. In addition to this, the system failure state can be divided into mutually exclusive states: system covered failure state and system uncovered failure state. The uncovered failure of the system occurs if at least one component is failed in the uncovered mode. The probability of this state can be calculated using a simple product over all components. This calculation can be performed in a linear-time with respect to the system size. The system fails in the covered mode, if no component fails in the uncovered mode and the system reaches the exhaustion of redundancy. Alternatively, it happens when the system failure condition is reached without the presence of uncovered failures. It is observed that the probability of this failure can be calculated using the same formula as for the perfect coverage case, except that we should use conditional component reliabilities (given that no uncovered failure has occurred) in the place of component reliabilities. The conditional reliability of all components can be computed in a linear-time with respect to the system size. Hence, the computational time to find the reliability of a system with imperfect coverage is almost equivalent to that of perfect coverage case where the effects of imperfect coverage are ignored.

Using the above separable method, [1, 5] proposed an algorithm called simple and efficient algorithm (SEA). The following proof of this algorithm is given in [1, p. 208]. Define the events:

- E: system failure
- E_1: at least one component in the system has failed in an uncovered mode.
- E_2: no component has failed in an uncovered mode.
- $Z[i]$: component i has failed in the uncovered mode (not-covered mode).

Here, E_1 and E_2 are mutually exclusive and exhaustive (complete) events. Further, we have:

$$E_1 = \bigcup_{i=1}^{n} Z[i]$$
$$E_2 = \bigcap_{i=1}^{n} \neg Z[i] \tag{22.22}$$

According to the total probability theorem [43, 57], the system unreliability can be expressed as:

$$U = \Pr\{E\}$$
$$= \Pr\{E \mid E_1\} \cdot \Pr\{E_1\} + \Pr\{E \mid E_2\} \cdot \Pr\{E_2\} \tag{22.23}$$

The system is failed if at least one component is failed in the uncovered mode. Hence, $Pr\{E|E_1\} = 1$. Because the components are independent, we have:

$$\Pr\{E_1\} = \Pr\left\{\bigcup_{i=1}^{n} Z[i]\right\} = 1 - \prod_{i=1}^{n} (1 - c[i])$$
$$\Pr\{E_2\} = 1 - \Pr\{E_1\} = \prod_{i=1}^{n} (1 - c[i]) \equiv P_u \tag{22.24}$$

The probability, $Pr\{E|E_2\}$, is calculated based on the condition that no uncovered failure has occurred in the system. Because all components are independent, it is equivalent to the unreliability of the same system computed using the conditional component reliabilities ($R[i]$) and unreliabilities ($Q[i]$) obtained using the condition that no uncovered fault has occurred in any component. Hence, we have: $R[i] = a[i]/(a[i]+b[i])$ and $Q[i] = b[i]/(a[i]+b[i])$. The conditional reliability (R_c) or unreliability (Q_c) can be calculated using any method that is applicable for the perfect coverage

case. Finally, the system reliability and unreliability are:

$$U = 1.(1 - P_u) + Q_c \cdot P_u$$
$$R = 1 - U = P_u \cdot R_c \quad (22.25)$$

Therefore, the algorithm to compute system reliability and unreliability is as follows:

SEA algorithm

1. Find P_u.

$$P_u = \prod_{i=1}^{n} (a[i] + b[i]) \quad (22.26)$$

where *a[i]+b[i] = 1-c[i]*.

2. Find the modified reliability and unreliability of each component.

$$R[i] = \frac{a[i]}{a[i] + b[i]}$$
$$Q[i] = \frac{b[i]}{a[i] + b[i]} \quad (22.27)$$

3. Using $Q[i]$ and/or $R[i]$ from step 2, find the reliability (R_c) or unreliability (Q_c) of the corresponding perfect coverage system by any method.
   a. Binary decision diagram (BDD) [51].
   b. Sum of disjoint products (SDP) [41].
   c. Any other method, *e.g.*, path-sets, cut-sets, binomial theorem, inclusion-exclusion method, modular fault-tree approach, pivotal decomposition, and simulation [43].
4. Find the reliability or unreliability of the imperfect coverage system as:

$$U = 1 - P_u + P_u \cdot Q_c = 1 - P_u \cdot R_c$$
$$R = 1 - U = P_u \cdot R_c \quad (22.28)$$

In other words, the SEA approach defines a method for adjusting the inputs and outputs for a given software package (or a method) to accommodate the additional information about fault coverage probabilities. No programming (or algorithm) changes to the reliability analysis package are necessary to implement this approach. Figure 22.13 demonstrates how the SEA approach wraps around any traditional fault tree analysis software package.

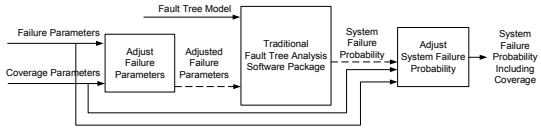

Figure 22.13. Integration of SEA with a traditional FTA package

In order to demonstrate this method, consider the three unit redundant system discussed in Section 22.7.2. We have:

$$P_u = (1 - c[1])(1 - c[2])(1 - c[3])$$
$$Q[1] = b[1]/(a[1] + b[1])$$
$$Q[2] = b[2]/(a[2] + b[2])$$
$$Q[3] = b[3]/(a[3] + b[3]) \quad (22.29)$$
$$Q_c = Q[1]Q[2]Q[3]$$
$$R_c = 1 - Q_c$$

Finally, the system reliability is: $R = P_u.R_c$. With some simple mathematical manipulations, the reliability can be expressed as:

$$R = \prod_{i=1}^{3} (a[i] + b[i]) - \prod_{i=1}^{3} b[i] \quad (22.30)$$

Similarly, we find the closed-form expressions for all systems whenever the closed-form expression for the corresponding perfect coverage case exists. Amari *et al*. [4] provided the closed-form expressions for several standard systems such series, parallel, parallel-series, series-parallel, *k*-out-of-*n*, and majority voting system. Using these closed-form expressions, [4] has provided efficient algorithms to find the optimal system configurations that maximize the overall system reliability.

22.7.4 Some Generalizations

22.7.4.1 Propagtion of Uncovered Failures

The SEA algorithm assumes that an uncovered failure of any component leads to the overall system failure. In other words, the effects of uncovered failures are global. However, this may not be the case in some situations. The uncovered

failure in a component may leads to the failure of a module (or subsystem) that contains the component, *i.e.*, the effects of uncovered failures are local to that module. As a result, the module failure may not always lead to the overall system failure and it depends on the states of other modules in the system. In such cases, the reliability of each module is calculated using the SEA algorithm (step 1) and overall system reliability is calculated using the reliabilities of individual modules (step 2) [1]. While calculating the overall system reliability (step 2), we assume perfect coverage. Hence, there is no need to apply the separable approach once again.

The above concept is generalized to the modular imperfect coverage case [66] where the uncovered failure of a component is limited to its local module with a certain probability p and may propagate to the next higher level with probability $q = 1-p$. Another way of modeling the same situation is that an uncovered failure of a component may cause immediate failure up to a certain higher level (hierarchies) according to a probability distribution. The latter approach requires more parameters as compared to the former. However, it provides a more detailed modeling capability. The solution to this problem is provided by recursively applying the concepts of separable method (SEA) from the lower level module to the higher level module.

Zing and Dugan [64] extended the concept of modular imperfect coverage to the phased-mission systems (PMS), where an uncovered component failure in a specific phase may be local to that phase (leads to phase failure) or global to the entire mission (leads to overall mission failure) with certain probabilities. It should be noted that we can only distinguish these local and global uncovered failure effects, when the phases are not in series. Therefore, [64] also proposed the concept of a non-series type phased mission system, which is a generalization to the traditional phased-mission system. Extending the same concept, the phased-mission system can be modeled as a multi-state system, where the state of the system is determined based on the specific combination of successful phases. The solution to this problem is obtained by applying the separable method twice.

22.7.4.2 Dependencies in Component Failures

Both the SEA and DDP algorithms assume that the failure or success logic of the system is combinatorial and the failures of components are statistically independent. These assumptions are too restrictive; particularly, they are not valid when there are induced failures, standby components, load-sharing components, priorities in repairs, limited repair resources, and sequential failures. If there is at least once such dependency, we cannot apply the SEA approach directly. Hence, we should once again go back to the complex Markov solutions.

Dugan [25] presented an effective solution to this problem when the system failure behavior is modeled using fault trees. It is assumed that the sequence dependencies are modeled using dynamic gates. Hence, using modularization techniques, the fault tree is partitioned into static modules and dynamic modules. The static modules are solved using combinatorial methods where we can apply the SEA algorithm to compute modules covered and uncovered failure probabilities. The dynamic modules are solved using Markov chains or simulation. Once we know the covered and uncovered probabilities for each module, we can once again use the SEA algorithm to compute the overall system reliability.

The same concept is further extended to the phased-mission systems, where the static phases are solved using combinatorial methods and the dynamic phases are solved using Markov chains. For details, refer to [64, 67].

22.7.4.3 Multi-state Systems and Components

The majority of published works on imperfect coverage assumes that both the system and its components have only two states if the effects of coverage are ignored. However, with the addition of imperfect coverage, the failure state of the system and its components are once again divided into: covered failure and uncovered failure. Only in this way, the system and its components have multiple states, *i.e.*, three states with single-fault coverage models. In this situation, using SEA we can convert the problem into an equivalent perfect

coverage problem having binary states. However, the binary models are not appropriate in several applications. This is because the system performance may decrease over time due to its component failure, but might not have reached a total failed state. In such cases, if the failure and repair follow exponential distributions, we can use Markov reward processes. To some extent, we can also use semi-Markov or non-homogeneous Markov reward models to handle the general distributions. However, with this approach we need to use the complex Markov chain based solutions that are efficient only for moderate size systems. Of course, using some approximations or bounds we can solve the large problems to some extent [15, 51].

Another approach to this problem is multi-state system (MSS) modeling. It should be noted that the Markov chain approach itself is a multi-state approach. However, in most cases, we can decompose the problem such that individual components, subsystems, or modules (or super-components) can be modeled using state-space methods (Markov chains). Further, the overall system performance or behavior can be expressed using combinatorial models as a combination of different component states. The MSS approach can be used to model degradation, dependencies associated with cold or warm spares, load-sharing components, *etc*. Now if we add the effects of coverage to the individual components of the original model, then the components and systems in the MSS model will have an additional state that represents the uncovered failure. The MSS model that includes the effects of coverage can be solved using several existing methods such as explicit enumeration, disjointing method based on critical state vectors (multi-state cut sets), binary decision diagrams with restrictions on variables, *etc*. [32, 43]. However, as in the case of the DDP algorithm for binary state systems, this method has some limitations. Due to the presence of uncovered failures, we cannot use the modularization methods. The state-space of the system increases quickly even though only one additional state is added to each component. With the addition of an uncovered failure to each component, when disjointing method is used, each product term contains the states from all components. For example, the above difficulties can easily be realized while solving the multi-state k-out-of-n system subjected to imperfect coverage. Therefore, the direct application of MSS solution methods is inefficient.

In order to overcome the above difficulties, Chang *et al*. [17, 18] extended the separable approach used in SEA to the case of multi-state components where the implicit assumption is that the system is subjected to single-fault coverage models. Consider that a multi-state component has $m + 1$ states: 0, 1,…,m. Where 0 indicates uncovered failure state, and 1,…,m indicates other m performance levels that include covered failure states. Let $p[i]$ be the unconditional probability of state i. The conditional probability that the component is in state i given that no uncovered failure has occurred in that component is:

$$P_c[i] = \frac{p[i]}{1 - p[0]} \quad . \tag{22.31}$$

Once we know these probabilities, we can apply any method that is applicable for solving MSS systems subjected to perfect coverage. Chang *et al*. [17, 18] used binary decision diagrams (BDD) with restrictions on variables. Then the overall system reliability is calculated using the total probability theorem [57]. Although the BDD method is efficient in general, it may not be the case for each and every system. Particularly, several other efficient methods are readily available for well structured systems.

Levitin [33] proposed a direct recursive method based on universal generating functions for solving modular systems represented using multi-state reliability block diagrams. In this method, as in [1, 66] the effects of coverage can be local (to subsystems) or global (system level).

22.8 Combinatorial Method for System Reliability with Multi-fault Models

In this section, we discuss the combinatorial solutions for solving multi-fault coverage models. We first consider k-out-of-n systems with identical

components and then generalize these results for the non-identical component case. Later we discuss modular systems consisting of independent *k*-out-of-*n* subsystems subjected to multi-fault models. Finally, we present the methods for computing general configurations.

22.8.1 *k*-out-of-*n* Systems with Identical Components

In this section, we describe the method provided in [1, 44] for analyzing *k*-out-of-*n* systems subjected to multi-fault models. The method assumes that the coverage probabilities are calculated using near-coincident failures. Assume that p is the reliability of each component and c_i is the coverage probability at the ith failure. If the coverage probabilities are calculated based on fixed recovery window, from (22.5) we have:

$$c_i = \exp[-(n-i)\lambda\tau]\,. \tag{22.32}$$

Because the system fails after $(n-k+1)$ failures (irrespective of fault coverage), c_i for $i \geq (n-k+1)$ are not applicable and can be considered as zero. Myers [44] used a slightly different approach to calculate the coverage probabilities where the mid-value-select voting scheme is used to find the failed components. It is assumed that as long as there are more than two good components in the system, the mid-value-select scheme covers all failures if there is no additional component failure within the recovery window. If there are only two components in the system, then the components' failures cannot be covered using the mid-value-select voting scheme. In such cases, the coverage of a component is based on built-in-tests. Hence, c_{n-1} is calculated using single-fault models associated with the built-in-tests. If there is only one component in the system, failure of that component leads to overall system failure for any value of k. Hence, c_n can be considered as zero. Of course, this value does not impact the reliability of a *k*-out-of-*n* system.

The above calculations can be generalized to the case where built-in-tests are performed at each failure instance in addition to the mid-value-select voting scheme. Let c be the coverage associated with the built-in-test of a component. Then the effective, coverage factor at the ith failure is:

$$c_i = 1-(1-c)(1-\exp[-(n-i)\lambda\tau]) \approx c+\exp[-(n-i)\lambda\tau \tag{22.33}$$

First consider the perfect coverage case, where the reliability of *k*-out-of-*n* system is [32]:

$$R = \sum_{i=0}^{n-k} P_i\,, \tag{22.34}$$

where P_i is the probability of exactly i components have failed. For the identical component case, P_i can be calculated using the binomial distribution.

$$P_i = \binom{n}{i} p^i q^{n-i}\,, \tag{22.35}$$

where $q = 1 - p$ = unreliability of each component. In the imperfect coverage case, we should multiply P_i with the cumulative coverage probability associated with the first i failures. The cumulative coverage up to the first i failures is:

$$r_i = \prod_{j=0}^{i} c_i\,. \tag{22.36}$$

Note that by definition, we have: $c_0 = r_0 = 1$. Therefore, system reliability is:

$$R = \sum_{i=0}^{n-k} r_i P_i\,. \tag{22.37}$$

The reliability in (22.37) can be computed using a linear-time algorithm.

Algorithm 1: Reliability with Identical Components

$x = p^n = \exp\{n \cdot \ln(p)\}$; y = q/p
for $i = 1$ to $(n-k)$ do
$x = c_i \cdot x \cdot y \cdot \dfrac{n-i+1}{i}$; $\mathrm{Re}\,l = \mathrm{Re}\,l + x$
done

At the end of the algorithm, the results for reliability will be accumulated in Rel.

22.8.2 *k*-out-of-*n* Systems with Non-identical Components

In this case, we assume that the components are non-identical. Let p_i be the reliability of component

i. In this case, the exact calculation of coverage probabilities c_i depends on a set of components that already failed. For example, the coverage probability at component *k* is calculated based on the effective failure rate (λ_{eff}) within the recovery window. The effective failure rate is the sum of failure rates of all non-failed components. If components *i* and *j* have already failed, then the coverage at component *k* failure is calculated by summing the failure rates of all components except the components *i, j, k*. Hence, the coverage probability is: $\exp(-\tau.\lambda_{\text{eff}})$. This approach is used in HARP [9]. However, such a calculation increases the computational time exponentially. Therefore, using the average failure rate approximation, the coverage probability calculations can be simplified to produce acceptable results. Using this approximation, we calculate the average failure rate of all *n* components first and then use (22.32) to compute the coverage probability at each failure.

Once we know component reliabilities and coverage probabilities, it is straightforward to extend the method discussed in Section 22.8.1 to the non-identical component case. The only difference is that P_i should be computed using an appropriate formula. For simplicity, consider a 2-out-of-3 system. We have:

$$R = P_0 + r_1 P_1 + r_2 P_2 . \qquad (22.38)$$

The probabilities for P_i can be calculated in several ways. For example, we show two different forms of equations:

FORM 1: truth-table

$$\begin{aligned} P_0 &= p_1 p_2 p_3 \\ P_1 &= q_1 p_2 p_3 + p_1 q_2 p_3 + p_1 p_2 q_3 \\ P_2 &= p_1 q_2 q_3 + q_1 p_2 q_3 + q_1 q_2 p_3 \end{aligned} \qquad (22.39)$$

FORM 2: inclusion-exclusion using path-sets

$$\begin{aligned} P_0 &= p_1 p_2 p_3 \\ P_1 &= p_1 p_2 + p_2 p_3 + p_1 p_3 - 3 p_1 p_2 p_3 \\ P_2 &= q_1 q_2 + q_2 q_3 + q_1 q_3 - 3 q_1 q_2 q_3 \end{aligned} \qquad (22.40)$$

Myers and Rauzy [45, 46] proposed an efficient $O(n(n\text{-}k))$ algorithm to compute the reliability of *k*-out-of-*n* systems with non-identical components subjected FLC models (multi-fault models). This algorithm slightly modifies the perfect coverage case algorithm discussed in [26].

Algorithm 2: Reliability with Non-identical Components

$R = 0; P[1] = 1;$ for $i = 2$ to $n - k + 1$ do $P[i] = 0;$ done
for $i = 1$ to n do
  for $j = n - k$ downto 1 do
    $P[j+1] = p_i \cdot P[j+1] + c_j \cdot q_i \cdot P[j]$
    if $(i == n)$ then $R = R + P[j+1]$
  done
  $P[1] = p_i \cdot P[1]$
done
$\text{Re}l = R + P[1]$

At the end of the algorithm, the results for system reliability will be accumulated in Re*l*.

22.8.3 Modular Systems

This section considers general configuration systems with embedded *k*-out-of-*n* subsystems subjected to multi-fault models. In other words, the system consists of several *k*-out-of-*n* type subsystems arranged in either a series-parallel or non-series-non-parallel structure. Each subsystem consists of identical or non-identical components, and these components form an FLC group. This means that the coverage probabilities of the components in a subsystem depend only on the number of good components in that subsystem.

As in Section 22.7.4.1 [1, 66], we consider two cases for the effects of uncovered failure: (1) local to each subsystem, and (2) global to system level. In the first case, we can calculate the reliability of each subsystem as mentioned in Sections 22.8.1 and 22.8.2. Using these subsystem reliabilities, we can compute the overall system reliability using an appropriate combinatorial method. In the second case, we can apply the separable method used in SEA. In order to apply this method, we should first calculate the reliability of each subsystem as mentioned in Sections 22.8.1 and 22.8.2. In

addition to this we should also calculate the covered and uncovered failure probabilities for each subsystem.

The uncovered failure of subsystem j can be calculated as:

$$U_j = \sum_{i=0}^{n(j)} [1 - c_i(j)] r_{i-1}(j) P_i(j), \qquad 22.41)$$

where c, r, P have the same meaning as in Sections 22.8.1 and 22.8.2. The uncovered failure probability can also be calculated by slightly modifying the reliability algorithms presented in Sections 22.8.1 and 22.8.2. The covered failure probability of subsystem j can be calculated as:

$$V_j = 1 - R_j - U_j. \qquad (22.42)$$

Once we know reliability, covered failure probability, and uncovered failure probability for each subsystem, we can use the SEA algorithm to compute the overall system reliability as in the case of ELC models.

22.8.4 General System Configurations

This section considers general configuration systems where the components in any FLC group can appear anywhere in the system, *i.e.*, they need not to belong to a specific k-out-of-n type subsystem.

22.8.4.1 System Description and Assumptions

The solution methods are proposed considering the following assumptions, which are applicable for most cases.

- The system consists of several s-independent components. The only dependency among the component failures is due to the uncovered failures caused by imperfect fault coverage mechanisms.
- The uncovered (not-covered) failure of any component causes immediate system failure, even in the presence of adequate redundancy. Note that, as discussed in the previous section, it is easy to relax this assumption.
- The system consists of several groups of components called FLC groups. Say there are m FLC groups. Each component belongs to one and only one FLC group. Note that if needed all components with perfect coverage can be grouped into a special FLC group where coverage is unity.
- The *fault-coverage* = Pr{system can recover | a fault occurs} depends on the number of faulty components in the FLC group corresponding to the faulty component.
- An s-coherent combinatorial model (fault tree, RBD, digraph, or network) can be used to represent the combinations of covered component failures that lead to system failure (or success).
- Fault occurrence probabilities are given either (a) as fixed probabilities (for a given mission time), or (b) in terms of a lifetime distribution. They are s-independent of the system state.

22.8.4.2 The Sum of Disjoint Product Approach

In this method, we represent the system structure using a sum of disjoint products (SDP) form. For example, consider the truth table method, which is a special type of SDP method. In this method, each product term contains a specific combination of states (good or failed) of all components. For each product term, we can find the number of failed components that belongs to each FLC group and then find the corresponding coverage probability. Then we can find the contribution of each product term to the overall system reliability by multiplying the corresponding component reliabilities, unreliabilities, and coverage probabilities. The sum of product contributions over all products gives the overall system reliability.

The truth table approach can be improved by grouping the product terms that belongs to specific number of failed components in each FLC group. Although this procedure produces correct results, it is computationally inefficient. Therefore, this method can only be applied for very small problems.

22.8.4.3 The Implicit Common-cause Failure Method

This method is proposed in [6] and it uses SEA-based calculations [5] and common-cause failure analysis concepts [62]. The basic idea of this method is that the conditional reliability of the system given that no uncovered failure in the system can be computed using implicit common-cause failure analysis. To apply implicit common-cause analysis, we should know the joint probabilities of events that belong to an *s*-dependent group (FLC group). The procedure is explained through a simple example of 2-out-of-3 system with non-identical components subjected to imperfect fault coverage. To apply this method, we should first compute the uncovered failure probability (U) of each FLC group using (22.41). Let x_i be the probability that only the ith component in the FLC group has failed in covered mode given that there is no uncovered failure in the FLC group. Similarly, x_{ij} represents the probability that only the ith and jth components have failed. Hence, we have:

$$\begin{aligned} x_1 &= r_1 q_1 p_2 p_3 /(1-U) \\ x_{12} &= r_2 q_1 q_2 p_3 /(1-U) \\ x_{123} &= r_3 q_1 q_2 q_3 /(1-U) \end{aligned} \tag{22.43}$$

Similarly, we can compute (1) x_2 and x_3, and (2) x_{13} and x_{23}. Let y_{ij} be the probability that at least components i and j have failed in the covered mode, and there are no uncovered failures in the FLC group. Hence, we have:

$$\begin{aligned} y_1 &= x_1 + x_{12} + x_{13} + x_{123} \\ y_{12} &= x_{12} + x_{123} \\ y_{123} &= x_{123} \end{aligned} \tag{22.44}$$

Similarly, we can compute (1) y_2 and y_3, and (2) y_{13} and y_{23}. Once we know these x and y values, it is straightforward to compute the system reliability. Most algorithms use the y values. For example, the conditional unreliability of a 2-out-of-3 system is:

$$Q^c = y_{12} + y_{13} + y_{23} - y_{123}. \tag{22.45}$$

Finally, the overall system reliability is: $(1-U)(1-Q^c)$. The method for general system configuration follows:

- For each FLC group j, find the uncovered failure probability, (U_j).
- Using U_j, for each FLC group, find the x and y values required for the common-cause analysis.
- Using these x and y values, compute the system conditional reliability, R_c.
- Compute the C = Pr{no uncovered failure in the system}.

$$C = \prod_{i=1}^{m} (1 - U_j), \tag{22.46}$$

  where m is the number of FLC groups in the system.
- Finally, the overall system reliability is:

$$R = C.R_c. \tag{22.47}$$

Although this method is slightly better than the SDP method discussed in Section 22.8.4.2, it is still computationally expensive for the general system configurations. In order to overcome this difficulty, reference [6] proposed a simple approximation.

22.8.4.4 The Approximation Method

The basic idea of this approximation is that "the conditional reliability of the system given that no uncovered failure in the system (R_c)" is almost equivalent to the "unconditional reliability of the system with perfect coverage (R_p)" [6]. In fact, $R_c \geq R_p$. Hence, this algorithm produces provably conservative results for the system reliability. The algorithm is follows :

- For each FLC group in the system, find the uncovered failure probability.
- Compute C = Pr{no uncovered failure in the system}.
- Using component reliabilities, compute the system reliability, R_p, using any combinatorial algorithm. This means that we compute the system reliability ignoring

effects of coverage, *i.e.*, assuming perfect coverage.

- Finally, the overall system reliability is:

$$R = C.R_p . \tag{22.48}$$

The computational time of this algorithm is equivalent to that of the perfect coverage case and the error in this approximation is very small and can be ingnored for any practical purposes [6].

22.8.4.5 Binary Decision Diagrams

Recently, Myers and Rauzy [45, 46] proposed an efficient method using binary decision diagrams (BDD) for computing the reliability of systems subjected to imperfect coverage. In this section, we describe this method for solving complex systems subjected to FLC models. The basic idea of this method is that the system is successful only if there are no uncovered failures in any FLC group and the number of working components in the system satisfies its structue function for success. Hence, we have:

$$R = \Pr\{X_0 \cap X_1 \cap ... \cap X_m\} , \tag{22.49}$$

where X_0 represents the Boolean function for system success when the coverage is perfect. X_i, i=1,…,m, represents the Boolean function for "no uncovered failures" in FLC group i. In order to find the intersection in (22.49) and its probability, Myers and Rauzy [46] used binary decision diagrams. In this method, we should first find the BDD for each X_i, I = 0,1,…,m. Then find the BDD for overall system success using AND operations.

Generating the BDD for X_0, *i.e.*, without considering the effects of coverage (perfect coverage) is discussed in several publications [51]. The remaining step is finding the BDD for X_i, i=1,…,m, that represents the "no uncovered failures" in FLC group i in terms of variables that represent component success, component failure, and success of coverage mechansims. Myers and Rauzy [46] proposed an efficient BDD representation for each FLC group. For example, consider an FLC group consisting of four components. Then the BDD for this FLC group can be represented as in Figure 22.14.

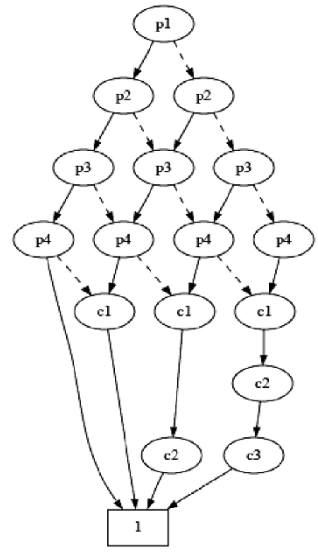

Figure 22.14. BDD for a 4-unit system subject to FLC models

In this BDD, the branches that lead to node 0 (uncovered failure) are removed to simplify the BDD representation. Once we generate the BDDs for all X_i, we can find the BDD for system success using standard BDD operations [51]. The calculation of system reliability is straightforward from the BDD representation of the system success and these details are available in several sources [16, 51].

The above method can be generalized to the case of induced failures, where failure of a component forces some other components to fail. For example, consider the quad power computer with cross channel data link (CCDL) discussed in [6, 44]. It has four computers (C1, C2, C3, and C4) and four sensors (S1, S2, S3, and S4). In this system, S1 is considered to be available only if C1 is available. Similarly, S2, S3, and S4 are considered to be failed if C2, C3, and C4 are respectively failed. Hence, while generating the BDD for the FLC group corresponding to sensors (S1, S2, S3, and S4), we should also consider the states of computers (C1, C2, C3, and C4). Hence, the BDD for sensors FLC success contains a total of 11 variables: 4 for computers, 4 for sensors, and 3 for sensor coverages.

22.8.5 Some Generalizations

All multi-fault coverage (FLC) models considered so far assume that the system and its components have binary states if the effect of coverage is ingored. Reference [36] generalized the concept of FLC to multi-state systems consisting of binary components with different performance and reliability characteristics. However, Levitin and Amari [36] assumed that the system is represented using modular reliability block diagrams where each FLC group represents a *k*-out-of-*n* subsystem. Similarly, Levitin and Amari [37] generalized this concept to performace based coverage, where the coverage factor of each FLC group depends on its performance instead of the number of failed components. Levitin and Amari [35] extended the concepts of FLC for the modular imperfect coverage case [66], where uncovered failures progatage from a lower system level to higher system level.

22.9 Optimal System Designs

Amari *et al.* [4] have proved that reliability of any system subjected to imperfect fault-coverage, particularly with single-fault models, decreases after a certain level of active redundancy. Therefore, there exists an optimal level of redundancy that maximizes the overall system reliability. These results coincide with the observations made in [23]. Specifically, Dugan and Trevedi have shown that both reliability and mean time to failure (MTTF) of parallel systems subjected to imperfect fault-coverage decreases with the increase in number of parallel components after reaching a certain limit. Initially, these observations seem counterintuitive. However, as explained in [23], the systems subjected to imperfect fault-coverage can fail in two modes: covered failure and uncovered (not-covered) failure. Irrespective of the system structure function, the system behaves like a series system for the uncovered failure mode, which is a dominant failure mode for the systems with a large number of components. Therefore, the system reliability decreases with an increase of redundant components after a certain limit. Several researchers have shown similar results for some special cases of *k*-out-of-*n* systems that include triple modular redundancy with spares [49], *k*-resilient protocols [50], multiprocessor systems [60], and gracefully degradable systems [47]. Amari *et al.* [4] provided closed-form solutions for optimal redundancy that maximize the reliability of various standard system models that include parallel systems, series-parallel systems, parallel-series systems, *N*-tuple modular systems, and *k*-out-of-*n* systems. Similarly, using the concepts of SEA [5], the cost-effective design policies for parallel systems subjected to imperfect fault-coverage are provided [3]. Later Amari *et al.* [2] extended these results for complex systems composed of *k*-out-of-*n* subsystems and provided easy to evaluate lower and upper bounds for optimal redundancy levels for both reliability optimization and cost minimization problems.

In all the previous studies, the aim is to (1) show the negative effects of imperfect fault-coverage, (2) emphasize the need for accurate analysis of the coverage factor, and (3) emphasize the use of optimal redundancy (thereby discouraging the use of too much redundancy). In addition to this, Amari [1] also discusses some alternative means for the provision of redundancy that include adding the spares in periodic intervals, use of standby redundancy, and adding the redundancy only when a certain predefined number of components have failed. Amari [1] studied the effects of imperfect fault-coverage on the cold standby redundancy policies. It shows that, unlike in active redundancy, the reliability of a cold standby system always increases with the additional redundancy. However, unlike in the perfect coverage models, there exists a maximum achievable reliability limit for the standby systems subjected to imperfect fault-coverage. A closed-form solution to the maximum achievable reliability limit is provided. Further, an algorithm is provided to find the optimal cost-effective redundancy level that strikes a balance between system failure cost and the cost of spares [1].

Levitin [34] considered the optimal redunancy problem of multi-state systems subjected to single-fault coverage models. The solution to this

problem is provided using the universal generating function method and genetic algorithms.

Almost all papers that consider optimal redundancy problems assume that the system is subjected to single-fault models. Not much work has been done on the multi-fault coverage models. Similarly, there is a need to develop optimal design policies for multi-state systems, phased-mission systems, and common-cause failure models subjected to imperfect coverage.

22.10 Conclusions and Future Work

Coverage is an important concept and it is used to assess the effectiveness of tolerant mechanisms. In this chapter, we discussed various coverage models for both single-fault models and multi-fault models. These models can be used to model both single-point failures and near-coincident failures. We also discussed the status and trends in analyzing the systems subjected to imperfect fault coverage models. Particularly, we emphasized the use of behavioural decomposition, Markov chain based solutions, combinatorial methods based on a separable method, and binary decision diagrams. Recently, several generalizations to imperfect coverage models are proposed that include the integration of coverage models into multi-state systems, phased-mission systems, hierachiel systems, dynamic fault trees, reliability block diagrams, and common-cause failure models.

The reliability of systems subjected to imperfect coverage models decreases after a certain level of redundancy. Therefore, there exists an optimal redundancy that maximizes the system reliability. Further, it is important to investigate the sparing policies that are specific to imperfect coverage cases.

In the past few years, multi-fault coverage models have gained a lot of research interest. New solution methods and generalizations are proposed by several researchers. At the same time, there is still a lot of scope for further research. Particularly, there is a need for integrating multi-fault coverage models into multi-state models, phased-mission systems, dependent failures, common-cause failures, *etc*. In addition to this, the methods for finding the optimal redundancy of systems subjected to multi-fault models are still limited.

Abstract: In this chapter, a state-of-the-art review of various analytical modeling techniques for reliability analysis of phased-mission systems (PMS) is presented. The analysis approaches can be broadly classified into three categories: combinatorial, state-space oriented, and modular. The combinatorial approaches are computationally efficient for analyzing static PMS. A combinatorial binary decision diagram based method is discussed in detail. Methods to consider imperfect fault coverage and common-cause failures in the reliability analysis of PMS will also be presented.

23.1 Introduction

The operation of missions encountered in aerospace, nuclear power, and many other applications often involves several different tasks or phases that must be accomplished in sequence. Systems used in these missions are usually called phased-mission systems (PMS). A classic example is an aircraft flight that involves take-off, ascent, level-flight, descent, and landing phases. During each mission phase, the system has to accomplish a specified task and may be subject to different stresses as well as different dependability requirements. Thus, system configuration, success criteria, and component failure behavior may change from phase to phase [1]. This dynamic behavior usually requires a distinct model for each phase of the mission in the reliability analysis. Further complicating the analysis are statistical-dependencies across the phases for a given component. For example, the state of a component at the beginning of a new phase is identical to its state at the end of the previous phase in a non-repairable PMS [2]. The consideration of these dynamics and dependencies poses unique challenges to existing analysis methods.

Considerable research efforts have been expended in the reliability analysis of PMS over the past three decades. Generally, there are two classes of approaches to the evaluation of PMS: analytical modeling [1–5] and simulation [6, 7]. Simulation typically offers greater generality in system representation, but it is often more expensive in computational requirements [5]. On the other hand, analytical modeling techniques can incorporate a desirable combination of flexibility in representation as well as ease of solution. The analytical modeling approaches can be further categorized into three classes: state space oriented models [3, 5, 8–10], combinatorial methods [1, 2, 4, 11, 12], and a phase modular solution [13–16] that combines the former two methods as appropriate. The state space oriented approaches,

which are based on Markov chains and/or Petri nets, are flexible and powerful in modeling complex dependencies among system components. However, they suffer from state explosion when modeling large-scale systems. With an effort to deal with the state explosion problem of the state space oriented approaches, some researchers proposed combinatorial methods, which exploit Boolean algebra and various forms of decision diagrams to achieve low computational complexity and less storage space consumption.

This chapter will give a state-of-the-art review of the various analytical modeling methods. It then focuses on a combinatorial binary decision diagrams based method for the reliability analysis of a class of generalized PMS (GPMS). Traditionally in a PMS, the mission is assumed to fail if the system fails during any one phase [17]. GPMS extends this phase-OR failure requirement to the more general combinatorial phase requirement (CPR) [1]. The outcome of the GPMS may also exhibit multiple performance levels between binary outcome (success or failure). Methods to consider imperfect fault coverage and common-cause failures in the reliability analysis of GPMS will also be discussed in this chapter.

23.2 Types of Phased-mission Systems

PMS can be categorized in several ways:

- *Static versus dynamic PMS:* If the structure of the reliability model for any phase of PMS is combinatorial, *i.e.*, the failure of the mission in any phase depends only on the combinations of component failure events, the PMS is said to be static. If the order in which the component failure events occur affects the outcome, *i.e.*, the failure of the mission in any one phase depends on both the combinations of the component failure events and sequence of occurrence of input events, the PMS is said to be dynamic. Systems involving functional dependencies and/or spares management are also dynamic. In Section 23.3, various approaches to the analysis of static and dynamic PMS will be presented.
- *Repairable versus non-repairable PMS:* In a non-repairable PMS, once a component has failed in one phase, it remains failed in all later phases. In a repairable system, the state of the system depends on the failure characteristics of its components as well as the maintenance plans that are conducted on the system. Maintenance can be classified into three categories according to the reason why it is conducted [13]: 1) *failure-driven maintenance* occurs when maintaining a system upon the occurrence of a component failure; 2) *time-driven maintenance* is performed on a pre-determined schedule; and 3) *condition-driven maintenance* is performed based on the observed condition of a system, for example, a component is repairable whenever the component fails and the system does not fail; no repair is possible upon the system failure. Meshkat [13] investigated these maintenance plans and analysis of PMS with certain kinds of time-driven maintenance. Xing [18] studied the dependability modeling and analysis of PMS with the failure-driven maintenance and the scheduled maintenance. This chapter will focus on the reliability modeling and analysis of non-repairable PMS.
- *Coherent versus non-coherent PMS:* In a coherent PMS, each component contributes to the system state, and the system state worsens (at lease does not improve) with an additional component failure [19]. On the other hand, the structure function of a noncoherent system does not increase monotonically with the additional number of functioning components. Specifically, a noncoherent system can transit from a failed state to a good state by the failure of a component, or transit from a good state to a failed state by the repair of a component. In other words, both component failures and repairs can contribute to the system failure in a noncoherent system. The failure behavior of a noncoherent PMS can be described using noncoherent fault trees, which are characterized by inverse gates (for example, NOT and exclusive-OR gates) besides logic gates used in coherent fault trees. This chapter will focus on coherent PMS.

- *Series/phase-OR PMS versus combinatorial phase requirements (CPR):* In a series PMS, the entire mission fails if the system fails during any one phase [17]. For a PMS with CPR, its failure criterion can be expressed as a logical combination of phase failures in terms of phase-AND, phase-*K*-out-of-*N*, and phase-OR. Thus, a phase failure does not necessarily lead to a mission failure; it may just produce degraded performance of the mission [1].
- *Sequential versus dynamic choice of mission phases:* In a sequential PMS, the sequence of phases traversed by the system to accomplish its goals is always constituted by a single path from the first phase to the last one. Most of existing PMS analysis techniques focuses on the sequential PMS. There are indeed examples of PMS for which the sequence of phases is better represented by a more generic direct acyclic graph [9]. In this scenario, at the end of a phase, the next phase may be selected according to a probability distribution, or depending on the current internal state of the PMS. Methods for considering the probabilistic choice of mission phases were presented in [8, 9]. A brief discussion on these methods is also given in Section 23.3.2.2.

23.3 Analytical Modeling Techniques

Three classes of analytical approaches to the reliability analysis of coherent PMS are described in this section. Section 23.3.1 presents the combinatorial approaches to the analysis of static PMS. Section 23.3.2 presents the state space oriented methods. Section 23.3.3 presents the phase modular approach, which provides a combination of combinatorial solution for static phase modules and Markov chain solution for dynamic phase modules.

23.3.1 Combinatorial Approaches

Combinatorial methods for analyzing PMS assume that all components fail/behave *s*-independently within each phase. However, they deal with the *s*-dependence across phases for a given component.

23.3.1.1 The Mini-component Technique

Esary and Ziehms [4] proposed to deal with the *s*-dependence across phases by replacing the component in each phase with a system of components (called *mini-components*), performing *s*-independently and in series. For example, a component *A* in phase *j* of a non-repairable PMS is replaced by a set of *s*-independent mini-components $\{a_i\}_{i=1}^{j}$ in series. The relation between a component and its mini-components is: $A_j = a_1 \bullet a_2 \bullet \ldots \bullet a_j$, meaning that *A* is operational in phase *j* (represented by $A_j = 1$ or $\overline{A}_j = 0$) if and only if it has functioned in all the previous phases.

Figure 23.1 shows the reliability block diagram (RBD) and fault tree (FT) format of the mini-component solution. Esary and Ziehms [4] showed that reliability of the resulted new system after the above transformation is the same as the reliability of the original PMS. Most importantly, the evaluation of the new system can proceed without considering the *s*-dependence across phases for a given component.

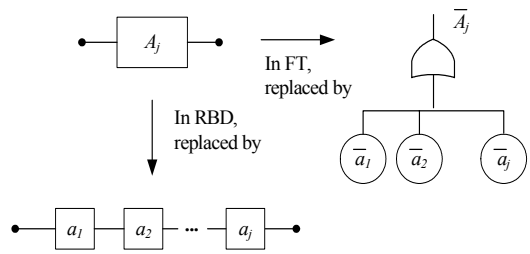

Figure 23.1. Mini-component method

Let *A(t)* be the state indicator variable of component *A*, and $q_{a_i}(t)$ be the failure function of mini-component a_i for component *A* in phase *i*, which conditionally depends on the survival of phase (*i*-1). The relationship between *A(t)* and $q_{a_i}(t)$ is:

$$q_{a_i}(t) = \begin{cases} \Pr(A(t) = 0) & i = 1, \\ \Pr(A(t + T_{i-1}) = 0 \mid A(T_{i-1}) = 1) & 1 < i \le j, t \le T_i. \end{cases} \quad (23.1)$$

In the system-level reliability analysis, $q_{a_i}(t)$ is given as the system input in the form of a

conditional failure distribution conditioned on the success of a_{i-1}.

Consider an example PMS with three components (A, B, and C) used in three non-overlapping consecutive phases (adapted from [3]). Figure 23.2 shows the failure criteria in each phase of the PMS in fault trees. In Phase 1, the system fails if all the three components fail. In Phase 2, the system fails if A fails or both B and C fail. In Phase 3, the system fails if any of the three components fails.

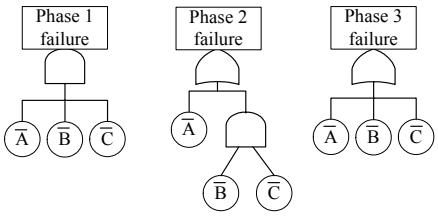

Figure 23.2. Fault tree model of a three-phase PMS

Figure 23.3 shows the equivalent system fault tree model in the mini-component method. Clearly the difficulty with this method is that the size of the problem becomes very large as the number of phases increases, for which a solution can be computationally very expensive.

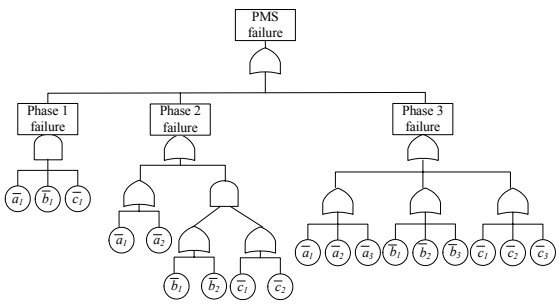

Figure 23.3. Equivalent mini-component system

23.3.1.2 The Boolean Algebraic Method

Another solution to the phased mission problem is to connect multiple phase models in series. Figure 23.4 shows the equivalent system at the end of mission in the Boolean algebraic method for the example PMS in Figure 23.2.

Based on the relation between a component and its mini-components, the failure function for component A in phase j can be calculated from $q_{a_i}(t)$ as (23.2):

$$F_{A_j}(t) = \begin{cases} q_{a_j}(t) & j = 1, \\ [1 - \prod_{i=1}^{j-1}(1 - q_{a_i}(T_i))] + [\prod_{i=1}^{j-1}(1 - q_{a_i}(T_i))] \bullet q_{a_j}(t) & j > 1 \end{cases} \quad (23.2)$$

where time t is measured from the beginning of phase j so that $0 \le t \le T_j$. T_j is the duration of phase j. The first term in (23.2) when $j > 1$ represents the probability that component A has already failed in the previous phases (1, 2, …, j-1). The second term denotes the probability distribution of lifetime of A in phase j.

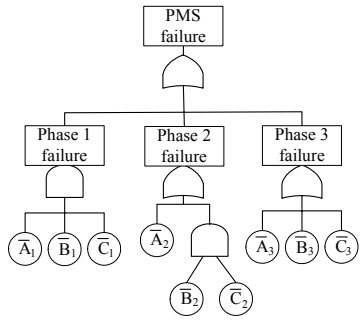

Figure 23.4. Example PMS in the Boolean algebra method

Because s-dependence exists among the same component in different phases, special treatment is needed for combination terms containing more than one A_i, $1 \le i \le m$, where m represents the total number of phases in the PMS. A set of Boolean algebraic rules called phase algebra rules was proposed to deal with the dependence (Table 23.1) [11, 20].

Table 23.1. Rules of phase algebra *($i < j$)*

$A_i \bullet A_j \to A_j$	$\overline{A}_i + \overline{A}_j \to \overline{A}_j$
$\overline{A}_i \bullet \overline{A}_j \to \overline{A}_i$	$A_i + A_j \to A_i$
$\overline{A}_i \bullet A_j \to 0$	$A_i + \overline{A}_j \to 1$

The phase algebra rules can be proved using the relation between the component and its mini-components ($A_j = a_1 \bullet a_2 \bullet \ldots \bullet a_j$) [2]:

- "$A_i \bullet A_j \to A_j$": the event "*A* is operational in phase *i* and the later phase *j*" is equivalent to the event "*A* is operational in the later phase *j*".

$$A_i \bullet A_j = (a_1 \bullet a_2 \bullet ... a_i)(a_1 \bullet a_2 \bullet ... a_j)$$
$$= a_1 \bullet a_2 \bullet ... a_j = A_j$$

- "$\overline{A}_i \bullet \overline{A}_j \to \overline{A}_i$": the event "*A* has failed in phase *i* and the later phase *j*" is equivalent to the event "*A* has failed in phase *i*".

$$\overline{A}_i \bullet \overline{A}_j = (a_1 \bullet a_2 \bullet ... a_i) \bullet \overline{(a_1 \bullet a_2 \bullet ... a_j)}$$
$$= \overline{a_1 \bullet a_2 \bullet ... a_i + a_1 \bullet a_2 \bullet ... a_j}$$
$$= \overline{a_1 \bullet a_2 \bullet ... a_i} = \overline{A}_i$$

- "$\overline{A}_i \bullet A_j \to 0$": the event "*A* has failed in phase *i*, but is operational in the later phase *j*" does not exist for a non-repairable PMS.

$$\overline{A}_i \bullet A_j = (\overline{a_1 \bullet a_2 \bullet ... a_i})(a_1 \bullet a_2 \bullet ... a_j)$$
$$= (\overline{a}_1 + \overline{a}_2 + ... + \overline{a}_i)(a_1 \bullet a_2 \bullet ... a_j) = 0$$

The three rules in the right column of Table 23.1 are just the complementary form of the rules in the left column, which have been proved in the above. Phase algebra rules do not account for $A_i \bullet \overline{A}_j$ and $\overline{A}_i + A_j$ combinations [2, 20]. $A_i \bullet \overline{A}_j$ means that *A* is operational until the end of phase *i* and then fails sometime between the end of phase *i* and the end of phase *j*; $\overline{A}_i + A_j$ has no physical meaning without considering repair. These phase algebra rules apply only to variables belonging to the same component.

23.3.1.3 Binary Decision Diagrams

Zang *et al.* [2] proposed a binary decision diagram (BDD) based method for the reliability analysis of static PMS with phase-OR requirement. As the first step of the method, phase algebra rules (Table 23.1) combined with heuristic variable ordering strategies are used to generate the PMS BDD model. Two types of ordering strategies were explored for variables that represent the same component in different phases: *forward* and *backward*. Thus, two types of phase-dependent operations (PDO) were proposed: *forward PDO* in which the variable order is the same as the phase order, and *backward PDO* in which the variable order is the reverse of the phase order. It is shown in [2] that in the PMS BDD generated by the backward PDO, the 0-edge always links two variables belonging to different components and the cancellation of common components can be done automatically during the generation of the BDD without any additional operation. So, the backward PDO is preferred in the PMS analysis.

After generating the PMS BDD, a recursive evaluation of the resulting PMS BDD yields the reliability/unreliability of the PMS. Special treatments are needed in the evaluation to deal with dependence among variables of the same component but different phases. The above BDD-based method [2] will be discussed in detail in Section 23.4.1. BDD-based methods for analyzing generalized PMS subject to imperfect fault coverage, modular imperfect coverage, and common-cause failures will also be discussed in Sections 23.4.2, 23.4.3, and 23.4.4, respectively.

23.3.2 State Space Based Approaches

Traditionally, if the failure criteria in any one phase of the PMS are dynamic, then a state space based approach must be used for the entire PMS. Section 23.3.2.1 presents Markov chains based methods for the reliability analysis of dynamic PMS. Section 23.3.2.2 presents Petri nets based methods for dynamic PMS analysis.

23.3.2.1 Markov Chains

Several different Markov chain based methods are available for the reliability analysis of PMS. The basic idea is to construct a single Markov chain to represent the failure behavior of the entire PMS or several Markov chains, each representing the failure behavior in each phase. These Markov models at once account for dependence among components within a phase as well as dependence across phases for a given component. Solving the Markov chain models yields the probability of the system being in each state. The system unreliability is obtained by summing all the failure state probabilities.

Specifically, Smotherman and Zemoudeh [5] (*SZ approach*) used a single non-homogeneous Markov chain model to perform the reliability analysis of a PMS. In their approach, the behavior of the system in each phase is represented using a different Markov chain, which may contain a different subset of states. The state transitions are described in terms of time dependent rates so as to include phase changes. Thus, state-dependent phase changes, random phase durations, time-varying failure and repair behavior can be easily modeled in the SZ approach.

Consider the example PMS in Figure 23.2. Assume the failure rates of the three components *A*, *B*, and *C* are *a*, *b*, and *c*, respectively. Figure 23.5 shows the Markov chain model of the entire PMS in the SZ approach. In the Markov chain representation, a 3-tuple represents a state indicating the status of the three components. A "1" represents the corresponding component is operational and a "0" represents the corresponding component has failed. For example, state (110) implies that *A* and *B* are operational and *C* has failed. A "F" represents a state in which the system has failed. A transition from one state to another state is associated with the failure rate of the failed component. The transitions $h_i(t)$ in Figure 23.5 represent the failure rates associated with the time at which phase changes occur.

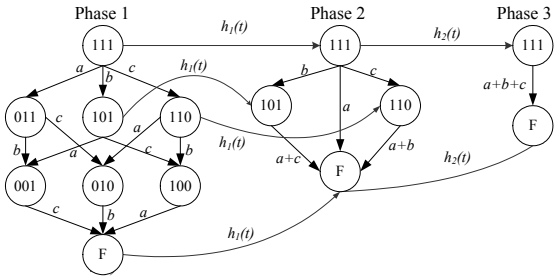

Figure 23.5. Markov chain model in the SZ approach

Since this model includes the configurations for all phases as well as the phase changes, it needs only be solved once. The major drawback of this approach, like the mini-component approach [4], is that a large overall model is needed. The size of the state space is as large as the sum of number of states in each of the individual phases. Since the state space associated with a Markov model of a system is exponential in the number of components in the worst case, the SZ method requires a large amount of storage and computational time to solve the model, thus limiting the type of system that can be analyzed.

Instead of generating and solving an overall Markov chain, Somani *et al*. [21] (*SRA approach*) suggested generating and solving separate Markov chains for individual phases of a PMS. The variation in failure criteria and system configuration from phase to phase is accommodated by providing an efficient mapping procedure at the transition time from one phase to another. While analyzing a phase, only states relevant to that phase are considered. Apparently, each individual Markov chain is much smaller than the overall Markov chain used in the SZ approach [5]. For the example three-phase PMS in Figure 23.2, Markov chains for the three phases are shown in Figure 23.5 (without considering the inter-phase mapping). In the SRA approach, three Markov chains with 8, 4, and 2 states, respectively, need to be solved. The reliability (or unreliability) of the system can be computed from the output of the last phase. While in the SZ approach, a single Markov chain with 12 states (after the three system failure states "F" are merged as one failure state) must be solved. Therefore, using the SRA approach, the computation time for large systems can be reduced significantly without compromising the accuracy of the results. Also, the SRA approach allows the phase duration to be modeled as fixed or random.

As another alternative to the reliability analysis of PMS using Markov models, Dugan [3] (*Dugan approach*) advocated generating a single Markov chain with state space equal to the union of the state spaces of the individual phases from the start. The transition rates are parameterized with phase numbers and the Markov chain is solved *n* times if the PMS has *n* phases. The final state probabilities of one phase become the initial state probabilities of the next phase. One potential source of the problem with the Dugan approach is that once a state is declared to be a system failure state in a phase, it cannot become an up state in a later phase. In practice, it is possible to have some states that are failure states in a phase but are up states in

a later phase. For example, if we swap the failure criteria of phase 1 and phase 3 in Figure 23.2, then the states of (011), (001), (010), and (100) are failure states in both phase 1 and phase 2, but are up states in phase 3. In the Dugan approach, all those states will be treated as forced failure states in phase 3. This problem would cause overestimated system unreliability.

23.3.2.2 Petri Nets

Mura and Bondavalli [9] (*MB approach*) proposed a hierarchical modeling and evaluation approach for analyzing PMS, where missions may evolve dynamically by selecting the next phase to perform according to the state of the system, and the duration of all phases are fixed and known in advance. Their approach combines the Markov analyses and Petri nets through a two-level modeling approach.

Specifically the upper level model in the MB approach is a single discrete-time Markov chain (DTMC), describing the overall behavior of the whole mission without any detail of the internal phase behavior. There are typically two absorbing states: loss of the entire mission and success of the mission. Each non-absorbing states in the DTMC represents a different phase in the mission. This allows simplifying the modeling of variety of mission scenarios by sequencing the phases in proper ways. Moreover, it allows probabilistic or dynamic choice of the mission phases according to the system states, which is not possible in other state space oriented approaches based only on Markov models. The lower level models are built using generalized stochastic Petri nets (GSPN). These lower level models are used to describe the system behavior inside each phase and they are built and solved separately. The separate modeling of each phase allows the reuse of the previously built models when the operation of a phase is repeated during the mission. The major advantages offered by the MB approach include the great flexibility by allowing the dynamic selection of mission phases and reusability of the defined phase models.

Later, Mura and Bondavalli [10] proposed a new methodology based on Markov regenerative stochastic Petri nets (MRSPN), which extended the MB approach by allowing random phase duration. This methodology is incorporated in the DEEM (dependability evaluation of multiple-phased systems) software package [8].

23.3.3 The Phase Modular Approach

Traditional approaches to PMS analysis are either combinatorial (Section 23.3.1) or state space based (Section 23.3.2). The combinatorial approaches are computationally efficient, but are applicable only when every phase of the PMS is static. Markov based approaches can capture the dynamic behavior such as functional dependencies, the sequence of failure events, and spares management. However, the major limitation with Markov methods is that if the failure criterion in only one phase is dynamic, then a Markov approach must be used for every phase. Due to the well-known state explosion problem of Markov approaches, it is often computationally intensive and even infeasible to solve the model.

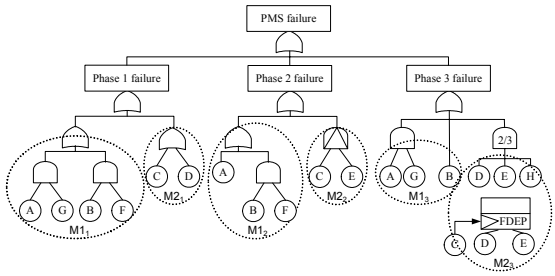

Figure 23.6. PMS fault free with defined modules

To take advantage of both types of solutions while addressing their limitations, a phase-modular fault tree approach employing both BDD and Markov-chain solution methods as appropriate was developed for the reliability analysis of PMS [13–16]. In applying this approach, first the modules of components that remain independent throughout the mission are identified, and then the reliability of each independent module in each phase is found using the appropriate solution technique. Finally, the modules are combined in a system-level BDD to find the system-level reliability. We illustrate the basic elements/steps of the phase-modular

approach using a simple example PMS, which has three phases and eight components (Figure 23.6) [22] as follows:

1) Represent each mission phase with a fault tree, and then link the phase fault trees with a system top event. For this example, the reliability of the PMS is the probability that the mission successfully achieves its objectives in all phases, the phase fault trees are linked using an OR gate to obtain the entire PMS fault tree.
2) Each phase fault tree is then divided into independent subtrees/modules. In Figure 23.6, Phase 1 fault tree has two main modules {A, G, B, F} and {C, D}. Phase 2 fault tree has two modules {A, B, F} and {C, E}. Phase 3 fault tree has three modules {A, G}, {B}, and {C, D, E, H}.
3) Characterize each phase module as static or dynamic. Static fault trees use only OR, AND, and *K*-out-of-*N* gates. Dynamic fault trees have at least one dynamic gate such as priority-AND gate, FDEP gate, or CSP/WSP/HSP gates. In Figure 23.6, both modules in Phase 1 fault tree are static; the module {A, B, F} in Phase 2 fault tree is static and the module {C, E} is dynamic; and Phase 3 fault tree has two static modules, {A, G} and {B}, and one dynamic module, {C, D, E, H}.
4) Identify each phase module as bottom-level (without child modules) or upper-level (with child modules). The module {C, D} in Phase 1 fault tree is a bottom-level module, and the module {A, G, B, F} is an upper-level module since it contains child modules {A, G} and {B, F} linked by an OR gate. The identification of child and parent modules is vital information used in solving for these modules' reliability.
5) Find the system-level independent modules. This identification is accomplished by finding the unions of components in all the phase modules that overlap in at least one component. The example PMS fault tree has two system-level independent modules, {A, B, F, G} and {C, D, E, H}.
6) Identify each system-level module as static or dynamic across the phases. Identification of a component as dynamic in at least one mission phase is sufficient for the identification of the corresponding system-level module as dynamic. In the example PMS, the system-level module {A, B, F, G} is static and {C, D, E, H} is dynamic.
7) Group the phase modules according to the corresponding system-level module. Components of {A, B, F, G} are labeled as $M1_i$ and components of {C, D, E, H} are labeled as $M2_i$, where i = mission phase (Figure 23.6). These are the modules that will be solved for the joint phase module probabilities.
8) Find the joint phase module probabilities for all system-level modules. The BDD method is used for modules that are static across all the phases, and the combined Markov chain method as presented in [13, 15] is used for modules identified as dynamic. Therefore, we can use the BDD method on the system-level module {A, B, F, G}; however, we must use the Markov chain method on the system-level module {C, D, E, H}.
9) Consider each module as a basic event of a static fault tree of the entire system and solve the corresponding fault tree using BDD to find the overall system reliability based on the reliability measures of the modules.

Each module's reliability is solved with a consideration of its own behavior in previous phases. For instance, for finding the reliability of $M1_2$, a combined BDD approach is used for $M1_1$ and $M1_2$; for finding the reliability of $M2_3$, the combined Markov chain approach is used for $M2_1$, $M2_2$, and $M2_3$. We then consider solving the static PMS fault tree with the basic events $M1_1$, $M2_1$, $M1_2$, $M2_2$, $M1_3$, and $M2_3$ using the combined BDD approach and the reliability measures for each individual phase module computed from previous steps. It is important to note that solving this simple PMS fault tree without using the modularization technique would involve solving a Markov chain with approximately 256 states, while the Markov chain involved in this example has a maximum of only 16 states. The phase-modular approach provides exact reliability measures for PMS with dynamic phases in an efficient manner. Readers may refer to [13, 15, 16] for more details about this approach.

23.4 BDD Based PMS Analysis

In this section, the binary decision diagrams (BDD) based approaches to the reliability analysis of PMS, PMS with imperfect fault coverage, and PMS with common-cause failures will be discussed. In the model for the BDD based PMS analysis, the following assumptions are made:

- Component failures are *s*-independent within each phase. Dependencies arise among different phases and different failure modes (when imperfect fault coverage is considered).
- Phase durations are deterministic.
- The system is not maintained during the mission; once a component transfers from the operation mode to a failure mode (either *covered* or *uncovered*), it will remain in that failure mode for the rest of the mission time.
- The system is coherent.

23.4.1 Traditional Phased-mission Systems

Reliability of a traditional phase-OR PMS is the probability that the mission successfully achieves the objective in all phases [17]. In the BDD-based method to the reliability analysis of PMS, three major steps are involved: 1) generating BDD for each phase fault tree, 2) combining single-phase BDD to obtain the entire PMS BDD, and 3) evaluating the PMS BDD to obtain the system reliability. Similar to the generation of BDD for non-PMS, the variable ordering can heavily affect the size of PMS BDD. Currently, there is no exact method of determining the best way of ordering basic events for a given fault tree structure. Fortunately, heuristics can usually be used to find a reasonable variable ordering.

In PMS, two kinds of variables need to be ordered: variables belonging to different components and variables that represent the same component in different phases. For the variables of different components, heuristics are typically used to find an adequate ordering. Several heuristics based on a depth-first search of the fault tree model can be found in [23]. For the variables of the same component in different phases, there are two ways to order them: *forward* and *backward*. In the forward method, the variable order is the same as the phase order, that is, $A_1 \prec A_2 \prec \ldots \prec A_m$, where A_i is the state variable of component A in phase i and m is the number of phases. In the backward method, the variable order is the reverse of the phase order, that is, $A_m \prec A_{m-1} \prec \ldots \prec A_1$.

After assigning each variable an index/order, for generating single-phase BDD in step 1), the traditional BDD operation rules based on Boolean algebra are applied. The reader may wish to review the traditional BDD operation rules in Chapter 38. In step 2), for combining single-phase BDD, dependence among variables of the same component but different phases is dealt with using the phase-dependent operation (PDO) [2]. According to the two ways to order variables of the same component, two types of PDO were developed: forward and backward. Assume component A is used in both phases i and j ($i < j$). A_i and A_j are state variables of A in phase i and phase j, respectively. A_i =0 or $\overline{A}_i$ =1 implies that A has failed in phase i. Using the *ite* format, the sub-BDD rooted at $\overline{A}_i$ and $\overline{A}_j$ respectively can be written as: $G = ite(\overline{A}_i, G_{\overline{A}_i=1}, G_{\overline{A}_i=0}) = ite(\overline{A}_i, G_1, G_2)$ and $H = ite(\overline{A}_j, H_{\overline{A}_j=1}, H_{\overline{A}_j=0}) = ite(\overline{A}_j, H_1, H_2)$. Let $\Diamond$ represent logic operation AND or OR, then we have:

$$G \Diamond H = ite(\overline{A}_i, G_1, G_2) \Diamond ite(\overline{A}_j, H_1, H_2) = \begin{cases} ite(\overline{A}_i, G_1 \Diamond H_1, G_2 \Diamond H) & \text{forward PDO} \\ ite(\overline{A}_j, G \Diamond H_1, G_2 \Diamond H_2) & \text{backward PDO} \end{cases} \quad (23.3)$$

The reader may refer to [2] for the proof of (23.3) using the phase algebra rules in Table 23.1. As discussed in Section 23.3.1.3, the backward PDO is preferred in the PMS analysis because in the PMS BDD generated by the backward PDO, the 0-edge always links two variables of different components and thus less dependence needs to be handled during the model evaluation.

Note that PDO of [2] is only applicable to non-repairable PMS. In addition, they can perform the task of combining BDD of individual phases into the overall PMS BDD correctly only given that the ordering strategies abide the following two rules:

- Orderings adopted in the generation of each single phase BDD are consistent or the same for all the phases.

- Orderings of variables that belong to the same component but to different phases stay together. In practice, this can be achieved by replacing each component indicator variable with a set of variables that represent this component in each phase after ordering components using heuristics.

These two rules are very stringent from the implementation point of view. Xing and Dugan relaxed the constraints by adding a removal procedure in the PMS BDD generation to allow arbitrary ordering strategies. For details, see [24].

After PMS BDD is generated, the final step to accomplish the reliability analysis is to evaluate the resulting PMS BDD. Note that 1-edges in the PMS BDD may link two variables of the same component but different phases. Dependence between these variables must be addressed during the evaluation. As a result, two different evaluation methods are needed for the PMS BDD generation. Specifically, consider the sub-BDD in Figure 23.7: The *ite* format is: $G = ite(x, G_1, G_2) = x \bullet G_1 + \bar{x} \bullet G_2$ $G_1 = ite(y, H_1, H_2) = y \bullet H_1 + \bar{y} \bullet H_2$. Let $p(x)$ be the failure probability of component represented by node x and P(G) be the unreliability with respect to the current sub-BDD rooted at node x. The recursive evaluation algorithm of PMS BDD is as follows:

- For 1-edge or 0-edge linking variables of different components, the evaluation method is the same as the ordinary BDD. For example, if x, y in Figure 23.7 belong to different components, the evaluation method is:

$$P(G)=P(G_1)+[1-p(x)]*[P(G_2)-P(G_1)] \quad (23.4)$$

- For 1-edge linking variables of the same component, for example, if x, y in Figure 23.7 belong to the same component, the evaluation method is:

$$P(G)= P(G_1)+[1-p(x)]* [P(G_2)-P(H_2)] \quad (23.5)$$

The phase algebra rules (Table 23.1) are applied to deal with the dependence between x and y in the derivation of (23.5). Refer to [2] for details of the derivation. Exit conditions of the recursive algorithm are: if G = 0, *i.e.*, the system is operational, then the unreliability P(G) = 0; if G = 1, *i.e.*, the system has failed, then P(G) = 1.

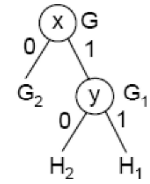

Figure 23.7. A PMS BDD branch

23.4.2 PMS with Imperfect Coverage

PMS, especially those devoted to safety-critical applications, such as aerospace and nuclear power, are typically designed with sufficient redundancies and automatic recovery mechanisms to be tolerant of faults or errors that may occur. However, the recovery mechanisms can fail, such that the system cannot adequately detect, locate, and recover from a fault occurring in the system. This uncovered fault can propagate through the system and may lead to an overall system failure, despite the presence of fault-tolerant mechanisms. As discussed in Chapter 22, the imperfect coverage (IPC) [25, 26] introduces multiple failure modes (*covered failure* and *uncovered failure*) that must be considered for accurate reliability analysis of fault-tolerant PMS. A covered component failure is local to the affected component; it may or may not lead to the system failure depending on the system configuration, failure criteria, and remaining redundancy. An uncovered component failure is globally malicious, and causes the system to crash.

This section presents a BDD-based approach called GPMS-CPR [1] for the reliability analysis of PMS with IPC, while considering the CPR and multiple performance levels for GPMS. The IPC behavior will be modeled using the fault/error handling model (FEHM) described in Figure 22.1. However, the near-coincident failure exit is not considered here. The probabilities of the three mutually exclusive exits R, C, and S in the FEHM are denoted as: r, c, and s, where $r + c + s = 1$.

The basic idea of the GPMS-CPR is to separate all the component uncovered failures from the combinatorics of the solution based on the simple and efficient algorithm (SEA) [1, 27] (Chapter 22) and the mini-component technique (Section 23.3.1.1). SEA represents a separable scheme for

incorporating IPC in the reliability analysis of single-phase systems. It cannot directly apply to PMS with *s*-dependence across phases. The mini-component concept can deal with the across-phase dependence. The basics of GPMS-CPR are to convert the PMS to an equivalent mini-component system so as to remove *s*-dependence, and then apply the SEA approach to address IPC. Figure 23.8 illustrates the GPMS-CPR approach.

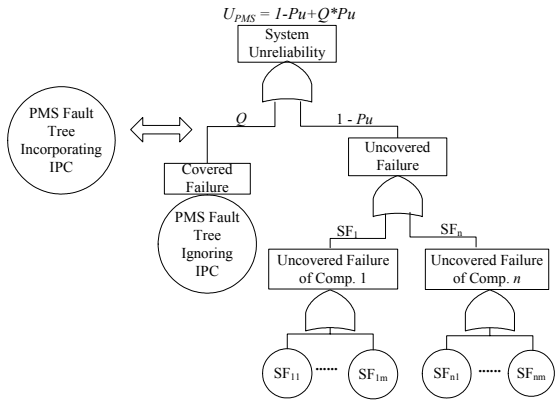

Figure 23.8. The separable GPMS-CPR approach

In Figure 23.8, SF_A denotes an event that component A fails uncovered. SF_A for different components are *s*-independent. SF_{a_i} represents an event that mini-component a_i fails uncovered. Different SF_{a_i} (i = 1,…,m) for the same component are not independent and the dependence must be addressed in the solution. The probability of no mini-component experiencing an uncovered failure (P_u) and the unreliability of the complementary perfect-coverage system (Q) are integrated using the total probability theorem:

$$U_{PMS} = 1 - P_u + Q * P_u \tag{23.6}$$

The derivation of (23.6) is similar to the derivation of the SEA in Chapter 22. Also, refer to [1] for details. The formulation of P_u in (23.6) is:

$$\begin{aligned} P_u &= \Pr(\overline{SF}_1 \cap \overline{SF}_2 \cap \ldots \cap \overline{SF}_n) \\ &= \prod_{A=1}^{n}(1 - \Pr(SF_A)) = \prod_{A=1}^{n}(1 - u[A]) \\ &= \prod_{A=1}^{n}(1 - u[A_m]) \end{aligned} \tag{23.7}$$

where n is the total number of components in the PMS, $u[A]$ is the probability that component A fails uncovered during the whole mission, that is, $u[A_m]$ is the probability that A has failed uncovered before the end of the last phase m. Let NF_{a_i}, CF_{a_i}, and SF_{a_i} denote events that A in phase i, namely, mini-component a_i does not fail, fails covered, and fails uncovered, respectively. The three events are mutually exclusive and complete. Define $n[a_i]$ = $\Pr(NF_{a_i})$, $c[a_i]$ = $\Pr(CF_{a_i})$, and $u[a_i]$ = $\Pr(SF_{a_i})$. According to the FEHM in Figure 22.1, these three probabilities can be calculated as:

$$\begin{aligned} n[a_i] &= 1 - q_{a_i}(t) + r_{a_i} \bullet q_{a_i}(t) \\ c[a_i] &= c_{a_i} \bullet q_{a_i}(t) \\ u[a_i] &= s_{a_i} \bullet q_{a_i}(t) \end{aligned} \tag{23.8}$$

Based on the relationship between a component and its mini-components depicted in Section 23.3.1.1 and on the fact that a component can fail uncovered in one phase only if it has survived all the previous phases, $u[A_j]$ can be calculated as:

$$\begin{aligned} u[A_j] &= \Pr(SF_{A_j}) \\ &= \Pr(A \text{ fails uncovered before the end of phase j}) \\ &= \Pr(\text{any mini - component } a_{i\in\{1\ldots j\}} \text{ fails uncovered}) \\ &= \Pr(SF_{a_1} \cup (NF_{a_1} \cap SF_{a_2}) \cup \ldots \\ &\qquad \cup (NF_{a_1} \cap \ldots \cap NF_{a_{j-1}} \cap SF_{a_j})) \\ &= u[a_1] + n[a_1] \bullet u[a_2] + \ldots \\ &\qquad + n[a_1] \bullet n[a_2] \bullet \ldots \bullet n[a_{j-1}] \bullet u[a_j] \\ &= u[a_1] + \sum_{i=2}^{j}(\prod_{k=1}^{i-1} n[a_k]) \bullet u[a_i] \end{aligned} \tag{23.9}$$

where j = 1, $u[A_1] = u[a_1]$. Similarly, the covered failure probability $c[A_j]$ and non-failure probability $n[A_j]$ can be calculated as in (23.10) and (23.11), respectively, when j = 1, $c[A_1 = c[a_1]$, $n[A_1] = n[a_1]$.

Next, consider the evaluation of perfect-coverage unreliability Q in (23.6). According to the SEA method, Q should be evaluated given that no component experiences an uncovered failure.

$$
\begin{aligned}
&c[A_j] = \Pr(CF_{A_j}) \\
&= \Pr(A \text{ fails covered before the end of phase j}) \\
&= \Pr(\text{any mini - component } a_{i\in\{1...j\}} \text{ fails covered}) \\
&= \Pr(CF_{a_1} \cup (NF_{a_1} \cap CF_{a_2}) \cup ... \\
&\qquad \cup (NF_{a_1} \cap ... \cap NF_{a_{j-1}} \cap CF_{a_j})) \\
&= c[a_1] + n[a_1] \bullet c[a_2] + ... \\
&\qquad + n[a_1] \bullet n[a_2] \bullet ... \bullet n[a_{j-1}] \bullet c[a_j] \\
&= c[a_1] + \sum_{i=2}^{j} (\prod_{k=1}^{i-1} n[a_k]) \bullet c[a_i]
\end{aligned}
\tag{23.10}
$$

$$
\begin{aligned}
&n[A_j] = \Pr(NF_{A_j}) \\
&= \Pr(A \text{ has not failed before the end of phase j}) \\
&= \Pr(\text{all mini - components } a_{i\in\{1...j\}} \text{ are not failed}) \\
&= \Pr(NF_{a_1} \cap ... \cap NF_{a_{j-1}} \cap NF_{a_j})) \\
&= n[a_1] \bullet n[a_2] \bullet ... \bullet n[a_{j-1}] \bullet n[a_j] = \prod_{i=1}^{j} n[a_i]
\end{aligned}
\tag{23.11}
$$

Therefore, before evaluating Q, the failure function of each component A in each phase j needs to be modified as a conditional failure probability, denoted by $F_{A_j}(t)$, conditioned on there being no uncovered failure during the whole mission, that is,

$$
F_{A_j}(t) = \Pr(CF_{A_j} \mid \overline{SF}_A) = \frac{c[A_j]}{1 - u[A]} = \frac{c[A_j]}{1 - u[A_m]} \tag{23.12}
$$

Using these modified component failure functions, Q can be evaluated using the efficient PMS BDD method that does not consider IPC [2] (Section 23.4.1). In summary, GPMS-CPR can be described as the following five-step algorithm:

1) Compute the modified failure probability for each component at the end of each phase using (23.12).
2) Order components using backward PDO and heuristics. Generate BDD for each phase.
3) According to the specified CPR and mission performance criteria, combine the single-phase BDD using phase algebra and backward PDO to obtain the final PMS BDD.
4) Evaluate Q recursively from the final PMS BDD using the algorithm of Section 23.4.1 and using $F_{A_j}(t)$ generated in step (1) as the component failure probability.
5) Evaluate the imperfect coverage probability (1 - P_u). Then integrate it with Q using (23.6) to obtain final GPMS unreliability/performance.

Due to the nature of BDD and the beauty of the SEA method, the GPMS-CPR method has low computational complexity and is easy to implement, as compared to the other potential methods such as Markov chain based methods. The Markov methods can address IPC by expanding the state space and number of transitions, worsening the state explosion problem [28]. In addition, the GPMS-CPR is capable of evaluating a wider range of more practical systems with less restrictive mission requirements, while offering more human-friendly performance indices such as multi-level grading as compared to the previous PMS methods. Next, we consider the analysis of a data gathering PMS using GPMS-CPR.

23.4.2.1 The Data Gathering System and Analysis

A space data gathering system [1], which is loosely based on a practical system in NASA, consists of four types of components that are used in different configurations over three consecutive phases (Figure 23.9):

- A_a, A_b: needed for all phases; one of them must be functional during all the three phases.
- B_a: only needed for phases 1 and 2; it must be functional during these two phases.
- C_a, C_b: work during phases 1 and 3; both must be functional during phase 1, at least one of them must be functional during phase 3.
- D_a, D_b, D_c: work during phases 2 and 3; all of them must be functional during phase 2, at least two of them must be functional during phase 3.

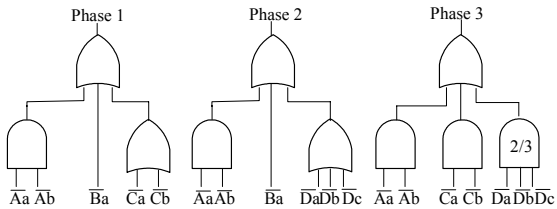

Figure 23.9. Data gathering system configuration

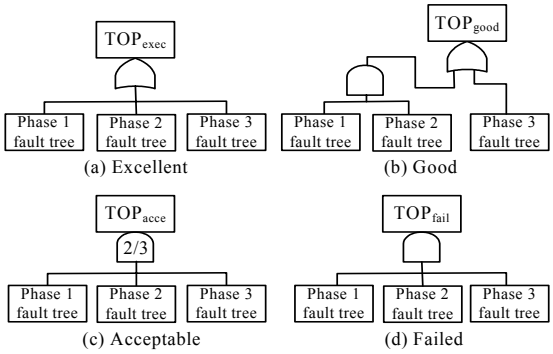

Figure 23.10. Four performance levels in the fault tree

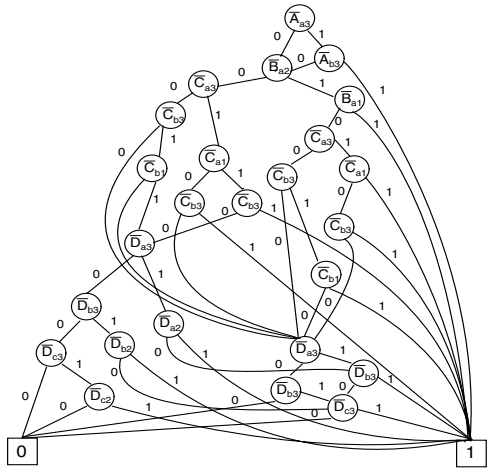

Figure 23.11. PMS BDD for the *good* level

According to the combination of data quality in the three phases, a four-performance-level result for the process can be defined as follows (Figure 23.10):

- *Excellent* level: data collection is successful in all the three phases.
- *Good* level: data collection is successful in phase 1 or 2 and in phase 3.
- *Acceptable* level: data collection is successful in only one of the three phases.
- *Failed* level: data collection fails in all the three phases.

Let P_{level} represent the multi-level reliability of the system, then we have:

$$P_{excellent} = 1 - \Pr(\text{TOP}_{\text{exce}}),$$
$$P_{good} = 1 - \Pr(\text{TOP}_{\text{good}}),$$
$$P_{acceptable} = \Pr(\text{TOP}_{\text{acce}}) - \Pr(\text{TOP}_{\text{fail}}),$$
$$P_{failed} = \Pr(\text{TOP}_{\text{fail}}). \quad (23.13)$$

For illustration purpose, the final PMS BDD for the *good* level is shown in Figure 23.11 [1]. The ordering of $A_a \prec A_b \prec B_a \prec C_a \prec C_b \prec D_a \prec D_b \prec D_c$ for variables of different components and backward ordering for variables of the same component and are used in the BDD generation.

By recursively traversing the PMS BDD of each performance level, the parameter Q in (23.6) is calculated. The U_{PMS}(level) is then found using (23.6). Lastly, the multi-level reliability P_{level} for each level is given as a simple and linear function of U_{PMS}(level) according to the corresponding grade-level performance criteria described in (23.13). Table 23.2 gives the input parameters (including phase duration, failure probabilities or rates, and coverage factors r, c, s) used in the analysis. Table 23.3 presents both the intermediate and final results for the analysis of the data gathering system.

Table 23.2. Input parameters (λ and λ_w are in 10^{-6}/hr; coverage factor r is 0 for all components in all phases)

Basic events	Phase 1 (33 hours)		Phase 2 (100 hours)		Phase 3 (67 hours)	
	p or λ	coverage c	p or λ	coverage c	p or λ	coverage c
A_a, A_b	0.0001	0.99	0.0001	0.99	0.0001	0.99
B_a	λ =1.5	0.97	λ =1.5	0.97	0.0001	0.97
C_a, C_b	0.0025	0.97	λ =1	0.99	λ_{Weibull} =1.6 α_{Weibull} =2	1
D_a, D_b, D_c	0.001	0.99	0.002	0.99	0.0001	0.97

Table 23.3. Analysis results of the data gathering system using GPMS-CPR

Performance level	Excellent	Good	Acceptable	Failed
P_u	0.999734	0.999734	0.999734	0.999734
Q	1.387e-2	1.261e-4	1.2602e-4	2.049e-7
$U_{PMS} = 1 - P_u + Q * P_u$.	0.0141326	3.9193e-4	3.9185e-4	2.6607e-4
Multi-level reliability: P_{level}	0.9858674	0.9996081	1.2578e-4	2.6607e-4

23.4.3 PMS with Modular Imperfect Coverage

In the traditional IPC, an uncovered component failure kills the entire mission. In the GPMS with CPR, however, the extent of the damage from an uncovered component fault can be just a phase loss, instead of the entire mission loss. Xing and Dugan proposed a generalized coverage model, called the modular imperfect coverage model (MIPCM) [29, 30], to exactly describe the behavior of a GPMS with CPR in the presence of a fault. As shown in Figure 23.12, MIPCM is a single entry, multiple exit black box. The model is activated when a fault occurs, and is exited when the fault is successfully handled or when the fault causes either a phase failure or the entire mission failure. The transient restoration exit R and permanent coverage exit C have the same meaning as in the traditional coverage model FEHM.

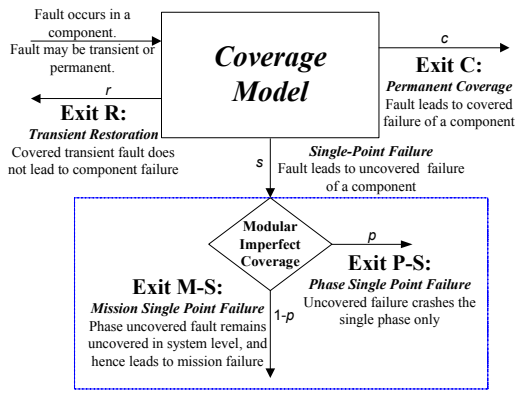

Figure 23.12. General structure of MIPCM

The following details the single-point failure exits. When a single fault (by itself) brings down a phase to which the fault belongs, single-point failure (or uncovered failure) is said to occur. Further, if such phase uncovered fault is covered at the higher system level, the phase single-point failure exit (labeled P-S) is reached, then a phase uncovered component failure occurs. If the phase uncovered fault remains uncovered at the system level, and hence leads to the failure of the entire mission, then the mission single-point failure exit (labeled M-S) is reached, and a mission uncovered failure is said to occur.

The four exits R, C, P-S, and M-S are mutually exclusive and complete. Define [*r, c, s*] to be the probability of taking the [transient restoration, permanent coverage, single-point failure] exit, given that a fault occurs, as in IPCM, and $r + c + s = 1$. Define p as a conditional probability that an uncovered fault fails a single phase, not the mission conditioned on an uncovered fault occurring in that phase. Then $s*p$ will be the probability of taking the P-S exit, and $s*(1-p)$ will be the probability of taking the M-S exit.

As compared with reliability analysis of PMS with traditional IPC, the analysis of GPMS with modular imperfect coverage (MIPC) is a more challenging task because the MIPC introduces more failure modes (covered failure, phase uncovered failure, and mission uncovered failure) and thus more dependencies into the system analysis. Building upon the above MIPCM, Xing and Dugan proposed two types of combinatorial methods for the reliability analysis of GPMS subject to MIPC: multi-state binary decision diagrams (MBDD) based method and ternary decision diagrams (TDD) based method. For each method, new phase algebra rules, new phase dependent operations for combining single-phase models into the overall system model, and new model evaluation algorithms were developed. The reader may refer to [29, 30] for the details of the MBDD-based method and the TDD-based method, respectively.

23.4.4 PMS with Common-cause Failures

Components in PMS can be subject to common-cause failures (CCF) during any phase of the mission. CCF are simultaneous component failures within a system that are a direct result of a common cause (CC) [31], such as extreme environmental conditions, design weaknesses, or human errors. It has been shown in many studies that the presence of CCF tends to increase a system's joint failure probabilities and thus contributes significantly to the overall unreliability of the system [32]. Therefore, it is crucial that CCF be modeled and analyzed appropriately. Considerable research efforts have been expended on the study of CCF for the system reliability analysis; refer to Chapter 38 for a discussion of various approaches, their contributions, and their limitations concerning the analysis of non-PMS. Actually, many of these limitations can also be found in the CCF models developed for PMS [33].

This section will present a separable solution that can address those limitations by allowing multiple CC to affect different subsets of system components and to occur *s*-dependently [34]. This separable approach is based on the efficient decomposition and aggregation (EDA) approach for the CCF analysis of single-phased systems (Chapter 38) and is easy to integrate into the existing PMS analysis methods.

Assume L_i elementary CC exists in each phase i of the PMS and they are denoted as: $CC_{11},.....,CC_{1L_1}$ for phase 1, $CC_{21},.....,CC_{2L_2}$ for phase 2, …, $CC_{m1},.....,CC_{mL_m}$ for the last phase m. Thus, total number of CC in PMS is: $L=\sum_{i=1}^{m}L_i$. According to the EDA approach, a common-cause event (CCE) space is built over a set of collectively exhaustive and mutually exclusive CCE that can occur in the PMS: $\Omega_{CCE}=\{CCE_1,CCE_2,...,CCE_{2^L}\}$. Each CCE in the set is a distinct and disjoint combination of elementary CC in the PMS:

$$CCE_1=\overline{CC_{11}}\cap...\cap\overline{CC_{1L_1}}\cap...\cap\overline{CC_{m1}}\cap...\cap\overline{CC_{mL_m}},$$
$$CCE_2=CC_{11}\cap...\cap\overline{CC_{1L_1}}\cap...\cap\overline{CC_{m1}}\cap...\cap\overline{CC_{mL_m}},$$
$$\cdots\cdots,$$
$$CCE_{2^L}=CC_{11}\cap...\cap CC_{1L_1}\cap...\cap CC_{m1}\cap...\cap CC_{mL_m}.$$

If $\Pr(CCE_j)$ denotes the occurrence probability of CCE_j, then $\sum_{j=1}^{2^L}\Pr(CCE_j)=1$ and $\Pr(CCE_i\cap CCE_j)=P(\phi)=0$ for any $i\neq j$.

As in the EDA approach, to find S_{CCE_j}, a set of components affected by event CCE_i is necessary. Define a common-cause group (CCG) as a set of components that are caused to fail due to the same CC. For non-PMS, S_{CCE_j} is simply the union of CCG whose corresponding CC occur. For example, assume $CCE_i=\overline{CC_1}\cap\overline{CC_2}\cap CC_3$ is a CCE in a non-PMS with three CC, S_{CCE_j} is simply equal to CCG_3 since CC_3 is the only active elementary CC. For a non-maintainable PMS, a component will remain failed in all later phases once it has failed in a phase. Therefore, S_{CCE_j} must be expanded to incorporate the affected components in all subsequent phases. The generation of S_{CCE_j} for PMS will be illustrated later on.

According to the total probability theorem, the unreliability of a PMS with CCF is calculated as:

$$U_{PMS}=\sum_{j=1}^{2^L}[\Pr(PMS\ fails\mid CCE_j)\Pr(CCE_j)] \quad (23.14)$$

$\Pr(PMS\ fails|CCE_j)$ in (23.14) is a conditional probability that the PMS fails conditioned on the occurrence of CCE_j. It is a reduced reliability problem, in which all components in S_{CCE_j} do not appear. Specifically, in the system fault tree model, each basic event appearing in S_{CCE_j} is replaced by a constant logic value "1" (true). After the replacement, a Boolean reduction can be applied to the PMS fault tree to generate a fault tree in which all components in S_{CCE_j} do not appear. Most importantly, the evaluation of the reduced problems can proceed without consideration of CCF. Thereby, the overall solution complexity is reduced.

Consider the *excellent* case of the data gathering PMS in Figure 23.9 with the following CCF scenario. The system is subject to CCF from hurricanes (denoted by CC_{11}) during phase 1, from lightning strikes (CC_{21}) during phase 2, and from floods (CC_{31}) during phase 3. A hurricane of sufficient intensity in phase 1 would cause A_a and C_a to fail, *i.e.*, $CCG_{11}=\{\overline{A_{a1}},\overline{C_{a1}}\}$, where A_{a1} is the

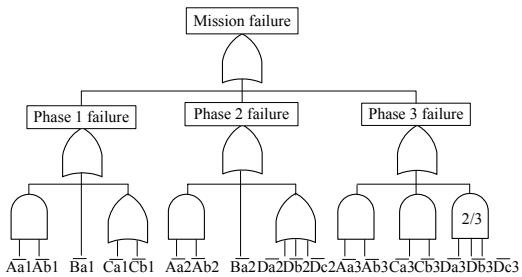
state indicator variable of component A_a in phase 1, and $\overline{A_{a1}}$ denotes the failure of A_a in phase 1. Serious lightning strikes in phase 2 would cause A_a, A_b, and B_a to fail, *i.e.*, $CCG_{21} = \{\overline{A_{a2}}, \overline{A_{b2}}, \overline{B_{a2}}\}$. Serious flooding in phase 3 would cause C_a and D_a to fail, *i.e.*, $CCG_{31} = \{\overline{C_{a3}}, \overline{D_{a3}}\}$. The probability of a hurricane occurring in phase 1 is $P_{CC_{11}} = 0.02$. The probability of a lightning strike occurring in phase 2 is $P_{CC_{21}} = 0.03$. Floods often occur in conjunction with hurricanes, and the *s*-dependence between the two CC can be defined by a set of conditional probabilities: the probability that floods occur in phase 3 conditioned on the occurrence of hurricanes in phase 1 is: $P_{CC_{31}|CC_{11}} = 0.6$. Similarly, $P_{CC_{31}|\overline{CC_{11}}} = 0.03$, $P_{\overline{CC_{31}}|CC_{11}} = 1 - P_{CC_{31}|CC_{11}}$, $P_{\overline{CC_{31}}|\overline{CC_{11}}} = 1 - P_{CC_{31}|\overline{CC_{11}}}$. These probabilities can typically be derived from available weather information.

Because there are three common causes in the example PMS, the CCE space is composed of $2^3 = 8$ CCE, as defined in the first column of Table 23.4. The second and third columns of the table show the set of components affected by each CCE (S_{CCE_j}) and occurrence probability calculation for each CCE based on statistical relation among those three CC, respectively.

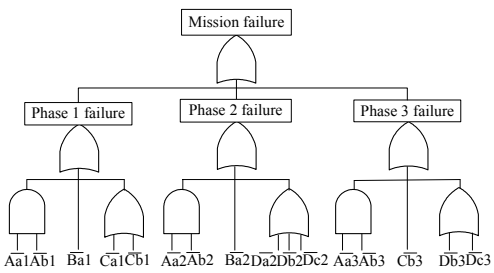
Table 23.4. CCE, affected components, and probabilities

CCE_i	S_{CCE_j}	$\Pr(CCE_i)$
$1: \overline{CC_{11}} \cap \overline{CC_{21}} \cap \overline{CC_{31}}$	ϕ	$P_{\overline{CC_{21}}} P_{\overline{CC_{11}}} P_{\overline{CC_{31}}\|\overline{CC_{11}}} = 0.9221$
$2: \overline{CC_{11}} \cap \overline{CC_{21}} \cap CC_{31}$	$\{\overline{C_{a3}}, \overline{D_{a3}}\}$	$P_{\overline{CC_{21}}} P_{\overline{CC_{11}}} P_{CC_{31}\|\overline{CC_{11}}} = 0.0285$
$3: \overline{CC_{11}} \cap CC_{21} \cap \overline{CC_{31}}$	$\{\overline{A_{a(2-3)}}, \overline{A_{b(2-3)}}, \overline{B_{a(2-3)}}\}$	$P_{CC_{21}} P_{\overline{CC_{11}}} P_{\overline{CC_{31}}\|\overline{CC_{11}}} = 0.0285$
$4: \overline{CC_{11}} \cap CC_{21} \cap CC_{31}$	$\{\overline{A_{a(2-3)}}, \overline{A_{b(2-3)}}, \overline{B_{a(2-3)}}, \overline{C_{a3}}, \overline{D_{a3}}\}$	$P_{CC_{21}} P_{\overline{CC_{11}}} P_{CC_{31}\|\overline{CC_{11}}} = 8.82e-4$
$5: CC_{11} \cap \overline{CC_{21}} \cap \overline{CC_{31}}$	$\{\overline{A_{a(1-3)}}, \overline{C_{a(1-3)}}\}$	$P_{\overline{CC_{21}}} P_{CC_{11}} P_{\overline{CC_{31}}\|CC_{11}} = 0.0078$
$6: CC_{11} \cap \overline{CC_{21}} \cap CC_{31}$	$\{\overline{A_{a(1-3)}}, \overline{C_{a(1-3)}}, \overline{D_{a3}}\}$	$P_{\overline{CC_{21}}} P_{CC_{11}} P_{CC_{31}\|CC_{11}} = 0.0116$
$7: CC_{11} \cap CC_{21} \cap \overline{CC_{31}}$	$\{\overline{A_{a(1-3)}}, \overline{C_{a(1-3)}}, \overline{A_{b(2-3)}}, \overline{B_{a(2-3)}}\}$	$P_{CC_{21}} P_{CC_{11}} P_{\overline{CC_{31}}\|CC_{11}} = 2.4e-4$
$8: CC_{11} \cap CC_{21} \cap CC_{31}$	$\{\overline{A_{a(1-3)}}, \overline{C_{a(1-3)}}, \overline{A_{b(2-3)}}, \overline{B_{a(2-3)}}, \overline{D_{a3}}\}$	$P_{CC_{21}} P_{CC_{11}} P_{CC_{31}\|CC_{11}} = 3.6e-4$

According to (23.14), the problem of evaluating the reliability of the data gathering system with CCF can be subdivided into eight reduced problems that need not consider CCF. Based on system configuration in Figure 23.9 and failure criteria for the *excellence* case described in Figure 23.10 (a), it is easy to derive that: Pr(PMS fails|CCE_j) = *1* for *j* = *3*...*8*. We apply the PMS BDD approach of [2] to evaluate the remaining two reduced problems, Pr(PMS fails|CCE_1) and Pr(PMS fails|CCE_2). Figure 23.13 (a) and (b) show the reduced fault tree models after applying the reduction procedure for removing components of S_{CCE_1} and S_{CCE_2}, respectively. Note that because no component is affected by CCE_1, the reduced fault tree in Figure 23.13(a) is actually the same as the original PMS fault tree (fault trees of the three phases in Figure 23.9 connected via an OR gate) but without considering CCF. Figures 23.14(a) and (b) show the PMS BDD generated from the fault tree models in Figures 23.13(a) and(b), respectively. Finally, results of the eight reduced problems are aggregated using (23.14) to obtain

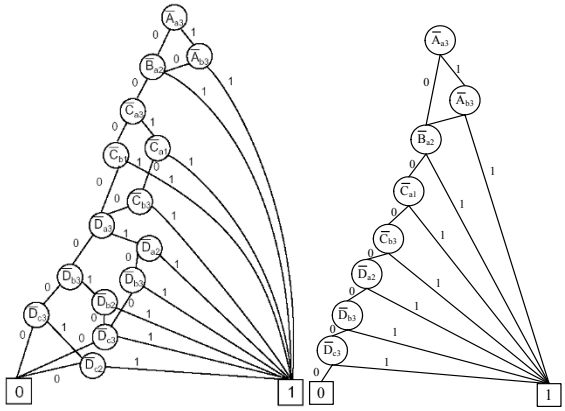


(a) PMS|CCE$_1$



(b) PMS|CCE$_2$

Figure 23.13. Reduced PMS fault trees



(a) PMS BDD|CCE$_1$ (b) PMS BDD|CCE$_2$

Figure 23.14. PMD BDD for reduced fault trees

the unreliability of the data gathering system with the consideration of CCF.

Figure 23.15 shows a conceptual overview of the separable approach for analyzing PMS with CCF. In summary, the methodology is to decompose an original PMS reliability problem with CCF into a number of reduced reliability problems based on the total probability theorem. The set of reduced problems does not have to consider dependence introduced by CCF, and thus can be solved using the efficient PMS BDD method [2]. Finally, the results of all reduced reliability problems are aggregated to obtain the entire PMS reliability considering CCF.

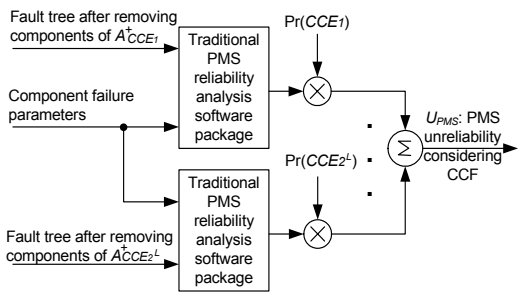


Figure 23.15. A conceptual overview

23.4.4.1 A Case Study: The Mars Orbiter System

To demonstrate this method, we considered a Mars orbiter mission system (originally described in [35]). As shown in the high-level dynamic fault tree (DFT) model of the system (Figure 23.16), this mission system involves launch, cruise, Mars orbit insertion (MOI), commissioning, and orbit phases. The triangles in the DFT are transfer gates to the DFT model for the Subsystem F.

Each mission phase is characterized by at least one major event in which the mission failure can occur. Examples of failure events for this system include the launch event during the launch phase, the deployment of the solar arrays (SA) and high-gain antennas (HGA), and the configuration of the heaters during the cruise phase, the propulsive capture into Mars' orbit during the MOI phase, and the release of an orbiting sample (OS) and the inclusion of a rendezvous and navigation (RAN) platform on the orbiter that might induce additional failure modes during orbit [35]. Table 23.5 gives occurrence probabilities of these failure events.

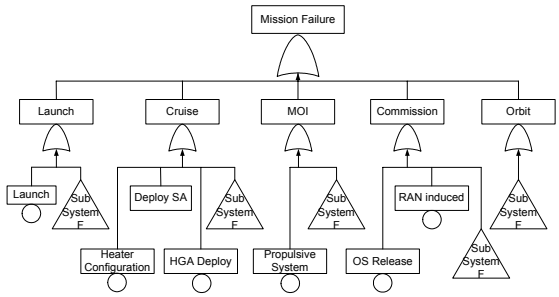

Figure 23.16. High-level DFT model

Table 23.5. Probabilities of failure events

Failure events	Probability
Launch	0.02
SA deployment	0.02
Heater configuration	0.02
HGA deployment	0.02
Propulsive capture	0.03
Orbiting sample release	0.02
RAN-induced failure	0.02

Subsystem F in Figure 23.16 consists of telecommunication, power, propulsion, the command and data handling system (CDS), the attitude control system (ACS), and thermal subsystems, which are connected through an OR gate (Figure 23.17).

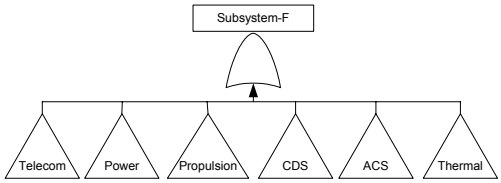

Figure 23.17. Fault tree of subsystem F

As described in [35], these subsystems can be subject to CCF due to two independent CC: CC_1 is a micrometeoroid attack that results in the failure of the entire system, and CC_2 is a solar flare that fails the subsystem's electronics, most notably the CDS in all pre-MOI phases. The orbiter will not be affected by solar flares after the MOI phase due to the increased distance of the orbiter from the sun. Assume that the occurrence probabilities of CC_1 and CC_2 are 0.01 and 0.02, respectively. Table 23.6 specifies the four CCE generated from the two CC, the set of components affected by CCE_i, and occurrence probability of each CCE_i, $\Pr(CCE_i)$.

A review of Table 23.6 implies that the CDS subsystem is the only subsystem affected by both CC_1 and CC_2 and therefore its failure will receive further analysis in this example. Figure 23.18 shows the fault tree model of the CDS subsystem.

Table 23.6. CCE, affected components, and probabilities

CCE_i	S_{CCE_j}	$\Pr(CCE_i)$
$CCE_1 = \overline{CC_1} \cap \overline{CC_2}$	ϕ	9.702e-1
$CCE_2 = CC_1 \cap \overline{CC_2}$	all spacecraft elements	9.980e-3
$CCE_3 = \overline{CC_1} \cap CC_2$	CDS	1.980e-2
$CCE_4 = CC_1 \cap CC_2$	all spacecraft elements	2.000e-4

Table 23.7 gives the failure rates for the CDS components and for the rest of the components (subsystems) of the subsystem F in each phase, as well as the phase duration. According to (23.14), the problem of evaluating the unreliability of the orbiter system with CCF is decomposed into four reduced problems that need not consider CCF. Based on the fault trees in Figures 23.16 through 23.18, we can derive that $\Pr(\text{orbiter fails}| CCE_i) = 1$ for $i = 2$, 3, and 4. Solving the phase-mission fault tree for a mission duration of 97368 hours using the PMS BDD method yields 0.14661 for $\Pr(\text{Orbiter fails}|CCE_1)$. Finally, according to (23.14), the unreliability of the proposed Mar's orbiter system with CCF is 0.172. This result is obtained by aggregating the results of $\Pr(\text{Orbiter fails} | CCE_i)$ and $\Pr(CCE_i)$ given in Table 23.6.

Table 23.7. Failure rates (10^{-7}/hr) of components in CDS and subsystem F

CDS components/ subsystem in F	Launch (504 hrs)	Cruise (5040 hrs)	MOI (144 hrs)	Comm. (4080 hrs)	Orbit (87600 hrs)
EPS-interface	0.05	0.04	0.05	0.05	0.04
Mass memory	0.02	0.01	0.02	0.02	0.01
AC-DC converter	0.02	0.01	0.02	0.02	0.01
CMIC (A and B)	0.03	0.02	0.03	0.03	0.02
FlightProc (A and B)	0.04	0.03	0.04	0.04	0.03
Bus (A and B)	0.02	0.01	0.02	0.02	0.01

23.5 Conclusions

This chapter presented three classes of analytical approaches to the reliability analysis of PMS, which subject to multiple, consecutive, and non-overlapping phases of operations. The combinatorial approaches are computationally efficient but are limited to the analysis of static PMS only. The state space oriented approaches are powerful in modeling the various dynamic behaviors and dependencies, but are limited to the analysis of small-scale systems due to the state explosion problem. A better solution is the phase modular approach that combines the advantages of both combinatorial analyses and state space oriented analyses. This chapter also discussed the efficient BDD based methods to the analysis of PMS with imperfect coverage or common-cause failures in detail. Since they are combinatorial, the BDD-based methods are applicable to static PMS only. Recently, a separable solution based on the phase modular approach was proposed for the reliability analysis of dynamic PMS subject to CCF. The reader may refer to [22] for details.

Abstract: This chapter presents the reliability of discrete-time semi-Markov systems. After some basic definitions and notation, we obtain explicit forms for reliability indicators. We propose non-parametric estimators for reliability, availability, failure rate, mean hitting times and we study their asymptotic properties. Finally, we present a three state example with detailed calculations and numerical evaluations.

24.1 Introduction

In the last 50 years, a lot of work has been carried out in the field of probabilistic and statistical methods in reliability. We do not intend to provide here an overview of the field, but only to point out some bibliographical references that are close to the work presented in this chapter. More precisely, we are interested in discrete-time models for reliability and in models based on semi-Markov processes that extend the classical *i.i.d.* or Markovian approaches. The generality is important, because we pass from a geometric distributed sojourn time in the Markov case, to a general distribution on the set of non-negative integers $\mathbb{N}$, like the discrete-time Weibull distribution.

It is worth noticing here that most mathematical models for reliability consider time to be continuous. However, there are real situations when systems have natural discrete lifetimes. We can cite here those systems working on demand, those working on cycles or those monitored only at certain discrete times (once a month, say). In such situations, the lifetimes are expressed in terms of the number of working periods, the number of working cycles or the number of months before failure. In other words, all these lifetimes are intrinsically discrete. However, even in the continuous-time modeling case, we pass to the numerical calculus by first discetizing the concerned model. A good overview of discrete probability distributions used in reliability theory can be found in [1].

Several authors have studied discrete-time models for reliability in a general *i.i.d.* setting (see [1–4]). The discrete-time reliability modeling via homogeneous and non-homogeneous Markov chains can be found in [5, 6]. Statistical estimations and asymptotic properties for

reliability metrics, using discrete-time homogeneous Markov chains, are presented in [7]. The continuous-time semi-Markov model in reliability can be found in [8–10].

As compared to the attention given to the continuous-time semi-Markov processes and related inference problems, the discrete-time semi-Markov processes (DTSMP) are less studied. For an introduction to discrete-time renewal processes, see, for instance, [11]; an introduction to DTSMP can be found in [12–14]. The reliability of discrete-time semi Markov systems is investigated in [14–18] and in [22].

We present here a detailed modeling of reliability, availability, failure rate and mean times, with closed form solutions and statistical estimation based on a censured trajectory in the time interval $[0,M]$. The discrete time modeling presented here is more adapted to applications and is numerically easy to implement using computer software, in order to compute and estimate the above metrics.

The present chapter is structured as follows. In Section 24.2, we define homogeneous discrete-time Markov renewal processes, homogeneous semi-Markov chains and we establish some basic notation. In Section 24.3, we consider a repairable discrete-time semi-Markov system and obtain explicit forms for reliability measures: reliability, availability, failure rate and mean hitting times. Section 24.4 is devoted to the non-parametric estimation. We first obtain estimators for the characteristics of a semi-Markov system. Then, we propose estimators for measures of the reliability and we present their asymptotic properties. We end this chapter by a numerical application.

24.2 The Semi-Markov Setting

In this section we define the discrete-time semi-Markov model, introduce the basic notation and definitions and present some probabilistic results on semi-Markov chains.

Consider a random system with finite state space $E=\{1,\ldots,s\}$. We denote by $\mathcal{M}_E$ the set of matrices on $E\times E$ and by $\mathcal{M}_E(\mathbb{N})$ the set of matrix-valued functions defined on the set of non-negative integers $\mathbb{N}$, with values in $\mathcal{M}_E$. For $A\in\mathcal{M}_E(\mathbb{N})$, we write $A=(A(k);k\in\mathbb{N})$, where, for $k\in\mathbb{N}$ fixed, $A(k)=(A_{ij}(k);k\in E)\in\mathcal{M}_E$. Put $\mathbf{I}_E\in\mathcal{M}_E$ for the identity matrix and $\mathbf{0}_E\in\mathcal{M}_E$ for the null matrix.

We suppose that the evolution in time of the system is described by the following chains (see Figure 24.1.):

- The chain $J=(J_n)_{n\in\mathbb{N}}$ with state space E, where J_n is the system state at the n th jump time.
- The chain $S=(S_n)_{n\in\mathbb{N}}$ with state space $\mathbb{N}$, where S_n is the n th jump time. We suppose that $S_0=0$ and $0<S_1<S_2<\ldots<S_n<S_{n+1}<\ldots$.
- The chain $X=(X_n)_{n\in\mathbb{N}^*}$ with state space $\mathbb{N}^*$, where X_n is the sojourn time in state J_{n-1} before the n th jump. Thus, for all $n\in\mathbb{N}^*$, we have $X_n=S_n-S_{n-1}$.

A fundamental notion for semi-Markov systems is that of semi-Markov kernel in discrete time.

Definition 1: A matrix-valued function $\mathbf{q}\in\mathcal{M}_E(\mathbb{N})$ is said to be *a discrete-time semi-Markov kernel* if it satisfies the following three properties:

1. $0\le q_{ij}(k)\le 1, i,j\in E, k\in\mathbb{N}$;
2. $q_{ij}(0)=0$ and $\sum_{k=0}^{\infty} q_{ij}(k)\le 1, i,j\in E$;
3. $\sum_{k=0}^{\infty}\sum_{j\in E} q_{ij}(k)=1, i\in E$.

Definition 2: The chain $(J,S)=(J_n,S_n)_{n\in\mathbb{N}}$ is said to be *a Markov renewal chain* (MRC) if for all $n\in\mathbb{N}$, for all $i,j\in E$ and for all $k\in\mathbb{N}$ it satisfies almost surely

$$\mathbb{P}(J_{n+1}=j,S_{n+1}-S_{n+1}=k\,|\,J_0,\ldots J_n,S_0,\ldots S_n)$$
$$=\mathbb{P}(J_{n+1}=j,S_{n+1}-S_{n+1}=k\,|\,J_n).$$

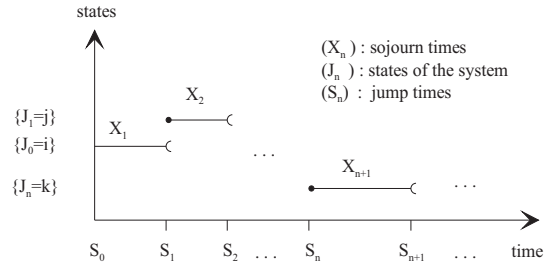

Figure 24.1. A typical sample path of a Markov renewal chain

Moreover, if the previous equation is independent of n, (J,S) is said to be homogeneous and the discrete-time semi-Markov kernel $\mathbf{q}$ is defined by

$$q_{ij}(k) := \mathbb{P}(J_{n+1} = j, X_{n+1} = k \big| J_n = i).$$

Figure 24.1 provides a representation of the evolution of the system.

We also introduce the cumulative semi-Markov kernel as the matrix-valued function $\mathbf{Q} = (\mathbf{Q}(k); k \in \mathbb{N}) \in \mathcal{M}_E(\mathbb{N})$ defined by

$$\begin{aligned} Q_{ij}(k) &:= \mathbb{P}(J_{n+1} = j, X_{n+1} \le k \big| J_n = i) \\ &= \sum_{l=0}^{k} q_{ij}(l), i, j \in E, k \in \mathbb{N}. \end{aligned} \tag{24.1}$$

Note that for (J,S) a Markov renewal chain, we can easily see that $(J_n)_{n\in\mathbb{N}}$ is a Markov chain, called *the embedded Markov chain associated to MRC* (J,S). We denote by $\mathbf{p} = (p_{ij})_{i,j\in E} \in \mathcal{M}_E$ the transition matrix of $(J_n)_{n\in\mathbb{N}}$ defined by

$$p_{ij} = \mathbb{P}(J_{n+1} = j \big| J_n = i), i, j \in E, n \in \mathbb{N}.$$

We also assume that $p_{ii} = 0$, $q_{ii}(k) = 0$, $i \in E$, $k \in \mathbb{N}$, *i.e.,* we do not allow transitions to the same state. Let us define now the conditional sojourn time distributions depending on the next state to be visited and the sojourn time distributions in a given state.

Definition 3: For all $i, j \in E$, let us define:

1. $f_{ij}(\cdot)$, the conditional distribution of $X_{n+1}, n \in \mathbb{N}$,

$$f_{ij}(k) := \mathbb{P}(X_{n+1} = k \big| J_n = i, J_{n+1} = j), k \in \mathbb{N}.$$

2. $F_{ij}(\cdot)$, the conditional cumulative distribution of $X_{n+1}, n \in \mathbf{N}$,

$$\begin{aligned} F_{ij}(k) &:= \mathbb{P}(X_{n+1} \le k \big| J_n = i, J_{n+1} = j) \\ &= \sum_{l=0}^{k} f_{ij}(l), k \in \mathbb{N}. \end{aligned}$$

Obviously, for all $i, j \in E$ and for all $k \in \mathbb{N} \cup \{\infty\}$, we have

$$f_{ij}(k) = \begin{cases} q_{ij}(k) / p_{ij}, \text{ if } p_{ij} \neq 0, \\ \mathbf{1}_{\{k=\infty\}}, \text{ if } p_{ij} = 0. \end{cases}$$

Definition 4: For all $i \in E$, let us define:

1. $h_i(\cdot)$, the sojourn time distribution in state i:

$$h_i(k) := \mathbb{P}(X_{n+1} = k \big| J_n = i) = \sum_{j\in E} q_{ij}(k), k \in \mathbb{N}.$$

2. $H_i(\cdot)$, the sojourn time cumulative distribution function in state i:

$$H_i(k) := \mathbb{P}(X_{n+1} \le k \big| J_n = i) = \sum_{l=0}^{k} h_i(l), k \in \mathbb{N}.$$

We consider that in each state i the chain stays at least one time unit, *i.e.*, for any state j we have

$$f_{ij}(0) = q_{ij}(0) = h_i(0) = 0.$$

Let us also denote by m_i the mean sojourn time in a state $i \in E$,

$$m_i = \mathbb{E}(S_1 \big| J_0 = i) = \sum_{k\ge 0} (1 - H_i(k)).$$

For G the cumulative distribution function of a certain *r.v.* X, we denote its *survival function* by $\overline{G}(k) = 1 - G(k) = \mathbf{P}(X > k), k \in \mathbb{N}$. Thus, for all states $i, j \in E$, we put $\overline{F_{ij}}$ and $\overline{H_i}$ for the corresponding survival functions.

The operation which will be commonly used when working on the space $\mathcal{M}_E(\mathbb{N})$ of matrix-valued functions will be the discrete-time matrix convolution product. In the sequel we recall its definition, we see that there exists an identity element, we define recursively the n-fold convolution and we introduce the notion of the inverse in the convolution sense.

Definition 5: Let $\mathrm{A},\mathrm{B}\in\mathcal{M}_E(\mathbb{N})$ be two matrix-valued functions. *The matrix convolution product* $A*B$ is a matrix-valued function $\mathrm{C}\in\mathcal{M}_E(\mathbb{N})$ defined by

$$C_{ij}(k):=\sum_{r\in E}\sum_{l=0}^{k}A_{ir}(k-l)B_{rj}(l),i,j\in E,k\in\mathbb{N}.$$

The following result concerns the existence of the identity element for the matrix convolution product in discrete time.

Lemma 1: Let $\delta I=(d_{ij}(k);i,j\in E)\in\mathcal{M}_E(\mathbb{N})$ be the matrix-valued function defined by

$$d_{ij}(k):=\begin{cases}1 & \text{if } i=j \text{ and } k=0,\\ 0 & \text{elsewhere.}\end{cases}$$

Then, δI satisfies

$$\delta I*A=A*\delta I=A,A\in\mathcal{M}_E(\mathbb{N}),$$

i.e., δI is *the identity element* for the discrete-time matrix convolution product.

The power in the sense of convolution is defined straightforwardly, using Definition 5.

Definition 6: Let $A\in\mathcal{M}_E(\mathbb{N})$ be a matrix-valued function and $n\in\mathbb{N}$. *The n-fold convolution* $A^{(n)}$ is a matrix-valued function in $\mathcal{M}_E(\mathbb{N})$ defined recursively by:

$$A_{ij}^{(0)}(k):=d_{ij}(k),$$

$$A_{ij}^{(1)}(k):=A_{ij}(k),$$

$$A_{ij}^{(n)}(k):=\sum_{r\in E}\sum_{l=0}^{k}A_{ir}(k-l)A_{rj}^{(n-1)}(l),n\geq 2,k\in\mathbb{N}.$$

For a MRC (J,S) the n-fold convolution of the semi-Markov kernel has the property expressed in the following result.

Lemma 2: Let $(J,S)=(J_n,S_n)_{n\in\mathbb{N}}$ be a Markov renewal chain and $\mathbf{q}=\left(q_{ij}(k);i,j\in E,k\in\mathbb{N}\right)$ be its associated semi-Markov kernel. Then, for all $n,k\in\mathbb{N}$ such that $n\geq k+1$, we have $\mathbf{q}^{(n)}(k)=0$.

This property of the discrete-time semi-Markov kernel convolution is essential for the simplicity and the numerical exactitude of the results obtained in discrete time. We need to stress the fact that this property is intrinsic to the work in discrete time and it is no longer valid for a continuous-time Markov renewal process.

Definition 7: Let $\mathrm{A}\in\mathcal{M}_E(\mathbb{N})$ be a matrix-valued function. If there exists a $B\in\mathcal{M}_E(\mathbb{N})$ such that $B*A=\delta I$, then B is called *the left inverse of* A *in the convolution sense* and it is denoted by $A^{(-1)}$.

It can be shown that given a matrix-valued function $\mathrm{A}\in\mathcal{M}_E(\mathbb{N})$ such that $\det A(0)\neq 0$, then the left inverse B of A exists and is unique (see [14] for the proof).

Let us now introduce the notion of the semi-Markov chain, strictly related to that of the Markov renewal chain.

Definition 8: Let (J,S) be a Markov renewal chain. The chain $Z=(Z_k)_{k\in\mathbb{N}}$ is said to be *a semi-Markov chain* associated to the MRC (J,S), if

$$Z_k:=J_{N(k)},k\in\mathbb{N},$$

where

$$N(k):=\left\{n\in\mathbb{N}\middle|S_n\leq k\right\}\qquad(24.2)$$

is the discrete-time counting process of the number of jumps in $[1,\mathrm{k}]\subset\mathbb{N}$. Thus, Z_k gives the system state at time k. We also have $J_n=Z_{S_n},n\in\mathbb{N}$. Let the row vector $\boldsymbol{\alpha}=\left(\alpha(1),\ldots,\alpha(s)\right)$ denote *the initial distribution* of the semi-Markov chain $Z=(Z_k)_{k\in\mathbb{N}}$, where $\alpha(i):=\mathbf{P}(Z_0=i)=\mathbf{P}(J_0=i)$, $i\in E$.

Definition 9: The transition function of the semi-Markov chain Z is the matrix-valued function $\mathbf{P}\in\mathcal{M}_E(\mathbb{N})$ defined by

$$P_{ij}(k):=\mathbb{P}(Z_k=j\middle|Z_0=i),i,j\in E,k\in\mathbb{N}.$$

The following result consists in a recursive formula for computing the transition function $\mathbf{P}$ of the semi-Markov chain Z.

Proposition 1: For all $i,j\in E$ and for all $k\in\mathbb{N}$, we have

$$P_{ij}(k)=\mathbf{1}_{\{i=j\}}\left(1-H_i(k)\right)+\sum_{r\in E}\sum_{l=0}^{k}q_{ir}(l)P_{rj}(k-l),$$

where

$$\mathbf{1}_{\{i=j\}} := \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{elsewhere.} \end{cases}$$

Let us define for all $k \in \mathbb{N}$:

- $I(k) := \mathbf{I}_E$ for $k \in \mathbb{N}$, $\mathbf{I} := (I(k); k \in \mathbb{N})$;
- $\mathbf{H}(k) := \mathrm{diag}(H_i(k); i \in E)$, $\mathbf{H} := (H(k); k \in \mathbf{N})$.

In matrix-valued function notation, the transition function $\mathbf{P}$ of the semi-Markov chain verifies the equation

$$\mathbf{P} = \mathbf{I} - \mathbf{H} + \mathbf{q} * \mathbf{P}.$$

This is an example of what is called the discrete-time Markov renewal equation. We know that the solution of this equation exists, is unique (see [14]) and, for all $k \in \mathbb{N}$, has the following form:

$$\begin{aligned} \mathbf{P}(k) &= (\delta I - \mathbf{q})^{(-1)} * (\mathbf{I} - \mathbf{H})(k) \\ &= (\delta I - \mathbf{q})^{(-1)} * (\mathbf{I} - \mathrm{diag}(\mathbf{Q} \cdot \mathbf{1}))(k). \end{aligned} \tag{24.3}$$

24.3 Reliability Modeling

In this section we consider a reparable discrete-time semi-Markov system and we obtain closed form solutions for reliability measures: reliability, availability, failure rate, mean time to failure, mean time to repair.

24.3.1 State Space Split

Consider a system (or a component) $\mathcal{S}$ whose possible states during its evolution in time are $E = \{1, \ldots, s\}$. Denote by $U = \{1, \ldots, s_1\}$ the subset of working states of the system (the up-states) and by $D = \{s_1 + 1, \ldots, s\}$ the subset of failure states (the down-states), with $0 < s_1 < s$ (obviously, $E = U \bigcup D$ and $U \bigcap D = \emptyset$, $U \neq \emptyset$, $D \neq \emptyset$). One can think of the states of U as different operating modes or performance levels of the system, whereas the states of D can be seen as failures of the system with different modes. According to the partition of the state space in up-states and down-states, we will partition the vectors, matrices or matrix functions we are working with.

Firstly, for $\boldsymbol{\alpha}, \mathbf{p}, \mathbf{q}(k), \mathbf{f}(k), \mathbf{F}(k), \mathbf{H}(k), \mathbf{Q}(k)$, we consider the natural matrix partition corresponding to the state space partition U and D. For example, we have

$$\mathbf{p} = \begin{pmatrix} \mathbf{p}_{11} & \mathbf{p}_{12} \\ \mathbf{p}_{21} & \mathbf{p}_{22} \end{pmatrix} \text{ and } \mathbf{q}(k) = \begin{pmatrix} \mathbf{q}_{11}(k) & \mathbf{q}_{12}(k) \\ \mathbf{q}_{21}(k) & \mathbf{q}_{22}(k) \end{pmatrix}.$$

Secondly, for $\mathbf{P}(k)$ we consider the restrictions to $U \times U$ and $D \times D$ induced by the corresponding restrictions of the semi-Markov kernel $\mathbf{q}(k)$. To be more specific, using the partition given above for the kernel $\mathbf{q}(k)$, we note that:

$$\mathbf{P}_{11}(k) := (\delta I - \mathbf{q}_{11})^{(-1)} * (\mathbf{I} - \mathrm{diag}(\mathbf{Q} \cdot \mathbf{1})_{11})(k),$$

$$\mathbf{P}_{22}(k) := (\delta I - \mathbf{q}_{22})^{(-1)} * (\mathbf{I} - \mathrm{diag}(\mathbf{Q} \cdot \mathbf{1})_{22})(k).$$

The reasons fort taking this partition for $\mathbf{P}(k)$ can be found in [19].

For $m, n \in \mathbb{N}^*$ such that $m > n$, let $\mathbf{1}_{m,n}$ denote the m-dimensional column vector whose n first elements are 1 and last $m - n$ elements are 0; for $m \in \mathbb{N}^*$ let $\mathbf{1}_m$ denote the m-column vector whose elements are all 1, that is, $\mathbf{1}_m = \mathbf{1}_{m,m}$.

24.3.2 Reliability

Consider a system $\mathcal{S}$ starting to function at time $k = 0$ and let T_D denote the first passage time in subset D, called *the lifetime of the system*, *i.e.*,

$$T_D := \inf\{k \in \mathbb{N} \,|\, Z_k \in D\} \text{ and } \inf \emptyset := \infty.$$

The reliability of a discrete-time semi-Markov system $\mathcal{S}$ at time $k \in \mathbb{N}$, that is the probability that the system has functioned without failure in the period $[0, k]$, is

$$R(k) := \mathbb{P}(T_D > k) = \mathbb{P}(Z_n \in U, n = 0, \ldots, k).$$

The following result gives the reliability of the system in terms of the basic quantities of the semi-Markov chain.

Proposition 2: The reliability of a discrete-time semi-Markov system at time $k \in \mathbb{N}$ is given by

$$\begin{aligned} R(k) &= \boldsymbol{\alpha}_1 \mathbf{P}_{11}(k) \mathbf{1}_{s_1} \\ &= \boldsymbol{\alpha}_1 (\delta I - \mathbf{q}_{11})^{(-1)} * (\mathbf{I} - \mathrm{diag}(\mathbf{Q} \cdot \mathbf{1})_{11})(k) \mathbf{1}_{s_1}. \end{aligned}$$

24.3.3 Availability

The point-wise (or instantaneous) availability of a system $\mathcal{S}$ at time $k \in \mathbb{N}$ is the probability that the system is operational at time k (independently of the fact that the system has failed or not in $[0,k)$). So, the point-wise availability of a semi-Markov system at time $k \in \mathbb{N}$ is

$$A(k) := \mathbb{P}(Z_k \in U) = \sum_{i \in E} \alpha(i) A_i(k),$$

where we have denoted by $A_i(k)$ the system's availability at time $k \in \mathbb{N}$, given that it starts in state $i \in E$,

$$A_i(k) = \mathbb{P}(Z_k \in U \big| Z_0 = i).$$

The following result gives an explicit form of the availability of a discrete-time semi-Markov system.

Proposition 3: The point-wise availability of a discrete-time semi-Markov system at time $k \in \mathbb{N}$ is given by

$$\begin{aligned} A(k) &= \boldsymbol{\alpha} \mathbf{P}(k) \mathbf{1}_{s,s_1} \\ &= \boldsymbol{\alpha} (\delta I - \mathbf{q})^{(-1)} * (\mathbf{I} - \mathrm{diag}(\mathbf{Q} \cdot \mathbf{1}))(k) \mathbf{1}_{s,s_1}. \end{aligned}$$

24.3.4 The Failure Rate

We consider here the classical failure rate, introduced by Barlow, Marshall and Proschan in 1963 (see [20]). We call it *the BMP-failure rate* and denote it by $\lambda(k), k \in \mathbb{N}$.

Let $\mathcal{S}$ be a system starting to function at time $k = 0$. The BMP-failure rate at time $k \in \mathbb{N}$ is the conditional probability that the failure of the system occurs at time k, given that the system has worked until time $k-1$.

For a discrete-time semi-Markov system, the failure rate at time $k \geq 1$ has the expression

$$\begin{aligned} \lambda(k) &:= \mathbb{P}(T_D = k \big| T_D \geq k), \\ &= \begin{cases} 1 - \dfrac{R(k)}{R(k-1)}, & R(k-1) \neq 0, \\ 0, & \text{otherwise}, \end{cases} \\ &= \begin{cases} 1 - \dfrac{\boldsymbol{\alpha}_1 \mathbf{P}_{11}(k) \mathbf{1}_{s_1}}{\boldsymbol{\alpha}_1 \mathbf{P}_{11}(k-1) \mathbf{1}_{s_1}}, & R(k-1) \neq 0, \\ 0, & \text{otherwise}. \end{cases} \end{aligned} \tag{24.4}$$

The failure rate at time $k = 0$ is defined by $\lambda(0) := 1 - R(0)$.

It is worth noticing that the failure rate $\lambda(k)$ in discrete-time case is a probability function and not a general positive function as in the continuous-time case. There exists a more recent failure rate, proposed in [2] as being adapted to reliability studies carried out in discrete time. Discussions justifying the use of this discrete-time adapted failure rate can also be found in [3, 4]. In this chapter we do not present this alternative failure rate. Its use for discrete-time semi-Markov systems can be found in [18, 19].

24.3.5 Mean Hitting Times

There are various mean times which are interesting for the reliability analysis of a system. We will be concerned here only with the mean time to failure and the mean time to repair.

We suppose that $\boldsymbol{\alpha}_2 = 0$, *i.e.,* the system starts in a working state. The *mean time to failure* (MTTF) is defined as the mean lifetime, *i.e.*, the expectation of the hitting time to down-set D, $MTTF := \mathbb{E}(T_D)$.

Symmetrically, consider now that $\boldsymbol{\alpha}_1 = 0$, *i.e.* the system fails at the time $t = 0$. Denote by T_U the first hitting time of the up-set U, called *the repair duration*, *i.e.*,

$$T_U := \inf\{k \in \mathbb{N} \big| Z_k \in U\}.$$

The *mean time to repair* (MTTR) is defined as the mean of the repair duration, *i.e.*, $MTTR := \mathbb{E}(T_U)$.

The following result gives expressions for the MTTF and the MTTR of a discrete-time semi-Markov system.

Proposition 4: If the matrices $I-\mathbf{p}_{11}$ and $I-\mathbf{p}_{22}$ are non-singular, then

$$MTTF=\boldsymbol{\alpha}_1(I-\mathbf{p}_{11})^{-1}\mathbf{m}_1,$$
$$MTTR=\boldsymbol{\alpha}_2(I-\mathbf{p}_{22})^{-1}\mathbf{m}_2,$$

where $\mathbf{m}=(\mathbf{m}_1\ \mathbf{m}_2)^{\mathrm{T}}$ is the partition of the mean sojourn times vector corresponding to the partition of the state space E in up-states U and down-states D. If the matrices are singular, we put $MTTF=\infty$ or $MTTF=\infty$.

24.4 Reliability Estimation

The objective of this section is to provide estimators for reliability indicators of a system and to present their asymptotic properties. In order to achieve this purpose, we firstly show how estimators of the basic quantities of a discrete-time semi-Markov system are obtained.

24.4.1 Semi-Markov Estimation

Let us consider a sample path of a Markov renewal chain $(J_n,S_n)_{n\in\mathbb{N}}$, censored at fixed arbitrary time $M\in\mathbb{N}^*$,

$$\mathcal{H}(M)=(J_0,X_1\ldots,J_{N(M)-1},X_{N(M)},J_{N(M)},u_M),$$

where $N(M)$ is the discrete-time counting process of the number of jumps in (see (24.2)) and $u_M:=M-S_{N(M)}$ is the censored sojourn time in the last visited state $J_{N(M)}$.

Starting from the sample path $\mathcal{H}(M)$, we will propose empirical estimators for the quantities of interest. Let us firstly define the number of visits to a certain state, the number of transitions between two states and so on.

Definition 10: For all states $i,j\in E$ and positive integer $k\le M$, define:

1. $N_i(M):=\sum_{n=0}^{N(M)-1}\mathbf{1}_{\{J_n=i\}}$ - the number of visits to state i, up to time M;
2. $N_{ij}(M):=\sum_{n=1}^{N(M)}\mathbf{1}_{\{J_{n-1}=i,J_n=j\}}$ - the number of transitions from i to j, up to time M;
3. $N_{ij}(k,M):=\sum_{n=1}^{N(M)}\mathbf{1}_{\{J_{n-1}=i,J_n=j,X_n=k\}}$ - the number of transitions from i to j, up to time M, with sojourn time in state i equal to $k,1\le k\le M$.

For a sample path of length M of a semi-Markov chain, for any states $i,j\in E$ and positive integer $k\in\mathbb{N},k\le M$, we define the empirical estimators of the transition matrix of the embedded Markov chain p_{ij}, of the conditional distributions of the sojourn times $f_{ij}(k)$ and of the discrete-time semi-Markov kernel $q_{ij}(k)$ by:

$$\begin{aligned}\widehat{p}_{ij}(M)&:=N_{ij}(M)/N_i(M),\\ \widehat{f}_{ij}(k,M)&:=N_{ij}(k,M)/N_{ij}(M),\\ \widehat{q}_{ij}(k,M)&:=N_{ij}(k,M)/N_i(M).\end{aligned}\qquad(24.5)$$

Note that the proposed estimators are natural estimators. For instance, the probability p_{ij} that the system goes from state i to state j is estimated by the number of transitions from i to j, devised by the number of visits to state i. As can be seen in [17] or [19], the empirical estimators proposed in (24.5) have good asymptotic properties. Moreover, they are in fact approached maximum likelihood estimators (Theorem 1). In order to see this, consider the likelihood function corresponding to the history $\mathcal{H}(M)$

$$L(M)=\prod_{k=1}^{N(M)}p_{J_{k-1}J_k}f_{J_{k-1}J_k}(X_k)\overline{H}_{J_{N(M)}}(u_M),$$

where $\overline{H}_i(\cdot)$ is the survival function in state i. We have the following result concerning the asymptotic behavior of u_M (see [19] for a proof).

Lemma 3: For a semi-Markov chain $(Z_n)_{n\in\mathbb{N}}$ we have $u_M/M\xrightarrow{a.s.}0$, as $M\to\infty$.

Let us consider the approached likelihood function

$$L_1(M) = \prod_{k=1}^{N(M)} p_{J_{k-1}J_k} f_{J_{k-1}J_k}(X_k), \qquad (24.6)$$

obtained by neglecting the last term in the expression of $L(M)$. Using Lemma 3, we see that the maximum likelihood function $L(M)$ and the approached maximum likelihood function $L_1(M)$ are asymptotically equivalent, as M tends to infinity. Consequently, the estimators obtained by estimating $L(M)$ or $L_1(M)$ are asymptotically equivalent, as M tends to infinity.

The following result shows that $\widehat{p}_{ij}(M)$, $\widehat{f}_{ij}(k,M)$ and $\widehat{q}_{ij}(k,M)$ defined in (24.5) are obtained in fact by maximizing $L_1(M)$ (a proof can be found in [17]).

Theorem 1: For a sample path of a semi-Markov chain $(Z_n)_{n\in\mathbb{N}}$, of arbitrary fixed length $M \in \mathbb{N}$, the empirical estimators of the transition matrix of the embedded Markov chain $(J_n)_{n\in\mathbb{N}}$, of the conditional distributions of the sojourn times and of the discrete-time semi-Markov kernel, proposed in (24.5), are approached nonparametric maximum likelihood estimators, *i.e.*, they maximize the approached likelihood function $L_1(M)$ given in (24.6).

As any quantity of interest of a semi-Markov system can be written in terms of the semi-Markov kernel, we can now use the kernel estimator $\widehat{q}_{ij}(k,M)$ in order to obtain plug-in estimators for any functional of the kernel. For instance, the cumulative semi-Markov kernel $\mathbf{Q} = (\mathbf{Q}(k); k \in \mathbb{N})$ defined in (24.1) has the estimator

$$\widehat{\mathbf{Q}}(k,M) := \sum_{l=1}^{k} \widehat{\mathbf{q}}(l,M).$$

Similarly, using the expression of the transition function of the semi-Markov chain Z given in (24.3), we get its estimator

$$\widehat{\mathbf{P}}(k,M) = (\delta I - \widehat{\mathbf{q}})^{(-1)}(\cdot,M) * (\mathbf{I} - \mathrm{diag}(\widehat{\mathbf{Q}}(\cdot,M)\cdot\mathbf{1}))(k).$$

Proofs of the consistency and of the asymptotic normality of the estimators defined up to now can be found in [16, 17, 19].

We are able now to construct estimators of the reliability indicators of a semi-Markov system and to present their asymptotic properties.

24.4.2 Reliability Estimation

The expression of the reliability given in Proposition 2, together with the estimators of the semi-Markov transition function and of the cumulative semi-Markov kernel given above, allow us to obtain the estimator of the system's reliability at time k given by

$$\widehat{R}(k,M) = \boldsymbol{\alpha}_1 \widehat{\mathbf{P}}_{11}(k,M)\mathbf{1}_{s_1}. \qquad (24.7)$$

Let us give now the result concerning the consistency and the asymptotic normality of the reliability estimator. A proof of the asymptotic normality of reliability estimator, based on CLT for Markov renewal processes (see [21]) can be found in [17]. An alternative proof based on CLT for martingales, can be found in [19].

Theorem 2: For any fixed arbitrary positive integer $k \in \mathbb{N}$, the estimator of the reliability of a discrete-time semi-Markov system at instant k is strongly consistent, *i.e.,*

$$\left|\widehat{R}(k,M) - R(k)\right| \xrightarrow{a.s.} 0, \text{ as } M \to \infty,$$

and asymptotically normal, *i.e.*, we have

$$\sqrt{M}\left[\widehat{R}(k,M) - R(k)\right] \xrightarrow{\mathcal{D}} \mathcal{N}\left(0, \sigma_R^2(k)\right), \text{ as } M \to \infty,$$

with the asymptotic variance

$$\sigma_R^2(k) = \sum_{i=1}^{s} \mu_{ii} \left\{ \sum_{j=1}^{s} \left[D_{ij}^U - \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\Psi_{ti} \right]^2 * q_{ij}(k) \right.$$

$$\left. - \left[\sum_{j=1}^{s} \left(D_{ij}^U * q_{ij} - \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\psi_{ti} * Q_{ij} \right) \right]^2 (k) \right\},$$

where

$$D_{ij}^U := \sum_{n\in U} \sum_{r\in U} \alpha(n)\psi_{ni} * \psi_{jr} * \left(\mathbf{I} - \mathrm{diag}(\mathbf{Q}\cdot\mathbf{1})\right)_{rr},$$

$$\boldsymbol{\psi}(k) := \sum_{n=0}^{k} \mathbf{q}^{(n)}(k), \quad \boldsymbol{\Psi}(k) := \sum_{n=0}^{k} \mathbf{Q}^{(n)}(k),$$

and μ_{ii} is the mean recurrence time of the state i for the chain Z.

24.4.3 Availability Estimation

Taking into account the expression of the availability given in Proposition 3, we propose the following estimator for the availability of a discrete-time semi-Markov system:

$$\widehat{A}(k,M) = \boldsymbol{\alpha}\widehat{\mathbf{P}}(k,M)\mathbf{1}_{s,s_1}.$$

The following result concerns the consistency and the asymptotic normality of the reliability estimator. A proof can be found in [19].

Theorem 3: For any fixed arbitrary positive integer $k \in \mathbb{N}$, the estimator of the availability of a discrete-time semi-Markov system at instant k is strongly consistent and asymptotically normal, in the sense that

$$\left|\widehat{A}(k,M) - A(k)\right| \xrightarrow{a.s.} 0, \text{ as } M \to \infty,$$

and

$$\sqrt{M}\left[\widehat{A}(k,M) - A(k)\right] \xrightarrow{\mathcal{D}} \mathcal{N}\left(0, \sigma_A^2(k)\right), \text{ as } M \to \infty,$$

with the asymptotic variance

$$\sigma_A^2(k) = \sum_{i=1}^{s} \mu_{ii} \left\{ \sum_{j=1}^{s} \left[D_{ij} - \mathbf{1}_{\{i\in U\}} \sum_{t=1}^{s} \alpha(t)\Psi_{ti} \right]^2 * q_{ij}(k) \right.$$

$$\left. - \left[\sum_{j=1}^{s} \left(D_{ij} * q_{ij} - \mathbf{1}_{\{i\in U\}} \sum_{t=1}^{s} \alpha(t)\psi_{ti} * Q_{ij} \right) \right]^2 (k) \right\},$$

where $D_{ij} := \sum_{n=1}^{s} \sum_{r\in U} \alpha(n)\psi_{ni} * \psi_{jr} * \left(\mathbf{I} - \text{diag}(\mathbf{Q}\cdot\mathbf{1})\right)_{rr}$.

24.4.4 Failure Rate Estimation

For a matrix function $A \in \mathcal{M}_E(\mathbb{N})$, we denote by $A^+ \in \mathcal{M}_E(\mathbb{N})$ the matrix function defined by $A^+(k) := A(k+1), k \in \mathbb{N}$. Using the expression of the failure rate obtained in (24.4), we obtain the following estimator:

$$\widehat{\lambda}(k,M) := \begin{cases} 1 - \dfrac{\widehat{R}(k,M)}{\widehat{R}(k-1,M)}, & \widehat{R}(k-1,M) \neq 0, \mathrm{k} \geq 1, \\ 0, & \widehat{R}(k-1,M) = 0, \mathrm{k} \geq 1, \end{cases}$$

$$\widehat{\lambda}(0,M) := 1 - \widehat{R}(0,M).$$

For the failure rate estimator we have a similar result as for reliability and availability estimators. A proof can be found in [18, 19].

Theorem 4: For any fixed arbitrary positive integer $k \in \mathbb{N}$, the estimator of the failure rate of a discrete-time semi-Markov system at instant k is strongly consistent and asymptotically normal, *i.e.*,

$$\left|\widehat{\lambda}(k,M) - \lambda(k)\right| \xrightarrow{a.s.} 0, \text{ as } M \to \infty,$$

and

$$\sqrt{M}\left[\widehat{\lambda}(k,M) - \lambda(k)\right] \xrightarrow{\mathcal{D}} \mathcal{N}\left(0, \sigma_\lambda^2(k)\right), \text{ as } M \to \infty,$$

swith the asymptotic variance

$$\sigma_\lambda^2(k) = \sigma_1^2(k) / R^4(k-1),$$

where $\sigma_1^2(k)$ is given by

$$\sigma_1^2(k) =$$

$$\sum_{i=1}^{s} \mu_{ii} \left\{ R^2(k) \sum_{j=1}^{s} \left[D_{ij}^U - \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\Psi_{ti} \right]^2 * q_{ij}(k-1) \right.$$

$$+ R^2(k-1) \sum_{j=1}^{s} \left[D_{ij}^U - \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\Psi_{ti} \right]^2 * q_{ij}(k) - T_i^2(k)$$

$$+ 2R(k-1)R(k) \sum_{j=1}^{s} \left[\mathbf{1}_{\{i\in U\}} D_{ij}^U \sum_{t\in U} \alpha(t)\Psi_{ti}^+ \right.$$

$$+ \mathbf{1}_{\{i\in U\}} \left(D_{ij}^U\right)^+ \sum_{t\in U} \alpha(t)\Psi_{ti} - \left(D_{ij}^U\right)^+ D_{ij}^U$$

$$\left. \left. - \mathbf{1}_{\{i\in U\}} \left(\sum_{t\in U} \alpha(t)\Psi_{ti} \right) \left(\sum_{t\in U} \alpha(t)\Psi_{ti}^+ \right) \right] * q_{ij}(k-1) \right\},$$

where

$$T_i(k) := \sum_{j=1}^{s} \left[R(k) D_{ij}^U * q_{ij}(k-1) - R(k-1) D_{ij}^U * q_{ij}(k) \right.$$

$$- R(k) \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\psi_{ti} * Q_{ij}(k-1)$$

$$\left. + R(k-1) \mathbf{1}_{\{i\in U\}} \sum_{t\in U} \alpha(t)\psi_{ti} * Q_{ij}(k) \right]$$

and D_{ij}^U is given in Theorem 2.

24.4.5 Asymptotic Confidence Intervals

The previously obtained asymptotic results allow one to construct asymptotic confidence intervals for reliability, availability and failure rate. For this purpose, we need to construct a consistent estimator of the asymptotic variances.

Firstly, using the definitions of $\boldsymbol{\psi}(k)$ and of $\boldsymbol{\Psi}(k)$ given in Theorem 2, we can construct the corresponding estimators $\widehat{\boldsymbol{\psi}}(k,M)$ and $\widehat{\boldsymbol{\Psi}}(k,M)$. One can check that these estimators are strongly consistent. Secondly, for $k \le M$, replacing $\mathbf{q}(k)$, $\mathbf{Q}(k)$, $\boldsymbol{\psi}(k)$ and $\boldsymbol{\Psi}(k)$ by the corresponding estimators in the asymptotic variance of the reliability given in Theorem 2, we obtain an estimator $\widehat{\sigma}_R^2(k,M)$ of the asymptotic variance $\sigma_R^2(k)$. From the strong consistency of the estimators $\widehat{\mathbf{q}}(k,M)$, $\widehat{\mathbf{Q}}(k,M)$, $\widehat{\boldsymbol{\psi}}(k,M)$ and $\widehat{\boldsymbol{\Psi}}(k,M)$ (see [17, 19]), we obtain that $\widehat{\sigma}_R^2(k,M)$ converges almost surely to $\sigma_R^2(k)$, as M tends to infinity. Finally, the asymptotic confidence interval of $R(k)$ at level $100(1-\gamma)\%$, $\gamma \in (0,1)$, is:

$$\left[\widehat{R}(k,M) - u_{1-\gamma/2}\frac{\widehat{\sigma}_R(k,M)}{\sqrt{M}}, \widehat{R}(k,M) + u_{1-\gamma/2}\frac{\widehat{\sigma}_R(k,M)}{\sqrt{M}}\right],$$

where $u_{1-\gamma/2}$ is the $(1-\gamma/2)$ fractile of $\mathcal{N}(0,1)$. In the same way, we can obtain the other confidence intervals.

24.5 A Numerical Example

Let us consider the three-state discrete-time semi-Markov system described in Figure 24.2.

The state space $E = \{1,2,3\}$ is partitioned into the up-state set $U = \{1,2\}$ and the down-state set $D = \{3\}$.

The system is defined by the initial distribution $\boldsymbol{\alpha} = (1\ 0\ 0)$, by the transition probability matrix $\mathbf{p}$ of the embedded Markov chain $(J_n)_{n\in\mathbb{N}}$ and by the conditional distributions of the sojourn times:

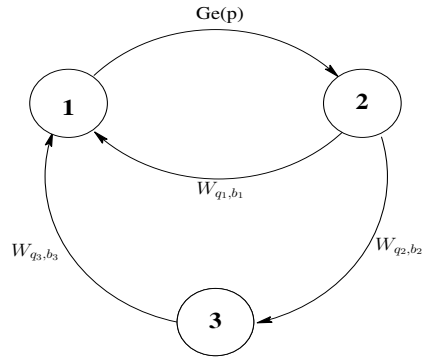

Figure 24.2. A three-state semi-Markov system

$$\mathbf{p} = \begin{pmatrix} 0 & 1 & 0 \\ 0.95 & 0 & 0.05 \\ 1 & 0 & 0 \end{pmatrix},$$

$$\mathbf{f}(k) = \begin{pmatrix} 0 & f_{12}(k) & 0 \\ f_{21}(k) & 0 & f_{23}(k) \\ f_{31}(k) & 0 & 0 \end{pmatrix}, k \in \mathbb{N}.$$

We consider the following distributions for the conditional sojourn time:

$-\ f_{12}$ is a geometric distribution on $\mathbb{N}^*$, of parameter $p = 0.8$.

$-\ f_{21} := W_{q_1,b_1}$, $f_{23} := W_{q_2,b_2}$, $f_{31} := W_{q_3,b_3}$ are discrete-time, first type Weibull distributions (see [1]), defined by $W_{q,b}(0) := 0$, $W_{q,b}(k) := q^{(k-1)^b} - q^{k^b}$, $k \ge 1$, where we take $q_1 = 0.3$, $b_1 = 0.5$, $q_2 = 0.5$, $b_2 = 0.7$, $q_3 = 0.6$, $b_3 = 0.9$. Note that we study here a strictly semi-Markov system, which cannot be reduced to a Markov one.

Using the transition probability matrix and the sojourn time distributions given above, we have simulated a sample path of the three state semi-Markov chain, of length M. This sample path allows us to compute $N_i(M)$, $N_{ij}(M)$ and $N_{ij}(k,M)$, using Definition 10, and to obtain the empirical estimators $\widehat{p}_{ij}(M)$, $\widehat{f}_{ij}(k,M)$ and $\widehat{q}_{ij}(k,M)$ from (24.5). Consequently, we can

obtain the estimators $\widehat{\mathbf{Q}}(k,M)$, $\widehat{\boldsymbol{\psi}}(k,M)$ and $\widehat{\boldsymbol{\Psi}}(k,M)$. Thus, from (24.7), we obtain the estimator of the reliability. In Theorem 2, we have obtained the expression of the asymptotic variance of reliability. Replacing $\mathbf{q}(k)$, $\mathbf{Q}(k)$, $\boldsymbol{\psi}(k)$ and $\boldsymbol{\Psi}(k)$ by the corresponding estimators, we get the estimator $\widehat{\sigma}_R^2(k,M)$ of the asymptotic variance $\sigma_R^2(k)$. This estimator will allow us to have the asymptotic confidence interval for reliability, as shown in Section 24.4.5.

The consistency of the reliability estimator is illustrated in Figure 24.3, where reliability estimators obtained for several values of the sample size M are drawn. We can note that the estimator approaches the true value, as the sample size M increases. Figure 24.4 presents the estimators of the asymptotic variance of the reliability $\sigma_R^2(k)$, obtained for different sample sizes. Note also that the estimator approaches the true value, as M increases. In Figure 24.5, we present the confidence interval of the reliability. Note that the confidence interval covers the true value of the reliability.

Binary Decision Diagrams for Reliability Studies

Antoine Rauzy

IML CNRS, 169, Avenue de Luminy, 13288 Marseille cedex 9, France

Abstract: Bryant's binary ecision diagrams are state-of-the-art data structures used to encode and to manipulate Boolean functions. Risk and dependability studies are heavy consumers of Boolean functions, for the most widely used modeling methods, namely fault trees and event trees, rely on them. The introduction of BDD in that field renewed its algorithmic framework. Moreover, several central mathematical definitions, like the notions of minimal cutsets and importance factors, were questioned. This article attempts to summarize fifteen years of active research on those topics.

25.1 Introduction

Binary decision diagrams (BDD for short) are state-of-the-art data structures used to encode and to manipulate Boolean functions. They were introduced in 1986 by R. Bryant [1] to handle logical circuits and further improved by Bryant and others in the early 1990s [2, 3]. Since then, they have been used successfully in a wide variety of applications (see [4] for a glance). Reliability and dependability studies are heavy consumers of Boolean functions, for the most widely used modeling methods, namely fault trees and event trees, rely on them. The introduction of BDD in that field [5, 6] renewed completely its algorithmic framework. Moreover, several central mathematical definitions, like the notions of minimal cutsets and importance factors, were questioned. This article attempts to summarize fifteen years of active research on those topics.

Fault tree and event tree analyses are classically performed in two steps: first, the minimal cutsets (MCS for short) of the model are determined by some top-down or bottom-up algorithm; second, some probabilistic quantities of interest are assessed from MCS (see, *e.g.*, [7, 8, 9]). Usually, not all of the MCS are considered: cut-offs are applied to keep only the most relevant ones, *i.e.* those with the highest probabilities. With BDD, the methodology is different: first, the BDD of the model is constructed. Then, a second BDD, technically a ZBDD [10], is built from the first one to encode MCS. Probabilistic quantities are assessed either from the BDD or from the ZBDD. From an engineering viewpoint, this new approach changes significantly the process: first, MCS are now used mainly for verification purposes since they are not necessary to assess probabilistic quantities. Second, probabilistic assessments provide exact results, for no cut-off needs to be applied. Last, both coherent (monotone) and non-coherent models can be handled, which is not possible, at least accurately, with the classical approach. However, the new approach has a drawback: the construction of the BDD must be feasible and, as with many Boolean problems, it is

of exponential worst case complexity. The design of strategies and heuristics to construct BDD for large reliability models is still challenging.
In this article, we focus on three issues: the computation of minimal cutsets, the assessment of various probabilistic quantities, and finally the treatment of large models.

A minimal cutset of a fault tree is a minimal set of basic events that induces the top event. The notion minimal cutset is thus related to the logical notion of prime implicant. For a coherent model the two notions actually correspond. For non-coherent models however, they differ. Until recently, the reliability engineering literature stayed at a very intuitive level on this subject. With the introduction of BDD, not only new efficient algorithms to compute MCS have been designed, but the mathematical foundations of MCS have been more firmly established [11].

Beyond the top event probability, a fault tree study involves in general the computation of various quantities like importance factors or equivalent failure rates. The BDD approach makes it possible (and necessary) to revisit these notions and to improve the computations in terms of both efficiency and accuracy [12, 13, 14].

Event trees of the nuclear industry involve up to thousands of basic events. The calculation of BDD for these models is still challenging, while the classical approach (based on the extraction of MCS) is always able to give results, approximate results of course, but still results. Recent studies showed however that, conversely to what was commonly admitted, these results may be not very accurate [15]. The design of heuristics and strategies to assess huge reliability models is therefore of a great scientific and technological interest.

The remainder of this article is organized as follows. Section 25.2 recalls basics about fault trees, event trees, and BDD. Section 25.3 presents the notion of minimal cutsets. Section 25.4 shows the various probabilistic quantities of interest that can be computed by means of BDD. Section 25.5 discusses the assessment of large models. Section 25.6 concludes the article.

25.2 Fault Trees, Event Trees and Binary Decision Diagrams

This section recalls basics about fault trees, event trees and BDD.

25.2.1 Fault Trees and Event Trees

A fault tree is a Boolean formula built over variables, so called basic events that represent failures of basic components (the e_i of Figure 25.1 , and gates (AND, OR, *k*-out-of-*n*). Gates are usually given a name, like the G_i's of Figure 25.1 and called intermediate events. The formula is rooted by an event, called the top event (T in Figure 25.1). The top event encodes the various combinations of elementary failures, *i.e.,* of basic events, that induce a failure of the system under study.

Fault tree studies are twofold. Qualitative analyses consist of determining the minimal cutsets, *i.e.* the minimal combinations of basic events that induce the top event. Quantitative analyses consist of computing various probabilistic quantities of interest, given the probabilities of occurrence of the basic events. Both problems are hard–counting the number of minimal solution of a Boolean formula in assessing the probability of the formula–and fall into the P-hard complexity class [16]. It is worth noting that these complexity results stand even in the case where the underlying function is monotone (coherent), which is in general the case (usually, fault trees do not involve negations).

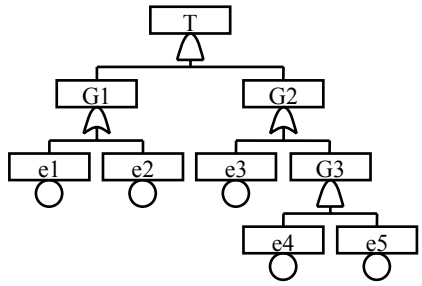

Figure 25.1. A fault tree

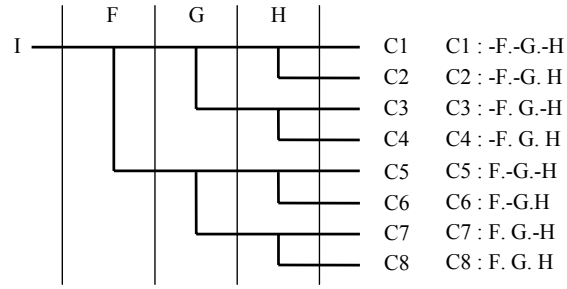

Figure 25.2. An event tree

Depending on the success or the failure of the system, the upper or the lower branch is taken. At the end, a consequence is reached (one of the C_i's on). Failures of safety systems are described by means of fault trees. Sequences are compiled into conjunctions of the initiating event and top events or negations of top events, as illustrated on the right hand side of Figure 25.2. The assessment of sequences, or groups of sequences, is similar to the assessment of fault trees. However, it is worth noting that, due to success branches, formulae may involve negations.

Fault trees are the most widely used method for risk analyses. Virtually all industries that present a risk for the environment use it. Event trees are used mainly in the nuclear industry. A good introduction to both techniques can be found in reference [9].

25.2.2 Binary Decision Diagrams

Binary Decision Diagrams are a compact encoding of the truth tables of Boolean formulae [1, 2]. The BDD representation is based on the Shannon decomposition: Let F be a Boolean function that depends on the variable v, then the following equality holds.

$$F = v.F[v \leftarrow 1] + \overline{v}.F[v \leftarrow 0]$$

By choosing a total order over the variables and applying recursively the Shannon decomposition, the truth table of any formula can be graphically represented as a binary tree. The nodes are labeled with variables and have two outedges (a *then*-outedge, pointing to the node that encodes F[v←1], and an *else*-outedge, pointing to the node that encodes F[v←0]). The leaves are labeled with either 0 or 1. The value of the formula for a given variable assignment is obtained by descending along the corresponding branch of the tree. The Shannon tree for the formula $F = ab + \overline{a}c$ and the lexicographic order is pictured Figure 25.3 (dashed lines represent *else*-outedges).

Indeed, such a representation is very space consuming. It is possible, however, to shrink it by means of the following two reduction rules.

- Isomorphic subtrees merging. Since two isomorphic subtrees encode the same formula, at least one is useless.
- Useless nodes deletion. A node with two equal sons is useless since it is equivalent to its son ($F = v.F + \overline{v}.F$).

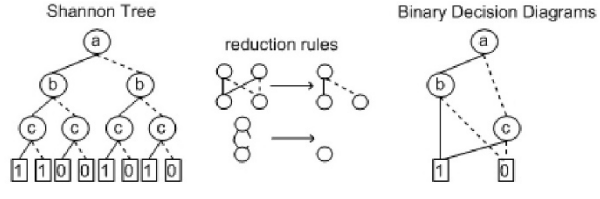

Figure 25.3. From the Shannon tree to the BDD

By applying these two rules as far as possible, one gets the BDD associated with the formula. A BDD is therefore a directed acyclic graph. It is unique, up to an isomorphism. This process is illustrated Figure 25.3.

25.2.3 Logical Operations

Logical operations (and, or, xor, ...) can be directly performed on BDD. This results from the orthogonality of the Shannon decomposition with usual connectives:

$$(v.F_1 + \overline{v}.F_0) \oplus (v.G_1 + \overline{v}.G_0)$$
$$=$$
$$v.(F_1 \oplus G_1) + \overline{v}.(F_0 \oplus G_0)$$

where $\oplus$ stands for any binary connective.

Among other consequences, this means that the complete binary tree is never built and then shrunk: the BDD encoding a formula is obtained by composing the BDD encoding its subformulae. Hash tables are used to store nodes and to ensure, by construction, that each node represents a different function. Moreover, a caching principle is used to store intermediate results of computations. This makes the usual logical operations (conjunction, disjunction) polynomial in the sizes of their operands. The complete implementation of a BDD package is described in reference [2].

25.2.4 Variable Orderings and Complexity Issues

It has been known since the very first uses of BDD that the chosen variable ordering has a great impact on the size of BDD and therefore on the efficiency of the whole methodology [1]. Finding the best ordering, or even a reasonably good one, is a hard problem (see *e.g.*, [17, 18]). Two kinds of heuristics are used to determine which variable ordering to apply. Static heuristics are based on topological considerations and select the variable ordering once for all (see, *e.g.*, [19, 20, 21]). Dynamic heuristics change the variable ordering at some points of the computation (see, *e.g.*, [3, 22]). They are thus more versatile than the former, but the price to pay is a serious increase of running time. Sifting is the most widely used dynamic heuristics [3]. We shall come back to this topic in Section 25.5.

25.2.5 Zero-suppressed Binary Decision Diagrams

Minato's zero-suppressed binary decision diagrams are BDD with a different semantics for nodes (and slightly different reduction rules) [10]. They are used to encode sets of minimal cutsets and prime implicants. Nodes are labeled with literals (and not just by variables). Let p be a literal and U be a set of products. By abuse, we denote p.U the set $\{\{p\} \cup \pi;\ \pi \in U\}$. The semantics of ZBDD is as follows.

The leaf 0 encodes the empty set: Set[0] = $\varnothing$.

The leaf 1 encodes the set that contains only the empty product: Set[1] = $\{\{\}\}$.

A node Δ(p,S1,S0), where p is a literal and S1 and S0 are two ZBDD encodes the following set of products.

Set[Δ(p,S1,S0)] = p.Set[S1] $\cup$ Set[S0]

It is possible to encode huge sets of MCS with relatively small ZBDD, provided MCS have some regularity that can be captured by the sharing of nodes.

25.3 Minimal Cutsets

Minimalcutsets (MCS for short) are the keystone of reliability studies. A minimal cutset is a minimal set of basic events that induces the realization of the top event. For coherent models, this informal definition is sufficient. It corresponds to the formal notion of prime implicant (PI for short). For non-coherent models, MCS and PI differ, for the latter contain negative literals while the former do not. A full understanding of both notions requires some algebraic developments (borrowed mainly to reference [11]).

25.3.1 Preliminary Definitions

A *literal* is either a variable v (positive literal), or its negation $\neg v$ (negative literal). v and $\neg v$ are said to be *opposite*. We write $\overline{p}$ the opposite of the

literal p. A *product* is a set of literals interpreted as the conjunction of its elements. Products are often written like words. For instance, the product {a, b, ¬c} is written $ab\bar{c}$. A *minterm* on a set of variables V = {v_1,...,v_n} is a product which contains exactly one literal built over each variable of V. We write minterms(V) for the set of minterms built on V. If V contains n variables, minterms(V) has 2^n elements.

An *assignment* of a set of variables V = {v_1,...,v_n} is a function σ from V to {0, 1} that assigns a value (true or false) to each variable of V. Using the truth tables of connectives, assignments are extended into functions from formulae built over V to {0, 1}. An assignment σ *satisfies* a formula F if σ(F) = 1. It falsifies F if σ(F) = 0.

There is a one-to-one correspondence between the assignments of V and the minterms built on V: a variable v occurs positively in the minterm π iff and only if σ(v)=1 in the corresponding assignment σ. For instance, the minterm $ab\bar{c}$ corresponds to the function σ such that σ(a)=σ(b)=1 and σ(c)=0, and vice-versa. Similarly, a formula F can be interpreted as the set of minterms (built on the set var(F) of its variables) that satisfy it. For instance, the formula $F = ab + \bar{a}c$ can be interpreted as the set $\{abc, ab\bar{c}, \bar{a}bc, \bar{a}b\bar{c}\}$. For the sake of convenience, we use set notations for formulae and minterms, *e.g.,* we note σ∈ F when σ(F)=1.

There exists a natural order over literals: ¬v < v. This order can be extended to minterms: $\pi \le \rho$ iff for each variable v, π(v)≤ ρ(v), *e.g.*, $\bar{a}\bar{b}c \le a\bar{b}c$ because a occurs negatively in $\bar{a}\bar{b}c$ and positively in $a\bar{b}c$. A physical interpretation of the inequality π≤ρ is that π contains less information than ρ for it realizes fewer basic events. From an algebraic viewpoint, the set minterms(V) equipped with the above partial order forms a lattice, as illustrated in Figure 25.4 (left). The order relation is represented by lines (bottom-up). For the sake of the simplicity, transitive relations are not pictured.

A formula F is said to be *monotone* if for any pair of minterms π and ρ such that $\pi \le \rho$, then ρ∈ F implies that π∈ F. The formula $F = ab + \bar{a}c$ is not monotone because, $\bar{a}\bar{b}c \in F$, $\bar{a}\bar{b}c \le a\bar{b}c$ but $a\bar{b}c \notin F$. This is graphically illustrated Figure 25.4 (right), where the minterms not in F are grayed. Coherent fault trees that are built over variables, and-gates, or-gates and *k*-out-of-*n* connectives are monotone formulae. Non-monotony is introduced by negations.

25.3.2 Prime Implicants and Minimal Cutsets

25.3.2.1 Prime Implicants

We can now introduce the notion of prime implicant. A *product* π is an implicant of a formula F if for all minterms ρ containing π, ρ∈ F. An implicant π of F is *prime* if no proper subset of π is an implicant of F. The set of prime implicants of F is denoted PI[F].

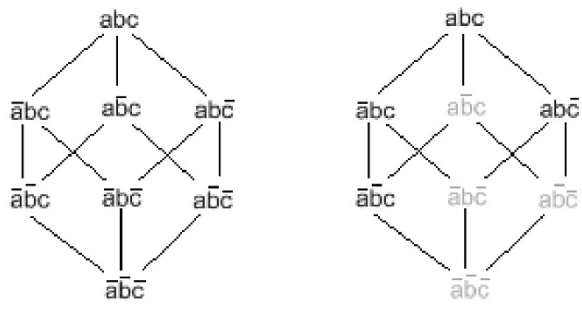

Figure 25.4. The lattice of minterms for {a,b,c}

For instance, the formula $F = ab + \bar{a}c$ admits the following set of prime implicants: $PI[F] = \{ab, \bar{a}c, bc\}$. Note that $\bar{a}b$ is an implicant of F because both $\bar{a}b\bar{c}$ and $\bar{a}bc$ satisfy F. It is prime because neither $\bar{a}$ nor b are implicants of F.

25.3.2.2 Minimal Cutsets

In reliability models, there exists a fundamental asymmetry between positive and negative literals. Positive literals represent undesirable and rare events such as failures. Negative literals represent thus the non occurrence of these events. Positive literals are the only ones that convey relevant information. This is the reason why most of the fault tree assessment tools never produce minimal cutsets with negative literals. To illustrate this idea, consider again the formula $F = ab + \bar{a}c$. We have $PI[F] = \{ab, \bar{a}c, bc\}$. This does correspond to the notion of minimal solutions of F, but this does not correspond to the intuitive notion of minimal cutsets. The expected minimal cutsets are ab and c which are the "positive parts" of prime implicants. There are cases however where negative literals are informative as well. This is typically the case when the values of some physical parameters have to be taken into account (see, *e.g.*, [23]). Thus, we have to consider the set L of literals that convey interesting information. L is typically the set of all positive literals plus possibly some negative literals. A literal p is *significant* if it belongs to L. It is *critical* if it is significant while its opposite is not.

Let V be a finite set of variables. Let L be a subset of significant literals built over V. Finally, let F be a formula built over V. We shall define minimal cutsets of F as minimal solutions (prime implicants) from which literals outside L are removed because they "do not matter". Let $PI_L[F]$ be the set of products obtained first by removing from products of PI[F] literals not in L and second by removing from the resulting set the non minimal products. Formally, $PI_L[F]$ is defined as follows.

$PI_L[F] = \{\pi \cap L;\ \pi \in PI[F]$ and there is no ρ in PI[F] such that $\rho \cap L \subset \pi \cap L\}$

This first definition captures the intuitive notion of minimal cutsets. For instance, it is easy to verify that $PI_{\{a,b,c\}}[ab + \bar{a}c] = \{ab, c\}$. However, it relies on the definition of prime implicants. This makes it not suitable for the design of an algorithm to compute MCS without computing prime implicants. The second way to define MCS which avoids this drawback is as follows. Let $\leq_L$ be the binary relation among opposite literals defined as follows.

$$p \leq_L \bar{p} \text{ if } p \notin L$$

The comparator $\leq_L$ is extended into a binary relation over minterms(V) as follows:

$$\sigma \leq_L \rho \text{ if for any variable v, } \sigma[v] \leq \rho[v],$$

where $\sigma[v]$ (or $\rho[v]$) denotes the literal built over v that belongs to σ (or. to ρ). Intuitively, $\sigma \leq_L \rho$ when σ is less significant than ρ. For instance, $ab\bar{c} \leq_{\{a,b,c\}} abc$ because $ab\bar{c}$ contains fewer positive literals than abc. The comparator $\leq_L$ is both reflexive ($\sigma \leq_L \sigma$ for any σ) and transitive ($\pi \leq_L \sigma$ and $\sigma \leq_L \rho$ implies $\pi \leq_L \rho$, for any π, σ and ρ). Therefore, $\leq_L$ is a pre-order.

A product π over V is a *cutset* of F w.r.t. L if $\pi \subset L$ and for all minterms σ containing π there exists a minterm $\delta \in F$ such that $\delta \leq_L \sigma$. A cutset π is *minimal* if no proper subset of π is a cutset. We denote by $MC_L[F]$ the set of minimal cutsets w.r.t. L of F.

Consider again the formula $F = ab + \bar{a}c$. If $L = \{a, \bar{a}, b, \bar{b}, c, \bar{c}\}$, minterms are pairwise incomparable. Therefore, MCS are products π such that all minterms σ containing π belong to F, $MC_L[F] = PI[F]$.

If $L = \{a,b,c\}$, $ab\bar{c} \leq_L abc$, and $\bar{a}\bar{b}c \leq_L abc$, $a\bar{b}c$, $\bar{a}bc$, therefore the cutsets of F w.r.t. L are abc, ab, ac, bc and c and $MC_L[F] = \{ab, c\}$. As an illustration, consider the product c. Four minterms contain it: abc, $\bar{a}bc$, $a\bar{b}c$, $\bar{a}\bar{b}c$. Except $a\bar{b}c$, they all belong to F. $\bar{a}\bar{b}c \leq_L a\bar{b}c$, therefore there is a minterm of F smaller than $\bar{a}\bar{b}c$. So, all the minterms containing c are covered and c is a cutset.

If $L = \{b, \bar{b}, c, \bar{c}\}$, the cutsets of F w.r.t. L are bc, b and c and $MC_L[F] = \{b,c\}$.

The two definitions of MCS are actually equivalent. Let F be a Boolean formula and let L be a set of literals built over var(F). Then, the following equality holds [11].

$$PI_L[F] = MC_L[F]$$

Note finally that if L=V, a positive product π is a cutset if and only if the minterm $\pi \cup \{\overline{v}; v \in V \text{ and } v \notin \pi\}$ is an implicant of F.

25.3.3 What Do Minimal Cutsets Characterize?

Any formula is equivalent to the disjunction of its prime implicants. A formula is not in general equivalent to the disjunction of its minimal cutsets. The widening operator ω_L gives some insights about the relationship between a formula F, its prime implicants and its minimal cutsets w.r.t. the subset L of the significant literals. The operator ω_L is an endomorphism of the Boolean algebra (minterms(V), $\cap$, $\cup$, $\overline{\ }$) that associates to each set of minterms (formula) F the set of minterms ω_L defined as follows.

$\omega_L = \{\pi$; there exists ρ s.t. $\rho \leq_L \pi$ and $\rho \in F\}$

Intuitively, ω_L enlarges F with all of the minterms that are more significant than a minterm already in F.

Consider again the formula $F = ab + \overline{a}c$.

If $L=\{a, \overline{a}, b, \overline{b}, c, \overline{c}\}$, then, $\omega_L[F] = F$.

If L={a,b,c}, then

$\omega_L[F] = abc + ab\overline{c} + a\overline{b}c + \overline{a}bc + \overline{a}\overline{b}c$.

If L={b, $\overline{b}$,c, $\overline{c}$ }, then

$\omega_L[F] = abc + ab\overline{c} + a\overline{b}c + \overline{a}bc + \overline{a}\overline{b}c$

The operator ω_L has the following properties.

ω_L is idempotent; $\omega_L(\omega_L(F)) = \omega_L(F)$.

$PI[\omega_L(F)] = MC_L[F]$.

The above facts show that ω_L acts as a projection. Therefore, the formulae F such that $PI[F]=MC_L[F]$ are the fixpoints of ω_L, *i.e.* the formulae such that $\omega_L(F) = F$. If L=V, fixpoints are monotone formulae. They also give a third way to define MCS: MCS of a formula F are the prime implicants of the least monotone approximation of F. This approximation is obtained by widening F with all of the minterms that are more significant, and therefore less expected, than a minterm already in F.

25.3.4 Decomposition Theorems

The recursive algorithms to compute prime implicants and minimal cutsets from BDD rely on so-called decomposition theorems. These theorems use the Shannon decomposition as a basis. They are as follows.

Decomposition Theorem for Prime Implicants [24]
Let $F = v.F_1 + \overline{v}.F_0$ be a formula (such that F_1 and F_0 don't depend on v). Then the set of prime implicants of F is the as follows.

$$PI[F] = PI_n \cup PI_1 \cup PI_0$$

where

$PI_n = PI[F_1.F_0]$
$PI_1 = \{v.\pi ; \pi \in PI[F_1]/PI_n\}$
$PI_0 = \{\overline{v} .\pi ; \pi \in PI[F_0]/PI_n\}$

and "/" stands for the set difference.

Decomposition Theorem for Minimal Cutsets [11]:
Let $F = v.F_1 + \overline{v}.F_0$ be a formula (such that F_1 and F_0 don't depend on v). Let L be the set of relevant literals. Then, the set of minimal cutsets F is the as follows.

Case 1: Both v and its negation belong to L. In that case, the decomposition theorem is the same as for prime implicants.

Case 2: v belongs to L, its negation does not. In that case, there are two ways to compute MCS[F].

First Decomposition:
$MCS[F] = MCS_1 \cup MCS_0$,
where

$MCS_0 = MCS[F_0]$
$MCS_1 = \{v.\pi; \pi \in MCS[F_1+F_0]/MCS_0\}$

Second Decomposition:
$MCS[F] = MCS_1 \cup MCS_0$,
where

$MCS_0 = MCS[F_0]$

$MCS_1 = \{v.\pi; \pi \in MCS[F_1] \div MCS_0\}$

and $P \div Q = \{\pi \in P ; \rho \in Q, \rho$ is not included in $\pi\}$

Case 3: Neither v nor $\overline{v}$ belong to L. In that case,

$$MCS[F] = MCS[F_1] \cup MCS[F0]$$

25.3.5 Cutoffs, p-BDD and Direct Computations

The number of prime implicants of a Boolean function involving *n* variables is in $O(3^n)$, and $O(2^n)$ if the function is monotone [25]. There is no direct relationship between the size of the BDD encoding the function and the ZBDD encoding its prime implicants. Not much progress has been done in establishing this relationship (see however [26]). In practice, it is sometimes the case that building the BDD is tractable, while building the ZBDD is not. Non-coherent models are more specifically subject to this phenomenon.

When the ZBDD takes too much time or space to build, it is still possible to apply cutoffs to keep only PI or MCS whose size (or equivalently probability) is lower than a given threshold. To do so, it suffices to introduce the threshold into the decomposition theorem (see [11] for more details).

Moreover, rather than computing the BDD and then the ZBDD encoding MCS, it is possible either to compute a truncated BDD and then the ZBDD from this truncated BDD [11] or to compute directly the ZBDD encoding (the most important) MCS [27] (see Section 25.5.1).

25.4 Probabilistic Assessments

One of the main advantages, if not the main, of the BDD technology for reliability and dependability analyses stands in the accuracy and the efficiency of the assessment of probabilistic quantities. In this section, we present algorithms to compute top event probabilities, importance factors, and to perform time dependent analyses.

25.4.1 Probabilities of Top (and Intermediate) Events

Top event probabilities can be assessed either from BDD or from ZBDD. Since these data structures are based on different decomposition principles, algorithms used in each case are different. Exact computations are performed with BDD. Rare events approximation is applied on ZBDD similarly to what is done with an explicit encoding of MCS, but with a better efficiency, thanks to sharing. The algorithm to compute the probability of a gate from a BDD is based on the Shannon Decomposition. It is defined by the following recursive equations [6].

$$\text{BDD-Pr}(0) = 0.0$$
$$\text{BDD-Pr}(1) = 1.0$$
$$\text{BDD-Pr}(v.F_1 + \overline{v}.F_0) = p(v).\text{BDD-Pr}(F_1) + (1-p(v)).\text{BDD-Pr}(F_0)$$

As a consequence, the result is exact. Moreover, a caching mechanism is used to store intermediate results. Therefore, the algorithm is linear in the size of the BDD.

The algorithm to compute the top event probability from a ZBDD is based on the rare events approximation, i.e: $p(S) \approx \sum_{\pi \in MCS[S]} p(\pi)$. It is defined by the following recursive equations.

$$\text{ZBDD-Pr}(0) = 0.0$$
$$\text{ZBDD-Pr}(1) = 1.0$$
$$\text{ZBDD-Pr}(v.S_1 \cup S_0) = p(v).\text{ZBDD-Pr}(S_1) + \text{ZBDD-Pr}(S_0)$$

The corresponding algorithm is also linear in the size of the ZBDD which is in general much smaller than the size of the set of MCS. Therefore, even when the BDD technology just mimics MCS calculations, it improves significantly the efficiency of the approach.

The assessment of importance factors rely on the computation conditional probabilities $p(S|e)$ and $p(S|\overline{e})$, where S is a gate and e is a basic event. BDD makes it possible to compute both (thanks again to the Shannon decomposition). Recursive equations are as follows.

BDD-Pr(0|e) = 0.0
BDD-Pr(1|e) = 1.0
BDD-Pr($v.F_1 + \overline{v}.F_0$ |e) = // if (v<e)
p(v).BDD-Pr(F_1|e) + (1-p(v)).BDD-Pr(F_0|e)
BDD-Pr($v.F_1 + \overline{v}.F_0$ |e) = // if (v>e)
BDD-Pr($v.F_1 + \overline{v}.F_0$)
BDD-Pr($v.F_1 + \overline{v}.F_0$ |v) = BDD-Pr(F_1|v)
BDD-Pr($v.F_1 + \overline{v}.F_0 | \overline{v}$) = BDD-Pr(F_0| $\overline{v}$)

Again, the corresponding algorithm gives exact results and is linear in the size of the BDD. The ZBDD algorithm is very similar and does not deserve a further presentation.

25.4.2 Importance Factors

One of the principal activities of risk assessment is expected to be either the ranking or the categorization of structures, systems and components with respect to their risk-significance or their safety significance. Several measures of such significance have been proposed for the case where the support model is a fault tree. These measures are grouped under the generic designation of "importance factors". Many articles and book chapters have been devoted to their mathematical expressions, their physical interpretations, and the various ways they can be evaluated by computer programs (see, *e.g.*, [7, 8]). Seminal work on the use of BDD to assess importance factors has been done by J. Andrews and his students [28 and 12], followed by Dutuit and Rauzy [14]. In this section, we review the main importance factors and we discuss the BDD and ZBDD algorithms to assess them. Our presentation follows mainly the reference [14].

25.4.2.1 Marginal Importance Factor

The first importance factor to consider is the marginal importance factor, denoted by MIF(S,e) which is defined as follows.

$$\mathrm{MIF}(S,e) = \frac{\partial(p(S))}{\partial(p(e))}.$$

MIF is often called the Birnbaum importance factor in the literature [29]. It can be interpreted, when S is a monotone function, as the conditional probability that, given that e occurred, the system S has failed and e is critical, *i.e.,* a repair of e makes the system work. The following equalities hold.

$$\mathrm{MIF}(S,e) = \frac{\partial(p(S))}{\partial(p(e))}$$

$$= p(S_{[e\leftarrow 1]}.\overline{S_{[e\leftarrow 0]}}) \qquad \text{(i)}$$

$$= p(S/e) - p(S/\overline{e}) \qquad \text{(ii)}$$

Equality (i) holds only in the case of monotone functions. Equality (ii) can be used to compute MIF(S,e), by means of two conditional probability calculations. However, MIF(S,e) can also be computed in a single BDD traversal using the following recursive equations.

BDD-MIF(0|e) = 0.0
BDD-MIF(1|e) = 0.0
BDD-MIF($v.S_1 + \overline{v}.S_0$ |e) = // if e < v
p(v).BDD-MIF(S_1|e) + (1-p(v)).BDD-MIF(S_0|e)
BDD-MIF($v.S_1 + \overline{v}.S_0$ |e) = 0.0 // if e > v
BDD-MIF($e.S_1 + \overline{e}.S_0$ |e) =
BDD-Pr(S_1|e) - BDD-Pr(S_0| $\overline{e}$)

The corresponding algorithm is linear in the size of the BDD. A last way to compute MIF(S,e) is to use a numerical differentiation. The ZBDD algorithm to compute MIF(S,e) is very similar and is also linear in the size of the ZBDD.

25.4.2.2 Other Classical Importance Factors: CIF, DIF, RAW and RRW

Beyond the MIF, the most diffuse importance factors and their definitions are reported in Table 25.1. We refer to [14, 30, 31] for a thorough discussion of the definitions of CIF, DIF, RAW and RRW. BDD and ZBDD algorithms to compute these importance factors are derived straight from their definition and the rare event approximation, respectively.

It is worth noting that there are many real-life models for which the ranking obtained with BDD and ZBDD algorithms do not coincide (see, *e.g.*, [15]). The effects of such a discrepancy are ignored

by most of the practitioners and by regulation authorities.

25.4.2.3 Discussion

The reliability engineering literature often refers to another importance factor called Fussel–Vesely which is defined as follows.

$$\mathrm{FV}(S,e) = \frac{p\left(\bigcup_{e.\pi \in \mathrm{MCS}[S]} e.\pi\right)}{p(S)}$$

If the rare event approximation is applied and the numerator is approximated by $\sum_{e.\pi \in \mathrm{MCS}[S]} p(e.\pi)$, we have FV(S,e) = CIF(S,e). Many authors consider thus that these two measures are actually the same. However, FV(S,e) as defined above has no interpretation in terms of system state. One of the merits of the introduction of BDD algorithm has been to show this kind of incoherence in the mathematical foundations of reliability engineering.

Recently,E. Borgonovo and G.E. Apostolakis introduced a new importance measure, called the differential importance measure (DIM), which is defined as follows [32].

$$\mathrm{DIM}(S,e) = \frac{\frac{\partial p(S)}{\partial p(e)} \mathrm{d}\,p(e)}{\sum_v \frac{\partial p(S)}{\partial p(v)} \mathrm{d}\,p(v)}$$

DIM(S,e) has a number of interesting properties. It is additive, so the DIM of a group of basic events is the sum of their DIM. It is shown in [32] that if the dp(v) are all the same then DIM(S,e) is proportional to MIF(S,e) and if the dp(v) are proportional to the p(v), then DIM(S,e) is proportional to CIF(S,e). As noted by the authors, the calculations of DIM(S,e) can be done at almost no cost once either the MIF(S,e)'s or the CIF(S,e)'s have been computed (depending of the chosen type of variations).

Table 25.1. Importance factors

Importance factor	Symbol	Definition	Rare event approximation
Top event probability	p(S)	p(S)	$\sum_{\pi \in \mathrm{MCS}[S]} p(\pi)$
Marginal importance factor	MIF(S,e)	$\frac{\partial(p(S))}{\partial(p(e))}$	$\sum_{e.\pi \in \mathrm{MCS}[S]} p(\pi)$
Critical importance factor	CIF(S,e)	$\frac{p(e)}{p(S)} \times \mathrm{MIF}(S,e)$	$\frac{\sum_{e.\pi \in \mathrm{MCS}[S]} p(e.\pi)}{\sum_{\pi \in \mathrm{MCS}[S]} p(\pi)}$
Diagnostic importance factor	DIF(S,e)	$p(e\|S) = \frac{p(e) \times p(S\|e)}{p(S)}$	$p(e) \times \mathrm{RAW}(S,e)$
Risk achievement worth	RAW(S,e)	$\frac{p(S\|e)}{p(S)}$	$\frac{\sum_{\pi \in \mathrm{MCS}[S]} p(\pi[e \leftarrow 1])}{\sum_{\pi \in \mathrm{MCS}[S]} p(\pi)}$
Risk reduction worth	RRW(S,e)	$\frac{p(S)}{p(S\|\overline{e})}$	$\frac{\sum_{\pi \in \mathrm{MCS}[S]} p(\pi)}{\sum_{\pi \in \mathrm{MCS}[S]} p(\pi[e \leftarrow 0])}$

25.4.3 Time Dependent Analyses

Another important issue stands in so-called time dependent analyses. A fault tree model makes it possible to assess system availability, *i.e.*, the probability that the system works at time t. The system reliability, *i.e.*, the probability that the system worked without interruption from time 0 to time t, can only be approximated if the system involves repairable components.

There are industrial systems for which the latter notion is more relevant than the former, *e.g.*, the safety instrumented system with a high demand described in the norm CEI 61508. Other norms require the assessment of an equivalent failure rate for the system, which is strongly related to its reliability, as we shall see. The accuracy and efficiency of BDD calculations make it possible to design interesting algorithms to approximate both reliability and equivalent failure rate. The following presentation follows reference [33].

25.4.3.1 Assumptions, Definitions and Basic Properties

Throughout this section, we make the following assumptions.

Systems under study involve repairable and non-repairable components.

Each component e has two modes (working and failed), a failure rate λ_e and repair rate μ_e. If the component is non-repairable, μ_e is null. λ_e and μ_e are constant through time. The probability $Q_e(t)$ that the component has failed at time t is therefore obtained by the following equation [9].

$$Q_e(t) = \frac{\lambda_e}{\lambda_e + \mu_e} \times \left(1 - e^{-(\lambda_e + \mu_e).t}\right)$$

Components are independent, *i.e.*, both their failures and their repairs are statistically independent.

Components are as good as new after a repair. They are as good as new at time 0. Failures of systems under study are modeled by means of coherent fault trees. In the sequel, we assimilate systems with their fault trees.

As a consequence, systems under study can also be represented as Markov models. Let S denote the system under study. Let T denote the date of the first failure of S. T is a random variable. It is called the lifetime of S.

The *availability* $A_S(t)$ of S at t is the probability that S is working at t, given that all its components were working at 0. The *unavailability* $Q_S(t)$ is just the opposite.

$$A_S(t) \stackrel{def}{=} \Pr\{\text{S is working at t}\}$$

$$Q_S(t) \stackrel{def}{=} 1 - A_S(t)$$

The *reliability* $R_S(t)$ of S at t is the probability that S experiences no failure during time interval [0,t], given that all its components were working at 0. The *unreliability*, or cumulative distribution function $F_S(t)$, is just the opposite. Formally,

$$R_S(t) \stackrel{def}{=} \Pr\{t < T\}$$

$$F_S(t) \stackrel{def}{=} \Pr\{t \geq T\} = 1 - R_S(t)$$

The curve $R_S(t)$ is a survival distribution. This distribution is monotonically decreasing. Moreover, the following asymptotic properties hold.

$$\lim_{t \to 0} R_S(t) = 1$$

$$\lim_{t \to \infty} R_S(t) = 0$$

Note that $Q_S(t) \leq F_S(t)$, for general systems and that $Q_S(t) = F_S(t)$, for systems with only non-repairable components. The algorithms described in Section 25.4.1 compute $F_S(t)$.

The *failure density* $f_S(t)$ refers to the probability density function of the distribution of T. It is the derivative of $F_S(f)$:

$$f_S(t) \stackrel{def}{=} \frac{d\,F_S(t)}{dt}$$

For sufficiently small dt's, $f_S(t).dt$ expresses the probability that the system fails between t and t+dt, given its was working at time 0.

The *failure rate* or hazard rate $r_S(t)$ is the probability the system fails for the first time per unit of time at age t. Formally,

$$r_S(t) \stackrel{def}{=} \lim_{dt \to 0} \frac{\Pr\{\text{S fails btw. t and t + dt} / C\}}{dt}$$

where C denotes the event "the system experienced no failure during the time interval [0,t]". The following property is well known.

$$R_S(t) = \exp\left[-\int_0^t r_S(u)\,du\right]$$

The *conditional failure intensity* $\lambda_S(t)$ refers to the probability that the system fails per unit time at time t, given that it was working at time 0 and is working at time t. Formally,

$$\lambda_S(t) \stackrel{def}{=} \lim_{dt\to 0} \frac{\Pr\{\text{S fails btw. t and t + dt / D}\}}{dt}$$

where D denotes the event: "the system S was working at time 0 and is working at time t". The conditional failure intensity is sometimes called Vesely rate. $\lambda_S(t)$ is an indicator of how likely the system is to fail.

The *unconditional failure intensity* $w_S(t)$ refers to the probability that the system fails per unit of time at time t, given it was working at time 0. Formally,

$$w_S(t) \stackrel{def}{=} \lim_{dt\to 0} \frac{\Pr\{\text{S fails btw. t and t + dt / E}\}}{dt}$$

where E denotes the event "the system was working at time 0". Note that $w_S(t) = f_S(t)$ for systems with only non-repairable components. The following property is easily deduced from the definitions [33]:

$$\lambda_S(t) = \frac{w_S(t)}{A_S(t)}.$$

The unconditional failure intensity is sometimes called the "instantaneous equivalent failure rate". In some reliability studies, regulation authorities require the computation of its mean value through a period of time. This *mean equivalent failure rate* is defined as follows:

$$\lambda_S^{[Mean]}(t) = \frac{\int_0^t \lambda_S(t).dt}{t}.$$

25.4.3.2 Calculations

The set of states in which the system S has failed can be decomposed in three subsets: the set S_1 of states in which the repair of the component e repairs the system, the set S_0 of states in which the failure of e repairs the system, and the set S_2 of states in which the system has failed, whatever the state of the component e.

Since the system is assumed to be coherent, $S_0 = \varnothing$. It follows that $S[e\leftarrow 1]$ describes $S_1 \cup S_2$ and $S[c\leftarrow 0]$ describes S_2. Let $CRIT_{S,e}(t)$ denote the probability that system S is in a critical state w.r.t. the component e at time t, *i.e.* a state in which S has not failed and a failure of e induces a failure of S. From the above developments, the following equality holds:

$$CRIT_{S,e}(t) = A_e(t) \times MIF_{S,e}(t).$$

For a sufficiently small value of dt, the probability that the system fails between t and dt is as follows:

$$\Pr\{\text{the system fails between t and t + dt}\} \approx \sum_{e\in S} dt.\lambda_e.CRIT_{S,e}(t).$$

Therefore, assuming that the system was perfect at time 0, the following equality holds:

$$w_S(t) = \sum_{e\in S} MIF_{S,e}(t).w_e(t),$$

where $w_e(t) = \lambda_e.A_e(t)$. In reference [33], four approximations of the reliability are considered, each having its own merits and drawbacks. They are given (without justification) in Table 25.2 .

Table 25.2. Approximations of reliability

Name	Approximation of $F_S(t)$
Murchland	$\int_0^t w_S(t).dt$
Barlow–Proschan [34]	$t.\lambda_S(\infty)$
Vesely	$1-\exp\left[-\int_0^t \lambda_S(u)\,du\right]$
asymptotic Vesely	$1-e^{-\lambda_S(\infty).t}$

The assessment of both the reliability and of equivalent failure rate rely on the evaluation of $w_S(t)$. Moreover, lots of calculations are required for numerical integrations. That is the reason why the BDD technology improves significantly, here again, the engineering process. In order to implement these computations, we need basically two algorithms: an algorithm to assess $Q_S(t)$ and an

algorithm to assess $MIF_{S,e}(t)$ or equivalently $w_S(t)$. Integrals are computed numerically using in general triangular approximation. Sections 25.4.1 and 25.4.2 present the algorithms to evaluate $Q_S(t)$ and $MIF_{S,e}(t)$. However, $w_S(t)$ can be obtained by means of two traversals of the BDD which avoids performing a computation of $MIF_{S,e}(t)$ for each basic event e. The corresponding recursive equations are as follows (for the sake of simplicity, the time t is omitted).

$$\text{BDD-w}(1) = 0$$
$$\text{BDD-w}(0) = 0$$
$$\text{BDD-w}(e.S_1 + \bar{e}.S_0) =$$
$$w_e \times [\text{BDD-Pr}(S_1) - \text{BDD-Pr}(S_0)] + p(e) \times \text{BDD-w}(S_1) + (1-p(e)) \times \text{BDD-w}(S_0)$$

The algorithm derived from the above equations is linear in the size of the BDD and therefore does not depend on the number of components, conversely to the algorithm that calculates the MIF of each component.

25.5 Assessment of Large Models

The assessment with BDD of large models, especially large event trees coming from the nuclear industry, is still challenging. Two different approaches can be tried to handle this problem: the first one consists of using ZBDD to implement classical MCS algorithms. The second approach consists of designing heuristics and strategies to reduce the complexity of the BDD construction. In this section, we discuss both approaches.

25.5.1 The MCS/ZBDD Approach

Set operations (union, intersection, elimination of non-minimal cutsets…) can be performed on ZBDD in the same way logical operations are performed on BDD. It is therefore possible to design ZBDD algorithms to compute MCS, without constructing BDD at all. Moreover, cutoffs can be applied on each intermediate ZBDD. By tuning these cutoffs, one is always able to get a result. In practice, the obtained results are often accurate enough. Such algorithms can be seen as ZBDD implementations of classical MCS algorithms, with the advantage of a compact representation and efficient set operations. The algorithm proposed in [27] outperforms the classical MCS algorithm previously implemented in the same fault tree tool. This additional success of the BDD technology should not hide the problems inherent in this approach.

These problems come from three sources: first, the MCS approximation of the underlying function; second, the use of cutoffs; and third, the use of rare event approximations. Rare event approximation is not really an issue if basic event probabilities are low (say below 10^{-3}), which is in general the case. Moreover, it is conservative. The effect of the two other approximations is pictured in Figure 25.5.

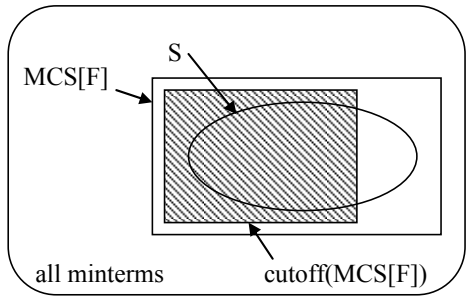

Figure 25.5. Effects of MCS approximation and cutoffs

Considering MCS[S] rather than the function S itself is an upper approximation of the function [11], *i.e.,* it is conservative. Note that MCS[S] = S if S is a coherent model. The use of cutoffs is an optimistic approximation of MCS[S]. It follows that if the model is not coherent, like success branches of event trees, what is computed and the actual function may be quite different. Epstein and Rauzy showed that the MCS approach may lead to erroneous results [15].

The determination of the "right" cutoffs requires some expertise and always results in a tradeoff between the complexity of calculations and the accuracy of the results [35, 36]. From a theoretical view point, nothing can prevent cutoffs from producing flawed results.

The MCS approach has another drawback: if the probability of a basic event varies (like in sensitivity analyses), the whole set of MCS should be recomputed which is indeed costly.

Despite all these problems, the MCS/ZBDD approach is the state-of-the-art technology used to assess large models of nuclear industry.

25.5.2 Heuristics and Strategies

Many techniques have been proposed to improve the construction of the BDD, including various preprocessing of the formula (rewritings, modularization), static and dynamic variable ordering heuristics, and strategies of construction. Dozens of articles have been published on those subjects. We give here only a few hints about their respective interest and limits.

Rewritings like those proposed in [37, 38] (coalescing, literal propagation, grouping of common factors, application of de Morgan's law) simplify formulae and must certainly be present in any fault tree assessment toolbox. However, they are not so easy to implement efficiently. Modularization [39, 40], which consists of isolating independent parts of the formulae, can also be helpful, but in our experience, large models have only few modules.

Most of the static variable ordering heuristics can be seen as two steps processes: first, arguments of gates are sorted according to some metrics and second, a depth first left most ordering is applied (*e.g.*, [20, 21]). This later ordering is interesting because it tends to keep close related variables. Static variable ordering heuristics can improve significantly the BDD construction. However, they are not versatile: a heuristic may be very efficient on one model and quite bad on another one. In [41], it is suggested to embed these heuristics into strategies. The idea is to rearrange more or less at random the arguments of gates and then to apply a heuristics. If the obtained formula is not tractable in a limited amount of time or space, then a new rearrangement is tried, and so on. The allowed time and space for each try may evolve based on the results of the first tries. This kind of strategy has been applied successfully to several large fault trees.

Dynamic variable reordering heuristics (see, *e.g.*, [3 and 22]) are considered as a significant improvement of the BDD technology when applied to logical circuits. Their application to large reliability models has been up to now quite deceptive: they are much too time consuming. It is often better to restart the calculation from scratch with a new candidate order, as suggested in [41].

Dramatic improvements can be obtained by combining the above ideas and there is room for innovation. Assessing large event trees of nuclear industry is still challenging.

25.6 Conclusions

Since their introduction in reliability and dependability studies, binary decision diagrams (BDD) have proved to be of great interest from both a practical and theoretical point of view. Not only does this technology provide more efficient and more accurate algorithms, but also mathematical foundations have been questioned and more firmly established.

In this chapter, we presented various aspects of the use of BDD for reliability and dependability studies. First, we discussed the mathematical basis of the notion of minimal cutsets (MCS). We described BDD algorithms to compute and to store MCS. Second, we reviewed the notion of importance factors. We gave recursive equations from which linear time BDD algorithms to compute MIF, CIF, DIF, RAW and RRW are easily derived. Third, we studied so-called time dependent analyses, which include approximations of reliability and computation of equivalent failure rates. Finally, we reviewed various techniques that can be used to handle large models.

The introduction of BDD in the reliability engineering framework has been successful. However, large event tree models coming from the nuclear industry are still out of the reach of an exact evaluation. It can be argued that these models are anyway too large to be mastered and that approximate computations are good enough. Nevertheless, the design of heuristics and strategies to handle these models and the integration of these

techniques into user friendly toolboxes would be a real accomplishment.

Field Data Analysis for Repairable Systems: Status and Industry Trends

David Trindade and Swami Nathan

Sun Microsystems Inc., USA

Abstract: The purpose of this chapter is to present simple graphical methods for analyzing the reliability of repairable systems. Many talks and papers on repairable systems analysis deal primarily with complex parametric modeling methods. Because of their highly esoteric nature, such approaches rarely gain wide acceptance into the reliability monitoring practices of a company. This chapter will present techniques based on non-parametric methods that have been successfully used within Sun Microsystems to transform the way reliability of repairable systems is analyzed and communicated to management and customers. Readers of the chapter will gain the ability analyze a large dataset of repairable systems, identify trends in the rates of failures, identify outliers, causes of failures, and present this information using a series of simple plots that can be understood by management, customers and field support engineers alike.

26.1 Introduction

Any system that can be restored to operating condition after experiencing a failure can be defined as a repairable system. The restoration to operating condition can be any action, manual or automated, that falls short of replacing the entire system. A non-repairable system, on the other hand, is discarded upon failure, *i.e.*, there are no cost effective actions to restore the system to its operating state. Repairable systems are common in all walks of life, *e.g.*, computer servers, network routers, printers, storage arrays, automobiles, locomotives, *etc*. Although repairable systems are very common, the techniques for analyzing repairable systems are not as prevalent as those for non-repairable systems. Most textbooks on reliability deal primarily with the analysis of non-repairable systems.

The techniques for repairable systems found in the literature are primarily parametric methods based on assuming a non-homogeneous Poisson process. These techniques demand a high degree of statistical knowledge on the part of the practitioner to understand various distributional assumptions, the concept of independence, and so on. This situation often leads to incorrect analysis techniques due to confusion between the hazard rate and rate of occurrence of failures [1, 2]. Furthermore, the difficulty of communicating these techniques,to management and customers (who often lack statistical background knowledge) renders them impractical for widespread usage within an organization.

Widespread adoption of any technique can become a reality within an organization only if it is easy to use as well as articulated by the lay person. Recently, analysis of repairable systems based on non-parametric methods have become increasingly popular due to their simplicity as well as their ability to handle more than just *counts of recurrent events* [3, 4, 5, 6, 7].

This chapter provides a simple yet powerful approach for performing reliability analysis of repairable systems using non-parametric methods. Simple plotting methods can be used for identifying trends, discerning deeper issues relating to failure modes, assessing effects of changes and comparing reliability across platforms, manufacturing vintages, and environments. These approaches have been applied with great success to datacenter systems (both hardware and software). This chapter is based on courses and training sessions given to sales, support services, management, and engineering personnel within Sun Microsystems™. These techniques can be easily applied within a spreadsheet environment such as StarOffice™ or Excel™ by anybody. Only a very rudimentary knowledge of statistics is needed. Interesting examples and case studies from actual analysis of computer servers at customer datacenters are provided for all concepts.

Notation and Acronyms

MTBF	mean time between failure
MCF	mean cumulative function
CTF	calendar time function
RR	recurrence rate
ROCOF	rate of occurrence of failures
HPP	homogeneous Poisson process
NHPP	non-homogeneous Poisson process

26.2 Dangers of MTBF

The most common metric used to represent the reliability of repairable systems is MTBF or mean time between failures. This term is used pervasively and indiscriminately in many industries. MTBF is calculated by adding all the operating hours of all the systems and dividing by the number of failures. The popularity of the MTBF metric is due to its simplicity and its ability to cater to the *one number syndrome*. MTBFs are often stated by equipment manufacturers with imprecise definitions of a failure. MTBF hides information by not accounting for any trends in the arrival of failures and treating machines of all ages as coming from the same population.

There are several assumptions involved in stating an MTBF. Firstly, it is assumed that the failures of a repairable system follow a renewal process, *i.e.,* all failure times come from a single population distribution. A further assumption is that the times between events are independent and exponentially distributed with a constant rate of occurrence of events, and consequently, we have what is called a homogeneous Poisson process (HPP). The validity of a HPP is rarely checked in reality. As a result, strict reliance on the MTBF without a full understanding of the consequences can result in missing developing trends and drawing erroneous conclusions.

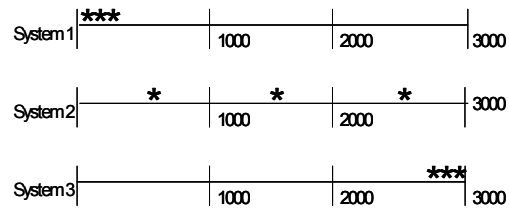

Figure 26.1. MTBF hides information

In Figure 26.1, we have three systems that have been operating for 3000 hours. Each system has experienced three failures within those 3000 hours. The MTBF for all three systems is 3000/3 = 1000 hours. The three machines have identical MTBFs but are their behaviors identical? Let us assume that each failure represents failure of an air regulator in scuba diving equipment. Which system should a user choose? Based on MTBFs, a customer may decide that any system is as good as the other for the next dive. However, System 1 had three early failures and none thereafter. System 2 had a failure in each 1000 hour interval while System 3 had three recent failures. The behaviors of the three systems are dramatically different and yet they have the same MTBF! When a customer is

shown the complete data instead of just MTBFs, the decision would be quite different. Thus, MTBF hides information. Relying entirely on a single metric can have severe consequences.

At the design stage of a product, the designer has to deal with components that are new and have no failure history. Often it may not be possible to find components from previous generations of the product that are "similar" in order to use field data. In these situations, it is permissible to use an MTBF for each component to build reliability estimates at the system levels. These metrics are used primarily to evaluate the relative merits of one design alternative against the other. It can also be used to make initial estimates of service costs and spares planning. However, it is not to be used as a guarantee on the reliability that a customer would experience. The following example illustrates how failures are actually distributed in the presence of a HPP.

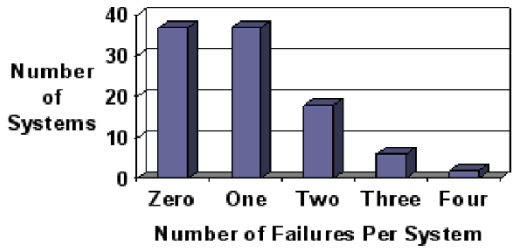

Figure 26.2. Distribution of 100 failures across 100 systems reaching MTBF

Consider a group of 100 identical HPP systems with an MTBF of 1000 hours. When all the systems reach 1000 hours, the expected number of failures is 1 failure per system or 100 total failures. However, we can use the Poisson distribution with an MTBF of 1000 hours to calculate the number of machines with zero, one, two failures and so on.

When all the systems reach 1000 hours (MTBF) there will be 37 systems with zero failures (on the average), 37 machines with 1 failure, 18 with 2 failures, 6 machines with 3 failures and 2 machines with 4 failures. It is obvious that from simple Poisson calculations there will be machines with 2, 3, and 4 failures. So a customer who assumes or is made to assume that the MTBF is a system life guarantee is going to be completely misled. Clearly there is a need for better reliability metrics that account for the time dependent nature of the reliability of repairable systems.

26.2.1 The "Failure Rate" Confusion

Despite Ascher's arguments more then 20 years ago [8], the term failure rate continues to be arbitrarily used in the industry and sometimes in academia to describe both a hazard rate of a lifetime distribution of a non-repairable system and a rate of occurrence of failures of a sequences of failure times of a repairable system. This lack of distinction can lead to poor analysis choices even by practicing reliability engineers.

Often the reciprocal of the MTBF is used to obtain what is commonly referred to as a failure rate. However the term failure rate has become a confusing term in the literature [1, 2] and even more so in the industry. Failure rate has been used for non-repairable systems, repairable systems and non-repairable components functioning within a repairable system. In each case, the meaning of the term changes slightly and the nuance is often lost on even the most well-intentioned of practitioners. Often engineers analyze data from repairable systems using methods for the analysis of data from non-repairable systems.

A non-repairable system is one that is discarded upon failure. The lifetime is a random variable described by a single time to failure. For a group of systems, the lifetimes are assumed to be *independent and identically distributed, i.e.*, from the same population. In this case, the "failure rate" is the hazard rate of the lifetime distribution and is a property of a time to failure. The hazard rate is the *conditional* probability that a component fails in a small time interval given that it has survived from zero until the beginning of the time interval. It is the *relative rate* of failure of a component that has survived until the previous instant.

A repairable system, on the other hand, is one that can be restored to an operating condition by any means short of replacing the entire system. The lifetime of the system is the age of the system or the total hours of operation. The random variables of interest are the *times between failures* and

number of failures at a particular age. In this case, the "failure rate" is the rate of occurrence of failures and is a property of a sequence of failure times. ROCOF or rate of occurrence of failures is the probability that a failure (not necessarily the first) occurs in a small time interval. It is the *absolute rate* at which failures occur.

Table 26.1 shows 10 failures. The failure times are provided in column 2 and the times between failures are provided in column 3. Each failure time represents failure of the server due to a CPU. The CPU is replaced with an identical CPU from the same population.

Table 26.1. Failure data for a CPU in a computer server

Failure Number	Failure Times	Time Between Failures
1	876	876
2	2382	1506
3	2576	194
4	2863	287
5	2912	49
6	2964	52
7	3120	156
8	3195	75
9	3249	54
10	3284	35

Let us consider the failure of a computer server due to a central processing unit or CPU. The computer server is a repairable system while the CPU is a non-repairable component. Table 26.1 provides the failure data.

If the data is analyzed as if it were from a non-repairable system, then the times between failures are treated as lifetimes of the CPU, *i.e.*, times to failure. The lifetimes can be sorted and a distribution can be fit to the ordered times to failure. There is no difference between the CPU being replaced 10 times within the server and 10 CPUs placed on a life test. Figure 26.3 shows a Weibull fit to the data. Maximum likelihood estimation provides a characteristic life of 277 and a shape parameter of 0.78. Since the shape parameter is less than 1, we can conclude that we have a decreasing hazard rate. In a repairable systems approach, we would plot the failures of

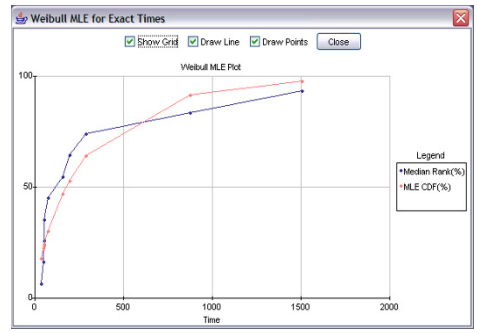

Figure 26.3. Weibull fit for the data in Table 26.1

CPUs as it would happen in the server, *i.e.*, against the age of the server.

In Figure 26.4, we have a plot of the cumulative number of CPU failures as a function of the age of the computer server. We can see that as the server gets older, CPU failures appear to be happening faster, *i.e.*, the slope of the curve which is the rate of occurrence of failures is actually increasing!

How can the rate of failures be increasing in reality when the Weibull analysis showed a decreasing rate? This behavior occurs because the times between failures are not independent and identically distributed. The time to first failure distribution is not identical to the time between first and second failure distribution and so on. The order of occurrence of failures is important because the component failures need to be viewed in the repairable system context. In fact, the fan was degrading in the computer, resulting in decreased ability of the system to remove thermal load. Increasing ambient temperatures decreased the

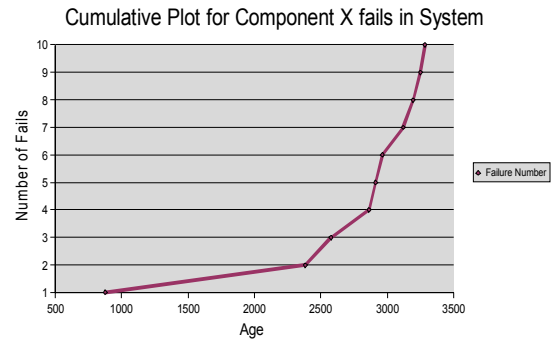

Figure 26.4. Cumulative CPU fails *vs*. system age

prospective lifetime of the CPU. Even though each replaced CPU was from the same population, it was performing in a harsher environment than its predecessor. Hence the Weibull analysis was invalid.

26.3 Parametric Methods

Most of the literature on the reliability of repairable systems deals with parametric methods. One of the common parametric approaches to modeling repairable systems reliability typically assumes that failures occur according to a non-homogeneous Poisson process with an intensity function. One of the popular intensity functions is the power law Poisson process [9, 10], which has an intensity function of the form

$$u(t) = \lambda\beta t^{\beta-1} \qquad \lambda, \beta > 0 \tag{26.1}$$

The probability that a system experiences n failures in *t* hours has the following expression:

$$P(N(t) = n) = \frac{(\lambda t^{\beta}) e^{-\lambda t^{\beta}}}{n!} \tag{26.2}$$

To estimate the two parameters in the model one can use maximum likelihood estimation. The equations for the parameter estimates are given in [8, 9]

$$\hat{\lambda} = \frac{\sum_{q=1}^{K} N_q}{\sum_{q=1}^{K} T_q^{\hat{\beta}} - S_q^{\hat{\beta}}}$$

$$\hat{\beta} = \frac{\sum_{q=1}^{K} N_q}{\hat{\lambda}\sum_{q=1}^{K}(T_q^{\hat{\beta}} \ln T_q - S_q^{\hat{\beta}} \ln S_q) - \sum_{q=1}^{K}\sum_{i=1}^{N_q} \ln X_{iq}} \tag{26. 3}$$

where we have *K* systems, *S* and *T* are start and end times of observation accounting for censoring, *Nq* is the number of failures on the *q*th system and *Xiq* is the age of the *q*th system at the *i*th failure.

These equations cannot be solved analytically and require an iterative procedure or special software. Crow [9] also provides methods for confidence interval estimation and a test statistic for testing the adequacy of the power law assumption. Further extensions of renewal process techniques known as the generalized renewal process were proposed by Kijima [11, 12]. Kijima models removed several of the assumptions regarding the state of the machine after repair that were present in earlier models. However, because of the complexity of the renewal equation, closed form solutions are not possible and numerical analysis can be quite tedious.

A Monte Carlo simulation based approach for the Kijima formulation was developed in [13]. Mettas and Zhao [14] present a general likelihood function formulation for estimating the parameters of the general renewal process in the case of single and multiple repairable systems. They also provide confidence bounds based on Fisher information matrix. A variety of intensity functions can be used and the software reliability literature has a plethora of such models.

Due to the complexity of these models, analysts often resort to using a simple HPP by hiding behind Drenick's theorem [15], which states that the superposition of a large number of stochastic processes over a long period of time behaves like a homogeneous Poisson process. This "central limit theorem" for renewal processes has been much abused similar to the indiscriminate usage of the normal distribution in day to day statistical analysis.

Despite the abundance of literature on the subject, parametric approaches are computationally intensive and not intuitive to the average person who performs data analysis. Special solution techniques are required along with due diligence in justifying distributional assumptions (rarely done in practice). The incorrect application of Weibull analysis shown in the previous section is a classic example. Communicating reliability information to customers using parametric methods can become quite difficult because often times customers think information is being hidden through *statistical cleverness*.

Non-parametric approaches based on MCFs are far simpler, understandable by lay persons and customers, and are easily implemented in a spreadsheet. The next sections cover the methodology.

26.4 Mean Cumulative Functions

26.4.1 Cumulative Plots

Given a set of failure times for a repairable system, the simplest graph that can be constructed is a cumulative plot.

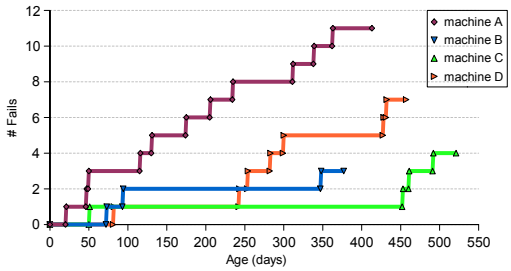

Figure 26.5. Cumulative plots for a group of four machines

The cumulative plot is a plot of the number of failures *versus* the age of the system.

The term failure is a generic term in the sense that one can plot hardware failures, software failures, outages, reboots, combinations of all failure modes, *etc*. The cumulative plot shows the evolution of failures over time. We can construct such a plot for every machine in the population. Figure 26.5 shows an example cumulative plot for a population with four machines. We have data on the age of the machine at various failure events. For example, machine C had one failure at 50 days and was failure free for over 400 days. After about 450 days machine, C had a rash of failures within the next 100 days of operation. Machine A has had the most number of failures at all ages.

Although a cumulative plot looks quite simple it is of great importance because of its ability to reveal trends. Figures 26.6, 26.7, and 26.8 show three different cumulative plots.

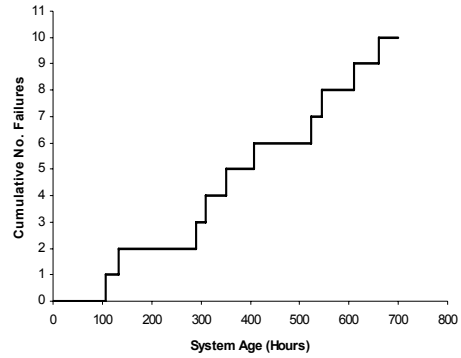

Figure 26.6. Cumulative plot for a stable system

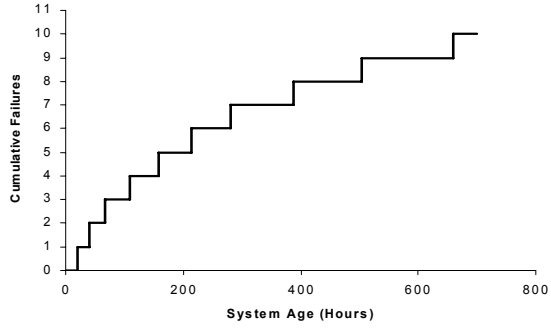

Figure 26.7. Cumulative plot for an improving system

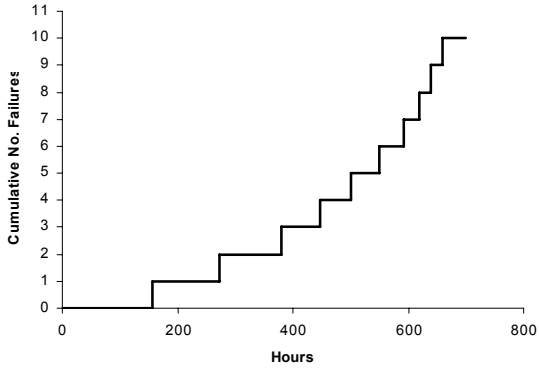

Figure 26.8. Cumulative plot for a worsening system

The shape of the cumulative plot can provide ready clues as to whether the system is improving, worsening, or stable. An improving system has the times between failures lengthening with age (takes longer to get to the next failure) while a worsening

system has times between failures shortening with age (takes less time to get to the next failure).

It is to be noted that all three plots show a system with 10 failures in 700 hours, *i.e.*, MTBF of 70 hours. Despite having identical MTBFs, the behaviors of the three systems are dramatically different.

26.4.2 Mean Cumulative Function *Versus* Age

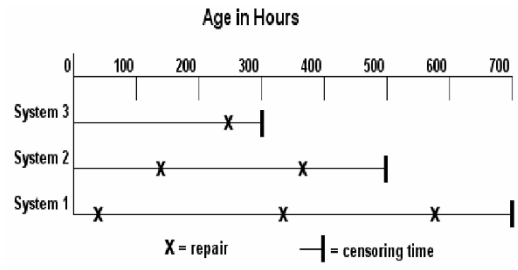
Typically a population consists of numerous machines, and so it could be quite tedious to construct a cumulative plot for each machine and visually extract the trend. A useful construct would be to plot the average behavior of these numerous machines. This is accomplished by calculating the mean cumulative function (MCF).

By taking a vertical slice on the set of cumulative plots at a particular point in time we can compute an average number of failures at that point in time. By moving this vertical slice along the time axis we can imagine an average function begin to emerge. The MCF is constructed incrementally at each failure event by considering the number of machines at risk at that point in time. The number of machines at risk depends on how many machines are contributing information at that particular point in time. Information can be obscured by the presence of censoring and truncation.

Right censoring occurs when information is not available beyond a certain age, *e.g.*, a machine that is 100 days old cannot contribute information to the reliability at 200 days, and hence is not a *machine at risk* when calculating the average at 200 days. Some machines may be removed from the population, *e.g.*, decommissioned. If a machine is decommissioned when it is 500 days old, then it is no longer a machine at risk when calculating the fails/machine at 600 days.

Left censoring occurs when information is not available before a certain age. Information may be obscured at earlier ages if for example a machine is installed on 1 June 2005 and the service contract was initiated on 1 June 2006. In this case there is no failure information available during the first year of operation. Therefore, this machine cannot contribute any information before 365 days of age but will factor into the calculation only after 365 days. One could also have interval or window censoring that is dealt with extensively in [16]. The MCF accounts for gaps in information by appropriately normalizing the number of failures by the number of machines at risk at each point in time and accumulating them.

The example below illustrates a step by step calculation of the MCF for three systems. The failure and censoring times are first sorted by magnitude. Now we can look at the population from a common time zero and see the evolution of failures and censoring with age. At age 33, system 1 had a failure, and since three machines operated beyond 33 hours (*i.e.,* number of machines at risk is three), the fails/machine is 1/3 and the MCF is 1/3. The MCF aggregates the fails/machine at all points in time where failures happen. At 135 hours, system 2 has a failure and there are still three machines at risk in the population. Therefore the fails/machine is 1/3, and the MCF aggregate of the fails/machine at points of failure is now 2/3. Similarly at 247 hours the MCF jumps to 3/3 due to a failure of System 3. At 300 hours, system 3



Time (Hrs)	Number of Systems at Risk	Failures per Machine	MCF
33	3	1/3	1/3
135	3	1/3	2/3
247	3	1/3	1
300	3		1
318	2	1/2	1.5
368	2	1/2	2
500	2		2
582	1	1/1	3
700	1	1/1	3

Figure 26.9. Step by step calculation of the MCF

drops out of the calculation, and the number of machines at risk becomes two. System 3 drops out not because it is removed (in this case), but simply because it is not old enough to contribute information beyond its current age, *i.e.*, it is not a machine at risk at ages beyond 300. At 318 hours, system 1 has a failure, and the fails/machine is now 1/2 since we have only two machines in the population that are contributing information. The MCF now becomes 3/3+1/2 and so on. This fairly straightforward procedure can be easily implemented in a spreadsheet.

Statistical software like SAS can be used to easily automate such a calculation for thousands of machines. Figure 26.10 shows the MCF for the population of machines shown in Figure 26.5. The MCF represents the average number of failures experienced by this population as a function of age. If a new machine enters the population, the MCF represents its expected behavior. It is to be noted that the parametric methods with all the distributional assumptions and mathematical complexities eventually attempt to estimate the same average number of failures *versus* system age. Confidence intervals can be provided for the MCF. Nelson [3, 7] provides several procedures for point-wise confidence bounds.

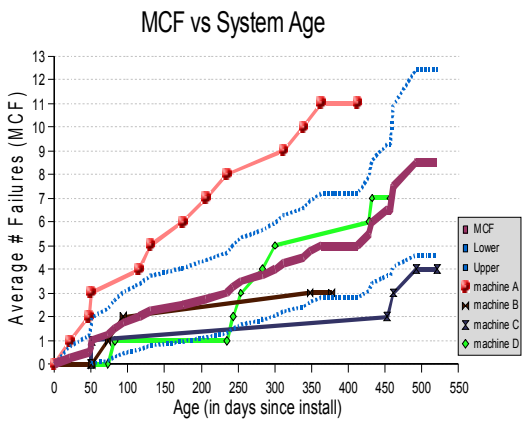


Figure 26.10. MCF and confidence intervals for the population in Figure 26.5

26.4.3 Identifying Anomalous Machines

In computer systems installed in datacenters, often a small number of misbehaving machines tend to obscure the behavior of the population at large. When the sample sizes are not too large, the simple confidence bounds can serve to graphically point out machines that have been having an excessively high number of failures compared to the average. In Figure 26.10, we can see that machine A has been having a much higher number of failures than the average at all ages. Although it is not a statistically correct test of an outlier, overlaying the cumulative plots of individual machines with the MCF and confidence bounds tend to visually point to problem machines when sample sizes are small. Support engineers can easily identify these problem machines and propose remediation measures to the customer. When sample sizes are larger, the confidence limits are close to the mean and so a visual approach would be meaningless to identify errant cumulative plots. More rigorous approaches for identifying these anomalous machines has been the subject of recent research. Glosup [17] proposes an approach for comparing the MCF with N machines with the MCF for (N−1) machines and arrive at a test statistic for determining if the omitted machine had a significant influence on the MCF. Heavlin [18] proposed a powerful alternate approach based on 2X2 contingency tables and the application of Cochran Mantel Hanzel statistic to identify anomalous machines. It can be thought of as an extension of the log rank test used to compare two Kaplan–Meier survival curves to mean cumulative functions.

26.4.4 Recurrence Rate *Versus* Age

Since the MCF is the cumulative average number of failures *versus* time one can take the slope of the MCF curve to obtain a rate of occurrence of events as a function of time. This slope is called the recurrence rate to avoid confusion with terms like failure rate [7].

The recurrence rate can be calculated by a simple numerical differentiation procedure, *i.e.,* estimate the slope of the curve numerically. This

can be easily implemented in a spreadsheet using the SLOPE(Y_1:Y_n, X_1:X_n) function where MCF is the Y axis and time is the X axis. One can take five or seven adjacent points and calculate the slope of that section of the curve by a simple ruler method and plot the slope value at the midpoint. The degree of smoothing is controlled by the number of points used in the slope calculation [19]. The rate tends to amplify sharp changes in curvature in the MCF. If the MCF rises quickly, it can be seen by a sharp spike in the recurrence rate, and similarly, if the MCF is linear the recurrence rate is a flat line. When the recurrence rate is a constant, it may be a reasonable assumption to conclude that the data follows a HPP, allowing for the use of metrics such as MTBF to describe the reliability of the population. It is also possible to fit an NHPP to the MCF and then take the derivative to get a smooth recurrence rate function which can be used for extrapolation and prediction.

Figure 26.11 is an example of a recurrence rate from a population of systems at a customer site. One can see from Figure 26.11 that the recurrence rate is quite high initially and drops sharply after around 50 days. Beyond 50 days the recurrence rate is fairly stable and keeps fluctuating around a fairly constant value. If the cause of failures were primarily hardware, then this would indicate potential early life failures, and one would resort to more burn-in or pre-release testing. In this case, the causes of the failures were more software and configuration type issues. This problem was identified as *learning curve issues* with systems administrators. When new software products are released, there is always a learning process to figure out the correct configuration procedures, setting up the correct directory paths, network links and so on. These activities are highly prone to human error because of lack of knowledge, improper documentation, and installation procedures. Making the installation procedure simpler and providing better training to the systems administrators resolved this issue in future installs of the product. Recurrence rates can be invaluable in identifying situations of interest to managing systems at customer sites.

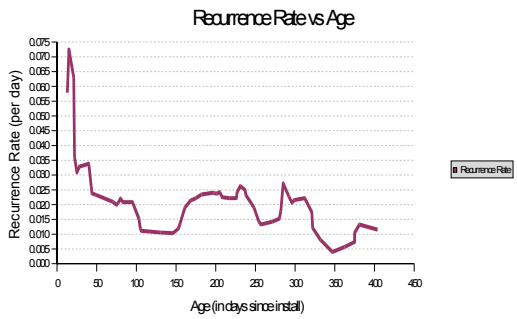

Figure 26.11. Example of recurrence rate *versus* age

26.5 Calendar Time Analysis

The reliability literature for the most part focuses on analyzing reliability as a function of the age of the system or the component. The time axis is always lifetime of the component from time zero. This approach is used because the systems are assumed not to undergo any dramatic changes during lifetimes other than routine maintenance. In the case of advanced computing and networking equipment installed in datacenters, the systems undergo changes on a routine basis that affect the reliability. There are software patches, upgrades, new applications, hardware upgrades to faster processors, larger memory, physical relocation of systems, *etc*. This situation can be quite different from other repairable systems like automobiles where the product configuration is fairly stable from production. Cars may undergo changes in the physical operating environment, but rarely do we see upgrades to a bigger transmission.

In datacenter systems many of the effects are a result of operating procedures that change the configuration and operational environment and not related to the age. So the textbook notion of the bathtub curve effects is often overwhelmed by activities that occur within a datacenter during particular periods of time. These changes are typically applied to a population of machines in the datacenter and the machines can all be of different ages. For example, we may have machines that were installed at various points during 2005. On 1 June 2006 all these machines will have different ages. However, an operating system upgrade may

be performed on all the machines on this particular date. If this improves or worsens the number of outages, then it is not an age related effect but a calendar time effect. It will be difficult to catch changes if the analysis is done as a function of the only of the age of the machine, but some effects will be quite evident when the events are viewed in calendar time [6]. This possibility is illustrated in Figures 26.12a and 26.12b.

Figure 26.12a shows the recurrence rate *versus* age for two systems, *i.e.*, the slopes of their cumulative plots. One can see that System 1 had a spike in the rate around 450 days while system 2 had a spike in the rate around 550 days. When looked at purely from an age perspective one can

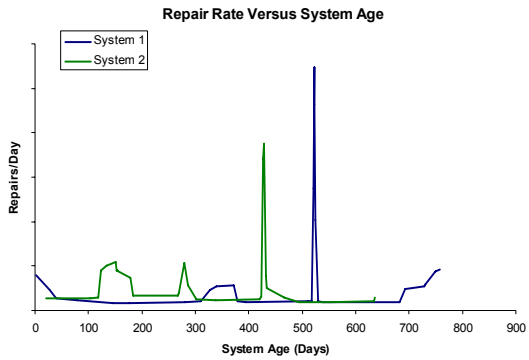

Figure 26.12(a). Recurrence rates for two systems *versus* age

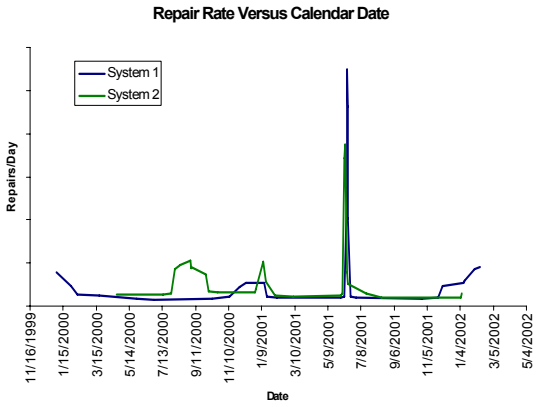

Figure 26.12(b). Recurrene rate for two systems *versus* date

easily conclude that they were two independent spikes related only to that particular system. One might falsely conclude that two different failure mechanisms may be in place. However, in Figure 26.12b, the recurrence rate *versus* date shows that the two spikes coincide on the same date. This indicates clearly that we are not dealing with an age related phenomenon but an external event related to calendar time. In this case it was found that a new operating systems patch was installed on both machines at the same time, and shortly thereafter, there was an increase in the rate of failures. By plotting the date as a function of calendar time one can easily separate the age related phenomenon from the date related phenomenon.

Calendar time analysis can reveal causes that will never be found by an age related analysis. In one study, a customer complained that all platforms from 2 processor machines to 32 processor machines were having serious quality problems. The customer mentioned that there were failures being observed at all ages of the machines indicating a severe quality problem. When the data was analyzed in calendar time, each platform showed a spike in the recurrence rate starting April of that year. When the customer was questioned about any special events that occurred in April, it was revealed that the customer had relocated all the machines from one datacenter to another and that the relocation was performed while construction was being complete. Clearly the stress of relocation and working in a not so clean environment was showing as problems in all platforms meaning there was not a severe quality problem with the products.

In order to analyze the data in calendar time, one can perform an analogous procedure by calculating the cumulative average number of fails per machine at various dates of failure. This result is called the calendar time function (CTF). We begin with the date on which the first machine was installed and calculate the number of machines at risk at various dates on which events occurred. As more machines are installed, the number of machines at risk keeps increasing until the current date. The population will decrease if machines are physically removed from the datacenter at

particular dates. This consideration is contrary to the machines at risk as a function of age where the number of machines will be a maximum at early ages and will start decreasing as machines are no longer old enough to contribute information. The calculation is identical to the table shown in Figure 26.9 except that we have calendar dates instead of age. The recurrence rate *versus* date is extremely important in practical applications because support engineers and customers can more easily correlate spikes or trends with specific events in the datacenter. The calculation of the recurrence rate *versus* date is identical to the procedure outlined for recurrence rate *versus* age. The SLOPE function in spreadsheets automatically converts dates into days elapsed and can calculate a numerical slope. This routine is an extremely useful and versatile function in spreadsheets.

26.6 Failure Cause Plots

The common approach to representing failure cause information is a Pareto chart or simple bar chart as shown in Figure 26.13. The frequencies of each failure cause are plotted independent of time. Based on Figure 26.13, one can conclude that cause A is the highest ranking cause while causes B,C and D are all equal contributors, and cause E is the lowest ranked cause in terms of counts. However, one can see that the Pareto chart has no time element, *i.e.*, one cannot tell which causes are current threats and which have been remediated. Yet this chart is one of the most popular representations in the industry. Sometimes stacked bar charts are used to divide the failure causes between multiple time periods, *i.e.*, a bar of one color representing time period one and a bar on top of a second color representing time period two. Use of these charts should be avoided due to their high ink-to-information ratio [20]. One can plot the failure causes as a function of time (age or calendar) to ascertain the evolution of failure mechanisms as a function of time.

Figure 26.14 shows the same plot as a function of calendar time, and it is quite revealing. One can see that even though cause A is only slightly higher than the other causes in Figure 26.13, its effect is

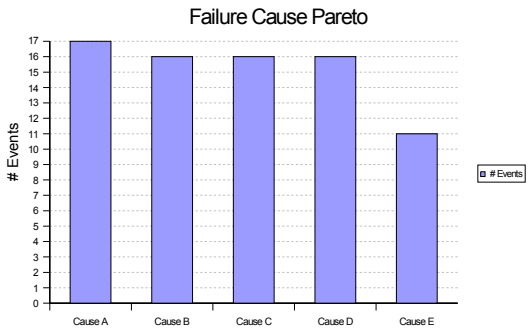

Figure 26.13. Example Pareto chart showing failure causes

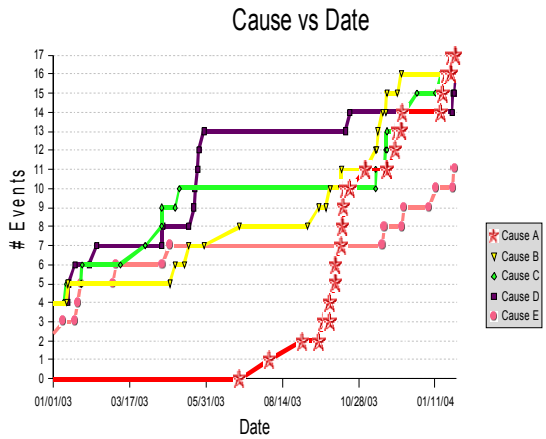

Figure 26.14. Failure causes *versus* date

dramatic when viewed in calendar time. It was non-existent for a while but became prevalent around September, with an extremely increasing trend. Even though Figure 26.13 showed that causes B,C and D were all equal contributors, their contributions in time are clearly not equivalent. Cause E was shown as the lowest ranked cause but we can see in Figure 26.14 that even though it has been dormant for a long time, there have been a rash of cause E events in very recent times, a situation that needs to be addressed immediately.

In Figure 26.14 the causes are plotted simply as counts. One can definitely plot MCFs as a function of age or calendar for each of the causes and normalize them by the machines at risk. One can easily imagine an MCF of all events with MCFs

for individual causes plotted along with it to show the contribution of each cause to the overall MCF at various points in time. This leads to one of the most useful aspects of MCFs which is the ability to compare one effect against another in a consistent fashion, *i.e.*, normalized and across time.

26.7 MCF Comparisons

26.7.1 Comparison by Location, Vintage or Application

Comparing one population with another in terms of reliability is a popular problem of interest in the industry. The company is interested in the performance of a particular server platform across all customers in a particular market segment, *e.g.*, finance, telecommunications, *etc*, to see if there are differences between customers. Customers are interested in comparing a population of machines in datacenter X with their machines in datacenter Y to see if there are differences in operating procedures between the two datacenters. Engineers might be interested in comparing machines running high performance technical computing with machines running online transaction processing to see if the effect of applications is something that needs to be considered in designs. Manufacturing might be interested in comparing machines manufactured in a particular year with machines manufactured in the following year to see if there are tangible improvements in reliability. The standard approach in the industry has been to calculate the MTBF of two populations and see if there is a significant difference. This approach is flawed because of inherent issues with the MTBF metric. The populations at multiple sites will be of different ages and comparing summary statistics will obscure all time dependent effects similar to the Pareto charts described in the failure cause plots section. The MCF by virtue of being time dependent and normalized by the number of machines at risk at all points in time facilitates meaningful comparisons of two or more populations. Figure 26.15 compares populations of machines belonging to the same customer but located in different datacenters.

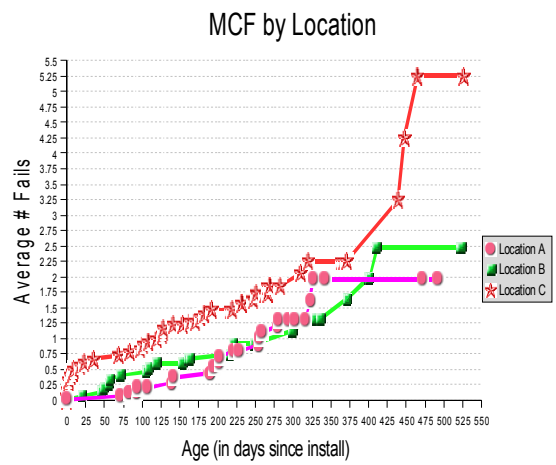

Figure 26.15. Comparison by location

One can see that location C has an MCF that has been consistently higher than the other locations. The difference between the locations starts to become visually apparent after about 300 days. Investigation into the procedures at location C revealed that personnel were not following correct procedures for avoiding electrostatic discharge while handling memory modules. This issue was rectified by policy and procedural changes and the reliability at this location improved. One can see that flattening of the MCF towards the end and becoming parallel with the MCFs for the other locations, *i.e.*, same slope or recurrence rate. Nelson provides procedures for assessing statistically significant difference between two MCFs [3]. However, procedures for comparing the differences of MCFs over the entire range and simultaneously comparing multiple MCFs are still topics of active research. Also, an approach to directly compare recurrence rates would be a quite useful notion and is also currently being researched. In most practical situations, a visual comparison is enough to initiate an investigation into the causes of differences between multiple platforms. It is easier to convince a lay person using visual significance than statistical significance, and a reliability engineer should err on the side of doing more root cause analysis (subject to resource constraints).

26.7.2 Handling Left Censored Data

Left censoring occurs when information on machines is not available before a certain age. Computers and storage equipment are installed at various times in a datacenter as part of the IT infrastructure. Often reliability data collection begins as an afterthought or possibly with the initiation of a service contract. Consequently, proper data is available only after a particular date. Due to the amount of missing information in the earlier ages, it would be difficult to compare MCFs because we do not know how many failures have occurred before we started collecting data. One way to deal with that is to do a parametric fit to the MCF, *e.g.*, linear or power law. We can then determine where the curve intersects the origin and use that intercept value as an estimate for the number of failures at the beginning of the measurement window. We can therefore create adjusted MCF curves as shown in Figure 26.16.

Alternatively, in this situation it would be advantageous to compare recurrence rates as a function of time instead of expected number of failures. This way we directly compare the rates in one time window with the rates in another time window to get an idea. With this we can avoid the estimation of the initial number of failures at the beginning of the time window; however, the rates being compared are in different time windows. This idea is shown in Figure 26.17. Machines manufactured in year XXXX appear to have the highest rate of failures. Year WWWW had small

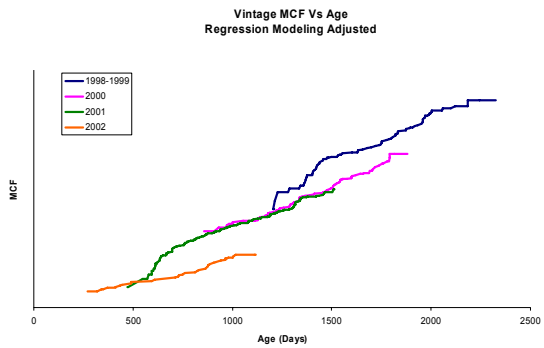

Figure 26.16. Adjusted MCF curve to account for window truncation

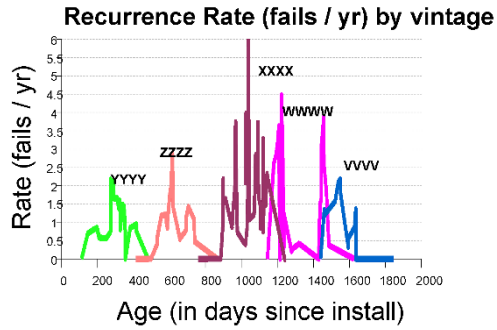

Figure 26.17. Comparison of recurrence rates *versus* age by vintage

spikes in the rate due to clustering of failures but otherwise has enjoyed long periods of low rates of failure. There appears to be no difference among years VVVV, YYYY and ZZZZ.

There does not appear to be a statistically rigorous procedure to assess significant difference between two recurrence rate curves. Visual interpretation has proved to be sufficient in practical experience.

One of the disadvantages of using MCF *versus* age is that the population at risk can fluctuate tremendously depending on the ages at which left and right censoring occurred and it can make interpretation quite difficult. It can be difficult to say with reasonable precision what the expected number of failures for a new machine entering the datacenter is going to be. Since computer systems are quite often subject to calendar time effects rather than age effects, we can look at the data in terms of date. By looking at the data in terms of date and not age we gain precision (sample size) in the later (recent) dates compared to the earlier dates. Hence the recurrence rate as a function of date can be used to state what the expected number of failures for a new machine entering the datacenter would be.

In Figure 26.18, we can see that the calendar time functions for all the manufacturing vintages begin on the same date because of left censoring. The difference between the vintages is clear. The newer vintages show significant reliability improvements over the older vintages. One can also take the slopes of these curves and plot the recurrence rates to compare the different vintages.

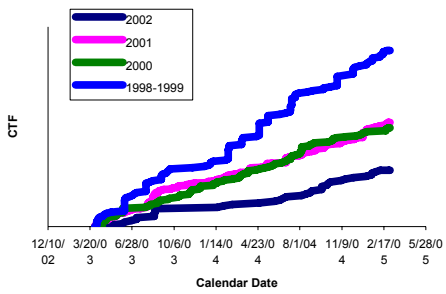

Figure 26.18. MCF *versus* calendar date by manufacturing vintage

Clearly these are superior approaches to simply comparing MTBFs.

26.8 MCF Extensions

All parametric methods apply primarily to "counts" data, *i.e.*, they provide an estimate of the expected number of events as they are generalizations of counting processes. However, the MCF is far more flexible than just counts data. It can be used in availability analysis by accumulating average downtime instead of just average number of outage events. MCFs can be used to track service cost per machine in the form of mean cumulative cost function. It can be used to track any continuous cumulative history (in addition to counts) such as energy output from plants, amount of radiation dosage in astronauts, *etc*. In this section we show two such applications that are quite useful for computer systems, namely downtime for availability and service cost.

26.8.1 The Mean Cumulative Downtime Function

Availability is of paramount importance to computing and networking organizations because of the enormous costs of downtime to business. Such customers often require service level agreements on the amount of downtime they can expect per year, and the vendor has to pay a penalty for exceeding the agreed upon guarantees. However, inherent availability defined as MTTF/(MTTF+MTTR) is merely a summary statistic. It is subject all the difficulties of interpretation described in the section on the dangers of MTBFs. The availability metric does not distinguish between a 50 minute outage and ten outages of 5 minutes each. However the two situations can be quite different for different customers. One customer might be able to live with numerous small outages while some customers prefer one single outage. For such situations it is useful to plot the cumulative downtime for individual machines and get a cumulative average downtime per machine as a function of time. The calculation would proceed identical to Figure 26.9 except that the integer counts of failure are replaced by the actual downtime due to the event. Since availability is a function of both the number of outage events and the duration of outage events, one needs to plot the mean cumulative downtime function as well as the MCF based on just outage events. Sometimes the cumulative downtime may be small but the number of outage events may be excessive, and this situation can be expensive because of the amount of failure analysis overhead that goes into understanding each outage. Contracts are often drawn on both the number of outage events as well as the amount of downtime. Figure 26.19 shows an example mean cumulative downtime function.

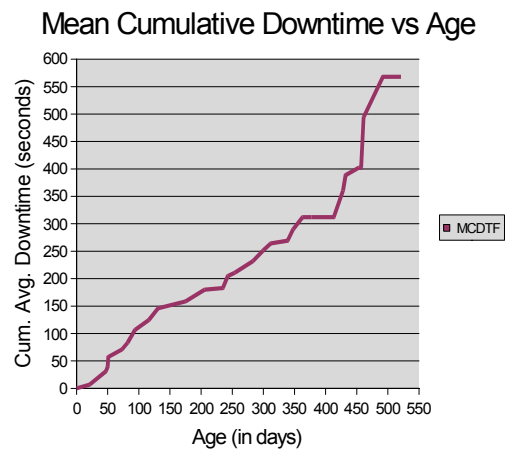

Figure 26.19. Mean cumulative downtime function

26.8.2 Mean Cumulative Cost Function

This application is quite similar to the downtime analysis mentioned in the previous section. This cost analysis could be performed by the vendor on service costs to understand one's cost structure, warranty program, pricing of subscription programs for support services, *etc*. The cost function could also be created by the customer to track the impact of failures on the business. The notion of downtime and the outage events can be combined to just one plot by looking at cost. The cost would be lost revenue due to loss of functionality plus all administrative costs involved in dealing with each outage. So in the situation of lots of outages with small amounts of downtime, the administrative costs will become noticeable. Again the calculation of the mean cumulative cost function would be similar to one of calculating an MCF for failure events except costs are used instead of counts of failures. These mean cumulative cost and downtime functions enjoy all the properties of an MCF in terms of being efficient, non-parametric estimators, and identifying trends in the quantity of interest.

In Figure 26.20, we have an example of a mean cumulative cost function for a population of machines in a datacenter. Similar to failure cause plots we can plot the breakdown of the total costs into their constituent costs, *i.e.*, cost of the event in terms of repair and root cause analysis costs and downtime costs in terms of lost revenue. This breakdown can provide invaluable information in understanding total cost of ownership as a function of time and assist in pricing service contracts and warranty offerings.

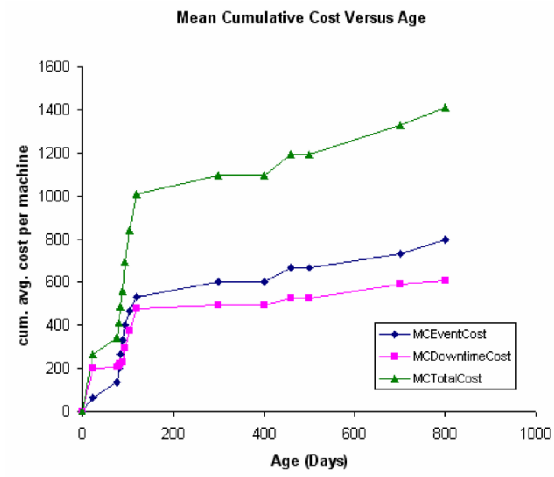

Figure 26.20. Mean cumulative cost function

26.9 Conclusions

This chapter discusses the analysis of repairable systems from the industry perspective. Parametric methods have been the mainstay of repairable systems research. However, they have not captured the attention of the industry because of the complexities of analysis as well as the difficulty in explaining the techniques to management and customers. These limitations are reasons why the industry persists on using summary statistics like MTBF. This chapter addresses the dangers of using summary statistics like MTBF and the important distinction between analyzing the data as a non-repairable or repairable system.

The analysis of repairable systems does not have to be difficult. Simple graphical techniques can provide excellent estimates of the expected number of failures without resorting to solving complex equations or justifying distributional assumptions. MCFs as a function of calendar time can provide important clues to non age related effects for certain classes of repairable systems. MCFs and recurrence rates are quite versatile because of their extensions to downtime and cost, while parametric methods mostly handle counts type data. The approaches outlined in this chapter have been successfully implemented at Sun Microsystems and also have found ready acceptance among people of varied backgrounds, from support technicians and executive management to statisticians and reliability engineers.

Non-parametric methods provide a happy medium between summary statistics and complex stochastic processes and are quite popular for non-repairable systems due to the huge survival analysis community in medical and biostatistics arena. However, the use of such techniques in repairable systems/recurrence analysis has not been as prolific as in survival analysis. There are still

several active areas of research in the use of MCFs, which will only serve to enhance the popularity of these techniques that are rapidly gaining acceptance within the industry.

Reliability Degradation of Mechanical Components and Systems

Liyang Xie, and Zheng Wang

Northeastern University, Shenyang, China

Abstract: This chapter focuses on time-dependent reliability assessment approaches. Two new methods are presented to depict the change of reliability with the increase of operation time or the number of applied load cycles. In the first part of this chapter, we present a time-dependent load-strength interference analysis method that models reliability degradation caused by a randomly repeated load. By describing the loading history as the Poisson stochastic process, time-dependent reliability models are developed, and the characteristics of the failure rate curve with respect to different component strength degradation patterns is discussed. In the second part, we present a residual life distribution based method by which we model the change of the residual fatigue life distribution with the number of load cycles. Based on the experimental study of residual fatigue life distributions of two metallic materials, a model is developed to calculate the parameters of residual fatigue life distribution under variable amplitude load history, by which residual life distribution parameters are determined with the known applied load history. Furthermore, a recursive equation is introduced to predict the probability of fatigue failure under variable amplitude load histories.

27.1 Introduction

Mechanical components or systems age in service, and their reliability decreases over service time or load history. The latter might result from strength degradation due to damage accumulation or simply from the multiple application effect of randomly imposed loads. To schedule a maintenance program reasonably, especially in the framework of reliability centered maintenance, the operation experience-dependent reliability of equipment in service must be correctly described and accurately predicted.

In contrast with the relatively mature reliability theory for electronic element and equipment, there are still difficulties with reliability design, reliability manufacturing, reliability assessment, and reliability management of mechanical systems. The techniques developed for the evaluation of electronic elements or systems are not always applicable to mechanical counterparts [1–2]. For instance, exponential distribution has been widely applied to electronic element or equipment life, but it is a serious drawback to the whole concept of RCM because the exponential distribution cannot be used to model items that fail due to wear, fatigue, corrosion or any other mode that is related to age [3].

Besides the more complicated failure mode and/or mechanism of mechanical components or systems compared with electronic element or equipment, more complex loading conditions, a

stronger dependence among different failure mechanisms or different component failures, more serious strength degradation and a more evident reliability decrease during operation also result in the complexity of the reliability problem of mechanical components and systems.

A great amount of research work has been done on reliability, availability and maintainability. For instance, Crocker [3] proposed a new approach for RCM to use the concepts of soft life and hard life to optimize the total maintenance cost. Xu *et al.* [4] developed a new class of computational methods, referred to as decomposition methods, to predict failure probability of structural and mechanical systems subject to random loads, material properties, and geometry. The idea of decomposition in multivariate functions originally developed by the authors for statistical moment analysis has been extended for reliability analysis. The methods involve a novel function decomposition that facilitates univariate and bivariate approximations of a general multivariate function, response surface generation of univariate and bivariate functions, and Monte Carlo simulation, and can solve both component and system reliability problems.

The necessity of time-variant reliability assessment of deteriorating structures is becoming increasingly recognized. Petryna [5] proposed an assessment strategy for structural reliability under fatigue conditions. It was illustrated that reliability assessment of structures under fatigue conditions is a highly complicated problem, which implies interaction of different scientific fields such as damage and continuum mechanics, non-linear structural analysis, and probabilistic reliability theory. In an earlier paper, Murty *et al.* [6] proposed an approach to describe residual fatigue strength distribution by which component fatigue reliability can be evaluated as a function of the number of load cycles.

Generally speaking, the conventional reliability model of component reliability calculation, *i.e.,* the well known load-strength interference model [7–12] underlies the hypothesis that the load is static or applied only once to the component during its life time. In other words, it cannot reflect the effect of the load history on reliability. For most mechanical systems, the operating loads subjected to components are dynamic or randomly repeated. In such a situation, the failure probability of a component or system will increase with the loading history, and a time-dependent reliability model is necessary.

27.2 Reliability Degradation Under Randomly Repeated Loading

FORM (first order reliability method) or SORM (second order reliability method) are widely used in reliability engineering. However, these methods cannot deal with time dependent random variables [13]. When fatigue reliability analysis has to consider certain time-dependent variables, it is difficult to incorporate discrete time dependent variables in FORM. Alternatively, the Monte Carlo method is applied when no case specific model can be used. The Monte Carlo method, although theoretically a universal approach, usually entails great computation effort, besides having other limitations.

A new time-dependent component reliability model is presented herein and the relationship between reliability/failure rate and service time (or the number of load cycles) is also described. First we analyze the failure process of a component subjected to randomly repeated load and the cumulative distribution function or the probability density function of the equivalent load. Based on the homogeneous Poisson process of the number of load cycles, time-dependent reliability models are derived with and without strength degradation, respectively, according to the load-strength interference relationship.

27.2.1 The Conventional Component Reliability Model

The load-strength interference model (as shown in Figure 27.1) is widely applied in the calculation and analysis of component reliability. According to this model, reliability is defined as the probability that the load does not exceed the strength. Here, both the load and the strength are general in meaning. Load can be any factors leading to

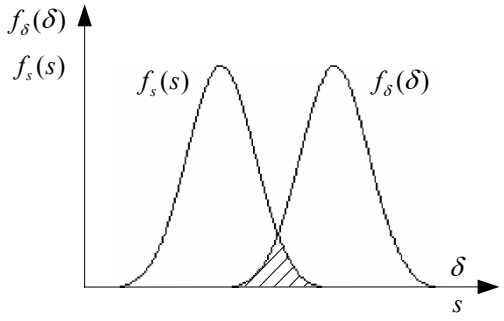

Figure 27.1. Load-strength interference relationship

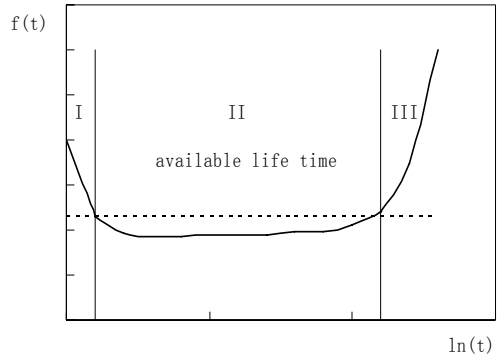

Figure 27.2. Typical failure rate curve (bathtub curve)

failure, such as mechanical loads, temperature, humidity or a corrosion environment, *etc*., and strength is the respective resistance capability to the load.

The load-strength interference model can be used to calculate component reliability when the probability distribution of load and that of strength are known. When the probability density function of strength is $f_\delta(\delta)$ and the probability density function of load is $f_s(s)$, the reliability of a component can be expressed as

$$\begin{aligned} R &= \int_{-\infty}^{+\infty} f_s(s) \int_{s}^{+\infty} f_\delta(\delta) d\delta ds \\ &= \int_{-\infty}^{+\infty} f_\delta(\delta) \int_{-\infty}^{\delta} f_s(s) ds d\delta \end{aligned} \tag{27.1}$$

Equation (27.1) is the general expression of the reliability model of a component with a single failure mode. Obviously, it is only reasonable for the situation that the load acts only once on the component during its service life. It cannot describe the relationship between reliability and time or the load action number when the load is not static.

Considering the performance of a product over its service life, the failure rate curve (*i.e.*, the bathtub curve) is also widely used to describe reliability-related behavior. A typical failure rate curve consists of three stages as shown in Figure 27.2. It is conventionally explained that the infant mortality phase (stage I) demonstrates a subpopulation dominated by quality-control defects due to poor workmanship, contamination, out-of-specification incoming parts and materials, and other substandard manufacturing practices [14]. It is also usually thought that mechanical systems may not appear to have an infant mortality period [14]. We will show below that the failure rate declination at the beginning of product service life is determined by both the strength distribution and the load distribution. Supposing that there is no strength degradation during the service life, a product will survive all the successive loads less than the highest load it has once resisted. Meanwhile, the likelihood that a higher load appears will become less and less with the increase of the number of the applied load cycles.

Concerning the situation of multiple actions of the random load, the component reliability can be modeled as [15]

$$R^{(m)} = \int_{-\infty}^{+\infty} f_\delta(\delta) \left(\int_{-\infty}^{\delta} f_s(s) ds \right)^m d\delta$$

or in a simpler form

$$R^{(m)} = R^m$$

based on the opinion that the failures caused by the individual loads applied to the component are independent of each other [15].

$R^{(m)}$ denotes the component reliability after m times of load action.

27.2.2 The Equivalent Load and Its Probability Distribution

The load acting on a mechanical component is normally stochastically repeated during operation. In the following, the cumulative distribution

function and probability distribution function of the equivalent load are defined by means of the order statistic of the load samples. Thereby, reliability models of components and systems in the situation of a stochastically repeated load are developed.

When component strength does not degrade, or the degradation is not evident, the event that a component survives m times of loading is equivalent to the event that the component does not fail under the maximum load of the m load samples. Thus, component reliability can be calculated through the interference relationship between strength and the maximum load among the m times of loading. Thus, the maximum load will also be called the equivalent load in the latter part of this chapter. Statistically, the maximum load is the maximum order statistic of the m load samples and is determined by the sample set $(s_1, s_2, \cdots, s_m)$ [16].

Let the cumulative distribution function and probability density function of a random variable x be denoted by $F_x(x)$ and $f_x(x)$, respectively, and the maximum of m samples be denoted by X_m. According to the order statistics theory, the cumulative distribution function of the maximum is

$$F_{X_m}(x) = \left[F_s(x)\right]^m \tag{27.2}$$

The probability density function of the maximum is

$$f_{X_m}(x) = m\left[F_s(x)\right]^{m-1} f_s(x) \tag{27.3}$$

If x denotes load, then the maximum X_m will be the equivalent load. Figure 27.3 shows the probability distribution of the load and the probability distributions of the equivalent loads of 10, 100 and 500 times the stochastic load, respectively. The stochastic load follows the normal distribution with mean $\mu_s = 50\text{MPa}$ and standard deviation $\sigma_s = 15\text{MPa}$.

It can be concluded that the mean of the equivalent load increases and the dispersion of the equivalent load decreases as the load sample sizes increase. When the strength distribution function $f_\delta(\delta)$ is known, the reliability $R^{(m)}$ of a component after m times of stochastic loading can be derived with the load-strength interference theory as

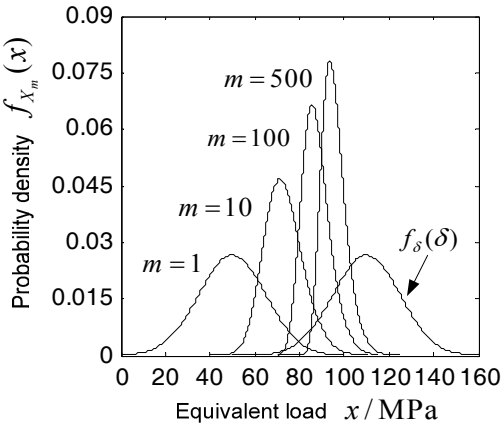

Figure 27.3. Probability distributions of equivalent loads and strength

$$\begin{aligned} R^{(m)} &= P(\delta > X_m) \\ &= \int_{-\infty}^{+\infty} f_\delta(\delta) \int_{-\infty}^{\delta} f_{X_m}(x)\,dx\,d\delta \\ &= \int_{-\infty}^{+\infty} f_\delta(\delta) \int_{-\infty}^{\delta} m\left[F_s(x)\right]^{m-1} f_s(x)\,dx\,d\delta \end{aligned} \tag{27.4}$$

Where, $f_{X_m}(x)$ is the probability density function of the equivalent load X_m, $f_\delta(\delta)$ is the probability density function of component strength, $F_s(x)$ is the cumulative distribution function of the stochastic load, and m is the times that the stochastic load is applied to the component. If the integration variable x is replaced with load s in (27.4), it can be rewritten as

$$R^{(m)} = \int_{-\infty}^{+\infty} f_\delta(\delta) \int_{-\infty}^{\delta} m\left[F_s(s)\right]^{m-1} f_s(s)\,ds\,d\delta \tag{27.5}$$

27.2.3 Time-dependent Reliability Model of Components

For most mechanical equipment and systems, the operation load during service can be described by a Poisson stochastic process [17, 18]. Let $M(t)$ denote the times of stochastic load subjected to a component in the time interval $(0,t)$. It is assumed to show the following characteristics:

(1) $M(0)=0$;

(2) For any $0<t_1<t_2<\cdots<t_m$, $M(t_1)$, $M(t_2)-M(t_1)$, …, $M(t_m)-M(t_{m-1})$ are independent of each other;

(3) The times of the load action depend only on the interval and not on the starting point, *i.e.*, $\forall s,t\geq 0,\ m\geq 0$,

$$P[M(s+t)-M(s)=m]=P[M(t)=m]$$

(4) For any $t>0$ and very small $\Delta t>0$,

$$\begin{cases}P[M(t+\Delta t)-M(t)=1]=\lambda\Delta t+o(\Delta t)\\ P[M(t+\Delta t)-M(t)\geq 2]=o(\Delta t)\end{cases}$$

Obviously, a loading process that satisfies the above conditions can be described by the homogeneous Poisson process with parameter λ and the probability of load acting m times ($M(t)=m$) over time t is

$$P\left[M(t)-M(0)=m\right]=\frac{(\lambda t)^m}{m!}e^{-\lambda t} \tag{27.6}$$

27.2.3.1 *Time-dependent Reliability Model Without Strength Degradation*

When strength does not degrade with the loading history, the component reliability at time t with load acting for m times can be calculated, according to (27.5) and (27.6), as:

$$\begin{aligned}R(m,t)&=P\left[M(s+t)-M(s)=m\right]\cdot R^{(m)}\\&=\frac{(\lambda t)^m}{m!}e^{-\lambda t}\int_{-\infty}^{+\infty}f_\delta(\delta)\\&\quad\int_{-\infty}^{\delta}m\left[F_s(s)\right]^{m-1}f_s(s)dsd\delta\end{aligned} \tag{27.7}$$

By means of the total probability formula, the reliability $R(t)$ of a component at time t is equal to

$$\begin{aligned}R(t)&=\sum_{m=0}^{+\infty}R(m,t)\\&=\sum_{m=0}^{+\infty}\frac{(\lambda t)^m}{m!}e^{-\lambda t}\int_{-\infty}^{+\infty}f_\delta(\delta)\\&\quad\int_{-\infty}^{\delta}m\left[F_s(s)\right]^{m-1}f_s(s)dsd\delta\end{aligned} \tag{27.8}$$

Using the Taylor expansion of the exponential function

$$e^x=1+\frac{x}{1!}+\frac{x^2}{2!}+\frac{x^3}{3!}+\cdots+\frac{x^m}{m!}+\cdots \tag{27.9}$$

Equation (27.8) can be simplified as

$$\begin{aligned}R(t)&=\int_{-\infty}^{+\infty}f_\delta(\delta)e^{-\lambda t}\sum_{m=0}^{\infty}\frac{(\lambda t)^m}{m!}\left[F_s(\delta)\right]^m d\delta\\&=\int_{-\infty}^{+\infty}f_\delta(\delta)e^{\left[F_s(\delta)-1\right]\lambda t}d\delta\end{aligned} \tag{27.10}$$

Equation (27.10) can be used to calculate the reliability of components without strength degradation. Further, the failure rate $h(t)$ can be derived as

$$\begin{aligned}h(t)&=\frac{f(t)}{R(t)}=-\frac{R'(t)}{R(t)}\\&=-\frac{\int_{-\infty}^{+\infty}f_\delta(\delta)\left[F_s(\delta)-1\right]\lambda e^{\left[F_s(\delta)-1\right]\lambda t}d\delta}{\int_{-\infty}^{+\infty}f_\delta(\delta)\lambda e^{\left[F_s(\delta)-1\right]\lambda t}d\delta}\end{aligned} \tag{27.11}$$

Let the parameter of the Poisson stochastic process λ be equal to 0.5 h^{-1}. The component strength follows the normal distribution with mean $\mu_\delta=600\mathrm{MPa}$ and standard deviation $\sigma_\delta=60\mathrm{MPa}$. The load follows the normal distribution with mean $\mu_s=400\mathrm{MPa}$ and standard deviation $\sigma_s=40\mathrm{MPa}$. The relationship between component reliability and time is shown in Figure

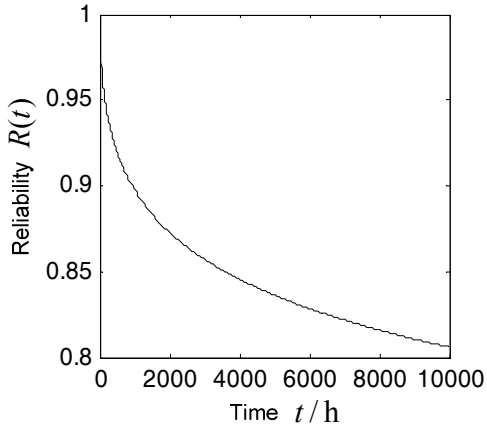

Figure 27.4. Relationship between reliability and time

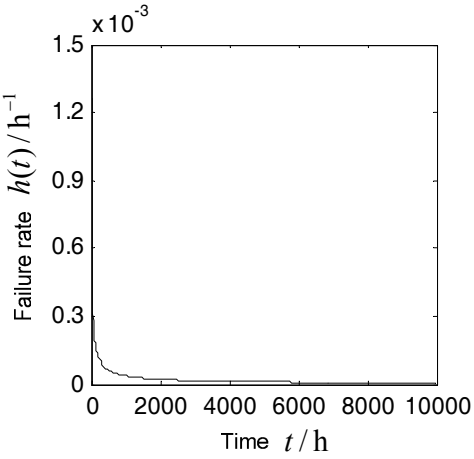

Figure 27.5. Failure rate curve

27.4, and the relationship between the component failure rate and time is shown in Figure 27.5.

It is shown that even if strength does not degrade, both the reliability and the failure rate decrease with time; the failure rate has the feature of the two former stages of a typical bathtub curve.

27.2.3.2 Time-dependent Reliability Model with Strength Degradation

When strength degrades with time or with the number of load actions, the effect of the strength degradation on reliability should be taken into account. In the following, a time-dependent component reliability model will be developed by means of the probability differential equation.

Assuming that the strength δ_t of a component at time t is a function of initial strength δ and time t, and the load appearing at time $t+\Delta t$ is independent with the load appearing at time t, the component failures are independent at time $t+\Delta t$ and time t. Based on the definition of the Poisson process, the probability that a load appears in the interval $(t,\ t+\Delta t)$ is $\lambda\Delta t$. If the reliability of the component at time t is $R(t)$, the reliability at time $t+\Delta t$ can be expressed as

$$\begin{aligned} &R(t+\Delta t)\\ &= R(t)P\left(\delta_\tau > s, \forall\tau\in[t,t+\Delta t]\right)\lambda\Delta t + R(t)\left(1-\lambda\Delta t\right)\\ &= R(t)+R(t)\lambda\Delta t\left[P\left(\delta_\tau > s, \forall\tau\in[t,t+\Delta t]\right)-1\right] \end{aligned} \tag{27.12}$$

According to the load-strength interference model, the above equation can be written as

$$\begin{aligned} R(t+\Delta t) &= R(t)+R(t)\lambda\Delta t\left[\int_{-\infty}^{\delta_\tau} f_s(s)ds - 1\right]\\ &= R(t)+R(t)\lambda\Delta t\left[F_s\left(\delta_\tau\right)-1\right] \end{aligned} \tag{27.13}$$

Note that the strength δ_t at time t is a function of the initial strength δ and time t, and

$$R(t+\Delta t)-R(t) = R(t)\lambda\Delta t\left[F_s(\delta,\tau)-1\right] \tag{27.14}$$

Dividing the items by Δt and letting $\Delta t\to 0$ and $\tau\to t$, (27.14) can be expressed as

$$\frac{dR(t)}{dt} = R(t)\lambda\left[F_s(\delta,t)-1\right] \tag{27.15}$$

Equation (27.15) is the differential equation of component reliability with strength degradation. Obviously,

$$\ln R(t) = \int_0^t \lambda\left[F_s(\delta,t)-1\right]dt \tag{27.16}$$

$$R(t) = e^{\int_0^t\left[F_s(\delta,t)-1\right]\lambda dt} \tag{27.17}$$

The above derivation is based on the precondition that the initial strength δ is deterministic. When the initial strength δ is a random variable with the probability density function $f_\delta(\delta)$, the time-dependent reliability model can be developed by means of the total probability formula for continuous variables,

$$R(t) = \int_{-\infty}^{+\infty} f_\delta(\delta)e^{\int_0^t\left[F_s(\delta,t)-1\right]\lambda\ dt}d\delta \tag{27.18}$$

It is easy to show that when the strength does not degrade (namely, $F_s(\delta,t)$ is independent of time t), (27.18) degenerates to (27.10).

Further, the component failure rate $h(t)$ can be derived as

$$\begin{aligned} h(t) &= \frac{f(t)}{R(t)} = -\frac{R'(t)}{R(t)}\\ &= -\frac{\int_{-\infty}^{+\infty} f_\delta(\delta)\left[F_s(\delta,t)-1\right]\lambda e^{\int_0^t\left[F_s(\delta,t)-1\right]\lambda dt}d\delta}{\int_{-\infty}^{+\infty} f_\delta(\delta)e^{\int_0^t\left[F_s(\delta,t)-1\right]\lambda dt}d\delta} \end{aligned} \tag{27.19}$$

Strength Degrades Exponentially

Assuming that the component strength degrades exponentially as $\delta_t = \delta \cdot e^{-0.00002\ t}$, when the parameter of the loading process (a Poisson stochastic process) λ equals $0.5\ \mathrm{h}^{-1}$, the component strength follows the normal distribution with mean $\mu_\delta = 600\mathrm{MPa}$ and standard deviation $\sigma_\delta = 60\mathrm{MPa}$, the load follows the normal distribution with mean $\mu_s = 400\mathrm{MPa}$ and standard deviation $\sigma_s = 40\mathrm{MPa}$. Figure 27.6 shows the relationship between component reliability and time and the relationship between the component failure rate and time is shown in Figure 27.7.

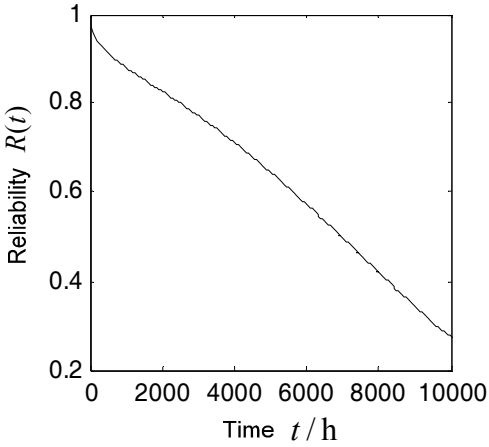

Figure 27.6. Relationship between reliability and time

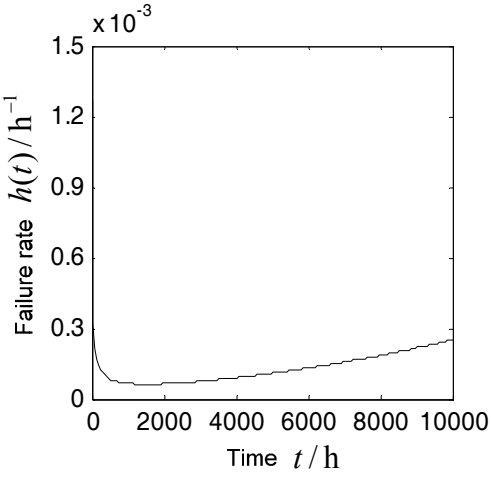

Figure 27.7. Failure rate curve

Strength Degrades Logarithmically

Assuming that the component strength degrades logarithmically as $\delta_t = \delta[1+\ln(1-0.0000125t)]$, when $\lambda = 0.5\ \mathrm{h}^{-1}$, the component strength follows the normal distribution with $\mu_\delta = 600\mathrm{MPa}$ and $\sigma_\delta = 60\mathrm{MPa}$, the load follows the normal distribution with $\mu_s = 400\mathrm{MPa}$ and $\sigma_s = 40\mathrm{MPa}$, the relationship between component reliability and time is shown in Figure 27.8, and the relationship between failure rate and time is shown in Figure 27.9.

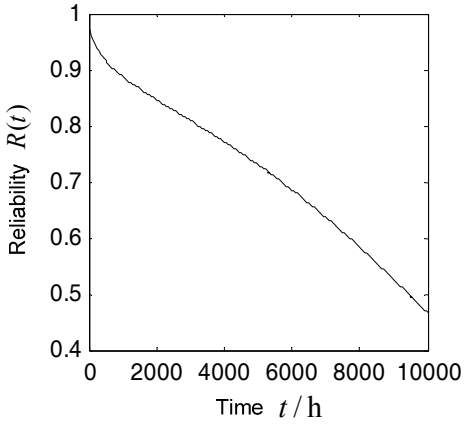

Figure 27.8. Relationship between reliability and time

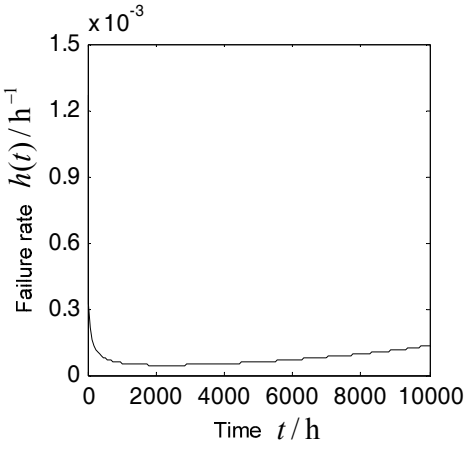

Figure 27.9. Failure rate curve

Strength Degrades Linearly

When the component strength degrades linearly, *e.g.*, $\delta_t = \delta(1-0.00002t)$, the Poisson process parameter $\lambda = 0.5\ \mathrm{h}^{-1}$, the component strength follows the normal distribution with $\mu_\delta = 600\mathrm{MPa}$ and $\sigma_\delta = 60\mathrm{MPa}$, the load follows the normal distribution with $\mu_s = 400\mathrm{MPa}$ and $\sigma_s = 40\mathrm{MPa}$. The relationship between component reliability and time, and the relationship between failure rate and time are shown in Figures 27.10 and 27.11, respectively.

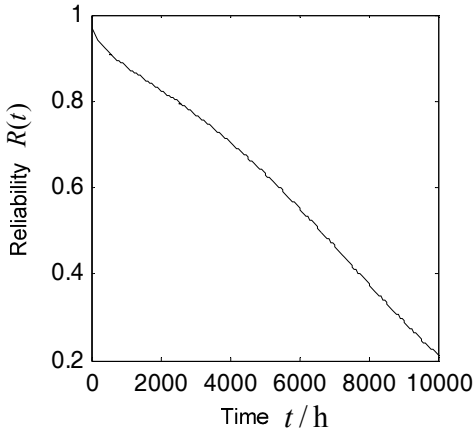

Figure 27.10. Relationship between reliability and time

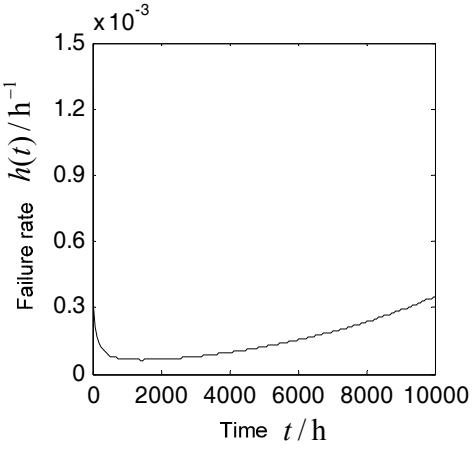

Figure 27.11. Failure rate curve

From Figures 27.6 through to Figure 27.11, it can be concluded that if the component strength degrades with time, the component reliability will decrease with time rapidly, while the component failure rate first decreases and then increases with time and shows the feature of the three stages of an entire bathtub curve.

27.2.4 The System Reliability Model

According to the system-level load-strength interference relationship [8], for the system composed of n independently identical distributed components, where the cumulative distribution function and the probability density function of the component strength are $F_\delta(\delta)$ and $f_\delta(\delta)$, respectively, and the load probability density function is $f_s(s)$. The respective reliability models for different systems are as follows.

Reliability of the series system

$$R_{seri} = \int_{-\infty}^{+\infty} \left(\int_{s}^{+\infty} f_\delta(\delta) d\delta \right)^n f_s(s) ds \quad (27.20)$$

Reliability of the parallel system

$$R_{para} = \int_{-\infty}^{+\infty} \left[1 - \left(\int_{-\infty}^{s} f_\delta(\delta) d\delta \right)^n \right] f_s(s) ds \quad (27.21)$$

Reliability of the k-out-of-n system

$$R_{k/n} = \int_{-\infty}^{+\infty} \sum_{i=k}^{n} C_n^i \left(\int_{s}^{+\infty} f_\delta(\delta) d\delta \right)^i \left(\int_{-\infty}^{s} f_\delta(\delta) d\delta \right)^{n-i} f_s(s) ds \quad (27.22)$$

27.2.5 The System Reliability Model Under Randomly Repeated Loads

If the strength does not degrade or the degradation can be neglected, the reliability that a system survives m times of randomly repeated loads is equal to the reliability that the system survives the maximum load of the m load samples.

Based on (27.20), (27.21) and (27.22), which are actually the reliability models under a single load action, the reliability models of different types of systems under multiple load actions can be developed for systems such as the series system for loads acting m times, the parallel system for loads acting m times, and the k-out-of-n system for loads acting m times. These systems are represented in (27.23), (27.24), and (27.25), respectively.

27.2.6 The Time-dependent System Reliability Model

Taking a series system as an example, when strength degradation can be neglected, according to (27.23) and (27.6), the reliability of a load acting m times at time t is given by (27.26).

Further, according to the total probability formula, the reliability model of the series system at time t is written as in (27.27).

$$\begin{aligned} R_{seri}^{(m)} &= \int_{-\infty}^{+\infty}\left(\int_{\mathrm{s}}^{+\infty} f_\delta(\delta)d\delta\right)^n m\left[F_s(s)\right]^{m-1} f_s(s)ds \\ &= \int_{-\infty}^{+\infty}\left[1-F_\delta(s)\right]^n m\left[F_s(s)\right]^{m-1} f_s(s)ds \end{aligned} \tag{27.23}$$

$$\begin{aligned} R_{para}^{(m)} &= \int_{-\infty}^{+\infty}\left[1-\left(\int_{-\infty}^{\mathrm{s}} f_\delta(\delta)d\delta\right)^n\right] m\left[F_s(s)\right]^{m-1} f_s(s)ds \\ &= \int_{-\infty}^{+\infty}\left\{1-\left[F_\delta(\delta)\right]^n\right\} m\left[F_s(s)\right]^{m-1} f_s(s)ds \end{aligned} \tag{27.24}$$

$$\begin{aligned} R_{k/n}^{(m)} &= \int_{-\infty}^{+\infty}\left(\sum_{i=k}^{n} C_n^{\,i}\left(\int_{s}^{+\infty} f_\delta(\delta)d\delta\right)^i \left(\int_{-\infty}^{\mathrm{s}} f_\delta(\delta)d\delta\right)^{n-i}\right) m\left[F_s(s)\right]^{m-1} f_s(s)ds \\ &= \int_{-\infty}^{+\infty}\left\{\sum_{i=k}^{n} C_n^{\,i}\left[1-F_\delta(s)\right]^i\left[F_\delta(s)\right]^{n-i}\right\} m\left[F_s(s)\right]^{m-1} f_s(s)ds \end{aligned} \tag{27.25}$$

$$\begin{aligned} R_{seri}(m,t) &= P\left[N(s+t)-N(s)=m\right] R_{seri}^{(m)} \\ &= \frac{(\lambda t)^m}{m!} e^{-\lambda t}\int_{-\infty}^{+\infty}\left[1-F_\delta(s)\right]^n m\left[F_s(s)\right]^{m-1} f_s(s)ds \end{aligned} \tag{27.26}$$

$$\begin{aligned} R_{\mathrm{seri}}(t) &= \sum_{m=0}^{+\infty} R_{\mathrm{seri}}(m,t) = \sum_{m=0}^{+\infty}\frac{(\lambda t)^m}{m!} e^{-\lambda t}\int_{-\infty}^{+\infty}\left[1-F_\delta(s)\right]^n m\left[F_s(s)\right]^{m-1} f_s(s)ds \\ &= \sum_{m=0}^{+\infty}\frac{(\lambda t)^m}{m!} e^{-\lambda t}\int_{-\infty}^{+\infty}\left[1-F_\delta(s)\right]^n d\left[F_s(s)\right]^m \\ &= \sum_{m=0}^{+\infty}\frac{(\lambda t)^m}{m!} e^{-\lambda t}\int_{-\infty}^{+\infty} n\left[1-F_\delta(s)\right]^{n-1}\left[F_s(s)\right]^m f_\delta(s)ds \\ &= \int_{-\infty}^{+\infty} n\left[1-F_\delta(s)\right]^{n-1} e^{-\lambda t}\sum_{m=0}^{+\infty}\frac{(\lambda t)^m}{m!}\left[F_s(s)\right]^m f_\delta(s)ds \end{aligned} \tag{27.27}$$

$$R_{\mathrm{seri}}(t) = \int_{-\infty}^{+\infty} e^{\left[F_s(s)-1\right]\lambda t} n\left[1-F_\delta(s)\right]^{n-1} f_\delta(s)ds \tag{27.28}$$

$$R_{para}(t) = \int_{-\infty}^{+\infty} e^{\left[F_s(s)-1\right]\lambda t} n\left[F_\delta(s)\right]^{n-1} f_\delta(s)ds \tag{27.29}$$

$$R_{k/n}(t) = \int_{-\infty}^{+\infty} e^{\left[F_s(s)-1\right]\lambda t}\left\{\sum_{i=k}^{n} C_n^{\,i}\left[1-F_\delta(s)\right]^{i-1}\left[F_\delta(s)\right]^{n-i-1}\left(i+nF_\delta(s)-n\right)\right\} f_\delta(s)ds \tag{27.30}$$

Using the Taylor expansion of an exponential function, the above equation can be simplified as (27.28). Similarly, the time-dependent reliability models of parallel system and *k*-out-of-*n* redundant system can be developed and are represented as in (27.29) and (27.30), respectively.

Taking the series system with three identical components, the parallel system with three identical components and the 2-out-of-3 system as examples, when the Poisson process parameter λ is $0.5\,\mathrm{h}^{-1}$, the component strength follows the normal distribution with mean $\mu_\delta = 600\mathrm{MPa}$ and standard $\sigma_\delta = 60\mathrm{MPa}$, the stress follows the normal distribution with mean $\mu_s = 400\mathrm{MPa}$ and standard $\sigma_s = 50\mathrm{MPa}$. The relationship between system reliability and time is shown in Figure 27.12. It can be concluded that the reliability of the series system decreases the fastest, the reliability of the parallel system decreases the most slowly and the reliability curve of the *k*-out-of-*n* system lies between those of the series system and the parallel system.

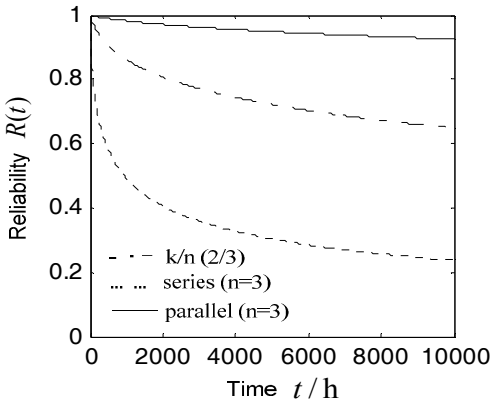

Figure 27.12. The relationship between system reliability and time

27.3 Residual Fatigue Life Distribution and Load Cycle-dependent Reliability Calculations

Stress-strength interference, or load cycle-fatigue life interference, is the most widely used concept in reliability analysis [19–31]. For a constant amplitude cyclic load, the interference model can be used directly to predict failure probability. For complex loading conditions, more comprehensive studies on probabilistic characteristics of fatigue failure can be found in many references [25–39], too. For instance, Kopnov [30] and Tanaka [31] studied the residual fatigue life distribution under both the constant amplitude cyclic loading condition and the two-stage loading condition, Bahring *et al.* [32] and Choukairi *et al.* [33] studied the impact of load changing on lifetime distributions, Wu *et al.* [34] developed a computer simulation approach, which was further developed in [35] for fatigue reliability analysis, Gauri *et al.* [36] and Tang *et al.* [37] investigated the mean residual life of lifetime distributions and its association with failure rate, Camarinopoulos *et al.* [38] and Zuo *et al.* [39] carried out reliability evaluations of engineering structures and components.

27.3.1 Experimental Investigation of Residual Fatigue Life

In the situation of variable amplitude loading, the residual fatigue life distribution changes considerably during the loading process. Therefore, it is necessary to investigate the variation of residual life distribution for the purpose of fatigue reliability prediction. To inspect the changing tendency of residual fatigue life, tests were conducted on a rotated-bending fatigue test machine, using smooth specimens made of normalized 0.45% carbon steel (St-45) and hot rolled alloy steel (16 Mn), respectively. The results are shown in Tables 27.1 and 27.2, in which residual lives are the test records of the residual life at the second level stress σ_2 after n_1 cycles of the first level stress σ_1. When failure occurs at the first-level stress, the residual life is negative and is calculated by $N_{2p}^1 = (N_1 - n_1)\bar{N}_2 / \bar{N}_1$, where N_1 is the number of cycles to failure at the first-level stress, n_1 is the assigned cycle number for the first level stress.

Table 27.1. Fatigue test results of normalized 0.45% carbon steel

Stress level and loading sequence	Sample size	Cycles of the 1st-level stress	Original fatigue life for constant amplitude stress tests or residual life at 2nd-level stress for two-level stress tests (in 100 cycles)	Mean of original life or mean of residual life	Std. of original life or std. of residual life

27.3.2 The Residual Life Distribution Model

Test results show that, for the residual fatigue life distribution in the condition of constant amplitude cyclic loading without the occurrence of fatigue failure, the standard deviation of the residual fatigue life remains unchanged. The only change in the fatigue life distribution parameters is that the mean life decreases from $\bar{N}$ to ($\bar{N}-n$), where n is the applied load cycle number (see Figure 27.13). After stress σ_1 acts a cycle number of n_1, the pdf (probability density function) of the residual life under the same stress changes from $f_1(N) \sim N(\bar{N}_1, s_1)$ to $f_{1p}^1(N) \sim N(\bar{N}_1 - n_1, s_1)$. Where, $f_i(N) \sim N(\bar{N}_i, s_i)$ stands for $f_i(N)$ being a normal pdf with mean $\bar{N}_i$ and standard deviation s_i.

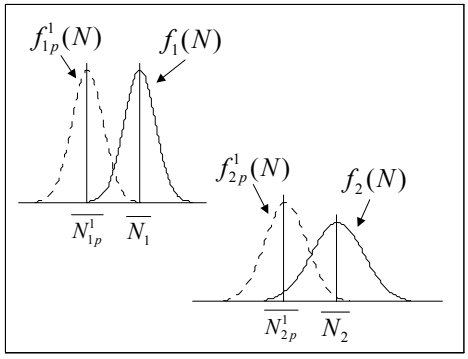

Figure 27.13. Illustration of (residual) life distributions

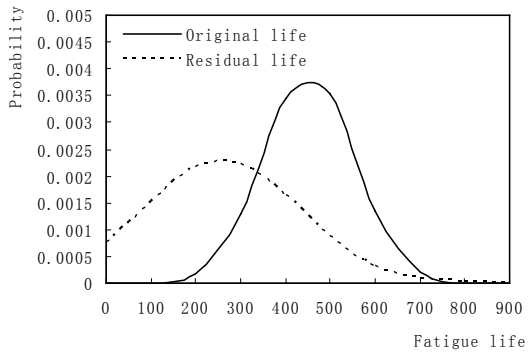
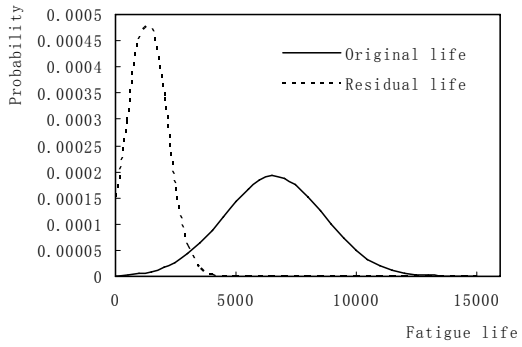
For the fatigue lives under variable amplitude load conditions, there are investigations (Bahring *et al.* [40] and Choukairi *et al.* [41]) to indicate that the change of residual life distribution is quite complicated. Nevertheless, for the two-level loading condition, an evident tendency can be found in the test results listed in the tables. In conditions of no failure occurrence, if low stress acts first, the standard deviation of the residual life under the subsequent high stress becomes greater, *i.e.,* the standard deviation of the residual life is greater than that of the original fatigue life under the pertinent high stress. If high stress acts first, the standard deviation of the residual life under the subsequent low stress becomes smaller, *i.e.,* the standard deviation of the residual life is less than that of the original life under the pertinent low constant stress. The greater the difference between the amplitudes of the high stress and the low stress is, the greater the change of the standard deviation of the residual life. All in all, the previously applied stress affects both the mean and the standard deviations of the residual fatigue life at subsequent stress (see Figs. 27.14–27.16).



(a) Distribution of the original life under 366 MPa and distribution of residual life under 366 MPa after 75711 cycles (half of the fatigue life under 331 MPa) of the lower stress (331 MPa) of St-45



(b) Distribution of the original life under 309 MPa and distribution of residual life under 309 MPa after 75711 cycles (half of the fatigue life under 331 MPa) of the higher stress (331 MPa) of St-45

Figure 27.14. Original life distribution and residual life distribution

It is shown that after stress σ_1 acts a cycle number n_1, the probability density function of the residual life under stress σ_2 changes from $f_2(N) \sim N(\bar{N}_2, s_2)$ to $f_{2p}^1(N) \sim N(\bar{N}_2 - n_{2d}, s_{2p}^1)$. n_{2d} is the equivalent cycle number of the stress σ_2 to that of the really applied n_1 cycles of σ_1, which is in the sense of mean life and can be estimated by the cumulative fatigue damage rule. The magnitude of the effect depends on the relative stress level of the first stress as well as its cycle number. According to regression analysis of the test data, a linear model can be developed to predict the residual life distribution parameters under two-level stress, and it will be extended to more complicated spectrum loading conditions, as well as variable amplitude loading histories.

Let $\bar{N}_i$ and s_i represent the mean and the standard deviation of the fatigue life under the i^{th} stress ($i = 1, 2$), respectively. The residual life distribution parameters ($\bar{N}_{2p}^1$, s_{2p}^1) under the second stress σ_2, after n_1 cycles of σ_1, can be expressed by the following equations:

$$\bar{N}_{2p}^1 = \bar{N}_2(1 - n_1 / \bar{N}_1) \tag{27.31}$$

$$s_{2p}^1 = s_2 + (s_1 - s_2) n_1 / \overline{N_1} \tag{27.32}$$

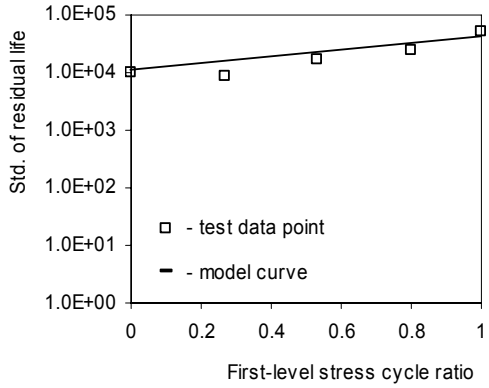
The pdf of the residual life is then:

$$f_{2p}^1(N) \sim N(\bar{N}_{2p}^1, s_{2p}^1) \tag{27.33}$$

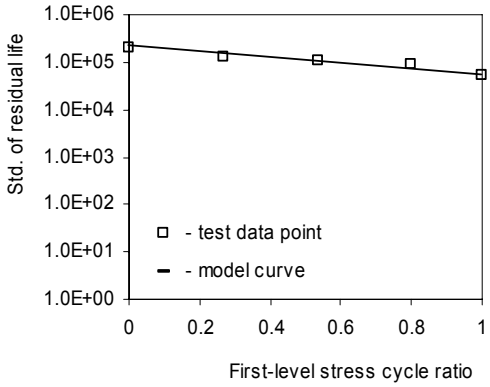
Obviously, (27.31) is equivalent to the well known Miner's rule, and (27.32) is an empirical model developed by the authors, which is taken as a primary approximation of the standard deviation of the residual life. This equation is developed mainly based on the test results listed in Tables 27.1 and 27.2, Figures 27.15 and 27.16 show the test results (denoted by boxes) and the mathematical model (solid line) of carbon steel St-45 and alloy steel 16-Mn. The abscissa stands for cycle ratio of the first level stress and the ordinate stands for the standard deviation of the residual life under the second level stress. Such a model can present the variation of the residual life distribution parameters under variable amplitude loads and can be applied, along with the other equation, to predict fatigue probability under variable amplitude loading.

If there is a third stress level or more, as in the condition of three-level stress or the complex loading spectrum, the residual life distribution parameters $(\bar{N}_{3p}^{12}, s_{3p}^{12})$ at the third stress σ_3, after n_1 cycles of σ_1 and n_2 cycles of σ_2, can be predicted as:

$$\bar{N}_{3p}^{12} = \bar{N}_{3p}^1 (1 - \frac{n_2}{\bar{N}_{2p}^1}) = \bar{N}_3 (1 - \frac{n_1}{\bar{N}_1} - \frac{n_2}{\bar{N}_2}) \tag{27.34}$$



(a) Std. of residual life at high stress



(b) Std. of residual life at low stress

Figure 27.15. Test result and model of std. of residual life of St-45

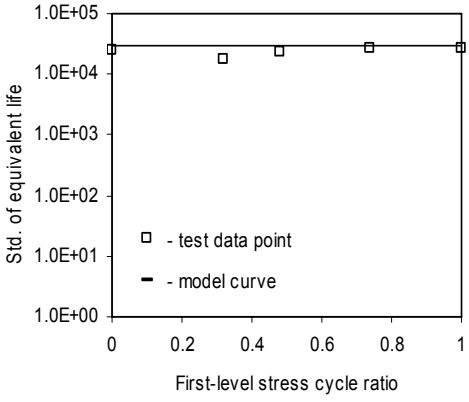
$$s_{3p}^{12} = s_{3p}^{1} + (s_{2p}^{1} - s_{3p}^{1})\frac{n_2}{\bar{N}_{2p}^{1}} = s_3 + (s_1 - s_3)n_1/\bar{N}_1 + (s_2 - s_3)\frac{n_2}{\bar{N}_2} \quad (27.35)$$

The pdf of the residual life is:

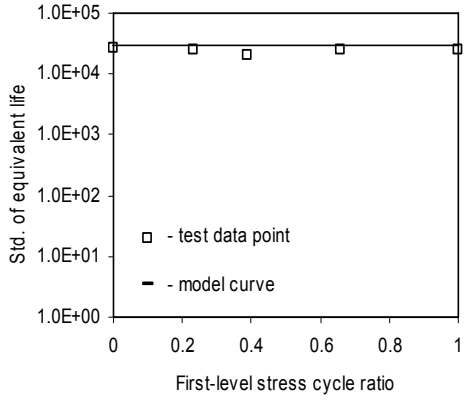
$$f_{3p}^{12}(N) \sim N(\bar{N}_{3p}^{12}, s_{3p}^{12}) \quad (27.36)$$

Similarly, for the i^{th} stress level in condition of multi-level stress or complex loading spectrum, the residual fatigue life distribution parameters $(\bar{N}_{ip}^{12...(i-1)}, s_{ip}^{12...(i-1)})$ can be predicted as:

$$\bar{N}_{ip}^{12...(i-1)} = \bar{N}_i\,(1 - \sum_{j=1}^{i-1} n_j/\bar{N}_j) \quad (27.37)$$



(a) Std. of residual life at the high stress



(b) Std of residual life at the low stress

Figure 27.16. Test result and model of std. of residual life of 16 Mn

$$s_{ip}^{12...(i-1)} = s_i + \sum_{j=1}^{i-1}[(s_j - s_i)(1 - \sum_{k=1}^{j-1}\frac{n_k}{\bar{N}_k})\frac{n_j}{\bar{N}_j}] \quad (27.38)$$

The *pdf* of the residual life is:

$$f_{ip}^{12...(i-1)}(N) \sim N(\bar{N}_{ip}^{12...(i-1)}, s_{ip}^{12...(i-1)}) \quad (27.39)$$

In the equations developed above, the cycle number of the applied stress is assumed to be a deterministic variable. When the cycles of the applied stress is a random variable, the mean of the random variable can be used to predict the residual life distribution parameters for the sake of simplification. The error caused by replacing the random variable with its mean is secondary in comparison with the change in the life distribution parameters caused by the cyclic loading.

When the applied load cycle number is greater than the minimum life, the failure probability is greater than zero (*i.e.,* $P_{fi}(t) > 0$). The *pdf* of the residual life represented in (27.39), (27.36) and (27.33) should be revised as:

$$f_{ipR}^{12...(i-1)}(N) = f_{ip}^{12...(i-1)}/(1 - P_{fi}(t)) \quad (27.40)$$

where $P_{fi}(t) = 1 - \int_0^{+\infty} f_{ip}^{12...(i-1)}(N)dN \quad (27.41)$

27.3.3 Fatigue Failure Probability Under Variable Loading

Let $f(N)$ represent the pdf of fatigue life at a given stress level and $h(n,t)$ the pdf of the applied cycles of the stress (t represents physical time). Obviously, failure occurs when the load cycle number n exceeds the fatigue life N . Fatigue failure probability is defined as:

$$P_f(t) = P(n > N) \quad (27.42)$$

By means of load cycles, fatigue life interference analysis, the fatigue failure probability can be calculated as:

$$P_f(t) = \int_0^{+\infty} h(n,t)[\int_{-\infty}^{n} f(N)dN]dn \quad (27.43)$$

Based on the residual life distribution model developed above (*e.g.*, (27.37) and (27.38)), the load cycles fatigue life interference analysis approach can be used to calculate the fatigue failure probability under variable amplitude loading conditions. For a two-level stress spectrum containing n_1 cycles of σ_1 and n_2 cycles of σ_2, let A_i represent the event of no failure occurrence at the i^{th} stress level ($i=1,2$) and $P(A_i)$ represent its probability. After n_1 cycles of the first-level stress σ_1, the probability of event A_1 (no failure occurrence) equals $P(A_1)$, which can be calculated as:

$$P(A_1)=\int_{n_1}^{+\infty} f_1(N)dN \tag{27.44}$$

Then stress level is transformed to the second stress σ_2. Because of the effect of the first level stress, the residual life distribution under the second stress σ_2 is no longer the same as that of the virgin material. The mean and the standard deviations should be calculated by (27.31) and (27.32), (27.37) and (27.38), respectively. The *pdf* of the residual life at the second-level stress is then presented by (27.33) or (27.39). In the case of the failure probability $P_{f2}(t)=1-\int_{n_1}^{+\infty} f_{2p}^1(N)dN>0$, (27.33) or generally, (27.39) should be modified to (27.40). The probability of no failure occurrence at this stress level, given the condition of no failure at the first stress level, is $P(A_2 \mid A_1)$. This conditional probability should be calculated by the interference relationship between the load cycle n_2 and the residual life N_{2p}^1, *i.e.*,

$$P(A_2 \mid A_1)=\int_{n_2}^{+\infty} f_{2pR}^1(N)dN \tag{27.45}$$

Obviously, the probability of no fatigue failure occurring after n_1 cycles of σ_1 and n_2 cycles of σ_2 equals the probability that the events A_1 and A_2 occur simultaneously. According to the conditional probability algorithm,

$$\begin{aligned} P(A_1A_2) &= P(A_1)P(A_2 \mid A_1) \\ &= \int_{n_1}^{+\infty} f_1(N)dN \int_{n_2}^{+\infty} f_{2pR}^1(N)dN \end{aligned} \tag{27.46}$$

The corresponding fatigue failure probability is

$$P_f(t)=1-\int_{n_1}^{+\infty} f_1(N)dN \int_{n_2}^{+\infty} f_{2pR}^1(N)dN \tag{27.47}$$

If there is a third-level stress in the load spectrum, the pertinent failure probability can be calculated as:

$$\begin{aligned} P_f(t) &= 1-P(A_1A_2A_3) \\ &= 1-P(A_1)P(A_2 \mid A_1)P(A_3 \mid A_1A_2) \end{aligned} \tag{27.48}$$

where, $P(A_3 \mid A_1A_2)=\int_{n_3}^{+\infty} f_{3pR}^{12}(N)dN$ (27.49)

The *pdf* and its parameters involved in (27.49) can be obtained from (27.34)–(27.36) or generally, from (27.37)–(27.39), or by the modified version of (27.36) or (27.39), *i.e.*, from (27.40).

For any complex loading spectrum, fatigue failure probability can be calculated in the same way, using (27.37)–(27.41), *i.e.,*

$$\begin{aligned} P_f(t)=1-&\int_{n1}^{+\infty} f_1(N)dN \int_{n2}^{+\infty} f_{2pR}^1(N)dN\cdots \\ &\int_{ni}^{+\infty} f_{ipR}^{12..(i-1)}(N)dN \end{aligned} \tag{27.50}$$

27.4 Conclusions

Time-dependent and load cycle-dependent reliability models are developed by means of load-strength interference analysis, order statistic theory and probability differential equations. The Poisson stochastic process is used to describe the load action. Both situations with and without strength degradation are taken into account. Time-dependent reliability models of the series system, the parallel system and the *k*-out-of-*n* redundant system are presented. The relationship between component/system reliability and time (or number of load cycles) and that between component failure rate and time (or number of load cycles) are studied, respectively.

The results show that when component strength does not degrade, both the component reliability and the failure rate decrease with time, and

component failure rate takes on the feature of the first two stages of a typical three-stage bathtub curve. If component strength degradation is taken into account, the reliability decreases with time more quickly, while the failure rate first decreases and then increases with time and takes on the whole the feature of a typical bathtub curve.

It can also be concluded that the quick decline of the failure rate in the first stage of a typical bathtub curve can not be merely attributed to a defect in product quality. The relationship between the failure rate and the number of stochastic loads shows that the decline in the failure rate curve is determined by both the strength distribution and the load distribution. For any product, no matter whether the quality is high or low, the failure rate will become lower and lower with the increase of the experienced load history, since once it has survived to a service time t, it will never fail unless a higher load (higher than any of the ones experienced during the time period $0-t$) appears if there is no strength degradation.

In addition to the investigation on strength degradation and its effect on reliability and failure rate, the residual fatigue life distribution is investigated experimentally, and a method is presented to predict fatigue probability under variable amplitude loading histories. For two-level stress, the test results show that when lower stress acts first, the standard deviation of the residual life under the subsequent higher stress becomes greater. That is, the standard deviation of the residual life is greater than that of the fatigue life of the virgin material under the pertinent high stress. When higher stress acts first, the standard deviation of the residual life under the subsequent lower stress becomes less than that of the fatigue life of the virgin material under the pertinent low stress. The greater the differences between the amplitude of the high stress and that of the low stress are, the greater the change of the standard deviation of the residual life.

In one word, previously acting cyclic stress affects both the mean and the standard deviation of the residual life under the following cyclic stress. The effect depends on the relative amplitude of the previously acting cyclic stress as well as its cycle number. A linear model is developed to predict the distribution parameters of residual fatigue life. A method based on such a model and a conditional probability algorithm, is presented to predict fatigue probability under variable amplitude loading condition.

New Models and Measures for Reliability of Multi-state Systems

Yung-Wen Liu[1] and Kailash C. Kapur[2]

[1]University of Michigan in Dearborn, Michigan, USA
[2]University of Washington in Seattle, Washington, USA

Abstract: This chapter descibes some new reliability models and measures for multistate systems. Equivalent classes and lower/upper boundary points are used for deriving the structure function for multistate system with multistate components. In addition to the static multistate reliability measures, several dynamic reliability measures are also introduced. Two stochastic models, Markov process and non-homogeneous continuous time Markov process are applied to formulate the probability that the system is in each state. With Non-homogeneous continuous time Markov, the age effect of the system is considered. Utility functions and disutility functions are incorporated with the stochastic models for the customer-centered reliability measures. Couple of potential applications are introduced and used to illustrate these reliability models and measures.

28.1 Introduction

The reliability of a product, process or system is a "time oriented" quality measure, and it must be defined and evaluated by the customer [22] just like any other quality characteristic. In the traditional reliability methods [21] the system and all of its components are assumed to have only two states of working efficiency: working perfectly or not working at all reslting in complete failure. Although this assumption simplifies complicated problems for reliability evaluation, it loses the ability to reflect the reality that most systems actually degrade gradually and have a wide range of states in terms of their function and performance [1, 3, 5, 18, 25, 30]. The degradation of the system and its components over time results in different levels of functional performance of the system, and hence effects the satisfaction of the customer with the system over time. Hence, a good reliability measure should not only capture the state transitions of the multi-state system, but also the customer's total experience with the system over time.

In the literature most of the work on multi-state reliability research makes the assumption that the system and all of its components have the same number of states [3, 30, 33]. This assumption is not realistic because in reality the system and its components have different numbers of states [2, 5, 7, 18]. The reliability measures described in this chapter can better capture the reality of multiple states for the systems and the components.

The degradation of a system is a stochastic process [34]. A customer's experience with the system also changes with this random degradation.

The reliability of a system is evaluated by the customer like any other quality [22]. In order to assess the reliability of the system from the customer's standpoint, we need to capture the customer's total experience with the system over time [7, 28]. Because the customer's experience is a function of the state of the system, we need to understand the degradation processes of the system, and model these underlying stochastic processes. To formulate the customer's total experience, we need to know the customer's utility function and how the utility changes with the transition of the state of the system. The dynamic reliability measures introduced in this chapter use the methodologies of stochastic processes and economic utility functions to capture the customer's total experience with the system.

The applications of these general measures and models include broad problems in

- engineering systems, design and analysis,
- supply chain and logistics,
- general networks for transportation and distribution ,
- computer and communication systems, and
- health systems.

Some of these applications will be described in the following sections.

28.2 Multi-state Reliability Models

For many systems, the binary-state reliability model is insufficient in terms of the evaluation of the system. For example, networks and their components perform their tasks at several levels of performance. Hence, it is necessary to evaluate the performance degradation of the network due to the partial failures of its components over time. In addition, customers experience the degradation of the network over time. To evaluate the system from the customer's standpoint, multi-state reliability modeling and evaluation should be implemented to avoid incorrect decision-making regarding network performance [37].

In this section, we first extend the concepts that are used to generate the structure functions for the binary-state system with binary-state components to develop the structure functions for the multi-state system with n multi-state components. The development of a new structure function for very general systems where the numbers of states of the system as well as of all of its components are different using the concept of lower and upper boundary points is proposed. This is very general and is more realistic than those approaches where the number of the states for the system and its components is the same. This structure function can be used by professionals in the industry for various applications.

It is well known that the development of the expected values of the states of the system using the structure function is a very difficult problem in terms of computational complexity. Hence, the bounds on a measure for reliability in terms of the expected values of the states of the system are also presented.

A numerical example is used to illustrate the structure function, the calculation of the expected value of the states of the system, and the bounds for this reliability measure.

28.2.1 Classification of States

Binary-state Model

Let y be the substitute characteristic [22] for the function of the component and y_0 be the ideal or target value for y. In the binary case, we classify the states of the component into two classes. The system is functioning if $y_0 - \Delta_0 \le y \le y_0 + \Delta_0$, and failed otherwise. The value of Δ_0 is based on the requirements of the customer. Let x_i, $i = 1, \ldots, n$, represent the state of component i for a system with n components. Then

$$x_i = \begin{cases} 1 & \text{if } y_0 - \Delta_0 \le y \le y_0 + \Delta_0 \text{ (component functions)} \\ 0 & \text{otherwise (component has failed)} \end{cases}$$

Multi-state Model

Again, let y be the substitute characteristic for the function of the component. Then the states of a multi-state component are defines as (see also Figure 28.1):

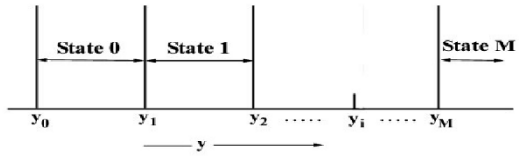

Figure 28.1. State classification

$$x_i = \begin{cases} 0 & \text{if } y_0 \le y < y_1 \\ 1 & \text{if } y_1 \le y < y_2 \\ \vdots & \vdots \\ M & \text{if } y \ge y_M \end{cases}$$

The range of each state can be decided by the reliability engineer based on the physical condition of the system and the customer's preferences.

Notation

n	number of components
(m_i+1)	number of states of component i
$M+1$	number of states of the system
S	$[0,1,\ldots, m_1]$x$[0,1,\ldots, m_2]$x…x$[0,1,\ldots, m_n]$ –
s	component state space $[0,1,\ldots, M]$ – system state space

$\phi(x,t): S \rightarrow s$ is the structure function

28.2.2 Model Assumptions

In a multi-state system with n different components, each component i is assumed to have $(m_i + 1)$ distinct levels of working efficiency called states. If $x_i(t)$ denotes the state for the ith component at time t, then $x_i(t) \in [0,1,\ldots, m_i]$ for $i = 1, 2, \ldots, n$. When $x_i(t) = 0$, the ith component is in the state of total failure at time t. On the other hand, when $x_i(t) = m_i$, the ith component is in the state of perfect functioning at time t. For the static model that considers the working efficiency of the system and its components at a fixed time t, x_i is used instead of $x_i(t)$ to denote the status of working efficiency for the ith component at time t. All the components are assumed to be mutually independent, which means that the working efficiency of each component is not affected by the working efficiency of any other component. The system itself is also assumed to have M+1 different levels of working efficiency. If the structure function of this multi-state system is denoted by $\phi(x,t)$, the status of the working efficiency of this system at some specified time t is given by $\phi(x,t) = k$, where $x = (x_1, x_2,\ldots, x_n)$ is a vector of the states of the n components and $k \in [0, 1,\ldots, M]$.

Therefore, the system is in the state of total failure at time t when $\phi(x,t) = 0$, and it is working perfectly at time t when $\phi(x,t) =$ M. Let $s = [0, 1,\ldots, m_1]\times[0,1,\ldots, m_2]\times\ldots\times[0, 1,\ldots, m_n]$ be the components state space that is the set of all possible states of the components, and $S = [0,1,\ldots,M]$ be the set of all possible states of the system. Then the relationship between the components and system can be expressed as

$$\phi(x,t): S \rightarrow s$$

Again, for the static model, $\phi(x)$ is used instead of $\phi(x,t)$ to denote the status of working efficiency for the system at time t.

Definition 1:

Let $x = (x_1, x_2,\ldots, x_n)$ and $y = (y_1, y_2,\ldots, y_n)$ be two vectors representing the states of the n components of a system. Then we say that $x < y$ if $x_i \le y_i$, for every $i = 1, 2, \ldots, n$, and $x_i < y_i$ for at least one i.

Equivalent Classes

An equivalent class is the collection of all combinations of the states of n components of the system that allows the system to be in state k ($k \in [0, 1,\ldots, M]$), and is defined as:

$$S_k = \{x \mid \phi(x) = k\}, \forall\ k \in [0, 1, 2, ..., M],$$
$$\text{where } x = (x_1, x_2, \cdots, x_n)$$

S_k is known as the equivalent class, the collection of all combinations of states of the n components that make the system to be in state k and S_k's are mutually exclusive, $\bigcup_{i=1}^{M} S_k = S$, where is S the component state space.

Let θ_k be the number of elements in each equivalent class S_k. Of those θ_k different elements, L_k are called "lower boundary points" and U_k are called "upper boundary points".

Definition 2: Lower Boundary Points

$x = (x_1,x_2,\ldots,x_k) \in S_k$ is called a lower boundary point if only if for any $y = (y_1,y_2,\ldots,y_k) < x$, $\phi(y) < k$.

When x is a lower boundary point, any of its component has a change to a lower state will result in a lower state for the system. The collection of all the lower boundary points for the equivalent class k is called the "lower boundary point set", which is denoted as

$$LB(k) = \left(\hat{x}_{(1k)}, \hat{x}_{(1k)}, \cdots, \hat{x}_{(L_k k)}\right) \subset S_k$$

and $\hat{x}_{(ik)}, \forall\, i \in [1, 2, \cdots, L_k]$, is the ith lower boundary point for S_k.

Definition 3: Upper Boundary Points

$x = (x_1, x_2,\ldots, x_k) \in S_k$ is called a upper boundary point if only if for any $y = (y_1, y_2,\ldots, y_k) > x$, $\phi(y) > k$.

When x is an upper boundary point, a change in any of its components to a higher state will result in a higher state for the system.

The collection of all the upper boundary points for the equivalent class k is called the lower boundary point set, which is denoted as

$$UB(k) = \left(\breve{x}_{(1k)}, \breve{x}_{(1k)}, \cdots, \breve{x}_{(L_k k)}\right) \subset S_k$$

and $\breve{x}_{(ik)}, \forall\, i \in [1, 2, \cdots, U_k]$, is the ith upper boundary point for S_k.

From the definition of the lower boundary point, we know that a system is in the state k or higher if x is greater than or equal to at least one lower boundary point in the lower boundary points set LB(k). This can be formulated as

$$\hat{I}(k) = 1 - \prod_{i=1}^{L_k} \left[1 - I(x \geq \hat{x}_{(i,k)})\right]$$

where $I(\,)$ is an indicator function, and its value is 1 if $x \geq \hat{x}_{(i,k)}$ and 0 otherwise.

Figures 28.2 and 28.3 show the concepts of equivalent classes and upper and lower boundary points.

From now on,we will use the notation $I(\,)$ as the indicator function and its value is 1 if the logical expression in $(\,)$ is true, and 0 otherwise. If $\hat{I}(k+1) > \hat{I}(k)$ then we set $\hat{I}(k) = \hat{I}(k+1)$. $k = 0$ means that the system is totally failed, and we let $\hat{I}(0) = 1$. Then the structure function is

$$\phi(x) = \sum_{k=0}^{M} \hat{I}(k) - 1$$

From the definition of the upper boundary point, we know that a system is in the state k or lower if at least one x is less than or equal to all of the upper boundary points in the upper boundary points set UB(k). Define

$$\breve{I}(k) = \prod_{i=1}^{U_k} \left[1 - I(x \leq \breve{x}_{(i,k)})\right]$$

If $\breve{I}(k+1) > \breve{I}(k)$ then we set $\breve{I}(k+1) = \breve{I}(k)$. $k = M$ means that the system is perfectly working, and we let $\breve{I}(M) = 0$. Then the structure function is

$$\phi(x) = \sum_{k=0}^{M} \breve{I}(k)$$

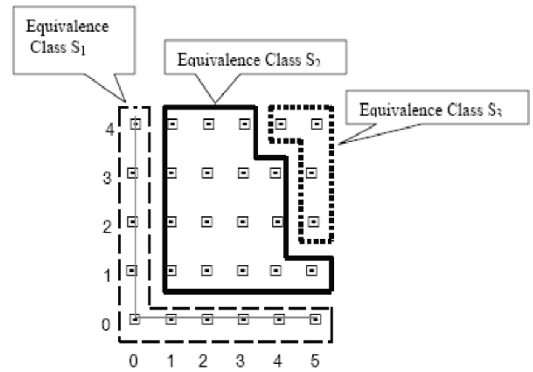

Figure 28.2. Equivalence classes

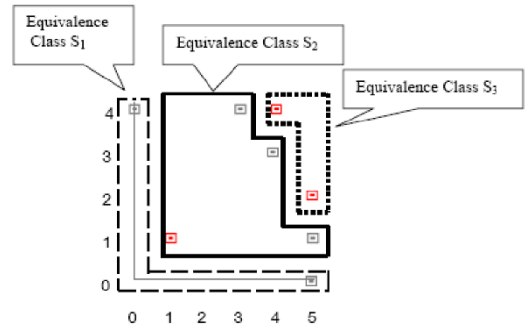

Figure 28.3. Upper/lower boundary points

With the above structure functions, we can find the expected value of the state of the system as follows:

1. With lower boundary points

$$E[\phi(x)] = E\left[\sum_{k=0}^{M} \hat{I}(k) - 1\right] = \sum_{k=0}^{M} E\left[\hat{I}(k)\right] - 1$$

2. With upper boundary points

However, as the number of components and the number of different states of components increase, the calculation of the exact expected state of the system with the method described in the previous section will take a long time due to the computational complexity [6, 19, 25, 41]. Based on the definition of the structure functions, the bounds on the expected value of states for the system are developed as follows:

Lower bounds

Using inclusion/exclusion, we can find bounds on the expected values of state of the system as below. The lower bound is

$$\sum_{l=0}^{M-1} \prod_{k=0}^{l} \prod_{i=1}^{U_k} \left[1 - \prod_{j=1}^{n} \text{Prob}\left(x_j \le \breve{x}_{[(i,k),j]}\right)\right]$$

Upper bounds

The upper bound is

$$M - \sum_{l=0}^{M-1} \prod_{k=M-l}^{M} \prod_{i=1}^{L_k} \left[1 - \prod_{j=1}^{n} \text{Prob}\left(x_j \ge \hat{x}_{[(i,k),j]}\right)\right]$$

Example

Consider a system with two components with m_1 = 3, m_2 = 2 and M = 3. The information on the boundary points is given in Table 28.1, and the information for the component state probabilities is given in the Table 28.2.

To illustrate both the structure functions, let us apply it to x = (2, 1).

Table 28.2. Component-state probability

Component	Component state (x)			
	0	1	2	3
1	0.2	0.4	0.1	0.3
2	0.3	0.2	0.5	

With the lower boundary points,

$\hat{I}(0) = 1$

$\hat{I}(1) = 1$ because $(2,1) \ge (1, 0)$ and $(2,1) \ge (0, 1)$,

$\hat{I}(2) = 1$ because $(2,1) \ge (1, 1)$, and

$\hat{I}(3) = 0$ because $(2,1) < (3, 2)$.

Using the structure function derived from the lower boundary points, for this vector of states of components, the system is in state 2:

$\phi(x) = \sum_{k=0}^{3} \hat{I}(k) - 1 = 2$.

Similarly, with the upper boundary points,

$\breve{I}(0) = 0$ because $(2,1) \ge (0, 0)$

$\breve{I}(1) = 0$ because $(2,1)$ is not less than or equal to either (3, 0) or (0, 2),

$\breve{I}(2) = 1$ because $(2,1) < (2,2)$, and

$\breve{I}(3) = 1$.

Using the structure function derived from the upper boundary points, for this vector of states of components, the system is in state 2:

$\phi(x) = \sum_{k=0}^{3} \breve{I}(k) = 2$.

For this system, we get $E[\phi(x)] = 1.65$, using either the structure function derived from the lower boundary or upper boundary points. Also, bounds on system reliability are $1.54 \le E[\phi(x)] \le 1.75$.

28.3 Measures Based on the Cumulative Experience of the Customer

In traditional binary reliability models, one reliability measure is defined as the probability that a system is functioning perfectly at some point in time $t \in (0, \infty)$. It is denoted by $R(t) = \Pr(\Phi(t) = 1)$, where $\Phi(t)$, the state of the system at time t, is 1 (success) or 0 (failure). In practice, most systems have more than two states of working efficiency (*i.e.,* $\Phi(t) = 0, 1, 2, \ldots, M$, and $M \ge 1$). After being working for some period of time, systems degrade gradually and perform at intermediate states between working perfectly and total failure [5, 7, 15, 25]. Therefore, a reliability measure for multi-state systems should consider all states above some intermediate state. One reliability measure for a

multi-state system is the probability that the system is in some intermediate state k, $k \in [1,\cdots,M]$, or higher at some target usage time t^*, $t^* \in (0,\infty)$. This definition can be expressed as

$$R_k(t^*) = \Pr(\Phi(t^*) \geq k), \forall\ k \in [1,\cdots,M]..$$

The reliability of the system (not repairability or maintainability) is the only concern here. Hence, with time, the system only degrades and does not make transitions to higher states [28, 46, 47]. It is also assumed to be able to degrade directly to any lower state during a transition (see Figure 28.4). With these assumptions and the properties of stochastic processes, models are developed to capture the degradation patterns of the system, and are used to calculate the reliability measures for multi-state systems.

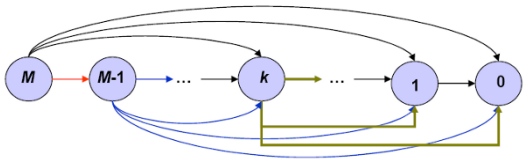

Figure 28.4. Multi-state system degradation

When the degradation pattern of the system is captured, $R_k(t^*) = \Pr(\Phi(t^*) \geq k), \forall\ k \in [1,\cdots,M]$ defines the reliability measure and can be used to evaluate the system at time t^*, $t^* \in (0,\infty)$. A good system should always function at the higher states of working efficiency. For a binary-state system, $R(t) = E[\Phi(t)]$. If the integration of the expected value of the state of this system from 0 to t^* is close to t^*, or if $\frac{1}{t^*}\int_1^{t^*} E[\Phi(t)]dt = \frac{1}{t^*}\int_1^{t^*} R(t)dt$ is close to 1, this system functions perfectly most of time from 0 to t^*.

Similarly, for a multi-state system with M+1 states, if the integration of the expected value of the state of this system from 0 to t^* is closer to Mt^* or $\frac{1}{Mt^*}\int_1^{t^*} E[\Phi(t)]dt = \frac{1}{t^*}\int_1^{t^*} R(t)dt$ is close to 1, this system functions at high levels of working efficiency from 0 to t^*. The advantage of this reliability measure is that with it, different systems can be easily evaluated and compared even though they have different numbers of states of working efficiency. The system with the measure closer to 1 would be considered the better system.

In addition, when evaluating multi-state systems, the customer's preference or utility/ disutility over time should also be taken into account. Some people might prefer a system that works perfectly even though it cannot work for a very long time at that level. However, others might prefer a system that works longer, even though it might not work close to perfection during part of its lifetime.

One numerical example is presented later on to illustrate the calculations and applications of these reliability measures for system performance evaluation.

28.3.1 System Deterioration According to a Markov Process

The degradation of the system from the perfect state, $\Phi(t) = M$, to lower states was first modeled with the Markov process [2, 47] which assumes that the next state of the system depends only on its current state, and that times between transitions follow the stationary exponential distributions. The reliability of the system (not with repairability or maintainability) is the concern here. Hence the system only degrades with time, and does not make transitions to higher states. This can be generalized to consider maintainability. The system is also assumed to be able to degrade directly to any lower state per transition. Models are developed to capture the degradation patterns of the system and are used to calculate the reliability measures for multi-state systems.

For the Markov process, the instantaneous degradation rate from state i to any lower state j is also assumed to be constant and is represented by $\lambda_{i,j}$, where $i > j$ and $i \in [M, M-1,\cdots,1]$. The instantaneous degradation rate matrix Λ summarizes all the instantaneous degradation rates.

$$\Lambda = \begin{bmatrix} \lambda_{M,M-1} & \lambda_{M,M-2} & \cdots & \lambda_{M,1} & \lambda_{M,0} \\ 0 & \lambda_{M-1,M-2} & \cdots & \lambda_{M-1,1} & \lambda_{M-1,0} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & \lambda_{1,0} \end{bmatrix}$$

To obtain the reliability measure:

- The probability that the system is in state M at time t is:

$$P(\Phi(t)=M)$$
$$=\exp\left[-\left(\lambda_{M,M-1}+\lambda_{M,M-2}+\cdots+\lambda_{M,1}+\lambda_{M,0}\right)\ t\right]$$
$$=\exp\left[-\left(\sum_{x=0}^{M-1}\lambda_{M,x}\right)\ t\right]$$

- The probability that the system is in state $M-1$ at time t is:

$$P(\Phi(t)=M-1)=\int_0^t \exp[-G_M\tau_1]\lambda_{M,M-1}$$
$$\exp[-G_{M-1}(t-\tau_1)]\,d\tau_1$$
$$=\frac{\lambda_{M,M-1}}{G_M-G_{M-1}}\{\exp(-G_{M-1}t)-\exp(-G_M t)\}$$

- For Pr(Φ(t)=$M-2$), the system can go from M to $M-1$ and then from $M-1$ to $M-2$,

$$P_1(\Phi(t)=M-2)$$
$$=\int_0^t\int_0^{\tau_2}\exp[-G_M\tau_1]\lambda_{M,M-1}\exp[-G_{M-1}(\tau_2-\tau_1)]$$
$$\lambda_{M-1,M-2}\exp[-G_{M-2}(t-\tau_2)]d\tau_1 d\tau_2$$
$$=\frac{\lambda_{M,M-1}\lambda_{M-1,M-2}}{G_M-G_{M-1}}\left\{\frac{\exp(-G_{M-2}t)-\exp(-G_{M-1}t)}{G_{M-1}-G_{M-2}}\right.$$
$$\left.-\frac{\exp(-G_{M-2}t)-\exp(-G_M t)}{G_M-G_{M-2}}\right\}$$

Or the system and go from M to $M-2$ directly.

$$P_2(\Phi(t)=M-2)=\int_0^t\exp[-G_M\tau_2]\lambda_{M,M-2}$$
$$\exp[-G_{M-2}(t-\tau_2)]d\tau_2$$
$$=\frac{\lambda_{M,M-2}}{G_M-G_{M-2}}\{\exp(-G_{M-2}t)-\exp(-G_M t)\}$$

There are two different ways to degrade to the state $M-2$ from the state M (*i.e.*, $M\to M-1\to M-2$ and $M\to M-2$); four different ways to degrade to the state $M-3$ from M (*i.e.*, $M\to M-1\to M-2\to M-3$ and $M\to M-2\to M-3$ and $M\to M-3$); eight different ways to degrade to the state $M-4$ from M. There are $\sum_{r=0}^{M-i-1}\binom{M-i-1}{r}$ ways to go from M to i. With the same logic, the probability that the system is in state i at time t is the sum the following probabilities:

1. From M to i directly (no intermediate states):

$$P_0=\int_0^t\exp[-G_M\tau_1]\lambda_{M,i}\exp[-G_i(t-\tau_1)]\,d\tau_1$$
$$=\frac{\lambda_{M,i}}{G_M-G_i}\{\exp(-G_i t)-\exp(-G_M t)\}$$

2. With one intermediate state

$$P_{1,k}=\lambda_{M,k}\lambda_{k,i}\int_0^t\int_0^{\tau_2}\exp[-G_M\tau_1]\exp[-G_k(\tau_2-\tau_1)]$$
$$\exp[-G_i(t-\tau_2)]\,d\tau_1 d\tau_2$$

where $k=[M-1,\ldots,i+1]$

3. With n intermediate states: $n=2,\ldots,M-i-1$

$$P_n=\lambda_{M,k_1}\left(\prod_{N=1}^{n-1}\lambda_{k_N,k_{N+1}}\right)\lambda_{k_n,i}\times\int_0^t\cdots\int_0^{\tau_2}\exp\ [-G_M\tau_1]$$
$$\left(\prod_{j=1}^{n}\exp\ [-G_{k_j}(\tau_{j+1}-\tau_j)]\right)$$
$$\exp\ [-G_i(t-\tau_{n+1})]\,d\tau_1\cdots d\tau_{n+1}$$

where $k_1=[M-1,\ldots,i+n]$ and $M>k_1>\ldots>k_n>1$, For each n, there are all $\binom{M-i-1}{r}$ combinations of k_1, $k_2,\ldots,k_n$.

28.3.2 System Deterioration According to a Non-homogeneous Markov Process

The assumption for the Markov process that the next state only depends on the current state is applicable only to systems that do not have an age effect such as software engineering systems, supply chains and transportation network systems. Sooner or later most systems wear out after being

used. Hence, the next state of the system and the length of time that a system stays in some state depend not only on the current state but also on how long the system has been in use. In this chapter, a general stochastic model, the non-homogeneous continuous time Markov process (NHCTMP) model, which is a stochastic model with discrete states and continuous time, is described. With this stochastic model, the age effect for the system is incorporated in the modeling of the process [29, 44].

NHCTMP assumes that system's next state depends not only on the current state but also on the time that the system entered the current state. This assumption reflects the age effect that is typical of many systems.

Let $\Phi(t)$ be the state of the system at time t, $\Phi(t) \in [0,1,\ldots,M]$, and $\Phi(t)$ follows NHCTMP. The transition probability from current state i to next state j from time s to time t is denoted by:

$$p_{i,j}(s,t) = \Pr(\Phi(t) = j \mid \Phi(s) = i),$$

$s<t$, $i, j \in [0,1,\ldots,M]$ and $i > j$.

Similar to the Markov process, the non-homogeneous Markov processes can be expressed with the instantaneous degradation rate matrix, $\Lambda(t)$, and

$$\Lambda(t) = \begin{bmatrix} \lambda_{M,M-1}(t) & \lambda_{M,M-2}(t) & \cdots & \lambda_{M,1}(t) & \lambda_{M,0}(t) \\ 0 & \lambda_{M-1,M-2}(t) & \cdots & \lambda_{M-1,1}(t) & \lambda_{M-1,0}(t) \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & \lambda_{1,0}(t) \end{bmatrix}$$

where

$$\lambda_{i,j}(t) = \lim_{\Delta t \to \infty} \frac{\Pr(\Phi(t+\Delta t) - \Pr(\Phi(t)}{\Delta t}$$

With the known $\Lambda(t)$, we can have the following:

- The probability that the system is in state M at time t is:

$$\Pr(\Phi(t) = M) = \exp[-\int_0^t \sum_{j=0}^{M-1} \lambda_{M,j}(\tau) d\tau]$$

- The probability that the system is in state $M-1$ at time t is:

- For $\Pr(\Phi(t) = M-2)$, the system can go from M to $M-1$ and then from $M-1$ to $M-2$,

$$\Pr_I(\Phi(t) = M-2) = \int_0^t \exp[-\int_0^{\tau_2} \sum_{j=0}^{M-1} \lambda_{M,j}(s) ds] \lambda_{M,M-2}(\tau_2) \exp[-\int_{\tau 2}^t \sum_{j=0}^{M-3} \lambda_{M-2,j}(s) ds] d\tau_2$$

Or the system and go from M to $M-2$ directly.

$$\Pr_{II}(\Phi(t) = M-2) = \int_0^t \int_0^{\tau_2} \exp[-\int_0^{\tau_1} \sum_{j=0}^{M-1} \lambda_{M,j}(s) ds] \lambda_{M,M-1}(\tau_1) \exp[-\int_{\tau 1}^{\tau 2} \sum_{j=0}^{M-2} \lambda_{M-1,j}(s) ds] \lambda_{M-1,M-2}(\tau_2) \exp[-\int_{\tau 2}^t \sum_{j=0}^{M-3} \lambda_{M-2,j}(s) ds] d\tau_1 d\tau_2$$

When the system is in state i at time t the following probabilities should be considered:

1. From M to i directly: (No intermediate states)

$$P_{0,i} = \int_0^t \exp[-\int_0^{\tau_1} \sum_{j=0}^{M-1} \lambda_{M,j}(s) ds] \lambda_{M,i}(\tau_1) \exp[-\int_{\tau 1}^t \sum_{j=0}^{i-1} \lambda_{i,j}(s) ds] d\tau_1$$

2. With only one intermediate state: $l = [M-1,\ldots, i+1]$

$$P_{1,l,i} = \int_0^t \int_0^{\tau_2} \exp[-\int_0^{\tau_1} \sum_{j=0}^{M-1} \lambda_{M,j}(s) ds] \lambda_{M,l}(\tau_1) \exp[-\int_{\tau 1}^{\tau 2} \sum_{j=0}^{l-1} \lambda_{l,j}(s) ds] \lambda_{l,i}(\tau_2) \exp[-\int_{\tau 2}^t \sum_{j=0}^{i-1} \lambda_{i,j}(s) ds] d\tau_1 d\tau_2$$

3. With n intermediate states: ($n = 2,\ldots,M-1$)

$$P_{(n,j),h} = \int_0^t \cdots \int_0^{\tau_2} \exp[-\int_0^{\tau_1} \sum_{j=0}^{M-1} \lambda_{M,j}(s) ds] \lambda_{M,l_1}(\tau_1) \prod_{g=1}^{n-1} \left\{ \exp[-\int_{\tau_N}^{\tau_{g+1}} \sum_{j=0}^{l_{g-1}} \lambda_{l_g,j}(s) ds] \lambda_{l_N,l_{g+1}}(\tau_{g+1}) \right\} \exp[-\int_{\tau_n}^{\tau_i} \sum_{j=0}^{l_{n-1}} \lambda_{l_n,j}(s) ds] \lambda_{l_n,l_i}(\tau_{g+1}) \exp[-\int_{\tau_i}^t \sum_{j=0}^{i-1} \lambda_{i,j}(s) ds] d\tau_1 \cdots d\tau_{n+1}$$

where $h = \binom{M-i-1}{r}$, $l_g = [M-1,\ldots, i+1]$, $M > l_1 > \ldots > l_n > i$, $g = 1, 2, \ldots, n$.

28.3.3 Dynamic Customer-center Reliability Measures for Multi-state Systems

A system might function for a very long time but always with poor efficiency, another might work perfectly in the beginning but then degrade sharply in the short term, and yet another might just degrade very slowly. These three systems may have the same area A in terms of the previous measure and thus are similar, but the customer's satisfaction with these systems may be very different based on their utility over time. This idea can also be visualized using Figure 28.5. Both system I and system II may have the same area, but system II stays in higher states during the early life periods and, of course, system I stays in higher states during the later life periods.

Customers may have different utilities at different life periods. When evaluating multi-state systems, the customer's preference or utility over time should also be considered. To obtain the customer's total experience with the system, we can use the customer's utility function typically used in economics. A utility function, U(x), is the function that transfers customer's preference for some element x to a numerical value. The bigger value indicates that the customer likes the element better [8, 13]. Different customers have different utility functions, and thus different customers will evaluate the same system differently.

With the customer's utility function as a function of the state of the system, we can calculate the customer's expected total utility for experience (ETUE) with the system from time 0 to t*.

$$ETUE = \int_0^{t^*} E[U(\Phi(t))]\, dt$$

$$= \int_0^{t^*} \sum_{\phi=0}^{M} U(\phi) \Pr(\Phi(t) = \phi)\, dt$$

$$= \sum_{\phi=0}^{M} \int_0^{t^*} U(\phi) \Pr(\Phi(t) = \phi)\, dt$$

The greater the ETUE, the better the system from the viewpoint of the customer.

Example

Let us assume that the utility function for a customer for some system is $U(\phi)=\phi^2$. It should also be pointed out that we can very easily use any other utility function. Two systems are evaluated by this customer. Systems I and II are assumed to have the following instantaneous degradation rates matrices:

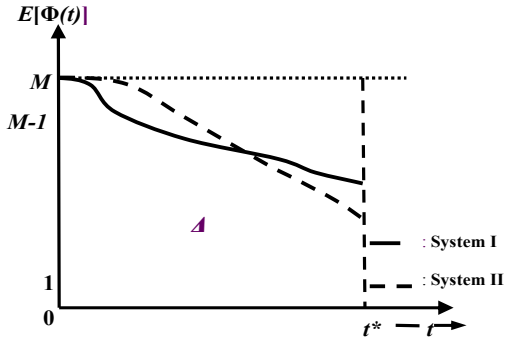

Figure 28.5. Reliability integration for multi-state systems

System I *System II*

$$\Lambda_I = \begin{pmatrix} 0.200 & 0.100 & 0.090 \\ 0 & 0.007 & 0.006 \\ 0 & 0 & 0.008 \end{pmatrix} \quad \Lambda_{II} = \begin{pmatrix} 0.080 & 0.060 & 0.050 \\ 0 & 0.120 & 0.112 \\ 0 & 0 & 0.260 \end{pmatrix}$$

The above two different instantaneous degradation rate matrices indicate that System II will stay at state 3 for longer than System I; System I will stay at states 2 and 1 much longer than system II. However, the accumulated areas from time 0 to 10 under the expected state function are almost the same. For System I, the integral area A_{I} is 16.7830 and for System II, integral area A_{II} is 16.7828. This means that these two system work equally well from time 0 to 10 using the area as a measure. However, this customer may have different experiences with these two systems based on this customer utility function.

The ETUEs show that the total utility that this customer perceives from System I and System II in the last section from time 0 to 10 is:

$$ETUE_I = \int_0^{10} E[U(\Phi(t))]\, dt = \int_0^{10} \sum_{\phi=0}^{3} \phi^2 \Pr(\Phi(t) = \phi)\, dt$$

$$= \sum_{\phi=0}^{3} \int_0^{10} \phi^2 \Pr(\Phi(t) = \phi)\, dt = 22.61 + 14.57 + 1.96$$

$$= 39.14,$$

and

$\text{ETUE}_{\text{II}} = 40.28+4.49+1.11 = 45.88$

The value of $\Pr(\Phi(t)= \phi)$ for this example can be very easily calculated with the equations mentioned in the previous section. Thus, for this example, the customer receives greater ETUE from System II than from System I and hence System II is a better system for the customer for use from 0 to 10 units of time.

Total Experience for the Life Term of the System

Another way to compare two systems is to compare the total utility that the customer receives from using the system until it fails. Thus it would be very interesting to know the expected time that system spends in each state for its whole life term. We can infer that the longer the system spends in higher states, the greater the total utility that will be perceived by the customer.

The expected time that system spends in the state of M for its life term is:

$$E[T_M] = \int_{t=0}^{\infty} P(X(t) = M)dt = \int_{0}^{\infty} \exp(-G_M t)dt = \frac{1}{G_M}$$

The expected time that the system spends in the state of $M-1$ for its life term is:

$$E[T_{M-1}] = \int_{t=0}^{\infty} P(X(t) = M-1)dt$$

$$= \int_{0}^{\infty} \frac{\lambda_{M,M-1}}{G_M - G_{M-1}} \{\exp(-G_{M-1}t) - \exp(-G_M t)\}dt$$

$$= \frac{\lambda_{M,M-1}}{G_M G_{M-1}}$$

Similarly, the expected time that the system spends in the state of $M-2$ for its life term is:

$$E[T_{M-2}] = \int_{t=0}^{\infty} P(X(t) = M-2)dt$$

$$= \frac{\lambda_{M,M-1}\lambda_{M-1,M-2}}{G_M G_{M-1} G_{M-2}} + \frac{\lambda_{M,M-2}}{G_M G_{M-2}}$$

and the expected time that the system spends in the state of i for its life term is:

$$E[T_i] = \int_{t=0}^{\infty} P(X(t) = i)dt = \frac{\lambda_{M,i}}{G_M G_i} + \sum_{k=i+1}^{M-1} \frac{\lambda_{M,k}\lambda_{k,i}}{G_M G_k G_i}$$

$$+ \sum_{n=2}^{M-i-1} \int_{t=0}^{\infty} P_n dt$$

For each n in the last equation, there are $\binom{M-i-1}{r}$ different P_n that can be obtained.

These expected times can be combined with the customer's utility function to develop other customer-centered measures for reliability and safety. A better system should give the customer more utility over time and thus these measures can be used for system design and analysis from the viewpoint of reliability and safety. These models can be generalized for other stochastic processes and we can also incorporate maintainability issues in these models.

28.4 Applications of Multi-state Models

Modern society increasingly relies on infra-structure networks such as the supply chain and logistics [36, 37], transportation networks [4, 9, 10, 20], commodity distribution networks (oil/water/gas distribution networks) [24, 31, 45], and computer and communication networks [23, 40] amongst others. With increasing emphasis on better and more reliable services in competitive global markets, reliability analysis has to be incorporated as an integral part of the planning, design and operations of these infrastructure and related networks. Networks and their components can provide several levels of performance ranging from perfect functioning to complete failure.

In clinical research, patients may experience multiple events that are observed and recorded periodically. For example, in a stroke study [11], patients can be classified into three states based on the Glasgow outcome score (GOS). State 1 is considered the unfavorable state that patients have GOS = 2 or 3. State 2 is considered as the favorable state that patients have GOS = 4 or 5. State 3 represents death. For a diabetes study [1], a patient can be dead or be alive with or without diabetic nephropathy (DN) at some point in time after he/she has been diagnosed with diabetes. To analyze patterns of a disease process, it is desirable

to use those multiple events over time in the analysis.

In order to provide the motivation for applications of the proposed research to potential problems, two examples are presented in the next section: the multi-state flow network reliability and a potential application in measuring the prostate cancer patients' quality of life using the dynamic customer-centered reliability models.

28.4.1 Infrastructure Applications – Multi-state Flow Network Reliability

A network consists of two classes of components: nodes and arcs (or edges). The topology of a network model (see Figure 28.6) can be represented by a graph, $G = (N, A)$ where $N = \{s, 1, 2, \ldots, n, t\}$ is the set of nodes with s as the source node and t as the sink node and $A = \{a_i | 1 \le i \le n\}$ is the set of arcs where an arc ai joins an ordered pairs of nodes $(i, i') \in N \times N$ such that $i \neq i'$. Let $m = \{m_1, m_2, \ldots, m_n\}$ be a vector of maximum capacities for the arcs.

Assume that all the nodes in the network are perfectly reliable. Based on the maximum capacity, we can easily find the maximum flow in the network from node s to node t. This maximum value of flow is equivalent to state M of the system for the development of the structure function, and $0 \le k \le M$. The actual capacity at any time of the arc degrades from m_i, i = 1, …, n, to 0. Let x_i be the actual capacity of the arc a_i, $0 \le x_i \le m_i$, where x_i takes only integer values. This x_i is like the state of the component in the development of the structure function in the Section 28.2.

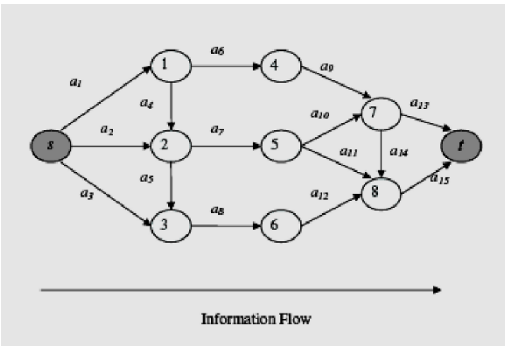

Figure 28.6. Network system

Let E be the node-arc incidence matrix denoted by

$$e(l, a_i) = \begin{cases} 1 & \text{if } l \text{ is the initial node of the arc } a_i \\ -1 & \text{if } l \text{ is the terminal node of the arc } a_i \\ 0 & \text{otherwise} \end{cases}$$

Let e_s be the column vector whose elements are all 0 except the first element, which is is 1; e_t is the column vector whose elements are all 0 except in the last element, where it is 1, and 0 denotes a column vector that has all zero values. The highest state of the network system is the maximum value of the flow, f, which is obtained by solving the following optimization problem:

$Max \;\; f$

$Subject \;\; to$

$Ex^t = (e_s - e_t) f$, E is the node-arc incidence matrix

$x^t \le m^t$

$x^t \ge 0$ and integer

f is the flow, and we want to find probabilities for all the values for the flow in the network to develop measures for reliability. Thus, $S_M = \{x \mid f(x) = M\}$, the equivalence class for the highest value, M, of the state of the system.

Research is under way (through methods in network flow optimization using various labelling algorithms) to generate all the equivalence classes and their boundary points. Then we can apply the methods discussed above to evaluate reliability of the infrastructure networks [38].

28.4.2 Potential Application in Healthcare: Measure of Cancer Patients' Quality of Life

When prostate cancer is diagnosed, the patient is given a stage that indicates the extent of the cancer. Prostate cancer is always categorized into more than two stages based on different staging systems such as Whitmore–Jewett staging and the TNM staging systems.

One of the most popular stage systems developed by the National Cancer Institute categorizes prostate cancer into five stages: 0, I, II, III, and IV (see Table 28.3 for the brief stage

Table 28.3. One definition of prostate cancer stages

Stage	Definition
0	Death
I	Tumors have spread to other parts of body such as bladder, bones, liver or lung
II	Tumors can be found outside of the prostate in nearby tissue
III	Tumors are located only in the prostate but are visible in the image
IV	Tumors are located only in the prostate and not visible in image

definitions). The patient stays in some stage with a lesser extent of cancer for a random period of time and then moves to another stage with more extensive cancer or death (see Figure 28.7). This movement is a stochastic process and it is commonly modeled with a Markov process that assumes that the next stage of cancer only depends on the current stage. In this chapter, we used the NHCTMP model (presented in the previous) to capture the process of the stage changes for the patient. The probability that a patient stays in each stage at some point in time, and the expected time for a patient to be in each stage can be estimated using the stochastic model described in the previous section [also see 12, 14, 16, 42].

Suppose that prostate cancer is categorized by five different stages, $\Phi(t) = 4, 3, 2, 1, 0$, where 4 is the best stage (lesser extent) and 0 is death. A prostate cancer patient can be in stage 4 straight after receiving two different interventions ($t = 0$).

Intervention I makes $\Phi(t)$ follow NHCTMP with instantaneous degradation rates $\lambda_{ij} = \frac{3}{(i-j)^4} t^3, i,$ $j = 4, 3, 2, 1, 0$ and $i > j$ and Intervention II makes $\Phi(t)$ follow NHCTMP with instantaneous degradation rates $\lambda_{ij} = \frac{3}{2(i-j)^2} t$, i, j = 4, 3, 2, 1, 0 and $i > j$.

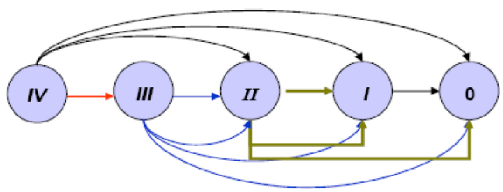

Figure 28.7. Possible stages of prostate cancer movement

We assume that the target or the normalized period of interest from the viewpoint of the patient is [0, 1.85]. Using the equations derived in last section, the probabilities that the patient is in some stage at time 1.85 after receiving two different interventions can be estimated. These are summarized in the Table 28.4.

Quality of life is an important consideration for making a decision about any intervention [14, 17, 26] . The patient's quality of life can reasonably be assumed to change with the stage of his cancer and the types of medical treatment received. With more severe illnesses or more unpleasant side effects from the treatment, the patient's quality of life is likely to be lower.

To measure the decrease in the quality of life, a disutility function can be formulated to measure

Table 28.4. Prostate cancer stage probability at time 1.85

stage (k)	Intervention I	Intervention II
	$Pr_I(\Phi(1.85) = k)$	$Pr_{II}(\Phi(1.85) = k)$
4	0.000	0.026
3	0.001	0.072
2	0.003	0.125
1	0.011	0.165
0	0.985	0.612

how unpleasant or how unsatisfied the patient feels about his illness and medical treatments. The disutility function can be used as one measurement of the patient's quality of life measurement. Disutility functions are commonly used in economics and transportation research [27, 43] and are defined as a function that transfers the customer's dissatisfaction with some item to a numerical value [See also 8, 13, 32, 35, 37]. The greater this numerical value, the more the customer dislikes the item.

A common disutility function in the decision-making literature is the exponential disutility function, which has different forms for different types of risk takers.

I. *Risk Averse*

A risk averse customer might have the disutility function

$$\mathrm{DU}_{ra}(d(t)) = a_1 \exp(\alpha\, d(t)) - a_2$$

a_1, a_2 and α are constant coefficients. a_1 and α show how the patient tolerates his illness. a_2 shows the patient's tolerance toward the side effects of the treatment.

II. *Risk Prone*

A risk prone customer might have the disutility function

$$\mathrm{DU}_{rp}(d(t)) = b_2 - b_1 \exp(-\beta d(t))$$

b_1, b_2 and β are constant coefficients. b_1 and β show how the patient tolerates his illness. b_2 shows the patient's tolerance toward the side effects of the treatment.

III. *Risk Neutral*

A risk neutral customer might have the linear disutility function:

$$\mathrm{DU}_{rn}(d(t)) = c + \gamma\, d(t)$$

c and γ are constant coefficients. $d(t)$ in the above three equations denotes the difference between the stage at time t and the best stage, so $d(t) = M - \Phi(t)$. A greater $d(t)$ results in a greater value of DU.

Suppose this patient is a risk averse patient and his disutility function for interventions is $\mathrm{DU}(\mathrm{d}(t)) = 0.309 \exp(0.289 d(t)) + 2$.

This patient's expected disutility in 1.85 units of time after receiving the two interventions will be:

I.

$$EDU_1(d(1.85)) = \sum_{d=0}^{4} DU(d(1.85)) \Pr_1(d(1.85) = d) = 2.977.$$

II.

$$EDU_{II}(d(1.85)) = \sum_{d=0}^{4} DU(d(1.85)) \Pr_2(d(1.85) = d) = 2.829.$$

This calculation shows that this patient will have greater disutility at time 1.85 after receiving Intervention I. Therefore, from this patient's point of view, Intervention II should be a better choice for him at this time point.

28.5 Conclusions

The traditional binary-state reliability model is insufficient for many systems in the real world, and hence the multi-state reliability models are being developed to meet the needs for real applications.

In this chapter, the development of generic structure functions using equivalent classes and sets of lower/upper boundary points for the multi-state system with multi-state components are presented. The developed structure functions can be applied for general multi-state systems where the numbers of states for the system and for all of its components are different. With the developed structure functions, some multi-state reliability measures can be calculated, such as the probability that the system will be each possible state and the expected value of the state of the system given that the component-state probabilities are known. When the number of components and the state of components and the system increase, the computation of these measures will become time-consuming. Thus, the bounds for the expected

value of the state of the systems are crucial and are also presented here.

The transition of the states of the multi-state system is a stochastic process. The multi-state reliability measure, which is the probability that the system is in state k or higher at some point in time, is first derived using the most commonly used stochastic process, the Markov process. It is reasonable to believe that the probability that some systems degrade from one state to any lower state not only depends on the current state that the system is in but also on the time that the system enters in this state. Therefore, a general stochastic process, NHCTMP, is explored and used to model the degradation of the system. The age effect is considered when estimating the reliability measures using NHCTMP for a multi-state system. With the possible degradation models, the newly accumulated/integrated expected performance is derived and presented.

The development of a new customer-centered dynamic reliability measure that can capture the effect of system degradation on the customer's utility over time is another topic for this chapter. Because the variation of the performance of the system would lower the customer's utility, the integrated variance of the performance over time should be considered in the new customer-centered reliability measure. Utility functions used in portfolio (investment) risk analysis are incorporated with the stochastic models for this purpose.

The potential applications of the multi-state reliability model in infrastructure reliability and in the quality of life measure for patients with multi-stage diseases are also presented to demonstrate the usage of the reliability models described in this chapter.

A Universal Generating Function in the Analysis of Multi-state Systems

Gregory Levitin

The Israel Electric Corporation Ltd., P.O. Box 10, Haifa, 31000 Israel

Abstract: Almost all work in reliability theory is based on the traditional binary concept of reliability models allowing only two possible states for a system and its components, *viz*, perfect functionality or complete failure. However, many real-world systems are composed of multi-state components, which have different performance levels and several failure modes with various effects on the system's entire performance. Such systems are called multi-state systems (MSS). For MSS, the outage effect will be essentially different for units with different performance rates. Therefore, the reliability analysis of MSS is much more complex when compared with binary-state systems. The recently emerged universal generating function (UGF) technique allows one to find the entire MSS performance distribution based on the performance distributions of its elements by using algebraic procedures. This chapter presents the generalized reliability block diagram method based on UGF and its combination with random processes methodology for evaluating the reliability of different types of MSS.

29.1 Introduction

Most works on reliability theory are devoted to traditional binary reliability models allowing only two possible states for a system and its components: perfect functionality and complete failure. However many real-world systems are composed of multi-state components, which have different performance levels and several failure modes with various effects on the system's entire performance. Such systems are called multi-state systems (MSS) [1]. Examples of MSS are power systems or computer systems where the component performance is characterized by the generating capacity or the data processing speed, respectively. For MSS, the outage effect will be essentially different for units with different performance rates. Therefore, the reliability analysis of MSS is much more complex when compared with binary-state systems. In real-world problems of MSS reliability analysis, the great number of system states that need to be evaluated makes it difficult to use traditional binary reliability techniques.

The recently emerged universal generating function (UGF) technique allows one to find the entire MSS performance distribution based on the performance distributions of its elements by using algebraic procedures. This technique generalizes the method that is based on using a well-known ordinary generating function. The basic ideas of the method were introduced by Professor I. Ushakov in the mid 1980s [2]. Since then, the method has been considerably expanded [3, 4].

The UGF approach is straightforward. It is based on intuitively simple recursive procedures and provides a systematic method for the system

states' enumeration that can replace extremely complicated combinatorial algorithms used for enumerating the possible states in some special types of system (such as consecutive systems or networks).

The UGF approach is effective. Combined with simplification techniques, it allows the system's performance distribution to be obtained in a short time. The computational burden is the crucial factor when one solves optimization problems where the performance measures have to be evaluated for a great number of possible solutions along the search process. This makes using the traditional methods in reliability optimization problematic. On the contrary, the UGF technique is fast enough to be implemented in optimization procedures.

The UGF approach is universal. An analyst can use the same recursive procedures for systems with a different physical nature of performance and different types of element interaction.

This approach enables one to obtain the performance distribution of complex MSS using a generalized reliability block diagram method (recursively aggregating multi-state elements and their replacement by single equivalent element).

Nomenclature

RBD	reliability block diagram
MSS	multi-state system
u-function	universal generating function
pmf	probability mass function
$\Pr\{e\}$	probability of event e
$E[X]$	expected value of X
$1(x)$	unity function: $1(\text{TRUE}) = 1$, $1(\text{FALSE}) = 0$
n	number of system elements
G_j	random performance of system element j
$\boldsymbol{g}_j$	set of possible realizations of G_j
g_{jh}	hth realization of G_j
p_{jh}	$\Pr\{G_j = g_{jh}\}$
V	random system performance
v_i	ith realization of V
q_i	$\Pr\{V = v_i\}$
ϕ	system structure function: $V=\phi(G_1,\ldots,G_n)$
θ	system demand
$f(V,\theta)$	acceptability function
$R(\theta)$	system reliability: $\Pr\{f(V, \theta^*)=1\}$
$W(\theta)$	conditional expected system performance
$u_j(z)$	u-function representing pmf of G_j
$U(z)$	u-function representing pmf of V
$\otimes_\varphi$	composition operator over u-functions
$\varphi(G_i,G_j)$	function representing performance of pair of elements

29.2 The RBD Method for MSS

29.2.1 A Generic Model of Multi-state Systems

In order to analyze MSS behavior one has to know the characteristics of its elements. Any system element j can have k_j+1 different states corresponding to the performance rates, represented by the set $\boldsymbol{g}_j=\{g_{j0}, g_{j1},\ldots, g_{jk_j}\}$, where g_{jh} is the performance rate of element j in the state h, $h \in \{0, 1, \ldots, k_j\}$. The performance rate G_j of element j at any time instant is a random variable that takes its values from $\boldsymbol{g}_j$: $G_j \in \boldsymbol{g}_j$. The probabilities associated with the different states (performance rates) of the system element j can be represented by the set

$$\boldsymbol{p}_j = \{p_{j0}, p_{j1},\ldots, p_{jk_j}\}, \qquad (29.1)$$

where

$$p_{jh} = \Pr\{G_j = g_{jh}\}. \qquad (29.2)$$

Since the element's states compose the complete group of mutually exclusive events (meaning that the element can always be in one and only in one of k_j+1 states)

$$\sum_{h=0}^{k_j} p_{jh} = 1. \qquad (29.3)$$

Expression (29.2) defines the *pmf* of a discrete random variable G_j. The collection of pairs g_{jh}, p_{jh}, $h = 0, 1,\ldots, k_j$, completely determines the performance distribution of element j.

When the MSS consists of n independent elements, its performance rate is unambiguously determined by the performance rates of these elements. At each moment, the system elements have certain performance rates corresponding to

their states. The state of the entire system is determined by the states of its elements. Assume that the entire system has K+1 different states and that v_i is the entire system performance rate in state $i \in \{0, \ldots, K\}$. The MSS performance rate is a random variable V that takes values from the set $M=\{v_1, \ldots, v_K\}$.

Let $L^n = \{g_{10},\ldots, g_{1k_1}\}\times\ldots\times\{g_{n0},\ldots, g_{nk_n}\}$ be the space of possible combinations of performance rates for all of the system elements and $M = \{v_0, \ldots, v_K\}$ be the space of possible values of the performance rate for the entire system. The transform $\phi(G_1,\ldots,G_n): L^n \to M$, which maps the space of the elements' performance rates into the space of system's performance rates, is named the system structure function.

The generic model of the MSS includes the *pmf* of performances for all of the system elements and system structure function [1]:

$$\boldsymbol{g}_j, \boldsymbol{p}_j, 1 \le j \le n, \tag{29.4}$$

$$V = \phi(G_1,\ldots,G_n). \tag{29.5}$$

From this model one can obtain the *pmf* of the entire system performance in the form

$$q_i, v_i, 0 \le i \le K, \text{ where } q_i = \Pr\{V = v_i\}. \tag{29.6}$$

The acceptability of system state can usually be defined by the acceptability function $f(V,\theta)$ representing the desired relation between the system performance V and some limit value θ named system demand ($f(V,\theta) = 1$, if the system performance is acceptable and $f(V, \theta) = 0$, otherwise). The MSS reliability is defined as its expected acceptability (the probability that the MSS satisfies the demand) [5]. Having the system *pmf* (29.6) one can obtain its reliability as

$$R(\theta) = E[f(V,\theta)] = \sum_{i=1}^{K} q_i f(v_i,\theta). \tag{29.7}$$

For example, in applications where the system performance is defined as a task execution time and θ is the maximum allowed task execution time, (29.7) takes the form

$$R(\theta) = \sum_{i=1}^{K} q_i 1(v_i < \theta), \tag{29.8}$$

in applications where the system performance is defined as system productivity (capacity) and θ is the minimum allowed productivity, (29.7) takes the form

$$R(\theta) = \sum_{i=1}^{K} q_i 1(v_i > \theta). \tag{29.9}$$

For repairable systems, (29.7)–(29.9) can be used for evaluating system availability.

Another important measure of system performance is the conditional expected performance $W(\theta)$. This index determines the system's expected performance given that the system is in acceptable states. It can be obtained as

$$W(\theta) = E[V \mid f(V,\theta) = 1] = \sum_{i=1}^{K} q_i v_i f(v_i,\theta) / R(\theta). \tag{29.10}$$

For some systems an unconditional expected performance $W = E[V] = \sum_{i=1}^{K} q_i v_i$ is of interest.

In order to calculate the indices $R(\theta)$ and $W(\theta)$, one has to obtain the *pmf* of the MSS random performance in the form (29.6) from the model (29.4) and (29.5). The RBD method for obtaining the MSS performance distribution is based on the universal generating function (u-function) technique, which was introduced in [2] and has proven to be very effective for the reliability evaluation of different types of multi-state systems [3, 4].

29.2.2 Universal Generating Function (u-function) Technique

The u-function representing the *pmf* of a discrete random variable Y_j is defined as a polynomial

$$u_j(z) = \sum_{h=0}^{k_j} \alpha_{jh} z^{y_{jh}}, \tag{29.11}$$

where the variable Y_j has k_j+1 possible values and $\alpha_{jh} = \Pr\{Y_j = y_{jh}\}$.

To obtain the u-function representing the *pmf* of a function of n independent random variables $\varphi(Y_1, \ldots, Y_n)$ the following composition operator is used:

$$U(z)=\underset{\varphi}{\otimes}(u_1(z),...,u_n(z))$$

$$=\underset{\varphi}{\otimes}\Big(\sum_{h_1=0}^{k_1}\alpha_{1h_1}z^{y_{1h_1}},...,\sum_{h=0}^{k_n}\alpha_{nh_n}z^{y_{nh_n}}\Big)$$

$$=\sum_{h_1=0}^{k_1}\sum_{h_2=0}^{k_2}...\sum_{h_n=0}^{k_n}\left(\prod_{i=0}^{n}\alpha_{ih_i}z^{\varphi(y_{1h_1},...,y_{nh_n})}\right) \quad (29.12)$$

The polynomial $U(z)$ represents all of the possible mutually exclusive combinations of realizations of the variables by relating the probabilities of each combination to the value of function $\varphi(Y_1, ..., Y_n)$ for this combination.

In the case of MSS u-functions

$$u_j(z)=\sum_{h_j=0}^{k_j}p_{jh_j}z^{g_{jh_j}} \quad (29.13)$$

represent the pmf of random performances of independent system elements. Having a generic model of an MSS in the form of (29.4) and (29.5), one can obtain the measures of system performance by applying the following steps:

1. Represent the *pmf* of the random performance of each system element j in the form of the u-function (29.13).
2. Obtain the u-function of the entire system $U(z)$ which represents the *pmf* of the random variable V by applying the composition operator $\underset{\phi}{\otimes}$ that uses the system structure function ϕ using (29.5).
3. Calculate the MSS performance indices applying (29.7) and (29.10) over system performance *pmf* (29.6) represented by the u-function $U(z)$.

While steps 1 and 3 are rather trivial, step 2 may involve complicated computations. Indeed, the derivation of a system structure function for various types of system is usually a difficult task. As shown in [4], representing the structure functions in the recursive form is beneficial from both the derivation clarity and computational simplicity viewpoints. In many cases, the structure function of the entire MSS can be represented as the composition of the structure functions corresponding to some subsets of the system elements (MSS subsystems).

The u-functions of the subsystems can be obtained separately and the subsystems can be further treated as single equivalent elements with the performance *pmf* represented by these u-functions. The method for distinguishing recurrent subsystems and replacing them with single equivalent elements is based on a graphical representation of the system structure and is referred to as the RBD method. This approach is usually applied to systems with a complex series-parallel configuration.

29.2.3 Generalized RBD Method for Series-parallel MSS

The structure function of complex series-parallel system can always be represented as composition of the structure functions of statistically independent subsystems containing only elements connected in a series or in parallel. Therefore, in order to obtain the u-function of a series-parallel system one has to apply the composition operators recursively in order to obtain u-functions of the intermediate pure series or pure parallel structures. The following algorithm realizes this approach:

1. Find any pair of system elements (i and j) connected in parallel or in series in the MSS.
2. Obtain the u-function of this pair using the corresponding composition operator $\underset{\varphi}{\otimes}$ over two u-functions of the elements:

$$U_{\{i,j\}}(z)=u_i(z)\underset{\varphi}{\otimes}u_j(z)$$

$$=\sum_{h_i=0}^{k_i}\sum_{h_j=0}^{k_j}p_{ih_i}p_{jh_j}z^{\varphi(g_{ih_i},g_{jh_j})}, \quad (29.14)$$

where the function φ is determined by the nature of interaction between elements' performances.

3. Replace the pair with single element having the u-function obtained in step 2.
4. If the MSS contains more than one element return to step 1.

The resulting u-function represents the performance distribution of the entire system.

The choice of the functions φ for series and parallel subsystems depends on the type of system.

For example, in flow transmission MSS, where performance is defined as capacity or productivity, the total capacity of a subsystem containing two independent elements connected in series is equal to the capacity of a bottleneck element (the element with least performance). Therefore, the structure function for such a subsystem takes the form

$$\phi_{\text{ser}}(G_1, G_2) = \min\{G_1, G_2\}. \quad (29.15)$$

If the flow can be dispersed and transferred by parallel channels simultaneously (which provides load sharing), the total capacity of a subsystem containing two independent elements connected in parallel is equal to the sum of the capacities of these elements. Therefore, the structure function for such a subsystem takes the form

$$\phi_{\text{par}}(G_1, G_2) = G_1 + G_2. \quad (29.16)$$

In task processing MSS, where the performance of each element is characterized by its processing speed, different subtasks are performed by different components consecutively. Therefore the time of the entire task completion (reciprocal of the processing speed) is equal to the sum of subtask execution times. In the terms of the processing speeds, one can determine the performance of a subsystem consisting of two consecutive elements as

$$\varphi_{ser}(G_1,G_2)=\text{inv}\,(G_1,G_2) = \frac{1}{1/G_1 + 1/G_2} = \frac{G_1 G_2}{G_1 + G_2}. \quad (29.17)$$

Parallel elements perform the same task starting it simultaneously. The task is completed by a group of elements when it is completed by any element belonging to this group. Therefore, the performance of the group is equal to the performance of its fastest available element. Therefore, for a subsystem of two parallel elements

$$\phi_{\text{par}}(G_1, G_2) = \max\{G_1, G_2\}. \quad (29.18)$$

Example 1

In order to illustrate the reliability block diagram method consider the series-parallel system presented in Figure 29.1A.

First, one can replace series subsystem consisting of elements with the u-functions $u_2(z)$ and $u_3(z)$ with single equivalent element having u-function $[u_2(z) \underset{\phi_{\text{ser}}}{\otimes} u_3(z)]$. By replacing this new element and element with the u-functions $u_4(z)$ with the element having u-function $U_1(z)=[u_2(z) \underset{\phi_{\text{ser}}}{\otimes} u_3(z)] \underset{\phi_{\text{ser}}}{\otimes} u_4(z)$ one obtains a system with the structure presented in Figure 29.1B. This system contains a purely parallel subsystem consisting of elements with the u-functions $U_1(z)$ and $u_5(z)$, which in their turn can be replaced by a single element with the u-function $U_2(z) = U_1(z) \underset{\phi_{\text{par}}}{\otimes} u_5(z)$ (Figure 29.1C). The structure obtained has three elements connected in a series that can be replaced with a single element having the u-function $U_3(z) = [u_1(z) \underset{\phi_{\text{ser}}}{\otimes} U_2(z)] \underset{\phi_{\text{ser}}}{\otimes} u_6(z)$ (Figure 29.1D). The resulting structure contains two elements connected in parallel. The u-function of this structure representing the *pmf* of the entire MSS performance is obtained as $U(z) = U_3(z) \underset{\phi_{\text{par}}}{\otimes} u_7(z)$.

Assume that in the series-parallel system presented in Figure 29.1A all of the system elements can have two states (elements with total failure) and have the parameters presented in Table 29.1.

Each element j has a nominal performance rate g_{j1} in working state and performance rate of zero when it fails. The probability that element j is in working state is p_{j1}.

The process of calculating $U(z)$ for the flow transmission system (for which ϕ_{ser} and ϕ_{par} functions are defined by (29.15) and (29.16), respectively) is as follows:

$$u_2(z) \underset{\min}{\otimes} u_3(z) = (0.8z^3+0.2z^0) \underset{\min}{\otimes} (0.9z^5+0.1z^0)$$
$$= 0.72z^3+0.28z^0;$$
$$U_1(z) = (u_2(z) \underset{\min}{\otimes} u_3(z)) \underset{\min}{\otimes} u_4(z)$$
$$= (0.72z^3+0.28z^0) \underset{\min}{\otimes} (0.7z^4+0.3z^0)$$
$$= 0.504z^3+0.496z^0;$$
$$U_2(z) = U_1(z) \underset{+}{\otimes} u_5(z)$$

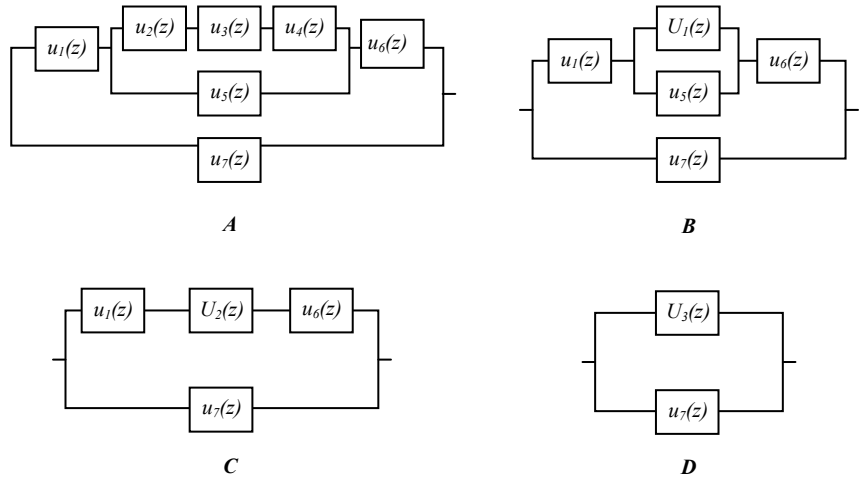

Figure 29.1. Example of RBD method

$= (0.504z^3+0.496z^0) \underset{+}{\otimes} (0.6z^3+0.4z^0)$

$= 0.3024z^6+0.4992z^3+0.1984z^0;$

$u_1(z) \underset{\min}{\otimes} U_2(z) = (0.9z^5+0.1z^0) \underset{\min}{\otimes} (0.3024z^6$

$+0.4992z^3+0.1984z^0)$

$= 0.27216z^5+0.44928z^3+0.27856z^0;$

$U_3(z)=(u_1(z) \underset{\min}{\otimes} U_2(z)) \underset{\min}{\otimes} u_6(z) = (0.27216z^5$

$+0.44928z^3+0.27856z^0) \underset{\min}{\otimes} (0.8z^6+0.2z^0)$

$= 0.217728z^5+0.359424z^3+0.422848z^0;$

$U(z) = U_3(z) \underset{+}{\otimes} u_7(z) = (0.217728z^5+0.359424z^3$

$+0.422848z^0) \underset{+}{\otimes} (0.8z^3+0.2z^0) = 0.1741824z^8$

$+0.2875392z^6+0.0435456z^5+0.4101632z^3$

$+0.0845696z^0.$

Having the system *u*-function that represents its performance distribution one can easily obtain the system expected performance $W = 4.567$. The system reliability for different demand levels can be obtained by applying (29.9) over the system *pmf* represented by the *u*-function $U(z)$:

$R(\theta) = 0.91543$ for $0 < \theta \le 3$;
$R(\theta) = 0.50527$ for $3 < \theta \le 5$;
$R(\theta) = 0.461722$ for $5 < \theta \le 6$;
$R(\theta) = 0.174182$ for $6 < \theta \le 8$;
$R(\theta) = 0$ for $\theta > 8$

The process of calculating $U(z)$ for the task processing system (for which ϕ_{ser} and ϕ_{par} functions are defined by (29.17) and (29.18), respectively) is as follows:

$u_2(z) \underset{\text{inv}}{\otimes} u_3(z)=(0.8z^3+0.2z^0) \underset{\text{inv}}{\otimes} (0.9z^5+0.1z^0)$

$= 0.72z^{1.875}+0.28z^0;$

$U_1(z) = (u_2(z) \underset{\text{inv}}{\otimes} u_3(z)) \underset{\text{inv}}{\otimes} u_4(z)$

$= (0.72z^{1.875}+0.28z^0) \underset{\text{inv}}{\otimes} (0.7z^4+0.3z^0)$

$= 0.504z^{1.277}+0.496z^0;$

$U_2(z)= U_1(z) \underset{\max}{\otimes} u_5(z))$

Table 29.1. Parameters of elements of a series-parallel system

j	1	2	3	4	5	6	7
g_{j1}	5	3	5	4	2	6	3
p_{j1}	0.9	0.8	0.9	0.7	0.6	0.8	0.8

$= (0.504z^{1.277}+0.496z^0) \underset{\max}{\otimes} (0.6z^2+0.4z^0)$

$= 0.6z^2+0.2016z^{1.277}+0.1984z^0;$

$u_1(z) \underset{\text{inv}}{\otimes} U_2(z)=(0.9z^5+0.1z^0) \underset{\text{inv}}{\otimes}$

$(0.6z^2+0.2016z^{1.277}+0.1984z^0)$

$= 0.54z^{1.429}+0.18144z^{1.017}+0.27856z^0;$

$U_3(z) = (u_1(z) \underset{\text{inv}}{\otimes} U_2(z)) \underset{\text{inv}}{\otimes} u_6(z)$

$=(0.54z^{1.429}+0.18144z^{1.017}+0.27856z^0) \underset{\text{inv}}{\otimes}$

$(0.8z^6+0.2z^0) = 0.432z^{1.154}+0.145152z^{0.87}$

$+0.422848z^0;$

$U(z) = U_3(z) \underset{\max}{\otimes} u_7(z) = (0.432z^{1.1}$

$+0.145152z^{0.87}+0.422848z^0) \underset{\max}{\otimes} (0.8z^3+0.2z^0)$

$= 0.8z^3+0.0864z^{1.154}+0.0290304z^{0.87}$

$+0.08445696z^0.$

The main performance measures of this system are:

$W = 2.549;$

$R(\theta) = 0.91543$ for $0 < \theta \le 0.87,$

$R(\theta) = 0.8864$ for $0.87 < \theta \le 1.429$;

$R(\theta) = 0.8$ for $1.429 < \theta \le 3;$

$R(\theta) = 0$ for $\theta > 3.$

The procedure described above recursively obtains the same MSS u-function that can be obtained directly by the operator

$$\underset{\phi}{\otimes}(u_1(z),u_2(z),u_3(z),u_4(z),u_5(z))$$

using the following structure function: $\phi(G_1, G_2, G_3, G_4, G_5, G_6, G_7) = \phi_{\text{par}}(\phi_{\text{ser}}(G_1, \phi_{\text{par}}(\phi_{\text{ser}}(G_2, G_3, G_4), G_5), G_6), G_7)$. The recursive procedure for obtaining the MSS u-function is not only more convenient than the direct one, but, and much more importantly, it allows one to reduce the computational burden of the algorithm considerably. Indeed, using the direct procedure corresponding to (29.12) one has to evaluate the system structure function for each combination of values of random variables $G_1,...,G_7$ ($\prod_{j=1}^{7} k_j$ times, where k_j is the number of states of element j). Using the recursive algorithm one can take advantage of the fact that some subsystems have the same performance rates in different states, which makes these states indistinguishable and reduces the total number of terms in the corresponding u-functions.

In our example, the number of evaluations of the system structure function using directly (29.12) for the system with two-state elements is $2^7 = 128$. Each evaluation requires calculating a function of seven arguments. Using the reliability block diagram method one obtains the system u-function just by 30 procedures of structure function evaluation (each procedure requires calculating simple functions of just two arguments). This is possible because of the reduction in the lengths of intermediate u-functions by the collection of like terms. For example, it can be easily seen that in the subsystem of elements 2, 3 and 4 all eight possible combinations of the elements' states produce just two different values of the subsystem performance: 0 and min (g_{21}, g_{31}, g_{41}) in the case of the flow transmission system, or 0 and $g_{21}g_{31}g_{41}/(g_{21}g_{31}+g_{21}g_{41}+g_{31}g_{41})$ in the case of the task processing system. After obtaining the u-function $U_1(z)$ for this subsystem and collecting like terms one obtains a two-term equivalent u-function that is used further in the recursive algorithm. Such a simplification is impossible when the entire expression (29.12) is used.

29.3 Combination of Random Processes Methods and the UGF Technique

In many cases the state probability distributions of system elements are unknown whereas the state transition rates (failure and repair rates) can be easily evaluated from history data or mathematical models. The Markov process theory allows the analyst to obtain the probability of any system state at any time solving a system of differential equations.

The main difficulty of applying the random processes methods to the MSS reliability evaluation is the "dimension damnation". Indeed, the number of differential equations in the system that should be solved using the Markov approach is equal to the total number of MSS states (product of numbers of states of all of the system elements). This number can be very large even for a relatively

small MSS. Even though the modern software tools provide solutions for high-order systems of differential equations, building the state-space diagram and deriving the corresponding system of differential equations is a difficult non-formalized process that may cause numerous mistakes.

The UGF-based reliability block diagram technique can be used for reducing the dimension of system of equations obtained by the random process method. The main idea of the approach lies in solving the separated smaller systems of equations for each MSS element and then combining the solutions using the UGF technique in order to obtain the dynamic behavior of the entire system. The approach not only separates the equations but also reduces the total number of equations to be solved

The basic steps of the approach are as follows:

1. Build the random process Markov model for each MSS element (considering only state transitions within this element). Obtain two sets $\boldsymbol{g}_j=\{g_{j1},g_{j2},\ldots,g_{jk_j}\}$ and $\boldsymbol{p}_j(t)=\{p_{j1}(t),p_{j2}(t),\ldots,p_{jk_j}(t)\}$ for each element j $(1\le j\le n)$ by solving the system of k_j ordinary differential equations. Note that instead of solving one high-order system of $\prod_{j=1}^{n}k_j$ equations one has to solve n low-order systems with the total number of equations $\sum_{j=1}^{n}k_j$.

2. Having the sets $\boldsymbol{g}_j$ and $\boldsymbol{p}_j(t)$ for each element j define u-function of this element in the form $u_j(z)=p_{j1}(t)z^{g_{j1}}+p_{j2}(t)z^{g_{j2}}+\ldots+p_{jk_j}(t)z^{g_{jk_j}}$.

3. Using the generalized RBD method, obtain the resulting u-function for the entire MSS.

4. Apply the operators (29.7) and (29.10) over the system *pmf* represented by the resulting u-function to obtain the main MSS reliability indices.

Example 2

Consider a flow transmission system (Figure 29.2) consisting of three pipes [1]. The oil flow is transmitted from point A to point B. The pipes performance is measured by their transmission

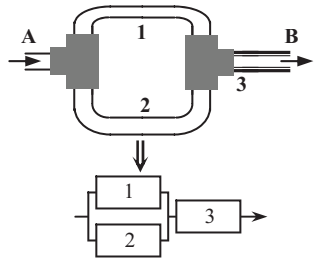

Figure 29.2. Simple flow transmission MSS

capacity (ton per minute). Elements 1 and 2 are binary. A state of total failure for both elements corresponds to a transmission capacity of 0 and the operational state corresponds to the capacities of the elements 1.5 and 2 tons per minute, respectively, so that $G_1(t)\in\{0,1.5\}$, $G_2(t)\in\{0,2\}$. Element 3 can be in one of three states: a state of total failure corresponding to a capacity of 0, a state of partial failure corresponding to a capacity of 1.8 tons per minute and a fully operational state with a capacity of 4 tons per minute so that $G_3(t)\in\{0,1.8,4\}$. The demand is constant: $\theta = 1.0$ ton per minute.

The system output performance rate $V(t)$ is defined as the maximum flow that can be transmitted between nodes A and B. In accordance with (29.15) and (29.16), $V(t)=\min\{G_1(t)+G_2(t),G_3(t)\}$.

The state-space diagrams of the system elements are presented in Figure 29.3. The failure rates and repair rates corresponding to these two elements are

$\lambda_{2,1}^{(1)}=7\,year^{-1},\mu_{1,2}^{(1)}=100\,year^{-1}$ for element 1,

$\lambda_{2,1}^{(2)}=10\,year^{-1},\mu_{1,2}^{(2)}=80\,year^{-1}$ for element 2.

Element 3 is a multi-state element with only minor failures and minor repairs. The failure rates and repair rates corresponding to element 3 are

$\lambda_{3,2}^{(3)}=10\,year^{-1},\lambda_{3,1}^{(3)}=0,\lambda_{2,1}^{(3)}=7\,year^{-1},$

$\mu_{1,3}^{(3)}=0,\mu_{1,2}^{(3)}=120\,year^{-1},\mu_{2,3}^{(3)}=110\,year^{-1}.$

According to the classical Markov approach one has to enumerate all the system states corresponding to different combinations of all possible states of system elements (characterized

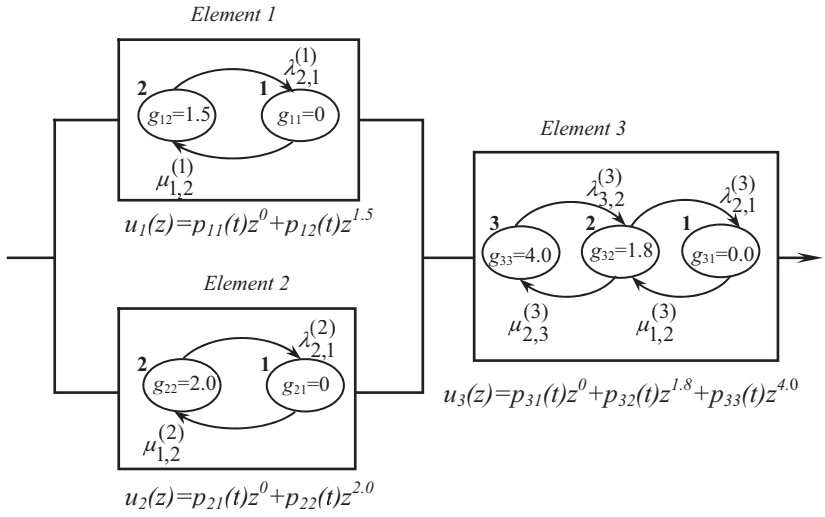

Figure 29.3. State-space diagrams and *u*-functions of system elements

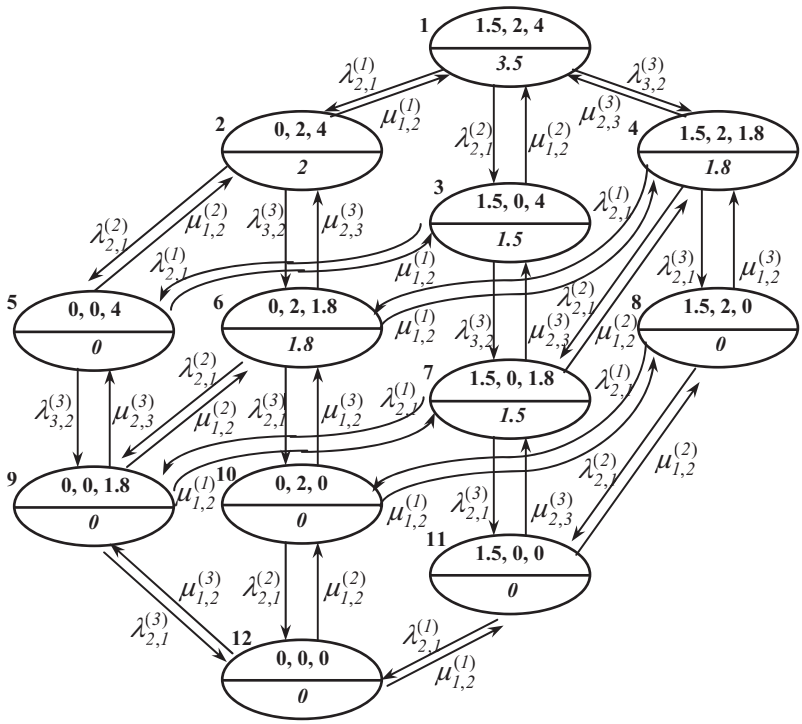

Figure 29.4. State-space diagram for the entire system

by their performance levels). The total number of different system states is $K = k_1k_2k_3 = 2*2*3 = 12$. The state-space diagram of the system is presented in Figure 29.4 (in this diagram the vector of element performances for each state and the corresponding system performance are presented, respectively in the upper and lower parts of the ellipses).

Then the state transition analysis should be performed for all pairs of system states. For example, for the state number 2 where states of the elements are $\{g_{11},g_{22},g_{33}\}=\{2,4,2\}$ the transitions to states 1, 5 and 6 exist with the intensities $\mu_{1,2}^{(1)}, \lambda_{2,1}^{(2)}, \lambda_{3,2}^{(3)}$, respectively.

The corresponding system of differential equations for the state probabilities $p_i(t)$, $2 \le i \le 12$ takes the form:

$$\frac{dp_1(t)}{dt} = -(\lambda_{2,1}^{(1)} + \lambda_{2,1}^{(2)} + \lambda_{3,2}^{(3)})p_1(t) + \mu_{1,2}^{(1)}p_2(t) + \mu_{1,2}^{(2)}p_3(t) + \mu_{2,3}^{(3)}p_4(t),$$

$$\frac{dp_2(t)}{dt} = \lambda_{2,1}^{(1)}p_1(t) - (\mu_{1,2}^{(1)} + \lambda_{2,1}^{(2)} + \lambda_{3,2}^{(3)})p_2(t) + \mu_{1,2}^{(2)}p_5(t) + \mu_{2,3}^{(3)}p_6(t),$$

$$\frac{dp_3(t)}{dt} = \lambda_{2,1}^{(2)}p_1(t) - (\mu_{1,2}^{(2)} + \lambda_{2,1}^{(1)} + \lambda_{3,2}^{(3)})p_3(t) + \mu_{1,2}^{(1)}p_5(t) + \mu_{2,3}^{(3)}p_7(t),$$

$$\frac{dp_4(t)}{dt} = \lambda_{2,3}^{(3)}p_1(t) - (\mu_{2,3}^{(3)} + \lambda_{2,1}^{(1)} + \lambda_{2,1}^{(2)} + \lambda_{2,1}^{(3)})p_4(t) + \mu_{1,2}^{(1)}p_6(t) + \mu_{1,2}^{(2)}p_7(t) + \mu_{1,2}^{(3)}p_8(t),$$

$$\frac{dp_5(t)}{dt} = \lambda_{2,1}^{(2)}p_2(t) + \lambda_{2,1}^{(1)}p_3(t) - (\mu_{1,2}^{(2)} + \mu_{1,2}^{(1)} + \lambda_{3,2}^{(3)})p_5(t) + \mu_{2,3}^{(3)}p_9(t),$$

$$\frac{dp_6(t)}{dt} = \lambda_{3,2}^{(3)}p_2(t) + \lambda_{2,1}^{(1)}p_4(t) - (\mu_{2,3}^{(3)} + \mu_{1,2}^{(1)} + \lambda_{2,1}^{(2)} + \lambda_{2,1}^{(3)})p_6(t) + \mu_{1,2}^{(2)}p_9(t) + \mu_{1,2}^{(3)}p_{10}(t),$$

$$\frac{dp_7(t)}{dt} = \lambda_{3,2}^{(3)}p_3(t) + \lambda_{2,1}^{(1)}p_4(t) - (\mu_{2,3}^{(3)} + \mu_{1,2}^{(2)} + \lambda_{2,1}^{(1)} + \lambda_{2,1}^{(3)})p_7(t) + \mu_{1,2}^{(1)}p_9(t) + \mu_{1,2}^{(3)}p_{11}(t),$$

$$\frac{dp_8(t)}{dt} = \lambda_{2,1}^{(3)}p_4(t) - (\mu_{1,2}^{(3)} + \lambda_{2,1}^{(1)} + \lambda_{2,1}^{(2)})p_8(t) + \mu_{1,2}^{(1)}p_{10}(t) + \mu_{1,2}^{(2)}p_{11}(t),$$

$$\frac{dp_9(t)}{dt} = \lambda_{3,2}^{(3)}p_5(t) + \lambda_{2,1}^{(2)}p_6(t) + \lambda_{2,1}^{(1)}p_7(t) - (\mu_{2,3}^{(3)} + \mu_{1,2}^{(2)} + \mu_{1,2}^{(1)} + \lambda_{2,1}^{(3)})p_9(t) + \mu_{1,2}^{(1)}p_{10}(t) + \mu_{1,2}^{(3)}p_{12}(t),$$

$$\frac{dp_{10}(t)}{dt} = \lambda_{2,1}^{(3)}p_6(t) + \lambda_{2,1}^{(1)}p_8(t) - (\mu_{1,2}^{(3)} + \mu_{1,2}^{(1)} + \lambda_{2,1}^{(2)})p_{10}(t) + \mu_{1,2}^{(2)}p_{12}(t),$$

$$\frac{dp_{11}(t)}{dt} = \lambda_{2,1}^{(3)}p_7(t) + \lambda_{2,1}^{(2)}p_8(t) - (\mu_{1,2}^{(3)} + \mu_{1,2}^{(2)} + \lambda_{2,1}^{(1)})p_{11}(t) + \mu_{1,2}^{(1)}p_{12}(t),$$

$$\frac{dp_{12}(t)}{dt} = \lambda_{2,1}^{(3)}p_9(t) + \lambda_{2,1}^{(2)}p_{10}(t) + \lambda_{2,1}^{(1)}p_{11}(t) - (\mu_{1,2}^{(3)} + \mu_{1,2}^{(2)} + \mu_{1,2}^{(1)})p_{12}(t).$$

Solving this system with the initial conditions $p_1(0) = 1$, $p_i(0) = 0$ for $2 \le i \le 12$ one obtains the probability of each state at time t.

According to Figure 29.4, in different states MSS has the following performance rates: in the state 1 $v_1 = 3.5$, in the state 2 $v_2 = 2.0$, in the states 4 and 6 $v_4 = v_6 = 1.8$, in the states 3 and 7 $v_3 = v_7 = 1.5$, in the states 5, 8, 9, 10, 11 and 12 $v_5 = v_8 = v_9 = v_{10} = v_{11} = v_{12} = 0$. Therefore,

$\Pr\{V=3.5\} = p_1(t)$,

$\Pr\{V=2.0\} = p_2(t)$,

$\Pr\{V=1.8\} = p_4(t)+p_6(t)$,

$\Pr\{V=0\}=p_5(t)+p_8(t)+p_9(t)+p_{10}(t)+p_{11}(t)+p_{12}(t)$.

For the constant demand level $\theta = 1$, one obtains the MSS instantaneous availability as a sum of states probabilities where the MSS output performance is greater than or equal to 1. The states 1, 2, 3, 4, 6 and 7 are acceptable. Hence $A(t) = p_1(t) + p_2(t) + p_3(t) + p_4(t) + p_6(t) + p_7(t)$. The MSS instantaneous expected performance is: $W(t) = \sum_{i=1}^{12} p_i(t)v_i$.

Solving the system of 12 differential equations is quite a complicated task that can only be solved numerically. Applying the combination of Markov

and UGF techniques, one can drastically simplify the calculations and even obtain an analytical solution for the reliability and expected performance of the given system. One should proceed as follows:

1. According to the Markov method build the following systems of differential equations for each element separately (using the state-space diagrams presented in Figure 29.3):
For element 1:

$$\begin{cases} dp_{11}(t)/dt = -\mu_{1,2}^{(1)} p_{11}(t) + \lambda_{2,1}^{(1)} p_{12}(t) \\ dp_{12}(t)/dt = -\lambda_{2,1}^{(1)} p_{12}(t) + \mu_{1,2}^{(1)} p_{11}(t) \end{cases}$$

The initial conditions are $p_{12}(0) = 1$, $p_{11}(0) = 0$.

For element 2:

$$\begin{cases} dp_{21}(t)/dt = -\mu_{1,2}^{(2)} p_{21}(t) + \lambda_{2,1}^{(2)} p_{22}(t) \\ dp_{22}(t)/dt = -\lambda_{2,1}^{(2)} p_{22}(t) + \mu_{1,2}^{(2)} p_{21}(t) \end{cases}$$

The initial conditions are: $p_{21}(0) = 1$, $p_{22}(0) = 0$.

For element 3:

$$\begin{cases} dp_{31}(t)/dt = -\mu_{1,2}^{(3)} p_{31}(t) + \lambda_{2,1}^{(3)} p_{32}(t) \\ dp_{32}(t)/dt = \lambda_{3,2}^{(3)} p_{33}(t) - (\lambda_{2,1}^{(3)} + \mu_{2,3}^{(3)}) p_{32}(t) \\ \quad + \mu_{1,2}^{(3)} p_{31}(t) \\ dp_{33}(t)/dt = -\lambda_{3,2}^{(3)} p_{33}(t) + \mu_{2,3}^{(3)} p_{32}(t) \end{cases}$$

The initial conditions are: $p_{31}(0) = p_{32}(0) = 0$, $p_{33}(0) = 1$.

After solving the three separate systems of differential equations under the given initial conditions, we obtain the following expressions for state probabilities:

For element 1:

$$p_{11}(t) = \lambda_{2,1}^{(1)}/\omega^{(1)} - (\lambda_{2,1}^{(1)}/\omega^{(1)}) e^{-\omega^{(1)} t},$$

$$p_{12}(t) = \mu_{1,2}^{(1)}/\omega^{(1)} + (\lambda_{2,1}^{(1)}/\omega^{(1)}) e^{-\omega^{(1)} t},$$

For element 2:

$$p_{21}(t) = \lambda_{2,1}^{(2)}/\omega^{(2)} - (\lambda_{2,1}^{(2)}/\omega^{(2)}) e^{-\omega^{(2)} t},$$

$$p_{22}(t) = \mu_{1,2}^{(2)}/\omega^{(2)} + (\lambda_{2,1}^{(2)}/\omega^{(2)}) e^{-\omega^{(2)} t},$$

where $\omega^{(i)} = \mu_{1,2}^{(i)} + \lambda_{2,1}^{(i)}$.

For element 3:

$$p_{31}(t) = A_1 e^{\alpha t} + A_2 e^{\beta t} + A_3,$$

$$p_{32}(t) = B_1 e^{\alpha t} + B_2 e^{\beta t} + B_3,$$

$$p_{33}(t) = C_1 e^{\alpha t} + C_2 e^{\beta t} + C_3, \text{ where}$$

$$\alpha = -\eta/2 + \sqrt{\eta^2/4 - \zeta}, \ \beta = -\eta/2 - \sqrt{\eta^2/4 - \zeta},$$

$$A_1 = \frac{\lambda_{2,1}^{(3)} \lambda_{3,2}^{(3)}}{\alpha(\alpha - \beta)}, \ A_2 = \frac{\lambda_{2,1}^{(3)} \lambda_{3,2}^{(3)}}{\beta(\beta - \alpha)}, \ A_3 = \frac{\lambda_{2,1}^{(3)} \lambda_{3,2}^{(3)}}{\zeta},$$

$$B_1 = \frac{(\mu_{1,2}^{(3)} + \alpha)\lambda_{3,2}^{(3)}}{\alpha(\alpha - \beta)}, \ B_2 = \frac{(\mu_{1,2}^{(3)} + \alpha)\lambda_{3,2}^{(3)}}{\beta(\beta - \alpha)},$$

$$B_3 = \frac{\mu_{1,2}^{(3)} \lambda_{3,2}^{(3)}}{\zeta}, \ C_1 = \frac{(\mu_{1,2}^{(3)} + \alpha)\lambda_{3,2}^{(3)} \mu_{2,3}^{(3)}}{\alpha(\alpha - \beta)(\alpha + \lambda_{3,2}^{(3)})},$$

$$C_2 = \frac{(\mu_{1,2}^{(3)} + \beta)\lambda_{3,2}^{(3)} \mu_{2,3}^{(3)}}{\beta(\beta - \alpha)(\beta + \lambda_{3,2}^{(3)})},$$

$$C_3 = \frac{\mu_{1,2}^{(3)} \mu_{2,3}^{(3)} (\beta + \lambda_{3,2}^{(3)}(\lambda_{3,2}^{(3)} - \alpha))}{\alpha\beta(\alpha + \lambda_{3,2}^{(3)})(\beta + \lambda_{3,2}^{(3)})},$$

$$\eta = \lambda_{2,1}^{(3)} + \lambda_{3,2}^{(3)} + \mu_{1,2}^{(3)} + \mu_{2,3}^{(3)},$$

$$\zeta = \lambda_{2,1}^{(3)} \lambda_{3,2}^{(3)} + \mu_{1,2}^{(3)} \mu_{2,3}^{(3)} + \mu_{1,2}^{(3)} \lambda_{3,2}^{(3)}.$$

After determining the state probabilities for each element, we obtain the following performance distributions:

For element 1:

$\boldsymbol{g}_1 = \{g_{11}, g_{12}\} = \{0, \ 1.5\}$,

$\boldsymbol{p}_1(t) = \{p_{11}(t), p_{12}(t)\}$.

For element 2:

$\boldsymbol{g}_2 = \{g_{21}, g_{22}\} = \{0, \ 2.0\}$,

$\boldsymbol{p}_2(t) = \{p_{21}(t), p_{22}(t)\}$.

For element 3:

$\boldsymbol{g}_3 = \{g_{31}, g_{32}, g_{33}\} = \{0, \ 1.8, \ 4.0\}$,

$\boldsymbol{p}_3(t) = \{p_{31}(t), p_{32}(t), p_{33}(t)\}$.

2. Having the sets $\boldsymbol{g}_j$, $\boldsymbol{p}_j(t)$ for $j = 1,2,3$ obtained in the first step we can define the *u*-functions of the individual elements as:

$u_1(z) = p_{11}(t)z^{g_{11}} + p_{12}(t)z^{g_{12}} = p_{11}(t)z^0 + p_{12}(t)\, z^{1.5}$.

$u_2(z) = p_{21}(t)z^{g_{21}} + p_{22}(t)z^{g_{22}} = p_{21}(t)z^0 + p_{22}(t)z^2$.

$u_3(z) = p_{31}(t)z^{g_{31}} + p_{32}(t)z^{g_{32}} + p_{33}(t)\, z^{g_{33}} = p_{31}(t)z^0 + p_{32}(t)z^{1.8} + p_{33}(t)z^4$.

3. Using the composition operators for flow transmission MSS we obtain the resulting u-function for the entire series-parallel MSS $U(z)=[u_1(z) \underset{+}{\otimes} u_2(z)] \underset{\min}{\otimes} u_3(z)$ by the following recursive procedure:

$u_1(z) \underset{+}{\otimes} u_2(z)) = [p_{11}(t)z^0 + p_{12}(t)z^{1.5}] \underset{+}{\otimes} [p_{21}(t)z^0$

$+p_{22}(t)z^2] = p_{11}(t)p_{21}(t)z^0 + p_{12}(t)p_{21}(t)z^{1.5} + p_{11}(t)p_{22}(t)$ $z^2 + p_{12}(t)p_{22}(t)z^{3.5}$.

$U(z) = u_3(z) \underset{\min}{\otimes} [u_1(z) \underset{+}{\otimes} u_2(z)] = [p_{31}(t)z^0 + p_{32}(t)z^{1.8}$

$+p_{33}(t)z^4] \underset{\min}{\otimes} p_{11}(t)p_{21}(t)z^0 + p_{12}(t)p_{21}(t)z^{1.5}$

$+p_{11}(t)p_{22}(t)z^2 + p_{12}(t)p_{22}(t)z^{3.5}) = p_{31}(t)p_{11}(t)p_{21}(t)z^0$
$+p_{31}(t)p_{12}(t)p_{21}(t)z^0 + p_{31}(t)p_{11}(t)p_{22}(t)z^0$
$+p_{31}(t)p_{12}(t)p_{22}(t)z^0 + p_{32}(t)p_{11}(t)p_{21}(t)z^0$
$+p_{32}(t)p_{12}(t)p_{21}(t)z^{1.5} + p_{32}(t)p_{11}(t)p_{22}(t)z^{1.8}$
$+p_{32}(t)p_{12}(t)p_{22}(t)z^{1.8} + p_{33}(t)p_{11}(t)p_{21}(t)z^0$
$+p_{33}(t)p_{12}(t)p_{21}(t)z^{1.5} + p_{33}(t)p_{11}(t)p_{22}(t)z^2$
$+p_{33}(t)p_{12}(t)p_{22}(t)z^{3.5}$.

Taking into account that $p_{31}(t)+p_{32}(t)+p_{33}(t) = 1$, $p_{21}(t)+p_{22}(t)=1$ and $p_{11}(t)+p_{12}(t)=1$, we obtain the u-function that determines the performance distribution $\boldsymbol{v}$, $\boldsymbol{q}(t)$ of the entire MSS in the following form $U(z)= \sum_{i=1}^{5} q_i(t)z^{v_i}$ where

$v_1=0$,
$q_1(t)= p_{11}(t)p_{21}(t)+p_{31}(t)p_{12}(t)+p_{31}(t)p_{11}(t)p_{22}(t)$,
$v_2=1.5$ tons/min,
$q_2(t)= p_{12}(t)p_{21}(t)[p_{32}(t)+p_{33}(t)]$,
$v_3=1.8$ tons/min, $q_3(t)= p_{32}(t)p_{22}(t)$,
$v_4=2.0$ tons/min, $q_4(t)= p_{33}(t)p_{11}(t)p_{22}(t)$,
$v_5=3.5$ tons/min, $q_5(t)= p_{33}(t)p_{12}(t)p_{22}(t)$.

4. Based on the entire MSS u-function $U(z)$ we obtain the MSS reliability indices:

The instantaneous MSS availability for different demand levels θ takes the form

$A(t) = q_2(t) + q_3(t) + q_4(t) + q_5(t)$ for $0 < \theta \le 1.5$;

$A(t) = q_3(t) + q_4(t) + q_5(t)$ for $1.5 < \theta \le 1.8$;

$A(t) = q_4(t) + q_5(t)$ for $1.8 < \theta \le 2$;

$A(t) = q_5(t)$ for $2 < \theta \le 3.5$;

$A(t) = 0$ for $3.5 < \theta$.

The instantaneous expected performance at any instant $t > 0$ is

$W(t) = \sum_{i=1}^{5} q_i(t)v_i$

$=1.5q_2(t)+1.8q_3(t)+2q_4(t)+3.5q_5(t)$.

The obtained function $W(t)$ is presented in Figure 29.5.

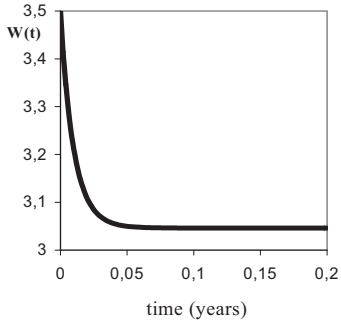

Figure 29.5. System instantaneous expected performance

29.4 Combined Markov-UGF Technique for Analysis of Safety-critical Systems

The UGF technique can be used not only in the cases when different element's states are characterized by quantitative measures of their performance. For example, in analysis of safety-critical systems the dangerous and non-dangerous failures are distinguished, that correspond to failure-safe and failure-dangerous states of the system.

The following section presents a Markov-UGF-based method for evaluating the probabilities of failure-safe and failure-dangerous states for arbitrary complex series-parallel systems with imperfect diagnostics and imperfect periodic inspections and repairs of elements [6]. Each kind of element failure whether failure-safe or failure-dangerous can be either detected or undetected.

29.4.1 Model of System Element

The model of any system element is based on the following assumptions:

1. A system is composed of elements and each element can experience two categories of failures: dangerous and non-dangerous, corresponding, respectively, to failure-dangerous and failure-safe events. Failure-dangerous and failure-safe events are independent.
2. Both categories of failures can be detected and undetected.
3. Detected and undetected failures constitute independent events.
4. Failure rates for both kinds of failures are constant.
5. The element is in operation state if no failure event (detected or undetected) has occurred.
6. The element is in failure-safe state if at least one non-dangerous failure (detected or undetected) has occurred and no dangerous failure has occurred.
7. The element is in failure-dangerous state if at least one dangerous failure (detected or undetected) has occurred.
8. The elements are independent and can undergo periodic inspections at different times.
9. The state of any composition of elements is unambiguously defined by the states of these elements and the nature of the interaction of the elements in the system.
10. The elements' interaction is represented by a series-parallel block diagram.

The safety-critical system is composed of elements to which diagnosis and periodic inspection and repair are applied. Failure-safe or failure-dangerous events can occur independently. The failure category depends on the effects of a fault occurrence. For example, if a failure results in the shutdown of a properly operating process, it is of the failure-safe (FS) type. This type of failure is referred to in a variety of ways as false trip and false alarm. However, if a safety-critical system fails in an operation that is required to shut down a process, this may cause hazardous results, such as the failure of a monitor that is applied to control an important process. This type of failure is generally called failure-dangerous (FD).

Both FS and FD events can be detected or undetected. The detected failure can be detected instantly by diagnostic devices. An imperfect diagnosis model presumes that a fraction d of detected failures can be detected instantaneously by diagnostic devices. Whenever the failure of this kind is detected, the on-line repair is initiated. The failures that cannot be detected by diagnostic devices or remain undetected because of imperfect diagnosis are considered to be undetected failures. These failures can be found only by the proof-test (periodical inspection) just after the end of a proof-test interval. We assume that failure rates of detected failure-safe and failure-dangerous (λ_{sd} and λ_{dd}, respectively) event, as well as undetected failure-safe and failure-dangerous (λ_{su} and λ_{du}, respectively) events can be calculated or elicited from tests.

The state of any single element can be represented as the combination of two independent states corresponding to detected and undetected failures. Each of the two failures can be in the three different states of no failure (state O), failure of the FS category, and failure of the FD category. According to assumptions 5–7, the state of each element can be determined based on each combination of states of failures using Table 29.2.

The state of each element j can be represented by a discrete random variable G_j that takes values from the set {O, FS, FD}. In order to obtain the element state distribution $p_{jO} = \Pr(G_j = \mathrm{O})$, $p_{jFS} = \Pr(G_j = \mathrm{FS})$ and $p_{jFD} = \Pr(G_j = \mathrm{FD})$, one should summarize the probabilities of any combination of states of detected and undetected failures that results in the element states O, FS and FD, respectively. Based on element state transition analysis, one can obtain the Markov state transition diagram presented in Figure 29.6. In this diagram, each possible combination of the states of detected and undetected failures (marked inside the ellipses) belongs to one of the three sets corresponding to three different states of element defined according to Table 29.2.

Practically, no repair action is applied to the undetected failure until the next proof-test. In general, periodic inspection and repair take a very

Table 29.2. States of single elements

		Detected failure		
		O	FS_d	FD_d
Undetected failure	O	O	FS	FD
	FS_u	FS	FS	FD
	FD_u	FD	FD	FD

short time when compared to the proof-test interval T_1, and the whole system stops operating during the process of periodic inspection and repair. Therefore, it is reasonable to set repair rates for undetected failures $\mu_{du} = \mu_{su} = 0$ when analyzing the behavior of a safety-critical system within the proof-test interval.

According to Figure 29.6, the following group of equations describes an element's behavior:

$$\boldsymbol{P}'(t) = \boldsymbol{P}(t)\,\boldsymbol{\Lambda}_j \qquad (29.19)$$

where, $\boldsymbol{P}(t) = (p_{j1}(t), p_{j2}(t), \ldots, p_{j9}(t))$ is the vector of state probabilities, $\boldsymbol{P}'(t)$ is derivative of $\boldsymbol{P}(t)$ with respect to t, and $\boldsymbol{\Lambda}_j$ is transition rate matrix presented in Figure 29.7.

According to Table 29.2, state 1 in the Markov diagram corresponds to state O of the element, states 2–4 correspond to state FS of the element and states 5–9 correspond to state FD of the element. Having the solution $\boldsymbol{P}(t)$ of (29.19) for any element j, one can obtain $p_{jO} = p_{j1}$, $p_{jFS} = p_{j2} + p_{j3} + p_{j4}$ and $p_{jFD} = p_{j5} + p_{j6} + p_{j7} + p_{j8} + p_{j9}$. The solution of (29.19) can be expressed as

$$\boldsymbol{P}_j(t) = \boldsymbol{P}_j(0) \cdot \exp(\boldsymbol{\Lambda}_j\, t), \quad \text{for } t \geq 0; \qquad (29.20)$$

$$\boldsymbol{P}_j(t) = \boldsymbol{P}_j(n\,T_1^+)\exp(\boldsymbol{\Lambda}_j\,(t - n\,T_1)),$$

$$\text{for } n\,T_1^+ \leq t \leq (n+1)\,T_1^+,\ n = 0, 1, 2, \ldots$$

According to imperfect inspection and repair model, the undetected fault cannot be repaired as good as new and some faults may still exist after

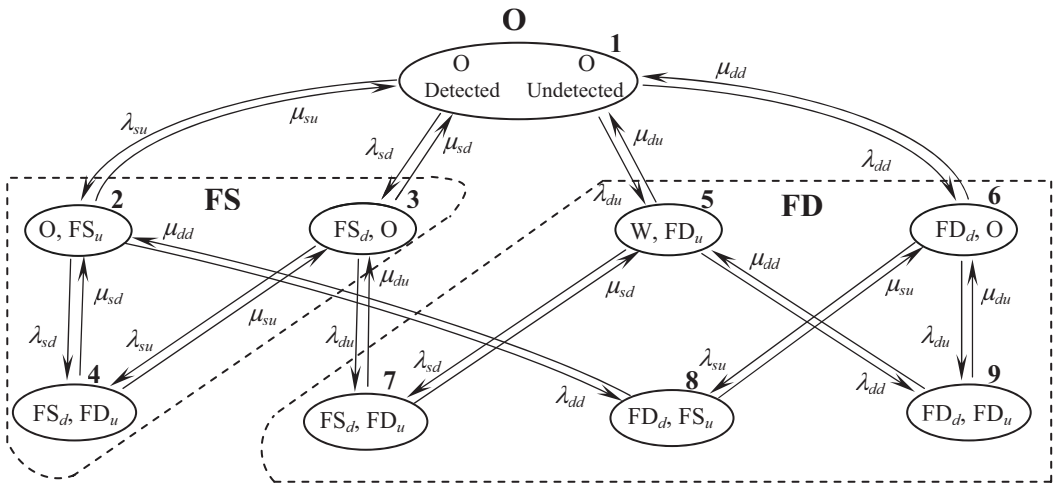

Figure 29.6. Markov state transition diagram used for calculating state distribution of a single element

$$\boldsymbol{\Lambda}_j = \begin{bmatrix}
-\lambda_{sd}-\lambda_{dd}-\lambda_{su}-\lambda_{du} & \lambda_{su} & \lambda_{sd} & \lambda_{du} & \lambda_{dd} & 0 & 0 & 0 & 0 \\
0 & -\lambda_{sd}-\lambda_{dd} & 0 & 0 & 0 & \lambda_{sd} & 0 & \lambda_{dd} & 0 \\
\mu_{sd} & 0 & -\lambda_{su}-\lambda_{du}-\mu_{sd} & 0 & 0 & \lambda_{su} & \lambda_{du} & 0 & 0 \\
0 & 0 & 0 & -\lambda_{sd}-\lambda_{dd} & 0 & 0 & \mu_{sd} & 0 & \mu_{dd} \\
\mu_{dd} & 0 & 0 & 0 & -\lambda_{su}-\lambda_{du}-\mu_{dd} & 0 & 0 & \lambda_{su} & \lambda_{du} \\
0 & \mu_{sd} & 0 & 0 & 0 & -\mu_{sd} & 0 & 0 & 0 \\
0 & 0 & 0 & \mu_{sd} & 0 & 0 & -\mu_{sd} & 0 & 0 \\
0 & \mu_{dd} & 0 & 0 & 0 & 0 & 0 & -\mu_{dd} & 0 \\
0 & 0 & 0 & \mu_{dd} & 0 & 0 & 0 & 0 & -\mu_{dd}
\end{bmatrix}$$

Figure 29.7. Transition rate matrix

inspection and repair. A matrix $\boldsymbol{M}_{ji}$ is used to describe this behavior. Each element of the matrix $\boldsymbol{M}_{ji}$ describes the transition rate of probability from one state to another. Thus, we have

$$\begin{aligned}
&\boldsymbol{P}_j(T_1^+)=\boldsymbol{P}_j(T_1)\,\boldsymbol{M}_{j1}=\boldsymbol{P}_j(0)\exp(\Lambda_j T_1)\boldsymbol{M}_{j1};\\
&\boldsymbol{P}_j(2T_1^+)=\boldsymbol{P}_j(2T_1)\boldsymbol{M}_{j2}\\
&=\boldsymbol{P}_j(0)\exp(\Lambda_j T_1)\boldsymbol{M}_{j1}exp(\Lambda_j T_1)\,\boldsymbol{M}_{j2};\\
&\boldsymbol{P}_j(nT_1^+)=\boldsymbol{P}_j(nT_1)\boldsymbol{M}_{jn}=\boldsymbol{P}_j((n-1)T_1^+)\exp(\Lambda_j T_1)\boldsymbol{M}_{jn}\\
&=\boldsymbol{P}_j((n-2)T_1^+)\exp(\Lambda_j T_1)\boldsymbol{M}_{j(n-1)}\exp(\Lambda_j T_1)\boldsymbol{M}_{jn}\\
&=\boldsymbol{P}_j(0)\exp(\Lambda_j T_1)\boldsymbol{M}_{j1}\exp(\Lambda_j T_1)\boldsymbol{M}_{j2}\times\ldots\\
&\times\exp(\Lambda_j T_1)\,\boldsymbol{M}_{j(n-1)}\exp(\Lambda_j T_1)\boldsymbol{M}_{jn}\ \text{for } n=3,4,\ldots
\end{aligned} \tag{29.21}$$

where n represents the number of proof-test intervals and $\boldsymbol{M}_{ji}$ (i=1,…,n) is matrix associated with the ith proof-test.

29.4.2 State Distribution of the Entire System

In order to obtain the state distribution of the entire system one can represent the performance distribution of the basic element j (*pmf* of the discrete random variable G_j) as

$$u_j(z)=\sum_{k=1}^{3} p_{jk} z^{g_{jk}}\ , \tag{29.22}$$

where g_{j1} = FD, g_{j2} = FS, g_{j3} = O for any j.

The structure functions ϕ_{ser} and ϕ_{par} for pairs of elements connected in parallel and in series should be defined for any specific application based on analysis of the system functioning. For example, in the widely applied conservative approach the following assumptions are made. Any subsystem consisting of two parallel elements is in the failure-dangerous state if at least one element is in the failure-dangerous state and it is in the operational state if at least one element is in the operational state. In all other cases, the subsystem is in the failure-safe state. This can be expressed by the structure function ϕ_{par} presented in Table 29.3.

Table 29.3. Structure function ϕ_{par}

		Element 1		
		O	FS	FD
Element 2	O	O	FS	FD
	FS	O	O	FD
	FD	O	FS	FD

Table 29.4. Structure function ϕ_{ser}

		Element 1		
		O	FS	FD
Element 2	O	FS	FD	FD
	FS	FS	FD	FD
	FD	FD	FD	FD

A subsystem consisting of two elements connected in series is in the operational state if both elements are in the operational state, whereas it is in the failure-dangerous state if at least one element is in the failure-dangerous state. In all other cases, the subsystem is in the failure-safe state. This can be expressed by the structure function ϕ_{ser} presented in Table 29.4.

In the numerical realization of the composition operators, we can encode the states O, FS and FD by integer numbers 3, 2 and 1, respectively, such that $g_{jk} = k$ for any j. It can be seen that in this case the functions ϕ_{ser} and ϕ_{par} defined above take the form:

$$\phi_{\text{par}}(g_{jk}, g_{ih}) = \begin{cases} \max(g_{jk}, g_{ih}), & \text{if } \min(g_{jk}, g_{ih}) > 1 \\ 1, & \text{if } \min(g_{jk}, g_{ih}) = 1 \end{cases}$$

and $\phi_{\text{ser}}(g_{jk}, g_{ih}) = \min(g_{jk}, g_{ih})$.

Note that the nine possible different combinations of element states produce only three possible states of the subsystem. Applying the RBD technique one obtains the u-function representing the state distribution of the entire system (the system has also three distinguished states O, FS and FD).

With the state probabilities of each element in the form of functions of time, one can use the RBD technique to obtain the probability values corresponding to any given time. Finally, the entire system state probabilities and the overall system safety (defined as the sum of operational probability and failure-safe state probability) as functions of time can be obtained.

Example 3

Consider a combined-cycle power plant with two generating units [6]. Each unit consists of gas turbine blocks and fuel supply systems. The fuel to each turbine block can be supplied by two parallel systems. The simplified RBD of the plant is presented in Figure 29.8.

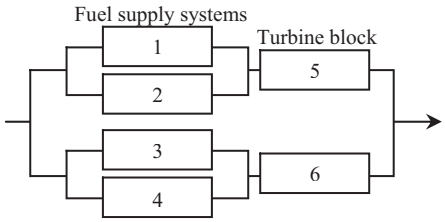

Figure 29.8. RBD of combine cycle power plant

Each fuel supply system as well as each turbine can experience both safe and dangerous failures (detected and undetected).

The parameters of fuel supply systems are: $\lambda_{sd} = 2.56\times10^{-5}$, $\lambda_{su} = 10^{-5}$, $\lambda_{dd} = 8.9\times10^{-6}$, $\lambda_{du} = 1\times10^{-6}$, $\mu_{sd} = 0.25$; $\mu_{dd} = 0.0833$, $\mu_{su} = \mu_{du} = 0$; $d = 0.99$; $T_1 = 1.5$ years. The fuel supply systems are statistically identical, but the inspection times of systems 2 and 4 are shifted 0.5 year earlier relatively to inspection times of systems 1 and 3.

The matrices $\boldsymbol{M}_{ji}$ associated with any system element take the form

$$\boldsymbol{M}_{ji} = \begin{array}{c} \begin{matrix} p_1 & p_2 & p_3 & p_4 & p_5 & p_6 & p_7 & p_8 & p_9 \end{matrix} \\ \begin{bmatrix} 1.0 & 0 & 0 & 0 & & & & & \\ \alpha & 1-\alpha & 0 & 0 & & & & & \\ 1 & 0 & 0 & 0 & \mathbf{0_9} & \mathbf{0_9} & \mathbf{0_9} & \mathbf{0_9} & \mathbf{0_9} \\ \beta & 0 & 0 & 1-\beta & & & & & \\ \mathbf{1_5} & \mathbf{0_5} & \mathbf{0_5} & \mathbf{0_5} & & & & & \end{bmatrix} \end{array},$$

where $\mathbf{0_k}$ and $\mathbf{1_k}$ are zero and unit column vectors of size $k\times1$ respectively. For the fuel supply systems: for $\boldsymbol{M}_{11}$ $\alpha = 0.9$ and $\beta = 0.8$; for $\boldsymbol{M}_{12}$ $\alpha = 0.88$ and $\beta = 0.776$; for $\boldsymbol{M}_{13}$ $\alpha = 0.85$ and $\beta = 0.747$; for $\boldsymbol{M}_{14}$ $\alpha = 0.808$ and $\beta = 0.711$.

The turbine blocks are also statistically identical. The parameters of the turbine blocks are: $\lambda_{sd} = 2.56\times10^{-5}$, $\lambda_{su} = 6.540\times10^{-6}$, $\lambda_{dd} = 7.9\times10^{-6}$, $\lambda_{du} = 7.8\times10^{-7}$; $\mu_{sd} = 0.25$, $\mu_{dd} = 0.0625$, $\mu_{su} = \mu_{du} = 0$; $d = 0.99$; $T_1 = 2$ years. The parameters of matrices $\boldsymbol{M}_{ji}$ for the turbine blocks are: for $\boldsymbol{M}_{21}$ $\alpha = 0.92$ and $\beta = 0.85$; for $\boldsymbol{M}_{22}$ $\alpha = 0.804$ and $\beta = 0.832$; for $\boldsymbol{M}_{23}$ $\alpha = 0.882$ and $\beta = 0.81$.

The probabilities of working, failure-safe and failure-dangerous states were obtained numerically using the combined Markov-UGF procedure for a time period of 65000 hours. The obtained system safety (the probability that the system does not enter the failure-dangerous state) as the function of time is presented in Figure 29.9.

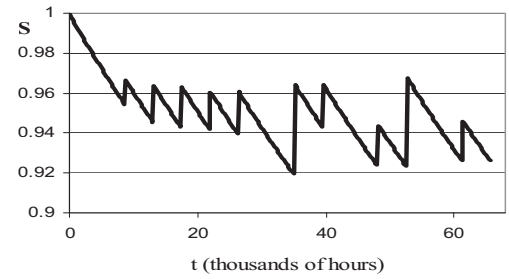

Figure 29.9. Overall system safety

29.5 Conclusions

The universal generating function technique is powerful computationally efficient tool for the reliability analysis of complex multi-state systems. It can be directly applied for calculating system reliability and performance indices based on the generalized reliability block diagram approach (recursively aggregating multi-state elements and replacing them by single equivalent ones). It can also be combined with the Markov random process technique to reduce drastically the dimension of differential equations to be solved.

The UGF approach is based on intuitively simple recursive procedures and provides a systematic method for the enumeration of the system states, which can replace extremely complicated combinatorial algorithms. The same recursive procedures can be used for systems with a different physical nature of the characteristics of elements' states and different types of element interaction. This provides the universality of the UGF method. The applications of the method can be found in fields such as internet services [7], communication networks [8], control and image processing [9], software systems [5], quality control and manufacturing [10], defense [11], and many other areas [4].

The reliability of multi-state systems is a recently emerging field at the junction of classical binary reliability and performance analysis. As a

relatively new discipline, it still has much to accomplish. Many promising directions for further research can be formulated.

The generic model of MSS provides a wide perspective for defining different new classes of systems. Various technical systems in combination with various failure criteria can produce new types of MSS models. Some of them can be extensions of corresponding binary models while others may not have any analogs.

In some cases, the system and its elements are characterized by several measures of functionality (for example, multiple product production systems). In these cases, the performance is a complex (usually vector) index. The extension of MSS models to the multi-performance case is necessary for the study of such systems.

In some systems, the effectiveness of their functioning cannot be measured numerically. Such measures as customer satisfaction or the safety level are usually represented and estimated using the fuzzy set approach. Integration of MSS and the fuzzy set techniques is a promising direction in the analysis of this type of system.

MSS models can be used for studying systems in which the performance of elements is influenced by factors such as deterioration, fatigue, learning, adaptation, *etc*. These factors should be considered in system design and in planning maintenance actions. For example, by incorporating dependencies of the elements failure rates on performance levels into MSS models one can determine the optimal load levels for the entire system or the optimal load distribution among system elements.

The combination of various types of multi-state systems with different criteria and constraints can produce many different interesting optimization problems. For example, incorporating economical indices associated with different levels of system performance provides a wide range of models in which design, maintenance activity, warranty policy, *etc*., are optimized.

When optimizing MSS, one deals with different measures of its reliability and efficiency. Some of these measures are contradictory. For example, a tradeoff usually exists between the availability of MSS and its performance deficiency. In this situation the problems of MSS optimization become multi-objective by their nature. The combination of algorithms for solving multi-objective problems with realistic formulations of MSS optimization problems with multiple criteria can be very fruitful in many applications.

When determining the maintenance of complex systems consisting of elements with different reliability and performance rates one can use the MSS models for estimating the effect of the technological changes on the replacement decisions, for determining the optimal number of spare parts and the optimal inventory management, replacement rules of the system components, the cannibalization policy, the scheduling of maintenance jobs, *etc*. Algorithms of the complex periodic inspection/replacement policies for MSS that maximize the maintenance efficiency are still to be developed.

The recent developments in sensors and measuring techniques have facilitated the continuous monitoring of the performance of systems and their elements. This has led to the development of a predictive maintenance approach. The development of decision rules in the predictive maintenance of MSS is a challenging task.

Since computers are used in almost every system, software reliability has become an important issue attracting the interest of researchers. Many software failures cause not only system failure, but also deterioration of the system performance (usually computational time), which is caused by restarts, self-testing, *etc*. Therefore, in order to assess the reliability indices of complex systems consisting of software and hardware components, one has to develop multi-state models. Further research is needed to estimate the influence of the resource distribution during the software development and testing on the system's reliability. In this research, software reliability models should be incorporated into the MSS paradigm.

New Approaches for Reliability Design in Multistate Systems

Jose Emmanuel Ramirez-Marquez

Stevens Institute of Technology,
Babbio Bldg. #537, Hoboken, NJ 07030, USA

Abstract: This chapter presents a new algorithm that can be applied to solve multi-state reliability allocation problems, namely: capacitated multistate and multistate with multistate components. The optimization problem solved considers the maximization of the system design reliability subject to known constraints on resources (cost and weight) by assuming that the system contains a known number of subsystems connected in series and for each of these subsystems a known set of functionally equivalent component types (with different performance specifications) can be used to provide redundancy. This is the first time an optimization algorithm for multistate systems with mutistate components has been proposed. The algorithm is based on two major steps that use a probabilistic discovery approach and Monte Carlo simulation to generate solutions to these problems. Examples for different series-parallel system behaviors are used throughout the chapter to illustrate the approach. The results obtained for these test cases are compared with other methods to show how the algorithm can generate good solutions in a relatively small amount of time. Although developed for series-parallel system reliability optimization, the algorithm can be applied in other system structures as long as minimal cut sets are known.

30.1 Introduction

The optimal design of systems is a classical optimization problem in the area of system reliability engineering [1]. In general, the objective of these problems is to optimize a function-of-merit of the system design (reliability, cost, mean time to failure, *etc*.) subject to known constraints on resources (cost, weight, volume, *etc.*) and/or system performance requirements (reliability, availability, mean time to failure, *etc*.).

To optimize this specific function, it is generally assumed that the system can be decomposed into a system that contains a known number of subsystems connected in series and for each of these subsystems a known set of functionally equivalent components types (with different performance specifications) can be used to provide redundancy. This problem is referred to as the series-parallel component reliability allocation problem (RAP) and in this chapter the objective of the problem is to maximize system reliability subject to resource constraints.

30.1.1 Binary RAP

Currently, most methods developed for the solution of the series-parallel RAP work under the

assumption that the system and its components are of a binary nature. That is, the system and its components are either perfectly working or completely failed. Whenever this assumption holds, the most common approach to solve RAP has been to restrict the search space and to prohibit the mixture of different components within a subsystem [2].

Ghare and Taylor [3] demonstrated that for, problems with nonlinear but separable constraints, many variations of the problem can be transformed into an integer programming model. A knapsack formulation using alternate constraints was proposed by Bulfin and Liu [4]

The problem of mixing functionally equivalent components within subsystems has been addressed by Coit and Smith [5]. In their study, it has been recognized that allowing mixing of components can yield a better solution to the problem since the solution space is expanded. They successfully obtained solutions for many problems to demonstrate the advantages of genetic algorithms (GA).

The use of GA requires problem-specific coding and parameter tuning, and the development of adequate initial solutions so that the converged solution is near optimal. Thus, researchers have analyzed other techniques to solve mixing components in RAP that include surrogate approaches allowing transforming the problem into a linear program. The max-min method proposed by Ramirez-Marquez *et al*. [6] transforms the original system RAP into a problem of the maximization of the minimum subsystem reliability. This new formulation allowed for the first time, the use of commercially available linear programming software for RAP with component mixture. In this respect, Lee *et al.* [7] have compared the max-min method with the Nakagawa and Nakashima approach [8] for various test cases concluding that the former generally out-performed the latter with respect to system reliability design.

More recently, Coit and Konak [9] presented an extension of the max-min method using a multiple weighted objectives heuristic, which involves the transformation of a single objective problem into one with multiple objectives.

30.1.2 Multistate RAP

For some systems, a binary assumption fails to recognize the true nature of the system performance. An incorrect binary state assumption could potentially overestimate system reliability leading to incorrect results and poor system design. Furthermore, this assumption imposes a restriction on both the type of system that can be designed and on the types of components that can be used. Namely, that the different component types that can be used to provide a defined function, contribute to the system performance in equal terms (*i.e.*, no difference in the nominal performance of the components of the system exists).

In practice, there are different component versions with known cost and reliability that can yield different system performance levels; measured as a capacity of system requirement. As an example, consider an electric distribution system [10] where a particular component type may be able to provide 100% of the daily demand, yet a different type of component could just supply 80% of the same demand level or yet, another component may be able to supply 90%, 50% or nothing, depending on its functional behavior.

Recognition of these performance considerations for system configuration is important due to the significant impact that component performance can have in an optimal system design.

These considerations have been recognized in the area of multi-state system reliability [11–16]; an area, concerned with the analysis of systems that have various performance levels and for which, performance is usually associated with the ability of the system to supply a known demand. In this respect, systems can be broadly categorized in one of two categories:

1. Systems that consist of binary capacitated components (*i.e.*, components that either work at a known nominal performance levels or that are completely failed), where in a given time interval, the system can have a range of different demands (*i.e.,* multi-state) depending on the performance levels of the selected components and their operating state [11, 13].

2. Systems for which a specific performance level must be guaranteed and where such performance is dictated by components that have multiple performance levels (*i.e.*, multistate components) [12, 14, 16].

For series-parallel RAP in the multi-state case, most studies have been concern with systems that fall into the first category. Such problem has been studied and analyzed by Levitin *et al.* [13], Lisnianski *et al.* [15], and Ramirez-Marquez and Coit [12]. These researchers developed heuristic approaches to solve the problem of minimizing system cost subject to a reliability or availability constraint. These methods do not guarantee an optimal solution although they have been demonstrated to yield very good results.

The GA developed in [13, 15] requires that the universal generating function method (an implicit enumeration method [16]) be used for solution representation and decoding procedure for calculating multistate system reliability. Furthermore, these methods require the development, coding and testing of a problem specific GA, complicating the solution process and are highly dependent on the quality of initial solutions.

In the second category, there are currently no algorithms that can be used to provide a solution for the series-parallel RAP. Similarly, it should be noted that there is no general approach that can be used for solving any of the multi-state problems. That is, the algorithms developed for a specific case of RAP cannot be immediately applied in other cases.

The remainder of the chapter is organized as follows. Section 2 presents the general series-parallel system reliability computation problem for each of the cases discussed. In Section 3, the heuristic approach is developed for solving the RAP for general series-parallel systems. Finally, Section 4 considers different literature examples to illustrate the proposed method and illustrate its efficiency and accuracy.

30.1.3 Notation

$\mathbf{X}$	System design vector $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$
$\mathbf{x}_i$	Subsystem design vector $\mathbf{x}_i = (x_{i11}, x_{i12}, \ldots, x_{i1u}, x_{i21}, \ldots, x_{i2u}, \ldots, x_{im1}, \ldots, x_{imu})$
x_{ijk}	Binary decision variable defining if the kth type j component in subsystem design vector $\mathbf{x}_i$ is present or not. k=1,…u
$R(\mathbf{x})$	Series-parallel reliability under design vector $\mathbf{x}$
$P(\varphi_i(\mathbf{x}) \geq d_v)$	Probability the supply of the ith subsystem is greater than or equal to d_v
d_v	Demand for the vth operating interval
$g_l(\mathbf{x})$	Value of the lth constraint under design vector $\mathbf{x}$
G_l	The lth constraint value, l=1,…,L
$\mathbf{x}_i^h$	The hth potential solution , h=1,…,DESIGN $\mathbf{x}_i^h = (x_{i11}^h, x_{i12}^h, \ldots, x_{i1u}^h, x_{i21}^h, \ldots, x_{i2u}^h, \ldots, x_{ijk}^h, \ldots, x_{im1}^h, \ldots, x_{imu}^h)$
$\boldsymbol{\gamma}_i$	Vector of probabilities, $\boldsymbol{\gamma}_i = (\gamma_{i11}, \gamma_{i12}, \ldots, \gamma_{i1u}, \gamma_{i21}, \ldots, \gamma_{i2u}, \ldots, \gamma_{ijk}, \ldots, \gamma_{imu}, \ldots, \gamma_{imu})$
γ_{ijk}	Defined as $P(x_{ijk}=1)$
$\mathbf{b}_{ij}$	Possible states for the jth component type in the ith subsystem. $\mathbf{b}_{ij}=(b_{ij1}, b_{ij2}, \ldots, b_{ijz})$
$\mathbf{p}_{ij}$	State probability vector for the jth component type in the ith subsystem. $\mathbf{p}_{ij}=(p_{ij1}, p_{ij2}, \ldots, p_{ijz})$
$\mathbf{y}_i$	Subsystem state vector $\mathbf{y}_i=(y_{i11}, y_{i12}, \ldots, y_{i1u}, \ldots, y_{ij1}, y_{i21}, \ldots, y_{i2u}, \ldots, y_{ijk}, \ldots, y_{im1}, \ldots, y_{imu})$
p_{ijw}	Defined as $p_{ijw}=P(y_{ijk}=b_{ijw})$
$\Delta_l(\mathbf{x}^h)$	The lth penalty function for the hth potential solution
$\overline{R}(\mathbf{x}^h)$	Penalized reliability for the hth potential solution
S	A subset of solutions
λ	Indexes the number of generations in the global and local cycles
$\mathbf{x}^*$	Optimal system design vector

30.1.4 Acronyms

RAP	Reliability allocation problem
MC	Monte Carlo
GA	Genetic algorithm
LOLP	Loss of load probability

30.1.5 Assumptions

1. Component characteristics are known.
2. Failures of individual components are *s*-independent.
3. All redundancy is active.
4. Component failures do not manage the system and no repair or maintenance is considered.

30.2 General Series-parallel Reliability Computation

For general series-parallel systems, the loss of load probability (LOLP) index can be used as a measure of system reliability. LOLP can be understood as the probability the system cannot supply a given demand load. Based on this index, for an operating period that is divided into V operating intervals with duration T_v and demand level d_v, the probability of system success at a given demand level is given by:

$$R(\mathbf{x}) = T_1' \prod_{i=1}^{n} P\left(\varphi_i(\mathbf{x}) \geq d_1\right) + T_2' \prod_{i=1}^{n} P\left(\varphi_i(\mathbf{x}) \geq d_2\right) + \ldots + T_V' \prod_{i=1}^{n} P\left(\varphi_i(\mathbf{x}) \geq d_V\right) = \sum_{v=1}^{V} T_v' \prod_{i=1}^{n} P\left(\varphi_i(\mathbf{x}) \geq d_v\right) \tag{30.1}$$

where $$T_v' = \frac{T_v}{\sum_{v=1}^{V} T_v}.$$

In the binary case, (30.1) would revert to the well-known series-parallel formulation if only one operating interval, a demand equal to 1 and binary (0, 1) component states are considered.

For the multistate cases, (30.1) can be solved either using the universal generation function approach presented by Levitin and Lisnianski [11] or by using a minimal cut/path vector approach [14]. Figure 30.1 illustrates the differences that are present in each of the series-parallel systems cases.

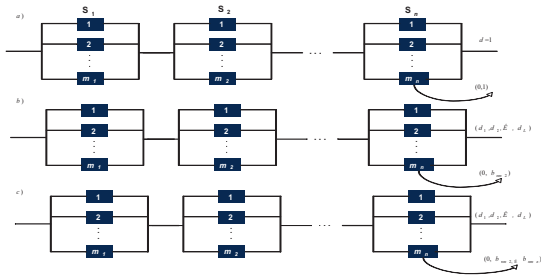

Figure 30.1. Series-parallel systems: **(a)** binary, **(b)** capacitated multistate and (**c**) multistate components

For the binary case, the demand is defined to be one unit and that each component in the subsystems can "process" one unit if it is working and nothing if it is failed. For case b, the system can experience different demands at different time intervals but the components either work at a nominal capacity or fail. Finally, the last case considers that components can have multiple capacities ranging from the nominal capacity to the complete failure.

30.3 Algorithm for the Solution of Series-parallel RAP

The mathematical model to be optimized in this chapter is presented in model 1. The objective of this model is to maximize the reliability of general series-parallel systems subject to a known number of constraints on resources. It is assumed that the system contains n subsystems connected in series and, for each of these subsystems a known set of functionally equivalent components types (with different performance specifications) can be used to provide redundancy.

Model 1

$$\text{Max} \sum_{v=1}^{V} T_v' \prod_{i=1}^{n} P\left(\varphi_i(\mathbf{x}) \geq d_v\right)$$

subject to

$g_l(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n) \le G_l \; \forall \; l=1,\ldots L$

$x_{ijk} \in Z^+$ (x_{ijk} the kth type j component in subsystem design vector $\mathbf{x}_i$).

30.3.1 Algorithm

The algorithm to solve model 1 uses two optimization cycles termed global and local. The global cycle contains three interrelated steps that are based on MC simulation, the cut sets of general series-parallel systems, the max-flow min-cut theorem [17], and a new method to select potential optimal system designs.

In the design development step, the first of the three steps of the global cycle, MC simulation is used to generate a specified number of potential system designs based on the probabilities defined by the vector $\boldsymbol{\gamma}_i$. This vector defines the probability that a specific component type will be present in the final system design and its level of redundancy. This step also contains the stopping rule of the algorithm. In essence, the rule dictates that the algorithm be stopped once the vector $\boldsymbol{\gamma}_i$ will no longer change (*i.e.*, all initial "appearance" probabilities are either zero or one).

Following this step, for each of the previously generated potential system designs, the second step simulates the performance behavior for each of the k possible component types in each subsystem (*i.e.*, generates a subsystem state vector $\mathbf{y}_i$). It is important to notice that the index k defines the maximum level of redundancy allowed for any given component. Once vector $\mathbf{y}_i$ is obtained, it is used along with the potential subsystem design obtained in Step 1 and with the max-flow min-cut theorem to generate an estimate of the system design reliability.

The final step in the global cycle penalizes the reliability of potential system designs both when the solutions exceed and when they fall short of the exact value of the constraints. The solutions are then ranked in decreasing order with respect to the penalized reliability. The best solution is stored and then a subset of size S of the whole set of solutions (a set of size DESIGN), is used to update the probabilities defined by the vector $\boldsymbol{\gamma}_i$. This new vector is sent to Step 1 to check for termination or for solution discovery.

The pseudo code of the global cycle optimization follows:

Global Cycle Optimization

Initialize: DESIGN, RUNS, S, h, $\boldsymbol{\gamma}_i$, λ=1, u,

Step 1:
(Design Development)
For h =1,…, DESIGN
For i= 1,..,n generate a subsystem design $\mathbf{x}_i$, as dictated by vector $\boldsymbol{\gamma}_i$

$$\mathbf{x}_i^h = \left(x_{i1}^h, x_{i12}^h, \ldots, x_{i1u}^h, x_{i21}^h, \ldots, x_{i2u}^h, \ldots, x_{ijk}^h, \ldots, x_{im1}^h, \ldots, x_{imu}^h\right)$$

and

$$\boldsymbol{\gamma}_i = \left(\gamma_{i11}, \gamma_{i12}, \ldots, \gamma_{i1u}, \gamma_{i21}, \ldots, \gamma_{i2u}, \ldots, \gamma_{ijk}, \ldots, \gamma_{im1}, \ldots, \gamma_{imu}\right)$$

where, $\gamma_{ijk}=P(x_{ijk}=1)$;

$\mathbf{x}^h = \left(\mathbf{x}_1^h, \mathbf{x}_1^h, \ldots, \mathbf{x}_i^h, \ldots \mathbf{x}_n^h\right)$; $h \rightarrow h+1$;

if ($\gamma_{ijk}=1 \vee \gamma_{ijk}=0 \; \forall$ i, j and k) Stop.

$\mathbf{x}_i^* = \arg\max\left\{R\left(\mathbf{x}^h\right), R\left(\overline{\mathbf{x}}^\lambda\right)\right\} \quad \forall i, \lambda \; \forall \; i$

Go to local cycle.
Else go to Step 2.

Step 2:
(Component State Simulation)
For h= 1,..,DESIGN
While ($t \le$ RUNS)
For i= 1,..,n generate a subsystem state vector $\mathbf{y}_i$ as dictated by vectors $\mathbf{b}_{ij}$ and $\mathbf{p}_{ij}$

$\mathbf{y}_i = (y_{i11}, y_{i12}, \ldots, y_{i1u}, \ldots, y_{ij1}, y_{i21}, \ldots, y_{i2u}, \ldots, y_{ijk}, \ldots, y_{im1}, \ldots, y_{imu})$

$\mathbf{b}_{ij}=(b_{ij1}, b_{ij2}, \ldots, b_{ijz})$ and $\mathbf{p}_{ij}=(p_{ij1}, p_{ij2}, \ldots, p_{ijz})$ where $p_{ijw}=\mathrm{P}(y_{ijk}=b_{ijw})$

(Design Reliability Analysis)
For i= 1,..,n calculate:

$$\Omega_i = \sum_{j=1}^{m} \sum_{k=1}^{u} x_{ijk}^h y_{ijk}$$

If $\Omega_i \ge d \; \forall \; i$:
$Q \rightarrow Q$; $t \rightarrow t+1$
Else
$Q \rightarrow Q+1$; $t \rightarrow t+1$;
$R(\mathbf{x}^h)=1-(Q/\mathrm{RUNS})$;

Step 3:
(Solution Discovery)
For h=1,…,DESIGN and l=1,…,L compute:

$$\Delta_l(\mathbf{x}^h)=\begin{cases}\max_h\left\{R(\mathbf{x}^h)-\dfrac{g_l(\mathbf{x}^h)}{\max_l\{g_l(\mathbf{x}^h)\}}\right\} & g_l(\mathbf{x}^h)>G_l\\ \dfrac{g_l(\mathbf{x}^h)}{G_l} & \text{o.w.}\end{cases};$$

$$\overline{R}(\mathbf{x}^h)=\begin{cases}R(x^h)\max_l\{\Delta_l(\mathbf{x}^h)\} & \Delta_l(\mathbf{x}^h)\le 1\,\forall l\\ R(x^h)\min_l\{\Delta_l(\mathbf{x}^h)\} & \text{o.w.}\end{cases};$$

List $\overline{R}(\mathbf{x}^h)$ by decreasing order of magnitude:

$$\overline{R}(\mathbf{x}^{(1)})\ge\overline{R}(\mathbf{x}^{(2)})\ge\cdots\ge\overline{R}(\mathbf{x}^{(h)})\ge\cdots\ge\overline{R}(\mathbf{x}^{(\mathrm{GEN})})$$

$$\overline{\mathbf{x}}_i^{\lambda}=\mathbf{x}_i^{(1)}\ \forall i;\ \overline{\mathbf{x}}^{\lambda}=(\overline{\mathbf{x}}_1^{\lambda},\overline{\mathbf{x}}_2^{\lambda},\ldots,\overline{\mathbf{x}}_n^{\lambda});\ \lambda\to\lambda+1;$$

For i= 1,..,n update vector $\boldsymbol{\gamma}_i$ as follows:

$$\gamma_{ijk}=\frac{\sum_{s=1}^{S}x_{ijk}^{(s)}}{S}\ \text{where } S\ll\text{DESIGN}$$

Go to Step 1.

Once the global cycle stops, the algorithm recognizes that the solution maybe improved by iteratively applying the global cycle to a reduced RAP based on the best subsystem designs previously obtained.

These new iterations start by ordering the subsystems obtained from the optimal solution by increasing unreliability. Then any slack in the constraints is proportionally assigned (based on a normalized unreliability) to each of the subsystems. The current values of the constraints for the least unreliable subsystem are updated and a new subsystem solution is obtained based on the global cycle. If the new solution is better, the system design is updated otherwise the design suffers no transformation.

The local cycle continues by proportionally assigning any slack in the constraints to the second least unreliable system until all subsystems have been reanalyzed.

The pseudo code for the local optimization cycle follows.

Local Cycle Optimization

For $i \notin$ A and $i\le n$;
List 1-$R_i(\mathbf{x}_i^*)$ by increasing order of magnitude;

$$a=\arg\min_i\left(1-R_i(\mathbf{x}_i^*)\right)$$

Compute: $S_l=g(\mathbf{x}^*)-G_l\quad\forall\quad l$ and

$$\vartheta_a=\frac{1-R_a(\mathbf{x}_a^*)}{\sum_{\substack{i\notin A\\ i\le n}}\left(1-R_i(\mathbf{x}_i^*)\right)}$$

Use global optimization cycle to solve sub-model:

$$\text{Max}\ \sum_{v=1}^{V}T_v'P(\varphi_a(\mathbf{z}_a)\ge d_v)$$

s.t.

$$g_l(\mathbf{z}_a)\le g_l(\mathbf{x}_a^*)+S_l\vartheta_a$$

$z_{ajk}\in Z^+$ (z_{ajk} the kth type j component of subsystem design vector $\mathbf{x}_a$)

Step 2.
Update $\mathbf{x}_a^*$ if needed; A→A∪{a};
Go to Step 1.

30.4 Experimental Results

In this section, three different RAP for series-parallel systems have been solved to illustrate the simplicity and power of the algorithm.

The first of three problems, considers a binary system and is used to illustrate how the algorithm can be used immediately used for these problems. The remaining exampless belong to the multistate case; the second one, introduced by Levitin *et al*. [15] and, the last one, a multistate system with multistate components for the first time solved in the area of multistate reliability.

All the examples were solved with a Pentium R laptop at 238 Mhz and 512 Mb of RAM.

30.4.1 Binary System

This first example was initially presented by Sung and Cho [18] and later analyzed by Ramirez-Marquez and Coit [6]. This problem has three

subsystems connected in series with three components to provide redundancy. The problem is to obtain a solution for RAP assuming reliability is to be maximized subject to cost and weight constraints with values of 17 and 30, respectively.

This RAP was solved using the proposed algorithm and presents a good example for illustration purposes. Table 30.1 presents data associated with the components reliability and resource characteristics. Table 30.2 illustrates the global cycle of the algorithm as the solution converges.

For this problem the initial potential system design probability defined by vector γ_i equals 0.5. After 14 generations, these initial probabilities have converged to a final solution. Notice how the algorithm immediately identifies the third choice in subsystem 3 as a very poor choice.

Table 30.1. Binary RAP component data

	Subsystem 1		
Choice	Reliability	Cost	Weight
1	0.99	4	2
2	0.95	13	3
3	0.92	7	5
	Subsystem 2		
Choice	Reliability	Cost	Weight
1	0.98	8	3
2	0.8	3	3
3	0.9	3	9
	Subsystem 3		
Choice	Reliability	Cost	Weight
1	0.98	11	4
2	0.92	5	6
3	0	100	100

Table 30.3 illustrates the solutions obtained for this same problem when different initial potential system design probabilities γ_i, are used. The solution for $\gamma_1 = 0.5$ corresponds to the generations described in Table 30.2 and is the optimal solution presented in previous studies [6, 18].

Subsystem	1	2	3
1	2	0	0
2	1	1	0
3	1	0	0
R=0.9785	C=30	W=14	T=24

For this specific example the local cycle was not implemented since the rationale was to understand how the global optimization cycle behaved with different initial probabilities. In this respect, it is important to note that for all the experiments run the initial probabilities always converged although not to the optimal solution. Moreover, the algorithm does not require the use of initial solutions

30.4.2 Multistate System with Binary Capacitated Components

The example in this section considers a multi-state system with binary capacitated components. This problem initially presented by Levitin *et al*. [13] was solved under the assumption that cost needed to be minimized subject to a reliability constraint. In order to apply the proposed algorithm to this problem, the minimum cost found by Levitin *et al*. [13] has been used as a constraint and reliability has been maximized.

Although the solutions are not equal, the purpose is to show how the algorithm can be used to generate very good solutions for this highly involved problem.

Table 30.4 presents data associated to the components reliability, nominal capacity and resource characteristics. During a specific time interval the system design must be able to provide 20% of the time 100% of the nominal system demand, 30% of the time 80% of the nominal system demand and the remaining time, 40% of the nominal system demand. A maximum cost of 6.924 is allowed for the system design.

Table 30.5 illustrates the solution obtained through the global and local cycles. The global cycle converged after 31 generations but for this example, the top solution in generation 20 yielded the best solution.

Finally, Figure 30.2 illustrates how the reliability and cost for the top solution converge as a function of the generations in the global cycle.

Table 30.4. Binary capacitated component data

30.4.3 Multistate System with Multistate Components

The remaining example constitutes the first time the RAP is considered for multistate series-parallel systems with multistate components. This problem was randomly generated assuming a demand of 10 units and a maximum cost of 60 units. Table 30.6 presents component states and cost while, Table 30.7 component states probability.

Table 30.8 illustrates the global and final solution design obtained from the algorithm. These solutions were obtained after 33 generations developed by the global cycle.

Table 30.6. Components states and cost

Subsystem	State choice 1				Cost
1	0	1	2	5	4
2	0	2	3	4	7
3	0	1	2	3	2

New Approaches to System Analysis and Design: A Review

Hong-Zhong Huang[1], Liping He[2]

[1]School of Mechatronics Engineering, University of Electronic Science and Technology of China, Chengdu, Sichuan, 610054, China
[2]School of Mechanical Engineering, Dalian University of Technology, Dalian, Liaoning, 116023, China

Abstract: Engineering design under uncertainty has gained considerable attention in recent years. A variety of reliability analysis strategies and methodologies are taken into account and applied increasingly to accommodate uncertainties. There exist two different types of uncertainties in practical engineering application: aleatory uncertainty, which is classified as objective and irreducible uncertainty with sufficient information on input uncertainty data and epistemic uncertainty, which is a subjective and reducible uncertainty that stems from a lack of knowledge on input uncertainty data. The nature of uncertainty depends on the mathematical theory within which problem situations are formalized. When sufficient data is available, probability theory is very effective to quantify uncertainty. However, when data is scarce or there is lack of information, the probabilistic methodology may not be appropriate. Among several alternative tools, possibility theory and evidence theory have proved to be computationally efficient and stable tools for reliability analysis under aleatory and/or epistemic uncertainty involved in engineering systems. Thus this chapter first attempts to give a better understanding of uncertainty in engineering design with a holistic view of its classifications, theories and design consideration, and then discusses general topics of foundations and applications of possibility theory and evidence theory. The overview includes theoretical research, computational development and performability improvement about possibilistic and evidential methodologies in the area of reliability during recent years, and it especially reveals the capability and characteristics of quantifying uncertainty from different angles. Finally, perspectives on future research directions are stated.

31.1 Introduction

One of the greatest challenges in engineering design is uncertainty, which can be observed from both epistemological and methodological angles in various environments. There has been an ever-increasing tendency to take uncertainty qualification analysis into account over the last two decades. In fact, uncertainty is associated with both qualitative and quantitative characteristics of design problems. The nature of uncertainty depends on the mathematical theory within which problems are formalized [1], and each method emphasizes a different paradigm [2]. The more general the theory is, the more types of uncertainty can be described by it. Mainly in response to criticism on the credibility of standard probabilistic analysis, the theories and methodologies that we summarize to deal with

uncertainty will shed light on practical problems in engineering design to be dealt with later.

31.1.1 Definitions and Classifications of Uncertainty

People often use different terms as synonyms of uncertainty: indefiniteness, unpredictability, indeterminacy, changeability, irregularity, arbitrariness, ambiguity, vagueness, randomness, variability and haphazardness, *etc*. [3], although each term has some specific nuances in meaning.

Uncertainty has several definitions. To a certain degree, it is associated with phenomena that are questionable, problematical, not definite or not determined, or not having certain knowledge, or even liable to change or to vary. The word uncertainty often refers to random variability. Uncertainty is also connected with the degree of belief in the validity of a particular proposition or datum [3]. Uncertainty can be categorized as aleatory uncertainty, epistemic uncertainty and error [4], [5], and [6], as illustrated in Figure 31.1.

In view of descriptions of the degree of uncertainty and simplifications of systems, uncertainty can naturally be categorized according to different meanings, as seen in Figure 31.2, which plays a fundamental role in the relevant theories between uncertainty and information [2].

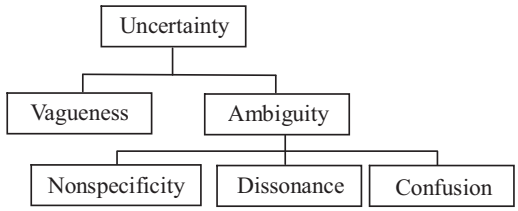

Figure 31.2. A semantic classification of uncertainty [2]

31.1.2 Theories and Measures of Uncertainty

There is an abundant collection of theories for modeling all types of uncertainty. Before fuzzy measure was proposed by Sugeno [7], probability theory was the dominant way to model uncertainty, especially for stochastic uncertainty when there is sufficient information supplied. However, this theory is not appropriate for reducible uncertainty and error because the additivity axioms, which the

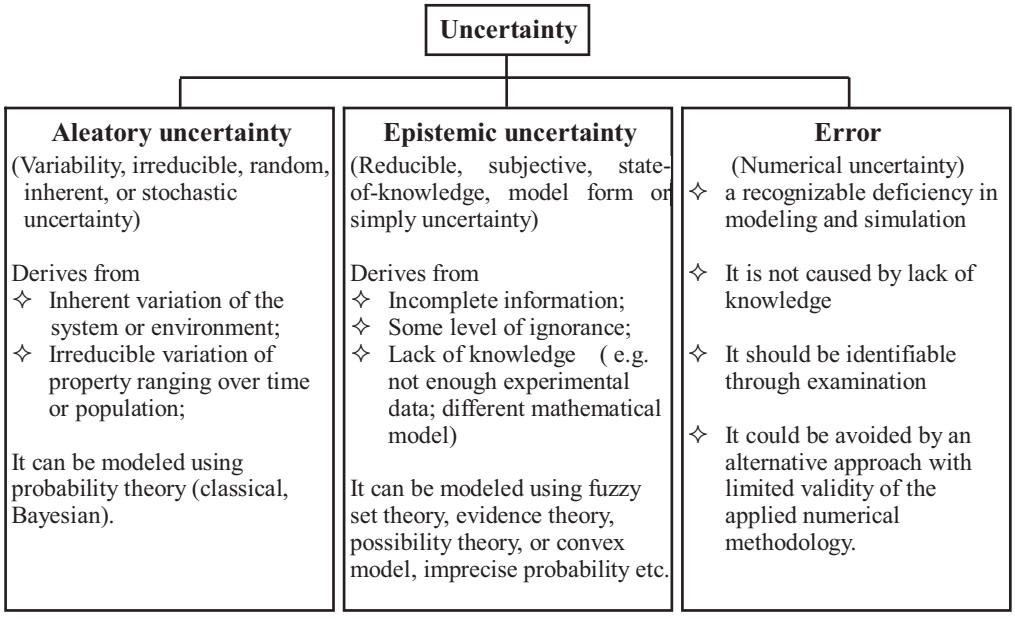

Figure 31.1. A well-known classification of uncertainty [4], [5], and [6]

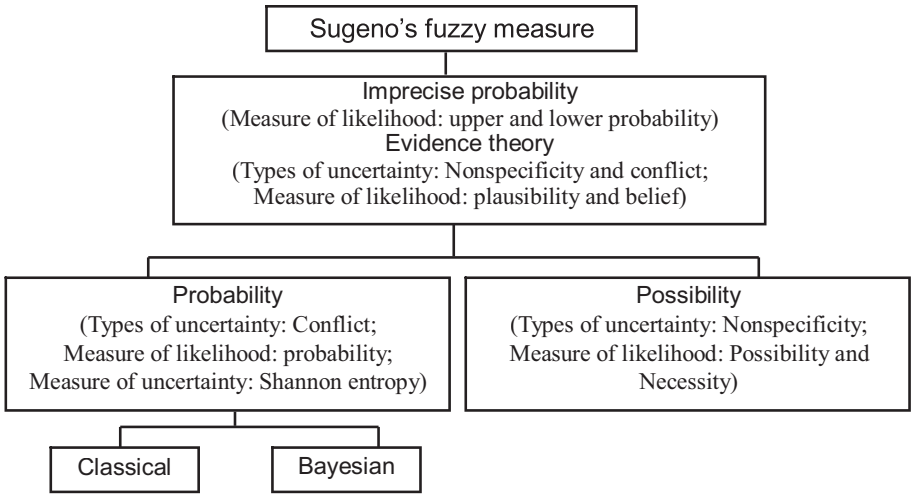

Figure 31.3. Families of theories of uncertainty [8]

probability theory relies on, are unable to express the lack of knowledge in scarce-data situations. Therefore, alternative uncertainty analysis tools such as imprecise probability and evidence theory, have been developed, which can be combined with probability theory to develop a framework in a specific field [8], *e.g.*, risk assessment of systems. And these theories are flexible enough to model both non-specificity and conflict types of uncertainty (see the classification in Figure 31.2.). A family of theories of uncertainty is presented in Figure 31.3.

After viewing the various types of uncertainty, Klir investigated their relation to information and complexity [1], [2], by the reason that each type of uncertainty requires a distinct framework within which appropriate measures of the corresponding type of uncertainty must be formulated. The understanding that measures are related to types of uncertainty has been widely accepted. The formulae are shown in Table 31.1.

Table 31.1. A Summary of measures of uncertainty by Klir [2]

Type	Name	Formula	Notation
Classical	Hartley information	$I(N)=\log_2 N$	U: a universal domain A: a crisp set of U N : cardinality of a crisp set P: probability distribution $P=(p_1,p_2,\cdots,p_n)$ Π: possibility distribution $\Pi=(\pi_1,\pi_2,\cdots,\pi_n)$ $\mu_A(u)$:membership function C :fuzzy complement m : a basic probability assignment (a mass function) **F** : set of focal elements $B_{el}(\cdot)$: belief measure $P_l(\cdot)$: plausibility measure
	Shannon entropy	$H(P)=-\sum_{i=1}^{n} p_i \log_2 p_i$	
General	U-uncertainty	$U(\Pi)=\sum_{i=1}^{n}(\pi_i-\pi_{i+1})\log_2 i$	
Vagueness	Measure of fuzziness	$f_C(A)=\lvert X\rvert-\sum_{u\in U}\lvert\mu_A(u)-C(\mu_A(u))\rvert$	
Ambiguity	Measure of non-specificity	$V(m)=\sum_{A\in\mathbf{F}} m(A)\log_2\lvert A\rvert$	
	Measure of dissonance	$E(m)=-\sum_{A\in\mathbf{F}} m(A)\log_2 P_l(A)$	
	Measure of confusion	$C(m)=-\sum_{A\in\mathbf{F}} m(A)\log_2 B_{el}(A)$	

31.1.3 Uncertainty Encountered in Design

In complicated situations of reliability analysis and engineering design, we encounter many indeterminable factors, both during the early stages of design, and in the manufacturing processes and use, due to lack of knowledge or the incomplete information. Common reasons for the lack of statistical data include the increased complexity of large-scale systems, the collection of statistical data being difficult and/or costly, the rarity of failures in some highly reliable systems, and data being imprecise or unavailable under various testing conditions.

The characteristics and formalisms of uncertainty have to be mathematically quantified, before a designer can seek the optimum design. A design or decision problem should take into account the main types of uncertainties arising during the design (manufacturing tolerances, uncontrollable variations in external operating conditions), uncertainties in decision making (vagueness in conflicting objectives), modeling and simulation [6]. Moreover, the experience and subjective assessment of experts is often given in natural language, which introduces vagueness and impreciseness [9], [10] and [11] Furthermore, in the investigation of complex man-made systems and multi-state systems, inaccuracy caused by human errors or poor definitions of failure should also be considered. It is inappropriate to represent all of them solely by probabilistic properties and the uncertainties in such cases are typically referred to as epistemic.

The aim of this chapter is to present a holistic view on reliability analysis and optimization methods in the context of possibility theory and evidence theory in engineering area when data is insufficient, mainly under epistemic uncertainty.

The outline of the remaining part of this chapter is as follows. Section 31.2 deals with the fundamentals of possibility theory and evidence theory and their applications. Sections 31.3 to 31.5 address various applications of possibility theory and evidence theory in engineering design, illustrating their superiority in handling epistemic uncertainty information especially for reliability analysis. Section 31.6 provides an indication of application of possibility theory and evidence theory to engineering designs. Concluding remarks are provided in the last section of the chapter.

31.2 General Topics of Applications of Possibility Theory and Evidence Theory

31.2.1 Basics of Possibility Theory and Evidence Theory

As one of three constituents of fuzzy theory (the others are fuzzy set theory and fuzzy logic, respectively) [12], possibility theory was originally introduced by Zadeh [13] to express the intrinsic fuzziness of natural languages as well as uncertainty information. Among all the multifarious interpretations of possibility theory, the fuzzy set interpretation is well-known and prominent. Possibility theory may be viewed as a special branch of fuzzy measure theory, which is based upon two dual fuzzy measures, *possibility measure* and *necessity measure*.

Compared with probability theory, possibility theory is similar to the former because it is a tool to represent uncertainty based on set functions. The difference between them, in the aspect of the axiom, is that probability is additive whereas possibility is subadditive [8]; with a view to information involved, probability is a quantitative ratio scale of uncertainly while possibility can be considered as a quasi-qualitative ordinal scale [4].

Evidence theory (or Dempster–Shafer theory) may be viewed as a branch of mathematics considering the combination of empirical evidence to construct a coherent picture of reality [14]. Compared with Bayesian theory, evidence theory is generally felt to be closer to our human perception and reasoning processes [15]. There have been many interpretations of evidence theory and also closely related developments. The most influential version is still Shafer's presentation in his book [16].Two large classes of fuzzy measures, referred to as *belief measure* and *plausibility measure*, respectively, characterize the theory of evidence. In fact, the classical probability theory is a subset of the possibility theory, which in turn, is

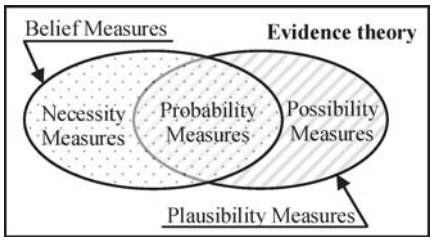

Figure 31.4. A pictorial description of uncertainty classification based on fuzzy measures

a subset of the evidence theory [2], seen in Figure 31.4.

31.2.2 Introduction to General Applications

Both possibility theory and evidence theory have been used recently in reliability analysis and uncertainty handling.

Possibility theory has been applied in many areas, including artificial intelligence, approximate reasoning, decision making, and data fusion [17]. It is usually used to quantify only epistemic uncertainty if there is no conflicting evidence among experts [18]. In the area of reliability engineering, the reliability estimation and design was investigated by Möller *et al.* [19], Kozine *et al*. [20], Mourelatos [21], and Huang *et al.* [22], and [23]. Besides reliability engineering, the application areas also cover civil (or structural) engineering engineering [19], computational mechanics, military, energy, forestry, aerospace and automobile engineering, and others.

As a more general uncertainty analysis tool, evidence theory has also been applied in many areas, including artificial intelligence [8] and [24], object detection and approximate reasoning [25] and [26], design optimization [27], uncertainty quantification [24], risk and reliability evaluation, pattern recognition and image analysis, decision making [28], data fusion [29], and fault diagnosis [30] and [31]. However, the popularity of evidence theory has remained low because evidence theory requires epistemological assumptions that are at odds with those underlying classical and Bayesian probability theories [14].

There is a tendency to use not only one framework to deal with complicated and changeful environments, *e.g*., integration of probabilistic approach and possibilistic approaches, of probabilistic and evidential approaches, *etc*.

The existing applications and developments of possibility theory and evidence theory, on the subject of uncertainty and reliability analysis of recent works, mainly focus on the following two aspects: theoretic development, which is related to the fundamentals or foundation of reliability theory, *e.g*., fuzzy reliability and imprecise reliability and computational (or algorithmic) development, which particularly emphasizes the analysis and design method, *e.g*., data fusion technology applied in reliability assessment and optimum design methods.

31.3 Theoretical Development in the Area of Reliability

31.3.1 Fuzzy Reliability

One tool to cope with the imprecision of available information in reliability analysis is fuzzy reliability theory, which was proposed by Cai [32]–[34] and has been developed by several other researchers [35]–[38], [39], who employed possibility theory as uncertainty analysis tools.

31.3.1.1 Motivation and Classifications

The origin of fuzzy reliability theory comes from the consideration of reliability aspects in gracefully degradable computing systems, where system states cannot be simply classified as failed or functioning. In addition to the nature of performance degradation, a failure does not necessarily occur at random.

Various forms of fuzzy reliability theories, including profust reliability theory [34], [37], posbist reliability theory [32], [40], and posfust reliability theory, have been proposed based on new assumptions of fuzzy state or possibility measure in place of the binary state and probability assumptions. The structure of fuzzy reliability theory is illustrated as Figure 31.5.

Possibility theory-based reliability theory can be classified as not only a member of fuzzy reliability theory, but also a member of non-

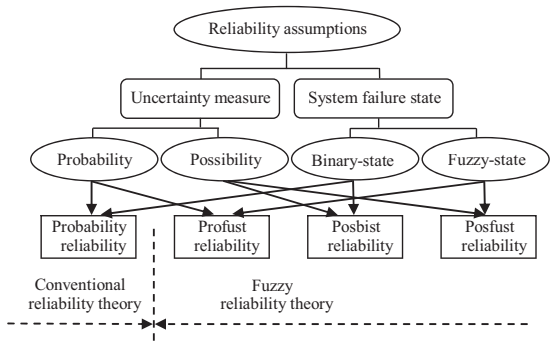

Figure 31.5. Reliability theories based on various fundamental assumptions

probabilistic or imprecise reliability theory. The former classification is due to the theoretic background of fuzzy set theory, while the latter classification is due to the non-statistical characteristics of the information involved.

31.3.1.2 Present Status and Challenging Problems

To date, most existing works are in theoretic construction and modification [39], [35]–[42], or practical connections in engineering [18], [19], [24] and [43]. Cai *et al.,* considered posbist reliability theory of typical systems, such as series, parallel, *k*-out-of-*n* systems [32], and cold and warm redundant systems [38]. Utkin *et al.* [44] provided an analysis of typical repairable systems in the possibility context. Aiming at more changeful systems, Utkin *et al.* [40] proposed a general formal approach to analyze the posbist reliability behavior of arbitrary systems by a system of functional equations, on the basis of a state transition diagram, which can avoid the extremely difficult time-domain analysis of the reliability behaviour.

Systematic work on maintenance policy and FTA in the presence of fuzzy state assumption has only been partially done. Huang and Tong [45] have developed a new model of fault tree analysis corresponding to posbist reliability theory to evaluate system reliability and safety when the statistical data is scarce or the failure probability is extremely small. With the concept of possibilistic logic proposed by Dubois and Prade [46], a new knowledge-based solution enables possibility theory to achieve wider applications in artificial intelligence or data fusion domain, compared with probability theory and evidence theory.

The exploration of fuzzy reliability theory itself and its extensions is not enough. Some difficulties are seen by practitioners in that this theory does not cover a large variety of possible judgments in reliability [47]. In some real cases, there does not exist a certain type of possibility distribution that is reasonably consistent with statistical data. A clear interpretation of the possibility distribution is further expected.

31.3.2 Imprecise Reliability

31.3.2.1 Origin and Objectives

In order to overcome the forementioned difficulties, the theory of imprecise probabilities and its analogs (the theory of *interval statistical models* and the theory of *interval probability*) [47] have been used as a unified tool for reliability and risk analysis. Here, the term imprecise probabilities is used as a generic one to cover mathematical models such as *upper and lower probabilities*, *upper* and *lower previsions* (or *expectations*), *possibilities* and *necessities*, *belief* and *plausibility* functions, and other qualitative models [20].

The general motivation for imprecise probabilities is that the confidence of a decision maker mainly depends on the evidence on which a probability estimate is based. Mathematical assumptions can lead to imprecision and further sources of uncertainty. Hence a main objective of imprecise reliability is to use only available information without additional assumptions or, even with a minimal number of assumptions to obtain the component reliability level and the best possible reliability bound. Furthermore, the effects of any possible imprecision of initial information can be reflected *via* the imprecision of resulting system reliability measures [47]. Conventional reliability models can be classified as a special case of imprecise models.

31.3.2.2 Development and Directions

Imprecise probabilities have been used in practical reliability and risk analysis by characterizing the state-of-knowledge uncertainty with intervals of probabilities. There are several theories of imprecise probabilities, including evidence theory and possibility theory. Moreover, recently a theory of *coherent imprecise probabilities* has been developed by Walley [48].

The coherent imprecise probability theories [48] are based on a behavioral interpretation and three fundamental principles, *i.e*., avoiding sure loss, coherence and natural extension. The basic concept associated with the behavioral interpretation is the concept of a gamble, which is a bounded real-valued function defined on domain Ω and which should be interpreted as a reward whose value depends on the uncertain state, each belongs to the domain Ω , in the context of decision theory and utility theory. The coherent imprecise probability theories are also based on two probabilistic models: *lower previsions* (or expectations) and *upper previsions*. In reliability and risk analysis problems, we will consider a particular case of gamble for which the reward can be either 0 or 1. In this case, lower and upper previsions are called *lower* and *upper probabilities*, respectively, just as the name means.

The combinative rules of multi-source information discriminate between consistent and inconsistent judgments (or models). The former contains the conjunction rule, which combines lower and upper previsions for the two consistent judgments; the latter includes an alternative one called the unanimity rule. These rules were obtained based on the concept of desirability and preference [48].

Kozine and Filimomov [20] developed imprecise probabilities as a particularly advantageous way of handling indeterminacy and summarized their experiences in dealing with the evidence theory relating to reliability assessments. With practical system reliability assessments for serial, parallel and general reliability structures, they demonstrated the advances in the application of the theory of coherent imprecise probabilities for system reliability assessments.

Aughenbaugh *et al.* [49] considered imprecise probabilities to express clearly the precision with which something is known, on the hypothesis that it is valuable to represent this imprecision by using imprecise probabilities in engineering design. Then, the example of the pressure vessel design problem was presented using two approaches, both variations of utility-based decision making. The computational experiments demonstrated that when designers only have access to a small set of sample data, a probability bounds analysis (PBA) approach that uses imprecise probabilities to model uncertainty can lead, on average, to better designs than a purely probabilistic approach.

Coolen [50] discussed a variety of issues (involving advantages and disadvantages) and reviewing the issues suggested applications of imprecise probability in reliability. A recently developed statistical approach, called *non-parametric predictive inference* (NPI), to reliability has been introduced as a coherent framework offering exciting opportunities when data is scarce, where inferences are directly on future observable random quantities such as the random time to failure of the next system. In this approach, imprecision depends on the available data in an intuitive way, as it decreases if information is added. Applications with regard to replacement and maintenance decisions were also presented.

Hall and Lawry [51] introduced a new method for constructing an imprecise limit state function from scarce data based on minimal assumptions about the underlying system behavior. A case study of reliability analysis has demonstrated how this conventional approach can be extended to handle imprecise knowledge about the system state variables, represented in general as random sets, in order to generate bounds on the probability of failure. The approach has provided new insights into the sources of uncertainty and the assumptions implicit in the conventional probabilistic approach.

We can conclude from those results that it is valuable to explicitly represent the imprecision in the available characterization of uncertainties with imprecise probabilities. A further introduction and examples of imprecise reliability analysis can be found in [8].

Although the applications of imprecise probability methods in reliability have shed light on many interesting research problems, some unsatisfactory points have been criticized (*e.g.,* difficulties of evidence combinations, diversity of judgments admitted in elicitation, *etc*.). By far the main difficulty in imprecise reliability is computation for imprecise probability. Recent work by Utkin and co-authors [47] has provided great progress in this aspect, yet much more needs to be done. Another topic that has not yet been studied is the design of experiments with uncertainty quantified *via* imprecise probabilities [8] and [50]. From this perspective, further research in this field may be of great benefit in future.

31.4 Computational Developments in the Reliability Area

To a certain extent, reliability analysis using the proposed possibilistic and evidential methods cannot be completely separated from reliability-based design optimization (RBDO).

Design optimization is now a mainstream discipline in high technology product development and a natural extension of the ever-increasing analytical abilities of computer-aided engineering [52]. The process of obtaining optimal designs with the availability of complex simulation models of actual systems is known as design optimization. It assumes a decision-making paradigm for the design process in the form of mathematical programming and the main criteria used to measure the effectiveness in a practical engineering optimization problem are cost and performance.

The presence of uncertainties in engineering practice complicates a the design problem of a system. Although the RBDO approach has a more consistent description of the safety of designs, it has a higher computational cost and the calculations may not always converge. Hence design methods considering uncertainty have been increasingly applied and various specialized optimization methodologies have been proposed in areas where it is not possible to obtain accurate statistical data due to restriction of resources or conditions (such as budgets, facilities, time, human factors, *etc*.).

The concrete design optimization methods can be categorized as the parallel-loop method, the serial-loop method, the single-loop method, and the adaptive-loop method. Because they are based on theories of uncertainty, these methods can be classified as the *probabilistic* (or statistical) approach and the *possibilistic* approach. The former approach includes *asymptotic reliability analysis*, *the first-order reliability method* (FORM), *the second-order reliability method* (SORM), Monte Carlo simulation (MCS), and the Bayesian method, *etc*.. The second approach involves interval analysis, convex modeling, and fuzzy modeling [39]. In addition, a unified approach integrates the two methods in a general framework. There have been some advances in exploring decomposition strategies or approximation concepts, as discussed next.

31.4.1 Possibility-based Design Optimization (PBDO)

The general PBDO can be formulated as

$$\begin{aligned} &\min \quad Cost(\mathbf{d}, \mathbf{Y}) \\ &\text{s.t.} \quad \Pi\left(G_i\left(\mathbf{d}(\mathbf{Y})\right) > 0\right) \le \alpha_{t_i},\ i = 1, 2, \cdots, np \\ &\mathbf{d}^L \le \mathbf{d} \le \mathbf{d}^U,\ \mathbf{d} = \mu(\mathbf{Y}) \in \mathbb{R}^n,\ \mathbf{Y} = [Y_i]^T \in \mathbb{R}^{nr} \end{aligned} \tag{31.1}$$

where $\mathbf{d}$ and $\mathbf{Y}$ are the design vector and the fuzzy random vector, respectively, while α_t is a target failure possibility. Moreover, n, nr, np are the number of design variables, the number of fuzzy random variables, and the number of possibility constraints, respectively.

Compared to other methods, the fuzzy (or possibilistic) analysis method is a very useful tool with the following main advantages: (1) It preserves the intrinsic random nature of physical variables through their membership functions. (2) The extended fuzzy operations are simpler than those using probability. (3) It yields a more conservative design than the probabilistic design method in terms of a confidence level. (4) It provides a system-level possibility different from reliability analysis. For numerical methods of fuzzy analysis, some reported methods [39], [50] are listed as: *the vertex method*, *the discretization method*, *the level-cuts (α-cuts) method*, *the*

Table 31.2. Comparison of PMA in RBDO and PBDO

Issues	PMA in RBDO	PMA in PBDO
Formulation	$\min \quad Cost(\mathbf{d};\mathbf{X})$ s.t. $G_{pi}(\mathbf{d}(\mathbf{X})) \le 0,(i=1,2,\cdots,np)$ $\mathbf{d}^L \le \mathbf{d} \le \mathbf{d}^U$	$\min \quad Cost(\mathbf{d};\mathbf{Y})$ s.t. $G_{\pi i}(\mathbf{d}(\mathbf{Y})) \le 0,(i=1,2,\cdots,np)$ $\mathbf{d}^L \le \mathbf{d} \le \mathbf{d}^U$
Objective and constraints	$Cost(\mathbf{d})$: Deterministic material cost, random quality loss and random manufacturing cost. G_{pi} : the ith probabilistic constraints	$Cost(\mathbf{d})$: Deterministic material cost, random quality loss and random manufacturing cost. $G_{\pi i}$: the ith possibilistic constraints
Evaluation of constraints	$\min \ G(\mathbf{U})$ s.t. $\|\mathbf{U}\|_2 \le \beta_t$	$\min \ G(\mathbf{V})$ s.t. $\|\mathbf{U}\|_\infty \le 1-\alpha_t$
Variables and parameters	$\mathbf{X}$: random variable $\mathbf{U}$: standard normal random variable $\mathbf{d}$: design variable. $\mathbf{d}=\mu(\mathbf{X}) \in R^n$ β_t : target reliability index or target reliability level	$\mathbf{Y}$: non-interactive fuzzy variables $\mathbf{V}$: fuzzy variable with isosceles triangular membership $\mathbf{d}$: design variable, $\mathbf{d}=\{\max[\Pi_{Y_i}(y_i)]\}$ α_t : target failure possibility

multilevel-cut method, *the possibility index approach*, *the performance measure approach* (PMA), *the most probable point* (MPP) *search* and *maximal possibility search* (MPS), *etc*.

In practical engineering design, the vertex method is popular but rather expensive and may yield inaccurate results of fuzzy analysis in the case when an output response has a maximum or minimum within the input range. A level-cuts method has been used to overcome the difficulties of non-linear problems using various design levels. Recently, a multilevel-cut method has been developed to improve the accuracy of the vertex method for non-linear structural design, but it is also very expensive to carry out PBDO with this method. However, PMA has been successfully applied with its advantages of numerical efficiency and stability in PBDO [50], [53].

Both RBDO and PBDO employ PMA to improve numerical efficiency, stability and accuracy. The difference of PMA in the reliability analysis [50], [53] and in fuzzy analysis [39] is illustrated in Table 31.2.

The fuzzy analysis method is different from reliability analysis in the following two aspects. Firstly, MPP in reliability analysis based on FORM results in a first order approximation, whereas MPP in fuzzy analysis is exact along with the related possibility. Secondly, their search domain is different, *i.e*., an *nr*-dimensional sphere in reliability analysis but an *nr*-dimensional hyper-cube in fuzzy analysis, thus leading to simpler computation in fuzzy analysis [54].

At present, one of the main concerns related to PBDO research is how to improve numerical efficiency, accuracy and stability during the optimization process. PMA is such a method satisfying the requirement, by replacing the probabilistic constraint with the performance measure under a specified reliability level [53], [55]. Choi *et al.* [54] provided a new formulation of PBDO using PMA to improve numerical efficiency, stability, and accuracy. They also proposed a new MPS method to resolve disadvantages of the vertex method and the multilevel-cut method, by evaluating possibility

constraints efficiently and accurately for non-linear structural applications. Youn and Choi [56] presented an integrated design platform of both RBDO and PBDO using PMA when modeling physical uncertainty with insufficient information. Mourelatos and Zhou [21] presented a hybrid optimization approach for calculation of the confidence level of fuzzy response efficiently. Although PMA is less expensive when the reliability index is very high, Tu and Choi [57] revealed that it might require more computations when the reliability index is lower than the required reliability level.

In order to improve computational efficiency and stability, the *enriched performance measure approach* (PMA+) has been proposed as an extension of PMA. It combines four key ideas [55]: a way to launch RBDO at a deterministic optimum design, a probabilistic feasibility check, an enhanced *hybrid-mean value* (HMV+) method, and a fast reliability analysis under the condition of design closeness.

Another concern of the extension of PBDO is to provide a general framework integrating various proposed design optimization methodologies such as RBDO, PBDO *etc*., under aleatory uncertainty or epistemic uncertainty, or both of them.

Researchers [8], [39] also consider the PBDO problem of design for maximal safety under uncertainty. It is shown that more conservative results are obtained with PBDO that may be appropriate especially for design against catastrophic failure compared with the probability-based design in reliability assessment. The existing work related to PBDO revealed the characteristics and advantages of the possibility theory for coherent systems; but a general solution (not only referring to method or algorithms) of all uncertainty-based optimization under diverse uncertainties is still needed, which could be the future direction of research.

31.4.2 Evidence-based Design Optimization (EBDO)

Recently, evidence theory has shown its qualitative value and computational efficiency in engineering design if limited and even conflicting information is provided from expert elicitation or experiments, by means of combining aleatory and epistemic uncertainty in a straightforward way.

However, to the best of our knowledge, reported exploration of evidence theory in engineering design is fairly limited, and even much less in a design optimization framework. It is only recently that evidence-based methods have been used to propagate epistemic uncertainty [52], [58]. One of the major difficulties of applications may be their high computational cost. Bae *et al.* [18], [58] adopted *multi point approximation* (MPA) to alleviate these difficulties. In their work, compared with the sampling method and the vertex method, the proposed MPA method enhanced its accuracy through local approximation, focusing the computational recourses on the failure region. Then the *two-point adaptive non-linear approximate* (TANA2) method was selected, evaluating the belief and plausibility functions without sacrificing the accuracy. Basic belief assignment (BBA) expressed the degree of confidence in a proposition. The detailed flow diagram is shown in Figure 31.6.

Although such a cost-effective algorithm is demonstrated by two structural examples [18], it is not an issue as to which one takes design problem

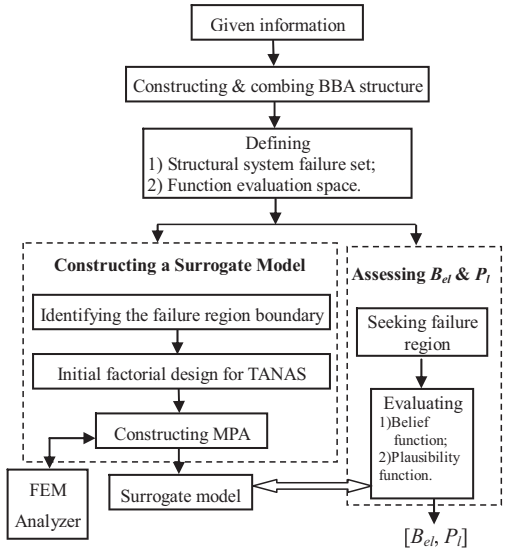

Figure 31.6. An uncertainty qualification approximation algorithm using evidence theory

into account. The study of design optimization that propagates epistemic uncertainty using evidence theory was first carried out by Agarwal *et al.* [6], who calculated optimum designs for multi-disciplinary systems. Since the belief functions are discontinuous to formulate non-deterministic constraints in this research, Agarwal *et al*., employed a trust region sequential approximate optimization method to drive the optimization process with surrogate models representing the uncertain measures as continuous functions. Their work is significant in throwing light on the use of evidence theory for optimization under uncertainty.

Mourelatos and Zhou [27] continued the research of EBDO and proposed an optimization method that can handle a mixture of aleatory and epistemic uncertainties efficiently in the formulation as follows,

$$\begin{aligned} &\min \ f\left(\mathbf{d}, \mathbf{X}^N, \mathbf{P}^N\right) \\ &\text{s.t.} \ P_f\left(G_i\left(\mathbf{d}(\mathbf{X})\right) > 0\right) \le p_{f_i},\ i = 1,2,\cdots,np \\ &\quad \mathbf{d}^L \le \mathbf{d} \le \mathbf{d}^U,\ \mathbf{X}_L^N \le \mathbf{X}^N \le \mathbf{X}_U^N \\ &\quad \mathbf{d} \in \mathbb{R}^n,\ \mathbf{X} \in \mathbb{R}^{nr},\ \mathbf{P} \in \mathbb{R}^q \end{aligned} \tag{31.2}$$

where **d**, **X** and **P** are the vectors of deterministic design variables, uncertain design variables and uncertain design parameters, respectively. Here *n*, *nr*, *q* are the numbers of the above variables or parameters, respectively, and *np* is the number of constraints. p_{f_i} is a prescribed probability value and the superscript "*N*" indicates the nominal value of each variable or parameter.

After a geometrical interpretation of the EBDO problems, a computationally efficient solution was presented to demonstrate the proposed EBDO method in [27]. The algorithm quickly identified the vicinity of the optimal point by a derivative-free optimizer calculating the evidence-based optimum, starting from the close-by RBDO optimum and moving a hyper-ellipse in the original design space. Moreover, only the identified active constraints were considered for local surrogate models. All these aspects keep the computational cost desirably low [27].

It is also shown that EBDO is conservative compared with all RBDO designs obtained with different probability distributions, but it is usually less conservative compared with the PBDO designs. It provides the possibility to investigate design optimization from a more broadened and general point of view, if the uncertainty representation tools can be further improved.

31.4.3 Integration of Various Approaches to Design Optimization

In recent years, more attention has been paid to the integrated framework of uncertainty analysis and optimization methods. The representative, but not exhausitive, work is illustrated below.

31.4.3.1 Integration of PBDO and RBDO

A design platform integrating both RBDO and PBDO when modeling physical uncertainty with insufficient information has been presented using PMA to improve numerical efficiency and stability in PBDO with MPS for highly non-linear and monotonic performance response in RBDO [56]. Such a structure is shown in Figure 31.7.

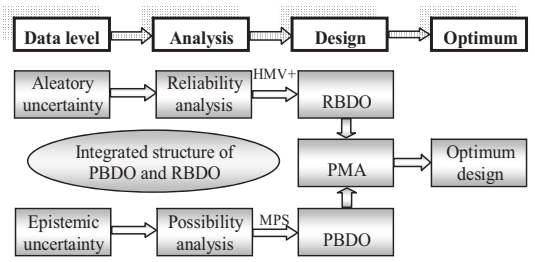

Figure 31.7. An integration of PBDO and RBDO by the PMA method [56]

Other integrating work has been done on the probabilistic and possibilistic methods. Although these two methods have tended to develop independently, with specialized algorithms for the implementation of each technique, it is possible to encompass them by a single mathematical algorithm according to the relation between them. Langley [59] realized the fact and then provided a unified approach to the assessment of structural integrity, for example, existing codes for FORM and SORM can potentially be employed for other methods in terms of a constrained minimization problem. Moreover, a second common algorithm

has been derived to assess the system reliability under a specified uncertainty or to derive the maximum tolerances for a reliability level.

31.4.3.2 Integrated Framework of Aleatory Uncertainty and Epistemic Uncertainty

In considering the integration of various design optimization methodologies under aleatory uncertainty or epistemic uncertainty, or both, a method called the *adaptive-loop* method has been explored [60]. It aims at improving numerical efficiency as well as maintaining numerical stability and accuracy.

The adaptive-loop method is composed of three phases of optimization. Deterministic design optimization is employed at the beginning of the process with the additional improvement of numerical efficiency by reducing the design iterations. Then the parallel-loop method is expedited addressing numerical convergence and statistical feasibility using PMA+. The last step uses the single-loop method, checking the design closeness and improving computational efficiency. Such an integrated framework is typical as an organic structure for uncertainty design optimization, as illustrated in Figure 31.8.

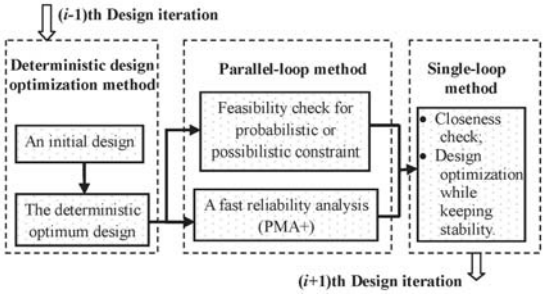

Figure 31.8. An adaptive-loop design optimization method [60]

31.4.3.3 Integration of Robust Design and PBDO

Considering the fact that, for epistemic uncertianties, PBDO deals with the failure rate, while a robust design optimization minimizes the product quality loss, researchers are interested in integration work for epistemic uncertainty. Since there is no metric for product loss defined under epistemic uncertianty, Youn and Choi [61] proposed a new framework integrating PBDO and a robust design optimization with a new metric of product quality loss by means of three different types of robust objectives for epistemic uncertainty. Such *possibility-based robust design optimization* (PBRDO) can be formulated as

$$\begin{aligned} &\min \quad Cost(\mathbf{d}, \mathbf{V}) \\ &\text{s.t.} \quad \Pi\left(G_i\left(\mathbf{d}(\mathbf{V})\right) > 0\right) \le \alpha_t,\ i = 1,2,\cdots,np \\ &\mathbf{d}^L \le \mathbf{d} \le \mathbf{d}^U,\ \mathbf{d} = m(\mathbf{V}) \in \mathbb{R}^{ndv}, \mathbf{V} = [V_i]^T \in \mathbb{R}^{nrv} \end{aligned} \tag{31.3}$$

where the design vector $\mathbf{d}$ is the maximum likely value of the fuzzy random vector and $\mathbf{V}$ is the fuzzy random vector. *np*, *ndv* and *nrv* are the number of possibilistic constraints, the number of design variables, and the number of fuzzy random variables, respectively.

Then MPS and PMA+ are employed to more effectively estimate possibilistic constraints and conducting the design optimization, respectively.

Actually, robust design can be integrated into any of uncertainty-based design optimization with the result of enhancing the product quality as well as the confidence level (*e.g.*, reliability). Du *et al.* [62] integrated robust design and RBDO in an inverse reliability strategy and gave a new search algorithm for the *most probable point of inverse reliability* (MPPIR), evaluating the performance robustness. Their engineering example of a vehicle combustion engine piston design illustrated the effectiveness of the method, solving the tradeoff problem encountered in the integration simultaneously, which has always been the difficulty in uncertainty handling.

31.4.4 Data Fusion Technology in Reliability Analysis

Along with optimization approaches, fusion technologies are necessary in reliability assessment and engineering design of complex large scale systems. As two of the most important fusion methods, the evidence method and the possibility method have been widely used recently. Data fusion is now a formal framework and tools for the

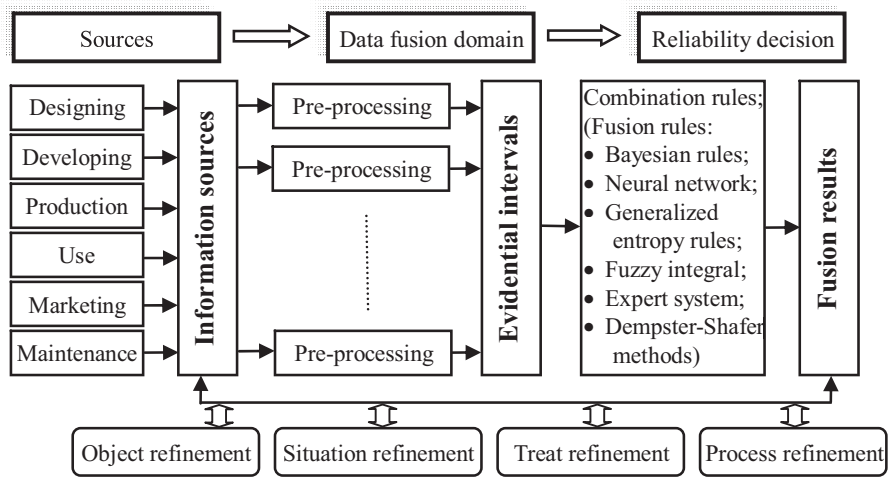

Figure 31.9. Dempster-Shafer methods as a part of reliability information fusion model

alliance of data originate from different sources of different nature. It aims at obtaining information of greater quality. If the information in the fusion process involves not only data, but also image, sensor and classifier, *etc*., the concept of data fusion can be extended, and the application area can also been extended. A fusion system is usually multi-leveled, e.g. from fixed level to feature level and then to decision level [63].

In the framework of possibility theory, the information available is represented by a possibility distribution corresponding to an interval (or a set). The fusion of uncertain information is equivalent to finding a compromise between a too accurate result which is certainly false and a sure result which is too imprecise.

Evidence theory allows the handling of non-exclusive and non-singleton events. Each measure attaches a probability to any element of the power set of the set of discernment [63]. The Dempster–Shafer rule is used to aggregate these input mass functions. Different modes of decision allow us to handle the compromise information. Based on this knowledge, with information theory, the D-S fusion method in reliability engineering can be illustrated as in Figure 31.9.

The essential strategy should be considered as combining fusion technology into a comprehensive approach. In the reliability assessment process, fusion technologies may be first applied to subsystems, then synthesizes all combine proper results together [64], as showed in Figure 31.10. More information about principles and applications can be found in reference [30],[31].

31.5 Performability Improvement on the Use of Possibility Theory and Evidence Theory

As far as we know, besides theoretical and computational developments by the means of possibilistic and evidential approaches, some physical problems have also been solved in the area of perfomability, which includes quality, reliability, maintenance and safety and risk. Physical problems such as failure mechanisms and detective methods are related to *system failure engineering*, which in some sense can be viewed as a part of operational research [66]. From this point of view, fuzzy (possibilistic) methodology and evidence theory have made their own contributions to various aspects of dependability and performability by adoptions of natural language expressions about reliability information [67].

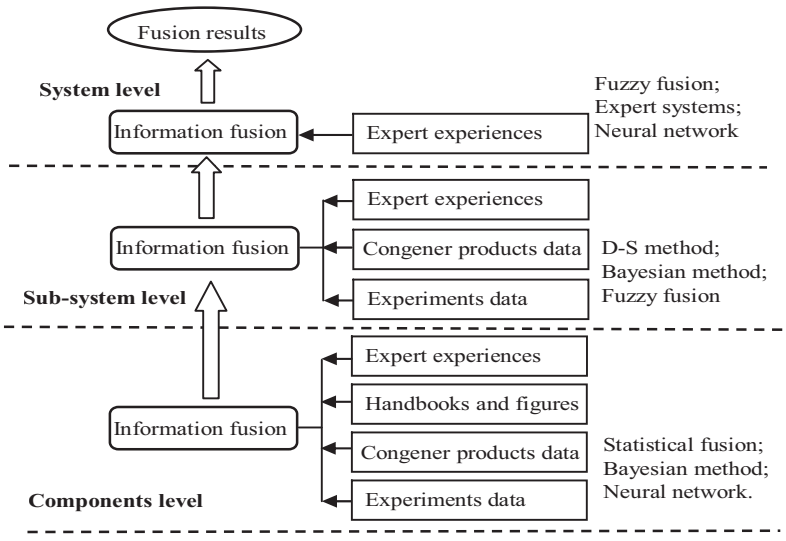

Figure 31.10. An information fusion structure for comprehensive reliability assessment [64]

31.5.1 Quality and Reliability

The characteristics of product quality consist of functionality, reliability and maintainability; reliability being the key point.

The first adoption of fuzzy methodology in reliability and failure analysis, *i.e*., the proposed notion of component possibility as a reliability index, may trace back to Kaufman's work [68], although the motivation and exact meaning of component possibility were not explained at that time. Currently more fuzzy-based approaches are appearing in reliability engineering [69] and Cai has summarized three main types of fuzzy methodology [66], respectively as,

- treating the probability as a fuzzy number;
- defining reliability in terms of a possibility measure; and
- considering failure as a fuzzy event.

31.5.1.1 Reliability Assessment and Evaluation

The reliability of a system is estimated in accordance with the probabilities of failures of its components. The information about reliability from an expert's elicitation may be imprecise and the uncertainty in parameters can be considered in a framework of *hierarchical uncertainty models*. Applications of the hierarchical models to reliability analysis using the possibility measure or imprecise probabilities have been considered by Utkin [47] as the extension of the Bayesian hierarchical model in the case of imprecise parameters of probability distributions, *e.g*., the component times to failure was characterized in a given confidence interval. Two methods (average parameters and average the system reliability) were analyzed with the result of simplicity from the computational viewpoint or minimal imprecision of results. However, further work is needed if there is no information regarding the independence of components.

Since one purpose of possibility is to represent and fuse uncertain data, and the existing fusion rules cannot deal rigorously with contradictory data, a new fusion rule merging different date sources was proposed by Delmotte and Borne [29], who used a vector expressing the reliability of the data sources and enabling a clear distinction between the data and their quality. Following the fusion rule, an algorithm assessing the indexes of reliability and moreover an index of the quality of the result

were provided. This was new in possibility theory and opened up its applications in the field of reliability.

Bai and Asgarpoor [43] presented an analytical method and Monte Carlo simulation method with fuzzy data to evaluate the substation reliability indices (such as the load point failure rate, the repair rate or repair time, and unavailability), which were represented by a possibility distribution. In the proposed models, the fuzzification rules were established by the extension principle and the techniques were tested to calculate the practical reliability indices for the substation configuration.

Besides fuzzy reliability theory in the context of possibility theory, the evidence-theory-based method is another approach to reliability analysis under incomplete information because of the simplicity of combination rules [18] and [24]. However, this approach also does not cover all possible judgments in reliability.

In attempting to implement the Dempster–Shafer and possibility theories into reliability and risk assessments, Kozine and Filimonov [20] summarized their experiences in the application of reliability areas. The criticism of the evidence theory is based on the following points:

- Failure to produce rational results in the case of inconsistent combined pieces of information according to Dempster's rule of combination.
- Inability to combine opinions of different people with overlapping experiences, especially in safety analysis applications.
- Being formally incoherent in safety assessment, just as in theory of probability.

They also encountered some difficulties that could not be solved in the frameworks of these theories [20]:

- Combination of homogeneous bodies of evidence.
- Combination of inconsistent pieces of information.
- Judgments admitted in elicitation.
- Dependence of imprecision on the amount of information, *etc*.

This indicates, in a final personal opinion, that Dempster's rule of combination can produce formally incoherent inferences.

31.5.1.2 Fault Tree Analysis (FTA)

The first implementation of fuzzy methods in the context of fault tree analysis was pioneered by Tanaka *et al.* [70], who treated imprecise probabilities of basic events as trapezoidal fuzzy numbers and employed the extension principle to describe the logical relationships leading to the top event. Furuta and Shiraishi [71] also proposed a type of importance measure but by means of max/min fuzzy operators and fuzzy integrals different than those in Tanaka's approach. With respect to to the fuzzy number, Singer [72] also regarded it as the perfectly straightforward way to overcome the deficiencies of inexact and inaccuracy knowledge. Soman and Misra [73] proposed a more general fuzzy method, also known as resolution identity to handle repeated events. Moreover, they extended this method to deal with multi-state FTA [74]. Another approach used to model imprecise relationships between physical and reliability states was proposed by Pan and Yun [75], who used fuzzy gates to describe output by triangular fuzzy numbers instead of crisp values 0 or 1. In fact, by defining fuzzy possibility of fuzzy event analogously to fuzzy probability, FTA can take into consideration subjective and expert opinions [45].

The literature on advances in FTA and fuzzy FTA is vast. Among others, we mention *fuzzy reliability theories* (see Section 31.3.1) and the *fuzzy logic* based method for linguistic (imprecise) quantification of fuzzy characteristics and construction of an approximate reasoning system.

Keller and Kara-Zaitri [76] observed the fact that interdependencies among various causes and effects may be assessed by rule-based reasoning and then introduced fuzzy logic to handle the impreciseness in fault representation.

Two possible strategies for integrating the possibilistic and the fuzzy logic-based approaches for FTA may be described as follows. One way is to construct an FTA model in the framework of possibility theory corresponding to different forms

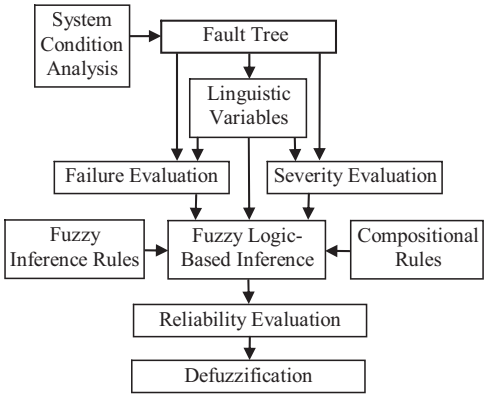

Figure 31.11. The procedure of an integrated approach of fuzzy FTA

of fuzzy reliability theory, using fuzzy logic as the fusion and reasoning strategy. The other one is to explore the FTA model in the context of fuzzy logic, applying possibility theory to meaning representation and inference. These two considerations may be integrated as in Figure 31.11.

31.5.1.3 Fault Diagnosis and Detection

Fault diagnosis partially interprets the reasons why a system fails. Some diagnosis methods are purely numerical in the sense that they exploit continuous models of the system based on automatic control methods, which are mainly regarded as fault detection. On the contrary, some diagnosis approaches focus on logical models of the system and perform consistency or inference analysis, mainly at the operational level. For example, a causal relational method for the application of a satellite fault diagnosis [77] is referred to as the latter type of method, in the framework of *fault mode effects and criticality analysis* (FMECA), where possibility calculus improved the discrimination power of the knowledge-based system, handling sequences of events consecutive to a fault.

Hence, the fuzzy approach together with the idea of fuzzy logic and the linguistic approach can be naturally used to deal with vagueness and ambiguity in system models and in human perceptions [66]. Furthermore, failure detection and identification problems can be addressed by fuzzy logic and D-S theory [67], or along with probabilistic approaches in multi-source data analysis, or the multiple-fault diagnosis problem.

Very recently, Fan and Zuo [30], [31] have proposed new decision rules based on the improved D-S evidence theory and employed the improved method in gearbox fault diagnosis, which enhance diagnostic accuracy and autonomy by means of combining expert knowledge and multi-source information.

Even now, application of D-S evidence theory in diagnosis has just begun. Issues deserving study involve how to transform expert diagnostic opinion into basic probability assignments and how to determine thresholds precisely.

31.5.2 Safety and Risk

With respect to a special kind of failure with catastrophic consequences, safety may be a part of reliability. Fuzzy methodology and fuzzy rules, together with many typical safety assessment approaches such as the *probabilistic risk assessment* (PRA) approach, have been applied in areas of safety design and risk analysis [78]–[80].

Cremona and Gao [81] developed an original possibilistic approach to evaluating the safety of structures, which was founded on the principles of possibility theory, with easy implementations compared to a probabilistic reliability approach. The development procedure contained the proof of existence of two reliability indicators (*failure possibility* and *the possibilistic reliability index*) and the application field, *i.e.*, linear and non-linear limit states involving non-interactive fuzzy intervals for welded joints damaged by fatigue. Such an example provided a full application, from uncertainty propagation (possibilistic variables transformation) and possibility distribution estimation to failure possibility determinations. Another approach to possibilistic assessment of the structures safety, where a realistic description of system behavior was obtained by applying high-quality algorithms in the structural analysis, can be found in [19].

In engineering safety analysis, in particular dealing with un-quantifiable information, several

researchers have investigated the relationships between fuzzy sets and D-S theory, and have suggested different integration approaches. Among others, we mention a belief *rule-based inference methodology using the evidential reasoning* (RIMER) approach established by Liu *et al.* [82] , for safety analysis and synthesis. The framework can be divided into two parts as follows. Safety estimation using the *fuzzy rule-based evidential reasoning* (FURBER) approach. In this part, information on various safety-related parameters can be described and transformed into an individual antecedent attribute in the rule base and in the inference process. The other is safety synthesis using the *evidential reasoning* (ER) approach to model hierarchical multi-expert analysis framework, with the final calculation of the risk level ranking index. The application of the proposed approach was illustrated by a case study of collision risk in [82].

If we must decide whether to operate or switch off a system based on available information that may be incomplete, evidence theory can be explored to meet such a demand. This is a kind of safety control problem and Dempster's rule of combination has been used for fusing a given set of information [66].

Risk concerns both failure consequences and failure occurrence uncertainty. Risk is also linked to decision-making policies. Subjects about risks are divided into two phases: risk assessments and risk management [83]. When risk management is performed in relation to PRA, the two activities are called *probabilistic risk assessment and management* (PRAM).

Quite a few research efforts have been made to establish a unified PRAM methodology where subjective assessment, value judgment, expertise and heuristics are dealt with more objectively. However, to express the uncertainty of the event occurrence in terms of a possibility measure, it is still an open and challenging problem as to how to define and assess the risk of an event.

When using possibility theory to estimate the risk of a certain act, risk is a combination of the likelihood of the occurrence and consequences of the action, which inhere in epistemic uncertainty. Two related techniques may include a numerical technique that applies classical possibility theory to crisp sets and, on the other hand, a linguistic technique that uses possibility theory on fuzzy sets. An adversary/defender model with *belief* and *plausibility* as the measure of uncertainty has been proposed as a linguistic model in an approximate reasoning rule base [84] .

31.5.3 Maintenance and Warranty

Product maintenance and warranty have received the attention of researchers from many different disciplines and are related to subareas including optimal system design, optimal reliability improvement, modeling imperfect repairs, and replacement.

A framework of possibilistic *assumption-based truth maintenance system* (ATMS), as an extension of the classical ATMS, was constructed by Bos-Plachez [85]. He combined model-based diagnosis theory and exploited possibilistic logic properties under the possibilistic principle for application in information engineering by means of the experimentation of an analog circuit diagnosis system. This approach is another solution based on approximate reasoning that can be exploited in order to detect more faults.

The contribution of the possibilistic ATMS to diagnosis problems involves the following aspects.

- Measuring non-detective faults by reducing the widths of intervals.
- Being a natural evolution towards the possibilistic ATMS by associating necessity measures in accord with certainty degrees of models and measurements.
- Remaining helpful in eliciting the values of certainty degrees from necessity measures.
- Updating the candidate set for generalization.

To the best of our knowledge, the three formal views of warranty are the exploitation theory, the signal theory, and the investment theory, respectively. On general grounds, there is a negative correlation between product quality and warranty costs. So warranty policies are structured according to the perspectives of manufacturer and buyer. Some exploration is exemplified as using

the fuzzy set approach to select maintenance strategies, working out maintenance and warranty policy with fuzzy lifetimes, or under fuzzy environment, and building up condition-based maintenance or reliability-centered maintenance with partial information. See [86] for more details.

One way to improve the reliability of a product is to eliminate infant mortality or the initial failure rate with a burn-in program. Another way is to upgrade the manufacturing process; and the third consideration may be outgoing inspection to eliminate non-conforming items [67]. In these studies, new technologies and design methods may be of benefit in providing measurable improvement in quality and investment.

31.6 Developing Trends of Possibility and Evidence-based Methods

Although significant progress has been made during the last two decades, the investigation and development of possibility theory and evidence theory is still an active domain of research. The probable and noticeable perspectives include:

1. Integrating or perfecting already-existing integration methods.
   - Integrating possibilistic and probabilistic methods that have been proven to be efficient and matured, *e.g.*, the D-S method with other related methods.
   - Reducing design iteration and shortening search intervals using combination algorithms or genetic algorithms.
   - Enhancing computational accuracy and stability and numerical efficiency.
2. Focusing on those methods that can ultimately be expressed in a common analytical framework.
   - Improving and solving the conflict problem of various uncertainties.
   - Propagating uncertainty in a global angle.
   - Constructing an error-compensation feedback loop as a software improvement or an adaptive loop as a correction mechanism.
3. Uncertainty quantification analysis and risk assessment of precise systems or difficult-to-measure systems.
4. Soft computing strategies as the cooperating framework with diverse methods.
   - Basic cooperation with fuzzy logic, probabilistic reasoning and neural networks.
   - More advanced cooperation with genetic algorithms, evidential reasoning, learning machines, and chaos theory.
5. Combining theoretical research and practical applications in real environments, from both the scientist's and the engineer's angle.

We strongly hope that reliability engineers will collaborate with statisticians in the development of models and methods to ensure applications in a field where uncertainty often plays a key role in decision making.

31.7 Conclusions

In this chapter, we have provided a detailed overview of possibility and evidence theories. Both are fundamental theories and are applicable to reliability, risk and uncertainty analysis in engineering design when there is not sufficient input data available due to specific uncertainty. From the comparison and relationship of the two measures, we conclude that possibility theory and evidence theory play a significant role in reliability analysis. Performability improvement considering various uncertainties, especially epistemic uncertainty from incomplete input data, are also important due to their given representations and theoretic fameworks. However, there is also room for further exploration of more general frameworks and performance characteristics needed for new modified design criteria. Our holistic view can provide a comprehensive understanding of existing approaches and for future work.

Abstract: Reliability is one of the most important attributes of performance in arriving at the optimal design of a system since it directly and significantly influences the system's performance and its life cycle costs. Poor reliability would greatly increase life-cycle costs of the system, and reliability based design must be carried out if the system is to achieve its desired performance. An optimal reliability design is one in which all possible means available to a designer have been explored to enhance the reliability of the system with minimum cost under the constraints imposed on the development of a system.

32.1 Introduction

Each system is unique, and its definition includes its intended functions, specification of its sub-systems, description of functional interrelationships between the constituent components and the environment in which these components are expected to operate. Once a hardware concept and technology of a system have been developed, a system designer is faced with the problem of designing a system that satisfies the performance requirements desired by the customer over the intended period of the system's use. These requirements generally take the form of some selected performance indices. There are a number of measures of system performance. Some of these measures that may be of interest are [64]:

1. Reliability,
2. Availability,
3. Mean time to failure (MTTF),
4. Mean Time to Repair (MTTR),
5. Operational readiness, *etc*.

An effective system design is one that satisfies these performances requirements depending upon the mission of the system.

Reliability is the probability of failure free operation and is generally chosen as the criteria of design of non-maintained systems, whereas availability is the probability that the system is working satisfactorily at any given point of time and is chosen as the design criterion for maintained systems. Alternatively, one may be interested in comparing the design alternatives based on the MTTF and MTTR. Whatever may be the index of performance assessment, one should be able to build a mathematical model for the system design problem that will fit into the present-day techniques of solution.

Modern systems are becoming more and more complex, sophisticated and automated, and a measure of effectiveness that cannot be sacrificed is their reliability. Reliability has become a mandatory requirement for customer satisfaction and is playing an increasing role in determining the

competitiveness of products. Because of these reasons, system reliability optimization is important in any system design. A survey of available literature indicates that a lot is written on system design that deals with the problem of reliability optimization (see references).

There are several alternatives available to a system designer to improve system reliability. The most known approaches are:

1. Reduction of the complexity of the system.
2. Use of highly reliable components through component improvement programs.
3. Use of structural redundancy.
4. Putting in practice a planned maintenance, repair schedule and replacement policy.
5. Decreasing the downtime by reducing delays in performing the repair. This can be achieved by optimal allocation of spares, choosing an optimal repair crew size, *etc*.

System complexity can be reduced by minimizing the number of components in a system and their interactions. However, a reduction in the system complexity may result in poor stability and transient response. It may also reduce the accuracy and eventually result in the degradation of product quality. The product improvement program requires the use of improved packaging, shielding techniques, derating, *etc.* Although these techniques result in a reduced failure rate of the component, they nevertheless require more time for design and special state-of-the-art production. Therefore, the cost of a part improvement program could be very high and may not always be an economical way of system performance improvement. Also, this way the system reliability can be improved to some degree, but the desired reliability enhancement may not be attained.

On the other hand, the employment of structural redundancy at the subsystem level, keeping system topology intact, can be a very effective means of improving system reliability to any desired level. Structural redundancy may involve the use of two or more identical components, so when one fails, the others are available and the system is able to perform the specified task in the presence of faulty components. Depending upon the type of subsystem, various forms of redundancy schemes *viz*., active, standby, partial, voting, *etc*., are available. The use of redundancy provides the quickest solution, if time is the main consideration, the easiest solution, if the component is already designed, the cheapest method, if the cost of redesigning a component is too high, and the only solution if the improvement of component reliability is not possible [64]. Thus, much of the effort in designing a system is applied to allocation of resources to incorporate structural redundancies at various subsystems which will eventually lead to a desired value of system reliability.

Maintenance, repairs and replacements, wherever possible, undoubtedly enhance system reliability [61] and can be employed in an optimal way. These facilities, when combined with structural redundancy, may provide any desired value of system reliability.

In addition to these methods, use of burn-in procedures to eliminate early failures in the field for components that have high infant mortality may also lead to an enhancement of system reliability [4].

Therefore, the basic problem in optimal reliability design of a system is to explore the extent of the use of the above mentioned means of improving the system reliability within the resources available to a designer. Such an analysis requires an appropriate formulation of the problem. The models used for such a formulation should be both practical and amenable to known mathematical techniques of solution.

Considerable amount of work has been done to systematize reliability design procedure. This chapter provides an overview of the development in the field of optimal reliability design of systems. Section 2 of this chapter provides a description of problem domain of reliability optimization. In Section 3 some of the formulations for reliability optimization are presented. Section 4 provides an overview of solution techniques. A brief review of current approaches for repairable system design is presented in Section 5 of this chapter. The last section concludes the chapter.

Notation:

R_s System reliability, $0 \le R_s \le 1$,
Q_s Unreliability of system,
R_j Component reliability of stage j, $0 \le R_s \le 1$,
Q_j Unreliability of subsystem,
$R_{j\min}$ Lower limit on R_s,
$R_{j\max}$ Upper limit on R_s,
R_0 Specified minimum R_s,
b_i Resources allocated to i^{th} type of constraint,
n Number of subsystems in the system,
m Number of resources,
$f(.)$ The system reliability function,
$g_i(.)$ The i^{th} constraint function,
x_j Number of components at subsystem j,
$x_{j\min}$ Lower limit on x_j,
$x_{j\max}$ Upper limit on x_j,
$E(X)$ Multi-state series-parallel system reliability index,
c_{jp} Cost of component of type p used in subsystem j,
x_{jp} Number of components of type p used in subsystem j,
$X = (x_{11,}x_{12,...}x_{21,}x_{22,...})$ System design vector,
k Number of components required for system surviving,
$x_{j.,v}$ Number of parallel components for $1 \le v \le V_j$,
V_j Number of versions available for component of type j $(1 \le j \le n)$,
T Operation period,
D Required demand level,
MP Maintenance policy,
$C_{j,v}$ Maintenance and acquisition cost of version v for component of type j,
$C(N)$ Average system cost per unit time with component vector N,
$C_d(N)$ Average downtime cost per unit time with component vector N,
$C_m(N)$ Average maintenance cost per unit time with component vector N,
c_d Cost of system downtime per unit time,
c_m Maintenance cost per unit time for each component in subsystem j,
$N = N_j$ Component vector for $j = 1,...n$,
$A(N), U(N)$ Availability, unavailability of system with component vector N, respectively,
$t_{\alpha,x}$ System percentile life,
C_s Total component cost of the system,
$c_j(x_j, R_j)$ Cost of x_j component having reliability R_j,
A_{ss} System inherent availability (steady-state), $0 \le A_{ss} \le 1$,
α_s Long-run cost rate of the system (cost of maintenance, cost of system unavailability),
t_M Recovery time,
μ_F Mean time to failure of component,
A_s System availability,
A_0 System availability Goal.

32.2 Problem Description

In the literature, reliability optimization problems are broadly put into three categories according to the types of their decision variables: reliability allocation, redundancy allocation, and reliability-redundancy allocation. If component reliabilities are the only variables, the problem is called reliability allocation; if the number of redundant units is the only variable, the problem becomes Redundancy Allocation Problem (RAP); if the decision variables of the problem include both the component reliabilities and redundancies; the problem is called a Reliability-Redundancy

Allocation Problem (RRAP). Misra and Ljubojevic [58] were the first to introduce this formulation in the literature. The type of reliability optimization problem determines the nature and value of decision variables such that the system objective function is optimized and all constraints are met. The criterion may be reliability, cost, weight or volume. One or more criteria may be considered in an objective function, while the others may be considered as constraints.

Reliability allocation is usually easier than redundancy allocation, but it is more expensive to improve the component reliability than to add redundant units. Redundancy allocation, on the other hand, results in increased design complexity and increased costs through additional components, weight, space, *etc*. It also increases the computational complexity of the problem, and is classified as NP-hard in the literature [14]. Classifications of published papers in the literature based on type of decision variables (component reliability, redundancy level or both) are provided in Table 32.1.

Table 32.1. Classification of published papers based on problem they addressed

Reliability allocation [2], [90], [104]
Redundancy Allocation [1],[5],[12],[15],[16],[18],[19],[33],[35],[36],[39], [40], [41], [47], [48], [52], [53], [55], [60], [61], [62], [65], [66], [67], [69], [72], [74], [75], [77], [79], [80], [81], [84], [90], [91], [96], [97], [106], [108], [110], [111], [112], [115]
Reliability and redundancy allocation [58], [13], [20], [23], [28], [31], [38], [50], [68], [79], [90], [99], [103], [105],[113],[114]

These three classifications have been researched for different system configurations like series, series-parallel, parallel-series, complex, bridge, *etc*. System configuration shows the functional relationship of components in a system. It plays a vital role in the reliability optimization problem. Series configuration or series-parallel configuration is comparatively easy to solve, but in many practical situations complex or mixed configurations have to be used. Reliability improvement is equally important for such systems. Kuo *et al.* [43], in their review classified the reliability optimization research on the basis of system configurations.

Researchers have considered issues like: types of redundancy, mixing of components, multi-state system, *etc*. Table 32.2 provides a list of references that have considered various issues in optimal reliability design problems.

Table 32.2. Classification by specific application.

Standby redundancy [28],[49],[57],[62],[87],[88], [107],[110],[111],[112]
Multi-state system [50], [76], [80], [81]
Where to allocate [10], [11], [85],[101],[102]
Mix of components [15], [16], [19], [34],[47],[68],[77],[106],[115]
Modular (multi-level) redundancy [9],[108],[109]

Misra [62] was also the first to introduce the formulation of mixed types of redundancies in the optimal reliability design of a system. Prior to [62], the formulations invariably considered only active redundancies in redundancy allocation design problems. This was made possible with the introduction of a zero-one type of formulation based on the Lawler and Bell algorithm [45], which was for the first time proposed by Misra [53] for reliability optimization problems and has been considered very useful for solving various design problems involving discrete variables. There are different ways to provide component

redundancy, *viz.,* active parallel redundancy, *k*-out-of-*n*:G type (also known as partial redundancy), voting redundancy and standby redundancy. In active parallel redundancy and *k*-out-of-*n*:G type of redundancy, all the m-redundant units are operating simultaneously but at least one or *k* must be good for the redundant subsystem to be good. Voting is similar to *k*-out-of-*n*:G redundancy. However, in standby redundancy, only one of the redundant elements operates at any given point of time, and whenever a redundant unit fails, another healthy redundant unit from standby mode takes over the operation from the failed one. The subsystem fails only when all redundant units have failed [62]. As mentioned earlier, there have been relatively very few studies that deal with the standby redundancy allocation problem.

Similarly, there has been more research on reliability optimization of systems that consist of units that can have only two states (namely, operate or fail) as compared to the multi-state system [81]. Unlike two-state systems, multi-state systems assume that a system and its components may take more than two possible states (from perfectly working to completely failed). A multi-state system reliability model provides more flexibility for modeling of system conditions than a two-state reliability model [97]. Among others, problem of where to allocate redundancy, problem of mix of component (that allows for selection of multiple component choice, with different attributes, for each subsystem) and modular or multi-level redundancy allocation are some of the important issues in reliability optimization problems.

Some studies have also considered the issue of multi-level redundancy. When redundancy is added to components, it is called single-level redundancy but if a module (group of subsystems) is chosen for redundancy, then it is called modular or multi-level redundancy. A well-known thumb-rule among design engineers is that redundancy at the component level is more effective than redundancy at the system level. However, Boland and EL Neweihi [9] have shown that it is not true in the case of redundancy in series systems with non-identical spare parts.

For a maintained (repairable) system design [61], reliability and maintainability designs are usually carried out right at the design stage, and failure and repair rates are allocated to each component of the system in order to maximize its availability and/or reliability. For such systems it becomes imperative to seek an optimal allocation for spare parts while maximizing availability/ reliability subject to some techno-economic constraints on cost, resources, *etc.*

32.3 Problem Formulation

Amongst the various design problems that have been considered in the literature, the following formulations are widely discussed.

32.3.1 Reliability Allocation Formulations

Formulation 1: From mathematical point of view, the reliability allocation problem is a nonlinear programming problem (NLP). It can be shown as follows:

Maximize

$$R_s = f(R_1, R_2, ..., R_n),$$

subject to

$$g_i(R_1, R_2, ..., R_n) \le b_i; \quad i = 1,2,...,m,$$

$$R_{j\min} \le R_j \le R_{j\max}; \quad j = 1,2,...,n.$$

For separable constraints,

$$g_i(R_1, R_2, ..., R_n) = \sum_{j=1}^{n} g_{ij}(R_j). \qquad (32.1)$$

For series configuration,

$$R_s = \prod_{j=1}^{m} R_j \ . \qquad (32.2)$$

For parallel configuration,

$$Q_s = \prod_{i=1}^{m} Q_j \ , \text{ and} \qquad (32.3)$$

$$R_s = 1 - Q_s = 1 - \prod_{j=1}^{n} Q_j = 1 - \prod_{j=1}^{n} (1 - R_j). \qquad (32.4)$$

Formulation 2: In the above formulations reliability of components takes any continuous value between zero and one. Suppose there are u_j discrete choices for component reliability at stage j for $j = 1,...,k(\leq n)$, and the choice for component reliability at stage $k+1,...,n$ is on a continuous scale. Let $R_j(1), R_j(2),..., R_j(u_j)$ denote the component reliability choices at stage j for $j = 1,...,k$. Then the problem of selecting optimal component reliabilities that maximize system reliability can be written as [43]:

Maximize

$$R_s = h[R_1(x_1),...R_k(x_k), R_{k+1},..., R_n],$$

subject to

$$g_i[R_1(x_1),..., R_k(x_k), R_{k+1},..., R_n] \leq b_i, \quad i = 1,2,...m,$$
$$x_j \in \{1,2,...,u_j\}, \quad j = 1,2,...,k,$$
$$R_{j\min} \leq R_j \leq R_{j\max}; \quad j = k+1, k+2,..., n. \qquad (32.5)$$

32.3.2 Redundancy Allocation Formulations

Formulation 3: It is generally formulated as pure integer nonlinear programming problem (INLP).

Maximize

$$R_s = f(x_1, x_2,..., x_n),$$

subject to

$$g_i(x_1, x_2,..., x_n) \leq b_i; \quad i = 1,2,...,m,$$
$$x_{j\min} \leq x_j \leq x_{j\max}; \quad j = 1,2,...,n,$$
$$x_j \text{ being an integer.}$$

For separable constraints,

$$g_i(x_1, x_2,..., x_n) = \sum_{j=1}^{n} g_{ij}(x_j). \qquad (32.6)$$

Formulation 4: Another type of formulation, where percentile life is optimized, was provided by Coit and Smith [18]. The problem is to maximize a lower percentile of the system time to failure distribution subject to resource constraints. The approach is particularly useful when no clear mission time is available. This formulation is given as follows:

Maximize

$$t_{\alpha,x}$$

subject to

$$g_i(t_{\alpha,x}; x) \leq b_i; \quad i = 1,2,...,m,$$
$$t_{\alpha,x} = \inf\{t \geq 0 : R_s \leq 1-\alpha\},$$
$$x_j \text{ being an integer.} \qquad (32.7)$$

Formulation 5: Redundancy allocation for cost minimization.

Minimize

$$C_s = \sum_{j=1}^{n} c_j(x_j),$$

subject to

$$g_i(x_1, x_2,..., x_n) \leq b_i; \quad i = 1,2,...,m,$$
$$x_{j\min} \leq x_j \leq x_{j\max}; \quad j = 1,2,...,n,$$
$$x_j \text{ being an integer.} \qquad (32.8)$$

Similarly the reliability allocation and reliability-redundancy allocation problem can also be formulated in the form of cost minimization problem.

32.3.3 Reliability and Redundancy Allocation Formulations

Formulation 6: This can be considered as mixed integer nonlinear programming problem (MINLP).

Maximize

$$R_s = f(x_1, x_2,..., x_n; R_1, R_2,..., R_n),$$

subject to

$$g_i(x_1, x_2,..., x_n; R_1, R_2,..., R_n) \leq b_i; \quad i = 1,2,...,m,$$
$$R_{j\min} \leq R_j \leq R_{j\max}; \quad j = 1,2,...,n,$$
$$x_{j\min} \leq x_j \leq x_{j\max}; \quad j = 1,2,...,n,$$
$$x_j \text{ being an integer.}$$

Here also for separable constraints,

$$g_i(x_1, x_2,..., x_n; R_1, R_2,..., R_n) = \sum_{j=1}^{n} g_{ij}(x_j, R_j), \qquad (32.9)$$

32.3.4 Multi-objective Optimization Formulations

Formulation 7: A multi-objective formulation for reliability-redundancy allocation problem can be shown as:

Maximize

$$[f_1(x_1,...,x_n;R_1,...,R_n), and - f_2(x_1,...,x_n;R_1,...,R_n)],$$

where f_2 represents a convex cost function, subject to,

$$g_i(x_1,x_2,...,x_n;R_1,R_2,...,R_n) \le b_i;\quad i=1,2,...,m,$$
$$R_{j\min} \le R_j \le R_{j\max};\quad j=1,2,...,n,$$
$$x_{j\min} \le x_j \le x_{j\max};\quad j=1,2,...,n,.$$

For separable constraints,

$$g_i(x_1,x_2,...,x_n;R_1,R_2,...,R_n) = \sum_{j=1}^{n} g_{ij}(x_j,R_j),. \tag{32.10}$$

Similarly the multi-objective formulation for redundancy allocation and reliability allocation can also be formulated.

32.3.5 Problem Formulations for Multi-state Systems

Formulation 8: The general problem formulation for minimizing the cost of a series-parallel system is shown below [81]. The objective function is the sum of the cost of the components chosen. The reliability constraint, or minimum acceptable reliability level, is E_o.

Minimize

$$\min \sum_{j=1}^{n}\sum_{p=1}^{s} c_{jp}x_{jp},$$

subject to

$$E(X) \ge E_0,$$
$$x_{jp}x_{jk} = 0,\ j, p \ne k. \tag{32.11}$$

32.3.6 Formulations for Repairable System

Formulation 9: In designing the systems for reliability and maintainability, one may be interested in determining the pair (MTBF, MTTR), for which availability reaches a maximum value subject to a cost constraint. This problem of failure and repair rates allocation can be formulated as [61]:

Maximize

$$A_{ss} = \prod_{j=1}^{n} (MTBF/MTBF + MTTR)_j,$$

subject to

$$\sum_{j=1}^{n} c_j(MTBF, MTTR) \le C_s,$$
$$(MTBF)_j \ge 0,\ (MTTR)_j \ge 0;\ \forall_j \quad \forall_j. \tag{32.12}$$

Alternatively a dual problem can also be formulated as follows.

Formulation 10: Yu *et al.* [107], have seen the reliability allocation problem of a cold-standby system from a maintenance point of view. They formulated the problem as:

$$\underset{t_M \ge 0, \mu_F > 0}{Minimize}$$
$$\alpha_S(t_M, \mu_F)$$

subject to

$$A_S(t_M, \mu_F) \ge A_0. \tag{32.13}$$

where the various symbols used above are defined as given in the notation.

Formulation 11: Nourelfath and Ait-Kadi [76] have extended the classical redundancy allocation problem to find, under reliability constraints, the minimal configuration and maintenance costs of a multi state series-parallel system with limited maintenance resources. They formulated the problem as:

Minimize

$$C_s = \sum_{j=1}^{n}\sum_{v=1}^{V_j} x_{j,v}C_{j,v},$$

subject to

$$R_s(x_1,x_2,...,x_n,D,T,MP) \ge R_0. \tag{32.14}$$

Formulation 12: For a *k*-out-of-*n* system Amari [4] modelled the problem of minimizing the average system cost per unit time. The average system cost is the sum of the average cost of downtime plus the average cost of maintenance.

$$C(N) = C_d(N) + C_m(N) \qquad (32.15)$$

The cost of down time can be calculated from percentage of downtime within a unit time duration and the loss (cost) per unit downtime. It should be noted that under steady-state conditions, the percentage of downtime is equivalent to the steady-state unavailability. Hence,

$$C(N) = c_d.U(N) = c_d.[1 - A(N)]. \qquad (32.16)$$

The cost of maintenance is proportional to the cost associated with repairs of individual components. The cost of repair of a failed component includes the miscellaneous fixed cost as well as the variable cost based on the repair time. The cost of maintenance per unit time for the whole system is:

$$C_m(N) = \sum_{j=1}^{n} N_j.c_m \ . \qquad (32.17)$$

Therefore, the average cost of the system is:

$$C(N) = \sum_{j=1}^{n} N_j.c_m + c_d.U(N) \ . \qquad (32.18)$$

The objective is to find the optimal N that minimizes $C(N)$. The problem can be further refined by considering the maximum acceptable unavailability (U_a) and the acceptable upper limit on total weight and volume. Therefore, the constraints are

volume constraint: $\sum_{j=1}^{n} v_j \le V;$

weight constraint: $\sum_{j=1}^{n} w_j \le W;$

unavailability constraint: $U(N) \le U_a$. (32.19)

32.4 Solution Techniques

From the previous sections it can be seen that reliability optimization is a nonlinear optimization problem. The solution methods for these problems can be categorized into the following classes:

1. Exact methods.
2. Approximate methods.
3. Heuristics.
4. Metaheuristics.
5. Hybrid heuristics.
6. Multi-objective optimization techniques.

Exact methods provide exact solutions to reliability optimization problems. Dynamic programming (DP) [7, 52], branch and bound [26, 51, 95], cutting plane techniques [27], implicit enumeration search technique [25] and partial enumeration search technique [45, 53] are typical approaches in this category. These methods of course provide high solution quality, but higher a computational time requirement limits their application to simple system configurations and systems with only a few constraints.

The variational method [71, 28, 55], least square formulation [56], geometric [23, 57], parametric programming [6], Lagrangian and the discrete maximum principle [22, 54] offer an approximate solution. In most of these methods, the basic assumption remains the same: the decision variables are treated as being continuous and the final integer solution is obtained by rounding off the real solution to the nearest integer. This approach produces near-optimal solutions, or solutions that are very close to the exact solution. This is generally true since reliability objective functions are well-behaved functions.

On the other hand, many heuristics have also been proposed in the literature to provide an approximate solution in relatively short computational time [37, 55, 91, 93]. A heuristic may be regarded as an intuitive procedure constructed to generate solutions in an optimization process. The theoretical basis for such a procedure in most cases is insufficient, and none of these heuristics establish the optimality of the final solution. These methods have been widely used to solve redundancy allocation problems in series systems, complex system configuration, standby redundancy, multi-state system, *etc*.

Recently, meta-heuristics have been successfully used to solve complex reliability

optimization problems. They can provide optimal or near optimal solution in reasonable time. These methods are based on artificial reasoning rather than classical mathematics-based optimization. GA (genetic algorithm) [16, 79, 108, 109], SA (simulated annealing) [38, 84], TS (tabu search) [34, 41], immune algorithm (IA) [13], and ant colony (AC) [46, 47] are some of the approaches in this category, which have been applied successfully to solve the reliability optimization problem. Meta-heuristic methods can overcome the local optimal solutions and, in most cases, they produce efficient results. However, they also cannot guarantee the global optimal solutions.

In the literature, hybrid heuristics [15, 50, 111, 112] have also been proposed to solve redundancy and reliability-redundancy allocation problems. Hybrid heuristics generally combine one or more metaheuristics or a metaheuristic with other heuristics.

In reliability optimization with a single objective function, either the system reliability is maximized subject to limits on resource constraints, or the consumption of one of the resources is minimized subject to the minimum requirement of system reliability along with other resource constraints. A design engineer is often required to consider, in addition to the maximization of system reliability, other objectives such as minimization of cost, volume, and weight. It might not be easy to define limits on each objective in order to deal with them in the form of constraints. In such situations, an engineer faces the problem of optimizing all objectives simultaneously. To deal with such situations, multi-objective optimization techniques [67, 87, 88, 100] have been applied for system reliability design.

Review on optimal system design problems has been available from time to time during the past three decades. Chronologically, the first review was published by Misra [63] in 1975. Subsequent reviews have been published by Misra [64], Tillman *et al.* [98], Kuo and Prasad [42], Kuo *et al.* [43], and more recently in 2007 by Kuo and Wan [44]. A brief survey of some of the optimization techniques is also presented in this chapter for the sake of completeness of information.

32.4.1 Exact Methods

Among these techniques, dynamic programming [7, 52] is perhaps the most well known and widely used. Dynamic Programming (DP) methodology provides an exact solution but its major disadvantage is the curse of dimensionality. The volume of computation necessary to reach an optimal solution increases exponentially with the number of decision variables [24]. Although this weakness can be compensated for by employing Lagrangian multipliers [7, 24], DP is still not applicable to non-separable objective or constraint functions as would arise in reliability optimization problems with complex structures [33]. Misra [52] and Misra and Carter [60] have described a summation form of functional equations with a view to overcome the computational hazards and memory requirements of dynamic programming formulation.

Yalaoui *et al.* [105], presented a new dynamic programming method for a reliability redundancy allocation problem for series-parallel systems, where components must be chosen among a finite set. This pseudopolynomial YCC algorithm is composed of two steps: the solution of the sub-problems, one for each of the stages of the system; and the global resolution using the results of the one-stage problems. They showed that the solutions converge quickly towards the optimum as a function of the required precision. In another study, Yalaoui *et al.* [104] have used dynamic programming to determine the reliability of the components in order to minimize the consumption of a system resource under a reliability constraint in a series-parallel system.

Ghare and Taylor [26] provided another approach to solve redundancy optimization, known as branch and bound in the literature. This technique basically involves methods for suitably partitioning the solution space into a number of subsets and determining a lower bound (for a minimization problem) of the objective function for each of these. The one with the smallest lower bound is partitioned further. The branching and bounding process continues until a feasible solution is found such that the corresponding value of the objective function does not exceed the lower

bound for any subset [65]. Most of the branch and bound algorithms are confined to linear constraints and linear/non-linear objective functions. In general, the effectiveness of a branch-and-bound procedure depends on the sharpness of the bound; the required memory increases exponentially with the size of the problem [43]. Sup and Kwon [95] have modelled redundancy allocation problem with multiple-choice constraints as a zero-one integer-programming problem. The problem is analyzed first to characterize some solution properties. An iterative Solution Space Reduction Procedure (SSRP) is then derived using those solution properties. Finally, the iterative SSRP is used to define an efficient branch-and-bound procedure algorithm. Misra and Sharma [51] have solved the reliability problem using zero-one programming and a non-binary tree search procedure. Ha and Kuo [33] proposed a branch-and-bound method to solve the INLP. The proposed method is based primarily on a search space elimination of disjoint sets in a solution space that does not require any relaxation of branched sub problems. The major merits of the proposed algorithm are its flexibility (*i.e*., it does not rely on any assumptions of linearity, separability, single constraint, or convexity) and its efficiency (in terms of computation time). Experiments were performed to demonstrate that the proposed algorithm is more efficient compared to other exact algorithms, in terms of computation time.

The implicit enumeration search technique and the partial enumeration search technique of Lawler and Bell [45], like the branch and bound techniques, involve the conversion of integer variable formulation into binary variables formulation. Both techniques yield an optimal solution in several stages of steps, excluding at each step a number of solutions that cannot possibly lead to a better value of the objective function than that obtained up to that stage. The former technique requires the assumption of separability of the objective function and constraints, whereas no such assumption is required in the latter. Lawler and Bell's technique [45] can handle non-linear constraints also, which is an added advantage over the former. Although these search techniques require an assumption of monotonicity of the objective function, it certainly is not suitable for problems in which the variables are bounded above by large integers.

The use of Lawler and Bell's [45] algorithm for reliability design was first introduced by Misra [53]. Subsequently, this algorithm came to be widely used for a variety of reliability design problems. It has been observed, however, that a major limitation of Lawler and Bell's algorithm is its computational difficulty caused by a substantial increase in the number of binary variables [62]. Misra in [62] proposed a modified L-B algorithm of Misra [53] for optimal design of a subsystem which may employ any general type of redundancy, *i.e*., standby, partial or active.

Inspired by the lexicographic search given by Lawler and Bell [45], Misra in 1991 suggested a simple and efficient algorithm for solving an integer programming problem, called MIP algorithm (Misra integer programming algorithm). It is based on a lexicographic search in an integer domain (and not in a zero-one variables domain like Lawler and Bell's algorithm). MIP requires only functional evaluations and carries out a limited search close to the boundary of resources. It can handle system-reliability design problems of any type (nonlinear functions and does not impose any convexity and concavity conditions) in which the decision variables are restricted to take integer values only. The method is applicable for both small and large problems and in [69], MIP search method was applied to integer programming problems which need not be of separable form and may have any arbitrary form of function.

Misra and Sharma [65] employed a new MIP search algorithm to attempt system reliability design problems, as it provides the advantage of exploring all the feasible design solutions near the boundary and eliminates many of the unwanted feasible points. MIP reduces the problem of extensive search effort usually involved with L-B algorithm. The MIP algorithm is conceptually simple and efficient for solving any design problem involving integer programming.

In the literature the MIP algorithm has also been used with other approaches. A bound dynamic programming partial enumeration search technique is proposed by Jianping [35], in which

the optimal solution is obtained in the bound region of the problem by using the general dynamic programming technique and the MIP bound search technique. The algorithm was later on modified by Jianping and Xishen [36] in his partial bound enumeration technique based on the bound dynamic programming and the MIP. With some examples, the author showed the efficiency and economy of the proposed algorithm in solving larger system reliability optimization problems. In 2000, Prasad and Kuo [80] proposed an implicit enumeration algorithm, which is basically similar to MIP lexicographic search, but differs in order of the search vector, to solve nonlinear integer programming redundancy allocation problems.

Another development in the field of reliability optimization took place when Misra and Ljubojevic [58] for the first time considered the fact that the globally optimum results will be achieved if the optimization of system reliability is done using both component reliability and redundancy level as decision variables in the problem. They formulated it as a mixed-integer programming problem and solved it by a simple technique. Later on, a search method to improve the solution time for the formulation of [58] was offered by Tillman *et al.* [99].

The well-known cutting plane techniques for solving linear integer programming problems are efficient tools for solving reliability optimization problems [27], but with these techniques also, the problem of dimensionality still remains difficult to tackle and the cost of achieving a solution is usually very high.

There are several other interesting methods for solving general integer programming problems. Rosenberg [86], Misra and Sharma [59], and Nakagama and Miyazaki [73] have proposed a surrogate constraints algorithm for the problem where system "costs" coefficients are integers and the formulation surrogates many constraints, thereby permitting a faster solution. The surrogate constraint method translates a multidimensional problem into a surrogate dual problem with a single dimension by using a vector of surrogate multipliers. This method then obtains an exact optimal solution to the original problem by solving this surrogate dual problem. Recently, Onishi *et al.* [77], presented an improved surrogate constraint method to solve redundancy allocation problem with a mix of components.

Apart from these, redundancy allocation problems in which the decision variables are the number of redundant units, the problem of where to allocate redundancies in a system in order to stochastically increase the system lifetime is also important in reliability theory [10]. This problem has been addressed by many researchers through stochastic ordering [10, 11, 85, 101, 102].

In general, all exact methods become computationally unwieldy, particularly in solving larger scale reliability optimization problems. It is because of this reason, the research on application of exact methods, for the complex problems like reliability-redundancy allocation problem and problems with issues like stand-by redundancy, multi-state system, component mixing and modular redundancy, *etc.*, is relatively meagre. Such problems are also classified in the literature as NP-hard problem [14]. Hence, one is quite often led to consider approximate methods, heuristics, metaheuristics, *etc.,* which can be considered economical to solve such problems.

32.4.2 Approximate Methods

Moscowitz and McLean [71] were perhaps the first to formulate mathematically the optimization of system reliability subject to a cost constraint. They derived the maximum reliability for a fixed system cost and therefore solved an unconstrained problem. Gordon [28] using a variational method also tried a problem of a single constraint employing standby redundancy. The method in [71] was extended by Misra [55] to include any number of linear constraints. This is an approximate method of solution and requires an estimate of system reliability. Misra [56] proposed a least square approach for system reliability optimization. This type of approach is found to be very simple and faster than other methods, although the solution is an approximate one.

Everett [22] attempted to solve redundancy optimization problems through the use of Lagrangian multipliers, but he considered only one constraint. Misra [54] described an approximate

method for any number of constraints yet keeping the computational effort to a minimum. Messinger and Shooman [49] have provided a good review of earlier methods and considered approximate methods of allocating spare units based on incremental reliability per pound and Lagrangian multiplier algorithm.

Federowicz and Mazumdar [23] solved the problem of optimal redundancy allocation using geometric programming formulation. It is again an approximate solution method. The numbers of redundancy are treated as continuous variables and rounded off to the nearest integer in the final solution. Geometric programming is fairly simple if one deals with a problem of single constraint, but not so attractive when a large number of constraints is involved. Misra and Sharma [57] provide a geometric programming formulation simpler than in [23] and also make possible the consideration of switching redundancy. Govil [29] also provides a geometric formulation for a series system reliability optimization problem.

32.4.3 Heuristics

The simplest method in the heuristic category was proposed by Sharma and Venkateswaran [91] and Misra [55] independently and simultaneously and so it is called the MSV (Misra, Sharma and Venkateswaran) method. It is applicable only for redundancy optimization in a series system. This method iteratively adds a component to the stage which has maximum stage unreliability. The procedure continues until either a constraint is satisfied as equality or a constraint is violated. It can be easily shown that this procedure can be used for any type of redundancy in a system.

Kalyan and Kumar [37] have proposed a heuristic based on the reliability importance of a component and showed that it provides a good and quick approximation of the implicit enumeration method. Reliability importance ($\delta h / \delta p_i$) of a component i is defined as the rate of change of the system reliability h due to a change in component reliability p_i. The heuristic allocates the redundancy with the objective of maximizing Δh.

In another study, Shi [94] proposed a heuristic based on minimal paths to yield the solution in relatively less computing time. As an improvement over previous methods, Kohda and Inoue [40] proposed a criterion of local optimality. They showed that their method generates solutions which are optimal in a 2-neighborhood, while the solutions obtained by the previous methods are optimal only in a 1-neighborhood. The Kohda and Inoue algorithm [40] performs a series of selection and exchange operations within the feasible region to obtain the improved feasible solution. While solving constrained redundancy optimization problems in complex systems, there is a risk of being trapped at a local optimum.

Kim and Yum [39] have proposed a heuristic that allows excursions over a bounded infeasible region to alleviate this risk. It is shown that in terms of solution quality, the performance of the proposed method is better than those of Shi [94] and Kohda and Inoue [40].

A heuristic algorithm for solving the optimal redundancy allocation problem for multi-state series-parallel system (MSSPS) with the objective of minimizing total system design cost has been proposed by Ramirez-Marquez and Coit [81]. The heuristic works in three steps. First, an initial feasible solution is constructed, followed by application of a methodology to improve this solution. Finally, from the best solution found, a specified number of new solutions that have both higher cost and reliability are investigated in branches to explore additional feasible regions in an attempt to lead to a better solution. These are now treated as initial solutions and the improvement methodology is reapplied.

The improvement and branching phases of this heuristic provides flexibility of choosing a number of different design alternatives, which although not optimal, are not dominated by other design solutions. Ha and Kuo [32] have presented a tree heuristic for solving the general redundancy allocation based on a divide-and-conquer algorithm which imitates the shape of a living tree. A main solution path is repeatedly divided into several sub-branches if some criterion is satisfied; otherwise, the main solution path expands without any sub-branches.

The branching criterion is the ratio of sensitivity factor gap to the maximum sensitivity factor at the current stage. The final solution is obtained by selecting the best local solution. The proposed tree heuristic outperforms some other heuristics in terms of solution quality and computation time. Xu *et al.* [103], developed a heuristic for the reliability-redundancy allocation problem, called the XKL (Xu, Kuo, Lin) method. The XKL iteratively improves the system reliability by updating redundancy allocation in the following two ways:

1. By adding redundancy to the component which has the largest value sensitivity factor;
2. By adding redundancy to the component which has the largest value of sensitivity factor and by reducing redundancy in the component which has the smallest sensitivity factor.

The solution is obtained by subsequently solving an NLP problem with the updated redundancy allocation. If there is no reliability improvement with all combination pairs of the components, the algorithm stops.

Another heuristic that uses sensitivity factors is the HKRRA (Ha Kuo Reliability-Redundancy Algorithm) heuristic. This heuristic, proposed by Ha and Kuo [31] is a multi-path iterative heuristic for reliability-redundancy allocation problems. To compute the sensitivity factors for all the variables simultaneously, a new scaling method is employed. The heuristic is compared with the XKL method through a series of experiments. The experimental results show that the HKRRA heuristic is superior to the XKL heuristic as well as other heuristics in terms of solution quality and computational time. Beraha and Misra [8] have presented a random search algorithm to solve reliability allocation problems. An initial point is chosen where all sub-stages have the same reliability and the search begins about this point. By successively improving the mean, the search ends when a desired standard deviation is obtained within the feasible region (satisfying all the constraint equations). For solving a redundancy allocation problem, Ramachandran and Sankaranarayanan [83] proposed a random search algorithm that looks at a random multisample of feasible solutions and takes the best one.

A heuristic approach based on the Hopefield model of neural networks has been used by Nourelfath and Nahas [75] to solve a redundancy allocation problem with multiple choice, budget and weight constraints incorporated. Allella *et al.* [2] have again used the well known Lagrange multipliers technique to solve the reliability allocation problem. Data uncertainty due to the scarce knowledge of component reliabilities is also taken into account by considering component reliabilities as random variables.

32.4.4 Metaheuristics

Metaheuristics such as genetic algorithms (GA), simulated annealing (SA), tabu search (TS), immune algorithms (IA), and the ant colony (AC) have been used by many researchers for reliability optimization problems. These are based on probabilistic and artificial reasoning. Genetic algorithms (GA), one of the metaheuristics techniques, seek to imitate the biological phenomenon of evolutionary production through a parent-children relationship and can be understood as the intelligent exploitation of random search. Coit and Smith [16] have solved a redundancy optimization problem by applying GA to a series-parallel system with mix of components in which each subsystem is a *k*-out-of-*n*:G system. Painton and Campbell [79] presented a GA approach to the reliability-redundancy allocation problem where the objective is to maximize the fifth percentile of the mean time-between-failures distribution. The approach is shown to be robust in spite of statistical noise and many local maxima in the space of solutions induced by statistical variations due to input failure-rate uncertainties.

Coit and Smith [18] used a GA based approach to solve the redundancy allocation problem for series-parallel systems, where the objective is to maximize a lower percentile of the system time to failure distribution. The problems for the multi-level redundancy allocation in series-parallel systems have also been solved using GA [108, 109].

Simulated annealing (SA) is an approach to seek the global optimal solution that attempts to avoid entrapment in poor local optima by allowing an occasional uphill move to inferior solutions. Ravi *et al.* [84], used this approach to solve the redundancy allocation problem subjected to multiple constraints. Recently, Kim *et al.* [38], applied it to seek the optimal solution for reliability-redundancy allocation problems with nonlinear resource constraints. Numerical experiments were conducted and compared with previous studies for the series system, series-parallel systems, and the complex systems. The results suggest that the best solution for the SA algorithm is better then most of the previous best solutions.

Hansen and Lih [34] and Kulturel-Konak *et al.* [41], have used the Tabu Search (TS) metaheuristic to solve the redundancy optimization problem. TS searches the solution in the direction of steepest ascent until a local optimum is found and then the algorithm takes a step in the direction of mildest descent, while forbidding the reverse move for a given number of iterations to avoid cycling. The procedure is then iterated until no improved solution is found in a given number of steps.

The redundancy allocation problems have also been solved by the ant system metaheuristic which is inspired by the behavior of real ants. A moving ant lays some pheromone on the ground, thus making a path by a pheromone trail. If an isolated ant moves randomly, it will detect a previously laid trail and decide where to go. The trail with more pheromone has a higher probability to be chosen by the following ants [46]. Liang and Smith [47] used this metaheuristic for solving the redundancy allocation problem with a mix of components for a series-parallel structure. A problem specific ant-system for a series-parallel redundancy allocation problem has been developed by Liang and Smith [46]. Unlike the original ant system, the author introduced an elitist strategy and mutation to the algorithm. The elitist strategy enhances the magnitude of trails of good selections of components. The mutated ants can help explore new search areas.

A penalty guided immune algorithm (IA) for solving various reliability redundancy allocation problems, which includes series system, series-parallel system, and complex (bridge) system, has been presented by Chen [13]. Unlike the traditional GA based approaches, IA based approach preserves diversity in the memory so that it is able to discover the optima over time. The author has showed that the proposed method achieves the global optimal solution or a near-global solution for each example problem tested.

Recently, Liang and Chen [48] used a Variable Neighborhood Search (VNS) type algorithm as a metaheuristic to solve the series-parallel redundancy allocation problem with a mix of components. This metaheuristic employs a set of neighborhood search methods to find the local optimum in each neighborhood iteratively and hopefully reaches the global optimum at the end. The author is reported to have tested 33 test problems ranging from less to severely constrained conditions and showed that the variable neighborhood search method provides a competitive solution quality in comparison with the best-known metaheuristics like ant colony optimization [47] , genetic algorithm [17], *etc*.

32.4.4 Hybrid Heuristics

In another development in the field of reliability optimization, different heuristics and/or metaheuristics have been combined to give hybrid heuristics. One such approach is the hybrid intelligent algorithm that combines GA and artificial neural networks for solving reliability optimization problems. Zhao and Song [111] and Zhao and Liu [112] have used this approach to solve the fuzzy chance-constrained programming model for standby redundancy. The algorithm uses fuzzy simulation to generate a training data set for a back-propagation neural network to approximate the uncertainty function and GA to optimize the system performance. In a study that utilizes stochastic simulation, neural networks and GA, a stochastic programming model for general redundancy-optimization problem for both parallel and standby redundancy has been proposed by Zhao and Liu [110]. The model is constructed to maximize the mean system-lifetime, α-system lifetime, or system reliability and solve through a

hybrid intelligent algorithm. Stochastic simulation, neural networks and GA are integrated to produce a hybrid intelligent algorithm for solving these models. Stochastic simulation is used to generate training data, and then a back-propagation algorithm is used to train a neural network to approximate the system performance. Finally, the trained neural network is embedded into a genetic algorithm to form a hybrid intelligent algorithm.

In a similar work, Coit and Smith [15] present a combined neural network and genetic algorithm (GA) approach for the redundancy allocation problem for series-parallel systems. You and Chen [106] used GA with greedy method for solving a series-parallel redundancy allocation problem with separable constraints.

For highly constrained problems, infeasible solutions may make a relatively big portion of the population of solutions, and in such cases feasible solutions may be difficult to find. Dynamic adaptive penalty functions have been used with genetic searches to solve such problems, and the effectiveness of the dynamic adaptive penalty approach is demonstrated on complex system structures with linear as well nonlinear constraints [1].

Meziane *et al.* [50], used a universal moment generating function and an ant colony algorithm for finding the optimal series-parallel multi-state power system configurations. The ant colony algorithm is combined with a degraded ceiling local search technique to give a hybrid algorithm to solve the redundancy allocation problem for series-parallel systems [72].

32.4.5 Multi-objective Optimization Techniques

Toshiyuki *et al.* [100], have considered a multi-objective reliability allocation problem for a series system with time dependant reliability allocation and preventive maintenance schedule. Sakawa [87, 88] formulated the multi-objective reliability optimization problem not only for parallel redundant systems, but also for standby redundant systems, which is solved by using the surrogate worth trade-off (SWT) and sequential proxy optimization Technique (SPOT). In one more article on the multi-objective optimization method, Sakawa [89] dealt with the problem of determining optimal levels of component reliabilities and redundancies in a large-scale system with respect to multiple objectives. The author considered following objectives:

1. Maximization of system reliability,
2. Minimization of cost, weight, and volume.

This approach derives Pareto optimal solutions by optimizing composite objective functions, which are obtained by combining these objective functions. The Lagrangian function for each composite problem is decomposed into parts and optimized by applying both the dual decomposition method and the surrogate worth trade-off method.

Misra and Sharma [67] have used the MIP algorithm and a multicriteria optimization method based on the min-max concept for obtaining Pareto optimal solutions of redundancy allocation problems in reliability systems. Another similar approach used to solve multi-objective reliability-redundancy allocation problems with mixed redundancies has been proposed by Misra and Sharma [68].

Dingra [20] and Rao and Dingra [82] used goal programming formulation and the goal attainment method to generate Pareto optimal solutions. A heuristic method based on steepest ascent is used to solve goal programming and the goal attainment model. A generalization of the problem in the presence of vague and imprecise information is also addressed using the techniques of fuzzy multiobjective optimization. The multiobjective ant colony system (ACS) meta-heuristic has been developed to provide solutions for the reliability optimization problem of series-parallel systems with multiple component choices [115]. Tian and Zuo [97] and Salazar *et al.* [90], have used a genetic algorithm to solve the nonlinear multi-objective reliability optimization problems.

32.5 Optimal Design for Repairable Systems

As already mentioned in [61], availability could be the better performance measure for repairable systems than reliability. Since in most of the

practical situations, the systems are repairable, the availability and/or reliability may be optimized for such systems to achieve their performance goal. Numbers of approaches have been proposed for the optimal design of a repairable system. Mohamed [70] presented a brief review of optimization models for systems that consist of repairable components. Besides [61], Sharma and Misra [92] have proposed a formulation for an optimization problem involving three sets of decision variables, *viz*. redundancy, spares and number of repair facilities, simultaneously. Here again, MIP was shown to be most effective method to solve the problem. In the following section a brief discussion of some of the current approaches for repairable systems is presented.

Gurov *et al.* [30] solved the reliability optimization problem for repairable systems using the dynamic programming method and found the allocation of redundant units and repairmen. The computational experiments showed that this approach is accurate in results.

Dinesh and Knezevic [21] presented three models for spares optimization. The objective is to maximize the availability (or minimize the space) subject to space constraint (or availability constraint). The main advantage of the models presented in this paper is that these models can be solved efficiently by using general purpose algorithms such as SOLVER of EXCEL. The paper in fact presents an efficient branch and bound procedure to solve the optimization problem.

For a repairable system, the cost associated with downtime can be lowered by reducing the unavailability of the system. System unavailability can be reduced by adding additional spares for each subsystem, but the cost of the system increases due to the added operational and maintenance costs. Thus, it is desirable to derive a cost-effective solution that strikes a balance between the system downtime costs and the maintenance costs of providing spares for the system. Amari *et al.* [3], have formulated the problem of finding the optimal number of spares in each subsystem that minimizes the overall cost associated with the system as shown in formulation 12, and the authors proposed a simple search algorithm to solve the problem. The main contribution of their work is in reducing the search space by providing the bounds for optimal spares for each subsystem.

Yu *et al.* [107], used probability analysis, and formulated the system design problem as minimizing the system cost rate subject to an availability constraint to find mean time to failure of the components and the policy time of good-as-new maintenances. Then, a resolution procedure is developed to solve this problem.

Nourelfath and Ait-Kadi [76] extended the classical redundancy allocation problem for a repairable system to find, under reliability constraints, the optimal configuration and maintenance costs of a series-parallel system for which the number of maintenance teams is less than the number of repairable components. The problem is presented in formulation 11 in this chapter, and the authors suggest a heuristic method based on a combination of the universal generating function method and the Markov model to solve this optimization problem.

Ouzineb *et al.* [78], proposed a Tabu Search (TS) metaheuristic approach to solve the redundancy allocation problem for multi-state series-parallel repairable systems. The proposed method determines the minimal cost system configuration under specified availability constraints.

32.6 Conclusion

Reliability Design of a system is one of the most studied topics in the literature. The present chapter presents the developments that have taken place in this field since 1960. During these past four decades, researchers have presented various reliability design problems depending on the kind of system structure, objective functions and constraints and have provided various problem formulations and solution techniques.

The kinds of the problems studied in the literature are mainly based on: type of decision variables (reliability allocation and/or redundancy allocation), kind of redundancy (active, stand-by, *etc*.), type of the system (binary or multi-state

system), levels of the redundancy (multi-level system) and choice of the components (multiple component choice). While the redundancy allocation problem is the most studied reliability optimization problem, the reliability-redundancy allocation problem is gaining greater attention from researchers. Standby redundancy, multi-state systems, and multi-level redundancy are some of the areas having practical applications and provide good scope for further research in this area. Further, the problems of repairable system design have also been studied in literature. Availability is generally used as a measure of performance of such systems. Spare parts allocation, failure and repair rate allocation problem are very common availability/ reliability optimization problems for such systems.

Optimal reliability design problems are usually formulated to maximize system reliability under resource constraints like cost, weight, volume, *etc*. Multi-objective programming approaches have been used where multiple criteria are considered simultaneously. Other performance measures like percentile life have been proposed as a measure of system performance in the absence of specified mission time. More investigation in this direction is needed, as this would provide a new dimension to system reliability design problems.

While exact solution techniques are available to solve reliability optimization problems, heuristic and metaheuristics techniques are gaining popularity due to the ease of computational effort. Especially, metaheuristics techniques like Genetic Algorithm (GA), Simulated Annealing (SA), Tabu Search (TS) and Ant Colony (AC) provide reasonably good quality solutions in comparatively less computational times. The effectiveness and efficiency offered by these methods provide good motivation for researchers. The future trend appears to be in the direction of application of hybrid optimization techniques that would combine either two metaheuristics or a heuristic with any of the metaheuristics for reliability optimization.

Further, the reliability design problem is generally seen as an independent exercise from quality, maintainability, safety and sustainability considerations. In case of repairable systems with a long life cycle, maintenance costs may be a critical component of its life cycle costs, so all the maintenance and maintainability issues like reliability, maintainability design, maintenance policies, *etc*., must be fully explored at the design stage only. Also, every stage of product life-cycle, be it extraction of material, manufacturing, use or disposal, energy and materials are required as inputs, and emissions (gaseous, solid effluents or residues) are always associated which influence the environmental health of our planet. Therefore, these environmental factors must also be considered while designing a system. Unless we consider all these factors in an integrated way, we cannot call the design of products, systems and services truly optimal from an engineering point of view.

Thus the system design process must be considered from a whole life-cycle point of view by extending the reliability design by integrating it with the other constituent criteria of performability to give a true optimal design process which may eventually be called design for performability.

MIP: A Versatile Tool for Reliability Design of a System

S.K. Chaturvedi[1] and K.B. Misra[2]

[1]Reliability Engineering Centre, IIT Kharagpur, Kharagpur (WB) India
[2] RAMS Consultants, Jaipur

Abstract: In many reliability design problems, the decision variables can only take integer values. There are many examples such as redundancy allocation, spare parts allocation, repairman allocation that necessitate integer programming formulations and solutions thereof. In other words, the integer programming plays an important role in system reliability optimization. In this chapter, a simple yet powerful algorithm is described, which provides an exact solution to any general class of integer programming formulations and thereby offers reliability designers an efficient tool for system design. The algorithm is presented with an illustration to make the readers understand various steps. Besides, the applications of the algorithm to various reliability design problems are also provided.

33.1 Introduction

Advances in technology have always led system engineers, manufacturers and designers to design and manufacture systems with ever increasing sophistication, complexity, and capacity. Unreliable performance of some of the constituent sub-systems in these systems may lead to disastrous consequences for the system and its environment and loss of lives including economic, legal and sociological implications. Therefore it necessarily requires designers to design systems with the highest possible reliability within the constraints of cost, time, space, volume, technological limits *etc*. As a result, reliability is one of the system attributes that cannot be compromised in system planning, design, development and operation. It is of paramount concern to practicing engineers, manufacturers, economists and administrators. However, it is an established fact that the occurrence of failure can not be completely eliminated even for well-designed, well-engineered, thoroughly tested and properly maintained equipment. As a consequence, a present day user is not prepared to compromise on reliability, yet would like to have its best value for resources consumed in designing a system. Reliability and maintainability design is one of the areas in reliability engineering which makes possible more effective use of resources and helps decrease the wastage of scarce finances, material, and manpower.

An optimal design is one in which all the possible means available to a designer have been explored to enhance the reliability of the system under certain objective(s), operational requirements and allocated resources. Some of the

means through which a designer might attempt to enhance system reliability are:

- Reducing the system complexity.
- Increasing the reliability of constituent components through some product improvement program.
- Use of structural redundancy.
- Putting in practice a planned maintenance and repair/replacement policy.

Although each of the aforementioned alternatives has its relative advantages and disadvantages, one may have to strike a balance between them to achieve a system's objectives.

The employment of structural redundancy at subsystem/component level, without disturbing the system topology, can provide a very effective means of improving system reliability to any desired level [1]. In fact, structural redundancy in combination with an appropriate maintenance strategy may lead to provide almost unity reliability. The structural redundancy involves the use of two or more identical components, to ensure that if one fails, the system operation does not get affected and continues to carry on the specified task even in presence of a faulty component. Depending on the type of system, various forms of redundancy schemes, *viz.,* active, standby, partial, voting, *etc*., are available, and this may provide the quickest, easiest, cheapest and sometimes the only solution. However, the only factors, which may influence such a decision, could be the time constraints, existence of an already designed component, a costly and prohibitive redesign, and of course the technological limits.

There are several kinds of reliability design problems a designer may face. For example, it may include reliability allocation, repairman allocation, failure/repair rate allocation, spare parts allocation problem, *etc.*, or a combination of these problems. Depending on the situation, appropriate techniques can be adopted.

The present chapter describes an exact and efficient search technique, known as *Misra Integer Programming* (MIP) in the literature to address many system design problems. Although the algorithm was originally conceived to deal with the redundancy allocation problem, it can solve not only several other problems in system reliability design but many other general integer programming problems with equal ease [12].

Before providing the details of the search algorithm and its applications, the next section presents a brief overview of the redundancy allocation problem and the necessity and importance of developing a useful yet very simple algorithm to solve many design problems.

33.2 Redundancy Allocation Problem

33.2.1 An Overview

The problem of redundancy allocation is concerned with the determination of the number of redundant units to be allocated to each subsystem to achieve an optimized objective function (usually the reliability or some other related attribute of the system, *e.g.*, average life, MTTF), subject to one or more constraints reflecting the availability of various resources. Mathematically, the problem can be stated as:

$$Max.\ R_s = f[R_1(x_1), R_2(x_2)...R_n(x_n)], \quad (33.1)$$

$$Sub.\ \text{to}\ g_i(x) = g(x_1, x_2...x_n) \le b_i, i = 1, 2...m, \quad (33.2)$$

where reliability R_s (of n sub-systems with x_j redundant units at the j^{th} subsystem, each with a component reliability of r_j) will be a function of its subcomponents' reliabilities, $R_j(x_j)$. The functional form of $f(\cdot)$ depends on the system configuration and the type of redundancy being used. The form of m number of constraints, $g_i(x)$ (linear/nonlinear, separable/non-separable) can usually be determined from physical system considerations. However, if the constraints are separable functions, we can write (33.2) as:

$$g_i(x) = \sum_{j=n}^{n} g_{ij}(x_j) \le b_i, i = 1, 2...m. \quad (33.3)$$

The decision variables x_j, in the above formulations can take only non-negative integer values; therefore, the problem belongs to the class of non-linear integer programming problems, and

expression R_s, in general, may not be separable in x_j. Also, the nonlinear constraints may not necessarily be separable. However, an active-parallel redundant system in a series model consisting of n subsystems with linear constraints can be written in a closed form [10, 13].

In general, a redundancy allocation problem involving integer programming formulation can be stated as:

$$Optimize\ f(x), \tag{33.4}$$

$$Sub.\ to\ \ g_i(x) \le b_i; i = 1,2...m. \tag{33.5}$$

The function *f(x)* in (33.4) can be minimized or maximized and could be set to $f(x^*) = \pm\infty$, in general, ("+" for minimization and "–" for maximization) to start the search process. The variable $x = (x_1, x_2, ...x_n)$ is a vector of decision variables in E^n (the n-dimensional Euclidian plane), which is allowed to take positive integer values belonging to the feasible region $\mathcal{R}$ only and bounded by (33.5). Further, some x_i can also assume a value equal to zero. However, most often all x_i, being non-negative integers, are defined between the limits: $x_j^l \le x_j \le x_j^u$. In a redundancy optimization problem, x_i would have positive integer values between $1 \le x_j \le x_j^u$.

The value of x_k^u for the kth subsystem can easily be determined through the consideration of the ith constraint and accepting a minimum of the upper limits computed over all i=1,2...m, while maintaining $x_j^l = 1, \forall j = 1,2...n, j \ne k$ for other subsystems, *i.e.,*

$$x_k^u = \min_i \{x_j^{\max}\}, \forall k = 1,2...n, i = 1,2...m, k \ne j. \tag{33.6}$$

Therefore, the search to optimize, $f(x^*)$ could begin at one of the corners of feasible region, *i.e.*, $\left(x_1^u, x_2^l ... x_n^l\right)$ of $\mathcal{R}$ and finish at another point $\left(x_1^l, x_2^l ... x_n^u\right)$. Both of these points are certainly in the feasible region.

Therefore, the MIP basically relies on a systematic search near the boundary of constraints and involves functional evaluations on feasible points satisfying a specified criterion that a feasible point x would lie within the constraints and the current test point is close to the boundary from within the feasible region. However, the stopping criteria can be chosen depending upon the problem and objective of analysis. One of the ways of choosing the stopping criterion could be a test for maximum permissible slacks defined as:

$$mps_i = \min_j \{c_{ij}\} - \varepsilon.$$

To initiate the search, we frequently require the computation of $x_1^{\max}$, and in case of linear constraints $x_1^{\max}$ could be computed as:

$$x_1^{\max} = \min \left\{ x_1 : x_1 = \frac{b_i - \sum_j g_i(x_j; j = 2,3...n)}{\cos t\ coefficients\ of\ i^{th}\ type\ constra\text{int}s\ corrresponding\ to\ x_1} \right\}, \tag{33.7}$$

where $g_i(\cdot)$ and b_i are the constraint functions of variables and resources available for an ith type of constraint, respectively.

In case of non-linear constraints, $x_1^{\max}$ can be obtained by incrementing x_1, successively, by one unit at a time until at least one of the constraints gets violated, while keeping x_j at a minimum level at all other stages. It would be computationally advantageous if we compute and store the nonlinear incremental costs for the whole range of x_1 in memory rather than evaluate it every time $x_1^{\max}$ is desired.

33.2.2 Redundancy Allocation Techniques: A Comparative Study

Among the well known methods to provide an exact solution are: (i) Dynamic Programming approach, and (ii) Search Technique, *e.g.,* Cutting plane, Branch and Bound, Implicit search, and

partial enumerations using functional evaluations and certain rules for detecting an optimal solution from as few feasible solutions as possible.

Besides the exact techniques, several approximate and earlier methods such as Lagrange Multiplier [1, 8], Geometrical programming and the maximum principle approach [8], Differential dynamic programming sequential simplex search, penalty function approaches, *etc*., have also been employed by treating the integer decision variables as real variables and the final solution is obtained by rounding off the optimal variables to the nearest integers. In view of the fact that a decision problem involving integer variables is NP-complete, a number of heuristic procedures for solving design problems have also been proposed. Some evolutionary techniques inspired by some natural phenomenon such as biological (GA) or functioning of brain (ANN) have also been applied to deal with reliability design problems. Such techniques are known as meta-heuristic algorithms in the literature. The interested reader may refer to [6] for a comprehensive survey and a good account of various reliability design problems, their types and classifications, solution approaches along with the applications of some meta-heuristic techniques (such as GA and ANN).

Summarily, most of the exact integer programming techniques mentioned above, except those which are strictly based on some heuristic criteria, are computationally tedious, time-consuming and sometimes unwieldy, and have limitations of one kind or the other. The other simple techniques are mostly heuristic and thus approximate.

However, the approach described later in this chapter can solve a variety of general integer programming problems also, is simple to comprehend, is amenable to computerization, and easy to formulate. The advantages of the approach over the existing techniques are briefly given as under:

1. It does not require the conversion of variables into binary variables as in [5, 7].
2. It is applicable to a very wide variety of problems, with arbitrary nature of objective and constraint functions and without any assumption on the separability of objective functions. However, the functions involved must be non-decreasing functions of decisions variables.
3. It can solve both integer programming as well as zero-one programming problems with ease and effectiveness.
4. As stated earlier, the present approach to solve redundancy allocation problem is a systematic search near the boundary of feasible reason, so it drastically reduces the number of search points.

33.3 Algorithmic Steps to Solve Redundancy Allocation Problem

The entire algorithm can be summarized in following eight steps [9]:

1. Compute the upper and lower bounds of the decision variables to determine the entire feasible region. Lower bounds are generally known from the system description whereas upper bounds are determined from constraints (see (33.6)). Set $t = 2$ and $\nu = 0$, $x \equiv \left(x_1^u, x_2^l \ldots x_n^l\right)$ and $x^* = x$. If this point is within the slack band $\langle b_i - mps_i, b_i \rangle, \forall i = 1, 2 \ldots m$, go to step 8.
2. Set $x_2 = x_2 + 1$. If $x_2 \le x_2^u$, go to next step. Otherwise go to step 4.
3. Keeping all other variables, x_j, $j = 2, 3 \ldots n$ at the current level, determine the value of $x_1^{\max}$ which does not violate any of the constraints (refer to (1.8) and subsequent paragraph). If $x_1^{\max} = 0$, go to next step. Otherwise go to step 7.
4. $\nu = \nu + 1$. if $\nu > (n\text{-}2)$, STOP and print the optimal result. Otherwise proceed to step 5.
5. Set $k = t + \nu$ and $x_k = x_k + 1$. If $x_k > x_k^u$, return to step 4. Otherwise proceed to step 6.

6. Set $x_j = x_j^l$ for $j = 2,3...k-1$. Also, set v=0. Return to step 3.
7. Calculate slacks for constraints, $s_i, \forall i = 1,2...m$. If the current point lies within the allowable slacks for all *i*, go to next step. Otherwise return to step 2.
8. Evaluate the objective function *f(x)* at the current point *x*. If it is better than $f(x^*)$, then replace $x^* = x$ and $f(x^*) = f(x)$. Return and continue from step 2.

The algorithmic steps are simple and self explanatory. However, for the reader's benefit some of the steps of algorithm are explained in the following illustration.

Illustration:
Consider a SP system with four subsystems, two linear constraints and with subsystem reliabilities as, $r = [0.85\ 0.80\ 0.70\ 0.75]$, respectively.
Mathematically, we can formulate it as:

$$\textit{Maximize} \qquad R_s = \prod_{j=1}^{4} (1-(1-r_j)^{x_j}),$$

Sub. to

$$6.2x_1 + 3.8x_2 + 6.5x_3 + 5.3x_4 \le 51.8$$
$$9.5x_1 + 5.5x_2 + 3.8x_3 + 4x_4 \le 67.8.$$

Let us determine the upper and lower bounds (step 1) of the variables involved using (33.6) and the search area bounded by its constraints.

By keeping $x_k = 1, \forall j = 1,2,3,4, k \ne j$, the upper bound of a variable, say x_1, can be determined from constraints as:

$$6.2x_1 + 3.8 + 6.5 + 5.3 \le 51.8 \Rightarrow x_1 \le 5.8387$$
$$9.5x_1 + 5.5 + 3.8 + 4 \le 67.8 \Rightarrow x_1 \le 5.7368,$$

i.e., $x_1^u = \min(5.8387, 5.7368) \cong 5$.

Similarly, $x_2^u = 8, x_3^u = 5, x_4^u = 6$, respectively. Therefore, the starting point in the search would be $x = [5111]$, and will finish once we reach $x = [1116]$.

After following the steps of the algorithm with minimum cost difference of 3.7 units, the optimum system reliability, $R^* = 0.8559967$ is obtained for $x^* = [2232]$. Although the total number of search points in the region is 1200, the functional evaluations performed by the algorithm were only done at 43 points, whereas the number of functional value comparisons to obtain maximum reliability was only 5.

The above steps are the essence of the algorithm, and other variables shown in the algorithmic steps are just to make the translation of the algorithm in a suitable programming language easy.

33.4 Applications of MIP to Various System Design Problems

Here we provide an exhaustive list of applications areas and problem formulations, where the MIP has been successfully applied. The areas are as follows:

33.4.1 Reliability Maximization Through Active Redundancy

33.4.1.1 SP System with Linear and/or Nonlinear Constraints

The series parallel (SP) model is one of the simplest and most widely used models in reliability studies. Mathematically, the problem for such systems could be formulated as:

$$\textit{Maximize } R_s = \prod_{j=1}^{n} (1-(1-r_j)^{x_j}), \tag{33.8}$$

$$\textit{Sub. to: } g_i(x_j) = \sum_{j=1}^{n} c_{ij} x_j \le b_i, i = 1,2...m, \tag{33.9}$$

where the constraints could either be linear, nonlinear or a combination of both (linear and nonlinear).

Example 1: The illustration taken belongs to this category, where the constraints are linear. The optimal solution point provided by the algorithm is $x^* = [2232]$, with optimal system reliability $R_s^* = 0.85599$, with resource consumptions as 50.1 and 49.9, respectively.

Example 2: Consider a SP System with five subsystems, three nonlinear constraints with subsystem reliabilities $r = [0.80\ 0.85\ 0.90\ 0.65\ 0.75]$, respectively. The problem is to

$$\text{Maximize } R_s = \prod_{j=1}^{5} (1-(1-r_j)^{x_j}),$$

Subject to:

$$x_1^2 + 2x_2^2 + 3x_3^2 + 4x_4^2 + 5x_5^2 \le 60,$$
$$7(x_1 + e^{-x_1/4}) + 7(x_2 + e^{-x_2/4}) + 5(x_3 + e^{-x_3/4}) + 9(x_4 + e^{-x_4/4}) + 4(x_5 + e^{-x_5/4}) \le 225,$$

and

$$7x_1 e^{x_1/4} + 8x_1 e^{x_1/4} + 8x_1 e^{x_1/4} + 6x_1 e^{x_1/4} + 9x_1 e^{x_1/4} \le 340.$$

The optimal solution point provided by the algorithm is $x^* = [22223]$ with an optimal value of system reliability of $R_s^* = 0.80247$, and resources consumed of 58, 122.63 and 152.78, units, respectively.

33.4.1.2 NSP System with Linear and/or Nonlinear Constraints

The general formulation of the problem for such systems is:

$$\text{Maximize } R_s = f(x, r) \quad (33.10)$$
$$\text{Sub. to } g_i(x) \le b_i,\ i = 1, 2...m, \quad (33.11)$$

where $f(x, r)$ is the reliability function of the NSP system.

Example 3: Consider a NSP system with five nodes and seven links as shown in Figure 33.1.

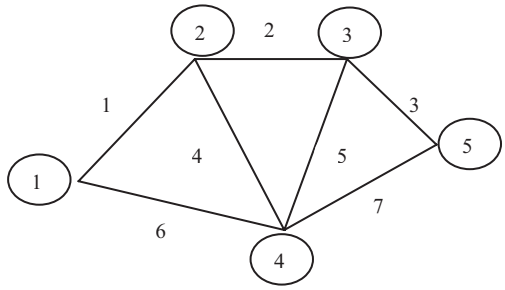

Figure 33.1. A five-node, seven-link NSP system

The objective is to maximize the reliability of the network with the following linear cost constraint:

$$4x_1 + 5x_3 + 2x_4 + 3x_5 + 3x_6 + 5x_7 \le 45,$$

given the component reliabilities as $r = [0.7, 0.9, 0.8, 0.65, 0.7, 0.85, 0.85]$. The optimal reliability of the network computed by the algorithm is $R_s^* = 0.99951$ at $x^* = [1121143]$ with no slacks. Also, out of a total of 11,61,600 search points, it carries out functional evaluations only at 815 points.

Example 4: Consider the bridge network shown in Figure 33.2 with the following three nonlinear constraints:

$$x_1^2 + 2x_2^2 + 3x_3^2 + 4x_4^2 + 5x_5^2 \le 110,$$
$$7(x_1 + e^{-\frac{x_1}{4}}) + 7(x_2 + e^{-\frac{x_2}{4}}) + 5(x_3 + e^{-\frac{x_3}{4}}) + 9(x_4 + e^{-\frac{x_4}{4}}) + 5(x_5 + e^{-\frac{x_5}{4}}) \le 175,$$

and

$$7x_1 e\frac{x_1}{4} + 8x_2 e\frac{x_2}{4} + 8x_3 e\frac{x_3}{4} + 6x_4 e\frac{x_4}{4} + 9x_5 e\frac{x_5}{4} \le 200.$$

The optimal allocation for maximizing the reliability of the bridge network is computed to be $x^* = [32343]$, with $R_s^* = 0.99951$, with resource consumption $g_1 = 110, g_2 = 156.55, g_3 = 198.44$,

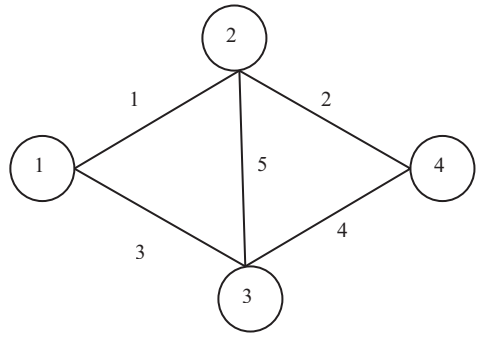

Figure 33.2. A bridge network

respectively. The total number of points visited by the algorithm was 3125, whereas the functional evaluations were at 173 points only.

33.4.2 System with Multiple Choices and Mixed Redundancies

In many engineering applications, it may be possible that the system might need the support of a mixture of available redundancy types (active-parallel, *k*-out-of-*m*, standby, partial, *etc*.) at various subsystems levels. The following example illustrates a typical problem type and its formulation.

Example 5: Consider a three stage series system. The system reliability can be increased by choosing a more reliable component out of four available candidates at stage one. The second stage needs active parallel redundancy whereas the third stage requires a 2-out-of-3:G configuration. The objective is to maximize system reliability with three nonlinear constraints. The formulation of the above problem is as follows.

The objective of the problem can be formulated as:

$$\textit{Maximize } R_s = \prod_{j=1}^{n} R_j(x_j), \tag{33.12}$$

where $R_j(x_j)$ is the *j*th subsystem reliability whose form would vary from subsystem to subsystem and therefore no closed form expression for R_s can be obtained. The constraints can either be linear or nonlinear of the type given by (33.11). For this case, we have four choices available for the components of reliability at the first stage, *i.e.*,

$$R_1 = \begin{bmatrix} 0.88 \\ 0.92 \\ 0.98 \\ 0.99 \end{bmatrix} \text{ (also called ultiple choice).}$$

At the second stage, there is an active redundant system with single component reliability equal to 0.81. Clearly, the subsystem reliability expression for this stage would be $R_2(x_2) = 1-(1-0.81)^{x_2}$, and third stage has a 2-out-of-*x*:G subsystem, with unit component reliability = 0.77, *i.e.,* the reliability expression for this stage is given by

$$R_3 = \sum_{2}^{x_3} \binom{x_3}{k} (0.77)(1-0.77)^{x_3-k}.$$

The constraints are:

$$4e^{\left\{\frac{0.02}{1-R_1(x_1)}\right\}} + 5x_2 + 2x_3 \le 45,$$

$$e^{\frac{x_1}{8}} + 3\left(x_2 + e^{\frac{x_2}{4}}\right) + 5(x_3 + e^{\left(\frac{x_3-1}{4}\right)}) \le 65,$$

and

$$8x_2 e^{\frac{x_2}{4}} + 6\left(x_3 - 1\right) e^{\frac{x_3-1}{4}} \le 230.$$

Clearly, the upper and lower bounds of stage one are 1 and 4, respectively, whereas for the others, the bounds would be decided by the constraints and can be computed by using (33.6) (see illustration for how to use the equation).

By following the algorithmic steps, the optimal solution is obtained at $x^* = [3,3,6]$ with $R^* = 0.9702399$. The resources consumed were $g = [37.87, 64.26, 155.52]$. The total search points were 144 with functional evaluations performed at 23 points only.

33.4.3 Parametric Optimization

In many cases, a decision maker would like to know the effects on the solution, if a certain change in constraints values are made. Besides, some constraints values may not be known with certainty (usually they are guessed at). In general, the problems of these types can be transformed into parametric nonlinear programming problems. Several formulations to such problems can be found in [2]. A general parametric programming formulation to reliability design for *n*-stage SP systems is:

$$\textit{Maximize } R_s = \prod \left(1-\left(1-r_j\right)^{x_j}\right), \tag{33.13}$$

$$\textit{subject to } \sum_{j=1}^{n} g\left(x_j\right) \le b \pm \theta u_i, i = 1,2...m, \tag{33.14}$$

where $0 = \theta_0 < \theta_1 ... < \theta_l = 1, \theta = \theta_0, \theta_1 ... \theta_l$, $x_j \ge 1$ and are integers, and θ, u_i are non-negative constants. The assumptions made in such formulations are:

1. Each stage is essential for overall operational success of the mission.
2. All components are mutually *s*-independent and in the same stage the probability of failure of components is the same.
3. All the components at each stage work simultaneously, and for the stage to fail, all components in that stage must fail.

We provide an illustration for the above formulation.

Example 6: Consider a series system having four stages and two constraints such that we wish to

$$\textit{Maximize } \begin{matrix} R_s = \left(1-\left(1-0.6\right)^{x_1}\right)\left(1-\left(1-0.9\right)^{x_2}\right) \\ \left(1-\left(1-0.55\right)^{x_3}\right)\left(1-\left(1-0.75\right)^{x_4}\right) \end{matrix},$$

subject to

$$\begin{matrix} 6.2x_1 + 3.8x_2 + 6.5x_3 + 5.3x_4 \le 51.8 + 10\theta \\ 9.5x_1 + 5.5x_2 + 3.8x_3 + 4.0x_4 \le 67.8 - 15\theta, \\ 0 \le \theta \le 1 \end{matrix}.$$

The optimal result was obtained at $\theta = \mathbf{0.37}$, by varying θ between zero to one inclusive, which were the same as obtained by [8]. The optimal allocation was $x^* = [2,2,3,3]$, with $R^* = 0.74401$, and consumed resources were $g = (55.4, 53.4)$.

The summary of optimal results of the numerical examples considered in above sections is shown in Table 33.1.

33.4.4 Optimal Design of Maintained Systems

33.4.4.1 Availability Maximization with Redundancy, Spares and Repair Facility

The availability is a more appropriate measure than reliability or maintainability for maintained systems. So the objective for such systems becomes to maximize availability subjected to multiple constraints (linear and/or nonlinear) taking into account the cost of redundancy, spares and repair facility. Therefore, the formulations to such problems are mostly concerned, directly or

Table 33.1. Summary of the optimal results

Ex. #	Results	Remark
1.	$x^* = [2232]$ $R_s^* = 0.80247$	SP system with two linear constraints
2.	$x^* = [22223]$ $R_s^* = 0.80247$	SP system with three nonlinear constraint
3.	$x^* = [1121143]$ $R_s^* = 0.99951$	NSP with a linear constraint.
4.	$x^* = [32343]$ $R_s^* = 0.99951$	NSP with three nonlinear constraints
5.	$x^* = [3,3,6]$ $R^* = 0.9702399$	Mixed redundant series system with three nonlinear constraints
6.	$x^* = [2,2,3,3]$ $R^* = 0.74401$	Parametric optimization, Series system, two linear constraints

indirectly, with either redundancy or spare parts or repairman allocations. Besides, since these three variables can only assume integer values, availability (a nonlinear function of these variables) optimization would necessitate a nonlinear integer programming formulation but increasing the actual number of variables to three times the number of subsystems as compared to the redundancy allocation problems discussed earlier.

The foregoing section has provided the versatility of the algorithm to deal with redundancy optimization problems related to non-maintained systems. However, it can be applied with equal ease to problems such as spares allocation, repairmen allocation, *etc.*, for maintained system and to multi-criteria optimization.

Let us consider a SP-system of n stages, and each stage not only has redundancy but also has a separate maintenance facility like spares and repair in terms of repair. The jth stage of such a system is shown in Figure. 33.3, where k_j, σ_j and ρ_j, are the minimum number of components (functional requirement), spares, and used repairmen provided for the jth subsystem, respectively. The problem statement of the system is as follows:

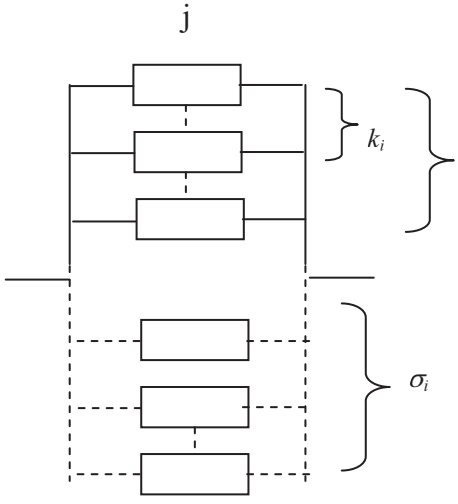

Figure 33.3. A General Subsystem Structure of a j^{th} Stage of a Maintained System

Maximize the availability of a series-parallel maintained system with redundancy, spares, and repair as decision variables, subject to linear constraints. Mathematically, the problem can be expressed as:

$$Maximize\ A_s^s = \prod_{j=1}^{n} A_j^s ,$$

where the steady-state subsystem availability is expressed as $A_i^s \equiv f(x_j, \sigma_j, \rho_j)$, assuming that all subsystems can be repaired independently. The formulation is subject to the constraints,

$$g_i \equiv \sum_{j=1}^{n} g_{ij}\left\{(x_j - k_j), \sigma_j, \rho_j\right\} \le b_i, i = 1, 2...m .$$

The details of various symbols, assumptions, mathematical formulation and solution of the above problem using the present algorithm have been provided in [15, 17].

33.4.5 Computer Communication Network Design with Linear/Nonlinear Constraints and Optimal Global Reliability/Availability

A CCN is defined as a collection of nodes, N, at which the computing resources reside, which communicate with each other via a set of data communicating channels (set of links), L. The main objective of such a CCN is to provide efficient communication among various computer centers in order to increase their utility and to make their services available to more users. One of the fundamental desiderata in designing such a system is that of global availability, *i.e.*, the probability that the network is at least simply connected (connectedness), which depends on the topological layout and the availability of individual computer systems and communication facilities.

Assuming link duplexity, a two state model (working or failed), and the presence/absence of a link in a network can be represented by a binary variable, taking a value either zero or one. The problem for such networks can be stated as [16]: determine an optimal CCN topology that gives maximum overall availability within the given

permissible cost. In other words, the objective is to find a set of links from a given set of links, which together constitute an optimal CCN topology within the budgetary constraints of C_s. Mathematically, the problem can be expressed as:

Maximize $A_s \equiv f(A_1, A_2 \ldots A_n) = f(x_1, x_2 \ldots x_n)$,

subject to:

$$\sum_{j=1}^{n} x_j (y_{j1} y_{j2} \ldots y_{jn}) = \{11 \ldots 1\}, \quad \text{with } \delta(x) \geq N-1 \tag{33.15}$$

$$\sum_{j=1}^{n} c_j x_j \leq c_s \,. \tag{33.16}$$

The form of A_s entirely depends on the network topology and is a minimized expression of global reliability/availability of the network, which can be obtained if the spanning trees of the network are known. In the above formulation, (33.15) signifies the continuity constraint, which ensures that the allocation of the decision variables provides a globally available network. The summation and product sign in the constraint represents binary sum and product, respectively. Note that here $x_j (y_{j1} y_{j2} \ldots y_{jn}) = (x_j y_{j1})(x_j y_{j2}) \ldots (x_j y_{jn})$, and $(y_{j1} y_{j2} \ldots y_{jn})$ is a string of binary variables corresponding to the *j*th link, *e.g.,* if L_j connects the *p*th and *q*th nodes, then $y_{jp}, y_{jq} = 1$, and $y_{jk} = 0 \forall k \neq p \neq q$, *e.g.,* if L_4 connects the second and fourth nodes in a five node network then $(y_{41} y_{42} y_{43} y_{44} y_{45}) = \{01010\}$. Variable x_j can be either one or zero and represents the presence/absence of the link in the network. The cost constraint (33.16) is self explanatory. The details of the above problem and application of the algorithm can be found in [17, 18].

33.4.6 Multicriteria Redundancy Optimization

In many situations, the reliability design problems of complex engineering systems may necessitate consideration of several non-commensurable criteria, which may be equally important. In order to offer alternatives to a system designer, it may be better to achieve some kind of balance among the several conflicting properties rather than to optimize just one property. This situation can be mathematically formulated as multicriteria optimization problem in which the designer's goal is to minimize or maximize not a single objective function but several functions simultaneously.

A multi-objective optimization problem, in general, can be stated as follows:

Find a vector $x^* = [x_1^*, x_2^* \ldots x_n^*]$, which satisfies m inequality constraints

$$g_i(x) \geq 0, i = 1, 2 \ldots m$$

and p equality constraints

$$h_u(x) = 0, u = 1, 2 \ldots p < n,$$

such that the vector function

$$f(x) = [f_1(x), f_2(x) \ldots f_k(x)]$$

gets optimized, where $x^* = [x_1^*, x_2^* \ldots x_n^*]$ is a vector of decision variables defined in the n-dimensional Euclidean space of variables E^n $f(x) = [f_1(x), f_2(x) \ldots f_k(x)]$ is a vector function defined in k-dimensional Euclidean space of objectives E^k, and $g_i(x)$, $h_u(x)$, and $f_l(x)$ are linear and/or nonlinear functions of variables $x_1^*, x_2^* \ldots x_n^*$. The constraints (equality and inequality) define the feasible region X and any point x in X defines a feasible solution.

In fact, the task involved in multi-criteria decision making is to find a vector of the decision variables which satisfies constraints and optimizes a vector function whose elements represent several objective functions. These functions form a mathematical description of the performance criteria, which are usually in conflict with each other. Therefore, the term "optimize" here would mean finding a solution which provides acceptable values for all the objective functions simultaneously.

The extension to MIP to such problems provides an efficient approach for solving multicriteria reliability design problems. This is accomplished in combination with the min-max approach for generating Pareto optimal solutions for multicriteria optimization. For detailed

discussions, examples and their solutions thereof, the interested reader can refer to [11].

33.5 Conclusions

The search approach presented in this chapter is quite versatile in dealing with problems involving integer programming formulations arising in reliability design. The approach can be easily programmed using any suitable language a user is familiar with. It does not require proving any conditions of convexity, concavity or differentiability of involved functions (objective and constraints) in the optimization process. It is simple, requiring only objective function evaluations for testing the feasibility of very few solution vectors in the search space bounded by the constraints and a comparison with the previous value of the evaluated function.

The major benefit that one can draw from such a search pattern is that for a given set of constraints, the search pattern is independent of the objective function involved. This allows a designer to change the objective function without changing the search pattern and one only need evaluate the objective function to arrive at a different optimal solution. This may be found useful in studying various configurations of constituent subsystems/ components for optimal reliability or any other measures of system performance.

The technique is not only an effective and efficient tool for problems involving single objective functions but is also suitable for problems involving multiple objective functions.

Reliability Demonstration in Product Validation Testing

Andre Kleyner

Delphi Corporation, USA

Abstract: This chapter presents an overview of reliability demonstration methods applied in the industry for product validation programs. Main emphasis is made on success run testing and test to failure approaches. It also presents a discussion on the underlying assumptions, complexities, and limitations of the reliability demonstration methods.

34.1 Introduction

Reliability testing is the cornerstone of a reliability engineering program. A properly designed series of tests, particularly during the product's earlier design stages, can generate data that would be useful in determining if the product meets the requirements to operate without failure during its mission life. Most of the product development programs require a series of environmental tests to be completed to demonstrate that the reliability requirements are met by the manufacturer and consequently demonstrated to the customer.

Reliability demonstration testing is usually performed at the stage where hardware (and software when applicable) is available for tests and is either fully functional or can perform most of the intended product functions. Designing adequate reliability demonstration tests also referred as product validation tests is an integral part of any reliability program. While it is desirable to be able to test a large population of units to failure in order to obtain information on a product's or design's reliability, time and resource constraints sometimes make this impossible. In cases such as these, a test can be run on a specified number of units, or for a specified amount of time, that will demonstrate that the product has met or exceeded a given reliability at a given confidence level. In the final analysis, the actual reliability of the units will of course remain unknown, but the reliability engineer will be able to state that certain specifications have been met. This chapter will discuss those requirements and different ways of meeting and exceeding them in the industrial setting. The examples and case studies in this chapter are taken from the automotive and consumer electronics industries, where most of the discussed methods are utilized on an every day basis.

34.2 Engineering Specifications Associated with Product Reliability Demonstration

The majority of the products designed to be utilized by consumers in the real world are

validated using a series of environmental tests. Product development usually begins with technical specifications covering various aspects of product requirements including the expected reliability. A model example of reliability specifications is the General Motors standard for validation of electrical and electronic products [1], one of the few such documents available in the open literature. This standard covers a wide variety of environmental tests including temperature, humidity, vibration, mechanical shock, dust, electrical overloads, and many others. Analysis of product specifications and the resulting development of the test plan is a critical stage of product validation, since it is where most of its engineering and business decisions are made. Due to a large variety of required test procedures it would take a long time to do all the required tests sequentially on the same set of units.

The test flow may have several test legs ran in parallel in order to reduce the total test time and also to accommodate the destructive tests, such as flammability, assembly crush, immersion, and others. Parallel testing saves time but increases the size of the sample population, since each leg would require its own set of test units. A truncated example of a GMW3172 [1] test flow is presented in Figure 34.1.
