Preface

Biological processes are driven by a complex system of functionally interacting signaling components within the cell. These signaling processes are initiated when a class of cell surface proteins, called receptors, receives information from the surrounding environment. This information is then routed through complex signaling pathways and decoded in the nucleus and other areas of the cell. In order to fully understand cell signaling, we must first appreciate the spatial and temporal dynamics of cell surface receptors as well as the downstream components of signaling pathways. The functional states and downstream interactions of cell signaling components are critical to the understanding of both normal and pathologic biological processes. In recent years, a steady increase in both clinical and experimental data on cell signaling has emerged. As we progress through the twenty-first century, it is clear that a systems biology approach, concomitant with the understanding of individual cell signaling components, is needed to delineate biologically relevant signaling networks. Furthermore, it is well understood that almost all diseases exhibit signaling pathway dysfunction. As a result, there has been a profound interest in identifying novel drug targets that regulate key signaling components in disease states.

Currently, there are more than 20,000 genes reported in the human genome; however, not all of the encoded proteins work equally to maintain homeostasis. Achieving a thorough understanding of the most potent signaling components and their associated signaling pathways will significantly improve our knowledge of the molecular mechanisms that regulate disease. Moreover, this insight will lead to the development of novel therapeutics. In recent years, there were multiple attempts to build molecule databases, which were still very partial and brief. Amid the excitement over the recent discoveries of new functional molecules, one of this century's greatest scientific tasks is to compile all information pertaining to signaling components into a single resource. Such an attempt may be arduous but, at the end, will fill the intellectual voids of the field and drastically streamline the understanding of critical signaling networks.

The *Encyclopedia of Signaling Molecules* is a testament to how far we have come in terms of identifying the function of and the interconnection between signaling molecules. This book represents biologically important signaling components from the level of a single gene, to that of gene families. The contents of this encyclopedia are built on the core concepts of the function of signaling components along with the early historical findings to show readers the progress the field has achieved. The encyclopedia not only focuses on individual and groups of signaling components, but also explores the interactions between these groups of signaling components within signal transduction networks. Additionally, it also provides an abundance of

information on the conversion of external signals generated by growth factors, hormones, neurotransmitters, chemokines, cytokines, etc., to the resultant cellular response. Applications of these data to disease and drug discovery efforts have also been discussed. Overall, the encyclopedia is designed to aid those who wish to investigate the function of specific signaling molecules and its role in signaling networks.

The encyclopedia is a Springer Major Reference Work, published in print and online. It consists of entries organized alphabetically. Each entry is concise, clearly written, and contains references to the literature for readers who wish to study each topic in depth. The broad coverage is expected to make the encyclopedia an indispensable reference tool in the field of biomedical research. The online version features colored illustrations and is fully searchable. In addition, cross-references are listed as hyperlinks to easily access related topics in the book.

There are many people to thank and whose help was critical for completing the *Encyclopedia of Signaling Molecules*. This encyclopedia is based on the expertise of hundreds of biomedical professionals who must receive my sincere gratitude for their dedication, efforts, and polite responsiveness to the continuous inquiries. Most importantly, the chapter authors have written outstanding pieces that provide the latest information in their respective field of research. I am grateful to the editors and staffs of Springer: Ann H. Avouris, Anil Chandy, Meetu Lall, Mansi Seth, and Rajneesh Roy for their outstanding help and assistance. Special thanks go to Mrs. Melanie Tucker who made certain that all the molecules were included for the final draft of the encyclopedia.

I hope that the information presented in the *Encyclopedia of Signaling Molecules* will not only aid in understanding the subject matter but also in using the biological information for the benefit of humankind.

Sangdun Choi

About the Editor

Prof. Dr. Sangdun Choi
Department of Molecular Science and Technology
Ajou University
Suwon, 443-749
Korea
sangdunchoi@ajou.ac.kr

Sangdun Choi is currently the Chair of the Department of Biological Sciences and a Professor at the Department of Molecular Science and Technology in Ajou University, Korea. He joined the faculty of the Department of Molecular Science and Technology, Ajou University, as an Associate Professor in 2006. His research interests include Toll-like receptor signaling, innate immunity, cellular signaling and systems biology. He earned his PhD at the Texas A&M University, USA. He was one of the pioneers in the development of Bacterial Artificial Chromosomes (BACs). He was instrumental in the construction of a complete human BAC library for the Human Genome Project (HGP). He was also involved in the consortium, Alliance for Cellular Signaling (AfCS). Furthermore, he served as the Director of the Transcription Analysis Laboratory at the California Institute of Technology (Caltech), USA. He has published more than 200 scientific articles in international journals including *Nature*, *Science*, *Cell*, *Nature Biotechnology*, *Nature Immunology*, *Immunity*, *Blood* and *Proceedings of the National Academy of Sciences*. He has edited seven books including *Encyclopedia of Signaling Molecules*, *Systems Biology for Signaling Networks* and *Introduction to Systems Biology*. He is an academic editor of *PLoS ONE*, an associate editor of *Experimental and Molecular Medicine*, and an active editor for several other international journals. He has also served as a reviewer for several international journals.

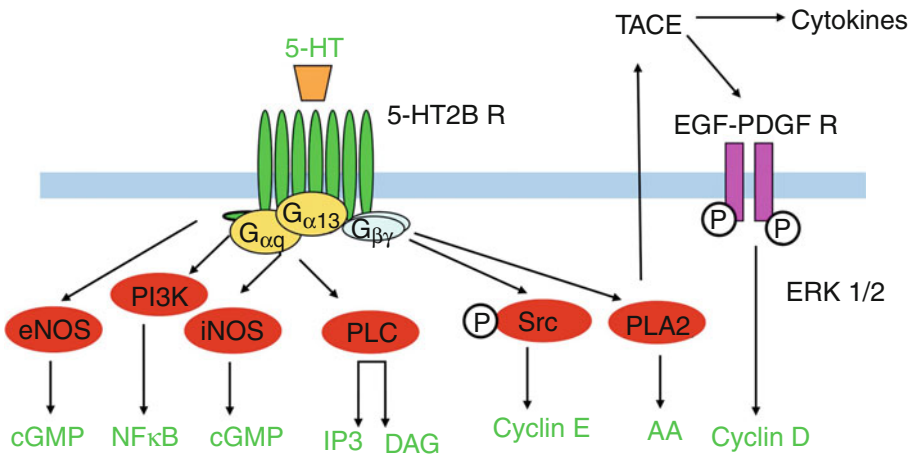
Historical Background

Because of its exquisite sensitivity to serotonin, the rat stomach fundus was used as a bioassay for serotonin before the development of more quantitative analytical assays for this biogenic amine (Vane 1957). Although the potency for the contractile effects of serotonin has been known for a long time, the receptors mediating such a response have eluded definitive characterization for long time. Pharmacological studies attempting to characterize the contractile serotonergic receptor in the rat stomach fundus documented the similarity to the 5-HT_{2C} receptor. In the absence of detectable 5-HT_{2C} receptor mRNA in the rat stomach fundus, only molecular cloning allowed the identification of a new receptor in 1992 in rat and mouse, and later (1994) human species, called 5-HT_{2B} receptor. Subsequent pharmacological characterization of this receptor subtype in different species including humans identified species difference in its pharmacology and confirmed the proximity of this pharmacology to that of 5-HT_{2C} receptors.

Pharmacological analysis has shown that the 5-HT_{2B} receptor displays high-affinity binding to its endogenous ligand serotonin (Kd ~10 nM), a value significantly different from that for the 5-HT_{2A} receptor. 5-HT_{2B} receptors are the targets of many 5-HT2 nonselective compounds, metabolites of therapeutic compounds, and drugs of abuse. Agonists include nordexfenfluramine (metabolite of dexfenflamine), methylergonovine (metabolite of methysergide), and MDA (metabolite of MDMA). Tryptamine, α-methyl-serotonin, BW 723C86: 1-methyl-2-[5-(2-thienylmethoxy)-1H-indole-3-yl]ethylamine hydrochloride, D-norfenfluramine, Ro 60-0175: 2(S)-1-(6-chloro-5-fluoro-1H-indol-1-yl)-2-propanamine fumarate, and LSD all exhibit the highest potencies for 5-HT_{2B}. BW 723C86 has been reported to have over a 10-fold higher selectivity for the 5-HT_{2B} receptor than the 5-HT_{2C} receptor and a 100-fold higher selectivity than the 5-HT_{2A} receptor. DOI is a nearly full agonist at 5-HT_{2B} receptors with similar affinity to 5-HT_{2A} and 5-HT_{2B} receptors. Nonselective 5-HT2 receptor antagonists such as ritanserin, metergoline, and LY 53857 antagonize 5-HT_{2B} receptor mediated effects. Also, the adrenergic α2 receptor antagonists yohimbine and rauwolscine are potent antagonists and have a low affinity for the 5-HT_{2C} and 5-HT_{2A} receptor sites. The first highly selective antagonists have been recently reported, LY266097: 1-(2-chloro-3,4-dimethoxybenzyl)-6-methyl-1,2,3,4-tetrahydro-9Hpyrido[3,4-b]indole hydrochloride, has a pKi of 9.7 for the human cloned 5-HT_{2B} receptor with a 100-fold greater selectivity for this receptor than the human 5-HT_{2C} and 5-HT_{2A} sites. SB 204741: N-(1-methyl-5-indolyl)-N′-(3-methyl-5-isothiazolyl)urea, has been reported as a selective 5-HT_{2B} receptor antagonist with lower potency (Ki around 100 nM). RS 127445: 2-amino-4-(4-fluoronaphth-1-yl)-6-isopropylpyrimidine was found to have sub-nanomolar affinity for the 5-HT_{2B} receptor (pKi = 9.5) and a 1,000-fold selectivity for this receptor as compared to numerous other receptor and ion channel binding sites and appears to be the most selective, high affinity 5-HT_{2B} receptor antagonist currently available. The tetrahydro-β-carboline, LY272015: 6-chloro-5-methyl-N-(5-quinolinyl)-2,3-dihydro-1H-indole-1-carboxamide is also a selective and potent antagonist. The SB 206553: 5-methyl-N-(3-pyridyl)-1,2,3,5-tetrahydrobenzo[1,2-b:4,5-b′]dipyrrole-1-carboxamide and SB 215505: 6-chloro-5-methyl-N-(5-quinolinyl)-2,3-dihydro-1H-indole-1-carboxamide behave as mixed 5-HT_{2C}/5-HT_{2B} receptor antagonist.

Like 5-HT_{2A} and 5-HT_{2C} receptors, the 5-HT_{2B} receptor when expressed in transfected cells can induce GTPase activation and inositol 1,4,5-trisphosphate production upon agonist stimulation. GTPase activation is blocked by antibodies against Gαq/11, but not by pertussis or cholera toxins or by anti-Gαi or anti-Gαs antibodies, indicating that this GTPase activation is mediated by the G-protein Gαq/11, but not by Gαs or Gαi. Interestingly, the GTPase activation can also be blocked by anti-β1-4, or -γ2 subunit antibodies. Agonist stimulation of the 5-HT_{2B} receptor causes a rapid

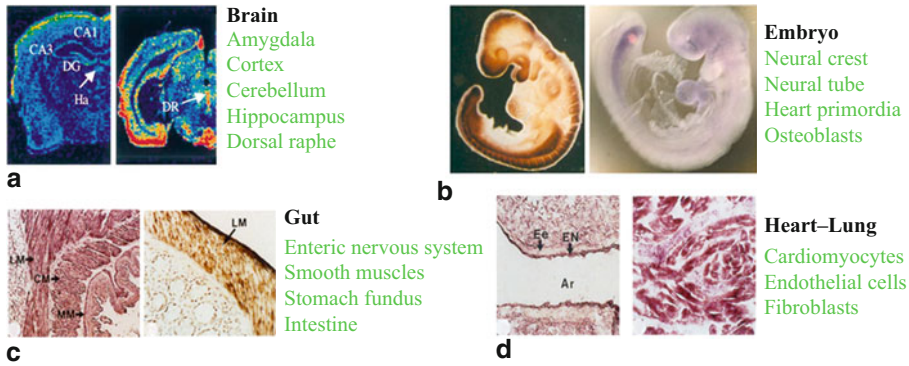
0–9



5-Hydroxytryptamine Receptor 2B, Fig. 1 Summary of some of the identified transduction pathways that can be used by 5-HT2B receptors adapted from Nebigil et al. (2000b), Manivet et al. (2000) and Nebigil et al. (2003)

and transient activation of the proto-oncogene product $p21^{ras}$ in response to serotonin, as measured by an increase in GTP bound-Ras. Furthermore, 5-HT_{2B} receptor stimulation activates the mitogen-activated protein kinases (MAPKs) p42mapk/p44mapk (ERK2/ERK1). In addition to a mitogenic action, a transforming activity of serotonin can be mediated by the 5-HT_{2B} receptor as it leads to the formation of foci and to the formation of tumors from foci in nude mice. Moreover, the 5-HT_{2B} receptors-dependent cell cycle progression occurs through retinoblastoma protein hyperphosphorylation and the activation of both cyclin D1/cdk4 and cyclin E/cdk2 kinases. The induction of cyclin D1 expression, but not that of cyclin E, is under mitogen-activated MAPK control, indicating an independent regulation of these two cyclins in 5-HT_{2B} receptor mitogenesis. Moreover, platelet derived growth factor receptor (PDGFR) kinase activity is essential for 5-HT_{2B}-triggered MAPK/cyclin D1, but not cyclin E, signaling pathways. The 5-HT_{2B} receptor activation also increases activity of the Src family kinases c-Src, Fyn, and c-Yes. Strikingly, c-Src, but not Fyn or c-Yes, is the crucial molecule between the Gq protein-coupled 5-HT_{2B} receptor and the cell cycle regulators. Inhibition of c-Src activity is sufficient to abolish the serotonin-induced: (1) PDGFR tyrosine kinase phosphorylation and MAPK activation, (2) cyclin D1 and cyclin E expression levels, and (3) thymidine incorporation. Thus, c-Src activation by the 5-HT_{2B} receptor controls cyclin E induction and, in concert with the receptor tyrosine kinase PDGFR, induces cyclin D1 expression via the MAPK/ERK pathway (Nebigil et al. 2000b). The 5-HT_{2B} receptor can also couple to the phospholipase A2 (PLA2)-mediated release of arachidonic acid. In addition, stimulation of the 5-HT_{2B} receptor triggers intracellular cGMP production through dual activation of constitutive nitric-oxide synthase (cNOS) and inducible NOS (iNOS). The group I PDZ motif at the carboxy terminus of the 5-HT_{2B} receptor is required for recruitment of the cNOS transduction pathways, and iNOS stimulation is under control of the Gα13 pathways. 5-HT_{2B} shares the C-terminal E-X-V/I-S-X-V sequence with 5-HT_{2C} receptors and also binds MUPP1-PDZ domains in vitro (Manivet et al. 2000) (Fig. 1).

Expression of 5-HT_{2B} receptors has been reported in mouse embryos in migrating neural crest cells, neural tube, heart primordia, and somites by immunohistochemistry and in situ hybridization. By Northern blot and immunohistochemistry, 5-HT_{2B} receptor expression has been detected in the stomach fundus, intestine, liver, kidney, pancreas, spleen, and lung, as well as in the myocardium of several species including rats, mice, and humans. In brain, 5-HT_{2B} expression has been reported in the cerebral cortex, cerebellar nuclei and their projection areas, lateral septum, dorsal hypothalamus, and medial amygdala. Expression of the serotonin 5-HT_{2B} receptor mRNA was also confirmed in several brain nuclei including dorsal raphe nuclei by gene expression profiling in the mammalian brain, and by in-situ hybridization. Reports using pharmacological or molecular studies indicate that the 5-HT_{2B}



5-Hydroxytryptamine Receptor 2B, Fig. 2 Major sites of expression of 5-H2B receptors are shown. This includes (**a**) brain as illustrated by in situ hybridization on rat brain sections, (**b**) embryos as illustrated by in situ hybridization and immunohistochemistry on mouse embryos, and (**c**) immmunohistochemistry on mouse gut and (**d**) cardiopulmonary systems, adapted from Choi and Maroteaux (1996), Choi et al. (1997) and Bonaventure et al. (2002)

receptor is also expressed in blood vessels, including both endothelial and smooth muscle cells as well as on the endothelial cells of meningeal blood vessels. In addition, 5-HT_{2B} receptor expression has been detected in spleen, thymus, peripheral blood lymphocytes, spinal cord tissue, superior cervical ganglion, and in the organ of Corti lateral wall and spiral ganglion subfractions. Lately, 5-HT_{2B} receptor expression was also demonstrated in osteocytes, osteoblasts, and a population of periosteal fibroblasts containing osteoblast precursor cells (Fig. 2).

The human 5-hydroxytryptamine receptor $_{2B}$ (5-HT_{2B} receptor) gene (HTR_{2B}; MIM 601122) located in chromosome 2q37.1 (Le Coniat et al. 1996) was identified as a candidate gene in obsessive-compulsive disorder: one single nucleotide polymorphism was described in intron 1, but no evidence for functional mutation was found in the sequenced regions of the 5-HT_{2B} receptor. Novel single nucleotide polymorphisms (SNPs), two of which confer a double-mutant R6G/E42G of the receptor protein that tends to associate with drug abuse, suggest that HTR_{2B} contributes to brain architecture and pathways that are involved in illegal drug reward. More recently, by investigating the 5-HT_{2B} receptor gene in patients who developed pulmonary hypertension after intake of fenfluramine, a heterozygous mutation was found in one female diagnosed with pulmonary hypertension who 5 years earlier had followed a 9-month anorexigen treatment. This heterozygous mutation R393X in the 5-HT_{2B} receptor generates a carboxy terminus-truncated receptor characterized by a switch of coupling to Gα13, reduced nitric oxide synthase (NOS) activation, and an increase in cell proliferation – modifications that are relevant to pathophysiological vasoconstriction.

Physiological Functions in Embryonic Development

The 5-HT_{2B} receptor mRNA was detected in mouse embryos since 8.5 days postcoitum (dpc), whereas there were only low levels of 5-HT_{2A} and no 5-HT_{2C} receptor mRNA expression at this stage. Expression of this receptor was confirmed by pharmacological assays. Teratogenesis by retinoic acid, or blockade of serotonergic signaling by 5-HT2 receptor antagonists, perturbs development, resulting in forebrain and olfactory placode anomalies, malformations of the face, eye, and lens, as well as posterior neural tube and cardiac defects (Bhasin et al. 2004). These pathways may act as opposing signals for common targets in the mouse embryo. The importance of 5-HT_{2B} receptors in cardiac development has been validated by genetic inactivation by homologous recombination of the 5-HT_{2B} receptor gene, which leads to embryonic and neonatal death due to the following defects in the heart: 5-HT_{2B} receptor mutant embryos exhibit a lack of trabeculae in the heart leading to mid-gestation lethality and newborn 5-HT_{2B} receptor mutant mice exhibit cardiac dilation resulting from contractility deficits and structural deficits at the intercellular junctions between cardiomyocytes (Nebigil et al. 2000a). Recent report

showed that serotonin acts downstream of lactogen signaling to stimulate beta cell proliferation. Blocking 5-HT_{2B} signaling in pregnant mice also blocked beta cell expansion and caused glucose intolerance (Kim et al. 2010).

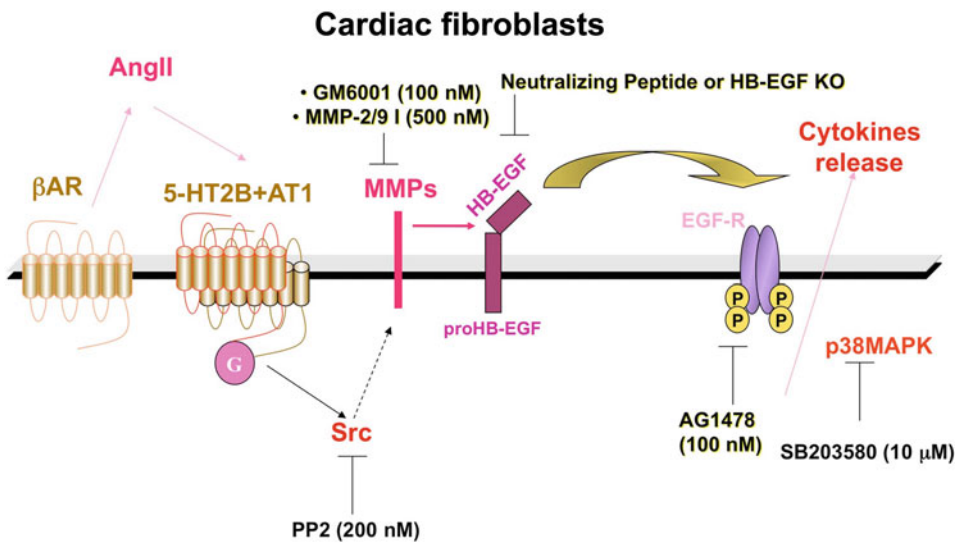
Physiological Cardiopulmonary Functions

Inactivation of the 5-HT_{2B} receptor gene by homologous recombination leads to partial embryonic lethality due to defects in the heart development. Neonates exhibit a second wave of partial lethality due to cardiac dilation resulting from contractility deficits and structural deficits at the intercellular junctions between cardiomyocytes. Echocardiography and electrocardiography studies in animals that past the first week and survive until adulthood, confirm the presence of left ventricular dilation and decreased systolic function. Serotonin, via the 5-HT_{2B} receptor, regulates differentiation and proliferation during development as well as cardiac structure and function in adults (Nebigil et al. 2000a). In adults, 5-HT_{2B} receptors are overexpressed in hearts from patients with congestive heart failure, this overexpression being positively correlated with cytokine and catecholamine plasma levels. The 5-HT_{2B} receptor has been shown functionally coupled to reactive oxygen species synthesis through NAD(P)H oxidase stimulation in neuronal cells and in angiotensin II and isoproterenol-induced cardiac hypertrophy. Recently, 5-HT_{2B} receptor blockade has been shown to prevent the cardiac hypertrophy induced by angiotensin II or isoproterenol infusion. The 5-HT_{2B} receptor has also been shown to be involved in cardiac hypertrophy by acting directly on cardiac myocytes. Serotonin plasma level and serotonin activity are increased in patients with heart failure and in animal studies with cardiac hypertrophy induced by aortic constriction. These findings may indicate that serotonin induces cardiac hypertrophy or heart failure through the 5-HT_{2B} receptor. These findings may have important clinical implications because sympathetic activity, 5-HT_{2B} receptor expression, and plasma cytokines were all increased in patients with heart failure (Jaffre et al. 2009).

In human pulmonary artery endothelial cells, 5-HT_{2B} receptor stimulation elicits a reversible endothelium-dependent relaxation of precontracted arterial ring segments and is associated with an increase in cyclic GMP. The vasoconstrictor serotonergic response induced in the autoperfused rat mesenteric vascular bed in situ seems mainly mediated by 5-HT_{2B} receptor activation. The contraction of the aorta in response to serotonin is primarily mediated by 5-HT_{2A} receptors in normotensive rats; however, it is mediated by both 5-HT_{2A} and 5-HT_{2B} receptors in hypertensive rats. The endothelium-denuded isolated superior mesenteric artery of hypertensive (DOCA-salt) rats displays a marked increase in maximum contraction to 5-HT_{2B} receptor agonists when compared with that of arteries from control rats, confirming that the 5-HT_{2B} receptor plays a greater role in serotonin-induced contraction in arteries from hypertensive rats (Banes and Watts 2003).

A role for serotonin in migraines has been supported by changes in circulating levels of serotonin and its metabolites during the phases of a migraine attack. Correlation of the receptor affinities with the potencies used in migraine prophylaxis showed significant correlations for the 5-HT_{2B} receptor. A migraine headache is thought to be transmitted by the trigeminal nerve from the meninges and their associated blood vessels. The 5-HT_{2B} receptor can activate the release of nitric oxide and induce relaxation of the cerebral arteries and the jugular vein. Various human meningeal tissues express 5-HT_{2B} mRNAs. 5-HT_{2B} receptors located in endothelial cells of meningeal blood vessels may trigger migraine headache through the formation of nitric oxide, which results in the dilation of cerebral blood vessels and the concomitant activation of sensory trigeminovascular afferents, thus initiating the manifestation of head pain. A recent report identified 5-HT_{2B} receptors as a susceptibility gene to migraine (Corominas et al. 2010).

In cardiac fibroblasts, expression of HB-EGF and Src activity are critical for either angiotensin II (AngII) or 5-HT-dependent cytokine release process. Matrix metalloproteinases (MMPs) are responsible for HB-EGF shedding and subsequent EGF-receptor transactivation that is induced by agonists such as AngII or 5-HT. TNF-α converting enzyme (TACE, ADAM-17) was found to control HB-EGF shedding in fibroblasts and 5-HT_{2B} receptors can directly regulate this enzyme activity in neuronal cells. These results also highlighted the importance of p38 but not ERK1/2 pathway for cytokine release. All these findings support that AT-1Rs and 5-HT_{2B} receptors share



5-Hydroxytryptamine Receptor 2B, Fig. 3 Signal transduction mediated by 5-HT2B receptors in cardiac fibroblasts to control the release of hypertrophic cytokines by interacting with AT1 receptors. Inhibitors used to determine this transduction pathway are shown, adapted from Jaffre et al. (2009)

common EGF receptor-dependent signaling pathways in adult cardiac fibroblasts. Blockade of one of the two receptors prevents cytokine release induced by the other receptor, supporting interactions between 5-HT_{2B} receptors and AT-1Rs. Using co-immunolocalization and a pull-down assay, the two receptors were shown to interact in a common cell compartment. Reports have suggested that these receptors exist in heterodimeric complexes that may play a key role in receptor maturation and trafficking to the plasma membrane and/or signaling. Together, these findings are consistent with the hypothesis that AT-1Rs and 5-HT_{2B} receptors exist in common signaling complexes and that they may interact together to regulate hypertrophic factors in heart (Jaffre et al. 2009) (Fig. 3).

Carcinoid heart disease occurs in over 65% of patients with the carcinoid tumors and is characterized by fibrous thickening of cardiac valves, leading ultimately to heart failure. The anorectic compound dexfenfluramine has been reported to be associated with cardiovascular disease, including pulmonary hypertension and valvular heart defects. The valvular changes (myofibroblast proliferation) are histopathologically indistinguishable from those observed in carcinoid disease or after long-term exposure to 5-HT2-preferring ergot drugs (such as ergotamine and methysergide). The mitogenic action of 5-HT2 receptor stimulation could contribute to this lesion. Fenfluramine or its N-de-ethylated metabolite norfenfluramine and other medications known to produce valvular heart disease have preferential high affinities for the 5-HT_{2B} subtype capable of stimulating mitogenesis (with or without accompanying 5-HT_{2A} receptor activation). Norfenfluramine, ergotamine, pergolide, cabergoline, and methysergide metabolite methylergonovine all are partial to full agonists at the 5-HT_{2B} receptor. MDMA and MDA, like norfenfluramine, elicit prolonged mitogenic responses in human valvular interstitial cells via activation of 5-HT_{2B} receptors and have been associated with valvulopathies. Thus, preferential stimulation of valvular 5-HT_{2B} receptors by norfenfluramine, ergot drugs, or serotonin released from carcinoid tumors has been proposed to contribute to valvular fibroplasia in humans (Roth 2007).

Primary pulmonary hypertension is a progressive and often fatal disorder in humans that results from an increase in pulmonary blood pressure associated with abnormal vascular proliferation. In the chronic-hypoxic-mouse model of pulmonary hypertension, the hypoxia-dependent increase in pulmonary blood pressure and lung remodeling are associated with an increase in vascular proliferation, elastase activity, and transforming growth factor-β levels. These parameters are all potentiated by dexfenfluramine treatment. In contrast, hypoxic mice with genetically or

pharmacologically inactive 5-HT_{2B} receptors manifest no change in any of these parameters. Pulmonary hypertension is associated with a substantial increase in 5-HT_{2B} receptor expression in pulmonary arteries in mice and humans. Activation of 5-HT_{2B} receptors is, therefore, a limiting step in the development of pulmonary hypertension (Launay et al. 2002). More recently, the restricted expression of 5-HT_{2B} receptors to bone-marrow cells was shown as necessary and sufficient for pulmonary hypertension to develop via an action at hematopoietic stem cells differentiation (Launay et al. 2012).

Physiological Functions in Central Nervous System

5-HT_{2B} receptor antagonists exhibit anxiolytic-like properties in both the rat social interaction test and two conflict models of anxiety: the rat Geller-Seifter and marmoset conflict test. The presence of neurons expressing 5-HT_{2B} receptor protein has been reported in the medial amygdaloid nucleus of the adult rat brain. Injection of 5-HT_{2B} receptor agonist into the medial amygdaloid nuclei increased the total interaction time of a pair of male rats in the social interaction test without altering locomotor activity, indicative of anxiolytic activity. Activation of 5-HT_{2B} receptors in the medial amygdala induces anxiolysis in the social interaction model but has little effect on behavior in a punished conflict model of anxiety (Kennett et al. 1996).

The "club drug" 3,4-methylenedioxymethamphetamine (MDMA also known as ecstasy) binds preferentially to and reverses the activity of the serotonin transporter, causing release of serotonin stores from nerve terminals. Subsequent activation of postsynaptic 5-HT receptors by released 5-HT has been shown to be critical for the unique psychostimulatory effects of MDMA. Acute pharmacological inhibition or genetic ablation of the 5-HT_{2B} receptor in mice completely abolishes MDMA-induced hyperlocomotion and 5-HT release in nucleus accumbens and ventral tegmental area. Furthermore, the 5-HT_{2B} receptor dependence of MDMA-stimulated release of endogenous 5-HT from superfused midbrain synaptosomes suggests that 5-HT_{2B} receptors act, unlike any other 5-HT receptor, presynaptically to affect MDMA-stimulated 5-HT release. Thus, the 5-HT_{2B} receptor is a novel regulatory component in the actions of MDMA (Doly et al. 2008). However, the role of serotonin–dopamine interactions in the behavioral effects of MDMA remains unclear. 5-HT_{2B}-/- mice do not exhibit behavioral sensitization or conditioned place preference following MDMA injections. In addition, MDMA-induced reinstatement of conditioned place preference after extinction and locomotor sensitization development are each abolished by a 5-HT2) receptor antagonist (RS127445) in wild type mice. Accordingly, MDMA-induced dopamine D1 receptor-dependent phosphorylation of extracellular regulated kinase in nucleus accumbens is abolished in mice lacking functional 5-HT_{2B} receptors. These results underpin the importance of 5-HT_{2B} receptors in the reinforcing properties of MDMA and illustrate the importance of dose-dependent effects of MDMA on serotonin–dopamine interactions (Doly et al. 2009). Moreover, another selective 5-HT_{2B} receptor antagonist LY 266097, which has no influence on basal accumbal and striatal DA outflow, reduces significantly accumbal DA outflow. A significant reduction of basal DA outflow in the nucleus accumbens (NAc) was also observed after i.p. administration of the 5-HT_{2B} receptor antagonist RS 127445. In contrast, the 5-HT_{2B} receptor agonist BW 723C86 had no influence on basal DA outflow in either brain region. The increase in striatal and accumbal DA outflow induced by the 5-HT_{2C}R inverse agonist SB 206553 was unaltered by LY 266097 pretreatment. Conversely, LY 266097 significantly diminished the increase in DA outflow induced by haloperidol or amphetamine in the NAc, but not in the striatum. Amphetamine-induced hyperlocomotion was also attenuated by LY 266097. Thus 5-HT_{2B} receptors exert a facilitatory control on mesoaccumbens DA pathway activity, and may constitute a new target for improved treatment of DA-related neuropsychiatric disorders (Auclair et al. 2010).

Rare alleles can be linked to complex behavior by applying deep sequencing in severely affected individuals. Recently a stop codon in 5-HT_{2B} receptors (Q20*) that is common but exclusive to Finns was found associated with psychiatric diseases marked by impulsivity (Bevilacqua et al. 2010). The receptor with the stop codon is non-functional and may act directly to lead to associated psychiatric diseases, severe impulsive criminal behavior, and suicide. Accordingly, 5-$HT_{2B}^{-/}$ mice display increased

impulsive behaviors validating the Human findings (Bevilacqua et al. 2010). This work is the first documented case of unique behavioral effects of a 5-HT_{2B} in human impulsivity.

The now-banned anorectic molecule, dexfenfluramine, promotes also 5-HT release through a SERT-dependent mechanism, and it has been widely prescribed for the treatment of obesity. Interestingly, the hypophagic response to dexfenfluramine observed in WT mice was eliminated in mice lacking 5-HT_{2B} receptors (5-$HT_{2B}^{-/-}$) or in WT mice treated with the selective 5-HT_{2B} receptor antagonist RS127445. Using microdialysis, we observed that in 5-$HT_{2B}^{-/-}$ awake mice, the dexfenfluramine-induced hypothalamic peak of 5-HT release was strongly reduced. Moreover, 5-HT release was only observed upon dexfenfluramine stimulation of synaptosome preparation from WT but not from 5-$HT_{2B}^{-/-}$ mice. The hypophagia induced by 5-HT_{2C} agonists is detected in 5-$HT_{2B}^{-/-}$ or $SERT^{-/-}$ mice (Banas et al. 2011). These findings strongly support an epistatic role of 5-HT_{2B} receptors on 5-HT_{2C} receptors in dexfenfluramine action with respect to feeding behavior.

The most widely used antidepressants are the so called serotonin-selective reuptake inhibitor (SSRI) since they initially block SERT uptake activity. Whereas blockade of SERT and increase of 5-HT levels are immediately attained after SSRI administration, therapeutic effects are only observed after weeks of treatment. The delay before the onset of clinical effects in depressive individuals appears to rely on the time required for stabilization of monoamine levels and other neuroadaptations, including adult hippocampal neurogenesis. Recent work showed that 5-HT_{2B} receptors are necessary not only for acute behavioral effects of SSRIs (Diaz and Maroteaux 2011), but also for long-term behavioral and neurogenic SSRI effects (Diaz et al. 2012). Conversely, direct agonist stimulation of 5-HT_{2B} receptors induces an SSRI-like response in behavioral and neurogenic assays. These work showed also that this receptor is expressed by raphe serotonergic neurons, and that the SSRI-induced increase in hippocampal extracellular 5-HT concentration is strongly reduced in the absence of functional 5-HT_{2B} receptors. The 5-HT_{2B} receptor thus positively regulates serotonergic neurons and is required for the therapeutic actions of SSRIs (Diaz et al. 2012). As novel antidepressants are being developed to both ameliorate efficacy of treatments and increase the number of responders, the positive contribution of the 5-HT_{2B} receptor to serotonergic homeostasis should be considered.

Pathophysiological Functions

In Fibrosis

The liver can regenerate its volume after major tissue loss. In a mouse model of liver regeneration, thrombocytopenia, or impaired platelet activity, results in the failure to initiate cellular proliferation in the liver. The expression of 5-HT_{2A} and 5-HT_{2B} subtype serotonin receptors in the liver increased after hepatectomy. Antagonists of 5-HT_{2A} and 5-HT_{2B} receptors inhibited liver regeneration. Liver regeneration was also blunted in mice lacking tryptophan hydroxylase 1, which is the rate-limiting enzyme for the synthesis of peripheral serotonin. This failure of regeneration was rescued by reloading serotonin-free platelets with a serotonin precursor molecule (Lesurtel et al. 2006). Bleomycin-induced fibrosis that was independently shown to be reduced in 5-$HT_{2B}^{-/-}$ mice as for dermal fibrosis (Dees et al. 2011). In the liver, fibrogenic hepatic stellate cells, which are negative regulators of hepatocyte regeneration, are known to express also 5-HT_{2A} and 5-HT_{2B} receptors that may regulate TGFβ-1 and Smads. Antagonism of 5-HT_{2B} attenuates fibrogenesis and improves liver function in disease models in which fibrosis is pre-established and progressive (Ebrahimkhani et al. 2011). These findings suggest that 5-HT_{2B} signaling links cardiovascular damage and platelet activation to tissue remodeling and identify 5-HT_{2B} as a novel therapeutic target to treat fibrotic diseases.

Serotonin is known to increase proliferation and collagen synthesis by fibroblasts. Serotonin concentrations in lung homogenates increased significantly over the time course of bleomycin-induced fibrosis, with a maximum at day 7. The expression of serotonin receptors 5-HT_{2A} and 5-HT_{2B} increased also in the lung after bleomycin treatment. Blockade of either 5-HT_{2A} receptors by ketanserin or 5-HT_{2B} receptors by SB 215505 reduced bleomycin-induced lung fibrosis, as demonstrated by reduced lung collagen content and reduced procollagen 1 and procollagen 3 mRNA expression. Serotonin antagonists promoted an antifibrotic environment by decreasing the lung mRNA levels of transforming growth factor-beta 1,

connective growth factor, and plasminogen activator inhibitor-1 mRNA, but had minimal effects on lung inflammation as assessed by bronchoalveolar lavage cytology analysis. Interestingly, the 5-HT_{2B} receptor was strongly expressed by fibroblasts in the fibroblastic foci in human idiopathic pulmonary fibrosis samples (Fabre et al. 2008).

In Gut

5-HT_{2B} receptor initially characterized as the receptor responsible for the rat fundus contraction in response to 5-HT (Vane 1957) is expressed in the small intestine as well as the stomach and it is expressed by enteric neurons as well as by muscle. By stimulating 5-HT_{2B} receptors, 5-HT affects the fate of the large subset of enteric neurons that arises after the development of endogenous sources of 5-HT (Fiorica-Howells et al. 2000). High levels of both mRNA and protein for 5-HT_{2B} receptors were found predominantly in the muscle layers and in the myenteric nerve plexus throughout the colon where they caused neuronally mediated contractile responses of longitudinal muscle (Borman et al. 2002). The 5-HT_{2B} receptor appears involved in regulating sensory pathways only under hyperalgesic conditions, suggesting the possible utility of 5-HT_{2B} receptor antagonism in reducing visceral hypersensitivity in patients with irritable bowel syndrome (IBS). 5-HT_{2B} receptors are involved in signaling from the colon in rats in which there is visceral hypersensitivity and a selective 5-HT_{2B} receptor antagonist could have therapeutic potential for the treatment of gut disorders characterized by visceral hypersensitivity (O'Mahony et al. 2010). Interstitial cells of Cajal (ICC) proliferate in adult mice and activation of 5-HT_{2B} receptors results in increased proliferation of ICC in vivo. Furthermore, lack of 5-HT_{2B} receptor signaling reduces the density of ICC networks in mature mice. Targeting 5-HT availability may have the potential to protect ICC networks from injury or can assist in repairing ICC networks after injury (Tharayil et al. 2010).

In Immune System

Positive signals were obtained for 5-HT_{2B} receptor mRNAs in spleen, thymus, and peripheral blood lymphocytes (Stefulj et al. 2000). The neurotransmitter serotonin can be stored at peripheral sites in mast cells and released from this peripheral source upon IgE cross-linking. Study of the expression of serotonergic receptors on human dendritic cells (DC) showed that immature DC preferentially expressed mRNA for the heptahelical 5-HT_{1B}, 5-HT_{1E}, and 5-HT_{2B} receptors, while mature DC mostly expressed 5-HT_4 and 5-HT_7. Moreover, 5-HT_{2B} receptor stimulation induced intracellular Ca2+ mobilization in immature, but not mature, DC. 5-HT stimulates, in a maturation-dependent manner, different signaling pathways in DC. These data point to a role for 5-HT in regulating the immune response at peripheral sites (Idzko et al. 2004).

In Cancer Cells

The 5-HT_{2B} receptor mRNA has been recently identified as a marker of adrenocortical carcinoma using genomewide gene expression profiling (Fernandez-Ranvier et al. 2008). High transcript levels of 5-HT_{2B} receptor gene were also found in uveal melanomas with monosomy 3 (metastatic) but not in tumors with disomy 3, identifying the 5-HT_{2B} receptor expression as a marker for patients with poor prognosis (Tschentscher et al. 2003). Expression of 5-HT_{2B} receptors has been detected in all prostate cancers (Dizeyi et al. 2005) and antagonists of these receptors were reported to inhibit prostatic cancers. The levels of eNOS were found to increase in carcinomas and to promote cancer progression by providing a selective growth advantage to tumor cells. Recent work showed that pharmacologic blockade of the 5-HT_{2B} receptor inhibits implanted cancer tumors in mice. A 5-HT_{2B} receptor antagonist, which suppress the phosphorylation of ERK1/2 and eNOS in HUVEC, also reduced tumor growth by suppressing angiogenesis (Asada et al. 2009).

In Bones

The 5-HT_{2B} receptor contributes in an autocrine manner to osteogenic differentiation and highlights a switch in the downstream targets of the receptor at the terminal stage of the program. The mRNA for the 5-HT_{2B} receptor, which was undetectable in anaplastic osteoblasts, became detectable in differentiated and matured osteoblasts. The differentiation and maturation of osteoblasts might be regulated by the activation of the 5-HT_{2B} receptor under the control of 5-HT inactivation (Hirai et al. 2009). Of interest, 5-HT_{2B} receptor mutant female mice displayed reduced bone density that was significant from age 4 months and had intensified by 12 and 18 months.

This histomorphometrically confirmed osteopenia seems to be due to reduced bone formation because (1) the alkaline phosphatase-positive colony-forming unit capacity of bone marrow precursors was markedly reduced in the 5-5-HT_{2B} receptor mutant mice from 4 to 12 months of age, (2) ex vivo primary osteoblasts from mutant mice exhibited reduced proliferation and delayed differentiation, and (3) calcium incorporation was markedly reduced in osteoblasts after 5-HT_{2B} receptor depletion (produced genetically or by pharmacological inactivation). The 5-HT_{2B} receptor facilitates osteoblast recruitment and proliferation and its absence leads to osteopenia that worsens with age (Collet et al. 2008). A functional link between the 5-HT_{2B} receptor and the activity of the tissue-nonspecific alkaline phosphatase (TNAP) was established using an osteoprogenitor cell line. During osteogenic differentiation, both 5-HT_{2B} receptor and TNAP mRNA translations are delayed with respect to extracellular matrix deposition. Once the receptor is expressed, it constitutively controls TNAP activity at a posttranslational level along the overall period of mineral deposition. Indeed, inhibition of the 5-HT_{2B} receptor intrinsic activity prevents TNAP activation. In contrast, agonist stimulation of the receptor further increases TNAP activity during the initial mineralization phase. Previous observations indicated that the 5-HT_{2B} receptor couples with the phospholipase A2 (PLA2) pathway and prostaglandin production at the beginning of mineral deposition. The 5-HT_{2B} receptor controls also leukotriene synthesis via PLA2 at the terminal stages of differentiation. These two 5-HT_{2B} receptor-dependent eicosanoid productions delineate distinct time-windows of TNAP regulation during the osteogenic program. Finally, prostaglandins or leukotrienes are shown to relay the posttranslational activation of TNAP via stimulation of the phosphatidylinositol-specific phospholipase C. In agreement with the above findings, primary calvarial osteoblasts from 5-HT_{2B} receptor null mice exhibit defects in TNAP activity (Baudry et al. 2010).

Summary

Although expressed quite widely but at low levels, 5-HT_{2B} receptors have been reported to play an important role at cardiac, intestinal, and central levels. Therapeutic interest concerning this receptor subtype has been delayed due to the lack of selective tools, radioligands, antibodies, etc. However, in the last decade, antagonists at 5-HT_{2B} receptors have gained much attention as new targets in therapeutics: 5-HT_{2B}R antagonists are under active investigation for pulmonary hypertension, since they produced encouraging results in animal models, and promising human trials are underway; 5-HT_{2B} receptor may represent a new therapeutic target to reduce cardiac hypertrophy and hypertrophy-induced heart failure. If the safety and efficacy of a 5-HT_{2B} receptor antagonist to treat cardiac hypertrophy or hypertrophy-induced heart failure can be confirmed, application of this kind of therapy to human study may be warranted.

These receptors have also been recognized as off-targets because their agonists play a significant role in the pathogenesis of valvulopathy.

Synonyms

5-HT2C; 5-HT1C

Historical Background

The 5-hydroxytryptamine type 2C receptor (5-HT2C, previously 5-HT1C) is one of the 13 G protein-coupled receptor subtypes activated by serotonin. 5-HT2C receptors are involved in a large variety of physiological functions such as nociception, motor behavior, endocrine secretion, thermoregulation, modulation of appetite, and the control of exchanges between the central nervous system and the cerebrospinal fluid. They have also been implicated in numerous pathologies such as schizophrenia, anxiety, depression, Parkinson's disease, drug addiction, and obesity (Berg et al. 2008). In line with their implication in various pathological situations, 5-HT2C receptors are considered as a major pharmacological target for the development of new treatments.

With regard to signaling, 5-HT2C receptors are positively coupled to phospholipase Cß protein via Gαq in several brain regions (Berg et al. 2008). Native 5-HT2C receptors also activate phospholipase D through a mechanism involving Gα13 and Gβγ subunits in choroid plexus. Transactivation of the small GTPase RhoA seems to be required for 5-HT2C receptor-mediated phospholipase D activation. Activation of phospholipase A2 and ERK1,2 by 5-HT2C receptors has also been reported in heterologous cells and/or native tissues (Berg et al. 2008; Labasque et al. 2008).

Protein Function

5-HT2C receptors expressed along ascending dopaminergic pathways play a prominent role in the control of mesocorticolimbic and nigrostriatal dopaminergic systems. Constitutive and/or agonist-induced 5-HT2C receptor activation inhibits dopamine release (Berg et al. 2008; Bubar and Cunningham 2008). Atypical antipsychotics and antidepressants, in particular those exhibiting inverse agonist activity at 5-HT2C receptors, relieve this inhibition, leading to activation of the mesocorticolimbic dopaminergic system (Berg et al. 2008). Systemic administration of RO600175 (agonist) and SB242084 (antagonist) inhibits and potentiates cocaine-induced behaviors, respectively. Microdialysis of RO600175 or SB242084 in the ventral tegmental area (VTA) or nucleus accumbens also revealed that dopamine efflux induced by systemic cocaine injection is controlled by 5HT2C receptors expressed in the VTA and the Nac (Berg et al. 2008; Bubar and Cunningham 2008).

5-HT2C receptor activation likewise exerts a tonic inhibitory influence on the activity of locus

coeruleus-derived noradrenergic pathways innervating cortico-limbic structures.

5-HT2C receptors are expressed in pro-opiomelanocortin (POMC)/cocaine amphetamine-regulated transcript neurons of the arcuate nucleus of hypothalamus (Heisler et al. 2003). A series of elegant studies have shown that 5-HT2C receptor activation by administration of fenfluramine, a 5-HT reuptake inhibitor/5-HT releasing compound, or by selective agonists like BVT.X regulates melanocortin signaling and inhibits food intake (Heisler et al. 2003; Miller 2005). More recent studies showed that mice lacking 5-HT2C receptors displayed hepatic insulin resistance. Moreover, 5-HT2C receptor-deficient mice are resistant to the antidiabetic effects of the 5-HT2C agonist mCPP. Specific reexpression of 5-HT2C receptors in POMC neurons restored the wild type phenotype (Xu et al. 2010), underlying the potential of 5-HT2C agonists for the treatment of obesity.

Indeed, 5HT2C receptor-deficient mice are obese due to an abnormal control of feeding behavior (Berg et al. 2008). Developmental studies on food intake have revealed a chronic hyperphagia in young mutants (from the first 2 months of life through the first year of age) without changes in their body weights, adiposity levels, and in total energy expenditures, compared to wild type animals (Nonogaki et al. 1998, 2003). In contrast, by 9/10 months of age, mutants exhibit elevations of body weight and adiposity, accompanied by an increase in leptin and insulin levels, and a reduction in the total energy expense in older mutant animals (Nonogaki et al. 1998, 2003).

Mice lacking 5HT2C receptors exhibit lower thresholds for the expression of generalized seizures (Applegate and Tecott 1998), an effect modulated by other genetic factors and aging (Brennan et al. 1997).

Mutant mice also exhibit an anxiolytic phenotype (Heisler et al. 2007) and an increased responsiveness to novelty. They are also more sensitive to the effects of acute cocaine treatment on both locomotor activity and on nucleus accumbens dopamine levels (Bubar and Cunningham 2008). Mutant mice display an approximately 50% reduction in DOI-induced head-twitch response compared to their wild type littermates, suggesting the involvement of 5-HT2C receptors in the psychoactive response to hallucinogenic drugs (Canal et al. 2010).

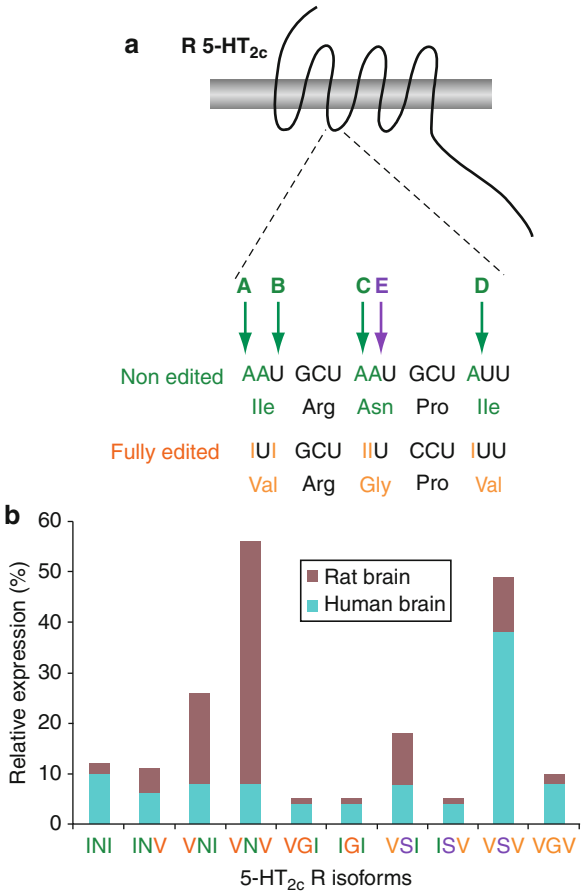
Regulation of Concentration and Activity

Exposure of 5-HT2C receptors to agonists leads to receptor desensitization (i.e., a decrease in receptor responsiveness) and down-regulation (i.e., a reduction in the total number of specific receptor binding sites without a change in apparent affinity for 5-HT) in vivo and in vitro (Bockaert et al. 2006). Several studies indicated that chronic treatment with antagonists and monoamine oxidase inhibitors induces an atypical down-regulation of 5-HT2C receptor in the choroid plexus as well as in several heterologous models (Berg et al. 2008). Chronic administration of SSRIs increases 5HT2C receptors density in the choroid plexus (Bockaert et al. 2006; Berg et al. 2008). Paradoxically, the density and functional status of 5-HT2C receptors is also elevated in experimental models of depression as well as in depressed patients (Berg et al. 2008).

Desensitization is initiated by receptor phosphorylation by G protein receptor kinase (GRK)2 (Berg et al. 2008). Receptor phosphorylation is followed by the recruitment of β-arrestins, which uncouple receptor from G protein and promote its internalization into endosomes. This phenomenon not only contributes to receptor desensitization but also allows receptor dephosphorylation and recycling to the plasma membrane in a fully resensitized state.

In addition to agonist-dependent activation, 5-HT2C receptors undergo constitutive activity. Constitutive activity toward phospholipase C effector pathway is accompanied by constitutive receptor desensitization and internalization (Berg et al. 2008). Constitutive activity at 5-HT2C receptors expressed on VTA GABAergic interneurons is responsible for tonic inhibition of mesocorticolimbic dopaminergic neurons (De Deurwaerdere et al. 2004).

RNA transcripts encoding the 5-HT2C receptor undergo adenosine to inosine editing at five sites located in the second intracellular loop in the receptor sequence, theoretically generating up to 32 different mRNAs that encode 24 receptor isoforms, ranging from the nonedited form (INI) to the fully edited one (VGV) (Fig. 1). The 5-HT2C receptor is to date the only known GPCR for which pre-mRNA editing generates multiple functional variants. RNA editing has multiple consequences on receptor function: (1) edited forms exhibit decreased constitutive activity, decreased agonist affinity, and decreased potency to



5-Hydroxytryptamine Receptor 2C, Fig. 1 RNA editing of 5-HT2C receptor transcripts. (**a**) The position of the editing sites (A, B, C, D, and the minor site E) within the exon V of human 5-HT2C receptor mRNA and the predicted amino acid sequences are shown for the nonedited INI isoform and for the fully edited VGV isoform. (**b**) 5-HT2C receptor editing efficiency at each editing site for human brain (*blue bars*) and rat brain (*brown bars*)

activate phospholipase C (Sanders-Bush et al. 2003; Werry et al. 2008); (2) the nonedited 5-HT2C receptor is capable of coupling to Gα13 protein, whereas the fully edited one fails to activate Gα13 (Sanders-Bush et al. 2003; Werry et al. 2008); (3) the nonedited form exhibits a constitutive activity at β-arrestin- and calmodulin-dependent ERK signaling (Labasque et al. 2010); and (4) editing alters 5-HT2C receptor trafficking in and out of the plasma membrane, a process reflecting their ability to associate with β-arrestins (Marion et al. 2004). Editing is modulated by 5-HT itself. Depletion of 5-HT increases the expression of receptor forms exhibiting the highest agonist affinity, whereas opposite changes of editing profile are detected following 5-HT2C receptor activation (Sanders-Bush et al. 2003; Werry et al. 2008). A recent study performed on mutant mice solely expressing the fully edited form of the receptor has suggested that editing may regulate the density of 5-HT2C receptor binding sites in brain (Olaghere da Silva et al. 2010).

Altered patterns of 5-HT2C receptor editing are observed in postmortem brains from suicide victims with a history of major depression (Iwamoto et al. 2009). Chronic treatments with antidepressants generate opposite changes of editing profiles (Sanders-Bush et al. 2003; Werry et al. 2008). Moreover, early life stress alters adult 5-HT2C receptor mRNA editing and expression of Gαq protein. Kishore and Stamm reported that Prader–Willy syndrome patients (characterized by neonatal muscular hypotonia, early childhood obesity, hypogonadism, and mental retardation) do not express the small nucleolar RNA HBII-52, a regulator of 5-HT2C receptor mRNA splicing. These patients exhibit abnormally low levels of nonedited 5-HT2C-INI receptor. Moreover, mutant mice solely expressing the fully edited form of the receptor display phenotypic characteristics of Prader–Willy syndrome, suggesting a role of serotonergic systems in Prader–Willi syndrome (Morabito et al. 2010).

Several studies have also demonstrated a critical role of 5HT2C receptors in the onset time of therapeutic response to antidepressants (Berg et al. 2008). Long-term treatment with selective 5-HT reuptake inhibitors (SSRIs) and other antidepressant classes progressively down-regulate 5HT2C receptor in rats and humans, a process paralleling their gradual onset of actions.

The 5-HT2C receptor is certainly one of the G protein-coupled receptors for which the largest number of G protein-coupled receptors-interacting proteins has been identified. Those proteins clearly control G protein-coupled receptors subcellular localization, as well as nature, kinetics, strength, and fine-tuning of G protein-coupled receptors signaling. 5-HT2C receptor interacts with a number of PDZ domain-containing proteins including Multiple PDZ domain protein (MUPP1), PostSynaptic Density protein 95 (PSD95), MAGUK p55 subfamily member 3 (MPP3), Veli3, Synapse-associated protein 97 (SAP97), Synapse-associated protein 102 (SAP102), and MAGI2

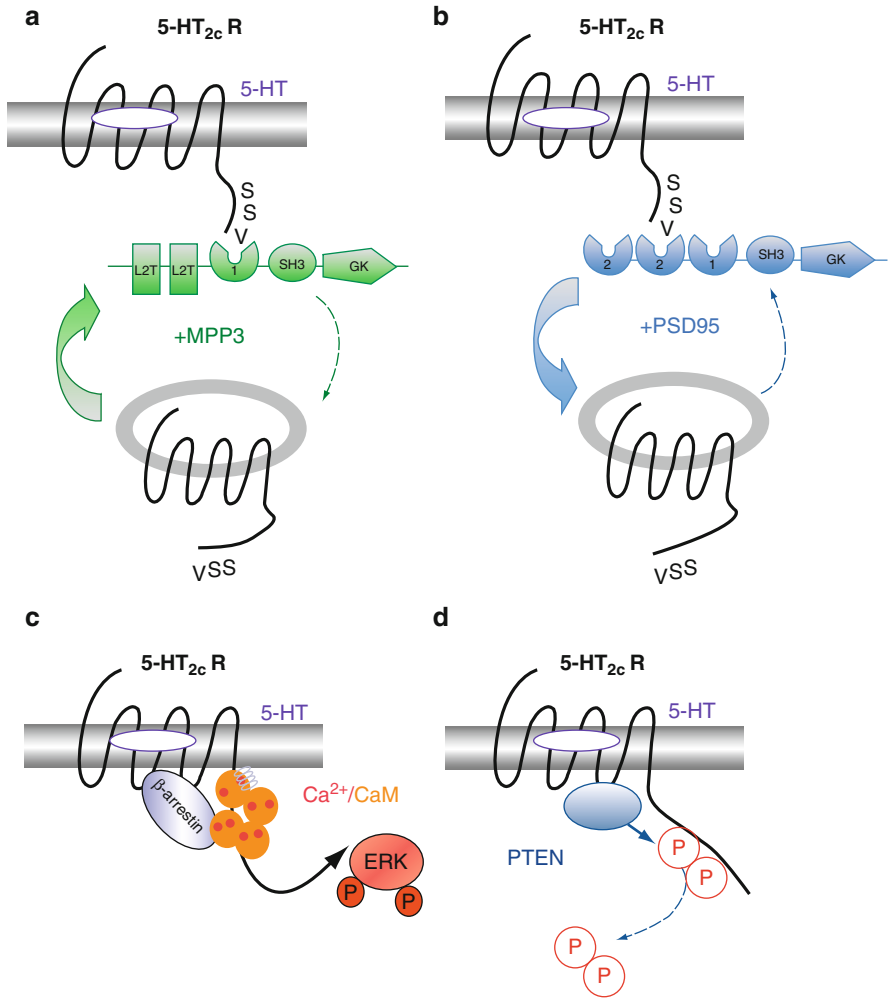
(for membrane associated guanylate kinase, WW and PDZ domain containing 2) via its C-terminal PDZ binding motif (SSV) (Becamel et al. 2002; Becamel et al. 2004). MUPP1 was the first 5-HT2C receptor-interacting protein identified using the yeast two-hybrid system (Ullmer et al. 1998). The interaction between 5-HT2C receptors and MUPP1 is dynamically regulated by agonist-dependent receptor phosphorylation of serine residues located in the PDZ binding motif (Parker et al. 2003). Receptor/MUPP1 interaction induces both conformational changes in the MUPP1 protein (Parker et al. 2003) and receptor clustering at the cell surface (Becamel et al. 2001). The 5-HT2 like *Caenorhabditis elegans* receptor SER-1 similarly interacts with a multi-PDZ domain containing protein similar to MUPP1 (designated as MPZ-1) in vulval muscle cell. This interaction facilitates SER-1 signaling (Xiao et al. 2006). PDZ partners of 5-HT2C receptor exhibit both presynaptic and post-synaptic localizations consistent with the differential distribution of the receptors at the synaptic junction. Several studies using receptors mutated on the PDZ ligand indicate that 5-HT2C receptor/PDZ protein interactions play a critical role in modulating their signal transduction properties and their desensitization (Gavarini et al. 2006). Interestingly, the effects depend on the nature of the PDZ protein associated with the receptor. For instance, association of the receptor with PSD-95 increases receptor desensitization and internalization, whereas its association with MPP3 prevents receptor internalization (Fig. 2a and b). These opposite actions highlight the importance of identifying which PDZ protein is associated with the receptor at a given time within a given neuron in native brain tissue.

PSD95 is essential for maintaining normal 5-HT2C receptor expression level and downstream signaling in vivo. $PSD95^{null}$ mice exhibit a significant reduction in 5-HT2C expression level particularly in the striatal and hippocampal regions and display a decrease in c-fos induction upon 5-HT2C receptor activation (Abbas et al. 2009). As previously reported for the association of 5-HT2C receptors with MUPP1, the interactions between the receptor and both PSD-95 and MPP3 are negatively regulated by the phosphorylation of 5-HT2C receptors on the PDZ ligand (Ser457, Ser458) (Gavarini et al. 2006).

5-HT2C receptors also interact with non-PDZ proteins. These include calmodulin, which binds to the receptor C-terminus (Becamel et al. 2002; Labasque et al. 2008). Additional calmodulin binding motifs have been identified in intracellular loops of the 5-HT2C receptor (Labasque et al. 2008). A combination of genetic and molecular approaches indicated that activation of Erk1,2 by 5-HT2C receptor, which is entirely independent of receptor' cognate G proteins, requires a physical association of CaM with the juxtamembrane region of the receptor C-terminus. CaM requirement was established in both heterologous system and authentic cellular contexts such as cortical neurons and choroid plexus epithelial cells. Differing from the classic mechanism of Erk1,2 activation by numerous GPCRs, phosphorylation of Erk1,2 induced by 5-HT2C receptor activation was entirely dependent on β-arrestins, which thereby acts in concert with CaM to activate Erk (Fig. 2c).

5-HT2C receptors interact with β-arrestins (mainly β-arrestin2) via their second intracellular loop (Berg et al. 2008). RNA editing of 5-HT2C receptors directly influences receptor interaction with β-arrestin2 (Marion et al. 2004). The unedited 5-HT2C-INI receptor is capable of interacting with β-arrestin2 in the absence of agonist, leading to constitutive receptor internalization and its accumulation within endocytic vesicles. Application of inverse agonists induces a marked redistribution of 5-HT2C-INI receptors to the plasma membrane of HEK-293 cells (Chanrion et al. 2008; Marion et al. 2004). Fully edited 5-HT2C-VGV receptors, which display the lowest level of constitutive activity, do not associate with β-arrestin2 in the absence of agonist and are mainly detected at the cell surface. Nevertheless, upon agonist treatment, the fully edited receptor associates with β-arrestin2 and undergoes rapid internalization.

5-HT2C receptors physically interact via their third intracellular loop with the tumor suppressor ▶ PTEN, an enzyme exhibiting both lipid and protein phosphatase activities (Ji et al. 2006). PTEN (for phosphatase and tensin homolog) association with 5-HT2C receptors prevents agonist-induced receptor phosphorylation at serine residues located in the receptor PDZ motif (Fig. 2d). Interaction between PTEN and 5-HT2C receptors occurs in dopaminergic neurons of the ventral tegmental area innervating the NAC, which are tonically inhibited by activated 5-HT2C receptors. This interaction plays an important role in mediating the reinforcing role of drugs (Ji et al. 2006).



5-Hydroxytryptamine Receptor 2C, Fig. 2 Interaction of 5-HT2C receptors with accessory proteins: modulation of receptor phosphorylation state and plasma membrane localization. (**a**) and (**b**) Opposite effect of PDZ proteins on 5HT2C receptors desensitization and trafficking. 5-HT2C receptors interact with MPP3 and PSD95 PDZ-containing proteins via their PDZ ligand (SSV) located at their carboxy terminal extremity. PSD95 increases desensitization of the Ca^{2+} response as well as constitutive and agonist-induced receptor internalization, whereas MPP3 stabilized the receptor at the plasma membrane and prevented desensitization of the receptor Ca^{2+} response. (**c**) Model of assembly of liganded 5-HT2C receptor with calmodulin and b-arrestin 2. In the presence of 5-HT, β-arrestin 2 binds to 5-HT2C receptor, probably via a recognition motif located in the i2 loop and common to the rhodopsin family GPCRs. β-arrestin 2 is also connected to receptor C-terminus by a Ca^{2+}-CaM dimer, that binds to the receptor upon agonist stimulation. This CaM-dependent scaffold might function to stabilize 5-HT_{2C} receptor/β-arrestin complex. (**d**) PTEN associated with the third intracellular loop of the 5-HT2C receptor induces receptor dephosphorylation and thereby reinforces effects of drugs of abuse

Major Sites of Expression and Subcellular Localization

5-HT2C receptors are exclusively expressed in the CNS. 5-HT2C receptors were first identified by radioligand binding using [^{3}H]-5-HT and [^{3}H]-mesulergine in pig choroid plexus. Further studies using autoradiography with [^{3}H]-mesulergine confirmed highest receptor density in choroid plexus in all mammalian species. 5-HT2C receptors expressed in choroid plexus control the secretion of the cerebrospinal fluid (Sanders-Bush et al. 2003). High receptor densities were detected in substantia nigra, globus pallidus, and ventromedial thalamus. A large amount of 5-HT2C receptors was also

detected in the suprachiasmic nucleus where they may be involved in the circadian rhythm. Recent studies have shown that 5HT2C receptors are expressed on GABAergic and dopaminergic neurons within the rat ventral tegmental area and on GABAergic neurons (preferentially in layers V/VI) within the prelimbic prefrontal cortex, a subregion of the medial prefrontal cortex (Berg et al. 2008; Bubar and Cunningham 2008).

[^{3}H]-mesulergine binding in monkey and human brains followed by receptor autoradiography has revealed both pre- and postsynaptic localizations of 5-HT2C receptor (Berg et al. 2008), which were further confirmed by electron microscopy studies (Becamel et al. 2002). 5-HT2C receptors exist as constitutive homodimers at the plasma membrane of living cells (Berg et al. 2008; Mancia et al. 2008). Two distinct dimerization interfaces have been characterized: the first one, located at TMI, is insensitive to receptor activation state, whereas the second one, located between TMs IV and V, depends on the nature of the ligand bound to receptors (Herrick-Davis et al. 2007).

As previously mentioned, cell surface expression of 5-HT2C receptor isoforms decreases in parallel with the degree of their constitutive activity (Marion et al. 2004). Inverse agonist treatments induce redistribution to the cell surface of constitutively active 5-HT2C receptors (Marion et al. 2004).

Ligands Interacting with the 5-HT2C Receptor

In line with its broad localization and physiological functions, the 5-HT2C receptor is considered as a therapeutic target for treating obesity, obsessive-compulsive disorder, drug abuse, sleep disorders, and anxiodepressive states (Jensen et al. 2010). During the last decade, the characterization of selective 5HT2C receptor ligands has been complicated by its close structural homology with the two other 5-HT2 receptor subtypes, namely, the 5-HT2A and 5-HT2B receptors. Accordingly, many compounds bind with high affinity to all three receptor subtypes.

1. Anorexic properties of Agonists
   5-HT2C receptors are activated by a variety of synthetic agonists such as RO60-0175, WAY163909, WAY 161503, YM348, VER2692, and BTV.X, which reduce food intake in rodents and enhance satiety (Jensen et al. 2010). More recently, Lorcaserin (ADP356) was characterized as a novel selective, high-affinity 5HT2C receptor agonist, which reduces food intake in rats (Thomsen et al. 2008).
2. Antidepressant effects of 5-HT2C ligands
   Several studies have suggested that some of the therapeutic effects of serotonin reuptake inhibitors (SSRIs) are mediated in part by the 5HT2C receptor. Chronic treatment with SSRI is associated with the down-regulation of 5HT2C receptors. This may lead to a disinhibition of the mesolimbic dopamine system that might contribute to their antidepressant action (Berg et al. 2008; Bubar and Cunningham 2008; Jensen et al. 2010). Numerous clinically effective antidepressants act as antagonists at 5-HT2C receptors. These include amitriptyline and clomipramine (tricyclics), trazodone and nefazodone (both behave as weak SSRI), citalopram and fluoxetine (SSRIs) (Berg et al. 2008), and agomelatine (a mixed 5-HT2C antagonist/melatonin agonist) (de Bodinat et al. 2010). Tetracyclic antidepressants such as mianserin and mirtazapine, which behave as antagonists of α2-adrenergic receptors and 5-HT3 receptors, were recently identified as inverse agonists at 5-HT2C receptors based on their ability to suppress basal inositol phosphate production and to increase plasma membrane localization of unedited 5-HT2C-INI receptors in HEK-293 cells as well as in cortical cultured neurons (Chanrion et al. 2008). Paradoxically, 5-HT2C receptor agonists such as WAY161503, RO 60-0175, and RO 60-0332 also exhibited antidepressant-like activity in selected models of depression, an effect that might reflect their ability to promote neurogenesis (Millan 2005).
3. Anxiolytic effects of antagonists
   Several 5-HT2C receptor antagonists (e.g., SB206553) exert a robust anxiolytic activity. These compounds also behave as inverse agonists at 5-HT2C receptors (Chanrion et al. 2008). Corroborating the anxiolytic action of antagonists, agonists like RO60-0175, WAY163909, and mCPP (*m*-chlorophenylpiperazine) display anxiogenic properties in the social interaction test (Millan 2005).
4. Antipsychotic properties of antagonists
   Numerous antipsychotics act as antagonists (or inverse agonists) at 5-HT2C receptors

(Berg et al. 2008; Jensen et al. 2010). Moreover, the 5HT2C inverse agonist SB 206553 potentiates the effect of haloperidol on dopamine release (Berg et al. 2008; Bubar and Cunningham 2008).

5. Other properties of 5HT2C ligands
   SB242084 behaves as a neutral antagonist at 5HT2C receptor signaling via Phospholipase C, whereas it acts as partial inverse agonist at Phospholipase A2, suggesting that it might be a protean ligand (Chanrion et al. 2008).
   PNU-69176E, a positive allosteric modulator, highly selective for 5-HT2C receptors has been characterized in different mammalian expression systems. PNU-69176E enhances [^{3}H]-5-HT binding to the human 5-HT2C receptor by selectively increasing 5-HT affinity for its low-affinity sites without affecting antagonist binding (Berg et al. 2008).

Summary

5-HT2C receptors still raise particular attention in view of their implication in many physiological functions and behaviors and in a large spectrum of psychiatric disorders such as anxiodepressive states, schizophrenia, obsessive-compulsive behaviors, and obesity. Accordingly, 5-HT2C receptors are considered as a major therapeutic target for the development of improved treatments of these diseases. Moreover, 5-HT2C is unique within G protein-coupled receptor superfamily to exhibit mRNA editing. Editing generates numerous 5-HT2C isoforms exhibiting different coupling properties, subcellular localization, and constitutive activity levels. Getting further insight into mechanisms controlling 5-HT2C receptor mRNA editing, signal transduction properties of receptor variants and their interaction with accessory proteins in neurons as well as their role in synaptic transmission and synaptic plasticity is, therefore, essential to discover innovative approaches in psychiatric disorders related to receptor dysfunction.

Historical Background

ATP-binding cassette (ABC) transporters represent members of a transmembrane protein superfamily that bind and hydrolyze ATP to mediate the transport of a wide array of substrates across extra- and intracellular membranes in organisms ranging from prokaryotes to man. Forty-eight ABC genes have been identified to date, which have been additionally divided into seven subfamilies ABCA through ABCG (Dean et al. 2001; Higgins 2001; Kaminski et al. 2006; Albrecht and Viturro 2007). This entry will focus on the ABCA subfamily consisting of 12 members uniformly present in humans and most vertebrate species: ABCA1-ABCA13, with the exception of ABCA11 which appears to be a pseudogene. Four additional members of the ABCA family, ABCA14-17, have been identified in rodents, however, as yet no orthologs have been described in humans, and as a result will not be discussed here. Within the ABCA subfamily, the transporters ABCA5, ABCA6, ABCA8, ABCA9, and ABCA10 share significant sequence homology and form a gene cluster locus on chromosome 17q (Table 1); these five transporters are sometimes referred to as the "ABCA6-like transporters." The importance of ABCA proteins are underscored by the fact that loss of function mutations in their genes are linked to a number of inherited diseases, such as

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

ABCA Transporters, Table 1 ABCA subfamilies and associated characteristics

Gene	Locus	Length (aa)	Expression	Functional significance	Associated diseases
ABCA1	9q31.1	2,261	Ubiquitous	Cholesterol homeostasis	Tangier disease
ABCA2	9q34	2,436	Brain	Neuronal associated lipid transport; drug resistance in cancer	Alzheimer's
ABCA3	16p13.3	1,704	Lung (alveolar type II cells)	Pulmonary surfactant secretion	Fatal surfactant deficiency, interstitial lung disease
ABCA4	1p22.1	2,273	Rod and cone photoreceptors	Transports retinal	STGD, AMD, CRD, RP
ABCA5	17q24	1,642	Skeletal muscle, kidney, and liver	Intracellular trafficking	Unknown
ABCA6	17q24	1,617	Ubiquitously liver, lung, heart, brain, and ovaries	Macrophage lipid transport	Unknown
ABCA7	19p13.3	2,146	Spleen, thymus, and bone marrow	Lipid transport	Unknown
ABCA8	17q24	1,581	Heart, liver, and muscle	Demonstrated to exert an ATPase-dependent drug transport function	Unknown
ABCA9	17q24	1,624	Heart, but found throughout the body	Macrophage lipid homeostasis	Unknown
ABCA10	17q24	1,543	Muscle, heart	Lipid transport	Unknown
ABCA12	2q34	2,595	Keratinocytes, placenta, skin, testis, and fetal brain	Lipid trafficking	Harlequin ichthyosis, lamellar ichthyosis type 2
ABCA13	7p12.3	5,058	Trachea, testis, and bone marrow		Schizophrenia and bipolar disorder

Tangier disease (ABCA1), Stargardt macular dystrophy (ABCA4), and Harlequin ichthyosis (ABCA12). An underlying theme in ABCA-associated diseases is defects in the transport of specific lipid-based substances. This entry will discuss ABCA subfamily protein structure and membrane topology, cellular function and disease associations, the intersection of ABCA transporters with cell signaling pathways, and future directions of ABCA research.

Common Structural Features of ABCA Subfamily Members

The prototypical mammalian ABCA transporter consists of two transmembrane domains (TMDs) and two nucleotide-binding domains (NBDs) encoded by a single polypeptide chain (Fig. 1). The nucleotide-binding domains (NBDs) are responsible for hydrolyzing ATP to provide energy to drive the conformational change required to transport substrates across extra- or intracellular membranes (Kaminski et al. 2006; Albrecht and Viturro 2007). The nucleotide-binding domains are the most highly conserved regions among members of the ABC transporter family. Each nucleotide-binding domain contains two sequence motifs, the Walker A (GXXGXGK(T/S) and Walker B ((R/K)XXXXGXXXXLhhhhD) motifs ("h" representing a hydrophobic amino acid), which are common to the general category of nucleotide-binding proteins. In ABCA proteins, the NBD1 and NBD2 domains are followed by conserved 80-residue signature sequences specific for the ABCA subfamily that contains the consensus sequence S/T-S/T-h-D/E-D/E. The TMDs are believed to participate in substrate translocation, and thus share little homology with other members of the subfamily. Structural topology varies significantly between the eight subclasses of ABC transporters. Topologically in the ABCA subfamily, each half transporter contains a transmembrane domain comprised of six membrane-spanning helices, followed by a soluble domain containing a NBD. In addition, each ABCA half transporter possesses a large extracellular loop, which is a characteristic unique to this subfamily (Fig. 1). The ABCA subfamily has some of the largest ABC proteins identified to date, one of which (ABCA13) is over 5,000 amino acids long and greater than 570 kDa in predicted molecular mass (Kaminski et al. 2006; Albrecht and Viturro 2007) (Table 1).

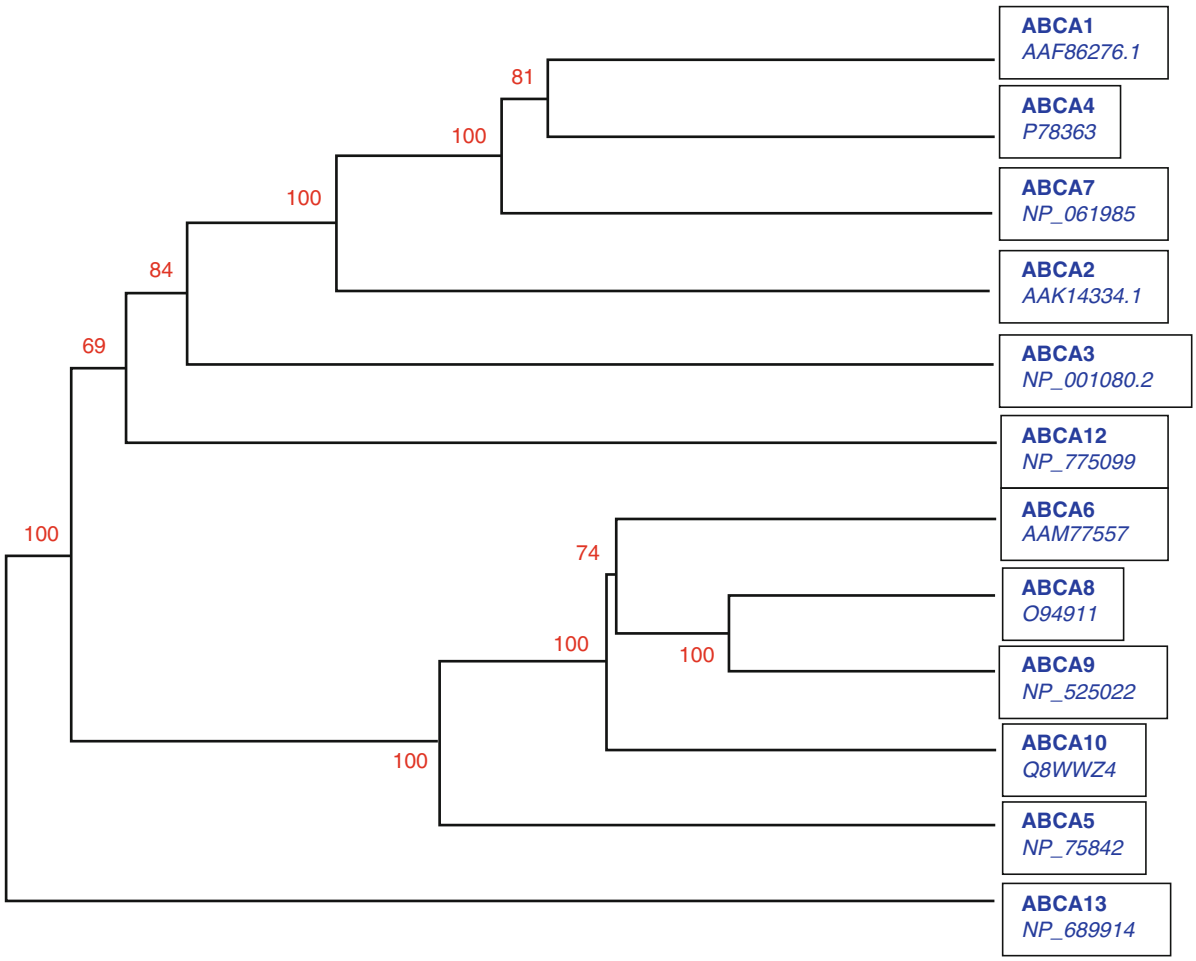
Unifying Themes Among ABCA Subgroups

The ABCA subgroup of 12 structurally related "full-size" transporters are responsible for the transport of a variety of physiologic lipid compounds in an ATP-dependent manner. A few subgroups have particular similarities between them; for example, ABCA12 and ABCA3 are exclusively localized to secretory intracellular lipid storage compartments such as lamellar granules in keratinocytes and lamellar bodies in pneumocytes. Besides cellular location, several subgroups have close sequence homology with one another. ABCA9 displays the highest amino acid sequence identity with ABCA8 (78%), ABCA6 (68%), ABCA10 (71%), and ABCA5 (53%) (Ordovas 2000; Kaminski et al. 2006; Albrecht and Viturro 2007) Fig. 2. The detailed mechanism of transport has yet to be determined for any of the mammalian ABCA transporters, so it is not yet know if that will prove to be a unifying feature of this group. Collectively, ABCA transporters are associated with a wide range of heritable disorders, display distinct tissue distribution and regulation of gene expression, yet together they underscore the critical importance of lipid homeostasis in human health and disease.

ABCA Subgroups

ABCA1 – The ABCA1 gene is expressed in a large number of human tissues with the highest levels present in the placenta, liver, lung, adrenal glands, and fetal tissues. The gene is localized to chromosome 9q31 and spans 50 exons. The 149kb ORF encodes a 2,261 aa polypeptide with a predicted molecular mass of 254 kDa (Table 1). ABCA1 has been identified to be a major regulator of HDL metabolism and mutations in this gene have been shown to be responsible for Tangier disease (Ordovas 2000). ABCA1 is believed to orchestrate cellular phospholipid and cholesterol active transport. It is required for optimal lipidiation of ApoA-1 in nascent HDL biogenesis and promotes the unidirectional efflux of cholesterol and phospholipids from the cell (Fitzgerald et al. 2010). To date, over 50 disease-associated mutations have been identified in the ABCA1 gene (Fasano et al. 2005). Individuals heterozygous for ABCA1 mutations are at increased risk for familial high-density lipoprotein deficiency (FHD), atherosclerotic cardiovascular disease (ACVD), and perhaps age-related macular degeneration (AMD) (Yu et al. 2011). Molecular diagnostic testing is increasingly available to aid in the diagnosis of ABCA1-related diseases.

In executing its cellular function, ABCA1 interacts with ApoA-I protein, oligomerizing to form a homotetramer which leads to the development of a high-affinity lipid-binding site. ApoA-I appears to interact with ABCA1 through its extracellular domains. Interaction with ApoA-I activates the phosphatidylcholine pathway by upregulating phosphatidylcholine synthase (Iatan et al. 2011). ▶ Interferon-gamma decreases ABCA1 expression levels in a JAK/STAT-regulated manner (Fitzgerald et al. 2010). Recent studies suggest that ABCA1-related ACVD could be treated using peroxisome proliferator-activated receptors (PPARs) and LSR agonists which have been shown to influence ABCA1 gene expression (Wakino and Itoh 2010).



ABCA Transporters, Fig. 2 *Phylogenetic tree of human ABCA subfamily transporter genes*. Full-length amino acid sequences were aligned using CLUSTALW2 (http://www.ebi.ac.uk/Tools/msa/clustalw2/) and phylogenetic analysis was performed utilizing the PHYLIP software (http://evolution.genetics.washington.edu/phylip.html). Bootstrap values (%) out of 100 iterations are indicated at each branch point

ABCA2 – ABCA2 is highly expressed in the cells of the ovary, nervous (CNS), and hematopoietic systems. Functionally, it is associated with lipid transport and drug resistance in cancer cells, including tumor stem cells. Cellular immunolocalization reveals co-localization of ABCA2 with late endolysosomes and trans-Golgi organelles where it appears to function in cholesterol homeostasis and LDL metabolism (Mack et al. 2006). The gene is localized to chromosome 9q34.3 and spans 48 exons. The 149kb ORF encodes a 2,436 aa polypeptide with a predicted molecular mass of 270 kDa. Alternative splicing of the first exon to the second results in two variants, 1A and 1B.

Studies have indicated a relationship between ABCA2 and both early onset and late onset/sporadic Alzheimer's disease. In vitro studies showed that; ABCA2 is highly expressed in human neuroblastoma cells and co-localizes with beta-amyloid; overexpression of ABCA2 increased amyloid precursor protein (APP) protein levels. A single-nucleotide polymorphism in human ABCA2 has been found to be associated with early development of this disease (Mace et al. 2005). ABCA2 is a cholesterol responsive gene along with ABCA1 and ABCA7. Micro RNA-mediated downregulation of the ABCA2 gene product has been observed in untreated colon cancer suggesting a possible therapeutic manipulation of gene expression in the future.

ABCA3 – The ABCA3 protein is highly expressed in the lung and has been localized primarily to the

outer, or limiting, membrane of the lamellar bodies of type II alveolar structures. The ABCA3 gene is localized to chromosome 16p13.3 and spans 33 exons. The ORF encodes a 1704 aa polypeptide with a molecular mass of 191 kDa (Table 1). Consistent with glucocorticoid-responsive regulation of gene expression, expression of ABCA3 increased more than 30-fold following stimulation of fetal lung explants with dexamethasone, cAMP, and isobutylmethylxanthine (Takahashi et al. 2005; van der Deen et al. 2005; Kaminski et al. 2006).

ABCA3 has been shown to play an important role in the formation of pulmonary surfactant which lowers the surface tension at the air–liquid interface thus preventing the collapse of the alveoli. A wide range of mutations (>150) within ABCA3 have been linked to fatal respiratory distress syndrome in the neonatal period, and with interstitial lung disease in older infants, children, and adults (Wert et al. 2009). ABCA3 appears to function to import surfactant phospholipids, such as phosphatidylcholine (PC) and phosphatidylglycerol (PG), from the cytosol into the lamellar body and is thought, therefore, to be important for lamellar body biogenesis. ▶ STAT3, activated by ▶ IL6, regulates ABCA3 expression and influences lamellar body formation in alveolar type II cells (Matsuzaki et al. 2008). The *C. elegans* protein, ced-7, is homologous to human ABCA3. Ced-7 functions in the engulfment of cell corpses during programmed cell death, although it is not known if mammalian ABCA3 also performs a similar function.

ABCA4 – ABCA4 (previously referred to as ABCR or the rim protein) is a retina-specific member of the ABCA subfamily. It was the first ABCA transporter to be causatively linked to genetic disease (Allikmets et al. 1997). The ABCA4 gene spans nearly 150 kb and contains at least 50 exons (Table 1). It encodes a 2,273 amino acid protein which is localized in the retina along the rims of rod and cone photoreceptor outer segment disk membranes. ABCA4 may act as an ATP-dependent flippase that translocates N-retinylidene-phosphatidylethanolamine (-PE) from the lumen to the cytoplasmic side of the disk membrane (Biswas-Fiss 2008; Tsybovsky et al. 2010; Pollock and Callaghan 2011). This view is supported by the observations that ABCA4 indeed binds the retinoid N-retinylidene-PE with high affinity (Molday et al. 2006). Recently, the ECD2 domain of ABCA4 was shown to bind all-*trans* retinal specifically (Biswas-Fiss et al. 2010). Efflux of all-*trans* retinal is required for the continued recycling of retinoids released from photobleached rhodopsin as part of the visual transduction cycle. Studies conducted with ABCA4 (+/−) mice support the hypothesis that lack of ABCA4 transport activity may lead to the accumulation of toxic all-trans retinal derivatives (lipofuscin) in the rod and cone photoreceptors. Accumulation of lipofuscin leads to apoptosis of the supporting retinal pigment epithelium and, eventually, the photoreceptors themselves (Mata et al. 2001).

To date >500 sequence variations in the ABCA4 gene have been identified which are linked to four macular degenerative diseases including Stargardt disease (STGD), cone-rod dystrophy (CRD), autosomal retinitis pigmentosa type 19 (RP19), and age-related macular degeneration (AMD) (Tsybovsky et al. 2010; Pollock and Callaghan 2011). The mutations are found throughout the entire reading frame of the gene and significant progress has been made in determining their biochemical significance (Biswas-Fiss 2008; Tsybovsky et al. 2010; Pollock and Callaghan 2011). ABCA4-related diseases vary in their age of onset and speed of progression – yet they all eventually lead to blindness. Genotyping of patients through microarray and DNA sequencing is currently available, and the future holds promise for some in the form of gene therapy. The challenge today is to correlate the numerous ABCA4 mutations with the broad range of clinical phenotypes and to understand how this translates to ABCA4 protein dysfunction at a molecular level. Development of a transport assay would be a major step forward toward accomplishing this goal.

ABCA6-Like Transporters – Five closely related members of the human ABCA subfamily form a compact cluster on chromosome 17q24.2–3, comprising the genes for ABCA5, 10, 6, 9, 8 (in that order) (Table 1). The common chromosomal location of these ABCA6-like transporters and their overall high peptide sequence homology strongly supports the hypothesis that these transporters evolved from a common ancestral gene (Dean et al. 2001). The exact cellular function of ABCA6-like transporters remains unclear. Recent studies suggest that ABCA6, ABCA9, and ABCA10 may play a role in the connective tissue disorder pseudoxanthoma elasticum (PXE) (Schulz et al. 2006). The finding that the genes for ABCA6, 9, and 10 are regulated by cholesterol in human macrophages suggests their potential involvement in lipid

transport processes in these cells (Takahashi et al. 2005; Kaminski et al. 2006; Fitzgerald et al. 2010). Immunohistochemical studies revealed that ABCA5 is highly expressed in cardiomyocytes of the heart, oligodendrocytes and astrocytes of the brain, alveolar type II cells of the lung, and Leydig cells of the testis. Much remains to be understood about this subgroup of ABCA transporters, including their disease associations, transported ligands, and the physiological significance of their clustering at the 17q24 locus.

ABCA7 – The ABCA7 transporter gene was initially cloned from human macrophages in which it is subject to regulation by cholesterol influx and efflux via the sterol regulatory-binding element 2 (Tanaka et al. 2011). The ABCA7 gene contains 46 exons and spans nearly 32 kb being localized to chromosome 19p13.3. The ORF encodes a 2,146 amino acid protein with a predicted molecular weight of 235 kDa. Its expression levels are regulated in a manner opposite that of ABCA1 protein, which is upregulated in the presence of sterols. ABCA7 is highly expressed in myelo-lymphatic tissues with highest expression in peripheral leukocytes, thymus, spleen, and bone marrow; however, it was also found in platelets and keratinocytes (Takahashi et al. 2005; Kaminski et al. 2006; Fitzgerald et al. 2010). ABCA7 shows the greatest homology with ABCA1 (55%) and ABCA4 (49%) transporters. ABCA7 has been implicated in the regulation of ceramide and phospholipid export from the macrophages of human microgila (Wang et al. 2003; Takahashi et al. 2005; Kim et al. 2008). The precise physiological role of ABCA7 remains uncertain. Tanaka and coworkers observed identity between the ECD1 domain (residues 195 and 352) of ABCA7 and a Sjögren's syndrome autoantigen (Tanaka et al. 2003). They determined that ABCA7 encodes the autoantigen SS-N and plasma cells infiltrating salivary glands of patients with Sjögren's syndrome were immunoreactive against a monoclonal antibody derived from the ABCA7 ECD1.

ABCA7 mediates the formation of HDL when exogenously transfected and expressed; however, no endogenous effect of ABCA7 in HDL formation has been found. Recently, ABCA7 has been linked to phagocytosis regulated by sterol regulatory element-binding protein 2. Coupled with the observation that HDL apolipoproteins stabilize ABCA7 against calpain-mediated degradation, ABCA7 may represent a link between sterol homeostasis and the host-defense response infection, inflammation, and apoptosis (Tanaka et al. 2003). Further research is required to delineate the specific substrate(s) of ABCA7 and its precise physiological function in these processes.

ABCA11 – ABCA11 is considered a pseudogene as no functional "ABCA11" gene been found in *Homo sapiens* (Kaminski et al. 2006).

ABCA12 – ABCA12 is a keratinocyte transmembrane lipid transporter protein associated with the transport of lipids in lamellar granules (LG) to the apical surface of granular layer keratinocytes. ABCA12 localizes throughout the entire Golgi apparatus to LGs at the cell periphery, mainly in the granular layer keratinocytes. ABCA12 was first identified in human placenta yet is highly expressed in the skin, testis, and fetal brain (Annilo et al. 2002; Kaminski et al. 2006; Wenzel et al. 2007). The gene is composed of 53 exons and maps to chromosome 2q35. ABCA12 mutations are known to underlie the three main types of autosomal recessive congenital ichthyoses: harlequin ichthyosis (HI), lamellar ichthyosis, and congenital ichthyosiform erythroderma (Albrecht and Viturro 2007). Fifty-two mutations have been identified to date. Studies have shown that the nature and severity of mutations in the ABCA12 gene accounts for the resulting clinical phenotype: Harlequin ichthyosis (HI), which is a severe form of congenital ichthyosis, is typically fatal in the first few days of life, while a second phenotype is a milder form manifesting as lamellar ichthyosis type 2 (Kaminski et al. 2006). Ceramide was reported to upregulate ABCA12 expression via PPAR (peroxisome proliferator-activated receptor) delta-mediated signaling pathway, providing a substrate-driven, feed-forward mechanism for regulation of this key lipid transporter.

ABCA13 – ABCA13 represents the largest ABC transporter comprising 5,058 amino acids (Prades et al. 2002). In normal tissues, the highest mRNA expression of the ABCA13 full-length mRNA was found in human trachea, testis, and bone marrow. Prades et al. (2002) determined that the ABCA13 gene contains 62 exons and spans more than 450 kb. Exons 17 and 18 are large, containing 4,779 and 1,827 bp, respectively. Research has found that ABCA13 shares a common genomic region on chromosome 7p12.3 with the locus linked to the T-cell tumor invasion and metastasis, INM7 (Prades et al. 2002). With this information and with the high expression levels in

leukemic cell lines, it has been suggested that ABCA13 may play a possible role in hemato-oncological pathologies (Kaminski et al. 2006). More recently, human genetic data suggest variants in the ABCA13 locus are associated with schizophrenia, bipolar disorder, and depression (Knight et al. 2009). Despite these insights into the physiological role of ABCA13, further studies are required to determine the exact functional role and physiological substrates of this transporter.

Summary

The ABCA subfamily form an intriguing group of transporters whose function broadly relates to lipid homeostasis. Although in several instances, such as with the ABCA6-like subgroup, the exact cellular function and mechanism of action remain unknown, their important physiological role is underscored by the often severe diseases that result from mutations in their genes. Prospects for future research relate to the degree in which each transporter is understood. For relatively well-characterized transporters such as ABCA1, ABCA3, and ABCA4, a significant amount is known about the prospective ligand a well-established link between a given monogenic disorder and mutations in the transporter-encoding gene exist. For these transporters, current and future research aimed at understanding the genotype–phenotype correlation (biochemical as well as clinical) is important, so that more accurate prognoses and specific therapies may be implemented. Ultimately, the development of transport assays, which can analyze the actual transport event itself, must be developed in order to determine the precise effect of a given mutation on transporter function. In the case of less well-understood transporters, such as the ABCA6-like subgroup, fundamental research is required to determine the nature of the transport ligand and how this relates to human health and disease. Finally, defining the role of protein–protein interactions in ABCA subgroup mechanism of action is necessary in order to determine the synergistic relationships between the other members of the ABCA and/or ABC protein family as well as to define a given ABCA proteome. Certainly, it can be said that the roadmap of ABCA disease-related mutations provide scientists with a wealth of clues to uncover the secrets of this important class of ABC transporters.

ACK1

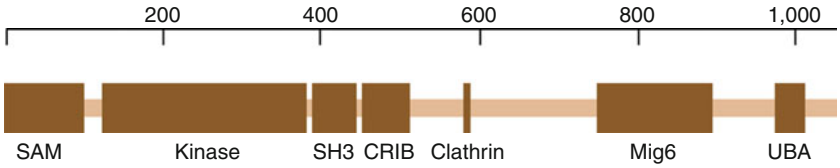
Takaya Satoh
Department of Biological Science, Graduate School of Science, Osaka Prefecture University,
Sakai, Osaka, Japan

Synonyms

Activated Cdc42Hs-associated kinase 1; CD38 negative kinase 2; Proline-rich tyrosine kinase 1; Pyk1; Tnk2

Historical Background

The tyrosine kinase ACK1 (activated Cdc42Hs-associated kinase 1) was first identified as a specific target of the small GTPase Cdc42 (Manser et al. 1993). ACK1, a related tyrosine kinase Tnk1, and the non-tyrosine kinase protein Mig6 (Gene 33/receptor-associated late transducer) constitute a family of proteins with conserved domain structures. In addition to the kinase catalytic domain, various domains and amino acid sequence motifs, which are responsible for the interaction with diverse signal transducing proteins, are found in ACK1 (Fig. 1). Several types of splice variants (including a protein previously designated ACK2 [activated Cdc42Hs-associated kinase 2]) are present. Two orthologues of the mammalian ACK1 gene, *DACK* and *DPR2*, exist in the *Drosophila melanogaster* genome. In *Caenorhabditis elegans*, two orthologues encode ACK family protein tyrosine kinases, ARK-1 and B0302.1.



ACK1, Fig. 1 Domain structure of ACK1. Domains found in the mouse ACK1 protein (NCBI accession: NP_058068) are schematically shown. SAM, sterile alpha motif domain; Kinase, tyrosine kinase catalytic domain; SH3, Src homology 3 domain; CRIB, Cdc42/Rac interactive binding domain; Clathrin, clathrin-binding motif; Mig6, Mig6 homology domain; UBA, ubiquitin-association domain. The upper scale indicates the amino acid position number

Regulation of ACK1 Activity

ACK1 is a multidomain non-receptor tyrosine kinase expressed in a variety of tissues in mammals. In addition to the N-terminally located kinase catalytic domain, ACK1 contains a membrane-targeting sterile alpha motif domain, a Src homology 3 (SH3) domain, a Cdc42/Rac interactive binding domain, a clathrin-binding motif, a Mig6 homology domain, a proline-rich domain (which overlaps with the clathrin-binding motif and the Mig6 homology domain), and a ubiquitin-association domain (Fig. 1). These domains are responsible for recognition and interaction of diverse binding partners (Mahajan and Mahajan 2010).

Originally, ACK1 was identified as a specific target of Cdc42: The active GTP-bound, but not inactive GDP-bound, Cdc42 interacts with the Cdc42/Rac interactive binding domain of ACK1. Thus, Cdc42 is expected to have a crucial role in the regulation of ACK1. Although co-expression of Cdc42 in cells results in tyrosine phosphorylation of ACK1, the binding of Cdc42·GTP to purified ACK1 was found to be insufficient for stimulating its tyrosine kinase activity in vitro (Yang et al. 1999; Yokoyama and Miller 2003). Given that many signaling molecules interact with ACK1, Cdc42 may not be a unique upstream regulator, but rather may collaborate with other regulatory proteins to modulate the activity of ACK1 in the cell.

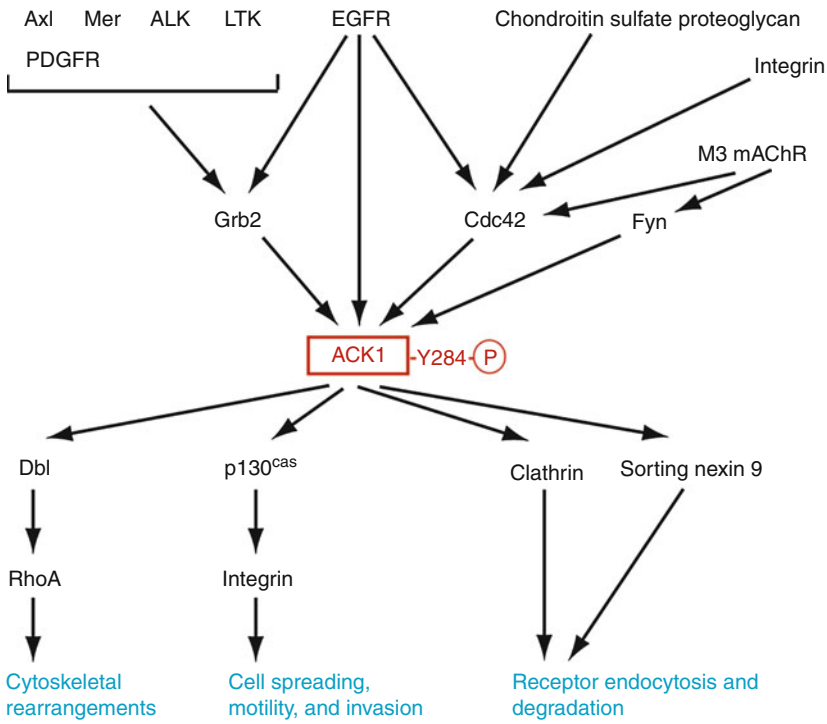
Many protein kinases are catalytically activated through conformational change of the activation loop triggered by its phosphorylation. Therefore, ACK1 kinase activity may also be modulated by phosphorylation of the activation loop. One tyrosine (Y284, all residue numbers hereafter are based on the mouse ACK1 sequence [NCBI accession: NP_058068]), which exists within the activation loop of ACK1, was identified as a primary autophosphorylation site (Yokoyama and Miller 2003). Comparison of tertiary structures of phosphorylated and unphosphorylated activation loops of ACK1, unexpectedly, revealed that ACK1 adopts an activated conformation independent of phosphorylation of Y284 (Lougheed et al. 2004). Therefore, the activation loop of ACK1 is not autoinhibitory, although it may have another role in the regulation of catalysis.

Recently, the intramolecular association between the N-terminal kinase catalytic domain and the C-terminal Mig6 homology domain, which may suppress the kinase activity, has been revealed (Prieto-Echagüe et al. 2010). In fact, amino acid changes in kinase catalytic (E346K) and Mig6 homology (F836A) domains disrupt this interaction, and markedly increase the kinase activity (Prieto-Echagüe et al. 2010). In addition, the former mutation has been characterized as a constitutively activated mutant in cancer cells (see below).

Although the underlying mechanism remains totally unknown, the tyrosine phosphorylation level of ACK1 significantly increased in response to temperature shift-down to 25°C and hyperosmotic shock (Satoh et al. 1996).

Role of ACK1 in Signaling Triggered by Cell-Surface Receptors

The role of ACK1 in growth factor receptor signaling has been well documented (Fig. 2). Epidermal growth factor (EGF) treatment of cells induces rapid and transient tyrosine phosphorylation of ACK1 (Satoh et al. 1996; Galisteo et al. 2006). In addition, ACK1 binds to the adaptor protein Grb2 through its N-terminal SH3 domain, which is enhanced by EGF stimulation (Satoh et al. 1996). The binding of ACK1 to Grb2 is required for EGF-dependent tyrosine phosphorylation of ACK1 (Kato-Stankiewicz et al. 2001).



ACK1, Fig. 2 Role of ACK1 in signaling triggered by cell-surface receptors. ACK1-mediated signaling pathways downstream of various receptors are shown. EGFR, epidermal growth factor receptor; mAChR, muscarinic acetylcholine receptor; PDGFR, platelet-derived growth factor receptor

Tyrosine-phosphorylated ACK1 in turn phosphorylates and activates its downstream target Dbl, leading to the induction of transient cytoskeletal rearrangements through RhoA (Ras homologue A) (Kato-Stankiewicz et al. 2001; see below). Mig6 binds to the EGF receptor and inhibits EGF signaling, sharing its EGF receptor-binding domain with ACK1. Thus, it is anticipated that ACK1 also binds to the EGF receptor directly, and negatively regulates downstream signaling. In addition to the EGF receptor, diverse receptor tyrosine kinases, such as Axl, Mer, ALK, LTK, and the platelet-derived growth factor receptor interact with ACK1 (Galisteo et al. 2006; Pao-Chun et al. 2009). The binding of ACK1 to Axl, ALK, LTK is mainly mediated by Grb2, having a role in ligand-induced down-regulation (Pao-Chun et al. 2009). In *C. elegans*, ARK-1 also physically interacts with SEM-5 (a *C. elegans* orthologue of Grb2), inhibiting LET-23 (a *C. elegans* orthologue of the EGF receptor)-mediated ovulation.

Melanoma chondroitin sulfate proteoglycan is a cell-surface antigen that stimulates integrin-$\alpha_4\beta_1$-mediated adhesion and spreading of melanoma cells. Clustering of this antigen induces the activation of Cdc42 and ACK1, leading to tyrosine phosphorylation of $p130^{Cas}$, a key molecule for the induction of tumor cell motility and invasion (Eisenmann et al. 1999). Therefore, ACK1 may play an important role in the regulation of melanoma chondroitin sulfate proteoglycan-dependent melanoma cell migration and invasion. ACK1 is also activated upon cell attachment to fibronectin in a Cdc42-dependent manner, suggesting a role in outside-in signaling of integrins (Yang et al. 1999; Galisteo et al. 2006). Stimulation of the M3 muscarinic acetylcholine receptor also triggers the activation of ACK1. Neither the increase in intracellular Ca^{2+} nor the activation of protein kinase C is required for this ACK1 activation. Instead, Cdc42 and the tyrosine kinase Fyn may be involved.

Beyond regulating downstream signaling cascades, ACK1 participates in the regulation of ligand-induced endocytosis and degradation of the receptor. ACK1 possesses a conserved clathrin-binding motif, which in fact interacts with the N-terminal head region of the clathrin heavy chain (Teo et al. 2001; Yang et al. 2001). Activated Cdc42 negatively regulates this interaction. When overexpressed, ACK1 competes with AP-2 for the binding to clathrin, and thus suppresses clathrin-mediated endocytosis of the transferrin receptor. Furthermore, ACK1 directly binds to sorting nexin 9 (SH3PX1) through the interaction between the

proline-rich domain of ACK1 and the SH3 domain of sorting nexin 9, thereby facilitating endocytosis of the EGF receptor. EGF-induced degradation of the EGF receptor is mediated by ubiquitination. ACK1 binds to the ubiquitinated EGF receptor through its ubiquitin-association domain, thereby regulating ligand-induced EGF receptor degradation (Shen et al. 2007). In addition, ACK1 is ubiquitinated by E3 ubiquitin ligases Nedd4-1 and Nedd4-2 and subjected to degradation along with the EGF receptor in response to EGF stimulation.

ACK1 as a Link Between Small GTPases

Dbl is the first-identified guanine nucleotide exchange factor (GEF) for Rho family GTPases. Upon tyrosine phosphorylation of Dbl by activated ACK1, GEF activity of Dbl toward the Rho family is significantly increased (Kato et al. 2000). Thus, ACK1 may act as a link between Rho family GTPases, forming a positive feedback loop of Cdc42 signaling (Fig. 3). Tyrosine-phosphorylated Dbl also activates RhoA, leading to cytoskeletal rearrangements (Kato-Stankiewicz et al. 2001).

Another GEF whose activity is regulated by ACK1 is Ras-GRF1 ($CDC25^{Mm}$ (mammalian homologue of cell division cycle 25)) (Kiyono et al. 2000). Ras-GRF1 targets both Ras and Rac1 through its CDC25 homology and Dbl homology domains, respectively. The latent GEF activity toward Rac1 is induced by G protein βγ subunits and ▶ Src-dependent tyrosine phosphorylation of Ras-GRF1 although its Ras GEF activity remains unchanged. In contrast, co-expression of activated ACK1 causes tyrosine phosphorylation of Ras-GRF1 and promotes its GEF activity toward Ras. Through this mechanism, ACK1 links Cdc42 to Ras. Tyrosine phosphorylation of Ras-GRF1 by ACK1, on the other hand, does not induce Rac1 GEF activity. Taken together, different tyrosine kinases including ACK1 phosphorylate different residues of Ras-GRF1, leading to selective induction of GEF activity toward Ras or Rac1.

ACK1, Fig. 4 ACK1 in Cancer. Signaling pathways downstream of activated ACK1 in cancer cells are shown. Androgen R, androgen receptor; Wwox, WW domain-containing oxidoreductase

ACK1 in Cancer

Several lines of evidence support the notion that ACK1 is intimately associated with cancer (Fig. 4). Overexpression of a dominant-negative mutant of ACK1 or small interfering RNA-mediated knockdown of ACK1 inhibited v-Ras-transformed cell survival and growth, suggesting a crucial role of ACK1 in cell transformation (Nur-E-Kamal et al. 2005). ACK1 is also involved in the regulation of $p130^{Cas}$-mediated

signaling, such as spreading of melanoma cells (Eisenmann et al. 1999) and migration of breast epithelial cells. Thus, ACK1 may have a critical role particularly in invasion and metastasis of cancer cells. In fact, overexpression of ACK1 in tumor cells enhances invasive phenotypes in vivo and in vitro (van der Horst et al. 2005). Furthermore, amplification of the *ACK1* gene identified in human primary tumors correlates with poor prognosis (van der Horst et al. 2005).

The involvement of ACK1 in prostate cancer progression has been well described. Expression and tyrosine phosphorylation levels of ACK1 are elevated in clinical specimens of androgen-independent prostate cancer (Mahajan and Mahajan 2010; van der Horst et al. 2005). A constitutively activated ACK1 mutant, when expressed in a human prostatic adenocarcinoma cells, remarkably promotes anchorage-independent growth and tumor formation in nude mice (Mahajan and Mahajan 2010). Transgenic mice expressing this constitutively activated ACK1 in the prostate indeed develop prostatic intraepithelial neoplasia (Mahajan and Mahajan 2010).

One mechanism for ACK1-dependent promotion of prostate tumorigenesis is negative regulation of the proapoptotic tumor suppressor WW domain-containing oxidoreductase (Mahajan and Mahajan 2010). Activated ACK1 associates with and tyrosine phosphorylates WW domain-containing oxidoreductase, leading to its polyubiquitination followed by degradation.

Another mechanism is tyrosine phosphorylation of the androgen receptor by ACK1 (Mahajan et al. 2007). Activation of the androgen receptor may be important in androgen-independent progression of prostate cancer. Activated ACK1 phosphorylates two tyrosine residues in the transactivation domain of the androgen receptor, leading to the recruitment of the androgen receptor to the androgen-responsive enhancer and subsequent androgen-inducible gene expression in the absence of androgen. Thereby, activated ACK1 promotes androgen-independent growth of prostate xenograft tumors (Mahajan et al. 2007). On the other hand, ACK1 is required for tyrosine phosphorylation and activation of the androgen receptor by ligand-activated HER2 as evidenced by the effect of knockdown and the treatment with a specific inhibitor, dasatinib (Mahajan et al. 2007; Liu et al. 2010). Therefore, ACK1 activation downstream of cell-surface receptor tyrosine kinases such as HER2 may be a crucial event in prostate cancer cells. Another ACK1-specific inhibitor, termed AIM-100, also suppresses phosphorylation and transcriptional activation of the androgen receptor (Mahajan and Mahajan 2010).

The activation of the pro-survival protein kinase Akt has been implicated in a variety of human cancers. It has been well documented that Akt activation occurs through specific phosphorylation of serine and threonine residues downstream of ▶ phosphatidylinositol 3-kinase. Recently, a novel signaling mechanism whereby ACK1 directly regulates Akt by phosphorylating a tyrosine residue located in the kinase domain (Mahajan and Mahajan 2010). Upon tyrosine phosphorylation, Akt is translocated to the plasma membrane and then activated. This mechanism, in fact, has become relevant to human cancers. The expression level of Akt that is phosphorylated by ACK1 is significantly increased in breast cancers, and is correlated with the severity of disease progression.

Four somatic missense mutations were identified in ACK1 in various cancers: Mutations in the N-terminal sterile alpha motif domain (R34L and R99Q) were identified in lung adenocacinoma and ovarian mucinous carcinoma, respectively, a mutation in the kinase catalytic domain (E346K) was found in ovarian endometrioid carcinoma, and a mutation in the SH3 domain (M409I) was identified in gastric adenocacinoma. All of these mutations increase ACK1 kinase activity, suggesting that somatic mutations may represent a mechanism for oncogenic activation of ACK1 (Prieto-Echagüe et al. 2010). Several somatic and germ-line mutations were detected also in tumor cell lines. Among them, a mutation in the ubiquitin-association domain (S1002N) renders ACK1 unable to bind ubiquitin, and maintains the epidermal growth factor receptor level after stimulation. Thereby, this ACK1 mutant may contribute to prolonged mitogenic signaling in cancer cells.

Summary

ACK1 is a non-receptor tyrosine kinase originally identified as a target of the small GTPase Cdc42. ACK1 interacts with diverse signal transducing proteins through multiple domains. The kinase activity of ACK1 is suppressed by the intramolecular interaction between the catalytic domain and the C-terminal Mig6 homology domain. Upstream signals are believed to

induce conformational change of inactive ACK1, leading to its activation. ACK1 functions downstream of a variety of receptor tyrosine kinases such as the EGF receptor. In addition, other types of cell-surface receptors, including melanoma chondroitin sulfate proteoglycan and integrins, employ ACK1 as a transducer of signals that regulate cell motility. ACK1 is also responsible for ligand-induced endocytosis of cell-surface receptors through the binding to the clathrin heavy chain and sorting nexin 9. ACK1 is ubiquitinated by E3 ubiquitin ligases and subjected to degradation. ACK1 acts as a link between small GTPases by phosphorylating GEFs, such as Dbl and Ras-GRF1. Gene amplification and mutational activation of ACK1 are closely associated with human cancers. Particularly, the involvement of ACK1 in prostate cancer is well addressed. ACK1 phosphorylates the androgen receptor and the serine/threonine kinase Akt, leading to their activation. Overall, ACK1 is a key regulator of cell-surface receptor signaling in various types of cell responses including cytoskeletal rearrangements and transcriptional activation. Once excessively activated, ACK1 causes unregulated proliferation and survival, properties characteristic of cancer cells. Thus, ACK1 may be a promising therapeutic target of cancers.

Activators of G-Protein Signaling (AGS)

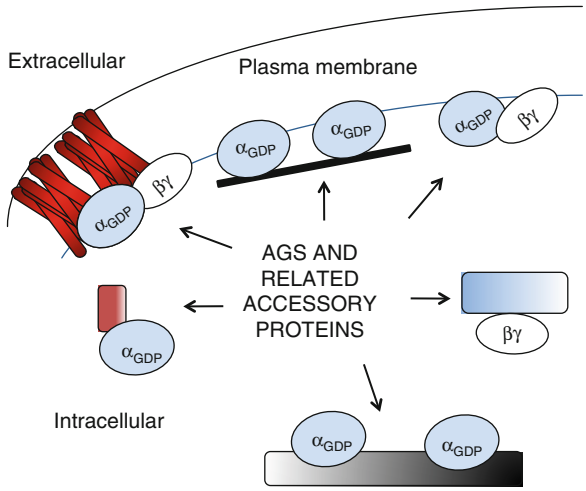
Joe B. Blumer and Stephen M. Lanier
Department of Cell and Molecular Pharmacology and Experimental Therapeutics, Medical University of South Carolina, Charleston, SC, USA

Synonyms

DYNLT1/Tctex-1 (AGS2); FNDC1/fibronectin type III domain containing 1 (AGS8); GNAO /Gαo/guanine nucleotide binding protein/alpha activating activity polypeptide O (AGS10); GPSM1/G-protein signaling modulator 1 (AGS3); GPSM3/G-protein signaling modulator 3/G18/NG1 (AGS4); GPSM2/G-protein signaling modulator 2/LGN/mPINS (AGS5); MITF/microphthalmia-associated transcription factor (AGS13); PSMD4/Rpn10/proteasome (prosome, macropain) 26S subunit, non-ATPase, 4 (AGS9); RAS D1/DEXRAS1 (AGS1); RGS 12/regulator of G-protein signaling 12 (AGS6); TFE3/transcription factor binding to IGHM enhancer 3 (AGS11); TFEB/transcription factor EB (AGS12); TRIP13/16E1BP/thyroid hormone receptor interactor 13 (AGS7).

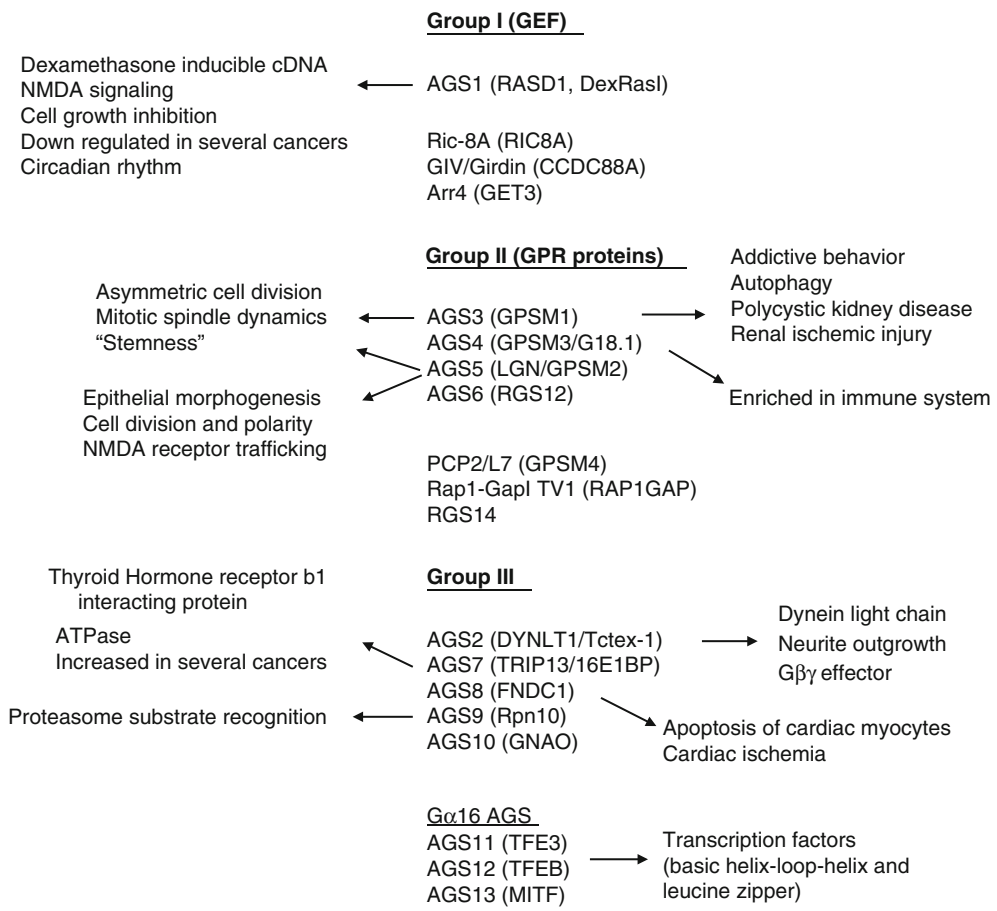
Historical Background

Activators of G-protein signaling (AGS) proteins define a group of proteins identified in a yeast-based functional screen of mammalian cDNA libraries as receptor-independent activators of the G-protein signaling cascade. Activators of G-protein signaling are one subgroup of accessory proteins for G-protein signaling systems. Accessory proteins are generally defined as proteins other than the core triad of receptor (R), G-protein, and effector (E) that regulate the efficiency and/or specificity of signal transfer from G-protein coupled receptors (GPCRs) to G-proteins, segregate a signaling complex to microdomains of the cell, regulate the basal activity of the system, and/or provide alternative modes of signal input to G-protein signaling systems that operate independent of a typical GPCR. Such accessory proteins may influence G-protein signaling systems operating at the cell cortex or at intracellular locations (Fig. 1).



Activators of G-Protein Signaling (AGS), Fig. 1 *Schematic diagram indicating points of influence of accessory proteins on G-protein signaling systems.* AGS and related proteins may serve as alternative binding partners for G-protein subunits and also regulate signal transfer at multiple points within the broader G-protein signaling system (The figure is a modification of the concept figure presented by Sato et al. 2006)

The concept of accessory proteins resulted from a confluence of several independent lines of investigation (see Blumer et al. 2007, 2011; Gonczy 2008; Knoblich 2010; Sato et al. 2006; Willard et al. 2004). These lines of investigation included cell-specific differences in signal transfer from R to G, the partial purification of a putative non-receptor G-protein activator from extracts of NG108-15 cells, identification of G-protein subunits in intracellular organelles, identification of unexpected binding partners for G-protein subunits, and the identification of non-receptor proteins that could influence the activation state of G-proteins eventually leading to the development of a functional yeast-based screen for mammalian entities that activated G-protein signaling in the absence of a receptor (Sato et al. 2006; Cismowski and Lanier 2005; Cismowski et al. 1999; Takesono et al. 1999). Interspersed with these biochemical approaches was the realization that there were changes in signal processing through G-protein signaling systems that occurred independent of any obvious changes in receptor number or G-protein expression levels, suggesting additional undefined regulatory mechanisms. Another line of investigation evolved out of the study of asymmetric cell division in *Drosophila melanogaster* neuroblasts and sensory organ precursor cells in parallel with the *Caenorhabditis elegans* embryo.



Activators of G-Protein Signaling (AGS), Fig. 2 *Functional roles of different Activators of G-protein signaling*. This figure includes proteins that were not isolated in the yeast-based functional screen as AGS proteins, but were identified in other protein interaction or functional screens and shown to exhibit biological activity consistent with their inclusion as Group 1 (RIC8A, CCDC88A, GET3) or Group II (GPSM4, RAP1GAP, RGS14) AGS proteins (Modified from Blumer et al. 2007)

Thus, a confluence of biochemical, cell biology, and model organism data indicated unexpected modes of regulation for heterotrimeric G-proteins associated with previously unknown functional roles for this signaling system.

The discovery of AGS proteins involved the development of a functional readout that would allow rapid screening of mammalian cDNAs for their ability to activate G-protein signaling in the absence of a receptor. The initial reports of the discovery of AGS proteins using the yeast-based functional screen (Cismowski et al. 1999) included three AGS proteins with each defining a distinct group of AGS proteins (Fig. 2) (Cismowski et al. 1999; Takesono et al. 1999). AGS1 behaved as a guanine nucleotide exchange factor for Gαi/Gαo. AGS3 is the prototype for Group II AGS proteins. AGS2 defined Group III AGS proteins, which generally interact with Gβγ. In the yeast-based functional platform, Group I and II AGS proteins were functionally active in yeast strains expressing Gαi2, Gαi3, but not Gα16 or Gαs whereas the activity of Group III AGS proteins was independent of the type of Gα expressed. Subsequent screening of different mammalian cDNA libraries generated from different tissues exposed to different challenge paradigms or exhibiting specific pathologies yielded 13 distinct mammalian cDNAs that exhibited bioactivity in this functional platform (Fig. 2). AGS11-13, which are actually transcription factors, were identified in the functional screen using yeast expressing Gα16, but

there is not currently enough information to determine how they should be subclassified within the larger group of AGS proteins (Sato et al. 2011).

Group I AGS Proteins

To date, AGS1 is the only cDNA isolated in the yeast expression cloning system exhibiting functional activity consistent with its classification as a guanine nucleotide exchange factor (GEF). Initially isolated as a dexamethasone-inducible cDNA (Kemppainen and Behrend 1998), AGS1 (RASD1) appears to inhibit cell growth (Vaidyanathan et al. 2004) and is downregulated in various cancers (Dalgin et al. 2007; de Souza Rocha Simonini et al. 2010; Furuta et al. 2006; Nojima et al. 2009). AGS1 is also reported to interact with Gβγ (Hiskens et al. 2005). Additional non-receptor GEFs such as ▶ Ric-8A and ▶ Ric-8B (Miller et al. 2000; Tall et al. 2003), GIV/Girdin (Le-Niculescu et al. 2005), and Arr4 (Lee and Dohlman 2008) have been identified by other functional and protein interaction screens, and these proteins would also fit the definition of Group I AGS proteins.

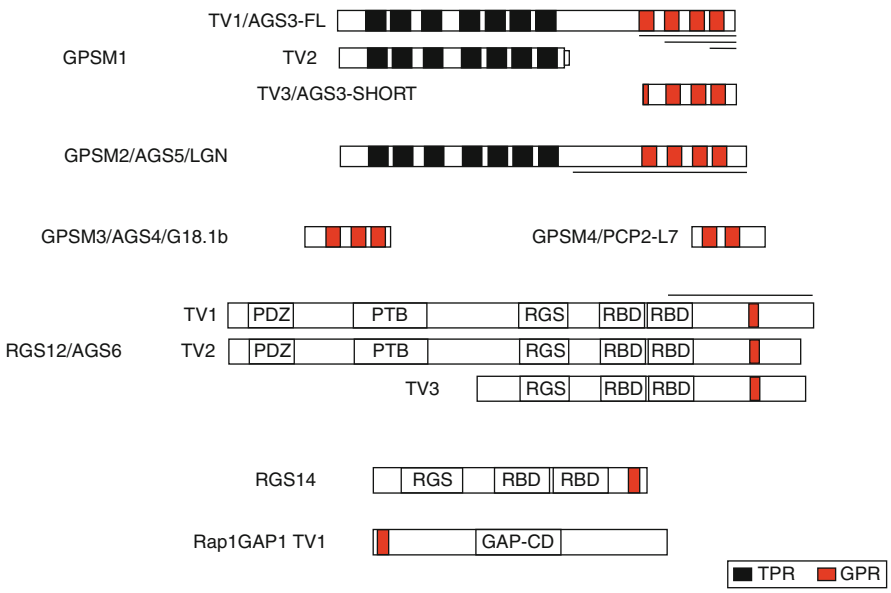
Group II AGS Proteins

Group II AGS proteins are characterized by the presence of one to four, evolutionarily conserved, G-protein regulatory (GPR) or GoLoco motifs (Takesono et al. 1999; Siderovski et al. 1999), which are 20–25-amino acid cassettes that interact with Gαi/o-GDP and Gαt-GDP. Although the core residues within GPR motifs are conserved, individual GPR motifs may differ in their relative affinities for different Gαi/o and ▶ Gαt family members. The GPR motif defines a novel, totally unexpected mechanism for regulation of the activation-deactivation cycle of heterotrimeric G-proteins with potentially broad conceptual implications. In contrast to Group I and III AGS proteins, each member of the Group II AGS proteins has a shared structural motif (GPR/GoLoco) (Fig. 3).

The genes encoding AGS3, AGS4, and AGS5 were named G-protein signaling modulator (GPSM) 1, 3, and 2, respectively, by the HUGO Gene Nomenclature Committee. There are at least three additional GPR proteins in mammals, Pcp2/L7 (GPSM4), RGS14, and Rap1Gap (Transcript Variant 1, isoform a, Rap1GapII), which to date have not been identified in any of the yeast-based functional screens described above, likely reflecting variations in cDNA representation in the libraries used for screening or other factors which affect their activity in the yeast screen. In silico screens based on conserved GPR consensus sequences also identified a putative GPR motif in the protein WAVE1/Scar, although it is not yet known if the motif actively engages Gα-GDP in the context of WAVE1 function in the cell (Song et al. 2006).

Proteins with GPR motifs can be further subgrouped based on the number of GPR motifs they contain. One subset (AGS3, AGS4, AGS5, and Pcp2/L7) has 2–4 GPR motifs, whereas a second subset (AGS6/RGS12, RGS14, Rap1Gap) contains a single GPR motif. Within the first subset, AGS3 and AGS5 share a similar domain architecture and are ~60% identical at the amino acid level with an amino-terminal tetratricopeptide repeat (TPR) domain and four carboxyl-terminal GPR motifs. AGS4 and Pcp2/L7, as well as the AGS3 variant AGS3-short, have 2–3 GPR motifs and lack any other clearly defined protein interaction domains. Within the second subset (AGS6/RGS12, RGS14, and Rap1Gap), in addition to their single GPR motif, each of the three proteins contain a GTPase-activating (GAP) domain in addition to other protein interaction or regulatory motifs. Thus, AGS6/RGS12 and RGS14 have an interesting arrangement of a GPR domain, which can dock $G\alpha_{GDP}$ independently of Gβγ, and a GAP domain which accelerates GTP hydrolysis on the transition state of activated Gα, thus acting to terminate $G\alpha_{GTP}$-based signaling. Although conceptually this is a very interesting combination of domains with completely different, but perhaps complementary, effects on the nucleotide-bound state of Gα, the functional roles of these intramolecular domains within AGS6/RGS12 and RGS14 on the integration of G-protein signaling are not yet fully understood. The GAP domain in Rap1Gap does not regulate heterotrimeric Gα subunits but rather targets the ras-related small GTPase Rap1.

GPR motifs serve as docking sites for Gαi-GDP free of Gβγ and this GPR-Gα signaling module is regulated by both cell surface G-protein coupled receptors and non-receptor GEFs (▶ RIC-8, GIV/Girdin), which promote exchange of GDP for GTP and dissociation or rearrangement of Gα and the GPR motif in a manner



Activators of G-Protein Signaling (AGS), Fig. 3 *Schematic representation of Group II AGS proteins*. Where indicated, the *lines* underneath the schematic representation of individual entities correspond to the coding region actually isolated in the initial yeast-based functional screen (The figure is reproduced from Blumer et al. 2011)

analogous to that observed for G-protein-coupled receptor-mediated regulation of Gαβγ (Garcia-Marcos et al. 2011; Tall and Gilman 2005; Thomas et al. 2008; Vellano et al. 2011). The GPR-Gα signaling module plays a central role in asymmetric cell division in multiple organisms and system adaptation (Fig. 1) (Blumer et al. 2007; Gonczy 2008; Knoblich 2010). Determination of the X-ray crystal structure of the GPR/GoLoco peptide-Gαi1 complex provides a structural basis for understanding interaction of the motif with GαGDP (Bosch et al. 2011; Kimple et al. 2002). Structure-activity studies have revealed specific amino acids in the GPR motif that influence interaction with Gα (Peterson et al. 2002) and a key residue in Gα that is required for interaction with GPR motifs (Bosch et al. 2011).

Mechanistically, proteins with GPR motifs may impart biological activity by influencing subunit interactions to promote or sustain dissociation of Gαβγ heterotrimers in the absence of nucleotide exchange. In the context of the G-protein activation-deactivation cycle, the GPR protein may also influence subunit interactions by binding $G\alpha_{GDP}$ prior to reassociation with Gβγ. In either situation, alterations in Gβγ-regulated effector pathways would be expected. The $G\alpha_{GDP}$-GPR complex itself is actually suggested to be a putative "bioactive" entity (Gonczy 2008). The Gα-GPR signaling module can also function as a discreet signaling system that is regulated by non-receptor guanine nucleotide exchange factors and perhaps G-protein-coupled receptors. Interplay between the Gα-GPR and the classical heterotrimer Gαβγ signaling modules offers additional interesting mechanisms for signal integration (Blumer et al. 2011).

A nonsense mutation in GPSM2, which truncates the reading frame of the protein, is associated with nonsyndromic hearing loss likely as a result of altered planar cell polarity in the auditory system (Walsh et al. 2010; Yariz et al. 2011). Renal AGS3 (GPSM1) is markedly elevated in polycystic kidney disease and in response to renal injury (Nadella et al. 2010; Regner et al. 2011). In cell culture, AGS3 traffics into the aggresome pathway and it is also a central player in regulating autophagy (Garcia-Marcos et al. 2011).

Group III AGS Proteins

The mechanisms by which the Group III AGS proteins activate G-protein signaling in the yeast functional screen and function in mammalian signaling systems are not yet fully understood. As more information becomes available, it is likely that members of this loosely defined Group III will exhibit different mechanisms of action in terms of their ability to lead to the end readout of Gβγ-dependent growth in the yeast functional screen. One mechanism by which the

Group III proteins may act is by an interaction with Gβγ and/or heterotrimer to influence subunit interactions in a way that there is productive effector engagement. AGS2 (tctex1/DYNLT1) is actually a light chain for the cytoplasmic motor protein dynein and regulates neurite outgrowth through its interaction with Gβγ and dynein (Sachdev et al. 2007). AGS7 (TRIP13) was identified as a thyroid receptor–interacting protein and AGS8 (FNDC1) promotes apoptosis of cardiac myocytes. AGS9 (Rpn10) is a component of the 26S proteasome.

Summary

The discovery of AGS and related proteins altered our basic concepts of G-protein signaling. First, Gα and Gβγ are processing signals within the cell distinct from their role as transducers for cell surface receptors and such signals involve previously unrecognized functional roles for heterotrimeric G-protein subunits. Secondly, Gα and Gβγ may complex with alternative binding partners independent of the classical Gαβγ heterotrimer, providing a distinct signaling pathway with its own set of activators and effectors.

AGS and related accessory proteins or signal regulators are intimately involved in generating signaling diversity in ways that are not yet fully recognized. Such accessory proteins have evolved to provide a mechanism for cells to adapt acutely and for a longer-term to physiological and pathological challenges without altering the major components of the signaling core itself. AGS proteins and related entities play unexpected and important functional roles in a number of systems and impact a number of signaling pathways that influence cell growth and survival. Rapidly accumulating data from disease tissue profiling and genomic-based technologies indicate that selected AGS proteins may serve as biomarkers for specific diseases and their altered expression or function in disease states suggests candidate signaling modules for therapeutic targeting.

Central questions in the field are as follows: What regulates the subcellular location of AGS proteins? What regulates the interaction of AGS proteins with Gα or Gβγ? What is downstream of the GPR-Gα signaling module? Are there pathologies associated with polymorphisms in AGS proteins? Are AGS proteins candidate therapeutic targets? How did the different "G-switch" modules (e.g., Gα-GPR, Gαβγ) and their regulation by non-receptor and cell surface receptors evolve in response to different evolutionary pressures in terms of signal processing?

ADAP

Ana Kasirer-Friede
Department of Medicine, University of California, La Jolla, San Diego, CA, USA

Synonyms

Fyn-binding protein (FYB); SLP-76 adapter-binding protein of 130 kDa (SLAP-130)

Historical Background

The adhesion and degranulation promoting adapter protein (ADAP) is a large protein which is alternatively spliced to produce a 120/130 kDa isoform, and is expressed in T cells, proB cells, and myeloid cells. ADAP was first cloned in 1997 by two independent labs that were working to elucidate signaling pathways induced by engagement of the T cell receptor. In early studies, the kinase, Fyn-T, was found to be an important mediator of mature, peripheral T cell activation. In order to identify potential substrates of Fyn-T, da Silva et al., used GST–FYN-SH2 domain fusion proteins to

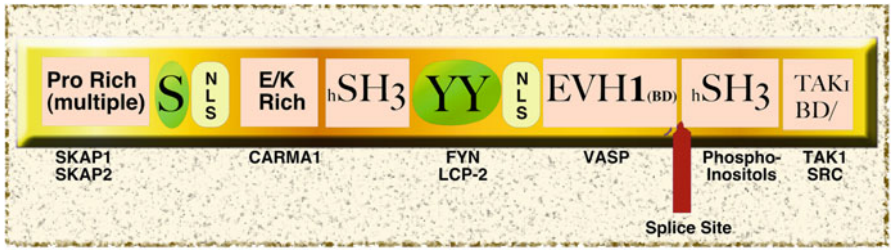
immunoprecipitate a 120/130 kDa phosphorylated protein from a TCR/antiCD3 stimulated T cell line. An antibody developed against this protein was used to screen a Jurkat cell line cDNA library, and led to the cloning of ADAP. In the same year, Musci et al., used the SH2 domain of another protein LCP2 (previously known as SLP-76) that is phosphorylated upon T cell stimulation and modulates T cell function, to precipitate out ADAP from pervanadate-stimulated JA2/SLP-SH2 Jurkat T cells expressing a chimeric surface protein with the extracellular and transmembrane domains from HLA.A2 and the SH2 domain from LCP2. The newly cloned proteins were named Fyn-binding protein, FYB, and SLP-76-associated protein of 130 kDa (SLAP-130) respectively, depending on the precipitating protein used in cloning; however, the name, adhesion and degranulation-promoting adapter protein, ADAP, was adopted in 2001. Another major milestone was achieved with the generation of chimeric and knockout ADAP mice ($ADAP^{-/-}$) by Griffiths et al., and Peterson et al., and helped resolve some of the controversies related to ADAP function that had surfaced using various cell lines (Peterson 2003). In recent years, the elucidation of new ADAP domains and interaction partners has expanded the repertoire of functions attributed to ADAP, that span from actin regulatory roles in lymphocytes, macrophages, and platelets, to mast cell degranulation, T cell proliferation, thymopoiesis, osteoclastogenesis, eosinophil survival, and integrin regulation (Koga et al. 2005;Wang and Rudd 2008).

ADAP Structure and Domains

ADAP fulfills its scaffolding function through a variety of domains that permit assembly of multimolecular complexes to modulate diverse functions (NP_001456.3;GI:42476118; NP_955367.1 GI:40788007). The human ADAP protein is reported to have 783 amino acids (AA) in the 120 kDa, or 803AA in the 130 kDa form. The full-length mouse ADAP is 819AA. The regulation of ADAP is likely to be complex due to the presence of several serine/threonine residues and lysine acetylation sites, two putative nuclear localization sequences (PKKKRKV), and 16 tyrosine phosphorylation sites, 13 of which are concentrated in the region between AA486 and 783 (Sylvester et al. 2010). Figure 1 highlights many of the domains that have been mapped to date. At the amino terminal end is one of four proline-rich domains that mediate association with SH3 domain-containing proteins: monomeric actin-binding protein (mABP, also known as HIP55), and the homologous adapter proteins SKAP1, and SKAP2, with ADAP residues 338–358 minimally required for stabilization of the SKAP proteins. There is a glutamic acid/lysine (E/K) rich region that constitutes a MAGUK binding domain. Downstream of this region is the first of two unusual helically extended SH3 domains (hSH3) that have lost the ability to bind the classical SH3 proline-rich recognition motif, but instead may associate with phospholipids (Heuer et al. 2004). Interposed between the hSH3 domains are the mid-protein tyrosines YEDI and two YDDV sequences (residues 461–464; 595–598; and 651–654), which are recognition sites for SH2 domains of FYN and LCP2 respectively, and a central FPPPP site that constitutes a VASP EVH1 binding domain. In mast cells, ADAP may bind the SH2 domain of the LCP2 family protein, mast cell immunoreceptor signal transducer (MIST). Limited structural data exists for ADAP: Zimmerman et al., have demonstrated that the two cysteines in ADAP that are adjacent to the $hSH3^{N}$ domain can be reversibly oxidized and reduced in vitro, and result in two distinct conformations of the variable arginine threonine loop (Zimmermann et al. 2007). A three-dimensional C-terminal domain NMR structure has been solved by Heuer et al. (2004) (Fig. 2), and depicts the hSH3 domain as a twisted β-sheet structure, with the N-terminal helical portion packed against the open side of the twisted sheet and contacting residues from the β-strands, thus forming an helically extended SH3 domain. In the very carboxy-terminus of ADAP, there are binding sites for TAK1 and SRC. In summary, the combinatorial binding possibilities that may exist depending on cell-specific expression of binding partners are complex and harbor potential for as yet undetermined functions.

ADAP Role in Proliferation and Transcription

Although evidence from studies in T cell lines and the $ADAP^{-/-}$mouse established that ADAP positively modulates T cell proliferation and cytokine production following stimulation of the T cell receptor (TCR), the potential ADAP effector binding partners that could regulate transcriptional events were not known. Medeiros et al. (2007) first described how ADAP may promote T cell proliferation by modulation of NF-KB. In T cells, activation of the NF-KB family of transcription factors and their translocation to the nucleus to transcription target sites is necessary for T cell

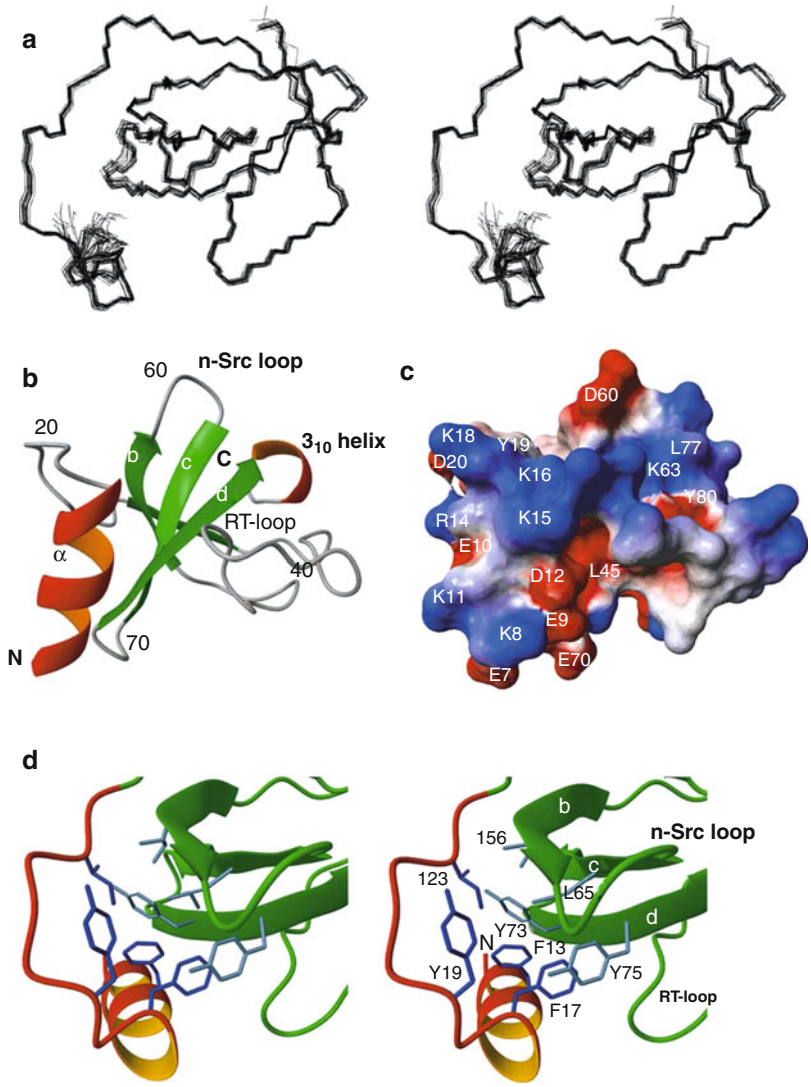


ADAP, Fig. 1 *Structural features of ADAP*. Adhesion and degranulation-promoting adapter protein (ADAP) is a large protein that harbors domains for scaffolding proteins of various classes. Shown here are many of the ADAP domains described to date. The N-terminus domain residues 1–300 support binding of monomeric actin-binding protein (mABP1; also known as HIP55), and the proline-rich regions (Pro-rich) support binding to SH3 domains of the homologous SKAP adapter proteins, SKAP 1 and SKAP2. There are several serine/threonines (S) and tyrosines (Y) that may be phosphorylated and mediate binding to SH2 domains of FYN and LCP-2 (formerly known as SLP-76), an E/K rich region within residues 426–541 for binding the MAGUK domain of CARMA1, two putative nuclear localization sequences (NLS), an FPPPP sequence within 616–624 region that binds the EVH1 domain of VASP, followed by an alternative splice site of 46AA. There are two helically extended SH3 domains (hSH3) that bind phosphoinositols and there is a recognition site for the phosphatase YopH in the C-hSH3 domain. In the very carboxy-terminus end are binding sites for the kinases TAK1 and SRC within -ADAP residues (AA691-708 in murine) and at Y807 respectively. Figure is not drawn to scale

survival. In resting T cells, NF-KB is held in an inhibited state by tight association with IKBα within the IKB family complex in the cytoplasm. T cell stimulation promotes the protein kinase C (PKC)θ dependent assembly of a multiprotein complex that serves to activate IKB. The complex consists of the caspase-like protein MALT1, the adapter Bcl-10, and caspase recruitment domain (CARD) membrane-associated protein1 (CARMA1), which contains a membrane-associated guanylate kinase (MAGUK) domain. Complex assembly results in phosphorylation of IKKα/β, ubiquitination of IKKγ, and degradation of IKBα, thereby freeing NF-KB to translocate to the nucleus. Using wild-type and mutant forms of HA-epitope tagged ADAP constructs expressed in Jurkat cells activated with PMA, Medeiros et al., elegantly showed that ADAP and CARMA1 directly associate and promote assembly of the MALT1/CARMA-1/BCL-10 complex and thereby, relocalization of MALT1 and BCL-10 to the membrane. ADAP and CARMA1 also colocalized at the membrane by way of an association between ADAP E/K rich residues within AA426-546, and the CARMA1 carboxy-terminal MAGUK region. As expected, in ADAP$^{-/-}$ mice, activation of the NF-KB pathway was impaired, and the MALT1/BCL-10 complex was mislocalized. ADAP may additionally drive NF-KB activation by binding the TGFβ-activated kinase1 (TAK1) at ADAP residues AA691-708, recruiting it to PKCθ (Srivastava et al. 2010) and inducing IKKα/β phosphorylation. Recombinant adenovirus constructs and ADAP$^{-/-}$ mice expressing the hCAR receptor (CD21 positive) were used to determine that the two sites on ADAP for TAK1 and CARMA1 appear to operate independently, as only the CARMA1 site is needed for IKKγ ubiquitination. As ADAP has been found to be necessary for thymopoiesis as well, it is possible that ADAP may yet have a further role in proliferation and differentiation, possibly by virtue of the putative nuclear localization signals that have been described but not yet mapped to specific functions.

ADAP Role in Integrin Regulation

Integrins are heterodimeric transmembrane proteins that can undergo conformational changes that enhance their affinity, and their activation state is intimately linked to the adhesive capacity of the cell. Hematopoietic cells, whether involved in immune or hemostatic function, require high affinity and/or high avidity bonds to establish strong and stable cell-matrix interactions in order to withstand hydrodynamic stress as they adhere, migrate, and transmigrate (diapedese). In T cells, integrins are additionally important for conjugate formation with antigen presenting cells (APC). Despite the presence of many integrins on the T cell surface, integrin LFA-1, consisting of subunits αL and β2, plays a particularly important role in T cell function. When transiently adhering to inflamed vessel walls through weak selectin-mediated interactions, integrin LFA-1 undergoes affinity modulation to



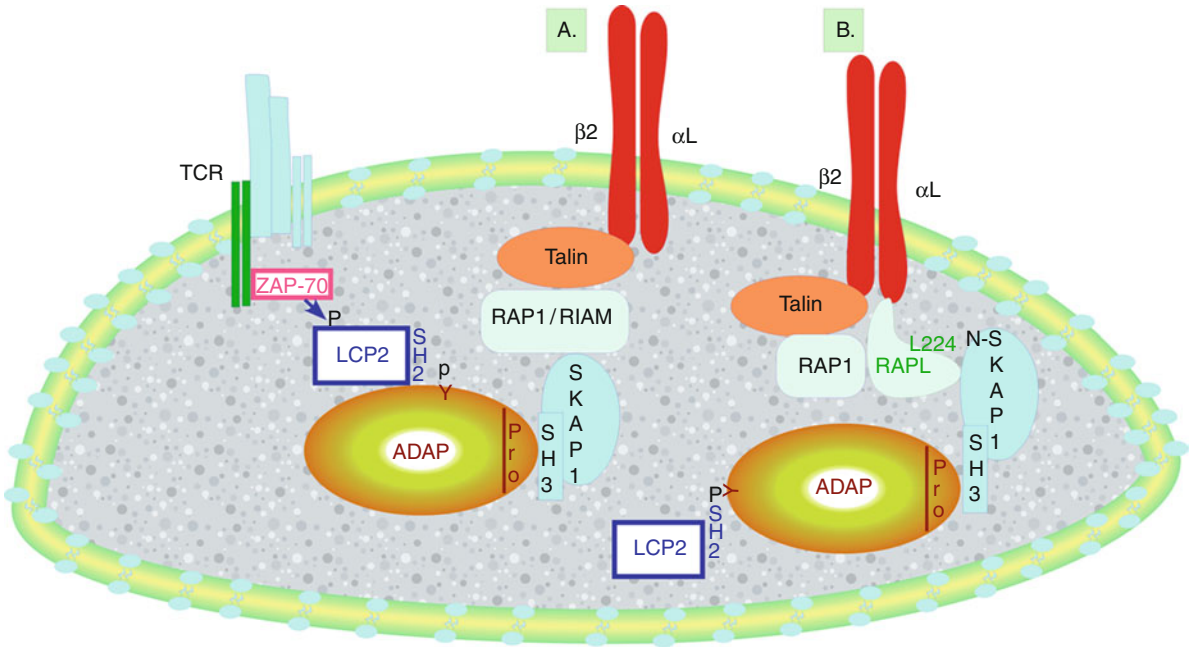
ADAP, Fig. 2 *Solution Structures of the ADAP-hSH3 Domain.* (**a**) Ensemble of the final 20 structures of ADAP-hSH3 domain. Structures are superimposed over the backbone atoms (C^{α}, C′, N) of residues 7–83. (**b**) Ribbon diagram of the lowest energy structure of ADAP-hSH3 domain, produced by the program MOLMOL. The backbone ribbon belonging to the regular SH3 fold is indicated in *green*, while the ribbon of the N-terminal extension is colored *red*. Side chains of residues of the extended N-terminus and the regular SH3 fold are in *blue* and *pale blue*, respectively. Structures in (**a**) and (**d**) are shown as stereo images. This research was originally published in Structure (Heuer et al. 2004)

mediate stable binding to ICAM 1, 2, or 3, expressed on endothelial cells or on APCs. It was first noted in T cells, that overexpression of ADAP led to enhanced TCR-induced integrin-dependent adhesion, while T cell lines lacking ADAP, and $ADAP^{-/-}$ mice showed deficient TCR-dependent upregulation of adhesiveness. Since the primary driving force for development of ADAP reagents and mice stemmed from interest in T cell physiology, mechanistic insights into ADAP's role in integrin activation have mostly been derived from studies in this cell type (Baker and Koretzky 2008; Jordan and Koretzky 2010; Wang and

Rudd 2008). However, experimental evidence for an ADAP role in integrin affinity modulation in platelets and macrophages is similarly strong. Stimulation of T cells through the TCR and CD28 is known to activate LFA-1 through a signaling cascade where ZAP-70 is recruited to ITAM domains of the TCR and phosphorylated by p59Fyn-T, thereby activating its kinase function to promote phosphorylation of multiple proteins including LCP2, SKAP1, phospholipase Cγ, and ADAP. As ADAP was found to be dispensable for TCR stimulated PLCγ phosphorylation and mitogen-activated protein kinase (MAPK) activation in the ADAP$^{-/-}$ mouse, further investigations focused on downstream events. Several lines of evidence have pointed to a functional partnership between ADAP and LCP2 for upregulation of integrin activation and adhesion. Transfection of Jurkat cells with constructs harboring mutations of ADAP tyrosines in the two YDDV sites that mediate LCP2 binding led to a loss of integrin clustering, T cell APC conjugate formation, and assembly of the peripheral supramolecular activation complex (pSMAC). The discovery that ADAP was constitutively associated with SKAP1, and more recently that ADAP was necessary to stabilize SKAP1 and its homologue SKAP2 in several cells in vitro and in vivo, suggested that SKAP1 may function in conjunction with ADAP and LCP2. Furthermore, it was not clear whether defects in integrin regulation observed in ADAP$^{-/-}$ mice were indeed due to ADAP or SKAP1. This was addressed using the SKAP1 knockout mouse, where ADAP expression is normal. Surprisingly, in SKAP1$^{-/-}$ T cells, similar integrin activation defects were seen to those observed in the ADAP$^{-/-}$ mouse, suggesting that ADAP may function to relocalize SKAP1, but that SKAP1 is the effector molecule of importance for integrin regulation.

Two overlapping models which incorporate ADAP scaffolding of SKAP1 and LCP2 were proposed to explain LFA-1 activation in T cells (Fig. 3) and link to known mediators of integrin activation: talin, Rap1, and the adapter, Rap1-interacting adhesion molecule (RIAM). Talin is a 280 kDa protein consisting of a FERM domain-containing head region that binds to the membrane proximal region and an NPXY motif on the β integrin cytoplasmic tail, to release the heterodimeric α/β subunit clasp and stabilize the open form of the integrin extracellular ligand-binding domain. The talin rod-like tail has binding sites for actin and vinculin, which also binds actin, and thereby reinforces links to the cytoskeleton. Active Rap1 binding to RIAM Ras association domain (RA) and membrane targeting have been shown to activate talin and enhance talin-mediated integrin activation (Shattil et al. 2010). Recently, it was demonstrated by Lee et al. that activation could occur when a 30 residue N-terminal fragment of RIAM directly binds talin to cause it to swing in toward the membrane and access an additional site on the β integrin tail to enhance integrin affinity. The ADAP-SKAP complex is linked to RIAM through a constitutive association between the SKAP1 N-terminal domain and RIAM PH domain. ADAP may thus function as a chaperone for a larger complex to escort effector molecules SKAP1/RIAM and Rap1 to the membrane (Kliche et al. 2006; Menasche et al. 2007). In support of this model, perturbation of the ADAP/SKAP1/RIAM association in turn disrupts recruitment of active Rap1 to the membrane and integrin activation. Activation of Rap1 also increases its affinity for RapL, a molecule often used as an indicator of Rap1 activation state. Interestingly, the alternative model for LFA-1 activation in T cells describes a new interaction of the SARAH RapL carboxy-terminal coiled-coil domain with the SKAP1 N-terminal region. The two molecules bind with a 1:1 stoichiometry as shown by isothermal titration calorimetry (Raab et al. 2010). In this model, the authors propose that an ADAP/SKAP1 module coordinates a Rap-RapL interaction that leads to RapL binding directly to the integrin αL cytoplasmic tail of LFA-1 to modulate integrin activation. It is possible that these models represent separate regulatory units that interface with individual α and β integrin subunits, or they may function together for maximal activation. In contrast, LCP2 and ADAP appear to function independently in integrin activation following stimulation through the cytokine receptor CXCR4 (Horn et al. 2009). Recently, it was noted that the adapter molecule HPK1 may compete with ADAP for LCP2 binding and negatively regulate integrin adhesion (Patzak et al. 2010).

In light of the scaffolding function of ADAP for effectors SKAP1 and LCP2, which were shown to be necessary components of signaling pathways to integrin activation in T cells, a role for ADAP modulation of integrin activation was hypothesized. Although biochemical studies in platelets identified ADAP in large complexes together with SKAP2 and



ADAP, Fig. 3 *The role of ADAP in TCR mediated integrin LFA-1 activation in T cells.* Stimulation through the TCR and CD28 results in binding of ZAP-70 to TCR ITAM domains and activation of its kinase activity, to phosphorylate LCP2. This induces the recruitment of several proteins, including ADAP, which is constitutively associated with SKAP1. (**a**) SKAP1 has been shown to bind the Rap1 binding protein, RIAM. Together, these are recruited to the membrane by ADAP to activate talin, which causes the splaying of the cytoplasmic tails of the integrin and a conformational change to upregulate LFA-1 affinity for its ligands. In an alternative model (**b**), an ADAP/SKAP1 module binds RapL L224 through the SKAP1 N-terminus and is necessary for the assembly of the Rap1/RapL complex and its recruitment to the membrane. Previously, RapL was shown to bind directly to the αL tail of integrin LFA-1 and regulate lymphocyte adhesion

LCP2 following stimulation with a collagen mimetic agonist, no mechanistic data was derived and no direct link between ADAP and activation of αIIbβ3, the platelet integrin crucial for platelet aggregation and spreading, was examined. In the course of investigating signaling pathways between the platelet adhesion receptor GPIb-IX-V and αIIbβ3 activation, Kasirer-Friede et al., found that ADAP underwent SRC-family kinase dependent phosphorylation upon GPIb-IX-V stimulation that occurred independently of intracellular calcium elevations. Subsequent studies using $ADAP^{-/-}$ mice clearly demonstrated a role for ADAP in αIIbβ3 activation downstream of several platelet agonists. The in vivo consequences of an ADAP deficiency were evidenced by increased rebleeding in these mice when challenged by tail vein transection, and by abnormal thrombus formation in the carotid artery upon chemical injury. However, unlike T cells, platelets do not express SKAP1, which is central to both T cell integrin activation models, and mice with a deletion of the homologous SKAP2, which leaves ADAP expression intact, showed no defects in αIIbβ3 integrin activation, or thrombus formation. Overexpression of ADAP in mast cells also enhances integrin activation-dependent adhesion to fibronectin. Similarly, ADAP has been implicated in macrophage, eosinophil, and pre-osteoclast development and/or functions where integrin activation is allegedly important. Nevertheless, sufficient variation exists in cell-specific expression of T cell pathway constituents that a simple unified mechanism to link ADAP to integrin activation is not feasible, and further studies are needed to identify relevant signaling pathways between upstream agonists and integrin activation that connect ADAP with appropriate binding partners in the context of diverse cellular environments.

ADAP Regulation of the Cytoskeleton

Reorganization of the actin cytoskeleton in response to stimulus is necessary for interaction of T cells with antigen presenting cells (APC's), phagocytosis by macrophages, and platelet spreading. Microscopic studies

have revealed a consistent association between ADAP and actin, or between ADAP and actin polymerization regulatory proteins in hematopoietic cells exhibiting a spectrum of distinct cell morphologies and underlying cytoskeletal networks (Peterson 2003; Wang and Rudd 2008). These results are supported by co-immunoprecipitation studies, and suggest that ADAP may be found in large molecular complexes associated with LCP2, which binds exchange factors and adapters that promote lamellipodial extension, and with NCK, Arp2/3, and VASP, which more proximally regulate actin polymerization. Furthermore, ADAP was shown to directly interact with VASP by screening a mouse embryonic expression library with antibodies against the VASP EVH1 domain binding motif, and with NCK, by yeast two-hybrid analysis (Sylvester et al. 2010). In T cells, a highly organized region composed of integrins, TCR, and many other signaling and structural proteins is formed between T cells and APCs, and is referred to as the immunological synapse (IS). The ADAP/VASP interaction helps recruit VASP to the IS, and inhibition of the association between ADAP and Ena/VASP impairs T cell polarization and formation of an actin cap at the T cell/APC junction. IS assembly is preceded by microclustering of several molecules including LCP2, ZAP70, and Linker for Activation of T cells (LAT) and their relocalization to the vicinity of the T cell/APC interface at the membrane events that occur independently of integrin clustering. Not surprisingly, primary T cells lacking ADAP are unable to relocalize LCP2 to microclusters. ADAP is additionally subject to dephosphorylation by SHP2 in response to increased cellular redox potential upon TCR stimulation, and may dampen ADAP-mediated cytoskeletal reorganization.

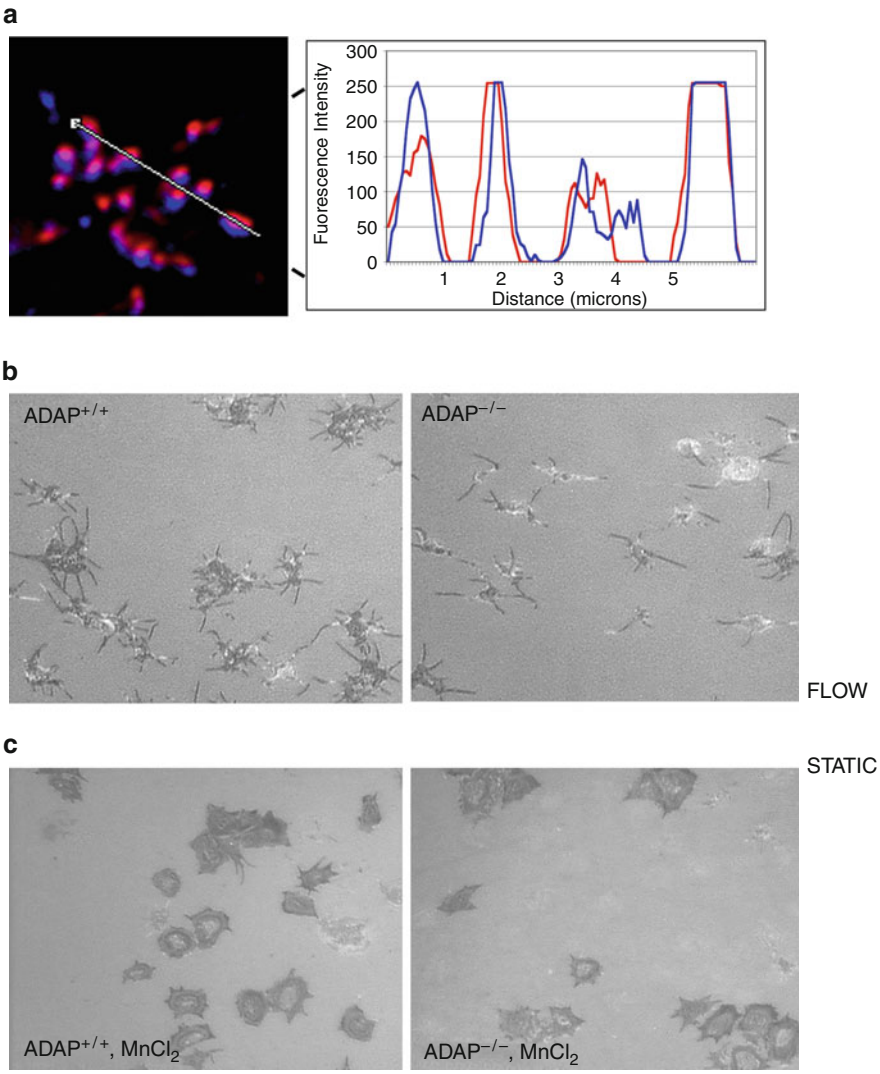
Upon stimulation through the T cell receptor (TCR) by anti-CD3 and CD28 antibodies, the β2 integrin LFA-1 becomes activated and TCRs and LFA-1 form clusters. LFA-1 clusters eventually encircle the TCR clusters to form a highly organized supramolecular activation complex where many signaling molecules also gather. Alternatively, integrins may be directly clustered in cells plated on fibronectin (Baker et al. 2009). Although ADAP is not needed for the immediate actin reorganization and TCR clustering, ADAP is necessary for clustering of LFA-1, a process that is actin dependent, as it is abrogated by cytocholasin D. ADAP regulation of β1 integrin clustering has also been demonstrated in mast cells.

T cell migration is required for T cell mobilization to sites of inflammation, to and within lymph nodes (LFA-1 dependent), and for transmigration through high endothelial venules. ADAP can increase migration in Jurkat T cells (Hunter et al. 2000; Sylvester et al. 2010). The case for an ADAP role in T cell migration is manifold: (1) ADAP expression in T cell blasts increased α4β1-mediated basal migration through fibronectin-coated transwells, and further enhanced migration speeds over those in untransfected cells when stimulated with the CXCR4 ligand, SDF-1α. (2) Mutation of ADAP tyrosines Y755, Y771, and Y780 within the hSH3 domain, to phenylalanine, led to decreased SDF-1α–induced migration of Jurkat cells through a transwell chamber. However, double mutation of the LCP2 binding sites, Y595 and Y651, produced the greatest reduction in SDF-1α induced migration. (3) In contrast, OVA peptide presentation on dendritic cells in lymph node slices decreased T cell mobility, in a manner dependent on an intact binding interface between ADAP/SKAP1 and RapL (Raab et al. 2010).

In platelets, under static, no flow conditions, ADAP is found at the periphery of platelets spread on fibrinogen. However, under shear flow conditions with hydrodynamic shear stresses acting on adhering platelets, the actin cytoskeleton is preferentially organized into actin-rich microclusters together with ADAP and other proteins (Fig. 4a), including VAV, LCP2, VASP, and the focal adhesion constituent, vinculin.

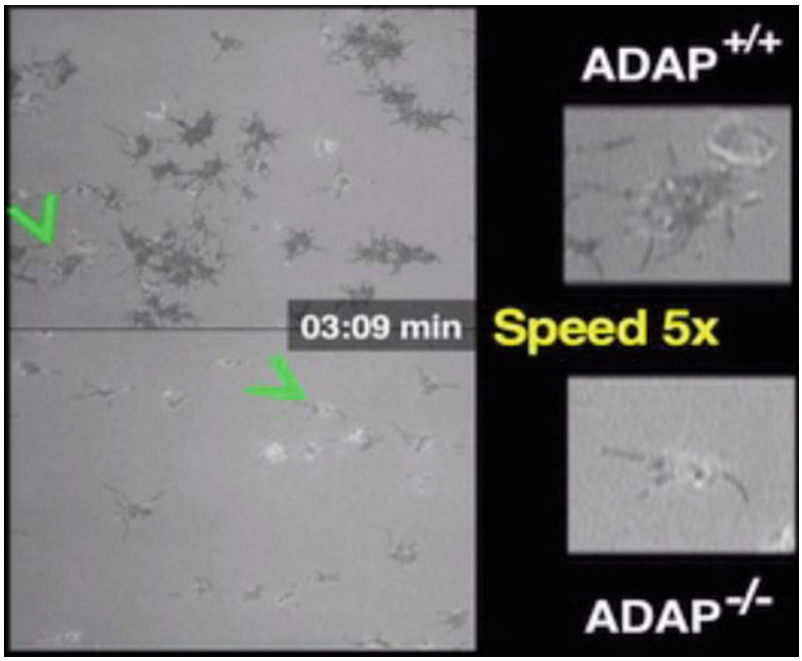
Live videomicroscopy was used to demonstrate that in ADAP$^{-/-}$ platelets, spreading and cluster assembly is greatly reduced under shear flow (Video 1), but not static conditions (Fig. 4b, c), (Kasirer-Friede et al. 2010). Furthermore, the phosphorylation of VAV, which occurs in response to shear stimulation, was almost completely absent in ADAP$^{-/-}$ mouse platelets. This led to a hypothesized role for ADAP in platelet mechanotransduction, mediated at least in part through its regulation of phospho-VAV activation of RAC for lamellipodia formation. ADAP may additionally mediate normal platelet responses under shear flow by additional, thus far unidentified, mechanisms.

In the macrophage, a cell that functions in immune defense by engulfing pathogens, ADAP localizes in membrane ruffles and plaques and at sites of phagocytosis along with actin. ADAP associates with actin regulatory proteins SLP-76, NCK, and VASP as in T cells, as well as with the C-terminal SH3 domain of monomeric actin-binding protein 1 (mAbp1, also



ADAP, Fig. 4 *ADAP in platelet adhesion to fibrinogen under shear flow conditions*. Flow chamber assay of unlabeled platelets adhering from whole blood onto fibrinogen-coated coverslips under shear flow, at a shear rate of 500 s^{-1}. (**a**) Platelets were perfusion fixed after 1.5 min of flow, permeabilized, and stained for F-actin (*red*) and ADAP (*blue*). Actin-rich structures form in $ADAP^{+/+}$ platelets adherent to fibrinogen, in which ADAP is also found. These structures were greatly reduced in $ADAP^{-/-}$ platelets, in which ADAP staining was negative. Furthermore, the normal localization of LCP-2, VAV, VASP, and vinculin to these structures was lost (not shown). A line profile of actin and ADAP fluorescence distribution in representative $ADAP^{+/+}$ platelets indicates almost identical localization. B./C. Identical $ADAP^{+/+}$ or $ADAP^{-/-}$ blood suspensions were either perfused over fibrinogen under shear flow at 500 s^{-1} (**b**) or pre-treated with $MnCl_2$ and gently applied to fibrinogen-coated coverslips within the flow chamber under static conditions (**c**), and continuously imaged by reflection interference contrast microscopy for 3 min. Images shown are after 1.5 min of blood exposure to the matrix. Well spread platelets are observed for both strains under static conditions, but only for $ADAP^{+/+}$ under shear flow, even when cells are treated with MnCl2 (not shown). This research was originally published in Blood (Kasirer-Friede et al. 2010. © the American Society of Hematology)

known as HPK1-interacting protein; HIP55). Thus, its high connectivity places ADAP in a strong position to modulate cytoskeletal dynamics. The pathogenic bacterial family *Yersinia* species has evolved mechanisms that interfere with the ability of macrophages to intercept infection, by injecting the phosphatases, YopH and YopE (Yuan et al. 2005). Interestingly, these proteins target amongst others, SKAP2 and ADAP. YopH binds ADAP C-terminal SH3 domain and central phosphotyrosines, leading to their



ADAP, Video 1 Platelet adhesion and spreading visualized by reflection interference contrast microscopy. $ADAP^{+/+}$ and $ADAP^{-/-}$ platelets adhere and spread onto immobilized fibrinogen from blood under shear flow conditions. A field of cells is shown for both strains (*left panels*), and a representative platelet (*arrowhead*) is highlighted and tracked from the time of capture for at least 1.5 min (*right panels*). Note that dark regions, depicting close surface contacts, grow rapidly in $ADAP^{+/+}$ platelets (*top*) but are greatly reduced in $ADAP^{-/-}$ platelets (*bottom*). This research was originally published in Blood (Kasirer-Friede et al. 2010. © the American Society of Hematology)

dephosphorylation and reduced phagocytosis (de la Puerta et al. 2009). ADAP/SKAP2 can also complex with macrophage inhibitory receptor SHPS-1 and SHP-1 via the SKAP2 SH3 domain, and mice lacking SHP-1 show increased p120/ADAP phosphorylation. In macrophage-like pre-osteoblasts, which also express ADAP, integrin-dependent tyrosine phosphorylation of ADAP occurs, and ADAP knockdown retards migration and progression to the multinucleate stage (Koga et al. 2005). Taken together, this suggests that in macrophages, the phosphorylation state of ADAP may be one of the factors regulating its interactions with actin and actin regulatory proteins.

Summary

Although ADAP was only cloned a little over a decade ago, studies have repeatedly detailed an important role for this protein in regulation of proliferation, adhesion, and cellular development. Although studies thus far have provided important insights into how ADAP interfaces with its binding partners, more work is required to identify novel regulatory mechanisms for the as yet "unassigned" residues such as serines and lysines that may be subject to post-translational modifications within individual cellular environments to effect cell-specific function. New studies likely will continue to expand the repertoire of ADAP binding partners, and increase the understanding of its regulation by virtue of the numerous and diverse domains within the molecule. In the coming era, ADAP mutations may be mapped to specific disease states and ADAP domains may be therapeutically targeted. This is already becoming a reality. ADAP has been implicated in hemostasis and thrombus formation, and in CD8 dependent homeostasis in small intestinal epithelium. As T cell invasion is an important component of allograft rejection, two studies have investigated the role of ADAP in this process. Using $ADAP^{-/-}$ mice, the lack of ADAP expression was found to significantly ameliorate heart allograft rejection, and synergistically ameliorate intestinal allograft rejection in the presence of additional costimulation blockade using anti CD40L

antibodies (Tian et al. 2010). Therefore, it will be interesting to see how basic research studies on ADAP can be translated into health benefits for human patients.

Synonyms

ARF GAP with dual pleckstrin homology (PH) domains; CENTA1; Centaurin alpha; GC1L; GCS1L; p42IP4; PIPBP

Historical Background

ADAP1 (ARF GAP with dual pleckstrin homology (PH) domains 1) was originally identified as a 42 kDa

protein that binds with high affinity to phosphatidylinositol (3,4,5)-triphosphate (PIP_3) or its inositol head group, inositol 1,3,4,5-tetrakisphosphate (IP_4). Hence, it was originally named PIP_3/IP_4-binding protein (PIP3BP/p42IP4) and has also been called Centaurin-α1 (Hammonds-Odie et al. 1996; Stricker et al. 1997; Tanaka et al. 1999). It has been renamed ADAP1, to more accurately describe the structure and function of this protein (Kahn et al. 2008). The membrane lipid PIP_3 and the water-soluble ligand IP_4 both serve as signal transducers that link extracellular stimuli to numerous intracellular signaling cascades required for cell growth, multiplication, differentiation, and death (Vanhaesebroeck et al. 2001; Hanck et al. 2004). ADAP1 contains an amino-terminal zinc-finger motif with an ADP-ribosylation factor (ARF) GTPase-activating protein (GAP) homology domain and two adjacent pleckstrin homology (PH) domains (one in the middle (N-PH) and the other at the carboxy terminus (C-PH)) that are required for binding to PIP_3. It has high sequence similarity to the Centaurin-α2 protein, with 58% amino-acid identity and 75% similarity (Hanck et al. 2004; Whitley et al. 2002). The *ADAP1* gene is located on human chromosome 7 (Hanck et al. 2004).

Protein Function and Regulation of Activity

ADAP1 has both GAP domain-dependent and -independent effects. The rat homolog was shown to have a role in dendritic density and branching in a GAP domain-dependent manner. Dendritic lamellipodia and filopodia have been implicated in dendritic branching and spine formation, and the same study demonstrated that ADAP1 plays a part in their formation; this effect was again dependent on the GAP domain (Moore et al. 2007). In HeLa cells, human ADAP1 prevents cortical actin reorganization, which was shown to be a consequence of its GAP activity toward the ARF6 small GTPase (Venkateswarlu et al. 2004). Additionally, it has been shown that co-transfection of HEK293 with ADAP1 and the β2 adrenoceptor leads to a decrease in receptor internalization and an increase in $G\alpha_s$ signaling (Lawrence et al. 2005); this effect was GAP domain dependent.

Cell spreading is a GAP domain-independent effect of ADAP1. Intriguingly, expression of a ΔGAP mutant, which lacks the GAP domain, increased cell spreading, suggesting that the interaction of ADAP1 with ARF6 may decrease this effect. This function might be linked to its co-localization with the ARF5 and ARF6 small GTPases (Thacker et al. 2004). Other studies unconcerned with its GAP activity found that ADAP1 induced the downstream activation of ERK1/2 and Elk-1 by a ▶ PI3K-dependent pathway (Hayashi et al. 2006), and infection of chick embryonic fibroblasts with retrovirus encoding ADAP1 led to anchorage-independent proliferation at an increased rate through AP-1 activation (Chanda et al. 2003), suggesting that ADAP1 could have oncogenic potential. Mitochondria isolated from neuroblastoma cells that overexpress ADAP1 showed significantly decreased Ca^{2+} capacity and lag-time for Ca^{2+} retention, suggesting that ADAP1 is involved in the regulation of mitochondrial Ca^{2+} transport (Galvita et al. 2009).

In unstimulated PC12 cells, ADAP1 localizes to the cytoplasm and nucleus. Upon stimulation of PC12 cells with EGF, ADAP1 translocates to the plasma membrane. This has been shown to be dependent on a PI3K-induced increase of PIP_3 at the plasma membrane, which binds to the PH domains of ADAP1 (Venkateswarlu et al. 1999; Venkateswarlu and Cullen 1999). The translocation was shown to be abrogated in HEK293 by pretreatment with thrombin, an effect that was exacerbated by increasing the intracellular IP_4 pool using LiCl (Sedehizade et al. 2005). As thrombin acts through a Gq-linked G- protein-coupled receptor (GPCR), it is possible that other Gq-linked GPCRs may have a similar effect.

All PKC isoforms (PKCα, λ, μ, and ζ) bind to and phosphorylate ADAP1 at Ser 87 in the GAP domain and Thr 276 in the C-PH domain (Zemlickova et al. 2003).

KIF13B is a kinesin motor protein that was shown to inhibit ADAP1 GAP activity but also relocate ADAP1 to the leading edge of the cell (Venkateswarlu et al. 2005; Kanamarlapudi 2005). This finding raises the possibility that KIF13B both temporally and spatially regulates the activity of ARF6.

As mentioned above, ADAP1 is an inositol phosphate–binding protein which binds to its ligands, the membrane-bound PIP_3 and the cytosolic IP_4, with similar affinities (Stricker et al. 1997; Tanaka et al. 1999). It also binds to phosphatidylinositol(3,4)-bisphosphate (PI(3,4)P_2) (Rao et al. 1999; Kalscheuer et al. 2009).

KIF13B was identified as an ADAP1-binding partner in a yeast two-hybrid screen. KIF13B contains an N-terminal motor domain, a large stalk domain at the center, and the CAPGLY domain (a putative microtubule interacting sequence) at the C terminus. ADAP1 directly interacts with the stalk domain of KIF13B through its GAP domain and this interaction is essential to maintain its localization at the leading edges of the cell. Moreover, KIF13B negatively regulates the GAP activity of ADAP1 in vivo. Together, these studies suggest that an ADAP1–KIF13B complex may provide a means for concentrating ADAP1 at the leading edges of the cell, where it regulates ARF6 activity (Venkateswarlu et al. 2005; Kanamarlapudi 2005). Moreover, in neurons, the ADAP1–KIF13B complex transports PIP_3 to the neurite ends, and thus regulates the establishment of neuronal polarity (Horiguchi et al. 2006).

All PKC isoforms (PKCα, λ, μ, and ζ) bind to ADAP1 in vitro by their cysteine-rich C1 domain, as demonstrated through affinity chromatography and GST pull-down assays. This interaction results in phosphorylation of Centaurin-α1 at Ser 87 and Thr 276 (Zemlickova et al. 2003).

ADAP1 has been shown to bind to the scaffolding protein RanBPM in vitro and in vivo by the SPRY domain of RanBPM and the ARF GAP domain of ADAP1. The association between these two proteins is inhibited by the ADAP1 ligand IP_4 (Haase et al. 2008).

ADAP1 also associates with casein kinase I (CKI) isoforms α, δ, ε, λ1, λ2, and λ3 but there is no evidence that this interaction modulates the activity of either ADAP1 or CKI, so it is difficult to assign a function to this protein–protein interaction. It has been suggested that ADAP1 may act as an adaptor protein for CKI lipid binding (Dubois et al. 2002). It is also possible that the ADAP1–CKI interaction has a role in the etiology of Alzheimer's disease due to an established role for CKI in disease pathology and an increased expression of ADAP1 in patients with Alzheimer's disease (Reiser and Bernstein 2002).

ADAP1 binds to the metalloendopeptidase NRDc (N-arginine dibasic convertase; also known as nardilysin), although the functional consequences of this interaction are not known (Stricker et al. 2006). A functional interaction is suggested by anatomical co-localization. In the human brain, considerable overlap was found between ADAP1 and nardilysin (NRDc). In the hypothalamic paraventricular nucleus (PVN), about two-thirds of ADAP1-immunoreactive neurons co-express NRDc, whereas 20% of the NRDc-containing neurons did not co-stain for ADAP1 (Bernstein et al. 2007). The proteins ADAP1 and nardilysin dissociate from each other in the presence of IP_4, but not of $Ins(1,4,5)P_3$ (Stricker et al. 2006). The ligand interaction of ADAP1 is stereospecific (Stricker et al. 1996).

In a study investigating nuclear-located binding proteins for ADAP1, nucleolin (which is also involved in the pathology of Alzheimer's disease (Reiser and Bernstein 2004)), the DNA-binding protein Pur-α, and the cerebellar leucine-rich acidic nuclear protein (LANP) were found to be ADAP1-interacting proteins. At lower concentrations, RNA polymerase II transcription cofactor 4 (mediator of RNA polymerase II transcription, subunit 8 (Med8)), the splicing factor arginine/serine-rich 2 (SFRS2), the pre-mRNA splicing factor SF3, the β2 subunit of the adaptor-related protein complex 3, and the protein similar to ribosomal protein S9 were shown to interact with ADAP1 (Dubois et al. 2003).

In vitro binding between ADAP1 and actin has also been demonstrated (Thacker et al. 2004). Actin binding is mediated through its PIP_3-binding PH domain, similar to that shown for Bruton's tyrosine kinase (BTK).

ADAP1 expression is upregulated in neurons in the brain of patients with Alzheimer's disease (Reiser and Bernstein 2002, 2004). In rats, after acoustic and electric fear stimulation (startle response), the mRNA and protein levels were downregulated within 2 h in the amygdala, hypothalamus, and cingulate/retrosplenial cortex. *ADAP1* mRNA decreased by about 50% for about 24 h (Reiser et al. 2004).

There were characteristic changes of *ADAP1* expression during development in the rat brain. mRNA levels of *ADAP1* were quantified at 7, 14, and 21 days of age, as well as in various brain regions of adult rats, including the cerebellum, cortex, striatum, thalamus, hypothalamus, olfactory bulb, hippocampus, and tectum (superior and inferior colliculus) (Aggensteiner and Reiser 2003).

Major Sites of Expression and Subcellular Localization

ADAP1 is abundantly expressed in the brain. It is also expressed at very low levels in nonneuronal tissues

such as spleen, lung, kidney, peripheral blood leukocytes, and retina (Hammonds-Odie et al. 1996; Venkateswarlu and Cullen 1999; Stricker et al. 1997). In the brain, *ADAP1* was found in neurons of the cortex, hypothalamus, and hippocampus (Sedehizade et al. 2002; Moore et al. 2007). Developmental expression analysis of *ADAP1* in rodent brains revealed that its expression is detectable as early as embryonic day 16 and peaks between 2 weeks and 4 weeks postnatally (Aggensteiner and Reiser 2003; Moore et al. 2007).

In the rat brain, high levels of developmentally regulated *ADAP1* expression are found in cerebellum, hippocampus, cortex, and thalamus. In adults, the immunoreactivity is localized in most neuronal cell types and probably also in some glial cells (Kreutz et al. 1997a). Prominent immunoreactivity is found in axonal processes and in cell types with long neurites. In the hypothalamus, a subpopulation of parvocellular neurons in the peri- and paraventricular nuclei is heavily labeled. This is confined by strong immunoreactivity in the lamina externa of the median eminence in close proximity to portal plexus blood vessels. Electron microscopy shows that ADAP1 protein is frequently associated with presynaptic vesicular structures (Kreutz et al. 1997a).

In rat, porcine, and bovine retina, *ADAP1* is localized by in situ hybridization in the ganglion cell layer, the inner nuclear cell layer, and the outermost part of the outer nuclear cell layer (Kreutz et al. 1997b). Wide-field amacrine and retinal ganglion cells are intensely immunostained. Prominent immunoreactivity in the on/off sublaminae of the inner plexiform layer and in the optic nerve layer indicates a pre- and/or postsynaptic localization of the protein. Moreover, there is significant ADAP1 protein expression in the inner segment of photoreceptors. The end-feet of Müller glial cells in the optic nerve layer are also stained (Kreutz et al. 1997b).

ADAP1 and KIF13B/GAKIN co-localize after transfection of tagged proteins at the tip of growing neurites in PC12 cells. In cultured hippocampal neurons, endogenous ADAP1 is localized in growth cones (Horiguchi et al. 2006).

ADAP1 localizes to the cytoplasm and nucleus (Tanaka et al. 1999; Venkateswarlu et al. 1999). In polarized cells such as neurons, ADAP1 also localizes to dendrites, dendritic spines, and the postsynaptic region (Moore et al. 2007). ADAP1 is also found in mitochondria, where it regulates calcium levels (Galvita et al. 2009).

Phenotypes and Splice Variants

No studies on the phenotypic effects of ADAP1 have been carried out due to the lack of ADAP1-knockout mice. However, knockdown of Centaurin-α1 by short interfering RNA in cultured hippocampal neurons inhibits dendritic branching and length (Moore et al. 2007) and in HEK cells results in a reduction of EGF-stimulated ERK activation (Hayashi et al. 2006). In yeast, the deletion of the gene encoding the ADAP1 homolog, *Gcs1*, hypersensitizes the mutant to sodium fluoride. This effect can be rescued through introduction of human *ADAP1* (Venkateswarlu et al. 1999).

Although there is no evidence yet for the expression of splice variants, northern analysis of rat brain Centaurin-α (renamed as "ADAP") revealed a major transcript at 2.5 kb and a minor one at 4.0 kb (Hammonds-Odie et al. 1996). Both *ADAP* and *ADAP1* were cloned from a rat brain cDNA library (Hammonds-Odie et al. 1996; Aggensteiner et al. 1998). ADAP is highly homologous to ADAP1, but contains a 43 amino-acid C-terminal extension and lacks the N-PH domain due to three frame-shift mutations in the cloned cDNA. However, ADAP has not been detected thus far by RT-PCR or immunoblotting, and therefore it is not yet possible to say whether ADAP is a splice variant of ADAP1 or not (Aggensteiner et al. 1998).

The *ADAP1* clone was corrected later in Thacker et al. (2004). Re-sequencing the original cDNA clone revealed two sequencing errors in the original submission (accession number U51013). Species comparisons with the revised rat sequence indicated that rat ADAP1 is the ortholog of human and murine ADAP1, porcine p42IP4, and bovine PIP3BP.

Immunoblot analysis of endogenous rat brain ADAP1 demonstrated that it migrates as a doublet, but the basis for the difference in molecular mass has not yet been determined (Moore et al. 2007).

Hammonds-Odie and coworkers raised polyclonal antibodies against a 19-amino-acid peptide (AGELRRALLELLTRPGNSR) from the N-terminal end of rat Centaurin-α and against a C-terminal fusion protein. These antibodies are used in Western blotting applications for the detection of Centaurin-α (Hammonds-Odie et al. 1996). The Reiser group has produced its own anti-p42IP4 rabbit polyclonal and mouse monoclonal antibody, raised against a peptide

consisting of amino acids 353–371 of pig ADAP1, and used it to detect human, pig, and rat ADAP1 by Western blot and immunohistochemistry (Stricker et al. 1997, 2003, 2006; Kreutz et al. 1997a; Aggensteiner et al. 1998; Sedehizade et al. 2002; Reiser and Bernstein 2002; Aggensteiner and Reiser 2003).

There are also several anti-Cetaurin-α1 antibodies that are commercially available. By far the most widely used commercially available antibody against ADAP1 is a mouse monoclonal (P421; IgG1 subtype) raised against full-length pig ADAP1. This antibody is available from Santa Cruz Biotech (sc-51836), Abcam (ab10168), and HyTest Ltd (4MA10), and has been used for detection of ADAP1 from human and pig by ELISA and Western blotting (Thacker et al. 2004; Venkateswarlu et al. 2005; Hayashi et al. 2006).

A goat anti-ADAP1 polyclonal antibody, raised against the synthetic peptide CQEYAVEAHFKHKP, which corresponds to amino acids 362–374 of human ADAP1, is available from Abcam (ab27476) and Everest Biotech (EB06120). This antibody can be used in ELISA, immunoctyochemistry, immunohistochemistry, and Western blotting applications to detect human, rat, and mouse ADAP1 (Moore et al. 2007).

A mouse polyclonal antibody, raised against the full-length human ADAP1 protein, is available from Novus Biologicals (H00011033-B01). This antibody is useful for ELISA, Western blot, and immunofluoresence, and detects human ADAP1. A rabbit anti-ADAP1 antibody generated against GST-fused full-length human ADAP1 is available from Proteintech Group (13911-1-AP) and can be used to detect human and mouse ADAP1 by Western blot and immunohistochemistry.

Summary

ADAP1 (also known as Centaurin-α1/PIP3BP/p42IP4/ADAP1) is a phosphatidylinositol (3,4,5)-trisphosphate (PtdIns(3,4,5)P_3)/IP_4-binding protein that regulates actin cytoskeleton organization and membrane trafficking by acting as a GTPase-activating protein (GAP) of ADP-ribosylation factor 6 (ARF6). The binding is stereospecific for D-inositol (1,3,4,5) P_4 (IP_4) as it does not bind to inositol 1,4,5-trisphosphate (Ins(1,4,5)P_3). It also associates with casein kinase Iα (CKIα), Ran-binding protein in microtubule-organizing center (RanBPM), nardilysin, kinesin motor protein (KIF13B), protein kinase C (PKC), and nucleolin. ADAP1 localization and activity have been shown to be regulated by phosphoinositol 3-kinase (▶ PI3K), protein kinase C (PKC) isoforms, and the kinesin motor protein KIF13B. It is abundantly expressed in brain tissue and is also detected in nonneuronal tissues at very low concentrations. ADAP1 expression is upregulated in neurons in the brain of patients with Alzheimer's disease and is detected in amyloid plaques, indicating that it may be involved in neuronal diseases. ADAP1 is normally localized in the cytoplasm, nucleus, and mitochondria and it translocates to the plasma membrane by binding to PIP_3 produced by agonist-activated PI3K to act as a GAP for ARF6. ADAP1 localizes to dendritic spines and synapses in neurons and can affect differentiation, PIP_3 transport, and vesicle secretion. It has also been implicated in regulation of Ca^{2+} transport in mitochondria. There is no information on ADAP1-null phenotypes in mammals, but due to its putative role in neuronal development, it is possible that loss of ADAP1 may affect the viability of the organism. There are no known polymorphisms of the *ADAP1* gene.

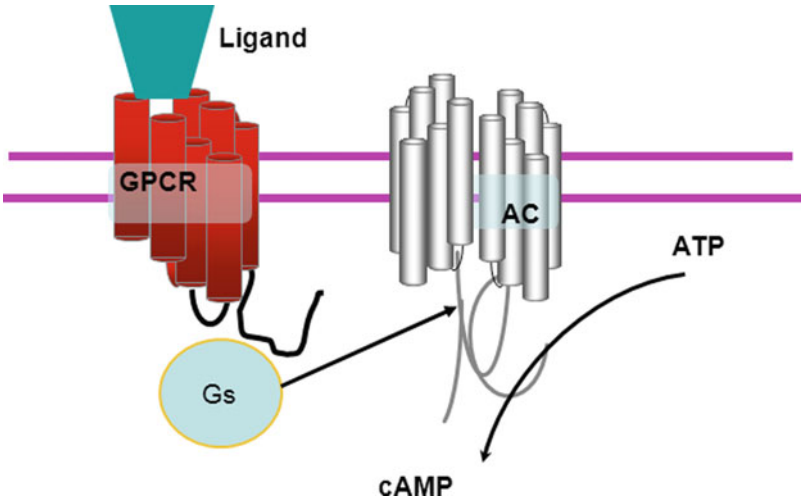
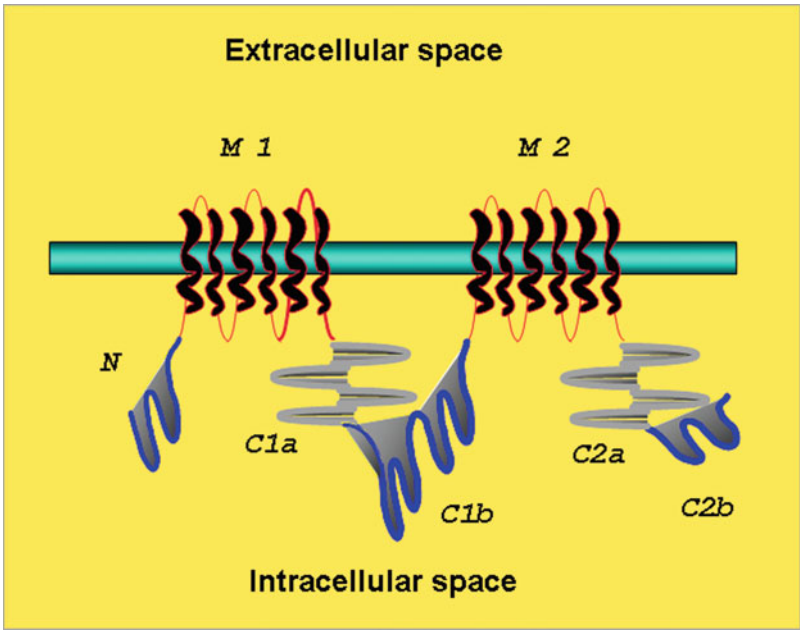
Historical Background

Adenylyl cyclase (AC) is the enzyme (EC 4.6.1.1) that converts Mg-ATP to adenosine 3′:5′monophosphate or cyclic AMP and pyrophosphate first reported in 1958 by Sutherland and Rall. Eventually, a membrane-delimited biochemical cascade (Fig. 1) was discovered as the molecular machinery of signal transduction by cell surface receptors *via* heterotrimeric G proteins (Ross and Gilman 1980). The era of gene cloning revealed an unexpectedly complex structure of membrane-bound adenylyl cyclase: a single large polypeptide chain that crosses the plasma membrane 12 times, the catalytic core being formed between two structurally homologous cytoplasmic domains (C1a and C2a) held together by noncovalent interactions (Fig. 2). The crystal structures of these domains in complex with Gsα and the likely mechanisms underlying catalysis have been reported (Tesmer and Sprang 1998). There are nine genes encoding membrane-bound adenylyl cyclases in vertebrates (Antoni 2000; Willoughby and Cooper 2007). Manifestations of the molecular diversity of adenylyl cyclases fall into three principal categories: (1) different allosteric mechanisms for the regulation of cAMP synthesis; (2) variation of tissue distribution through the control of gene expression; and (3) selective intracellular targeting (Antoni 2000; Willoughby and Cooper 2007). However, the biological reasons for the complexity of the structure of the holoenzyme as well as the respective physiological roles of the nine paralogues of membrane-bound adenylyl cyclase remain largely unknown (Antoni 2000; Willoughby and Cooper 2007).



ADCY9 (Adenylyl Cyclase 9), Fig. 1 Basic scheme of the activation of adenylyl cyclase by heptahelical receptors in the plasma membrane. Upon binding of the ligand the heterotrimeric G protein Gs becomes active and the Gsa subunit binds to adenylyl cyclase and induces an increase of catalytic activity



ADCY9 (Adenylyl Cyclase 9), Fig. 2 Blueprint of the structure of membrane-bound adenylyl cyclases. A single polypeptide chain crosses the plasma membrane (in *blue cylinder*) 12 times forming the M1 and M2 transmembrane domains. The N terminus (N) is in the cytoplasm just as the C1 and C2 cytoplasmic domains. On the basis of structure activity studies it is useful to subdivide in the latter into a and b subdomains. The C1a and C2a domains show significant sequence homology and are known to form the catalytic core of the enzyme, which is responsive to G proteins and forskolin. Catalysis requires Mg^{2+} as well as Mn^{2+}. In the case of AC9 the preC1a segment as well as C1b and the C2b domains contain phosphorylation cluster

Protein Structure and Regulation

The primary structure of adenylyl cyclase 9 (AC9) has two notable features when compared with its mammalian paralogues (Paterson et al. 2000). Firstly, the nonconserved cytoplasmic domains C1b and C2b (Fig. 2) are considerably longer, e.g., in the case of C2b 112 amino acid residues for AC9 versus 16 for AC2. Secondly, there is a segment of amino acid residues in all adenylyl cyclases between the predicted sixth intramembrane helix and the relatively conserved C1a domain (pre-C1a) that is highly variable between

AC paralogues; in the case of AC9 it consists of 34 amino acid residues (in other ACs it is 16 or less) and contains a phosphorylation cluster <http://www.phosphosite.org/proteinAction.do?id=8311&showAllSites=true>.

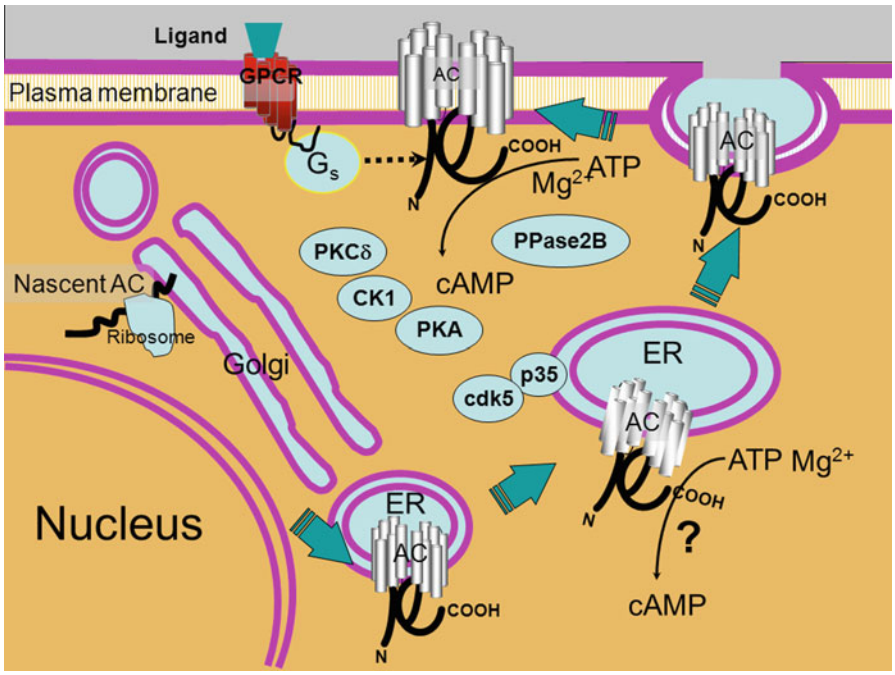
Adenylyl cyclases are subject to three main classes of physiological regulation by (1) heterotrimeric G proteins, (2) calcium ions, and (3) protein phosphorylation. All isoforms of AC, including AC9, are activated by the alpha subunit of the heterotrimeric G protein, G protein alpha s, and are thus stimulated by a variety of heptahelical cell surface receptors (7-TMR). There are apparently no effects of G protein beta/gamma subunits or Gi alpha on AC9 activity in membranes prepared from human embryonic kidney cells (HEK 293) overexpressing human AC9 or Sf9 cells infected with baculovirus encoding AC9 (Premont et al. 1996). In accordance, a putative Giα binding site sequence delineated in AC5 is absent from AC9. However, in intact AtT20 cells where the cAMP response to the activation of 7-TMR is predominantly through AC9 (Antoni et al. 1995), prominent inhibition of cAMP production by somatostatin acting through SST2/5 receptors in a pertussis toxin-sensitive manner has been demonstrated. Moreover, in HEK293 cells stably overexpressing AC9 and the long form of the D2 dopamine receptor, the D2 agonist quinpirole-inhibited isoproterenol evoked cAMP accumulation – an effect blocked by pertussis toxin (Cumbay and Watts 2004). A possible caveat in the latter study is that the expression plasmid for human AC9 used does not code for the entire correct sequence of AC9, as the C-terminal region contains a double frameshift mutation (Paterson et al. 2000). Taken together, the action of Gi-coupled receptors on AC9 is in need of further investigation.

Adenylyl cyclase 9 (AC9) was discovered on the basis of unique sensitivity of the agonist-evoked cAMP response to inhibitors of calcineurin in a pituitary tumor cell line (Antoni et al. 1995). The molecular choreography of the regulation by calcineurin is not known; currently it cannot be excluded that it is indirect, i.e., via a protein phosphatase cascade the main effector of which would be protein phosphatase 1. Pharmacological evidence indicates that activation of protein kinase C inhibits Gsα-mediated activation of AC9 (Cumbay and Watts 2004). Proteomic analysis has revealed at least 12 sites of phosphate incorporation in the isoform-specific segments (preC1a, C1b, and C2b) of human AC9 <http://www.phosphosite.org/proteinAction.do?id=8311&showAllSites=true>. Some of these phosphorylations, especially those in the pre-C1a cluster as well as Ser1307 in the C2b domain, which is an amino acid residue unique to AC9 in primates, have been analyzed in detail in HEK293 cells (Simpson et al. 2006). Specifically, Ser 365 and Ser1307 are constitutively phosphorylated by cyclin-dependent protein kinase 5 in HEK293 cells. Stimulation by cAMP leads to a marked increase in the levels of phosphoSer374 and a reduction in phosphoSer1307. The functional impacts of these changes of phosphorylation await elucidation.

Tissue Distribution and Subcellular Targeting

AC9 mRNA is widely expressed in the body (Paterson et al. 1995; Premont et al. 1996). The brain, heart, skeletal muscle, endocrine organs, the aorta, and the prostate all express high levels of AC9 mRNA whereas the spleen and thymus have low levels. Within the brain all neurons appear to express AC9, with particularly high levels of protein in the hippocampus and the cingulate cortex (Antoni et al. 1998). The promoter region of the *Adcy9* gene has not been analyzed in detail.

It is assumed that ACs are largely localized to the plasma membrane where they would be concentrated and ready for interaction with Gsα. This concept is supported in HEK293 cells and other epithelial cell lines, where transfected ACs, including AC9 (Paterson et al. 2000; Antoni et al. 2006) appear predominantly in the plasma membrane. However, the situation may be different in neurons where the bulk of adenylyl cyclase appears to localize to discrete punctae in the cytoplasm (Antoni et al. 2006). Within nerve cells of the adult rodent brain AC9 appears to be restricted to the somatodendritic compartment and is also found throughout the cytoplasm with no obvious enrichment in the plasma membrane. In this context it is worth recalling a salient structural feature of membrane-bound adenylyl cyclases: the cytoplasmic domains are sufficient for Gsα-mediated cAMP biosynthesis. Thus the cytoplasmic domain of a fully synthesized and folded adenylyl cyclase located in the smooth endoplasmic reticulum is, at least in principle, fully responsive to physiological stimulation provided Mg^{2+}



ADCY9 (Adenylyl Cyclase 9), Fig. 3 Intracellular trafficking of membrane-bound adenylyl cyclase poses important questions. As the cytoplasmic loops of the protein are catalytically active in the presence of ATP and Mg^{2+}, it is plausible that cAMP is produced in the cytoplasm. Indeed, adenylyl cyclases could be targeted to relevant cellular compartments other than the plasma membrane. Data on AC9 indicate that at least four different types of protein kinase, protein kinase C delta (PKCd), protein kinase A (PKA), casein kinase 1(CK1), and cyclin-dependent protein kinase 5/p35 complex (cdk5/p35) phosphorylate this enzyme; moreover the protein phosphatase calcineurin and calyculin A sensitive phosphatases contribute to its regulation. All of these enzymes can be attached to cell membranes. Similarly AC1 and AC8 which are stimulated by Ca^{2+} calmodulin acting on the cytoplasmic domain could provide for propagating cAMP signals that move in concert with intracellular Ca^{2+} waves

and ATP are present in sufficient amounts (Fig. 3). Indeed, it has been reported that upon receptor activation at the cell surface Gsα translocates into the cell interior (Allen et al. 2005). Furthermore, stimulators of V2-type vasopressin receptors that are cell membrane permeant can induce cAMP production *via* mutant V2 receptors that fail to be exteriorized to the cell surface (Robben et al. 2009). This latter finding also implies that functionally active signalosomes containing heptahelical receptor, Gs and adenylyl cyclase can be assembled in intracellular membranes.

Physiological Role and Phenotypes

AC9 is by far the most abundant adenylyl cyclase in the brain, yet relatively little is known about its role in the CNS. AC9 mRNA levels in the hippocampal CA1 field and the dentate gyrus were reduced in aged mice (Mons et al. 2004). Moreover, AC9 mRNA levels in the hippocampus of young adult mice were significantly increased after training sessions in the Morris water maze (fixed hidden platform paradigm) and showed a significant correlation with the level of performance in this test of spatial memory (Mons et al. 2004). While these data indicate that higher AC9 levels are associated with superior cognitive performance, further evidence is required to substantiate this notion.

In the neuroendocrine system, AC9 appears to play an important role in glucocorticoid feedback regulation of the secretion of adrenocorticotropin by the anterior pituitary gland (Antoni et al. 2003).

Although AC9 is not abundant in the immune system, this enzyme is implicated in the response of macrophages to stimuli activating pattern recognition receptors (Alper et al. 2008).

A mutation in the AC9 coding sequence has been identified which is present in 30% of the North American Caucasian and Oriental population and leads to a substantial reduction of receptor-induced cAMP

synthesis (Small et al. 2003). This may potentially contribute to vulnerability to certain polygenic disorders. Intriguingly, a significant association between the same mutation and the familial occurrence of bipolar depression has been reported in a cohort of patients in Japan (Toyota et al. 2002).

Pharmacology and Therapeutic Potential

Adenylyl cyclases have been considered as therapeutic targets for a long time, but potent and selective drugs to modulate these enzymes have remained elusive. The paucity of data on the physiological role of AC9 is also reflected by the dearth of ideas concerning its potential in clinical therapy. Forskolin has no or very little effect on AC9 heterologously expressed in HEK293 or SF9 cells. Moreover, soluble miniproteins constructed from AC9 C1 and C2 domains also fail to respond to this drug (Yan et al. 1998; Haunsø et al. 2003). Yan and coworkers have shown that mutation of a single amino acid, Tyr1082Leu, will render AC9 sensitive to the stimulatory action of forskolin. Another unusual feature of AC9 is that it is largely resistant to inhibition by adenosine analogs (Haunsø et al. 2003) which are "dead-end" inhibitors of all other ACs. Calmidazolium is a very effective (Ki = 5 μM), albeit nonspecific inhibitor of AC9 (Haunsø et al. 2003).

Summary

Adenylyl cyclase 9 is a membrane-bound adenylyl cyclase with unique regulatory properties. While the enzyme is prominently expressed in vital organs of the body such as the brain, the heart, and most endocrine glands, precious little is known about its physiological role and potential involvement in the pathogenesis of human diseases. More work with genetically modified models is required to understand the biological role of the molecular diversity of adenylyl cylcases.

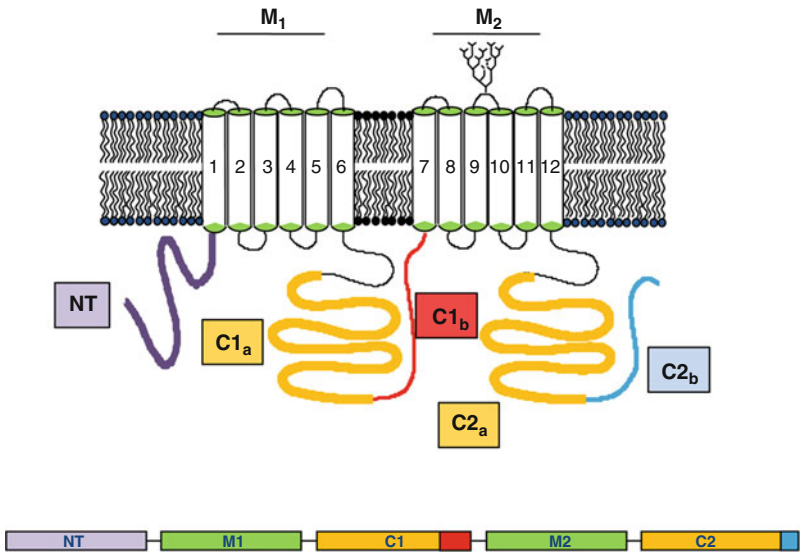
Historical Background

Adenylyl cyclases (ACs), ATP-pyrophosphate lyases, comprise a family of enzymes that catalyze the synthesis of cyclic AMP from ATP. Cyclic AMP (cAMP) was identified in 1957 as the first "second messenger," relaying signals from hormone-bound receptors to protein kinase A (PKA) and other cAMP-sensitive effectors, including cyclic-nucleotide gated channels, cAMP-activated exchange proteins (EPAC), and a subset of phosphodiesterases that degrade cyclic nucleotides. Catalytic activity of AC is regulated in response to activation of G protein-coupled receptors (GPCRs) by a number of hormones and neurotransmitters. Various studies using biochemical and genetic tools have implicated the importance of cAMP in a variety of physiological functions that include but are not limited to oogenesis, embryogenesis larval development, hormone secretion, glycogen breakdown, smooth muscle relaxation, cardiac contraction, olfaction, water homeostasis, and learning and memory (Sadana and Dessauer 2009). The discovery of cAMP and subsequent studies related to the regulation and physiological functions of AC has given rise to four Nobel Prizes in Medicine and remains a highly active area of research (Beavo and Brunton 2002).

Nine mammalian transmembrane ACs have been cloned and characterized since the initial cloning of AC1 in 1989. A tenth "soluble" form of AC (sAC) has also been characterized that lacks transmembrane domains and has distinct regulatory properties. Based upon homology and regulation patterns, membrane-bound ACs are classified into four groups; Group I comprises the Ca^{2+}-stimulated AC 1, 3, and 8; Gβγ-stimulated AC 2, 4, and 7 belong to Group II, Group III contains Giα/Ca^{2+}-inhibited AC5 and 6, while Group IV contains the distantly related forskolin-insensitive AC9.

Topology and Structure

Mammalian transmembrane ACs share a common structure that can be divided into five sections: a variable N-terminus (N), the first transmembrane domain (M1, with six membrane spans), a large cytoplasmic domain (C1), followed by a second transmembrane domain (M2, also with 6 membrane spans), and a second cytoplasmic domain (C2) (Fig. 1).



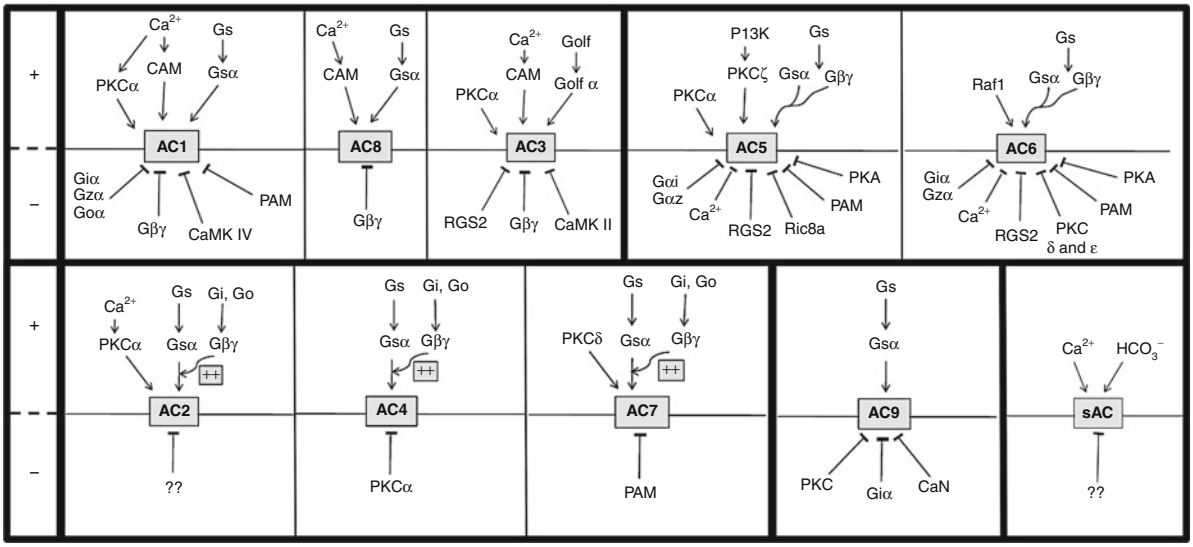
Adenylyl Cyclase, Fig. 1 Topology of membrane-bound ACs

The N-terminal portions of the two cytoplasmic domains (C1a and C2a; ~ 230 aa residues) are roughly 40% identical to each other and are highly homologous among isoforms. The topology of ACs is based largely on prediction programs for membrane spanning regions, whereas knowledge of the catalytic site comes from X-ray structures of a complex containing the C1a/C2 domains bound to the activators forskolin and Gsα. The catalytic site of AC lies at the interface of the cytoplasmic domains (C1a and C2a), forming a pseudo-symmetrical site that is primed for bidirectional regulation. The two related pockets, a substrate binding site and a forskolin site, lie along the domain interface. Although neither cytoplasmic domain has catalytic activity on their own, AC enzyme activity and many forms of regulation can be reconstituted by simple mixing of purified C1 and C2 domains of AC. The active site of ACs share similarities with the active site of DNA polymerases despite the differences in sequence and surrounding structures (Sinha and Sprang 2006).

The "soluble" form of adenylyl cyclase (sAC) has homology to cyanobacterial adenylyl cyclases with several known splice variants. The overall structure of the catalytic core of sAC is highly conserved with the transmembrane ACs, although the primary sequences differ significantly. Unlike transmembrane ACs, it does not respond to the classical G protein mode of activation but is regulated by calcium and bicarbonate levels. The sAC isoform has clear roles in male fertility and sperm motility, in addition to potential roles in acid/base homeostasis and metabolic sensing.

Regulation of ACs by G Proteins

All isoforms of membrane-bound mammalian AC are stimulated by the heterotrimeric G protein Gs (reviewed in (Sadana and Dessauer 2009; Sinha and Sprang 2006; Willoughby and Cooper 2007; Beazely and Watts 2006), Fig. 2). Appropriate agonist-bound, GPCRs activate Gs by catalyzing the exchange of GDP for GTP and facilitating the dissociation of the GTP-bound α-subunit (Gsα) from a complex of G protein α and βγ subunits. The GTP-bound α-subunit of Gs in turn activates AC, increasing the rate of synthesis of cAMP. The intrinsic GTPase activity of the G protein α subunit hydrolyzes bound GTP to GDP, terminating the activation of AC by GTP-Gsα after several seconds. GDP-Gsα then reassociates with Gβγ and awaits a new cycle of activation. This seemingly straightforward pathway is regulated at every step, from the phosphorylation and desensitization of the GPCR to the control of cAMP breakdown by numerous phosphodiesterases. Much of this regulation is targeted directly at the enzyme AC, which serves to integrate a large number of different signaling inputs. Golf,α which is highly homologous to Gsα and expressed in the olfactory



Adenylyl Cyclase, Fig. 2 *Regulatory patterns for AC isoforms*. Group I is represented by AC 1, 8, and 3, Group II contains AC 2, 4, and 7, Group III contains AC 5 and 6, and AC9 is in Group IV. The enzyme sAC is a distinct class of AC and does not respond to direct regulation by heterotrimeric G proteins

system and brain striatum, also stimulates AC. Gsα interacts with the C2 domain of AC to facilitate closure of the active site, increasing the affinity of the C1 and C2 domains for each other.

Select AC isoforms (AC 1, 5, and 6) are directly inhibited by members of the inhibitory class of G proteins, Giα, Gz, Go (Beazely and Watts 2006). This regulation can be dependent on the form of activation. For example, calmodulin-stimulated AC1 is potently inhibited by Gi family members (i, z and o), whereas AC1 is either very weakly inhibited or not at all when stimulated by Gsα- or forskolin. AC 5 and 6 are inhibited by Giα and Gzα. Giα interacts in a cleft formed in the C1 domain of AC5, analogous to the Gsα binding site in C2, and acts in opposition to Gsα. AC9 can also be inhibited by Gi-coupled receptors, which is presumably due to direct inhibition by the Giα subunit.

In addition to the α subunit, Gβγ subunits of heterotrimeric G proteins can regulate AC activity. For example, in Group I ACs 1 and 8 are inhibited by Gβγ, often more potently than the inhibition by Giα. Although Gβγ alone is not able to stimulate Group II ACs (AC2, 4, and 7), it can greatly enhance the activation by Gsα (∼five- to tenfold for AC2). This conditional Gβγ stimulation is the hallmark of the Group II family of ACs. Gβγ also conditionally stimulates AC5 and 6 in the presence of Gsα (∼1.5–2-fold), but not to the same extent as the AC2 family (Fig. 2).

Additional Modes of AC Regulation

Forskolin, a diterpene derived from the root of the Indian plant *Coleus forskohlii*, highly activates all the membrane-bound AC isoforms except AC9. This reagent is a highly useful tool for studying AC and the effects of cAMP. It has also been explored for possible medicinal uses and was originally characterized as a vasodilator. Forskolin binds at the interface of the C1 and C2 domains at a site distinct from the catalytic site (Tesmer et al. 1997) and is either additive or synergistic with regulation by Gsα. AC9 is not activated by forskolin because it lacks a key amino acid residue within this forskolin binding pocket. No physiological analogs of forskolin have been identified that can bind at the forskolin binding pocket to regulate AC activity.

AC activity can also be controlled by calcium, protein kinases, and a number of additional regulatory and scaffolding proteins. Most of this regulation is highly isoform specific. For example, although all AC isoforms are inhibited by high, nonphysiological concentrations of calcium, sub-micromolar calcium concentrations inhibit AC5 and 6 by directly binding to a magnesium ion binding site within the catalytic core. When bound to calmodulin, calcium can activate AC1 and 8, and conditionally stimulate AC3 in the presence of Gsα or forskolin. The calcium/calmodulin binding

sites for AC1 have been mapped to the C1b and C2 domains; whereas the sites on AC8 reside within the N-terminus and C2 domain. Finally, calcium/calmodulin-bound protein kinases can inhibit ACs. AC3 and AC1, but not AC8, are subject to feedback inhibition by calmodulin kinases (CamK) CaMK II and CaMK IV, respectively.

Several protein kinases regulate AC activity by directly phosphorylating AC isoforms. Feedback inhibition of AC 5 and 6 occurs via phosphorylation of the C1b domain by cAMP-activated PKA. This type of regulation is facilitated by A-kinase anchoring proteins (AKAPs) that anchor the regulatory subunit of PKA (Dessauer 2009). AKAPs are scaffolding proteins that bring together a large number of regulatory and downstream effector proteins. They can also bind to a subset of ACs. For example, AKAP79/150 (AKAP5) binds to ACs 2, 3, 5, 6, 8, and 9. The formation of an AKAP79/150-AC-PKA complex facilitates preferential phosphorylation of AC 5/6 by anchored PKA to inhibit AC activity. Much like calcium/calmodulin regulation of AC1, this sets up an important negative feedback loop to temporally regulate cAMP production and downstream signaling. A similar type of regulation also occurs for mAKAP-AC5-PKA complexes that regulate stress-responsive pathways in the heart.

Regulation by protein kinase C (PKC) isoforms is quite complex. Conventional PKCs (α and β; activated by calcium and diacylglycerol) often stimulate AC 2 and 5 and are synergistic with other forms of regulation. The novel PKCδ isoform (activated by only diacylglycerol) displays synergy with Gsα in activating AC7, while the atypical PKCζ stimulates AC5. Conventional or novel PKCs can also inhibit AC activity. AC4 is inhibited by PKCα when stimulated by Gsα, but not under basal or forskolin-stimulated conditions. Gsα-stimulated AC9 is also inhibited by conventional PKCs. The novel PKC δ and ε isoforms inhibit AC6 by phosphorylating several sites within its N-terminus. The sites of PKC phosphorylation on ACs vary between these different isoforms.

Additional kinases that regulate AC activity include ▶ Raf1 that can stimulate AC6 activity. The role of phosphatases in regulating ACs should not be overlooked. Although this has not been greatly examined, AC9 is inhibited by the phosphatase calcineurin (also known as protein phosphatase 2B, PP2B); however, it is unknown whether calcineurin acts directly on AC9. Another phosphatase, PP2A, is scaffolded by AC8, although a direct regulatory role is still unclear.

Finally, a wide range of additional proteins have been reported to regulate specific AC isoform activity including, ▶ regulators of G-protein signaling 2 (RGS2; inhibition of AC 3, 5, and 6), the protein associated with myc (PAM; inhibition of AC 1, 5, 6, and 7), the synaptic vesicle protein snapin (prevents PKC inhibition of AC 6), and the guanine nucleotide exchange protein Ric8a (inhibits AC 5). The functional roles for some of these proteins are further discussed below.

AC Physiological Roles

The physiological roles for ACs have been defined based upon localization and animal studies of genetic ablation or overexpression of an individual AC isoform (reviewed in (Sadana and Dessauer 2009); Table 1). However, since few specific antibodies against individual AC isoforms exist, much of the tissue specificity is based upon the detection of mRNAs for ACs. Some of the early noted functions included roles for AC1 and 8 (primarily expressed in brain) in learning and memory; AC3 (most abundant in olfactory epithelium) in olfaction; and AC5 and 6 (dominant in heart) for cardiac contractility. However, studies of physiological roles for additional AC isoforms have lagged behind, and in some cases no knockout animal models exist (AC 2) or the mice are embryonic lethal for unknown reasons (AC9). The largest difficulty in defining specific roles for ACs stems from the expression of multiple isoforms in any given cell type. For example, cardiac myocytes express AC 5, 6, and 9 (and possibly others) while AC 2, 3, 4, 6, and 7 are readily detected in cardiac fibroblasts. Is the expression of multiple AC isoforms a form of redundancy within the system or does each AC have a specific role(s) in these cell types? The answer may be both. Discussion of specific systems will attempt to address some of this complexity.

In Learning and Memory

Nearly all AC isoforms are expressed in brain but they display distinct roles. Early studies with Drosophila mutants *rutabaga* (deficient in Ca^{2+}/CAM stimulated AC activity whose sequence is closely related to AC1) demonstrated that mutant flies failed to learn to avoid a neutral odor. The role for AC1 in learning and

Adenylyl Cyclase, Table 1 Tissue distribution and physiological functions of individual mammalian AC isoforms

AC isoform	Sites of expression	Physiological functions
AC1	Brain, adrenal medulla, SA node	Learning, memory, synaptic plasticity, opiate withdrawal, pain memory, neuronal excitotoxicity
AC8	Brain, lung, pancreas, testis, adrenal	Learning, memory, synaptic plasticity, opiate withdrawal, stress anxiety, ethanol consumption
AC3	Olfactory epithelium, pancreas, brain, heart, lung, testis, BAT	Olfaction, sperm function, kidney function
AC2[a]	Brain, lung, skeletal muscle, heart	
AC4[b]	Widespread	
AC7	Widespread	Ethanol dependency, immune response
AC5	Heart, striatum, kidney, liver, lung, testis, adrenal, BAT	Cardiac contraction, motor coordination, opiate dependency, pain responses
AC6	Heart, kidney, liver, lung, brain, testis, skeletal muscle, adrenal, BAT	Cardiac contraction and calcium sensitivity, water homeostasis
AC9[b]	Widespread	
sAC	Testis and detected in all tissues	Sperm capacitation, fertilization

[a]Knockout not available
[b]Not fully characterized

memory in mammalian systems correlates well with its expression in brain and the phenotypes of mice deficient in AC1 ($AC1^{(-/-)}$). AC8 is also expressed mainly in brain and shares many regulatory properties of AC1, thus it is not surprising that it also is involved in learning and memory.

The formation of memories relates to the change in connections between neurons in the brain, often referred to as synaptic plasticity. This change is often measured as long-term potentiation (LTP) which is a long-lasting enhancement of neuronal connections, which enhances synaptic transmission or communication. Synaptic plasticity is dependent on calcium, therefore it is not surprising that AC 1 and 8 play such a large role. $AC1^{(-/-)}$ and $AC8^{(-/-)}$ animals show decreased LTP in the mossy fiber bundles of neurons that form connections with the CA3 region of the hippocampus (Wu et al. 1995; Wang et al. 2003). A complete loss of mossy fiber LTP was observed in the double knockout of AC 1 and 8. In contrast, the overexpression of AC1 actually enhanced recognition memory and LTP (Wang et al. 2004). These and many additional studies suggest that AC 1 and 8 are redundant in learning and memory and the formation of fear-related memories. However, there are some distinct roles for AC 1 and 8. For example, AC1 is important for the stability of neuronal circuits in response to activation deprivation, while AC8 is more involved in synaptic plasticity related to anxiety. This correlates well with the high expression of AC8, but not AC1, in the thalamus, habenula, and hypothalamus, regions involved in responses to stress. In summary, although AC 1 and 8 are not necessary for survival, they play clear roles related to learning and memory.

In Pain

Signaling pathways associated with cAMP have long been known to play a crucial role in the processing of painful stimuli (reviewed in (Pierre et al. 2009)). Various AC isoforms (AC 1, 2, 5, 6, and 8) are expressed in spinal cord, but deletion of AC1 and AC5 results in attenuated pain responses. AC1, but not AC8, knockout mice have significantly reduced behavioral responses to acute muscle pain. These findings were confirmed by use of a specific AC1 inhibitor. Chronic muscle inflammatory pain was also significantly reduced in AC1 and the AC1/8 double knockouts, but could be rescued by activating other ACs using forskolin. Thus AC1 plays an important role in acute and chronic muscle pain, although clearly additional ACs are present that can rescue impaired effects.

Mice deficient in AC5 also have attenuated pain responses in acute thermal and mechanical pain tests. They display decreased sensitivity to inflammatory pain and inflammatory visceral pain (induced by injection of sulfate or acetic acid). $AC5^{(-/-)}$ mice also display strongly attenuated mechanical and thermal

allodynia (an exaggerated response to normal stimuli) in neuropathic pain models. Although AC1 and AC5 belong to different families in term of their regulatory properties, they share a common feature in that both are inhibited by PAM, which is upregulated in the spinal cord in response to pain.

In Addiction

The analgesia properties of opiates such as morphine are mediated by Gi-coupled opiate receptors and are related in part to the inhibition of adenylyl cyclase (reviewed in (Watts and Neve 2005) and (Pierre et al. 2009)). Long-term morphine use causes an upregulation of AC signal transduction components (AC 1 and 8, PKA, and ▶ CREB) in regions of the brain associated with drug reinforcement and withdrawal. The deletion of AC 1 and 8 causes a reduction in opiate withdrawal behaviors and the double knockout of AC 1 and 8 displays less morphine-induced hyper-locomotion, and no activation of the cAMP-dependent transcription factor, CREB in the reward response circuitry of the brain (ventral tegmentum). AC1 and AC8 also have some distinct functions during chronic morphine exposure, based upon nonoverlapping patterns of gene expression changes. This difference is also reflected in the addictive properties of ethanol where mice deficient in AC8, but not AC1, had decreased voluntary ethanol consumption.

AC5 also plays an important role in opiate actions. The region of the brain (striatum) that shows the highest μ-opiate receptor levels also contain high levels of AC5. Deletion of AC5 results in a loss of opioid-induced Gi-inhibition of AC activity in striatum. In addition, the major behavioral effects of morphine including locomotor activation, pain relief, tolerance, reward and physiological dependence, and withdrawal symptoms were attenuated in $AC5^{(-/-)}$ mice. Thus AC activity plays important roles in opioid responses and addiction; with AC1 and AC8 having roles in withdrawal, hyper-locomotion, and the learned responses to morphine; whereas AC5 is involved in all major behavioral effects of morphine.

In Motor Functions

Motor functions can be divided into voluntary and involuntary (or reflex) movements. Those non-reflex actions require higher cognitive activity in several brain regions, including the striatum. The striatum region of brain is known to be important for the decision-making of voluntary movements which often requires input from dopamine-releasing neurons. Genetic ablation of AC1 and AC8 did not affect motor coordination. However, $AC5^{(-/-)}$ mice no longer respond to the dopamine D2 antagonist class of antipsychotic drugs, although general motor control is unaltered (reviewed in (Sadana and Dessauer 2009)). This behavior correlates well with the high expression of AC5 in striatum. Other $AC5^{(-/-)}$ models exhibit Parkinson's like motor dysfunction, displaying abnormal coordination, a slowness in the execution of movement (bradykinesia), and locomotor impairment (Iwamoto et al. 2003). Motor coordination can be restored by stimulation of dopamine D2 receptors, while bradykinesia was largely restored by either D1 or D2 stimulation of residual striatal AC activity. Although other Gi-inhibited ACs (AC1 and AC6) are present in striatum, they cannot fully compensate for AC5 function in dopamine-dependent motor coordination.

In Cardiac Functions

As discussed above, all of the AC isoforms except AC8 are expressed in cardiac myocytes or fibroblasts. AC1 is expressed only in sinoatrial mode, where it modulates the I(f) pacemaker current. Two closely related isoforms, AC5 and 6 are the major isoforms expressed in cardiac myocytes and have been the focus of several deletion and overexpression studies (reviewed in (Sadana and Dessauer 2009)). These ACs appear to exert opposite effects on the heart, since cardiac overexpression of AC6 appears to be protective, whereas disruption of type 5 AC prolongs longevity and protects against cardiac stress (Yan et al. 2007). However, some overlapping functions must exist in the heart, as deletion of AC 5 or 6 does not give rise to a complete loss of sympathetic regulation.

The deletion of AC5 results in ~40% decreased isoproterenol- (an agonist of the beta-adrenergic receptors; βAR) and forskolin-stimulated AC activity in cardiac membranes and isolated myocytes. There is also a loss of acetylcholine-mediated (Gi) inhibition and reduced calcium-mediated inhibition of cAMP production in $AC5^{(-/-)}$ heart. Although differences in AC5 deletion strains exist, the loss of AC5 results in decreased isoproterenol-stimulated left ventricular (LV) ejection fraction (e.g., the volume of blood pumped out of the heart with each beat). Effects of AC5 deletion are not limited to sympathetic regulation,

as loss of AC5 also eliminates parasympathetic control of cAMP levels and attenuates baroreflexes that maintain blood pressure. The deletion of AC6 represents a functional double knockout of AC5 and AC6 because of reduced AC5 levels in AC6 $^{(-/-)}$ mice (Tang et al. 2008). As expected, βAR-stimulated cAMP levels were reduced ~80% in these animals with greatly reduced βAR-stimulated LV contractile function and reduced calcium transients. The latter effect on calcium handling is likely due to the loss of AC6, rather than AC5.

When the heart is stressed by chronic activation of cAMP (often due to prolonged beta-adrenergic receptor activation), a decrease in cardiac function is observed (cardiac myopathy). The levels of AC5 are also known to increase under these conditions. Deletion of AC5 protects the heart against chronic βAR stimulation and chronic pressure overload by attenuating the decline in cardiac function and defending against increased apoptosis. AC5 disruption is also protective against age-related cardiac myopathy and gives rise to an increased lifespan as compared to wild-type animals.

The differing roles for AC5 and AC6 may lie in the types of AKAP complexes that they are associated with. For example, AC6 is found in complex with AKAP79/150 in heart. Deletion of AKAP150 results in loss of βAR stimulated calcium transients (Navedo et al. 2008), reminiscent of AC6 deletion phenotypes. In contrast, AC5 is found in complex with mAKAP which is associated with the regulation of cardiac hypertrophy and related stress responses (Dessauer 2009). Another AKAP, Yotiao, is important in mediating sympathetic control of cardiac action potential duration. Yotiao is associated with several AC isoforms including AC9 which is present at lower levels in cardiac myocytes. The role for this latter AC isoform is as yet unknown.

In Olfaction

AC 2, 3 and 4 are expressed in the olfactory system. However, AC3 is the predominant isoform in the olfactory epithelium and is largely responsible for odorant and pheromone detection (reviewed in (Wang et al. 2007)). Odorants interact with G protein-coupled receptors to stimulate adenylyl cyclase via Golf. Genetic deletion of AC3 confirms its role in olfaction, as AC3$^{(-/-)}$ mice suffer from major effects on odorant-induced signaling and are impaired in olfactory-dependent learning and olfaction-based behavioral tests. In addition, AC3$^{(-/-)}$ mice are unable to detect mouse urine or pheromones. AC3$^{(-/-)}$ mice also lack intermale aggressiveness and male sexual behavior. AC3 has also been ascribed a role in spermatozoa function and male fertility. In general the vomeronasal organ expressing AC2 is thought to be responsible for pheromone detection, but as discussed, AC3 are also associated with these functions.

In Immune Responses

The role of cAMP in the immune system is complex since cAMP generation can induce apoptosis as well as cell proliferation, differentiation, and activation of various immune cell types. AC7 is the major isoform that regulates cAMP synthesis in both B and T cells. AC 7 $^{(-/-)}$ mice produce fewer leukocytes and have a high mortality rate upon bacterial infections (Duan et al. 2010), which was attributed to changes in the production of certain serum factors required for regulating AC7 activity. AC7 null mice also produce less antigen-specific antibodies to fight infections even though overall immune responses were hyperactive, as measured by the overproduction of cytokines. The unique regulation of AC7 by Gs- and G12/13-coupled receptors makes it well suited to respond to multiple signals and facilitates its multifaceted roles in regulating both innate and adaptive immune responses.

In Kidney

AC6 is localized in the renal tubule and collecting duct of kidneys (Chien et al. 2010). AC6$^{(-/-)}$ mice had normal glomerular filtration rate but were deficient in water homeostasis (Rieg et al. 2010). AC6-deficient mice drank more water, urinated more, and had low urine solute concentrations. The major protein required for transport of water through the plasma membrane (aquaporin) is also mis-localized, displaying reduced phosphorylation in kidneys of AC6 null mice, consistent with a malfunction in water retention. This phenotype is similar to that of nephrogenic diabetes insipidus and is consistent with a loss of vasopressin-induced cAMP in the inner medullary collecting ducts of AC6$^{(-/-)}$ kidney. AC3 has also been ascribed a role in kidney function. Key components of the olfactory signal transduction machinery (olfactory receptor, AC3, and Golf) are expressed in the renal distal nephron. Unlike AC6,

mice deficient in AC3 suffer from reduced glomerular filtration rate and also display low levels of plasma renin (Pluznick et al. 2009).

Summary

ACs can be found in every cell type and tissue, consistent with the very large role for cAMP in so many physiological processes. In addition to those outlined above, cAMP has important roles in development and differentiation, cell proliferation, neurodegeneration and neurotoxicity, asthma, diabetes, fertilization, and hormone secretion. Many GPCRs that regulate cAMP levels are currently targeted for treating conditions that include asthma, heart failure, diabetes, pain, migraines, peptic ulcer disease, obesity, Schizophrenia, Parkinson's, and nausea (Pierre et al. 2009). The roles for specific AC isoforms in these pathophysiological conditions have sparked much interest in exploring AC as a drug target. For example, AC5 inhibitors are currently being considered for treatment of heart failure (Ho et al. 2010), while an AC1 activator could be a memory-enhancing drug (Pierre et al. 2009). Analogs of forskolin that specifically target an AC isoform or selective P-site inhibitors could also prove useful (Iwatsubo et al. 2006). Finally, the local lipid environment of individual AC isoforms or the macromolecular complexes that link ACs to downstream effectors may play a large role in the specificity of downstream signaling. Thus despite the rich history of cAMP research, much work remains to be done.

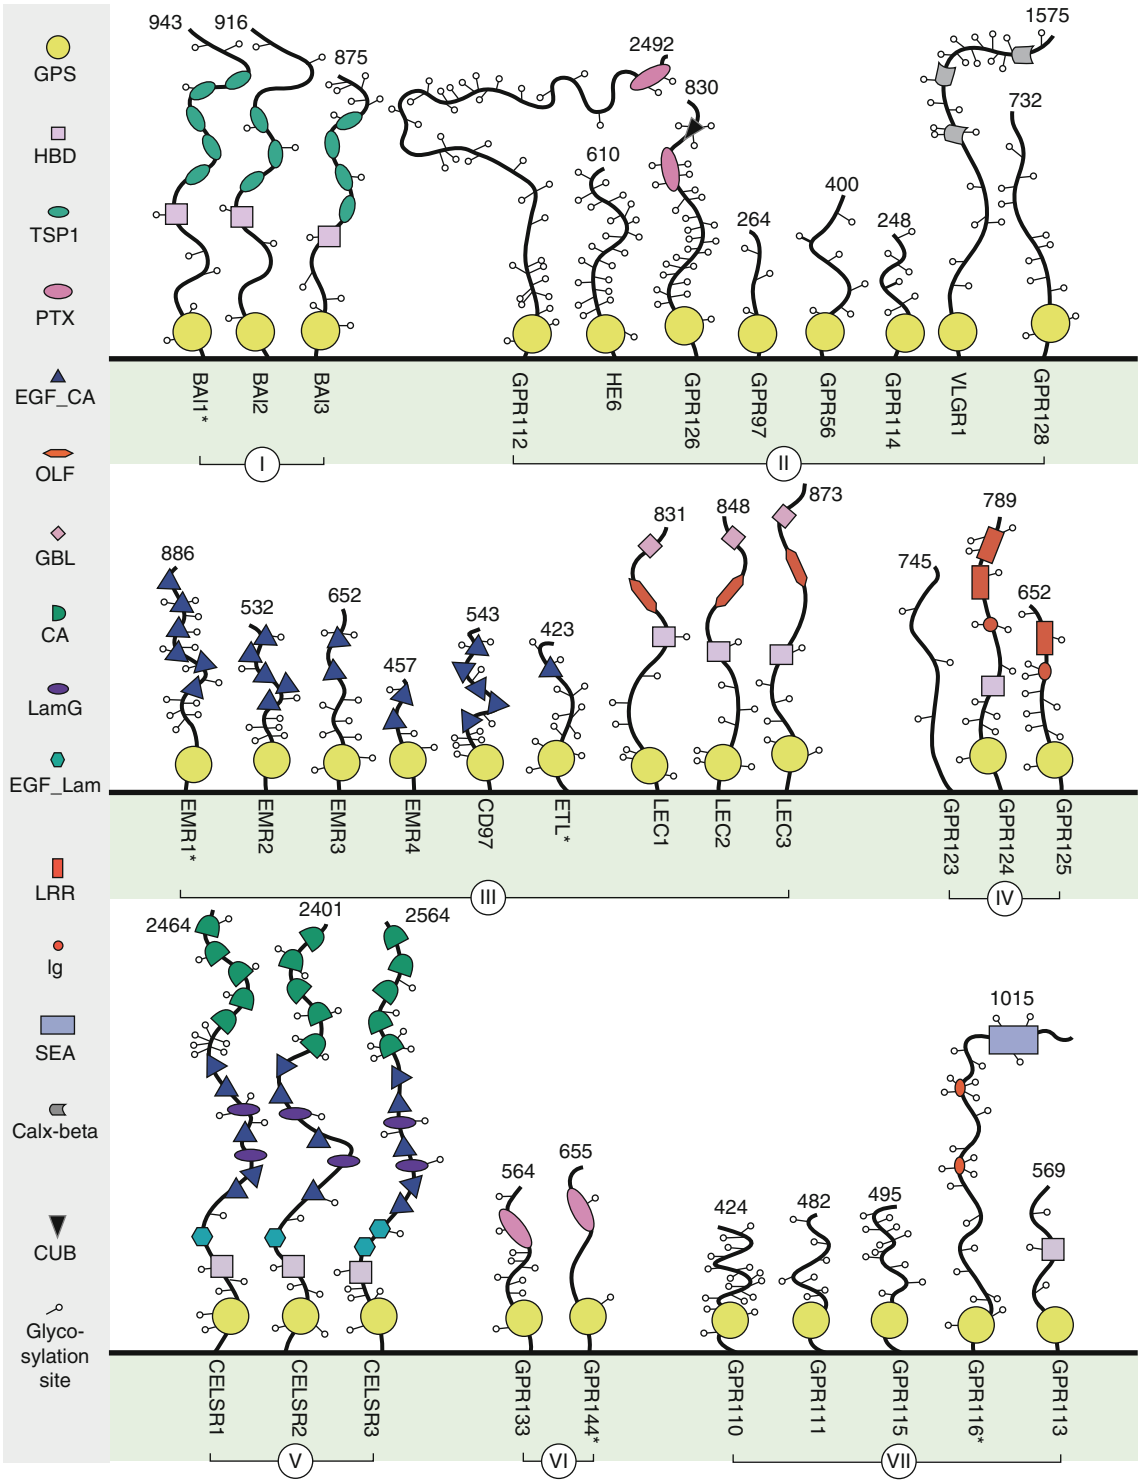
LNB-TM7 receptors

Historical Background

Among the superfamily of G-protein-coupled receptors, the adhesion GPCRs form the second largest family with 33 members in humans (for review, see Bjarnadottir et al. 2007). They are also the most diverse and complex GPCR family, often encoded by very large genes with numerous introns, and comprising highly diverse and variable N-terminal extracellular regions. Despite a remarkable structural diversity and low sequence homology, hydropathy analysis and biochemical data suggest that the adhesion GPCRs share the structural hallmark of all GPCRs – a heptahelical conformation with extracellular N-terminus and intracellular C-terminus. Approximately 150 distinct orthologues have been identified in the animal kingdom to date. The name adhesion GPCRs emphasizes the presence of multiple motifs in their long extracellular N-termini predicting adhesive properties, such as cadherin-, laminin-, lectin-, epidermal growth factor-, olfactomedin-, immunoglobulin-, calcium exchanger β-, thrombospondin-, and mucin-like domains (see Fig. 1).

The Epidermal growth factor Module-containing Receptor EMR1, its mouse homologue F4/80, and CD97, all members of the Epidermal Growth Factor (EGF)-TM7 receptor subfamily, were the first-described adhesion GPCRs (for review, see McKnight and Gordon 1996; 1998). Derived from a single precursor polypeptide, they are expressed at the surface of leukocytes in two parts, (1) a large extracellular domain with variable numbers of modular EGF-like domains and (2) a membrane-spanning domain consisting of seven hydrophobic stretches connected by three intracellular and three extracellular loops. Both parts are associated via a highly glycosylated mucin-like "stalk" which serves as a spacer. The unusual structure of their extracellular regions indicated a function related to cell adhesion and leukocyte migration. Indeed, the ability to bind to extracellular matrix molecules and cellular ligands has been experimentally demonstrated for several members of the EGF-TM7 multigene family (see below).

The subsequent discovery of an increasing number of GPCR-related molecules with a similar domain configuration led to the proposal to reclassify this group of heptahelical membrane proteins as a novel class of receptors (for review, see Stacey et al. 2000). Following the example of the EGF-TM7 receptors, the entire class was termed the LNB-TM7 receptors, where LN stands for their large and complex N-terminal extracellular regions, and B indicates a significant amino acid sequence similarity to G-protein-coupled receptor family B, also named the *Secretin* GPCRs (following the GRAFS classification system, Fredriksson et al. 2003). Progress in molecular biology and bioinformatics techniques led to the sequencing and assembly of whole genomes, and allowed the identification of the full repertoire of human GPCRs. This enabled a phylogenetic analysis based on the complete sequences of the TM7 regions, which demonstrated that the adhesion GPCRs did indeed form a distinct receptor family (Fredriksson et al. 2003). Based on the sequence similarity within their heptahelical regions and intervening loops, the human adhesion GPCRs were further subdivided into different groups or clans (Fig. 1; for review, see Bjarnadottir et al. 2007; Lagerström and Schiöth 2008). Interestingly, this group structure at the same



Adhesion GPCRs, Fig. 1 A schematic presentation of the functional domains found in the N-termini of human adhesion GPCRs (reproduced with permission from Bjarnadottir et al. 2007). GPS = GPCR proteolysis site; HBD = hormone binding domain; TSP1 = thrombospondin type 1 repeat; PTX = Pentraxin doamain; EGF_CA = calcium-binding EGF-like domain; OLF = Olfactomedin-like domain; GBL = galactose binding lectin domain; CA = Cadherin-like

time reflected a functional classification based on the various adhesion motifs present in the N-termini (Fig. 1). Also, receptors within the same phylogenetic clusters showed similar expression profiles in human tissues.

More recently, Schiöth and coworkers suggested that the adhesion GPCRs were an ancient receptor class, and the *Secretin* GPCRs descended from a subgroup during metazoan evolution (Nordström et al. 2009). *Secretin* GPCRs bind polypeptide hormones at a hormone-binding domain (HBD) in their N-termini, and, in response to ligand binding, signal via G-protein activation, predominantly $G_{\alpha S}$. Although several adhesion GPCRs contain a HBD motif in their N-termini as well (compare Fig. 1), no hormone ligands have been identified for this receptor family, and there is only scant evidence of receptor activation and G-protein coupling (see below). Adhesive interactions have been verified for some family members (see below) while the functional role of a majority of adhesion GPCRs is still poorly understood. Thus, their description as LNB-TM7 receptors may still be more correct, although the name adhesion GPCRs now prevails in the literature.

Posttranslational Processing

The adhesion GPCRs are chimeras, composed of a hydrophilic extracellular adhesion part and a hydrophobic membrane-spanning *signaling* part. This chimeric configuration already suggested a dual function, combining interactions with the surrounding extracellular matrix and/or cellular counter receptors with coupling to the intracellular signaling machinery. Different from other GPCRs, however, the "mature" adhesion GPCRs almost invariably consist of two separate subunits which appear to be a defining feature of this receptor class. The two subunits are derived from cleavage at the so-called GPCR proteolytic site (GPS), a characteristic Cys-box-containing motif located in the ectodomain adjacent to the first transmembrane domain (Krasnoperov et al. 1997, 2002; Chang et al. 2003; Lin et al. 2004; Figs. 1 and 2). This site is also involved in the cleavage of other membrane-spanning proteins, but is not found in any other GPCR family in the human and mouse genomes.

The GPS is one of the few conserved motifs present in all the N-termini of adhesion GPCRs, except GPR123 (see Fig. 1). In addition to this site, most adhesion GPCRs share a second homologous stretch in their extracellular domains, a serine-, threonine-, and proline-rich (STP) "stalk," typical of a highly O-glycosylated protein domain. Conservation of these motifs in nearly all adhesion GPCRs suggests an important role. The first functional hint of the GPS motif was revealed when intracellular proteolytic processing of cell surface marker CD97 (cluster of differentiation) was demonstrated (Gray et al. 1996). Translated as a single polypeptide, CD97 cleavage results in the formation of the two subunits. Cloning and Western blot analysis of the lectin-like domain-containing calcium-independent receptor of α-latrotoxin (Krasnoperov et al. 1997; Lelianova et al. 1997), GPR116/Ig-Hepta (Abe et al. 2002) and the GPR64/HE6 receptor (Obermann et al. 2003) has revealed additional "split" receptors. The exact cleavage site was determined for CIRL/Latrophilin/lectomedin receptor 1 (Krasnoperov et al. 2002) and also for the EGF-TM7 receptors (Chang et al. 2003). It is located at homologous sites in the C-terminal part of the GPS domain (see Fig. 2).

The GPS motif is necessary, but not sufficient for cleavage. Rather, cleavage also requires the presence of the "stalk" next to the membrane (Chang et al. 2003; Hsiao et al. 2009). As an example, the ectosubunit of the GPR64/HE6 receptor, which is predominantly expressed in the microvilli of the epididymal duct epithelium (Obermann et al. 2003; Kirchhoff et al. 2008), is characterized by the presence of 20 potential

Adhesion GPCRs, Fig. 1 (continued) (Calcium-dependent adhesion-like) domains; LamG = Laminin G domain; EGF_Lam = EGF-like, fibronectin type III and laminin G domains; LRR = leucine-rich repeats; Ig = Immunoglobulin-like domains; SEA = Sea-urchin sperm protein, enterokinase and agrin module; Calx-beta = motif in Na-Ca exchangers and integrin-beta4; CUB = Domain first found in complement C1r, C1s, uEGF, and bone morphogenetic protein. Subdivision into different groups or clans (Roman numerals I–VII) was based on the sequence similarity within the heptahelical regions and intervening loops. According to a more recent classification, Group III can be further divided into two clusters (Lagerstrom and Schioth 2008). The first cluster contains LEC1-3 and ETL receptors, whereas the second cluster includes EMR1-4 and CD97 receptors

Conserved amino acid residues of the GPCR proteolysis site (GPS) are highlighted. The arrow points to the hypothetical cleavage site within the GPS domain. Amino acid sequences obtained from the NCBI database were aligned with the ClustalW program followed by manual adjustment. 7 TM – adhesion GPCRs; h = human; m = mouse; r = rat; 1 TM – suREJ1 = sea urchin Receptor for Egg Jelly 1; 11 TM – suREJ3 = sea urchin Receptor for Egg Jelly 3; TM1 = first amino acid of transmembrane domain 1

N-glycosylation (Asn-Xaa-Ser/Thr) sites and more than 100 potentially O-glycosylated Ser and Thr residues, largely located within the STP region, and most probably forming a hydrophilic mucin-like "stalk" (Obermann et al. 2003). From the large number of glycosylation sites and helix-breaking proline residues, the ectosubunit was predicted to be highly charged and extend from the cell surface like a rod. Similar structural predictions have been made for other adhesion GPCRs, including the EGF-TM7 receptors and the latrophilins (LPHN; synonyms CL/CIRL/Lph). More recently, glycosylation at specific sites of the EGF-TM7 "stalk" has been implicated in cleavage at the GPS (Hsiao et al. 2009).

Proteolytic cleavage is a well-known regulatory mechanism for receptor activation. For example, the G-protein-coupled protease-activated receptors (PARs) signal in response to N-terminal cleavage by extracellular proteases. The new N-terminus then acts as a tethered ligand and binds intramolecularly to the receptor to trigger transmembrane signaling. The mechanism and role of GPS-mediated cleavage seems to be different. Experiments on EMR2, member of the EGF-TM7 family, suggested that it occurs intracellularly in the endoplasmic reticulum (Lin et al. 2004). Whether it could trigger or modulate any signaling events, in analogy to the PAR example, remained unknown. A role in signaling, however, was proposed for GPS cleavage of the Cadherin, EGF LAG seven-pass G-type receptor (CELSR) family members. The extracellular subunits of CELSR2 and CELSR3, including their Cadherin repeats, were proposed to act as a ligand of the seven-transmembrane-spanning part, stimulating calcium release and regulating neurite growth (Shima et al. 2007).

Different from PAR activation, GPS-mediated cleavage is mediated by an autocatalytic reaction rather than by protease activity (Lin et al. 2004). The mechanism is similar to that of N-terminal nucleophile hydrolases, involving the generation and hydrolysis of a (thio)-ester intermediate. Yet, GPS-mediated cleavage appears to be a regulated process, requiring additional modifications like phosphorylation (Kaur et al. 2005) and glycosylation (Hsiao et al. 2009). Endogenous cleavage of the precursor protein may be incomplete; however, full-size, non-cleaved molecules are not normally found in tissues and may not reach the cell surface. Indeed, efficient latrophilin/CIRL receptor trafficking to the cell surface requires proper GPS cleavage (Volynski et al. 2004). Furthermore, deficiency in GPS cleavage caused by mutations has been linked to various human genetic disorders and diseases, including bilateral frontoparietal polymicrogyria (BFPP), and autosomal dominant

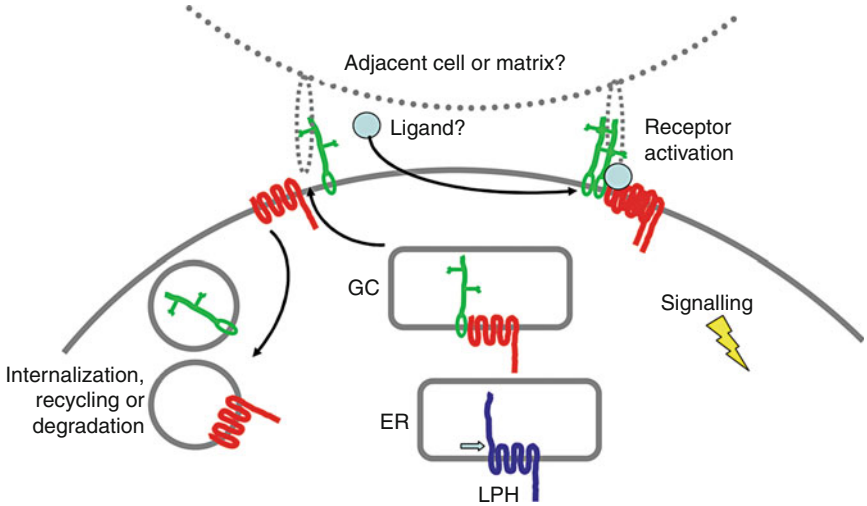
polycystic kidney disease (ADPKD), emphasizing the critical role of this modification (for review, see Yona et al. 2008a).

Surprisingly, GPS-mediated cleavage of adhesion GPCRs does not yield much soluble ectoprotein; rather, both subunits remain frequently tethered at the cell membrane. Observations from different subgroups showed that the extracellular subunits behave as membrane proteins despite a lack of transmembrane regions (Gray et al. 1996; Krasnoperov et al. 1997, 2002; Obermann et al. 2003). Initially, this was thought to be mediated by a non-covalent interaction with the TM7 domain subunit. However, in the case of latrophilin/CIRL and the EGF-TM7 receptors, the two subunits are delivered to different plasma membrane domains, are recycled separately, and can be patched independently by specific antibodies (Volynski et al. 2004; Davies et al. 2007; Silva et al. 2009a). Apparently, both subunits behave as independent membrane proteins, the ectosubunit being anchored in the plasma membrane by an unknown mechanism. Similarly, both GPR64/HE6 subunits were individually solubilized from different parts of the epididymis (Obermann et al. 2003; Davies et al. 2004). In membrane fractions prepared from the proximal part of this organ, the amount of extractable ectosubunit by far exceeded that of the endosubunit. This peculiar observation was in apparent discrepancy with the expected 1:1 stoichiometry of subunits. While the significance of this observation remains unclear, it may reflect different solubilization characteristics of the two subunits, rather than different locations. Despite their independence, however, subunits of latrophilin/CIRL and the EGF-TM7 receptors can reassemble in the plasma membrane to form heterodimers (Davies et al. 2007; Silva et al. 2009a). This observation has led to the concept of a "split personality" receptor (Volynski et al. 2004; see Fig. 3 and below) which may also be applicable to other adhesion GPCRs.

Nevertheless, there are also reports of "shedding" of the extracellular subunit. Increased expression of CD97 at sites of inflammation, for example, is accompanied by detectable levels of soluble extracellular subunit (Gray et al. 1996). The mechanism of this release is not known but might include augmented matrix metalloproteinase activity in a pathological situation. The Brain Angiogenesis Inhibitor 1 (BAI1), on the other hand, seems to release its extracellular subunit in the normal brain. It was inferred that the secreted fragment, named Vasculostatin for its antiangiogenic function, resulted from BAI1 cleavage at the GPS (Kaur et al. 2005). However, the precise cleavage site(s) was not determined. It could be that such "shedding" requires cleavage of the BAI1 molecule at multiple sites (compare Koh et al. 2004) as was shown for other adhesion GPCRs (see below). In summary, GPS cleavage which occurs exactly between the two structurally and functionally different domains is an intrinsic posttranslational modification of many, if not most, adhesion GPCRs. For the family members studied, it occurred largely autocatalytically inside the cell, probably at the endoplasmic reticulum (ER). It is a prerequisite for receptor trafficking and functional expression at the cell surface; however, it may not be a common step in signaling.

Soluble fragments may also be generated by alternative mRNA splicing, providing a mechanism for the generation of soluble ligand or receptor desensitization (for review, see Yona et al. 2008a). For a number of adhesion GPCRs, there is evidence for additional proteolytic cleavage events which might lead to the release of N-terminal fragments. CIRL/Latrophilin can be cleaved in vivo by an unknown protease in the remaining short N-terminal stretch of the seven-transmembrane-spanning endosubunit to yield a small 15 amino acid residue oligopeptide (Krasnoperov et al. 2009). While the majority of receptor molecules remained membrane-bound after cleavage at the GPS (see above), this additional cleavage resulted in the formation of soluble subunits. It was assumed that the soluble fragments contained the non-covalently bound 15-mer at their C-terminal ends (Krasnoperov et al. 2009).

Results by Koh et al. (2004) indicated that the extracellular region of brain-specific angiogenesis inhibitor 1 (BAI1) was cleaved at three sites, and that the BAI1-thrombospondin type 1 repeat fragment was the core extracellular fragment for BAI1's antiproliferative activity. A specifically complex processing was described for Ig-Hepta/GPR116 (Fukuzawa and Hirose 2006), an adhesion GPCR of unknown function which is abundantly expressed in lung and kidney (Abe et al. 2002). These authors further suggested involvement of some fragment(s) in cellular signaling (Fukuzawa and Hirose 2006). GPS-independent cleavage was also described for GPR126/DREG/VIGR (Moriguchi et al. 2004), an adhesion GPCR which



Adhesion GPCRs, Fig. 3 Proposed scheme of latrophilin/CIRL (LPH) processing, activation, and internalization (modified from Volynski et al. 2004). LPH is cleaved intracellularly in the ER. Proteolysis is required for the delivery of the mature, "split" receptor protein to the cell surface. Further posttranslational processing in the Golgi complex (GC) involves glycosylation and may endow the N-terminal fragment with an own membrane anchor; however, the structure of this anchor is currently unknown. On the cell surface, the two subunits behave as independent membrane proteins. Agonist binding to the ectosubunit promotes its association with the endosubunit and or receptor dimerization, presumably leading to the activation of endosubunit-mediated cell signaling pathways. Internalization of subunits may be independent processes.

was recently shown to be essential for myelination in Schwann cells (Monk et al. 2009). Besides cleavage at the GPS, the protein was further cleaved in the middle of the extracellular domain, generating a soluble fragment containing the CUB (for complement C1r/C1s, Uegf, Bmp1) and pentraxin (PTX) domains (Moriguchi et al. 2004). This processing step was inhibited by an inhibitor of furin but not of matrix metalloproteinases. It was speculated that the subfragment could play a role as a secreted ligand (Moriguchi et al. 2004).

It is unknown whether non-GPS cleavage is a common phenomenon of adhesion GPCRs, and its functional significance remains unclear. Members of other GPCR families, including the V2 receptor and endothelin B receptor, undergo a ligand-induced proteolysis to produce peptides with possible bioactivity. Similarly, the liberated fragments of adhesion GPCRs might be a physiological ligand; alternatively, the cleavage might unmask a hidden ligand binding site, or may activate the receptor (for review, see Yona et al. 2008a). For latrophilin, it was suggested that the non-GPS cleavage(s) served to release defective receptor protein from the cell membrane and/or, in conjunction with GPS cleavage, control cell surface expression (Krasnoperov et al. 2009). Finally, regulated intramembrane proteolysis of membrane receptors produces C-terminal fragments that function inside the cell, even in the nucleus. For most adhesion GPCRs, however, it is as yet unclear whether such C-terminal fragments are generated, probably due to the fact, that the appropriate assays have not been performed.

Ligand Binding

In the absence of endogeneous ligands, a first key concept of ligand binding and activation came from studies involving an exogenous agonist, α-latrotoxin. It is a component of the black widow spider venom, and an activating ligand (=agonist) of CIRL/latrophilin (Krasnoperov et al. 1999). α-latrotoxin binding occurs as two sequential steps: (1) the toxin interacts with the ectodomain with medium affinity followed by (2) an interaction with either the first transmembrane domain, with the membrane lipids, or with both. As a result α-latrotoxin penetrates into the lipid bilayer. The second step increases the affinity of the interaction and requires a longer time. The first site

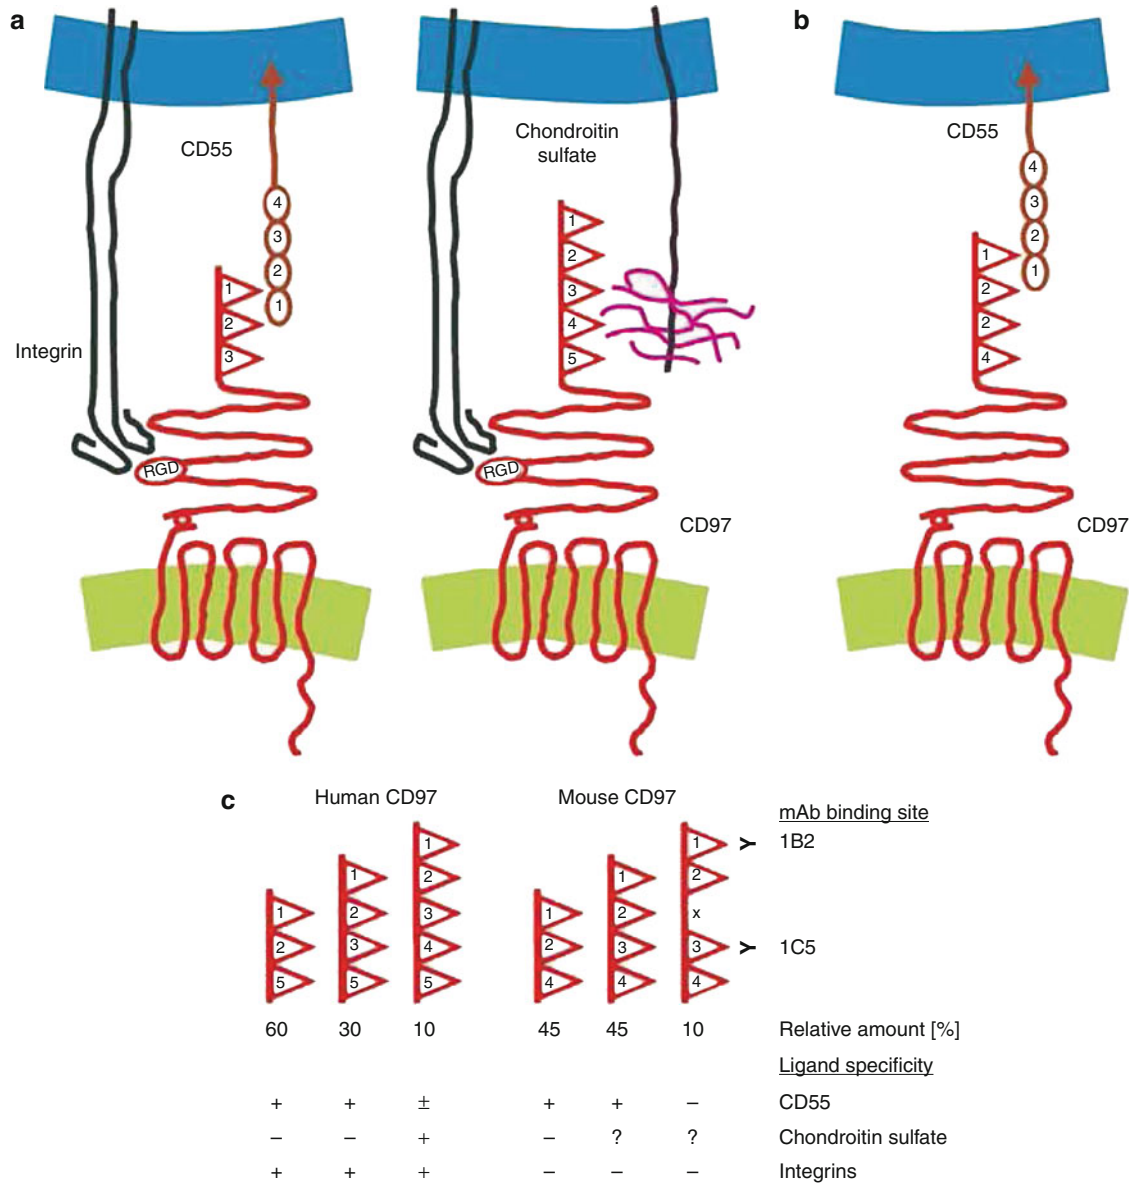
of agonist binding encompassed an area comprising the HBD, stalk, and GPS domain while the N-terminal rhamnose lectin-like (RBL) and olfactomedin-like motifs were *not* required (Krasnoperov et al. 2002). Also, the extracellular loops of the heptahelical domain were apparently not necessary to stabilize the complex with α-latrotoxin (Krasnoperov et al. 1999). It should, however, be kept in mind that this mechanism of interaction may be completely different from the interaction with a putative endogenous CIRL ligand. The recent identification of a latrophilin-associated synaptic surface protein ("Lasso") may be the first step to elucidate the interaction with a physiological ligand (Silva et al. 2009b).

The α-latrotoxin receptor is highly conserved among metazoa; in *Caenorhabditis elegans* the homologous lat-1 is required to coordinately orient cells along a two-dimensional plane lying orthogonal to the axis of apical-basal polarity. Interestingly, different from its mammalian homologue, the extracellular RBL domain of lat-1 was absolutely required for receptor function; constructs lacking the RBL domain but retaining the HBD, GPS, and TM7 domains did not show any biological activity in the *C. elegans* model (Langenhan et al. 2009). This result is consistent with an essential role of the RBL domain in ligand binding; however, results concerning the structure of this domain argued strongly against a carbohydrate ligand for lat-1.

Concerning the binding of endogenous ligands, members of the EGF-TM7 clan are probably the best studied group. Their ligands are large cell-surface proteins and/or components of the extracellular matrix (see below), justifying the name adhesion GPCRs. Still, even for this subfamily it remains unclear whether ligand binding of ectosubunits leads to the activation of endosubunit-mediated cell signaling. CD97, the prototypic EGF-TM7 receptor on leukocytes, was the first receptor for which a cellular ligand, CD55 (also termed decay-accelerating factor, DAF), was demonstrated (Hamann et al. 1996). CD55/DAF is a GPI-anchored molecule expressed by all blood cells and cells in contact with blood and tissue fluid. CD97 binds CD55/DAF via the N-terminal EGF-like domain region (Hamann et al. 1996, 1998; Lin et al. 2001). This was not unexpected as the EGF-like short consensus repeats are the most characteristic structural elements in the extracellular domain, and are common modules used in cell adhesion and chemotaxis. As a result of alternative mRNA splicing, CD97 exists as three major isoforms that contain between three and five EGF-like domains (compare Fig. 4).

All human CD97 isoforms bind CD55/DAF, albeit with different affinities, the smallest isoform binding the ligand with the highest affinity (Hamann et al. 1996, 1998; Lin et al. 2001). The functional consequences of CD97-CD55 binding have not been fully elucidated, and G-protein-mediated signal transduction has not been demonstrated (see below). The largest isoform of human CD97 also interacts with the glycosaminoglycan chondroitin sulfate B (CS; Stacey et al. 2003; Kwakkenbos et al. 2005; compare Fig. 4). Ligand specificity for CS is shared by EMR2, whose EGF domain region is highly similar to that of CD97, but not by other family members. Indeed, only marginal sequence differences in the EGF-like domains result in dramatic differences in their affinity toward the ligand. EMR2, differing from CD97 by only three amino acids within the EGF domains, binds CD55 with a K_d at least an order of magnitude weaker than that of CD97 (Lin et al. 2001). Finally, a third ligand of human CD97 was identified by demonstrating that integrin α5β1 (very late antigen [VLA]-5) and possibly also integrin αvβ3 binds the Arg-Gly-Asp (RGD) motif in the stalk region (Wang et al. 2005; compare Fig. 4). The ability of CD97 isoforms, and also other EGF-TM7 receptors, to interact with such a diverse range of ligand types is based on their variable numbers and sequences of N-terminal EGF-like domains (compare Fig. 4). The first two EGF domains of CD97 (but not EMR2) bind CD55 (decay-accelerating factor), while the fourth EGF domain of both CD97 and EMR2 interacts with CS (Kwakkenbos et al. 2005).

The majority of such receptor–ligand interactions at the cell surface appear to be weak and transient. Lin and coworkers developed a screening strategy which is specifically suited to identify low-affinity ligands for the EGF-like short consensus repeat domains of EGF-TM7 receptors (Lin et al. 2005). In brief, recombinant expression constructs were engineered encoding the variable EGF-like domains coupled to a mouse Fc fragment and a biotinylation signal sequence. These constructs were then expressed, purified, and biotinylated. Finally, the biotinylated proteins were coupled in a specific orientation to avidin-coated fluorescent beads to screen for ligand-bearing cells or tissues (Lin et al. 2005). Based on these multivalent



Adhesion GPCRs, Fig. 4 Cartoon representation of CD97 interacting with its cellular ligands (reproduced with permission from: Hamann J, Veninga H, de Groot DM et al. CD97 in leukocyte trafficking. In: Yona S, Stacey M, eds. Adhesion-GPCRs: Structure to Function. Austin/New York: Landes Bioscience/Springer Science + Business Media, 2010: epub ahead of print http://www.landesbioscience.com/curie/chapter/ 4547/.). (**a**) At the cell surface, CD97 is expressed as a non-covalently associated heterodimer consisting of an extracellular chain and a membrane-spanning chain. The two chains result from autocatalytic processing of a single CD97 propeptide. Alternative splicing generates isoforms with 3, 4, or 5 EGF domains. Shown here are the smallest and the largest isoform. While EGF domains 1 and 2 interact with CD55, EGF domain 4, which only is present in the largest isoform, binds chondroitin sulfate. Integrins bind a RGD motif in the "stalk" region of human CD97. (**b**) Mouse CD97 has a similar structure but the maximum number of EGF domains is only 4. Shown here is the middle isoform. In the largest isoform of mouse CD97, the EGF domains 2 and 3 are separated by 45 amino acids. (**c**) Comparison of binding characteristics of human and mouse CD97 isoforms. Depicted is the composition of the EGF domain region, the relative amount of transcripts present in leukocytes and the ligand specificity. In humans, affinity for CD55 correlates inversely with the number of EGF domains. An interaction of EGF domain 3 of mouse CD97 (the counterpart of EGF domain 4 in humans) with chondroitin sulfate still needs to be proven. The binding site of monoclonal antibodies recognizing specific EGF domains in mouse CD97 is indicated

protein probes, putative cell surface ligands were also identified for other members of the EGF-TM7 clan (Stacey et al. 2001, 2002, 2003).

GPR56, also known as TM7XN1 (7-transmembrane protein with no epidermal growth factor-like NH2-terminal domains 1) functions in tumor cell adhesion and has a role in the development of neural progenitor cells. The amino-terminal domain contains a large number of possible N- and O-linked glycosylation sites similar to mucin-like proteins, but no further adhesion motifs (compare Fig. 1). Tissue transglutaminase 2 (TG2), an integrin-binding adhesion co-receptor for fibronectin, was proposed as a candidate ligand (Xu et al. 2006). Ubiquitously expressed in tissue and tumor stroma, it localizes mainly in the cytoplasm; yet recent reports suggest its presence also at the cell surface, and in the extracellular matrix. TG2 was reported to specifically bind to GPR56 in the mouse (Xu et al. 2006), but not in the human (Nien-Yi Chiang and Hsi-Hsien Lin, personal communication). The significance of this species difference is not known. Although TG2 seemed to interact with the N terminus of mouse GPR56, it is not clear whether it indeed functions as a traditional ligand. As no specific adhesion motifs have been recognized within the N-terminal domain of GPR56, a specific site of interaction remains unknown.

Brain angiogenesis inhibitor 1 (BAI1) is expressed on glial cells within the brain, but also on monocytes and macrophages. Its surface expression is dramatically downregulated in many glioblastomas, consistent with its ability to inhibit angiogenesis and tumor growth in vivo. The large extracellular domain contains one HBD motif and five tandem copies of thrombospondin type 1 repeats (TSRs) (compare Fig. 1). The latter seem to interact with phosphatidylserine (PS), and cells that expressed BAI1 have been shown to selectively engulf a synthetic substrate containing PS. Genetic manipulation of the BAI1 extracellular domain showed that the TSRs were essential for the recognition of PS on apoptotic cells, and direct binding to lipid overlays showed stereospecific binding to PS as well (Park et al. 2007). Also, soluble TSRs derived from BAI1 were shown to inhibit macrophage engulfment of apoptotic thymocytes both ex vivo and in vivo. The adhesive Arg-Gly-Asp (RGD) motif, also present in BAI1, was dispensable under these conditions. Given previous data supporting a role for thrombospondin 1 as a bridging molecule that recognizes apoptotic cells, it may be assumed that PS is a novel ligand for BAI1 that promotes the engulfment activity of cells (see below).

Despite long-standing efforts, no further ligands have as yet been identified for any other members of the adhesion GPCR family. Unavailable 3D structures, heterogeneity of ectodomains, and/or ambiguous relationships within the family make an *in silico* ligand prediction difficult and error-prone. Although phylogenetically related to the *Secretin* GPCRs (Nordström et al. 2009), the peptide hormone ligands of the latter receptor family do not provide a clue. Finally, the idea needs to be considered that orphan adhesion GPCRs may have ligand-independent functions. The concept of ligand-independent receptor activation is connected with the observation that some orphan receptors can heterodimerize with structurally unrelated GPCRs which have identified ligands, thereby regulating functions of the latter, while other receptors were shown to be constitutively active without any ligand.

Reassembly of Subunits and Receptor (Hetero-)Oligomerisation

According to the common and well-established paradigm of GPCR activation, ligand binding leads to conformational changes in the heptahelical domain and cytoplasmic tail, thereby activating intracellular signaling pathways. The adhesion GPCRs may be assumed to follow this paradigm. However, the two-subunit configuration with seemingly independent ecto- and endosubunits ("split receptors"; Fig. 3) and receptor dimerisation/ oligomerisation are specific complications which may explain the difficulties in identifying intracellular signaling pathways. Several models are suitable to explain experimental observations concerning subunit interaction and receptor activation (according to Davies et al. 2007; Silva et al. 2009a; Yi-Shu Huang and Hsi-Hsien Lin, personal communication):

(a) The mature adhesion GPCR molecule exists as a stable heterodimer. After GPS-cleavage in the ER, the two subunits remain non-covalently bound at the cell surface. Upon ligand binding by the ectosubunit, conformational changes are induced in the non-covalently bound endosubunit, followed by signal transduction into the cell.

(b) GPS cleavage, possibly in conjunction with additional processing steps, creates two independent molecular entities at the cell surface. Upon ligand binding, the ectoprotein changes its conformation and is enabled to reassociate with the endoprotein, followed by signal transduction into the cell.
(c) Ectoprotein and endoprotein are independent membrane receptors, each of them binding different ligands. The anchoring mechanism holding the ectoprotein in place is unknown. Upon ligand binding, both membrane proteins are independently capable of signal transduction.
(d) Ectoprotein and endoprotein are independent membrane proteins. Upon ligand binding, signal transduction into the cell is performed by the endoprotein, while the ectoprotein is shed from the cell surface, possibly serving different biological functions.

In the case of CIRL/latrophilin, reassembly of the subunits occurs upon binding of α-latrotoxin to the N-terminal subunit, as suggested in scenario (b); (compare Fig. 3). Subsequently, an intracellular signal is generated via the C-terminus. Thus, the two CIRL/latrophilin fragments do in fact interact; however, the proportion of truly associated, rather than simply colocalized, fragments is difficult to assess (Volynski et al. 2004; Silva et al. 2009a). In *C. elegans*, constructs expressing an N-terminal lat-1 fragment tethered to the cell surface by a single transmembrane helix instead of the GPS-TM7 regions were not able to complement the lat-1 mutant phenotype (Langenhan et al. 2009). Thus, both subunits seem to be necessary for signaling. The adhesive and signaling properties of Celsr/flamingo, that is, functions of the endo- and ectosubunits, appear to be separated in signaling processes during zebrafish gastrulation (Carreira-Barbosa et al. 2009) as suggested in model (c). This contrasts with results obtained for the lat-1 receptor.

Data presented by Volynski et al. (2004) indicate that agonist-induced dimerisation/ oligomerization of the endoprotein accompanies latrophilin signaling (compare Fig. 3). Similarly, EMR2 is constitutively expressed as a dimer, and the dimerization is mediated exclusively by the heptahelical part (Davies et al. 2007). Interestingly, these adhesion GPCRs can also form hybrid receptor complexes by cross-interaction of heterogeneric receptor subunits. Heterodimerisation between different, but closely related members of the EGF-TM7 family resulted in the modulation of expression and ligand binding properties (Davies et al. 2007). Again, the dimerization seemed to be mediated by the TM7 region and did not involve the posttranslational GPS autoproteolysis. Most recently, "promiscuous" interactions between the endosubunits of completely unrelated receptors were observed, and these cross-complexes seemed to be functionally active, although the in vivo amounts were relatively small (∼10%; Silva et al. 2009a).

Coupling to G Proteins

Activated heptahelical receptors interact with and activate heterotrimeric guanine nucleotide–binding proteins (G proteins) at the inner side of the cell membrane. This association is so well established that the term "G protein-coupled receptor" (GPCR) is used as a synonym. Still, only limited data are available which unequivocally demonstrate G protein-coupling for the adhesion GPCRs. CIRL/Latrophilin/lectomedin receptor 1 (LEC1/LPHN2) was the first receptor of this group shown to bind to G proteins (Lelianova et al. 1997), specifically Gαq/11 and Gαo (Rahman et al. 1999). The interaction was found to be strong and functional; it was disrupted by conditions that allow G protein activation and dissociation from the receptor (Rahman et al. 1999). The latrophilin–G protein complex was stable in the presence of GDP but dissociated when incubated with GTP, suggesting a functional interaction. Like other receptors, CIRL/Latrophilin was able to activate more than one G protein subtype. As revealed by colocalization studies, it interacted with Gαq/11 and Gαo, but not with Gαs, Gαi, or Gαz, indicating that coupling is specific and not promiscuous. The {alpha}-subunits of Gq and G11 are almost ubiquitously expressed and couple to {beta}-isoforms of phospholipase C (PLC). Activation leads to the production of inositol-1,4,5-trisphosphate causing subsequent release of Ca2+ from intracellular Ca2+ stores (for review, see Silva et al. 2009b). Despite these reports, G protein-coupled signaling of latrophilin/LEC1 remains controversial. A review by Foord et al. (2002) reported that α-latrotoxin did not activate latrophilin/LEC1 in the classical sense as it is still effective when the transmembrane domains of the

receptor had been removed. This may be explained by the fact that the toxin itself has the ability to form membrane pores, and that these pores are permeable to cations, especially Ca2+, bypassing any signaling that can be triggered by the receptor. Thus, many questions concerning CIRL signaling remain in the absence of its endogenous ligand(s).

G protein-coupling was also reported for GPR56 (Little et al. 2004; Iguchi et al. 2008), but again no final conclusion can be drawn regarding a general principle of signaling. Mass spectrometry screening in retinoic acid–differentiated NT2 teratocarcinoma cells suggested that GPR56 specifically associates with Gαq/11 as part of a larger complex with tetraspanins CD9 (Tspan29) and CD81 (Tspan28) (Little et al. 2004). These authors at the same time reported a lack of Gαq/11 association for CD97. In an overexpression system, Iguchi et al. (2008) observed that GPR56 signaled via a Gα12/13 and Rho pathway. GPR56-mediated intracellular Ca2+ mobilization, on the other hand, was not observed. G proteins G12 and G13 are often activated by receptors which also couple to Gq/G11. A well-established downstream effector of G alpha 12/13-mediated signaling is the monomeric GTPase RhoA, which is a regulator of actin stress fibers and assembly of focal adhesions, gene transcription, and control of cell growth. Indeed, ectopic expression of GPR56 in NIH3T3 cells induced F-actin accumulation in a Gα12/13- and Rho-dependent manner (Iguchi et al. 2008). The transcriptional activation and actin reorganization were found to be inhibited by an RGS domain of the p115 Rho-specific guanine nucleotide exchange factor (p115 RhoGEF RGS) and a dominant negative form of Rho (Iguchi et al. 2008).

Monk et al. (2009) proposed that DREG/Gpr126 drives the differentiation of promyelinating Schwann cells by elevating intracellular cAMP levels. Since many GPCRs induce the production of cAMP by adenylate cyclase activation, the logical supposition would be that Gpr126 may likewise act as an upstream effector of adenylate cyclase. Still, it remains to be demonstrated that Gpr126 actually associates with a G protein complex, or that the regulation of cAMP by Gpr126 is direct. Similarly, a recent study showed that targeted mutation of the very large G protein-coupled receptor 1 (VLGR1), also known as MASS1 or GPR98, resulted in an increase in the expression and in the redistribution of adenylate cyclase 6 in stereocilia of the cochlea (Michalski et al. 2007). The restricted adenylate cyclase immunostaining just nearby the ankle-link molecular complex (ALC) in wild-type mice and its spreading out along the stereocilia in knockout mice argue in favor of a functional coupling between Vlgr1 and adenylate cyclase 6. Vlgr1 is thus expected to activate the Gαs subunit, which in turn activates cAMP-dependent signaling pathways via adenylate cyclase and protein kinase A (PKA) activation. A-kinase anchoring proteins (AKAPs) are believed to localize PKA to the GPCR-associated molecular complex. Again, however, additional studies showing specific interactions are clearly warranted.

For some other adhesion GPCRs, G protein-coupling is described in the patent literature. Summarizing such patent data, Foord et al. (2002) reported that CD97, EMR1, and HE6/GPR64 will activate the G-proteins Gαs/Gq when overexpressed in Xenopus melanophores (C. Jayawickreme, personal communication). These data seem to be at odds with the reported lack of Gαq/11 association for CD97 by Little et al. (2004). However, the signaling properties of GPCRs may depend on the cellular context. According to Foord et al. (2002), CD55/DAF interaction with CD97 (see above) did not appear to induce any G-protein signaling. Thus, whether signaling after EGF-TM7 ligand interaction occurs via classical heterotrimeric G proteins or uses alternative G-protein-independent signaling pathways remains to be seen. Increasing evidence indicates that many heptahelical receptors, including the adhesion GPCRs, signal through G protein-independent pathways, involving JAK/STATs, Src-family tyrosine kinases, GRKs/β-arrestins, and PDZ domain-containing proteins (see below).

Interactions with Other Proteins

Apart from G protein-coupling, GPCRs can associate with a variety of interacting proteins, such as the β-arrestins, PDZ(PSD95/Dlg/ZO-1), SH2, and polyproline-binding proteins. These GPCR interacting proteins (GIPs) may help to create signaling specificity by engaging additional signaling pathways or localizing signaling events to specific subcellular sites.

The predominant target of GIPs is the intracellular C-terminus of GPCRs. PDZ domain proteins, first discovered in the postsynaptic density 95 (PSD95), disk-large (Dlg) and zona occludens-1 (ZO-1) proteins, constitute the largest protein family among the GIPs. They primarily bind a C-terminal S/TXV(L/I) consensus motif, also called a PDZ "ligand." The ability of PDZ domain proteins to bind short and extreme C-terminal sequences offers a way to interact with target proteins without disrupting their overall structure and function. Their predominant function as GIPs is to assemble signaling pathway components into close proximity by recognition of the last four C-terminal amino acids of GPCRs, but they may also regulate the function of their ligands.

A number of adhesion GPCRs express a PDZ recognition motif at their extreme C-terminus, including CD97, BAI1–3, CIRL1/2, VLGR1, as well as GPR123, GPR124, GPR125, and GPR133 (for review, see Bjarnadottir et al. 2007). The consensus motif often is conserved between species, suggesting a functional role. Physical interaction of C-termini with PDZ domain proteins has been described for a several adhesion GPCRs by means of a yeast two-hybrid screen. Using the C-terminus of the receptor molecule as bait, PDZ domain proteins of the Shank family were identified as binding partners of the G protein-coupled α-latrotoxin receptor CL1 (Tobaben et al. 2000; 2002). Shank proteins are multidomain scaffold proteins of the postsynaptic density, connecting neurotransmitter receptors and other membrane proteins with signaling proteins and the actin cytoskeleton (see below). Correspondingly, Kreienkamp et al. (2002) identified the intracellular C-termini of CIRL1 and CIRL2 as interaction partners of the PDZ domain of the proline-rich synapse-associated protein (ProSAP)/somatostatin receptor-interacting protein (SSTRIP) family of postsynaptic proteins (SSTRIP, ProSAP1, and ProSAP2, also known as shank1–shank3, respectively). Shank proteins colocalized with latrotoxin binding GPCR latrophilin 1 (LPHN1; also known as CL1 and CIRL1) at synapses in native brain tissue and may induce clustering of latrophilin 1 in membrane-associated signaling complexes.

The clade of BAI receptors, on the other hand, did not bind to ProSAP/shank (Kreienkamp et al. 2002). Rather, a novel protein was cloned by a similar approach, BAP1 (BAI1-associated protein), which interacts with the cytoplasmic region of BAI1 (Shiratsuchi et al. 1998). The interaction was mediated by the PDZ recognition motif in the carboxy-terminal region of the BAI1 receptor and the PDZ domains of BAP1. BAP1 is a member of the MAGUK (membrane-associated guanylate kinase homologue) family; it possesses a guanylate kinase domain, WW domains, and multiple PDZ domains. The purpose of the interaction is believed to be several fold: (1) the targeting of BAI receptors to their sites of action (e.g., synaptic membranes), (2) anchoring to the actin-based cytoskeleton (see below), and (3) physical association of BAI receptors with elements of the signal transduction machinery (Shiratsuchi et al. 1998).

VLGR1 is involved in the Usher syndrome, an autosomal recessive disorder characterized by combined hearing loss and retinal degeneration. The extreme C-terminus also corresponds to the consensus motif that is recognized as a ligand for the class I subfamily of PDZ domains. Yeast two hybrid and in vitro protein association experiments have shown direct physical interactions between the C-terminus of VLGR1 and the PDZ domain-containing submembrane protein whirlin (Michalski et al. 2007). The large transmembrane protein usherin, the putative transmembrane protein vezatin, and whirlin are colocalized with Vlgr1 at the stereocilia base in developing cochlear hair cells; they are absent in Vlgr1 knockout mice that lack the ankle links (Michalski et al. 2007). The data support the existence of an ankle-link molecular complex (ALC) in the cochlea that includes VLGR1, usherin, vezatin, and whirlin. As all of these proteins bind to myosin VIIa, Michalski et al. (2007) suggested that this actin-based motor protein conveys both transmembrane and submembrane ALC proteins to the stereocilia of the inner ear.

Interactions of adhesion GPCRs and PDZ domain-containing scaffolding molecules with filamentous (F)-actin, as indicated in the examples above, suggest a role in the maintenance and remodeling of the actin cytoskeleton. CIRL-binding ProSAP/shank interacts with fodrin and cortactin–F-actin-binding proteins enriched at cell-matrix contact sites (Kreienkamp et al. 2002). VLGR1 is indirectly connected via its C-terminus to the actin cytoskeleton of stereocilia through the motor domain of myosin VIIa dimers. Similarly, HE6/GPR64 and CD97 colocalize with F-actin in the stereocilia of male excurrent duct

epithelia (Kirchhoff et al. 2008; Veninga et al. 2008). In intestinal epithelial cells, CD97 is located in E-cadherin-based adherens junctions and seems to regulate epithelial strength (Becker et al. 2010). Partial co-staining of CD97 and cortical F-actin indicated that the receptor might be involved in anchoring adherens junction components to the cytoskeletal network. The related EMR2 receptor colocalizes with Rac1 (Yona et al. 2008b), a small Rho-GTPase which regulates actin polymerization. When leukocytes were treated for a short period with small amounts of N-formyl-methionine-leucine-phenylalanine, a peptide chain produced by some bacteria, EMR2 and Rac1 were rapidly translocated to the leading edge and other lamellipodia and colocalized with F-actin (Yona et al. 2008b).

ELMO/Dock180/Rac proteins comprise a conserved signaling module which promotes the internalization of apoptotic cells; ELMO and Dock180 function together as a Guanine nucleotide Exchange Factor (GEF) for Rac, and thereby regulate the phagocyte actin cytoskeleton during engulfment. Using yeast two-hybrid screening to identify upstream ELMO-interacting proteins, Park et al. (2007) identified the BAI1 receptor. Mutational analysis showed that ELMO1 bound to a short alpha-helical stretch within the BAI1 cytoplasmic tail, which was necessary and sufficient for ELMO binding. Furthermore, the formation of a trimeric complex of BAI1–ELMO–Dock180 was associated with enhanced Rac–GTP levels and the greatest increase in apoptotic cell uptake (Park et al. 2007). In addition, the cytoplasmic tail of BAI1 interacts with the Src homology 3 (SH3) domain of a BAI-associated protein 2 (BAIAP2; Oda et al. 1999), also known as the insulin receptor tyrosine kinase substrate of 53 kDa (IRSp53).

GPR56 associates in a complex with Gαq and tetraspanins (Little et al. 2004). Tetraspanin-associated microdomains also connect to the actin cytoskeleton, regulating cell motility and polarity. The C-termini of CD81 and CD9 both possess potential PDZ-domain-binding sites and thus could indirectly link GPR56 to the actin cytoskeleton through the PDZ domains of as yet unknown intracellular proteins. Together with the observation of Rho-dependent actin reorganization during GPR56 signaling (Iguchi et al. 2008), a general role in the dynamic reorganization of the actin cytoskeleton seems likely.

Summary

Although molecular biological and bioinformatics techniques made the identification of all human adhesion GPCRs amenable, the vast majority are still poorly studied orphans with largely unknown structures and functions. Thus, the most important limitation in our current understanding is the persistent paucity of data concerning adhesion GPCR signaling. Being aware of this limitation, the chapter made an effort to list known ligands and to summarize aspects of signal transduction of individual family members in comparison with canonical GPCRs. However, any general characteristics of adhesion GCPR ligands, as well as a generally valid mechanism of receptor docking, ligand-induced activation, signal transduction, and receptor desensitization has remained undiscerned. There are several issues which may account for this shortage. (1) Ligands may be exogenous or may be only expressed in a specific tissue at a particular time under distinct conditions, and a better knowledge of the biology of such receptor/ligand pairs is required before an effort of deorphanization can be undertaken. (2) Orphan adhesion GPCRs may function in the absence of receptor occupation, or some orphans do not activate a signaling cascade alone, but only in conjunction with others. Thus, they may not induce their own second messenger pathway but rather modulate that of others. (3) Some adhesion GPCRs may not stimulate but rather inhibit cell signaling. (4) Although some adhesion GPCRs induce second messenger responses via G proteins, there are indications that others may link to different, perhaps unknown signaling pathways. If this were the case, deorphanization of the remaining will have to wait until these pathways have been defined more clearly. Future challenges in common with other orphan receptors thus are to find endogenous ligands, and to elucidate the general mechanisms underlying the signaling and regulation of receptor desensitization. A unique aspect of the adhesion GCPRs which awaits future elucidation is the significance of their complex posttranslational processing. Many aspects of this processing, including glycosylation, cleavage at the GPS, and the role of "split receptors" subunits remain unclear. The fates of the two subunits and their reassociation at the plasma membrane might provide a variety of different signaling mechanisms which are specific for the adhesion GPCRs.

Synonyms

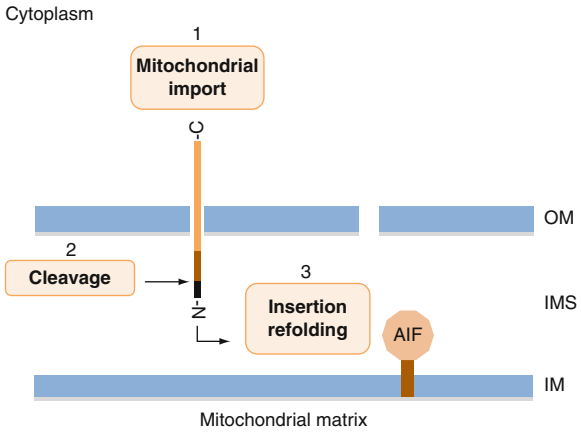
AIFM1 (apoptosis-inducing factor, mitochondrion-associated, 1); PCD8 (programmed cell death 8)

Historical Background

Apoptosis-inducing factor (AIF), which is confined to mitochondria of normal healthy cells, was initially described by Kroemer and coworkers (Susin et al. 1999) as the first caspase-independent death effector. Under conditions of cell death induction, AIF is released from mitochondria and translocated to the nucleus where it contributes to chromatin condensation and DNA fragmentation, two features that are classically associated with apoptosis (Hangen et al. 2010a). Since its initial discovery, the structure of the AIF protein has been resolved and the *AIF* gene has been subjected to genetic manipulations in mice, flies, nematodes, and yeast, revealing the phylogenetically conserved contribution of AIF to cell death, as well as its role in cell survival, proliferation, and differentiation (Hangen et al. 2010a).

AIF Protein Synthesis and Regulation

The *AIFM1* gene resides on human chromosome X (Xq25-Xq26) and is spread out over 16 exons (Susin et al. 1999). The most abundant and ubiquitously expressed AIF transcript (AIF1) is translated in the cytoplasm and imported into the mitochondria of healthy cells with the help of an N-terminal mitochondrial localization signal (MLS) (Fig. 1) (Hangen et al. 2010a). Upon mitochondrial import, the N-terminal part of the MLS is eliminated by a mitochondrial peptidase that cleaves the AIF1 protein after residue M53 (Hangen et al. 2010a).



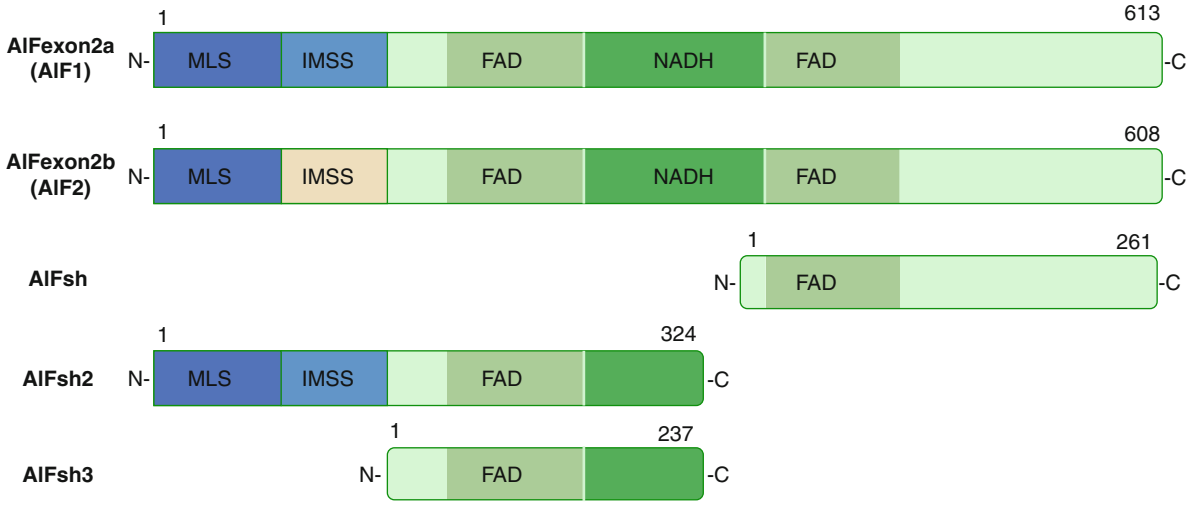
AIF, Fig. 1 Mitochondrial localization of AIF in healthy cells. The scheme delineates: (1) the import of unprocessed full length AIF into mitochondria; (2) the cleavage of its N-terminal MLS by a mitochondrial peptidase; (3) the insertion of AIF into the inner mitochondrial membrane (*IMM*), via its N-terminal transmembrane region. *OM* outer membrane, *IMS* intermembrane space, *IM* inner membrane

The correct targeting of the protein toward the inner mitochondrial membrane is ensured by the C-terminal part of the MLS that functions as an inner membrane sorting signal (IMSS) and harbors a transmembrane (TM) region (residues 66–84) (Hangen et al. 2010a). As the imported and fully processed AIF is inserted into the inner membrane facing the intermembrane space, it adopts its mature folded configuration through the incorporation of its cofactor, flavin adenine dinucleotide (FAD) (Modjtahedi et al. 2006). Analyses of AIF's crystal structures revealed that the flavoprotein AIF bears a similar fold as bacterial nicotinamide adenine dinucleotide (NAD)–dependent oxidoreductases, and contains two FAD-binding segments (residues 128–262 and 401–480) and an NADH-binding domain (residues 263–400) (Fig. 2) (Modjtahedi et al. 2006). Although AIF is able to oxidize NADH and NADPH in vitro, the substrate (s) targeted by its enzymatic activity in vivo remain elusive. Published data indicate that the conformational modifications of AIF must play a tight control over its unknown enzymatic activity via redox-dependent monomer–dimer transitions (Hangen et al. 2010a).

The primary AIF transcript is subjected to tissue-specific alternative splicing (Hangen et al. 2010a) (Fig. 2). The alternative usage of exon 2 (2a or 2b) allows for the production of two splice variants (AIF1 and AIF2). Exon 2a is included in the most abundant AIF isoform (AIF1). The two isoforms exhibit a limited difference, which is confined to the C-terminal part of their MLS (Hangen et al. 2010b). While AIF1 is expressed in almost all tissues, AIF2 mRNA expression is restricted to brain and retina. The modulation of AIF2's expression during brain development and in vitro–induced neuronal differentiation indicates that the expression of this isoform is influenced by differentiation signals (Hangen et al. 2010b). Several additional AIF isoforms have been described (Hangen et al. 2010a). AIFsh is a short variant that is produced from an alternative transcript whose transcriptional start site is located within intron 9 of AIFM1. This variant lacks the N-terminal MLS and the enzymatic domain, but retains the C-terminal domain (which harbors the pro-apoptotic segment). Transfection-enforced expression of AIFsh results in its accumulation in the nucleus and triggers apoptosis (Hangen et al. 2010a). Another short form of AIF (AIFsh2) results from the alternative usage of exon 9b, which contains a stop codon. This isoform maintains the conserved mitochondrial localization and redox function, but lacks the C-terminal pro-apoptotic domain (Hangen et al. 2010a). A third short form of AIF (AIFsh3) lacks the mitochondrial localization signal but otherwise resembles AIFsh2 (Hangen et al. 2010a). Quantitative profiling of mRNA expression and proteomics will be required to assess the precise distribution of each isoform in various tissues.

The Involvement of AIF in Cell Death

Upon mitochondrial outer membrane permeabilization (MOMP) – a feature of most, if not all, apoptotic pathways (Green and Kroemer 2004) – AIF is released from mitochondria and translocates to the nucleus, where it mediates chromatin condensation and DNA degradation (Hangen et al. 2010a). The mitochondrio-nuclear translocation of AIF has been observed during developmental cell death, in cells that die in response to genotoxic agents, in the context of exitotoxicity induced by glutamate or other NMDA receptor agonists, in hypoxia-ischemia followed by reperfusion, in neurodegeneration, and in pathogen exposure. As a result, it has been hypothesized that AIF's lethal activity could regulate a wide range of cell death paradigms (Hangen et al. 2010a). Nonetheless, the genetic deletion or downregulation of murine *Aifm1* revealed

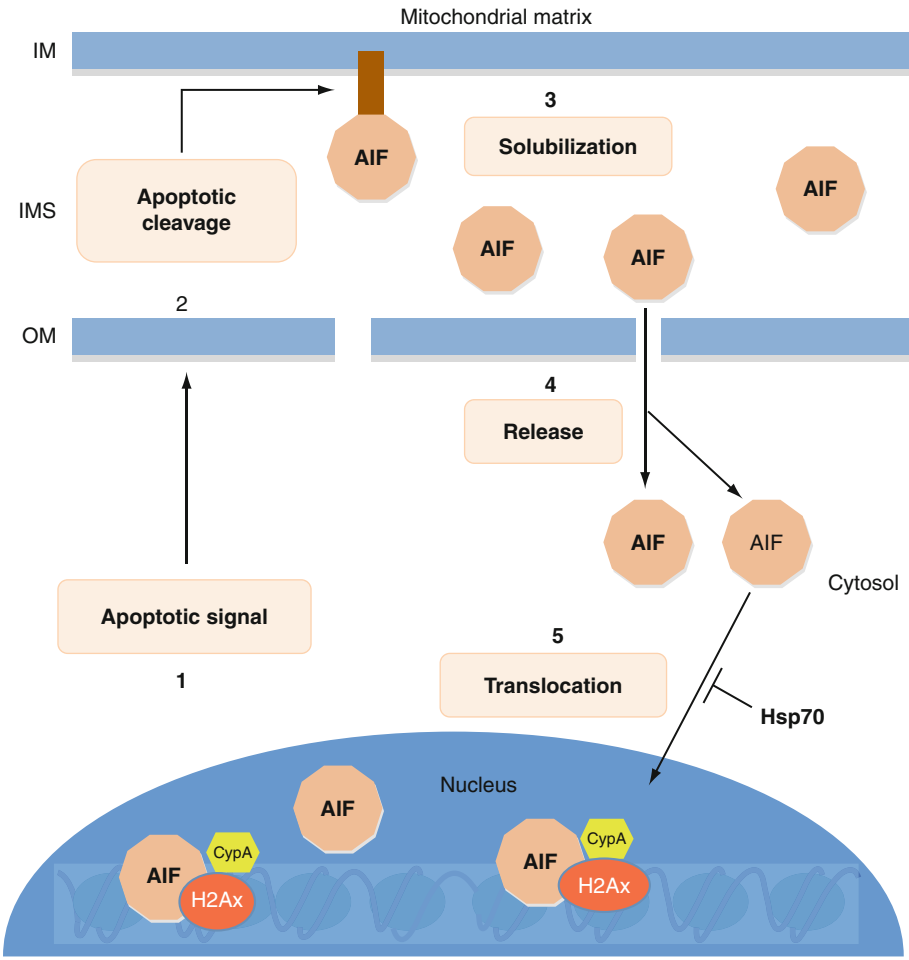


AIF, Fig. 2 Schematic presentation of AIF splice variants. Alternative splice products of human AIF (AIF1, AIF2, AIFsh, AIFsh2, and AIFsh3) are depicted. MLS (*blue*), IMSS (*blue or cream*), FAD-binding domain (FAD; *light green*), NADH-binding domain (NADH; *dark green*), and the C-terminal domain (*green*). Numbers correspond to the first and last amino acids of each variant

that AIF was not a general death effector and that its contribution to cell death depended on the cell type and/or the apoptotic insult (Hangen et al. 2010a). Today, AIF's lethal activity is considered to be required for the programmed death of neurons and photoreceptor cells provoked by excitotoxins, hypoxia-ischemia, hypoglycemia, or withdrawal of trophic support, as in the case of retinal detachment (Hangen et al. 2010a). The neuro-specific death activity of AIF was first suspected from in vitro observations, which implicated AIF in poly (ADP-ribose) polymerase I (PARP-1)–dependent neuronal death (Wang et al. 2009) and then confirmed through the characterization of the mutant Harlequin (Hq) mice, which carries a hypomorphic *Aifm1* mutation that provokes an 80% reduction in the expression level of AIF compared to wild type animals (Klein et al. 2002; Hangen et al. 2010a). For example, in vivo excitotoxic studies using kainic acid–induced seizures revealed that the brains of Hq mice developed less hippocampal damage than wild type animals. In addition, compared to wild type animal, the brain of Hq mouse is more resistant to ischemia-induced damage. Likewise, the prevention of AIF's nucleo-mitochondrial translocation has a neuroprotective effect (Hangen et al. 2010a).

It is generally assumed that the mitochondrial release of AIF requires the proteolytic activity of calcium-dependent cysteine-proteases of the ▶ calpain family that cleave-off the N-terminal transmembrane segment after the leucine 101 (human numbering) and render the protein soluble (Hangen et al. 2010a) (Fig. 3). In neurons that die in response to ischemia or excitotoxicity, it was observed that the proteolytic cleavage of AIF is secondary to the hyperactivation of PARP1, a nuclear DNA repair enzyme involved in the DNA damage response (Schreiber et al. 2006; Hangen et al. 2010a). Other mechanisms of AIF release may exist because the sole accumulation of poly(ADP-ribose) (PAR) polymers, generated by PARP1, may cause the release of AIF from mitochondria of dying neurons without any requirement for AIF proteolysis (Wang et al. 2009). In this latter case, a pool of AIF molecules, which reportedly is associated with the surface of the outer mitochondrial membrane, would be targeted by PAR molecules (Yu et al. 2009).

The lethal activity of AIF is also determined by the nucleic acid binding potential of AIF. Crystal structures of AIF and mutagenesis experiments revealed the existence of positively charged amino acids that are scattered at the surface of the molecule and that are required for the interaction with DNA or RNA and for the induction of nuclear apoptosis by over expressed AIF. Recombinant AIF provokes DNA condensation through direct, sequence-independent interactions with single or double stranded DNA (Hangen et al. 2010a). In addition, AIF interacts with several proteins, in particular cyclophilin A (Artus et al. 2010; Hangen et al. 2010a) and histone H2AX (Artus et al. 2010),

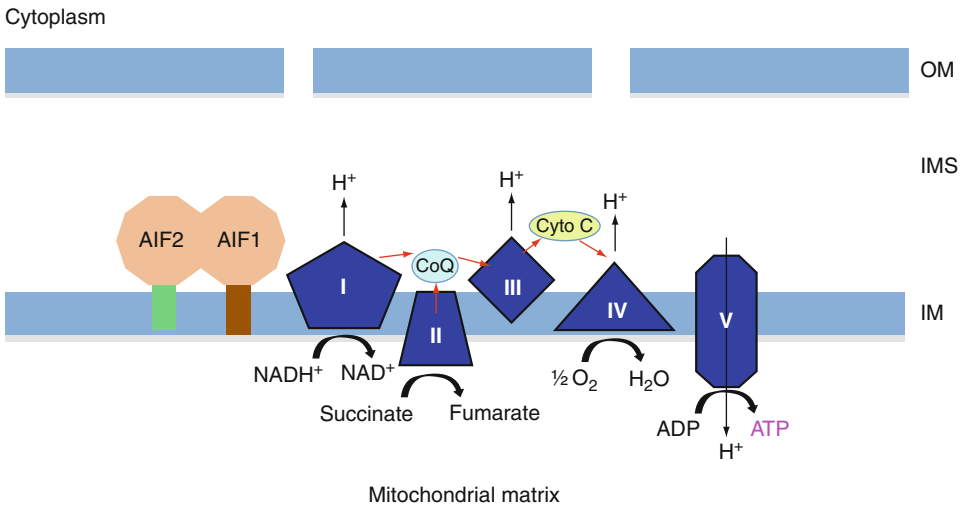


AIF, Fig. 3 Lethal activities of AIF. In cells undergoing programmed death, the activation of AIF lethal function requires: (1) mitochondrial membrane permeabilization in response to lethal signals; (2) the proteolytic activity of a calcium-dependent protease that belongs to calpain family; (3) the solubilization of the membrane-anchored AIF protein; (4) the release of the solubilized protein into the cytosol; and (5) its translocation to the nucleus. The translocation and the chromatin-condensing activity of AIF are positively regulated by its interaction with protein partners, cyclophilin A, and histone H2X

and these interactions are required for the lethal action of nuclear AIF. The RNA binding activity of AIF that was revealed in vitro requires also further investigation (Hangen et al. 2010a).

The Involvement of AIF in Cell Survival, Proliferation, and Differentiation

AIF is a bifunctional flavoprotein. Indeed, in addition to its lethal function within the nucleus of dying cells, AIF plays a vital role in healthy cells, likewise by its impact on mitochondrial bioenergetics (Hangen et al. 2010a). Initially, the revelation of a significant homology between the internal, non-apoptotic, segment of AIF and bacterial NADH-oxidases hinted toward the possibility that AIF could fulfill a non-apoptotic enzymatic function in healthy cells (Hangen et al. 2010a). Later, the phenotypic characterization of Harlequin (Hq) mouse, a model of late-onset neurodegeneration, was instrumental in highlighting the vital non-apoptotic activity of AIF and its impact on cell survival, proliferation, and differentiation (Hangen et al. 2010a). Hq mice develop ataxia and blindness due to an age-associated, progressive loss of terminally differentiated cerebellar and retinal neuron

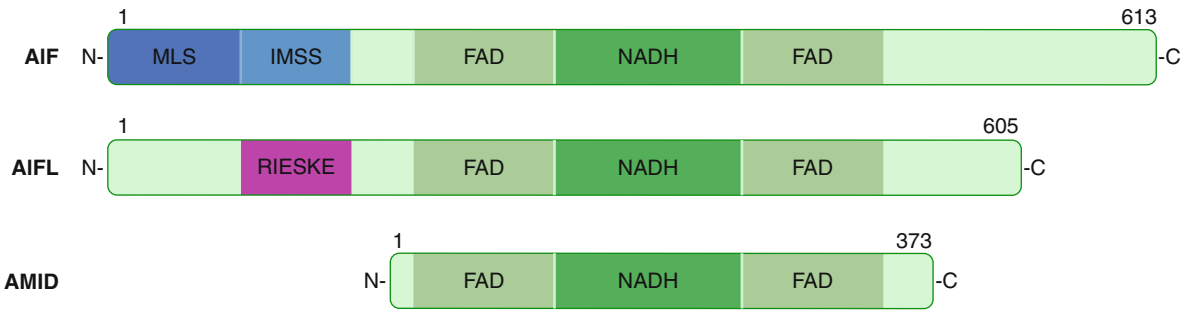


AIF, Fig. 4 Regulation of mitochondrial respiratory chain complexes by AIF. In the mitochondria of healthy cells, the respiratory chain complex I activity depends on the presence of AIF. Schematic presentation of electron transfer activity (*red arrow*) from respiratory chain complexes I to V (*blue*). The proton gradient (H^+) produced by the activity of complexes I, III, and IV is used by complex V for ATP synthesis. Mitochondrial AIF1 (brown transmembrane segment) and AIF2 (green transmembrane segment) both allow for the normal function of complex I subunits. *CoQ* coenzyme Q, *Cyt c* cytochrome *c*

(Klein et al. 2002). Moreover, signs of oxidative stress are detected in the degenerating organs and in dying neurons of Hq animal (Hangen et al. 2010a). All the neurodegenerative traits of Hq mouse are secondary to a retroviral insertion in the first intron of *Aifm1*, which causes an 80% reduction in AIF expression (Klein et al. 2002; Hangen et al. 2010a).

All attempts to create AIF null mice by homologous recombination were unsuccessful because AIF is indispensable for cell survival during embryogenesis (Hangen et al. 2010a). Conditional genetic deletion of *AIFm1* has been possible by targeting specific mouse organs. The specific deletion of AIF in the prospective midbrain and cerebellum revealed that AIF is necessary for cell-type specific neurogenesis in the developing brain (Ishimura et al. 2008). A major defect in cortical development and reduced neuronal survival was observed when *AIFm1* was specifically lost in the telencephalon (Cheung et al. 2006). The conditional deletion of *AIFm1* in muscle and liver has an important impact on whole-body metabolism. Compared to control littermates, muscle- and liver-specific AIF mutant mice are resistant to diet-induced obesity and diabetes (Pospisilik et al. 2007). With aging, mutant mice with muscle-specific loss of AIF develop severe skeletal muscle atrophy and a dilated cardiomyopathy before becoming lethargic around the age of 5 months (Joza et al. 2005).

Biochemical analyses of Hq mice or mice with organ-specific AIF defects revealed that the deletion or depletion of AIF led to a major dysfunction of the mitochondrial respiratory chain (Hangen et al. 2010a) (Fig. 4). Among the five multi-protein complexes that constitute the respiratory chain, complex I is the most reduced by AIF deficiency. Biochemical studies revealed that the observed dysfunction was due to a post-transcriptional loss of complex I protein subunits (Hangen et al. 2010a). Occasionally, a dysfunction of complexes III, IV, or V could also be detected in specific cells or tissues lacking AIF (Hangen et al. 2010a). The global downregulation of AIF in Hq mice also provokes a complex I dysfunction that is limited to those tissues that exhibit degenerative changes (Hangen et al. 2010a). Although the molecular basis for the tissue-specificity of this manifestation is not understood, there is a clear correlation between the downregulation of AIF in degenerating Hq organs, the progressive aggravation of complex I dysfunction, and the phenotypic evolution. Thus, Hq mice constitute a valuable, tissue-specific model of complex I deficiency (Hangen et al. 2010a). In the past, we proposed that AIF was necessary for the maintenance or for the assembly of the mitochondrial respiratory chain complex I subunits (Hangen et al. 2010a). The mechanistic exploration of these effects requires the identification and characterization of the substrates



AIF, Fig. 5 AIF homologs. Schematic presentation of the functional domains of human AIF, AMID, and AIFL. Important domains are the FAD-binding domain (*green*), the NADH-binding domain (*dark green*), the C-terminal domain (*light green*), and the Rieske domain (*fuchsia*)

affected by the enzymatic activity of AIF. In addition to its redox-active domain, AIF could harbor additional functional segments that regulate the structure and/or stability of the inner mitochondrial membrane. This is suggested by the fact that the loss of AIF in the telencephalon entails a degenerative phenotype accompanied by fragmentation of the mitochondrial network and aberrant cristae in cortical neurons (Cheung et al. 2006). The potential inner membrane-stabilizing activity of AIF may reside in its transmembrane segment. This possibility is supported by the recent description of a brain-specific isoform of AIF (AIF2) that is produced through the alternative usage of exon 2 (Fig. 2) and differs from the ubiquitously expressed AIF (AIF1) only within its transmembrane region (Hangen et al. 2010b) (Fig. 4). Both AIF1 and AIF2 localize to the same mitochondrial subcompartment and are similar in their capacity to regulate the stability of complex I subunits, yet differ in their membrane anchorage capacity and in their effects on mitochondrial morphology (Hangen et al. 2010b).

AIF Homologs

AIF is the founding member of the AIF family of proteins, whose members share structural and functional features (Fig. 5). This family has two additional members in humans. AIFL, which is ubiquitously encoded by *AIFM3* located on chromosome 22 (GeneCards; http://www.genecards.org), is a 605 amino acid protein that localizes to mitochondria but lacks a manifest MLS (Modjtahedi et al. 2006). The main homology between AIF and AIFL resides in their shared pyridine nucleotide-disulfide oxidoreductase domain (Modjtahedi et al. 2006) (Fig. 5). AMID (also called PRG3), which is encoded by *AIFM2* located on chromosome 10 (GeneCards) is the third member of the family (Fig. 5). No mitochondrial localization sequence (MLS) was found at the N-terminus of AMID, but mutagenesis experiments suggest the existence of an internal MLS that targets a fraction of AMID to mitochondria while another fraction is found in the cytosol (Modjtahedi et al. 2006). AMID is transcriptionally activated by ▶ p53, and its expression is downregulated in tumors (Modjtahedi et al. 2006). AMID binds DNA in a sequence-independent manner, and its enzymatic activity is affected by this interaction (Gong et al. 2007). Moreover, instead of FAD, AMID uses the cofactor 6-hydroxy FAD for its oxidoreductase activity (Marshall et al. 2005). *Saccharomyces cerevisiae* AIF1P (Ynr074cp), which was initially characterized based on its AIF-like pro-death activities, is phylogenetically equidistant from human AIF, AIFL, and AMID (Modjtahedi et al. 2006).

The Implication of AIF in Disease

When exploring two male infant patients born from monozygotic twin sisters and unrelated fathers, Ghezzi et al. (2010) discovered that a specific mutation in AIFM1 can cause a severe early-onset progressive mitochondrial encephalomyopathy. This pathogenic AIF mutation consists in the deletion of three base pairs coding for arginine residue 201 of the precursor protein. The expression of the pathogenic allele negatively affects OXPHOS. The biochemical examination of fibroblasts from both patients revealed an important

defect in CIII and CIV that was partially corrected by the over expression of recombinant wild type AIF or by continuous culture of mutant fibroblasts in the presence of riboflavin, the precursor of FAD. Muscle biopsies from both patients revealed a severe loss of mitochondrial DNA that could be responsible for the combined multi-complex (CI, CIII, and CIV) dysfunction (Ghezzi et al. 2010). Molecular modeling of the mutant AIF, as well as in vitro experiments realized by Ghezzi et al. (2010), indicate that pathogenic AIF protein is unstable and possesses altered enzymatic properties compared to the unmutated AIF protein. Moreover, the deletion of arginine 201 enhanced the DNA-binding capacity of the mutant AIF and rendered cells more sensitive to death stimuli (Ghezzi et al. 2010).

Summary

Although AIF is not a universal cell death effector, it plays an important role in the programmed death of neurons and photoreceptors triggered by excitotoxins, hypoxia-ischemia, hypoglycemia, or the withdrawal of trophic support. The molecular bases for the tissue-specific and signal-dependent lethal action of AIF are largely elusive and await the exploration of mouse models that allow for the conditional and tissue-specific deletion of each splice variant of AIF. It is conceivable that the mitochondrial dysfunction generated by the release and the nuclear translocation of AIF, in certain circumstances, may influence the cellular response to lethal signals. The creation of mouse models carrying knock-in mutations in each of the functional domains of AIF, including those involved in the regulation of respiratory chain complexes, will be instrumental for understanding the vital and lethal roles of AIF, including that of AIF in human mitochondrial diseases.

AKAPs

AKAPs are a diverse family of scaffold proteins that form multi-protein complexes, integrating 3'-5'-cyclic adenosine monophosphate (cAMP) -signaling with protein kinases, phosphatases, and other effector proteins.

AKAP Historical Background

Early physiology experiments illustrated that stimulation of 3'-5'-cyclic adenosine monophosphate (cAMP) synthesis by different agonists mobilize cAMP-dependent protein kinase; PKA to elicit distinct physiological outputs, even within the same tissue. For example, adrenergic stimulation selectively activates a pool of PKA associated with the particulate fraction of isolated cardiomyocytes, while prostenoids predominantly activate cytosolic PKA. These observations led to the concept of compartmentation of PKA signaling inside cells (reviewed in Steinberg and Brunton 2001). Initial evidence supporting this concept came from experiments demonstrating that type II PKA co-purifies with microtubules as a consequence of protein–protein interactions between regulatory RII subunits of PKA and microtubule-associated protein MAP2 (the first identified AKAP) (Theurkauf and Vallee 1982).

In the order of 40 RII-binding proteins have since been identified (Welch et al. 2010). The majority of these proteins have been identified through the use of the RII overlay technique and a variety of interaction cloning strategies.

The identification and characterization of AKAP family members has allowed the comparison of their primary sequences as well as their subcellular distribution. Almost all AKAPs bind to the RII dimer of PKA through a well-conserved amphipathic α-helical motif (Carr et al. 1991). The majority of known AKAPs bind specifically to the RII holoenzyme, however, several dual specificity AKAPs, which bind to both PKA subtypes, have also been identified. These include the dual-function anchoring proteins D-AKAP1 and 2 (Huang et al. 1997).

Analysis of AKAP subcellular location shows that each AKAP has a unique distribution within a cell type that is generally conferred by a targeting motif (Colledge and Scott 1999).

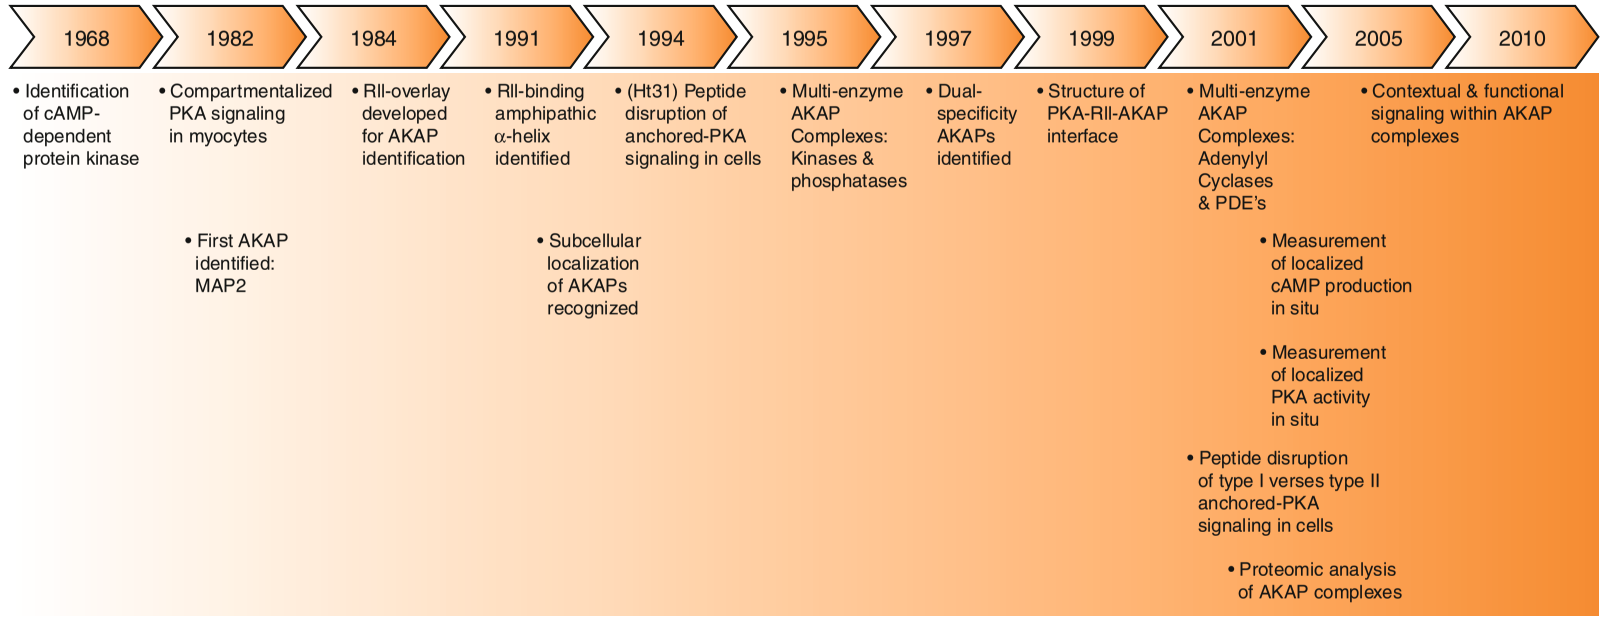
AKAPs are recognized as diverse proteins that assemble multi-protein complexes, to integrate cAMP-responsive events with other signaling processes. For example, AKAP79 binds PKA and also interacts with protein kinase C (PKC) and protein phosphatase 2B (PP2B/calcinuerin) (Klauck et al. 1996). There are now many examples of AKAPs that coordinate enzymes with opposing actions, such as ► adenylyl cyclases and phosphodiesterases.

The historical perspective described here is summarized in Fig. 1. See Smith et al. 2006 for additional details.

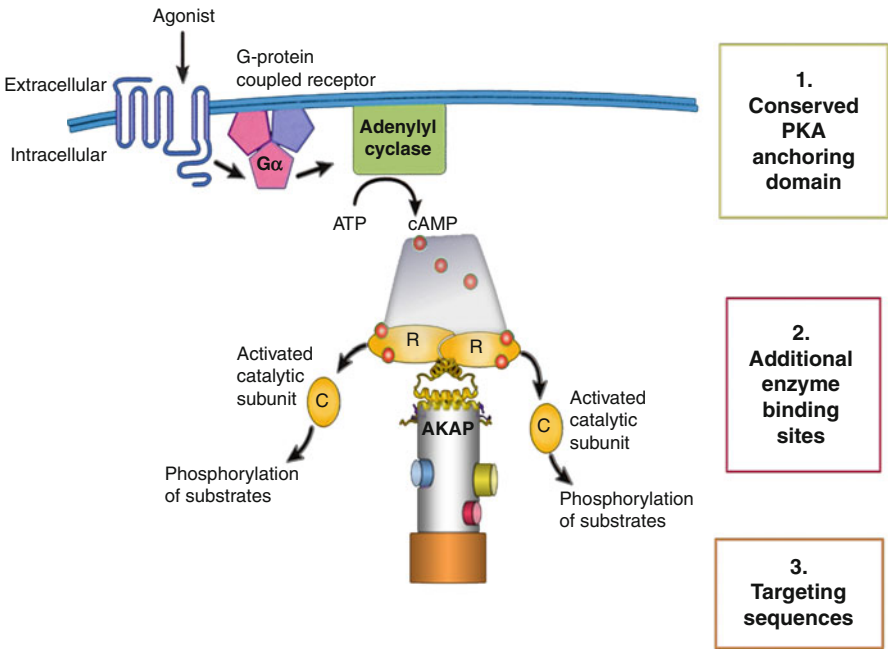
Properties of AKAPs

As depicted in Fig. 2, all members of the AKAP family possess:

1. A conserved protein kinase A (PKA) anchoring domain.
2. Binding sites for additional signaling components. For example, AKAPs act to directly couple PKA to upstream activators of the cAMP cascade (i.e., β-adrenergic receptors and ► adenylyl cyclase), signal terminators (i.e., phosphodiesterases and protein phosphatases), and other elements of signal transduction pathways (i.e., protein kinases, calmodulin, and small molecular weight GTPases).
3. A targeting domain, functioning to compartmentalize signaling complexes to distinct subcellular locations, thereby generating substrate specificity (Colledge and Scott 1999).



A-Kinase Anchoring Protein (AKAP), Fig. 1 *Major discoveries in the study of compartmentalized cAMP signaling and AKAP function*. For further detail, see accompanying text and review by Smith et al. 2006



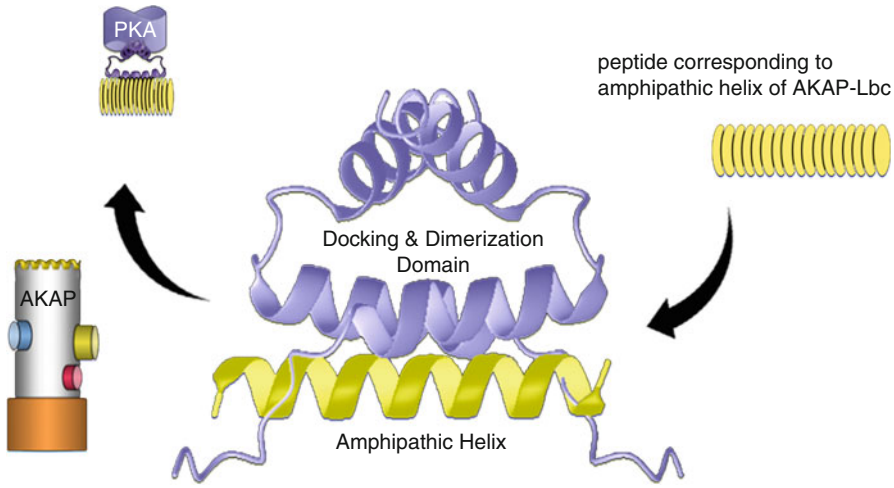
A-Kinase Anchoring Protein (AKAP), Fig. 2 *Properties of AKAPs.* AKAPs regulate the subcellular localization of PKA, thereby generating substrate specificity for PKA. AKAPs have three general properties: (1) AKAPs possess a conserved PKA anchoring domain. (2) AKAPs also bind additional signaling proteins (e.g., other protein kinases, protein phosphatases, phosphodiesterases, adenylyl cyclases, and small G proteins). (3) AKAPs possess targeting sequences directing signaling complexes to discrete subcellular locations

AKAP Nomenclature

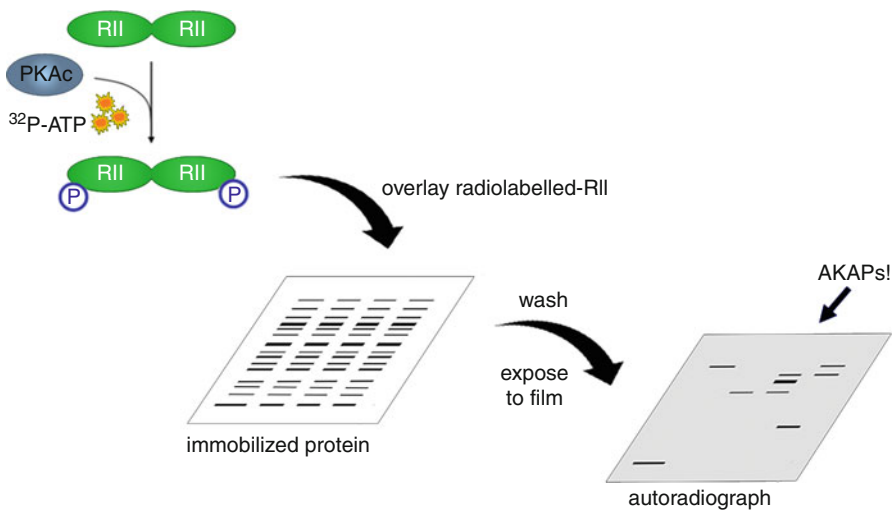
AKAPs have little primary sequence similarity and thus are classified purely on the basis of their ability to bind PKA (Carr et al. 1991). These anchoring proteins were originally named according to their apparent molecular mass determined by SDS polyacrylamide gel electrophoresis (SDS-PAGE) or by prediction from the open reading frame: AKAP79, for example, migrates at ~79 kDa by SDS-PAGE. Several AKAPs, such as the muscle-selective mAKAP (originally known as AKAP100) and AKAP-Lbc, were subsequently found to be fragments or smaller transcripts of larger genes and were renamed. More recently identified AKAPs, for example, Gravin, Ezrin, Rab32, WAVE-1, SKIP and cardiac Troponin T retain their original designations. In the context of nucleotide and protein database nomenclature, AKAPs are numbered sequentially (e.g., AKAP79 is termed "AKAP5"). More recent AKAPs with different names, such as Ezrin, Rab32, WAVE-1, and cTnT have not been included in this classification. See Pidoux and Tasken 2010 and Welch et al. 2010 for comprehensive tables of AKAPs (with gene nomenclature committee names).

Techniques for Identification of AKAPs and Disruption of AKAP-Mediated Protein Kinase a Signaling

Most AKAPs contain a recognizable hallmark sequence (approximately 20 amino acid residues, predicted to form an amphipathic helix) that forms a binding site for the R subunits. Structural studies indicate that the hydrophobic face of this region fits into a binding pocket formed by the N-terminal regions of the RII dimer of PKA (Newlon et al. 1997). Cellular delivery of a peptide or related derivatives (cell-soluble stearated forms, or plasmid-based expression) originally based on the RII-binding region in AKAP-Lbc has become a standard means to establish whether anchored pools of PKA participate in various cAMP signaling events by disrupting PKA-RII anchoring inside cells (see Fig. 3). The utility of this peptide as a disruptor of PKA anchoring was first demonstrated in studies showing that perfusion of this peptide into cultured hippocampal neurons disrupts the localized phosphorylation of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor by anchored PKA. The functional consequence of this disruption was to decrease the responsiveness of the ion channel to synaptic signals (Rosenmund et al. 1994).



A-Kinase Anchoring Protein (AKAP), Fig. 3 *Study of AKAP function by peptide-mediated disruption of protein kinase A anchoring*. The AKAP-amphipathic helix-PKA-RII interaction can be disrupted in vivo by introduction of a competing peptide (originally called Ht31). The disruptor peptide will bind to PKA-RII, thereby displacing PKA from an AKAP inside a cell. Mislocalization of PKA by displacement from an AKAP may lead to uncoupling of site-specific PKA signaling. This has been demonstrated in the processes of channel and receptor regulation, insulin secretion, sperm motility, and oocyte maturation



A-Kinase Anchoring Protein (AKAP), Fig. 4 *Identification of AKAPs by RII overlay*. Purified PKA regulatory subunit RII is radiolabeled with γ-[^{32}P]-ATP and overlayed on to a membrane with immobilized protein. Following incubation with RII and extensive washing of the membrane, AKAPs are identified by autoradiography

The high affinity interaction between AKAPs and the RII subunit dimer of PKA also underlies the RII overlay procedure (shown in Fig. 4), which has been used extensively, with great success, to identify AKAPs.

AKAP Function

AKAPs have been implicated in diverse physiological processes (reviewed in Carnegie et al. 2009), including reproduction and development, learning and memory, cardiac function, and diseases such as cancer and diabetes.

AKAPs, and Reproduction and Development

AKAPs function in the regulation of motility, sperm capacitation, the acrosome reaction, and oocyte maturation. As oocytes undergo meiosis, a change in PKA localization is observed (Rawe et al. 2004), through the expression and localization of different AKAPs. Thus PKA activity is specifically targeted to specific sites and substrates in the oocyte.

Gravin (*AKAP12*) has been implicated in embryogenesis, regulating cell migration through inhibition of a Rho/ROCK/myosin II pathway (Weiser et al. 2007).

AKAPs, and Learning and Memory

One of the first physiological roles identified for AKAPs was the synchronization of synaptic signaling events that underlie learning and memory. AKAP79 (*AKAP5)* (or the mouse ortholog, AKAP150) can regulate synaptic plasticity by coordinating PKA, PKC, and PP2B/calcineurin at the post-synaptic membrane (Klauck et al. 1996). Phosphorylation of channel subunits modulates synaptic efficiency either by regulating the conductance of ion channels or by regulating surface expression of the channel complex.

WAVE-1 (Wiskott–Aldrich syndrome, verprolin-homology domain containing protein) is another AKAP with defined neuronal functions; WAVE-1 null mice display defects in hippocampal learning and memory (Soderling et al. 2003). Expression of the WAVE-1 isoform is restricted to the central nervous system where it functions to organize protein networks involved in the regulation of the actin assembly and synaptic plasticity. WAVE-1 is likely to exist in many different protein complexes, relating to its spatiotemporal function. For example, the RII-binding region of this protein overlaps with the actin-binding domain, whereas the C-terminal region of the protein interfaces with the Arp 2/3 complex, a constellation of actin-related proteins that control changes in cytoskeletal shape.

Cardiac AKAPs

As depicted in Fig. 5, several AKAPs have been identified in the heart. These "cardiac" AKAPs have been implicated in the regulation of cytoskeletal proteins and cardiac ion channels, that coordinate excitation-contraction (EC) coupling. Thus AKAPs mediate cardiac inotropy, chronotropy, and lusitropy. For example, the long splice variant of *AKAP7*; AKAP15/18δ targets PKA to phospholamban, which is a critical regulator of the sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) (Lygren et al. 2007), leading to the effects of adrenergic stimulation on calcium reuptake.

AKAP79 (*AKAP5)* also plays a role in the regulation of Ca^{2+}, specifically by targeting PKCα to the L-type Ca^{2+} channel in arterial myocytes. Recent studies demonstrate that AKAP150 null mice were found to lack persistent Ca^{2+} sparklets and have lower arterial wall intracellular calcium and decreased myogenic tone. These null mice were hypotensive and did not develop angiotensin II–induced hypertension (Navedo et al. 2008).

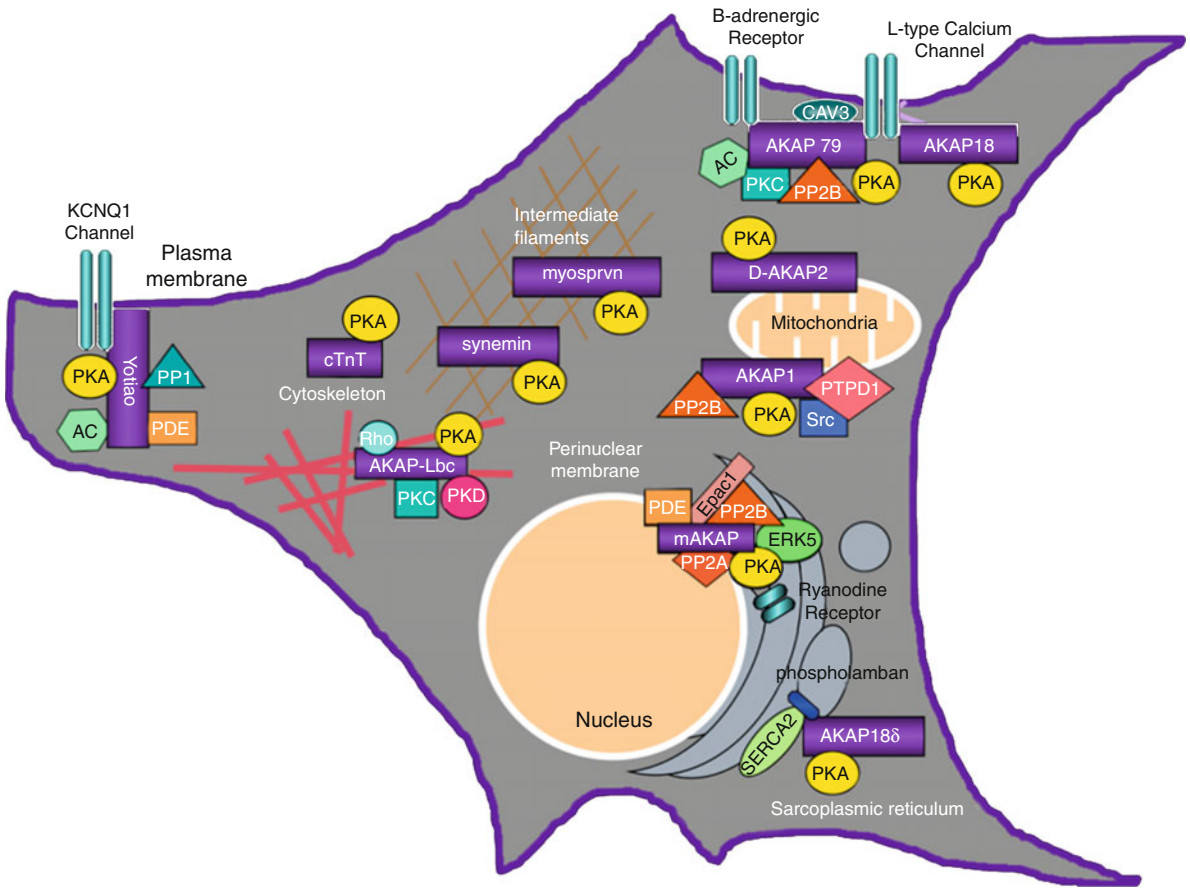
Interestingly, a mutation in Yotiao (*AKAP9*) has been identified in patients with familial long-QT syndrome (LQTS) (Chen et al. 2007). Long QT syndrome (LQTS) is a congenital disorder characterized by a prolongation of the QT interval on ECG and often, ventricular tachyarrhythmias, which may lead to cardiac arrest. Yotiao forms a macromolecular complex (targeting PKA, PP1, and PDE4D3) with the slowly activating cardiac potassium channel I_{Ks}, which is critical for repolarization of the ventricular action potential in the heart. Mutations in either yotiao or the I_{Ks} channel subunits that disrupts their interaction cause a reduction in PKA-mediated phosphorylation of the channel, leading to prolonged ventricular action.

The muscle-specific A kinase–anchoring protein (mAKAP; *AKAP6*) is highly expressed in cardiac tissue and localized to the perinuclear membrane and junctional sarcoplasmic reticulum where it is in close proximity to a variety of substrates such as L-type Ca^{2+} channels and the ryanodine receptor (RyR), thereby functioning in the regulation of contractility. mAKAP scaffolds multiple signaling molecules including PKA, PDE4D3, Epac1, ERK5, PP2A, and PP2B (calcinuerin). mAKAP has also been implicated in cardiac hypertrophy through ERK5 and calcineurin signaling (Bauman et al. 2007).

AKAP-Lbc (*AKAP13*) also plays a role in the induction of hypertrophy, through integration of multiple signal transduction components including Rho and ▶ PKD (Appert-Collin et al. 2007; Carnegie et al. 2008).

AKAPs and the Immune System

cAMP-PKA signaling is well established as a potent negative regulator of T-cell immune function. Prostaglandin E_2 (PGE2) and other ligands promote the production of cAMP, which in turn activates PKA to inhibit TCR-induced T-cell proliferation. Type I PKA is the predominant PKA isoform in T cells and plays a prominent role in immunomodulation. Studies examining the role of RIIα in the immune system in vivo show that T-cell development, homeostasis, and the generation of a cell-mediated immune response are not altered in RIIα null mice. Recently, the dual specificity



A-Kinase Anchoring Protein (AKAP), Fig. 5 *Cardiac AKAPs*. AKAPs are important in the regulation of cardiac function. AKAP18, AKAP79, and yotiao function in channel regulation, while myospryn, synemin, and cTnT act to target PKA to actin filaments, regulating contractility. mAKAP, AKAP121, and AKAP-Lbc play a role in pathological cardiac hypertrophy

AKAP ezrin has been identified, acting to target type I PKA to the TCR-CD3 complex present at membrane microdomains (lipid rafts) in T cells. Targeting of PKA by ezrin facilitates the phosphorylation and activation of the tyrosine kinase Csk. In turn, ▶ Csk negatively regulates Lck tyrosine kinase activity and T-cell receptor activation (Mosenden and Tasken 2011).

AKAPs and Disease

Several SNPs have been identified in patients with different diseases. For example, mutations identified in the gene encoding the AKAP pericentrin (*PCNT*) were demonstrated to cause Seckel syndrome (Rauch et al. 2008). Seckel syndrome is a disorder associated with defective ATR-dependent DNA damage signaling, resulting in a marked reduction of brain and body size. While the mechanism underlying this disorder is not fully understood, the authors demonstrated that collectively, these mutations result in the loss of expression of all mammalian *PCTN* isoforms.

Cancer

Gravin (*AKAP12*) is down-regulated in a number of tumor types including prostate, ovarian, and breast cancer and is associated with metastatic progression of these tumors, providing evidence supporting the role of gravin as a tumor suppressor (Gelman 2002). The observed role of gravin in embryogenesis also supports a tumor supressor function for this AKAP. It is thought that gravin may act to inhibit the migratory movements observed in some tumors that may cause cell invasion and metastasis.

A truncated form of AKAP-Lbc (*AKAP13*) missing both N- and C-terminal regulatory sequences was originally identified as an oncogene from myeloid leukemia patients.

Diabetes

A role for AKAPs in the regulation of hormone (GLP-1)-mediated insulin secretion was first identified in studies using the PKA-AKAP disruptor peptide (Lester et al. 1997). Results demonstrate that insulin secretion can be regulated by the reversible phosphorylation of β-cell proteins through the AKAP79 targeted effects of PKA and PP2B. More recently, AKAP18α or γ has also been implicated in the regulation of glucose-stimulated insulin secretion (Josefsen et al. 2010).

Summary

AKAP-mediated kinase anchoring is acknowledged as a vital means to synchronize spatial and temporal aspects of signal transduction. In addition, AKAPs are now regarded as signaling nodes that integrate a variety of intracellular signals to modulate a plethora of cellular processes. With the extensive molecular, biochemical, and cellular characterization of many AKAPs, in combination with large functional genomic screens and the study of tissue or whole animal models, the future of this field likely lies in precisely defining how specific AKAPs play their part in maintaining normal physiology and what happens to AKAP signaling complexes in disease states.

Alpha E Integrin

Bryan A. Anthony and Gregg A. Hadley
Department of Surgery, The Ohio State University Medical Center, Columbus, OH, USA

Synonyms

Alpha polypeptide; CD103; Human mucosal lymphocyte antigen 1

Historical Background

CD103 (integrin αEβ7) was first identified through the binding of a monoclonal antibody (HML-1, human mucosal lymphocyte antigne-1) to a population of lymphocytes that is preferentially associated with gut epithelium (Cerf-Bensussan et al. 1987). It was later identified that HML-1 bound to CD103 which was expressed predominantly on CD3+ CD8+ T cells, and the vast majority of these cells were found in the intestinal mucosa (Russell et al. 1994). Several functionally distinct epitopes were identified. The HML-1 and αE7-1 epitopes were found to function as costimulatory molecules in lymphocyte proliferative responses to a breast cancer epithelial cell line while the αE7-2 and αE7-3 epitopes did not provide such costimulation (Russell et al. 1994).

It is now clear that CD103 is a classic integrin heterodimer composed of the β7 and αE integrin (CD103) subunits. As described above, early studies identified CD103 as an adhesion molecule expressed exclusively by CD8+ T cells in the gut mucosa; however, subsequent studies revealed that CD103 is also expressed by peripheral CD8+ T cells and diverse leukocyte subsets. Recent studies indicate that CD103 is promiscuously expressed by different leukocyte subsets with known immune functional capabilities including not only CD8+ T cells but also interstitial dendritic cells and regulatory T cells. This review is focused on the mechanisms by which CD103 expression is regulated by these leukocye subsets, and the functional impact of CD103 expression on CD8+ T cells, dendritic cells, and regulatory T cells (Tregs). The therapeutic potential of CD103 blockade is also discussed.

Regulation of CD103 Expression

The precise mechanisms regulating CD103 expression by the different leukocyte subsets remain poorly defined. A leading hypothesis is that leukocytes expressing the CD49d/β7 integrin (i.e., gut homing CD8+ T cells) downregulate CD49d and upregulate CD103 in the presence of bioactive transfoming growth factor beta (TGF-β) to generate CD103 expressing cells. There is also evidence that TGF-β directly induces transcription of the αE gene (Itgae) (Robinson et al. 2001). Regardless of the mechanisms involved, it has been clear that bioactive TGF-β plays a dominant role in regulating CD103 expression since the initial reports on the subject by Kilshaw and Murant nearly 20 years ago (Kilshaw and Murant 1990). A key role for TGF-β in regulating CD103 expression by non-CD8 cells is supported by the observation that conversion of naive T cells into CD4+ CD25+ T regs is dependent on TGF-β activity (Coombes et al. 2007). Similarly, TGF-β induces CD103 expression on CD8 T effectors elicited to allogeneic spleen cells cocultured with TGF-β, and CD103 expression by CD8+ T effectors elicited to allogeneic epithelial cells is blocked by TGF-β neutralizing antibody (Hadley et al. 1997). That TGF-β plays a similar role in vivo is supported by the studies of El-Asady et al. who showed that alloreactive CD8+ T cells

deficient in the ability to respond to TGF-β were unable to upregulate CD103 in a murine model of GVHD (El-Asady et al. 2005). Studies from the tumor immunology field reveal that TGF-β has a profound impact on the capacity of CD8+ T cells to upregulate CD103 expression following reexposure to cognate antigen (Le Floc'h et al. 2007). Thus, while the precise mechansims likely differ among cell types, the existing data on the subject indicate that TGF-β plays a key role in the process. In this regard, it is important to note that bioactive TGF-β is ubiquitous at sites of inflammation due to its role in wound healing processes, suggesting that the overall impact of this poorly characterized cytokine may promote rather than down modulate immune responses as is often tacitly assumed.

CD103+ CD8+ T Cells

The majority of studies characterizing CD103 expression by CD8+ T cells initially focused on its role as a homing molecule for lymphocytes in the mucosal immune system. Indeed, the elegant studies of Cepek et al. established that CD103 recognizes the epithelial-specific ligand, E-cadherin (Cepek et al. 1994), which is highly expressed on gut epithelial layers. However, there is compelling evidence that CD103/E-cadherin interactions also play a key role in promoting the effector function of peripheral CD8 T effector populations. In vitro studies indicate that CD103 is upregulated on alloreactive CD8+ T cells cocultured with allogeneic renal epithelial cells, and that such expression promotes lytic activity to epithelial cell targets (Hadley et al. 1997). Wang et al. showed that CD8+ T cells do not express CD103 at early timepoints following renal transplant; however, CD8+ T cells in the graft acquire CD103 expression over time (Wang et al. 2004). Interestingly, in a vascularized renal transplant model, kidneys rejected before CD103 expression was acquired. If acute rejection was delayed using cyclosporin, CD8+ T cells gained expression of CD103 and promoted long-term renal injury (Yuan et al. 2005). Studies from the tumor immunology field indicate that CD103 also plays an important role in effective lysis of tumor cells expressing E-cadherin. Le Floc'h et al. found that CD103 was required for tumor lysis of E-cadherin expressing tumor cells, and that the CD103/E-cadherin interaction is required for cytotoxic granule localization to the immunological synapse and exocytosis (Le Floc'h et al. 2007). Importantly, however, it is important to recognize that CD8+ T effectors generally express high levels of CD49d/CD18 (leukocyte function-associated antigen-1, LFA-1), and that interaction of this integrin with its ligand CD54 (intercellular adhesion molecule-1, ICAM-1) plays a dominant role in regulating lytic activity with interaction of CD103 with E-cadherin apparently serving a backup role in providing the requisite signaling pathways in the event that CD54 is down modulated or otherwise not present on the target cell. In humans, CD103 expression by peripheral CD8+ T cells is confined to small subset (<1%) of circulating memory-phenotype cells. In mice, CD103 is expressed at low levels by 40–60% of peripheral CD8+ T cells, the exact frequency of which is strain-dependent.

CD103+ Dendritic Cells

Dendritic cells (DCs) are a highly heterogeneous cell type requiring numerous molecules to classify each of a variety of subsets. CD103+ DCs have been described as involved in generating gut homing T cells and Tregs (Coombes et al. 2007; Jaensson et al. 2008). CD103+ DCs are found in the spleen, skin, lung, and gut-associated lymphoid tissue (GALT). Because the lung and the GALT are in contact with many nonpathogenic antigens, it is likely that the microenvironments of the lung and GALT promote an immunomodulatory phenotype to prevent excess nonspecific inflammatory responses. CD103+ DCs are ideally suited for this purpose. There is evidence that GALT-derived CD103+ DCs produce lower levels of anti-inflammatory cytokines when cocultured with TLR agonists, have increased costimulatory molecule expression, and are less efficient phagocytes than their CD103− counterparts (Coombes et al. 2007; del Rio et al. 2010). CD103+ DCs in the lung display similar functional characteristics (del Rio et al. 2010). Moreover, there is evidence that CD103+ DCs induce Treg formation in the presence of TGF-β and retenoic acid (Coombes et al. 2007). Naive T cells that are activated in the gut by CD103+ DCs acquire the expression of the transcription factor forkhead box protein 3 (FoxP3). In addition to a critical role in inducing Tregs, CD103+ DCs play an important role

in generating gut homing CD8+ T cells. CD8+ T cells primed by CD103+ DCs have increased CCR9 and CD49d/β7 expression as compared to CD8+ T cells primed by CD103- DC (Johansson-Lindbom et al. 2005). Lamina propria–derived DCs express higher levels of CD103 than do mesenteric lymph node–derived DCs. Consequently, lamina propria DCs are more potent than mesenteric lymph node DCs in generating gut tropic CD8+ T cells. Although CD103− and CD103+ mesenteric lymph node DCs both activate CD8+ T cells capable of producing interferon gamma, only CD103+ DCs generate gut tropic CD8+ T cells. This phenomenon does not appear to be a product of the gut microenvironment, but rather DC imprinting that occurs prior to DC localization to the gut (Johansson-Lindbom et al. 2005). It is important to note that depletion of CD103-expressing DCs does not compromise host immune responses (Zhang et al. 2009), calling into question the importance of CD103+ DCs in promoting overall immune responses.

CD103+ Tregs

Tregs define an immunomodulatory T cell subset characterized by the capacity to suppress immune responses. There are two populations of CD4+ CD25+ Tregs: natural and adaptive. Natural Tregs are generated in the thymus, while adaptive Tregs are derived in the periphery (Sakaguchi 2005). CD103 is a marker found on a subset of adaptive Tregs (Huehn et al. 2004). It has been shown that CD103+ Tregs have immunosuppressive properties that are equal to, or greater than those of CD103− Tregs. Typically, Tregs are CD4 + CD25+ and express FoxP3; however, there is a population of CD25-CD103+ Tregs that express CTLA-4, suppress T cell proliferation in vitro, and prevent severe colitis in the SCID mouse (Lehmann et al. 2002). There is also a distinct cytokine profile expressed in CD103+ CD25+ Tregs. CD103-CD25+ Tregs secrete levels of IL-4, IL-5, and IL-13 that are similar to Th2 CD4+ T cells, but there is almost no IL-4, IL-5, or IL-13 produced by CD103 + CD25+ Tregs (Lehmann et al. 2002). CD103+ Tregs are also more potent suppressors of T cell proliferation. CD103+ Tregs almost completely prevented naive CD4+ T cell proliferation when nonspecifically stimulated. CD103− Tregs also suppressed proliferation, but to a lesser extent (Lehmann et al. 2002). CD4+ CD25+ CD103+ Tregs also exhibit immunosuppressive properties in vivo. Ongoing chronic graft versus host disease (GVHD) can be suppressed through an in vivo transfer of CD4+ CD25+ CD103+ Tregs. Infusion of CD4+ CD25+ CD103+ Tregs has been shown to reduce the number of alloantibody producing plasma cells in mice with chronic GVHD as well as reduce the number of pathogenic effector T cells in GVHD target organs (Zhao et al. 2008). Moreover, infusion of CD103+ Tregs resulted in twofold lower levels of alloantibody as compared to in vitro activated natural Tregs. Additionally, CD103 defines a population of CD8+ Tregs. CD8+ Tregs can acquire their antigen specificity peripherally and promote systemic tolerance. Injection into the anterior chamber of the eye will generate CD8+ Tregs specific for the injected antigen. CD103 has been shown to be essential for the development and function of the CD8+ Tregs (Keino et al. 2006). Koch et al. characterize CD103+ CD8+ Tregs as phenotypically different from other CD8+ suppressor T cell populations. CD103+ CD8+ Tregs express CD28, but lack FoxP3, CD25, LAG-3, CTLA-4, and GITR (Koch et al. 2008).

Therapeutic Potential of CD103 Blockade

The utility of therapeutic strategies for targeting the CD103 pathway are clouded by promiscuity in CD103 expression and uncertainty regarding its precise function on different cell types. CD103 is regulated by TGF-β, but the activation state of the CD8+ T cells at the time it encounters TGF-β determines the function of the CD8+ T cell (Hadley et al. 1997); consequently TGF-β is not a viable therapeutic target. Targeted disruption of CD103 on CD8 effector T cells prevents intestinal GVHD and prolongs renal allograft survival (El-Asady et al. 2005; Yuan et al. 2005), suggesting that CD103 itself may be the optimal therapeutic target. However, CD103+ Tregs have been shown to ameliorate chronic GVHD (Zhao et al. 2008), and CD103+ DC have been shown to promote Treg development (Coombes et al. 2007), arguing against the therapeutic poential of CD103 blockade. Depletion of CD103-expressing cells in vivo dramatically attenuates CD8+ T cell responses, arguing that CD103+ DC or Tregs do not serve critical immune functions in all immune responses (Zhang et al. 2009). Consequently, the overall role of CD103 in promoting disease

remains controversial, and this ambiguity has hindered the development of therapeutic agents to target the pathway.

Summary

CD103 is a classic integrin heterodimer composed of the β7 and αE integrin (CD103) subunits that recognizes the epithelial cell-specific ligand, E-cadherin. CD103 is expressed by diverse leukocyte populations, and there is increasing evidence that it plays a key role in both promoting and regulating immune responses. Whether or not CD103 provides a viable therapeutic target remains to be determined.

Historical Background

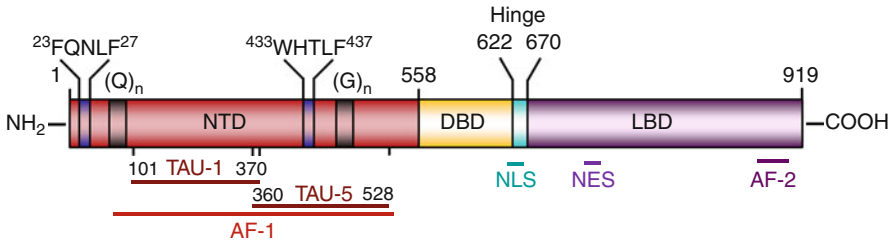
Androgen receptor (AR) mediates the effects of androgens that are responsible for diverse biological functions, such as development and maintenance of the male reproductive system as well as involvement in disease states, such as prostate cancer (for a review, see Brinkmann 2011). AR is a ligand-activated transcription factor (TF) that belongs to the steroid hormone receptor (SHR) family within the nuclear receptor (NR) superfamily of TFs (for a review, see Mangelsdorf et al. 1995). In addition to AR, the SHR family contains the glucocorticoid receptor (GR), mineralocorticoid receptor (MR), progesterone receptor (PR), and the estrogen receptor (ER). SHRs are structurally and functionally related and mediate the action of steroid hormones that affect nearly all aspects of development and homeostasis; they are also implicated in a number of pathological conditions.

The first reports on the protein nature of AR and its isolation from androgen target tissues were published at the end of the 1960s (Fang et al. 1969; Mainwaring 1969; Baulieu and Jung 1970). During the 1970s and 1980s, much effort went into the purification and further characterization of AR from different sources. The human AR cDNA was finally cloned in 1988 and 1989 by several groups just a few years after cloning of the cDNAs of the human SHRs (Chang et al. 1988; Lubahn et al. 1988; Trapman et al. 1988; Tilley et al. 1989). AR is expressed at low to moderate levels in a variety of cell types with high levels present especially in male and female reproductive tissues, adrenal gland, kidney, and skeletal muscle. In addition to androgens, AR can be activated in an androgen-independent manner through other signaling pathways which can significantly contribute to the diversity of AR action.

AR Domains and Function

Similar to other SHRs, AR has four distinct functional domains: N-terminal domain (NTD), DNA-binding domain (DBD), hinge region, and ligand-binding domain (LBD). As the names indicate, these domains are responsible for DNA and ligand binding, as well as additional functions, such as dimerization, translocation into and from the nucleus, and interaction with diverse coregulators and TFs (for a review, see Lamb et al. 2001) (Fig. 1). Moreover, there are intramolecular interactions between the NTD and LBD, which are important for AR activity and binding to chromatin (e.g., Ikonen et al. 1997). Several studies found the synthesis of alternatively spliced transcripts in vivo that encode truncated AR isoforms that lack the LBD (for a review, see Dehm and Tindall 2011). Many of these truncated ARs function as constitutively active, ligand-independent TFs which may have implications in disease states.

In the absence of ligand, AR is inactive and exists in the cytosol in a complex with heat shock proteins (HSPs), such as Hsp56, Hsp70, and Hsp90, as well as



Androgen Receptor (AR), Fig. 1 Schematic presentation of the AR protein. Structural and functional domains of AR are shown. The AR N-terminal domain (NTD) contains a ligand-independent activation function (AF-1) with two transactivation units, TAU-1 and TAU-5, containing binding motifs for coregulators. The ^{23}FQNLF^{27} motif contributes to the interaction between the NTD and ligand-binding domain (LBD), whereas the ^{433}WHTLF^{437} motif may influence AR signaling by acting as an autonomous activation domain. The length of the human AR protein can vary due to poly-glutamine ((Q)n) and a poly-glycine ((G)n) stretches of variable lengths in the NTD. The nuclear localization signal (NLS) resides in the flexible hinge region. The LBD harbors a ligand-dependent AF-2 and the nuclear export signal (NES). The numbering of amino acids shown is based on 21 and 23 residues in the poly-glutamine and poly-glycine repeats, respectively

cytoskeletal proteins and other chaperones (for reviews, see Lamb et al. 2001; Brinkmann 2011). Upon ligand binding, AR undergoes a conformational change, dissociates from HSPs and other chaperones, dimerizes, and translocates to the nucleus. Although AR usually acts as a homodimer, it has been shown to form heterodimers with other nuclear receptors including ER, GR, and testicular orphan receptor-4 (TR4). However, the functional consequences of these interactions in vivo are currently not clear. Once in the nucleus, AR binds chromatin in the vicinity of target genes at specific sites known as androgen response elements (AREs), recruits various coregulators, other TFs, and components of the general transcription machinery, and modulates gene expression (Lamb et al. 2001) (Fig. 2).

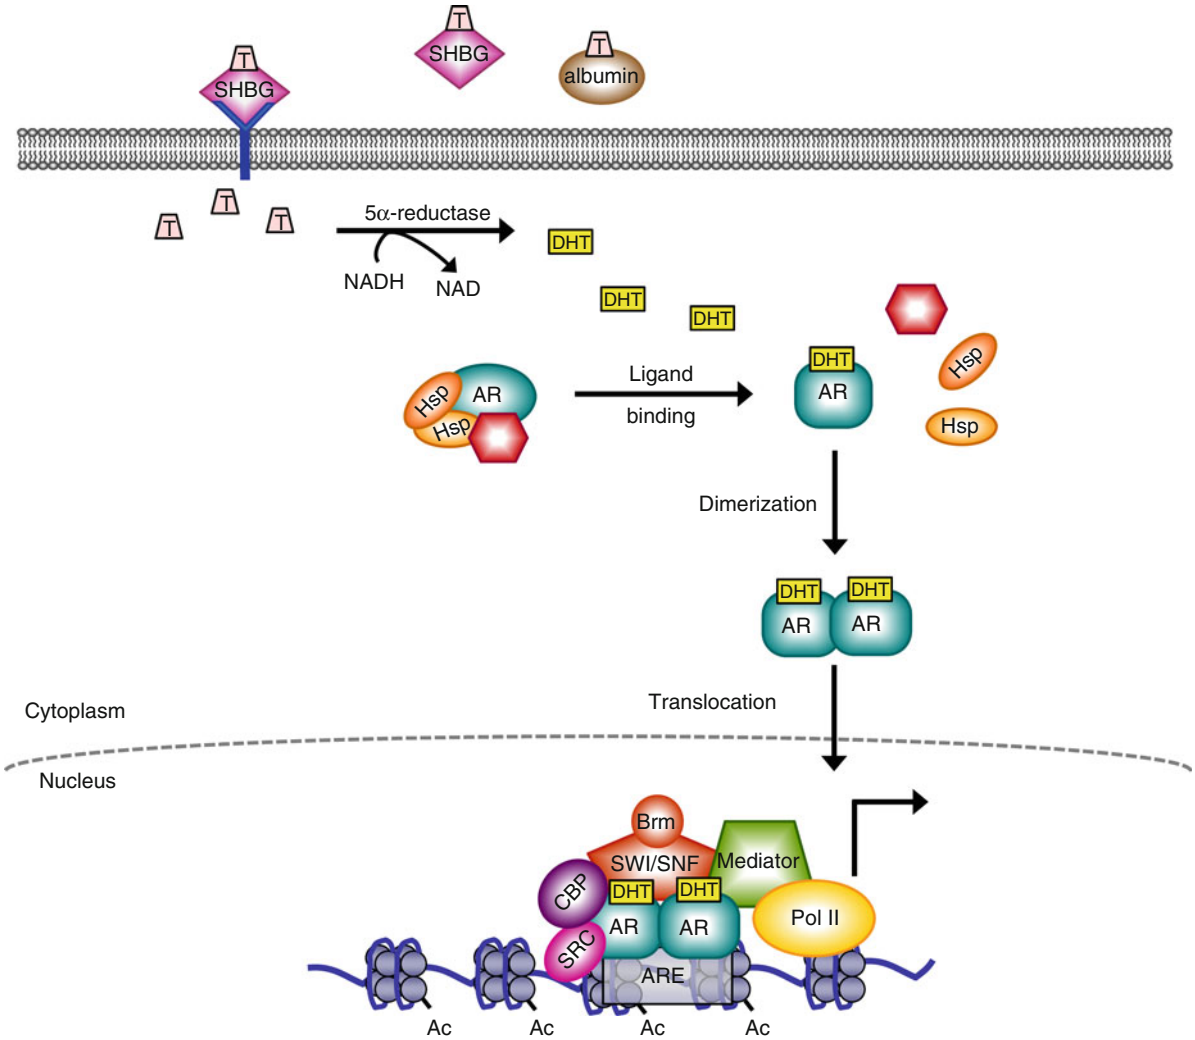
Based on biochemical studies and similar to other TFs, AR has been shown to stably bind its chromatin template in the presence of the ligand. However, development of live cell imaging and advances in green fluorescent protein (GFP) technology have demonstrated dynamic interactions of AR with its specific regulatory sites. Using fluorescence recovery after photobleaching (FRAP) analysis, residence times of these transient interactions were measured on a time scale of seconds and were influenced by the nature of the ligand (Klokk et al. 2007).

In addition to the dynamic, chromatin-binding-dependent transactivation function of AR, liganded AR can regulate transcription independently of its ability to bind DNA. This happens through the direct protein–protein interactions between AR and coregulators and/or TFs that alter their intrinsic transcriptional activities. For example, there is evidence that AR increases the activity of coactivators GR interacting protein-1 (GRIP1), cAMP-response element-binding protein (CBP), and p300, whereas it inhibits activity of other TFs and signaling pathways, such as those involving activator protein-1 (AP1) and nuclear factor-κB (NF-κB) (for reviews, see Kaarbo et al. 2007; Bennett et al. 2010). This greatly increases the repertoire of genes that can be regulated by AR.

Given the importance of androgens in the normal physiology and disease states, several studies have sought to identify genome-wide AR target gene profiles using ChIP-chip and ChIP-seq (e.g., Yu et al. 2010; Massie et al. 2011). These studies started to identify not only the genes that are AR targets, which for example involve different aspects of cell cycle and metabolism, but also other factors that may be important for AR activity, such as FOXA1 as an AR pioneer factor.

In addition to regulation by its cognate ligand, AR is subject to modification by phosphorylation, acetylation, methylation, sumoylation, and ubiquitination (for a review, see Gioeli and Paschal in press). Although the exact consequences of these modifications to AR function in normal physiology and implications for disease states are not yet known, they likely have a role in at least fine tuning of AR function.

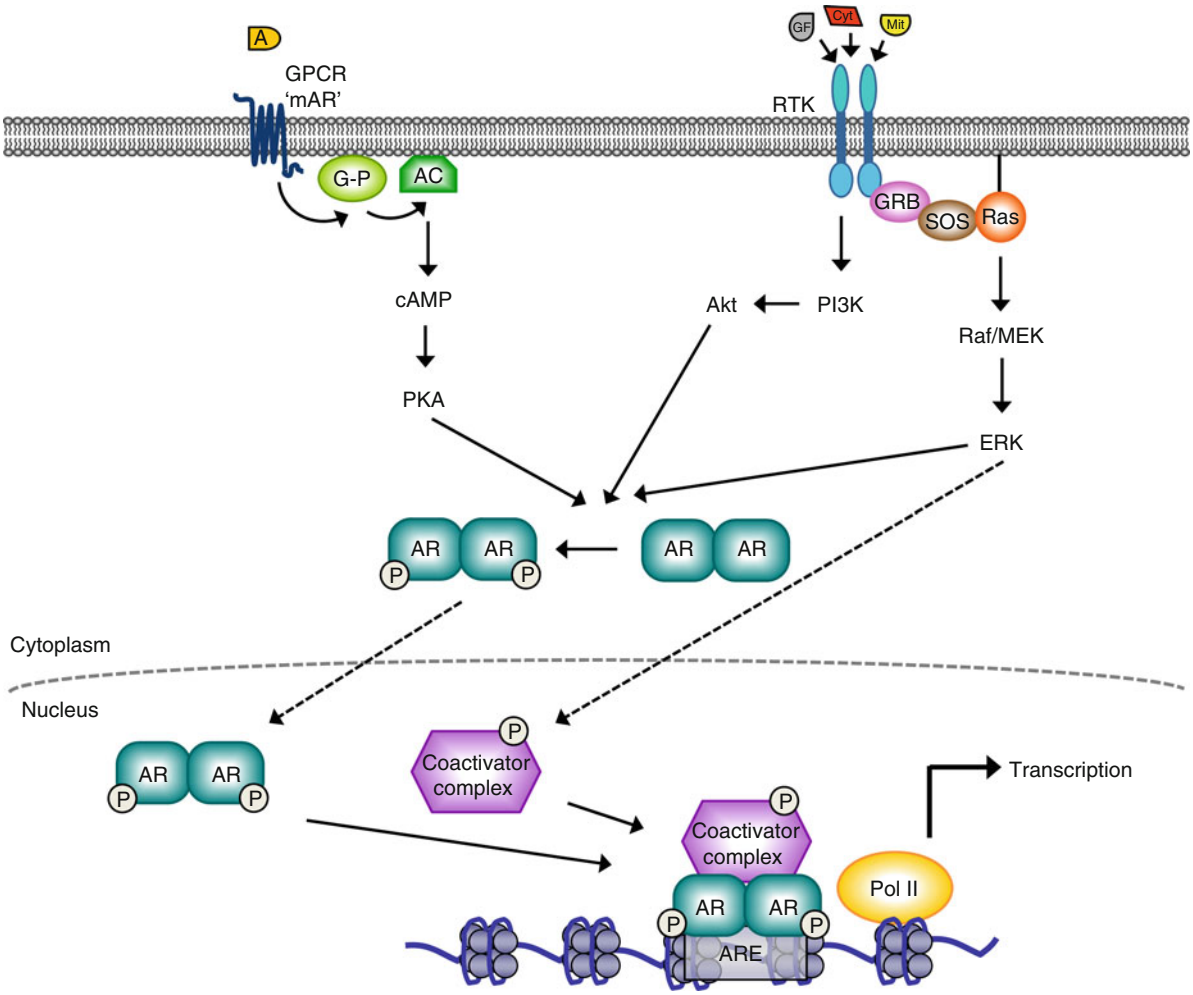
The importance of posttranslational modifications to AR activity is illustrated by modulation of AR action by a number of signaling pathways initiated by growth factors, cytokines, and mitogens (Fig. 3). Several growth factors, such as insulin-like growth factor-1 (IGF-1), keratinocyte growth factor (KGF), epidermal growth factor (EGF), and interleukin-6 (IL-6), were found to transactivate AR independently



Androgen Receptor (AR), Fig. 2 AR transcriptional activation. Testosterone (T) circulates in the blood bound to steroid hormone-binding globulin (SHBG) or albumin and enters the cells through diffusion or through a SHBG receptor at the plasma membrane. In some cells, T is converted to the more active metabolite dihydrotestosterone (DHT) through the action of 5α-reductase. Upon ligand binding, AR undergoes a conformational change followed by dissociation from the multi-subunit chaperone complex. It then forms dimers and translocates to the nucleus where it binds androgen response elements (AREs) of target genes and recruits coregulators (some examples of which are shown) and basal transcription machinery, resulting in transcriptional regulation. HSP, heat shock protein; CBP, CREB binding protein; SRC, steroid receptor coactivator; BRM, Brahma; SWI/SNF, a chromatin modifying complex

of androgens (for a review, see Foradori et al. 2008). Such cell surface signals stimulate downstream ▶ mitogen-activated protein kinase (MAPK) and phosphatidylinositol-3 kinase (PI3K)/Akt signaling pathways, increasing AR activity as well as the activity and interaction of different coactivators with AR. This increase in activity is achieved, at least in part, through phosphorylation of AR and the coactivators. For example, AR has been shown to be phosphorylated on Ser650 upon EGF stimulation in prostate cancer cells. Similarly, IL-6 stimulation leads to phosphorylation of the AR coactivator SRC-1.

To better understand the molecular mechanisms of AR action, several AR knockout and knockin mouse models have been generated, both systemic and tissue specific (for a review, see Kerkhofs et al. 2009). Use of these models resulted in the identification of specific AR roles in male fertility, prostate development,



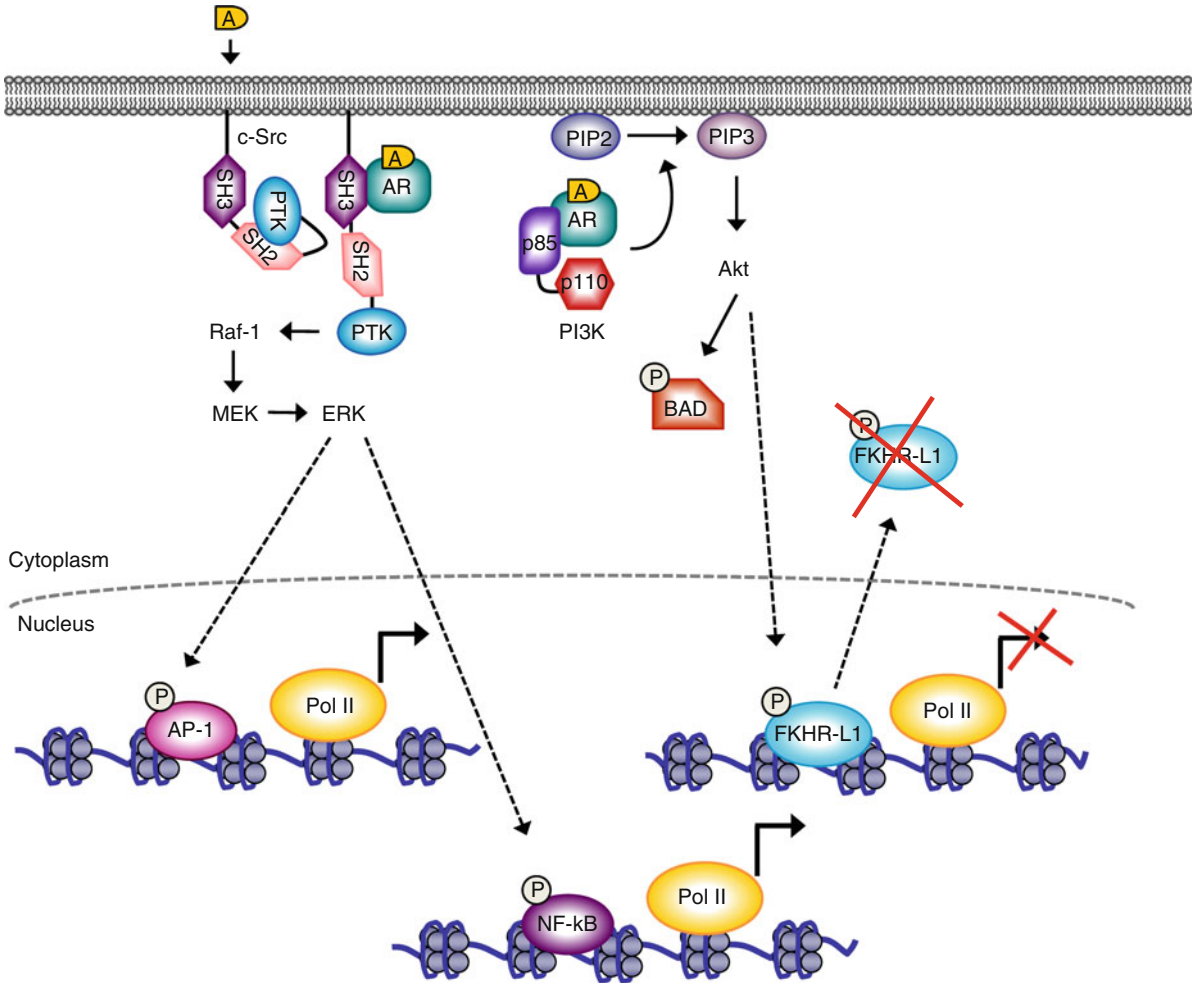
Androgen Receptor (AR), Fig. 3 AR-mediated cytoplasmic and nuclear signaling pathways through activation of plasma membrane receptors. Androgens (A) may activate the cytoplasmic kinase PKA via binding to a G-protein-coupled receptor (GPCR) at the plasma membrane and may thereby change the intracellular levels of second messenger molecules, such as cAMP. This can lead to phosphorylation and nuclear translocation of AR where it can act as a transcription factor. Nonsteroid molecules, such as growth factors (GF), cytokines (Cyt), and mitogens (Mit), arriving at the cell surface activate MAPK (Ras/Raf/MEK/ERK) and PI3K/Akt signaling pathways which similarly phosphorylate and activate the AR, leading to its translocation into the nucleus. ERK may also increase phosphorylation of AR coactivators which may activate them and thus increase AR activity

metabolism and diabetes, immune functions, bone metabolism, and several cancers. These models are facilitating the delineation of the molecular mechanisms of AR function in vivo.

Non-genomic Actions of AR

Over the past two decades, a number of studies have demonstrated non-genomic actions of AR, characterized by rapid cellular response and lack of transcription and translation of androgen-target genes. These activities are initiated at the plasma membrane or in the cytosol, triggering activation of intracellular signaling molecules, such as the extracellular-signal regulated kinase (ERK), protein kinase A (PKA), PI3K/Akt, and protein kinase C (PKC) (for reviews, see Foradori et al. 2008; Bennett et al. 2010) (Fig. 4).

For example, following androgen binding, AR interacts with the p85 regulatory subunit of ▶ PI3K



Androgen Receptor (AR), Fig. 4 Non-genomic actions of AR. Androgen-bound AR interacts with the SH3 domain of the tyrosine kinase c-► Src in the cytosol and activates the MAPK (Raf-1/MEK/ERK) signaling. This then enhances phosphorylation events that activate TFs (e.g., AP-1 or ► NF-κB) and promotes cell survival and growth. Liganded AR can also directly interact with the p85 subunit of ► PI3K and mediate activation of the protein kinase Akt which in turn phosphorylates the cytoplasmic (e.g., BAD) and nuclear (e.g., FKHR-L1) pro-apoptotic proteins which results in their degradation. These events promote cell survival by inhibiting apoptosis. P, phospho; BAD, BCL2-associated agonist of cell death; FKHR-L1, forkhead transcription factor like 1 (also known as FOXO3A)

in the cytosol which then phosphorylates and activates the downstream effector serine-threonine kinase Akt. The AR-mediated phosphorylation of Akt is inhibited by the AR antagonist bicalutamide documenting the direct involvement of AR in this process.

Another example of non-genomic AR action is where androgen-bound AR physically interacts with and activates the tyrosine kinase ► Src blocking its auto-inhibitory effect. This stimulates the ► Src/Raf-1/MEK/ERK-2 signaling cascade. One of the targets of ► Src is the adaptor molecule SH2-containing protein (Shc) which is an upstream regulator of MAPK. ► Src-activated MAPK pathway modulates AR-mediated transcription by phosphorylating AR and p160 family of steroid receptor coactivators (SRCs) and thereby regulates several cellular processes such as cell proliferation, migration, and differentiation.

AR and Disease States

Given the diverse role of androgens in a variety of cell types, perturbances to AR action have been linked to

a number of disease conditions. For example, AR dysregulation has been associated with cancer (e.g., prostate, testicular, colorectal), cardiovascular defects (coronary artery disease), immune diseases (e.g., type I diabetes), metabolic disorders (i.e., obesity and androgen insensitivity syndrome, osteoporosis), neurological conditions (e.g., Alzheimer's disease), and other diseases such as Kennedy's syndrome (for reviews, see Lamb et al. 2001; Brinkmann 2011).

AR has been most widely studied in terms of its involvement in prostate cancer (for a review, see Wang and Tindall 2011). The key role of androgens in prostate cancer genesis and progression was first observed in 1940s and has formed the basis of androgen ablation/castration therapies for prostate cancer. Although initially highly effective, this therapy ultimately fails and the disease progresses to a castration-resistant state which is fatal. It has been shown that one of the key proteins in both the androgen-sensitive and castration-resistant prostate cancer is AR. During this progression, several mechanisms involving AR are activated, such as local prostate cancer tissue androgen production, AR gene amplification, increased mitogen signaling, increased expression of AR coactivators, and increased sensitivity of AR to low androgen levels (for a review, see Wang and Tindall 2011).

Another disease in which dysregulation of AR has a role is spinal and bulbar muscular atrophy (SBMA) or Kennedy's disease (Kumar et al. 2011). This condition involves expansion of the CAG repeat encoding a poly-Q stretch in the AR NTD; whereas 34 or fewer is normal, 38 or more repeats in the poly-Q stretch gives rise to SBMA. The SBMA is characterized by the degeneration of the motor neurons which are located in the spinal cord and bulbar regions that express AR.

A third AR-linked disease, androgen insensitivity syndrome (AIS), is characterized by partial or complete lack of response to androgens in cells which normally would be androgen sensitive (for a review, see Hughes and Deeb 2006). This results in the failure of normal masculinization in 46XY male individuals. In AIS patients, the AR gene is frequently mutated in the DBD and/or the LBD, making AR lose its function. Mutations can range from complete or partial deletions of the AR gene, which are rare, to point mutations and frame shift mutations. These can disrupt the DNA binding, AR expression levels, and ligand binding specificity or efficacy, which results in at least a partial functional loss in AR.

Summary

AR is a ligand-activated TF which mediates the biological effects of androgens in diverse tissues. Upon ligand binding, AR translocates into the nucleus, binds AREs on target genes, and regulates transcription. In addition, AR can interact with other TFs or cofactors, as well as initiating rapid non-genomic cellular responses by direct interactions with several signaling molecules at the plasma membrane or in the cytoplasm. Conversely, AR can also be activated by mitogens, cytokines, and growth factors through signaling pathways which can regulate AR/coactivator activity through posttranslational modifications. Dysregulation of AR expression and/or function has been associated with a variety of disease states, including prostate cancer, SBMA, and AIS. Thus, AR is a prime target for therapy in a number of conditions.

Angiotensin II receptor type 2

Historical Background

The angiotensin II type 2 receptor (AT2R) shares a high degree of homology with its well-known sister gene, the angiotensin II type 1 receptor (AT1R), and is similarly a part of the renin-angiotensin II system (RAS). The RAS is best known for its powerful effects on regulation of blood pressure and body fluid volume. The AT2R is activated after specific binding of the eight amino acid peptide angiotensin II (AngII), which is generated from angiotensin I by the angiotensin-converting enzyme. The AT2R is a member of the family of seven transmembrane receptors, the largest group of cell surface receptors in the body. Like its family members, the AT2R traverses the cell membrane seven times creating an NH_2-terminal and three loops on the extracellular side and a COOH-terminal plus three loops on the intracellular side. The AT2R is present on multiple different cell types, although its expression level is often lower than that of AT1R. The AT2R's biological functions and intracellular signaling partners have been difficult to tease out before the arrival of AT2R-specific agonists and antagonists. In line with the widespread location of the AT2R, it has effects in most biological systems including the central and peripheral nervous system, the cardiovascular system, endocrine systems, renal function, and the reproductive system. Although AT2R expression is generally low in normal adult tissues, it is highly important in development and in injury/repair mechanisms. Thus, the AT2R is highly expressed in the developing fetus and upregulated after adult tissue injury as well as in several pathological conditions. Expression of the AT2R can be modulated by pathological states associated with tissue remodeling or inflammation

such as hypertension, atherosclerosis, myocardial infarction, stroke, and diabetes. Interestingly, the biological effects are often opposite to the AT1R effects. The most characterized AT2R effect being vasodilatation as opposed to the well-characterized AT1R-mediated vasoconstriction. Hence, from a pharmacological perspective, it would be valuable to have specific AT2R agonists, as these could be potential blood pressure–lowering drugs. The AT2R also elicit cardioprotective-, anti-inflammatory-, anti-proliferative effects and it also regulates apoptosis. Accordingly, studies have been performed to understand and map the location and function of the ligand-binding site and the intracellular signaling systems activated by the AT2R. While the receptor does not seem to activate the canonical G proteins (except Gi in some systems), several different signaling molecules appear to bind to the AT2R COOH-terminal including different kinases, phosphatases, and scaffolding molecules.

Receptor Structure, Ligand Binding, and Antagonists

Seven transmembrane (G protein-coupled) receptors for angiotensin (Ang) peptides include the AT1Ra and AT1Rb subtypes and the AT2R, that all bind the octapeptide AngII with subnanomolar affinities. The AT2R also binds the AngIII and Ang-(1-7) peptides with high affinity. In addition, at least two other receptors have been described, the AT4R (that binds AngIII) and the Mas receptor, that binds Ang-(1-7). Although no AT1R crystals have been described, the AT1R is one of the best characterized seven transmembrane receptors. Computer models indicate that the structure is much like the recently crystallized β2-adrenergic receptor (Adrenergic Receptor). The AT2R receptor is much less characterized, but it is thought that it too possesses a similar three-dimensional structure. Regarding the angiotensin receptor ligands, several different peptides exist and there has been some discussion as to which of these peptides actually bind to the different angiotensin receptors in vivo. For example, both the AngII, Ang-(1-7), and AngIII peptides activate the AT2R. AngIII is almost as potent as AngII, at least in the coronary vascular bed. Finally, there has been some data showing that the AT2R can dimerize with itself and with other seven transmembrane receptors, but not with the AT1R.

The best characterized ligand peptide is AngII that in turn is metabolized into several bioactive peptides. Aminopeptidases cleave AngII to Ang-(2-8) (AngIII) and Ang-(3-8) (AngIV). In addition, carboxypeptidases generate Ang-(1-7) from AngI-(1-10) and AngII-(1-8).

Historically, it has been difficult to separate the AT2R actions from the other Ang receptors because of the common main ligand AngII. The advent of *specific AT2R agonists and antagonists* has made it possible to better study the receptor's biological actions. At least three specific AT2R agonists have been described. The AT2R agonist CGP-42112A was the first non-peptide agonist with reasonably high affinity for the receptor, and it has been widely used. Recently, a novel agonist, referred to as compound 21 and which binds the AT2R with almost as high affinity as AngII, has been developed. Compound 21 exhibits a dissociation constant for AT2R of 0.4 nM, while the dissociation constant for the AT1R is >10,000 nM. Compound 21 reduced the mean blood pressure in spontaneously hypertensive rats and induced vasodilatation in isolated arteries via AT2R stimulation (Bosnyak et al. 2010). A third agonist candidate is compound 22 that stimulates neurite outgrowth, phosphorylates p42/p44 (ERK1/2 MAPK), enhances duodenal alkaline secretion in Sprague-Dawley rats, and also lowers the blood pressure in anesthetized rats (Alterman 2010).

Selective AT2R antagonists are equally important. The most widely used antagonist is PD-123319. Among others, this molecule has been reported to block the effects of Ang-(1-7) in many studies, suggesting that Ang-(1-7) also activates the AT2R.

AT2R Signal Transduction

The AT2R signal transduction has been controversial since the receptor does not activate canonical G proteins (except Gi in a reconstituted system). Instead, the AT2R activates a series of kinases, phosphatases, and scaffold proteins including the AT2R receptor-interacting protein (ATIP) family that binds to the intracellular COOH-terminal tail of the receptor. Somewhat indirectly, an array study in cardiac fibroblasts with AT2R blockade (with PD123319) ascribed 24 genes to be specific for AT2R activation and these genes were related to ten different signaling pathways including cAMP/PKA, Ca^{2+}, PKC, PTK, ERK1/2 (MAPK), PI-3 K, NO/cGMP, Rho, NF-kappaB, and JAK-STAT pathways. Specifically, collagen I and tissue inhibitor of metalloproteinase (TIMP)-1 mRNA

levels decreased after AT2R blockade as compared to an AngII-treated group (Jiang et al. 2007).

Several signaling pathways have been studied in more detail (some of these are slightly overlapping), including:

- Activation of protein phosphatases causing protein dephosphorylation.
- Bradykinin/nitric oxide (NO)/cyclic guanosine 3',5'-monophosphate (cGMP) pathway leading to NO release and vasodilatation.
- Stimulation of phospholipase A(2) and release of arachidonic acid.
- Rho inhibition, which may link the AT2R to the pathogenesis of hypertension and vascular proliferative disorders (Guilluy et al. 2008).
- Activation of scaffolding/adapter proteins like the ATIP family that associate with molecular motors on microtubules.
- Increased VEGF secretion that could increase angiogenesis and play a role in cancer and kidney disease.

The ATIP interaction was first discovered using the yeast two-hybrid system. This protein family presently includes six members that all interact with the AT2R: ErbB3, PLZF, CNK1 Na^+/H^+ exchanger NHE6, TIMP-3, and ATIP/ATBP; for review, see (Rodrigues-Ferreira and Nahmias 2010). Interestingly, association with these angiotensin receptor-binding proteins may change the intracellular location of the AT2R and underlie its roles in neuronal differentiation, tumor growth, and vascular remodeling. Using ATIP1 overexpressing mice (ATIP1-Tg), it has been shown that the ATIP1 plays an inhibitory role in the AT2R-mediated vascular remodeling. The ATIP1-Tg mice exhibited reduced neointima formation of the femoral artery after injury as compared to WT mice, which is in line with the perceived reduced AT2R signaling (Fujita et al. 2009). Control experiments confirmed the result by showing reduced NO, ERK1/2 phosphorylation, and TGFβ levels in the overexpression mice.

Finally, an important notion regarding the effect of AngII stimulation: Since the two AT1R and AT2R subtypes compete for available ligand, the AngII in vivo effect depends on the relative expression of the two receptors on the cell surface in a given biological system. Thus, blocking the AT1R with losartan leaves more AngII for AT2R stimulation yielding a "dual effect" because the receptors often have opposite actions. In addition, losartan also inhibits the renin/angiotensin feedback loop that functions as a negative feedback loop; therefore, blocking AT1R increases the production of AngII peptide. For example, the activated AT1R stimulates fibrosis and the AT2R attenuates fibrosis in many models; hence, losartan would inhibit fibrosis both by blocking the AT1R and by more available AngII for binding to unoccupied AT2Rs. In line with this notion, studies on transgenic mice with or without AT2 receptor expression reveal that the effects of AngII on injury-induced pancreatic fibrosis are determined by the balance between AT1R and AT2R signaling (Ulmasov et al. 2009).

The AT2R Is Important in the Central Nervous System (CNS)

Possible AT2R roles in CNS function, which affect learning, memory, satiety, and behavior have been suggested in both humans and rodents. At2r, gene knockout mice (At2r (-/y)) showed significant defects in their spatial memory, exhibited abnormal dendritic spine morphology, and had lost the AngII reduced food-intake response (Ohinata et al. 2008; Pawlowski et al. 2009). In line with these data, intracerebroventricularly administered AngII and AngIII dose-dependently suppressed food intake in mice and their anorexigenic activities were inhibited by an AT2R-selective antagonist (Ohinata et al. 2008).

Interestingly, the AT2R may also play a role in neurological disorders such as Alzheimer's disease, depression, and Parkinson's disease and possess a neuroprotective effect in response to brain injury such as stroke. The AT2R can attenuate inflammation and oxidative stress that have been suggested to be key factors in the pathogenesis and progression of several, if not all, of the here mentioned diseases. It should be noted that the exact molecular dysfunctions behind the progressive neurodegenerative disorder in Parkinson's and Alzheimer's diseases remain unidentified. It has therefore been suggested that AT2R agonists may protect neurons against cell death, and thus would prove beneficial in the treatment of these diseases. In the case of Parkinson's disease, AngII may attenuate dopaminergic cell death. The AT2R agonist can reduce damage after an ischemic insult to the brain. Indeed, centrally administered CGP42112 (an AT2R agonist) exhibits a neuroprotective effect, which is independent of blood pressure in conscious rat models of stroke. This effect is likely enhanced by AT2R-induced

vasodilatation and an increase in blood flow to the ischemic brain zone improving the brain function and limiting the infarct extension.

Furthermore, it is believed that the neuroprotective AT2R effect on stroke plays a role in the beneficial effects of AT1R blockade in stroke. Thus, losartan is superior in stroke treatment to other antihypertensive drugs that are equipotent with respect to their blood pressure–lowering effect. Losartan's effect appears to be blood pressure independent and mediated through a dual action: selective AT1R blockade and indirect AT2R stimulation by leaving AngII for the unoccupied AT2Rs. This dual action is unique to AT1R blockers.

At the cellular level, AT2R signaling and phenotypic effects on nerve cell differentiation, apoptosis, and morphology have been studied extensively. In NG108-15 cells, the AT2R induces neural outgrowth, a process that requires parallel activation of ERK1/2 and Fyn, a member of the ▶ Src family kinases (Guimond et al. 2010).

The ATR2 Elicits Vasodilatation and Cardioprotection in the Cardiovascular System

The AT2R's actions in the cardiovascular system are well characterized and include *relaxation of cardiac and vascular smooth muscle tone* most likely through increased NO production and bradykinin release. This is the classical AT2R effect; however, the AT2R also *affects cellular apoptosis, inhibits proliferation, diminishes atherosclerotic lesions in humans, and limits the actions of the immune system after cardiac injury*. Accordingly, AT2R agonists are under development for potential therapeutic use in hypertension. In addition, AT2R activation suppresses renin biosynthesis and release in renal juxtaglomerular cells, potentially further adding to the blood pressure–lowering effect.

Treatment of Wistar rats with the AT2R agonist compound 21, 24 h after an experimentally induced myocardial infarction, significantly reduced scar size and improved systolic and diastolic ventricular function (Kaschina et al. 2008). At the molecular level, compound 21 exerted anti-apoptotic effects (diminished myocardial infarction-induced Fas-ligand and caspase-3 expression in the peri-infarct zone) and anti-inflammatory effects (decreased serum monocyte chemoattractant protein-1 and myeloperoxidase as well as reduced cardiac interleukin-6, interleukin-1beta, and interleukin-2 expression). Finally, compound 21 treatment reduced phosphorylation of the ERK1/2 and p38 mitogen-activated protein kinases that are both involved in cell survival after myocardial infarction. Along with similar results from other groups, these data strongly suggest that AT2R agonists should be investigated for beneficial effects on systolic and diastolic function after myocardial infarction.

Since the AT1R and AT2R have opposite effects on vascular smooth muscle tone, and yet bind the same ligand, there are several possible explanations for a given experimental result. An interesting variation over this theme may exist, as spontaneous hypertensive rats may have lost the AT2R vasodilatory effect. In the heart, coronary constriction induced by Ang II, Ang III, and Ang-(1-7) is enhanced in spontaneous hypertensive rats as compared to Wistar rats that have normal blood pressure. The defect in the spontaneous hypertensive rats could be explained either by absence of counter-regulatory AT2R-mediated relaxation and/or by a change of the AT2R phenotype from relaxant to constrictor.

Caution is warranted in interpretation of the literature on AT2R effects on the cardiovascular system, since there have been conflicting reports concerning the in vivo effects of AT2R activation on cardiomyocyte apoptosis and hypertrophy. In some studies, the AT2R appears to be required for hypertrophic growth whereas in the work of others there are no effects on cardiac hypertrophy. Similar controversial findings have been reported in atherosclerosis with regard to AT2R effects on plaque morphology and neointima formation.

In an attempt to tease out the cardiovascular phenotype of the different Ang receptors, triple knockout mice lacking the AT1Ra, AT1b, and AT2R have been generated. As expected, ATR1 deletion alone reduced the heart rate and impaired the in vivo pressor response to an AngII bolus injection. In the triple knockout mice, AngII had no effect on blood pressure suggesting that there are no other AngII-sensitive receptors involved in blood pressure regulation (Gembardt et al. 2008).

Interestingly, the AT2R is expressed in human and rodent atherosclerotic lesions, and a series of papers suggest *an atheroprotective action* of these receptors. Chronic Ang-(1-7) administration inhibits the progression of atherosclerosis and improves endothelial function in a mouse model of atherosclerosis (apolipoprotein E-deficient (ApoE(-/-)) mice). These effects

were reversed with either AT2R or Mas receptor blockade. At the molecular level, Ang-(1-7) decreased superoxide production and increased endothelial nitric oxide synthase immunoreactivity, thus improving NO bioavailability as a result of activation of AT2R and/or Mas receptors (Tesanovic et al. 2010). In agreement with these data, AT2R overexpression decreases collagen accumulation in atherosclerotic plaques.

Increasing the complexity of the RAS system, *sex differences in blood pressure regulation* exists. In females, a low AngII dose decreased blood pressure while it had no effect in men. Surprisingly, a high dose increased mean blood pressure more in men than in women. This could be attributed to an enhancement of the AT2R vasodilatory effects in women as underlined by increased AT2R mRNA levels. These data are consistent with the notion that estrogen upregulates AT2R expression. In turn, this could contribute to the lower blood pressure during pregnancy. In this condition, an enhanced AT2R-mediated vascular relaxation pathway involving increased expression/activity of endothelial AT2Rs and increased postreceptor-activated phospho-eNOS have been reported.

Although controversial because of contradictory results, there is accumulation of evidence suggesting that *genetic polymorphisms in the AT2R gene* can modify disease risk in both cancer and cardiovascular diseases. This is an important field to follow in the future because better understanding of the response in different patients can lead to more individually tailored medicine. Several different genetic polymorphisms have been described, although these mutations do often not appear to influence AT2R function. However, one of these, A1675G in the AT2R gene possibly decreases cardiovascular risk and the severity of atherosclerosis by modifying systemic inflammation especially in hypertensive males (Tousoulis et al. 2010).

The AT2R Affects Cancer and Inhibits Inflammation

While the AT1R proinflammatory effects are rather well established, most current evidence suggests the AT2R instead interferes with and *inhibits proinflammatory pathways*, though the AT2R data in inflammation are still rather preliminary and somewhat controversial. However, the principal mechanisms of AT2R putative anti-inflammatory actions support new possibilities in AT2R research and potential utilization of AT2R stimulation as a novel pharmacological concept in anti-inflammation as reviewed in (Rompe et al. 2010). Expression of AT2R protein is generally upregulated in injury animal models such as experimentally induced stroke, myocardial infarction, and neointima lesions, and AT2R activation interferes with multiple inflammatory pathways. The agonist compound 21 inhibits key proinflammatory cytokines and nuclear factor kappaB. Compound 21 dose-dependently (1 nM–1 μM) reduces tumor necrosis factor-alpha-induced interleukin 6 levels in primary human and murine dermal fibroblasts. After myocardial infarction in the mouse, compound 21 also decreases serum MCP-1 and myeloperoxidase as well as cardiac interleukin expression (IL-6, IL-1beta, and IL-2).

In general, the AT2R has effects that theoretically could *play a role in cancer development* including anti-proliferative, anti-angiogenic, and pro-apoptotic effects. In fact, AT2R expression seems to be upregulated in different types of tumor tissues, including mammary, prostate, and pancreatic cancer. However, the literature contains conflicting reports about the AT2R effect in cancer, so at this stage, it is not entirely clear if blocking or stimulating the receptor would inhibit tumor development.

Regarding prostate cancer, several reports show that AT2R activation induces apoptosis of cancer cells. AT2R overexpression in prostate cancer cells using an adenoviral vector induced apoptosis even without addition of AngII, suggesting that AT2R is constitutively active in this situation. The cell death–signaling pathway was evidenced by increased terminal deoxynucleotidyl-transferase-mediated dUTP nick-end-labeling staining and was dependent on activation of p38 mitogen-activated protein kinase, caspase-8, caspase-3, and p53 activation. AT2R overexpression also induced inhibition of proliferation, a significant reduction of S-phase cells, and an enrichment of G1-phase cells indicating that AT2R is a promising novel target gene for prostate cancer therapy (Li et al. 2009). In other experiments using LL/2 and 3-MCA tumor cells, the AT2R induced the release of vascular endothelial growth factor (VEGF), a soluble pro-angiogenic factor. Blocking this effect revealed a significant decrease in angiogenesis after antagonist (PD123,319) treatment or in AT2R-KO mice suggesting AT2R inhibition would impair tumor development by blocking malignant cell proliferation and tumor angiogenesis (Clere et al. 2010).

These studies thus imply that the effect of AT2R could be different depending on the cancer type and biological setting.

Roles of AT2R in Kidney Disease and Diabetes

It has been appreciated for some time that the RAS acts as a local paracrine system in the kidney with presence of all the known molecular components including angiotensinogen, renin, AngI, angiotensin-converting enzymes, AngII, the AT1R, and the AT2R. Overall, the AT2R is perceived to increase renal blood flow (likely by increasing local NO production), inhibit growth, increase sodium excretion, as well as to participate in fibrosis and remodeling after renal injury. The natriuretic effect is also strongly stimulated by AngIII, further underscoring its role as an AT2R ligand. Interestingly, the AT2R is also important for normal renal development. Inhibition of the AT2R using PD123319 during pregnancy induces malformations in the developing rat kidney.

The AT2R kidney effects on blood pressure and natriuresis add further evidence in favor of using AT2R agonists as antihypertensive agents. However, when reviewing AT2R effects on kidney remodeling and fibrosis, conflicting data appears (Wenzel et al. 2010). One line of data points to a role for the receptor in nephroprotection. AT2R-knockout mice exhibit increased renal injury and mortality in chronic kidney disease suggesting that pharmacological stimulation of the AT2R may positively influence renal pathologies. Other data support the notion that the AT2 receptor mediates pro-inflammatory effects and promotes renal fibrosis and hypertrophy, and consequently blocking the receptor would be the choice of therapeutic intervention.

At the molecular level, the AT2R upregulates slit diaphragm-associated molecules such as nephrin, that is, a key molecule for preventing proteinuria. In a mouse model for proteinuria, AT2R activation improves kidney function by regulating the cell cycle and principal molecular components in the podocyte. Podocytes have important functions in sealing of the glomerular permeability barrier, and therefore the AT2R is considered an interesting pharmacologic target for preventing proteinuria (Kawachi et al. 2009).

One of the most interesting roles of Ang receptors is their involvement in diabetes. Diabetics have more cardiovascular and kidney disease than the background population, and the RAS is considered a highly important pathophysiological component in both diseases. Not only does blocking of the AT1R reduce the development and progression of diabetic nephropathy. This treatment also delays onset of diabetes as compared to other antihypertensive agents even though these reduce the blood pressure to the same extent as AT1R blockers. It has been shown that the beneficial effects on glomerular injury achieved with AT1R blockers are contributed to, not only by blockade of the AT1R, but also by increasing AngII effects mediated through the AT2R (Naito et al. 2010).

The big question is: What is the quantitative significance of AT2R in the establishment of diabetic vascular dysfunction? Although, we do not have the answer to this, it is at least known that the enhanced AT2R and iNOS-induced, NO-mediated vasodilation, impairs AngII-induced contraction in an endothelium-independent manner at the early stage of type 2 diabetes. It is also known that insulin activation of the phosphatidylinositol 3-kinase (PI3K) pathway stimulates glucose uptake in peripheral tissues and NO synthesis in the endothelium. Since AT2R activation increases NO availability in the endothelium, the AT2R activation would contribute to better glucose uptake and delay insulin resistance. Shared insulin and AT2R signaling pathways could underlie the beneficial AT2R effects in metabolic and hypertensive cardiovascular diseases.

Diabetic conditions increase expression of the AT2R in the proximal tubule with a beneficial effect in kidney function and blood pressure regulation. In the hyperglycemic kidney, the AT2R is suggested to regulate key signaling pathways including Akt-mTOR-p70(S6K)and VEGF signaling.

Another interesting mechanism is that the AT2R mediates AngII and high glucose induced decreases in renal prorenin/renin receptor expression, which would protect the kidney in diabetic conditions where increased AngII is harmful. Low renin levels controlled by the AT2R also play a role in nephroprotection in obese Zucker rats.

Gene polymorphisms in the AT2R additionally suggest a link to diabetes, as high RAS activity and the A-allele of the AT2R G1675A polymorphism associate with high risk of severe hypoglycemia in type 1 diabetes. A potential preventive effect of RAS-blocking drugs in patients with recurrent severe hypoglycemia could be interesting to examine (Pedersen-Bjergaard et al. 2008).

Summary

The investigation of AT2R signal transduction and biological effects has increased considerably after the advent of specific, high affinity, and non-peptide AT2R agonists and antagonists that can now be used as tools to identify AT2R-specific effects in the scenario of multiple different Ang receptors. It has become clear that this receptor does not activate classical heterotrimeric G proteins, but rather signals through a series of small G proteins, kinases, phosphatases, and scaffolding molecules that mostly bind to the receptor COOH-terminal. A novel family of scaffolding proteins including ATIP that are especially attached to the AT2R have been identified. These events have lead to increased interest in the AT2R signaling and biology and especially in its putative pathophysiological roles. A long line of recent evidence suggests that pharmacological manipulation of AT2R activity could be clinically applicable in a wide range of diseases especially in hypertension, myocardial infarction, stroke, and diabetes. It has also become clear that the canonical notion that the AT2R antagonizes the effects of the AT1R probably is an oversimplification. Especially since the AT2R also possesses high affinity for Ang-(1-7) and AngIII that do not activate the AT1R. Nevertheless, many of the AT2R effects are counterbalanced by AT1R activation. Solid experimental evidence has demonstrated that AT2R elicits vasodilatation through NO release, and has anti-inflammatory and anti-proliferative effects, and lastly regulates apoptosis in many cell systems. A lot of interest centered on possible shared signaling pathways between insulin and AT2R signaling suggests that AT2R agonist could have beneficial and synergistic effects both in metabolic and cardiovascular disease by a dual mechanism of action including vasodilatation and NO metabolism.

However, effects still remain that we need to understand in more detail including clarification of contradictory results such as the dual roles of AT2R to both inhibit and enhance inflammation, fibrosis, and apoptosis, and we have only begun to investigate the AT2R's role in malignant cells. Furthermore, it will be interesting to follow clinical trials of AT2R agonists and get a preliminary picture of the benefits these drugs may play in future medicine, especially, since we do not yet know which unwanted side effects might turn up.

Adenine nucleotide translocase; ADP/ATP carrier

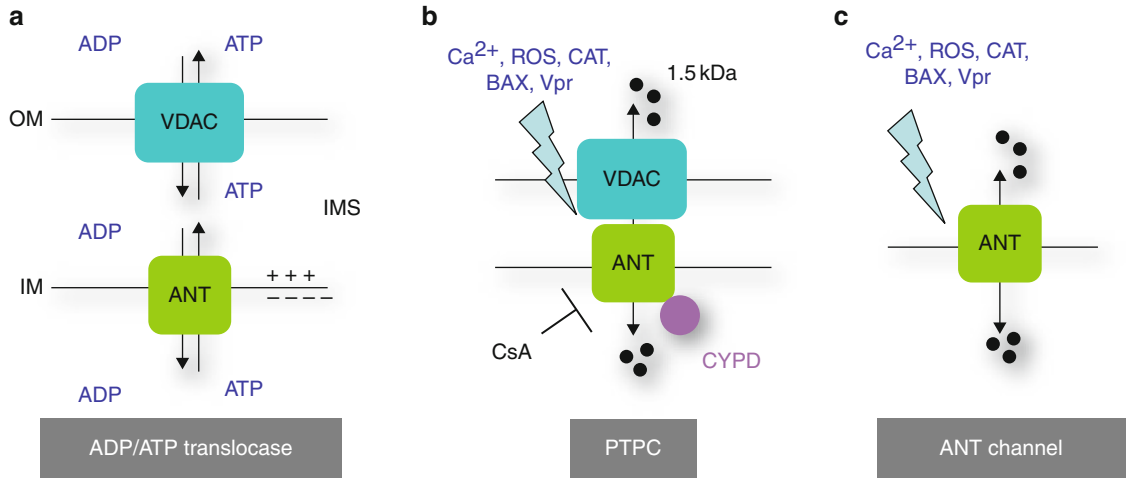
Historical Background

The adenine nucleotide translocase (ANT) belongs to the evolutionarily conserved family of mitochondrial carriers (for a recent review see Palmieri et al. 2010). ANT constitutes one of the most abundant proteins of the mitochondrial inner membrane (IM), in which it is inserted via six transmembrane helices. Both the C- and N-termini of ANT face the mitochondrial matrix. ANT was first characterized as an antiporter that mediates the export of ATP from the mitochondrial matrix to the intermembrane space together with the import of ADP from the intermembrane space to the matrix (Pfaff et al. 1968) (Fig. 1a). This antiporter activity is electrogenic, as it drives the stoichiometric exchange of ATP^{4-} and ADP^{3-}. ANT may also act as a nonselective IM channel, playing a critical role in the permeabilization of mitochondrial membranes that accompanies apoptosis and programmed necrosis (Rück et al. 1998; Brustovetzki et al. 1996; Marzo et al. 1998) (Fig. 1b and c).

Recently, the 3D crystallization of the bovine heart ANT monomer with carboxyatractyloside (CAT) established a structural organization based on a threefold repeat of about 100 amino acids, 6 transmembrane helices with a depression at the intermembrane space surface, and a short mitochondrial carrier sequence (RRRMMM) at the bottom. Each ANT monomer has turned out to associate with several cardiolipin molecules, correlating with functional studies indicating that ANT activity depends on this IM-specific lipid. CAT binding excluded that of adenosine nucleotides (i.e., ADP and ATP), suggesting that the residues of ANT that are involved in the nucleotide binding site are also important for the physical association with CAT. A close-open conformation switch has been suggested to facilitate ADP/ATP antiport and to result from the cooperative binding of the nucleotides. However, the exact molecular and enzymatic mechanisms that account for ADP/ATP exchange by ANT remain elusive.

A Vital Mitochondrial ADP/ATP Carrier

The enzymatic function of ANT as an ADP/ATP exchanger has been first characterized in isolated mitochondria from rodent livers, in yeast, and in native ANT-containing proteoliposomes. These studies have benefited from two specific inhibitors, namely,



ANT, Fig. 1 *Two functions for one protein.* (**a**) ANT is an ADP/ATP translocase inserted in the mitochondrial inner membrane (IM), where it exchanges ATP and ADP between the mitochondrial intermembrane space (IMS) and the mitochondrial matrix. The ADP/ATP exchange rate is dependent on the mitochondrial membrane potential ($\Delta\psi_m$), whose polarity across the IM is indicated with (−) and (+). Moreover, in response to specific stimuli, ANT can function as a nonspecific channel (for molecules with a molecular weight <1.5 kDa), either in association with the voltage-dependent anion channel (VDAC) and cyclophilin D (CYPD) within a multiprotein complex known as permeability transition pore complex (PTPC) (**b**) or on its own (**c**). Calcium (Ca^{2+}), reactive oxygen species (ROS), proteins and peptides (e.g., the pro-apoptotic BCL-2 family member BAX; Vpr, which is encoded by the human immunodeficiency virus 1, HIV-1), as well as small molecules (e.g., carboxyatractyloside, CAT) can all stimulate the pore function of ANT, which in turn can induce mitochondrial membrane permeabilization and hence cell death. Cyclosporine A (CsA) prevents the binding of CYPD to ANT, thereby functioning as a PTPC inhibitor. OM, mitochondrial outer membrane

CAT and bongkrekic acid (BA), which bind different sites within the protein and favor the c- and m-conformation of the protein, respectively (Klingenberg 2008). The efficacy of ANT in exchanging ADP with ATP is moderate, and the relatively high abundance of the carrier at the IM might reflect an adaptation to the high intracellular demand for mitochondrial ATP export (Klingenberg 2008). It is still unclear whether *in cellula* ANT can function independently, as a monomer and/or an homodimer, or whether (at least in some tissues) it requires the physical binding of a partner such as the voltage-dependent anion channel (VDAC), cyclophilin D (CYPD), the mitochondrial phosphate carrier protein (SLC25A3, also known as PIC), the F_OF_1-ATP synthase, and/or the mitochondrial creatine kinase (MTCK1). An association with such mitochondrial proteins might improve the channeling of ATP to hexokinase and of ADP to the F_OF_1-ATP synthase in response to increased ATP demands, and might be particularly relevant for the metabolic adaptation of mitochondria in cancer cells.

The enzymatic characterization of ANT can be carried out with radiolabeled nucleotides. Briefly, isolated mitochondria are loaded with tritiated ATP ([^{3}H]ATP) in a suitable energizing buffer, allowing for oxidative phosphorylation and for the maintenance of a mitochondrial transmembrane potential ($\Delta\psi_m$). Upon the elimination of extramitochondrial nucleotides, ADP/ATP exchange is initiated by addition of exogenous ADP. Then, the import reaction is blocked by CAT, mitochondria are centrifuged, separated from their supernatant, and the exported radioactive ATP is quantified. This methodology has been successfully used to estimate the V_{max} and K_m of ANT from various origins (Pfaff et al. 1968). Alternatively, the addition of an extramitochondrial ATP detection system (containing $NADP^+$, hexokinase, glucose-6-phosphate dehydrogenase, and glucose) to mitochondria suspended in energizing buffer avoids the use of radioactivity and is suitable for the high-throughput screening of molecules that affect ANT antiporter activity (Belzacq-Casagrande et al. 2009).

A Lethal Channel

In response to a number of stimuli, ANT can be converted into a poorly selective cation channel

(Fig. 1b and c). Single-channel current measurements in giant bovine ANT proteoliposomes revealed the reversible opening of a Ca^{2+}-dependent channel (Brustovetsky and Klingenberg 1996). This might be caused by the binding of Ca^{2+} to cardiolipin, a mitochondrial IM lipid that is tightly bound to ANT, in turn triggering a conformational change that results in pore opening. The ANT channel has also been studied upon purification from rat heart, reconstitution of ANT-containing proteoliposomes, and measurement of the release of a fluorescent probe (Rück et al. 1998; Marzo et al. 1998). Several classes of natural or synthetic molecules have been shown to activate or inhibit the channel function of ANT, suggesting that ANT can constitute a pharmacological target (Halestrap and Brenner 2003). In support of this hypothesis, inhibition of ANT by Nelfinavir, a small molecule used in antiretroviral therapy, has been shown to inhibit pathological manifestations linked to massive cell death in mice undergoing septic shock, cerebral ischemia-reperfusion, and fulminant hepatitis (Weaver et al. 2005). Thus, ANT might be targeted to repress cell death signaling in vivo.

Due to similarities in channel conductance and sensitivity to pharmacological inhibitors, ANT has been proposed to constitute the IM channel of the permeability transition pore complex (PTPC), a multiprotein structure assembled at the interface between mitochondrial membranes that is involved in both mitochondrial homeostasis and cell death (Fig. 1b). Of note, despite striking structural similarities, not all ANT isoforms support the formation of the PTPC.

Four ANT Isoforms

The human ANT gene family is composed of four homologues, *ANT1* to *ANT*4. Primary sequence homology ranges from 68% to 88% (Dolce et al. 2005). The expression of distinct ANT isoforms is highly regulated and exhibits tissue specificity, suggesting a differential role for each isoform. Accordingly, the promoter region of *ANT* genes contains elements that can be bound by multiple transcription factors including (though presumably not limited to) members of the OXBOX-REBOX family, GRBOX, SP1, and AP2. ANT1 is mainly expressed in nonproliferating tissues, including skeletal muscle and brain. In contrast, ANT2 is upregulated during growth, and ANT2 constitutes the prevalent ANT isoform that is expressed in hepatocytes, fibroblasts, and lymphocytes. The ANT3 gene is transcribed ubiquitously at a comparatively lower level. In humans, ANT4 can be detected mainly in liver, testis, and brain. In mice, ANT4 is exclusively expressed in embryonic stem cells (Dolce et al. 2005). The genetic invalidation of *Ant1* and *Ant2* in the mouse liver renders mitochondria insensitive to ANT ligands (e.g., CAT). Moreover, the *Ant1*/*Ant2* double knockout enhances the capacity of mitochondria to accumulate Ca^{2+} ions, decreases the probability of PTPC opening, and yet does not compromise cell death, suggesting that ANT1 and 2 are dispensable for apoptosis or that other proteins (e.g., ANT4, other members of the mitochondrial carrier protein family) may substitute for the lethal functions of ANT1 and 2 in their absence. However, genetic strategies to modulate the expression levels of various ANT isoforms in human cancer cell lines revealed that ANT1 and 3 overexpression favors apoptosis (Bauer et al. 1999), whereas increased levels of ANT2 and 4 augment the resistance of cancer cells against death induction (Le Bras et al. 2006; Gallerne et al. 2010).

ANT1 in Cardiopathy

ANT1 has been associated with several cardiac diseases (Dörner and Schultheiss 2007). In particular, five-point mutations of *ANT1* have been identified in patients with autosomal dominant progressive external ophthalmoplegia (adPEO), an adult-onset pathology characterized by weakening of external eye muscles, generalized myopathy, exercise intolerance, and multiorgan disorders including cardiomyopathy. Muscle biopsies of individuals affected by adPEO revealed common intracellular features, including deficient oxidative phosphorylation, scattered ragged red fibers, and multiple mitochondrial DNA deletions. When introduced in yeast, these mutations decrease oxidative growth and lead to diminished ADP/ATP exchange.

Cardiac ischemia/reperfusion and alteration of the myocardium have also been associated with reduced ANT function. It has been speculated that oxidative stress and/or alterations of the lipid metabolism can negatively affect ANT activity, inhibit energy supplies and, therefore, favor PTPC opening and apoptosis.

Surprisingly, transgenic mice that overexpress ANT1 in the heart are protected from cardiac

insufficiency and diabetic cardiomyopathy, correlating with improved mitochondrial ANT functionality and oxidative phosphorylation. In contrast to in vitro studies, no signs of enhanced apoptosis were detected in ANT-transgenic animals. In addition, these animals showed features of athlete's hearts, including enlarged end-diastolic and end-systolic volumes and raised heart rate with unchanged ejection fraction, but no signs of abnormal dilatation.

ANT2 in Cancer

According to the Expressed Sequence Tags database (EST, Unigene), cancer patients often show the deregulated expression of ANT isoforms. In particular, the ANT2 isoform is overexpressed in biopsies from distinct types of cancers as well as in several human tumor cell lines. Changes in the expression levels of ANT2 neither have major effects on cell metabolism and morphology nor negatively affect cell viability or proliferation, suggesting compensatory effects from other ANT isoforms (Le Bras et al. 2006). However, ANT2 overexpression decreases the sensitivity of cancer to some pro-apoptotic stimuli. Accordingly, ANT2 silencing by RNA interference (RNAi) induced apoptosis in breast cancer cells in vitro and tumor regression in mice. Overexpression of ANT4 also protects cancer cells from apoptosis (Gallerne, et al. 2010), but the anti-apoptotic potential of ANT4 in vivo awaits confirmation.

Summary

Mitochondria, which are the cell's powerhouse but also centralize lethal pathways, constitute a crossroad among numerous intracellular signaling pathways. Mitochondrial dysfunction is frequently associated to severe human diseases, including cancer and cardiomyopathies. Some of these pathologies are closely linked to the deregulation of apoptosis as well as that of energy metabolism. The adenine nucleotide translocase (ANT), which possesses two opposite functions (as a vital ADP/ATP antiporter and as a lethal channel), appears to occupy a central position in controlling cell fate. It is now clearly established that both ANT functions can be modulated by pharmacological agents. However, a more detailed knowledge of the specific pathophysiological role of each isoform is required to validate ANT as a potential therapeutic target.

Historical Background

The cytoplasm of all eukaryotic cells is organized into a complex set of membrane-bound organelles with defined protein and lipid composition. Proteins and lipids of the endocytic and exocytic pathways are transported between these compartments by small vesicles and tubules which pinch off from one compartment and fuse with another and so deliver their contents. The budding of vesicles and tubules from membranes is driven by the recruitment of coat protein complexes from the cytoplasm. Coat complexes have two main functions in this process: First, they select cargo proteins to be packaged into the vesicle, and second, they recruit accessory proteins that help deform the membrane into a bud and bind machinery required for vesicle fission.

In mammalian cells, there are five related adaptor protein (AP) complexes (AP-1 through 5) (Hirst et al. 2011). Each complex is localized to a specific post-Golgi compartment and is required for the transport of a defined set of cargo molecules (Fig. 1 and Table 3). The AP-1 complex is localized to the trans-Golgi network and tubular endosomes and plays a role in the trafficking of proteins between these compartments such as the mannose 6-phosphate receptors and the R-SNARE, VAMP4. The AP-2 adaptor complex is localized to the plasma membrane and is required for the internalization of cell surface receptors such as the transferrin receptor and the low-density lipoprotein receptor. The AP-3 complex is localized to tubular endosomes and is required for the trafficking of lysosomal proteins such as LAMPI and LIMPII. The ▶ AP-4 complex is localized to the TGN and endosomes and is involved in the trafficking of the amyloid precursor protein. The AP-5 complex is localized to late endosomes. However, what cargo proteins it traffics is not known.

Adaptor protein complexes are heterotetramers consisting of a related set of subunits. The AP-1 complex consists of γ, β1, μ1, and σ1; AP-2 of α, β2, μ2, and σ2; AP-3 of δ, β3, μ3, and σ3; AP-4 of ε, β4, μ4, and σ4; and AP-5 of ζ, β5, μ5, and σ5. Each subunit within the adaptor complex plays a specific role in the process of vesicle budding, for example, the μ subunits bind cargo proteins; the β subunits bind clathrin in the case of β1-3, the structural component of the vesicle required for membrane deformation; and the α/γ type subunits bind accessory proteins that regulate the process.

The first AP complexes to be characterized were AP-1 and AP-2 as they are major components of clathrin-coated vesicles. The next AP complex to be identified was AP-3. The first subunits of the AP-3 complex were isolated by expression cloning in the early 1990s and the subsequent subunits of the complex were identified through their sequence homology to subunits of the AP-1 and AP-2 complexes, reviewed in (Odorizzi et al. 1998).

The first insights into the function of the AP-3 complex came through the discovery that *garnet* fruit flies are missing the δ subunit of the AP-3 complex. *Garnet* flies have reduced pigmentation in their eyes suggesting that the AP-3 complex is involved in the biogenesis of pigment granules, which are a lysosome-related organelle. In support of this hypothesis it was then discovered that the mouse coat color mutants *mocha* and *pearl* have disruption in the β3A and δ subunits respectively, and that people with Hermansky–Pudlak syndrome type 2 are missing the β3A subunit, reviewed in (Odorizzi et al. 1998; Badolato and Parolini 2007). People with HPS type 2 have reduced pigmentation (skin, hair, and eyes), defects in blood clotting, and susceptibility to recurrent infections. The majority of these phenotypes can be explained by defects in melanocytes, platelet dense granules, and lytic granules which are lysosome-related organelles (Badolato and Parolini 2007). In addition to defects in specalized compartments there is also increased trafficking of lysosomal integral membrane proteins over the cell surface in cells isolated from mice or patients lacking functional AP-3 complexes (Table 3) (Dell'Angelica et al. 1999).

This entry will primarily focus on outlining what is currently known regarding the function and regulation of the mammalian AP-3 complex in generic cell types. For detailed reviews regarding the biology of the AP-3 complex in non-vertebrate systems and in specalized cell types such as melanosomes and neurons, see (Raposo and Marks 2007; Dell'Angelica 2009; Danglot and Galli 2007).

AP-3 Complex Subunit Composition, Expression, and Function

The AP-3 complex is a heterotetramer of approximately 320 kDa. The complex consists of two large subunits δ (130 kDa), β3 (120 kDa), a medium subunit μ3 (47 kDa), and a small subunit σ3 (21 kDa) (see Table 1 and Fig. 2) (Simpson et al. 1997). Once the individual subunits of the AP complexes are synthesized they assemble very rapidly into a complex so the levels of individual subunits in the cytoplasm are negligible under normal conditions. Deletion or disruption of either of the large subunits leads to disassembly and degradation of the other subunits of the complex.

Tissue-Specific Expression

There are two isoforms of the β3, μ3, and σ3 subunits. All tissues express δ, β3A, μ3A, σ3A, and σ3B, and neuronal and pancreatic tissues express β3B and μ3B in addition (see Table 1). It has been proposed that there are ubiquitous (δ, β3A, μ3A, σ3A/B) and neuronal (δ, β3B, μ3B, σ3A/B) forms of the AP-3 complex. This hypothesis is partially supported by phenotypic analysis of mice either lacking both complexes (*mocha* mice) or just the neuronal (μ3B) complex, reviewed in Danglot and Galli (2007).

Large Subunits

The large subunits (also known as adaptins) of the AP-3 complex have three domains: a folded trunk domain of approximately 70 kDa, a flexible linker domain of around 20 kDa, and a folded appendage domain of 30 kDa (Fig. 2). The trunk domains of δ and β3 consist of α solenoid fold and interact with the σ3 and μ3 subunits respectively. The trunk domain of the δ subunit may also be involved in membrane binding as the comparable region on the α subunit of AP-2 binds phosphatidylinositol 4,5-bisphosphate (PIP_2) (Jackson et al. 2010).

Very little is known about the appendage domains of β3 and δ adaptin. Based on homology they are predicted to have a bi-lobal structure. The appendage domains of α (AP-2) and γ (AP-1) adaptin bind accessory proteins that regulate vesicle budding and fission. At present no appendage domain binding proteins have been identified for AP-3. However, it is likely that they exist because AP-3 complexes lacking the β3 appendage domain are unable to traffic lysosomal proteins efficiently, and *mocha*^{2J} mice that lack the δ appendage domain have a coat color phenotype. Interestingly, the δ ear does not have the conserved platform required for binding accessory proteins found on the α subunit indicating that the δ subunit must bind accessory proteins in an alternate manner.

AP-3, Table 1 AP-3 complex subunits

Subunit name	Official NCBI symbol	Gene ID	Splice isoforms (aa)	Expression	Function within complex
δ	AP3D1	8943	2 (1153 and 1112aa)	Ubiquitous	Binding membranes and accessory proteins?
β3A	AP3B1	8546	1 (1094aa)	Ubiquitous	Binding accessory proteins
β3B	AP3B2	8120	1 (1101aa)	Neuronal and pancreatic tissue	Binding accessory proteins
μ3A	AP3M1	26985	2 (418)	Ubiquitous	Binding cargo, Yxx∅
μ3B	AP3M2	10947	2 (418)	Neuronal and pancreatic tissue	Binding cargo, Yxx∅
σ3A	AP3S1	1176	1 (193aa)	Ubiquitous	Binding cargo, [D/E]xxxL[L/I]
σ3B	AP3S2	10239	1 (193aa)	Ubiquitous	Binding cargo, [D/E]xxxL[L/I]

AP-3, Fig. 2 *Schematic of the AP-3 adaptor complex*. Structure of the AP-3 complex based on its homology to the AP-2 adaptor complex. Diagram shows subunit interactions and functional domains

Medium Subunits

The main function of the μ3 subunit is to bind cargo molecules that contain tyrosine-based sorting signals (see section "AP-3 Cargo Proteins" and Table 2) (Ohno et al. 1998). The μ3 subunit is predicted to have two folded domains connected via a short linker. The N-terminal domain has a longin type fold and interacts with the other subunits of the complex, and the C-terminal domain binds cargo molecules (see section "AP-3 Cargo Proteins"). μ3A and B have been shown to bind similar cargo molecules using yeast two-hybrid analysis.

Small Subunits

The main known function of the σ3 subunit is to bind cargo molecules that contain dileucine type motifs (see section "AP-3 Cargo Proteins" and Table 2) (Janvier et al. 2003). The σ3 subunits are predicted to be globular and have a longin type fold. Based on the structure of the σ2–dileucine interaction is predicted that σ3 binds dileucine signals using a conserved hydrophobic pocket on its surface (Jackson et al. 2010). σ3A and B are both ubiquitously expressed and at present it is unclear why there are two isoforms. It is possible that having both isoforms may increase the repertoire of cargo molecules the AP-3 complex can bind, or there may be as yet unidentified interacting partners. In addition to binding cargo molecules, σ3A/B have also been shown to be capable of interacting with the appendage domain of the δ subunit, and this interaction may regulate AP-3 recruitment onto membranes (see section "Regulation of the AP-3 Complex").

AP-3 Complex Interacting Proteins

Over the past 15 years, many approaches have been used to identify AP-3 complex interacting partners. These include yeast two-hybrid screens, proteomic studies on immuno-isolated AP-3 complexes, vesicles, and AP-3-coated liposomes. Thus, the number of proposed AP-3 interacting proteins has increased steadily. However, the numbers are relatively low compared to the AP-1 and 2 complexes suggesting that there are more to be discovered. It must be noted that for many of the AP-3 interacting partners it is still not known what domains and/or subunits of the AP-3 complex are involved in mediating the interaction. In the following section, I have outlined some of the known AP-3 interacting proteins. This list is not exhaustive but focuses only on the interacting partners who have had their binding to AP-3 mapped.

AP-3, Table 2 AP-3 interacting proteins

Interacting protein	Interaction motif/domain on binding protein	Interaction domain on AP-3	Method used to show interaction
Clathrin	β-propeller of clathrin's N-terminal domain	Flexible linker domains of β3A (LLDLD) and β3B (LLDLE)	Biochemical "pull down"
ARF1	Switch 1 and switch 2	δ/σ3 subcomplex	Yeast two-hybrid and co-IP
KIF3A	C-terminus (601–702)	β3A hinge (676–902)	Yeast two-hybrid and biochemical pull down
AGAP1	PH domain	δ/σ3 subcomplex	Yeast two-hybrid
BLOC-1 (Dysbindin subunit)	Dysbindin	μ3 or β3B?	Biochemical "pull downs"

A representative list of mammalian AP-3 interacting proteins which have had their binding site mapped

Clathrin

The AP-3 complex has been shown to bind clathrin in vitro and partially colocalize with clathrin in vivo. The β3A/B subunits have a clathrin-binding motif called a clathrin box (L∅x∅[D/E]), where ∅ is a bulky hydrophobic residue and x is any residue (Dell'Angelica et al. 1998). Mutation of this motif abolishes AP-3's interaction with clathrin. Surprisingly, AP-3 is not enriched in purified clathrin-coated vesicles and does not require clathrin to function. Mutation of the clathrin-binding box in AP-3 does not drastically affect lysosomal protein trafficking, and depletion of clathrin from an AP-3 based in vitro budding assay did not inhibit AP-3 budding. Furthermore, a significant fraction of AP-3 positive vesicles and tubules do not label for clathrin. Thus, the role of clathrin in AP-3 function still remains uncertain. Not all adaptor complexes require clathrin to function. For example, AP-4 and AP-5 do not contain clathrin-binding boxes and do not colocalize with clathrin in vivo and yeast AP-3 does not require clathrin for function. At present it is unclear why certain AP complexes require clathrin as a structural scaffold to help generate a vesicle and others do not. It is possible that other proteins may be performing the same function as clathrin. In yeast, it has been proposed that Vps41 may be playing this role for AP-3, and for AP-5 SPG11 may be performing this function.

ARF1 and AGAP1

ARF1 is required for AP-3 recruitment to membranes. The binding domain of ARF1 has been mapped to the trunk domain of the δ/σ3 subcomplex. This interaction has been shown to be modulated by the interaction of the δ-appendage domain with the C-terminal domain of the σ3 subunit (Lefrancois et al. 2004). The ARF1 GAP, AGAP1 also binds to AP-3 (Nie et al. 2003) (see section "Regulation of the AP-3 Complex").

KIF3A

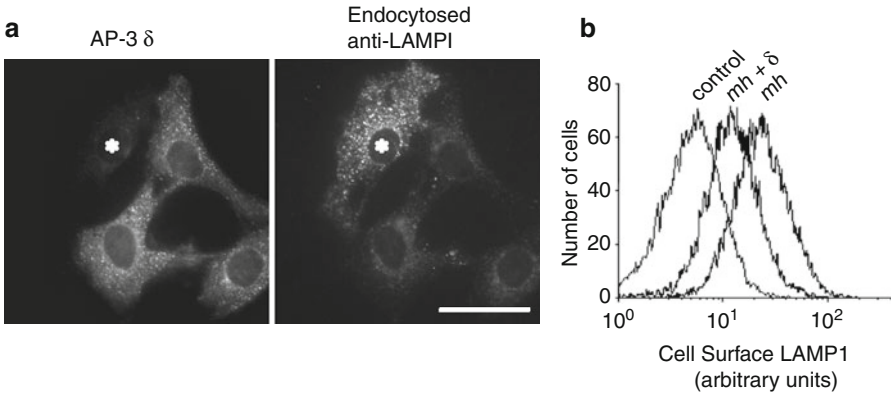
The motor protein KIF3A has been shown to bind to the hinge region of β3A and disruption of this interaction causes a defect in HIV budding (Azevedo et al. 2009). KIF3A is a component of the plus end directed motor Kinesin-2. Kinesin-2 has been shown to play a role in the transport of endosome-derived vesicles.

BLOC-1 Complex

The AP-3 complex interacts with biogenesis of lysosome-related organelles complex-1 (BLOC-1) (Di Pietro et al. 2006). BLOC-1 consists of 8 known subunits: pallidin, cappuccino, muted, snapin, dysbindin, BLOS1, BLOS2, and BLOS3. Disruption of BLOC-1 function leads to defects in the biogenesis of lysosome-related organelles and increased cell surface trafficking of lysosomal proteins. The molecular function of this complex is still unknown. It is likely that the interaction between BLOC-1 and AP-3 occurs through the dysbindin subunit of the complex. However, it remains unclear which subunit or subunits of the AP-3 complex mediate this interaction as μ3 and β3 have both been proposed to bind dysbindin.

AP-3 Cargo Proteins

One of the main functions of an AP complex is to select cargo molecules into forming vesicle (Bonifacino and



AP-3, Fig. 3 *Loss of AP-3 causes increased trafficking of lysosomal proteins over the cell surface*. (**a**) *Mocha* fibroblasts were transfected with the δ subunit of the AP-3 complex and allowed to internalize antibodies to the lysosomal protein LAMPI for 30 min at 37°C. The cells were fixed and stained for δ adaptin and LAMPI. Scale bar 30 μm. *Asterisk marks* cell not expressing δ adaptin. (**b**) *Mocha* (*mh*) fibroblasts were transfected with the δ subunit of the AP-3 complex and the cell surface levels of LAMPI determined using flow cytometry

Traub 2003). Loss of AP-3 complex function leads to increased cell surface trafficking of lysosomal proteins as well as defects in the targeting of certain cargoes to lysosome and lysosome-related organelles (Fig. 3). The AP-3 complex, like the other well-characterized adaptor complexes (AP-1/2), is capable of binding two types of linear motifs found in the cytoplasmic tails of cargo molecules. Studies using yeast two-hybrid assays have shown that the C-terminal domain of the μ3 subunit binds tyrosine-based motifs Yxx∅ (where ∅ is a bulk hydrophobic residue and x is variable but tends to be hydrophilic in nature) (Ohno et al. 1998). Studies using yeast three-hybrid assays have shown that di-leucine-based motifs [D/E]xxxL[L/I] (where x is any residue) bind a hemi-complex formed from the δ/σ3 subunits (Janvier et al. 2003). The binding affinities of both types of motifs for AP complexes are relatively weak and in the μM KD range.

The AP-3 complex can also bind cargo that does not contain either tyrosine or di-leucine-based motifs. For example, the endosomal R-SNARE ▶ VAMP7 and the HIV-GAG protein have shown to interact with the hinge domain of the δ subunit of the complex, and disruption of this interaction alters the trafficking of both proteins. For a detailed list of proposed AP-3 cargo proteins, see Table 3. It must be stated that for many of these proteins it has still to be confirmed whether there is a direct interaction between these proteins and the AP-3 complex. Thus, it is possible that changes observed in their trafficking in AP-3-deficient cells may be indirect.

Regulation of the AP-3 Complex

For AP complexes to function they must continually cycle on and off membranes. This cycle is regulated through a combination of weak μM–KD interactions involving small GTPases, lipids, and cargo proteins. This cycle has been best elucidated for the AP-2 complex (Jackson et al. 2010). The AP-2 complex is initially recruited onto membranes via its interaction with PIP_2. This interaction leads to a conformational switch in the complex that allows the μ2 and σ2 subunits to bind cargo proteins thereby increasing the affinity/avidity of the interaction. In addition to the conformational switch there is also further regulation where the linker domain of the μ2 subunit is phosphorylated, which greatly increases the affinity of the μ2 subunit for binding of cargo molecules. At present very little is known about the regulation of the AP-3 complex. However, it is clear that ARF1 plays a major role in this process.

ARF1, GEFs, and GAPs

The main GTPase-regulating AP-3 membrane association is ARF1 (Table 2). ARF1 is a small GTPase that cycles between an active GTP and an inactive GDP form. In the active form, ARF1 recruits AP-3 onto membranes. Disruption of the GTP cycle using the fungal metabolite Brefeldin A causes ARF1 to accumulate in the GDP locked form and causes AP-3 to dissociate from membranes. Yeast two-hybrid mapping experiments have indicated that ARF1 binds to

AP-3, Table 3 AP-3 cargo proteins

Proposed AP-3 cargo	Interaction motif on cargo	Interaction domain on AP-3	Method used to show interaction	Observed phenotype of cargo protein when interaction with AP-3 is perturbed
LAMPI	GYQTI	μ3	Biocore and yeast two-hybrid	Increased cell surface trafficking in the absence of AP-3
LAMPII	GYEQF	μ3*		Increased cell surface trafficking in the absence of AP-3
LIMPII	ERAPLI	δ/σ3	Biocore and yeast two-hybrid	Increased cell surface trafficking in the absence of AP-3
CD63	GYEVM	μ3	Yeast two-hybrid	Increased cell surface trafficking in the absence of AP-3
CD164/Endolyn	NYHTL	μ3	Yeast two-hybrid	Increased cell surface trafficking in the absence of AP-3
Tyrosinase	EERQPLL	δ/σ3	Biocore, yeast two-hybrid, and biochemical pull down	Altered trafficking in AP-3-deficient melanocytes
ZnT3	C-terminus	?	co-IP	Significant changes in localization and levels in mocha brains
Battenin/CLN3	EEEAESAARQPLI	δ/σ3*	Biochemical pull down	Altered trafficking in mocha and pearl fibroblasts
OCA2	ENTPLL	δ/σ3	Yeast two-hybrid and biochemical pull down	Altered trafficking of transiently expressed OCA2 that can no longer interact with AP-3
HIV-GAG	Matrix fragment	δ-hinge domain	Yeast two-hybrid and biochemical pull down	Altered trafficking to multivesicular bodies when interaction with AP-3 is perturbed
CD1b	SYGNI	μ3	Biocore and yeast two-hybrid	Increased cell surface trafficking and loss of lysosomal localization in the absence of AP-3
VAMP7	VAMP7 longin domain	δ-hinge domain	Yeast two-hybrid and co-IP	Altered trafficking in AP-3-deficient fibroblasts
PI4KIIa	ERQPLL	δ/σ3*	Biochemical pull down and co-IP	Altered trafficking in mocha fibroblasts and changes in distribution in mocha brains
Elastase	YPDA	μ3	Yeast two-hybrid	Altered trafficking/expression in AP-3-deficient neutrophils
High-affinity choline transporter/CHT	?	?		Significant changes in localization and levels in mocha brains
CB_1 cannabinoid receptor	?	?	co-IP	Change in cellular distribution when AP-3 depleted

IP immunoprecipitation
*Based on the motif found in the cargo protein it is likely to interact with the indicated subunits of the AP-3 complex. However, this has not been formally shown for this cargo

the trunk domain of the δ/σ3 hemicomplex. Further mapping indicated that the C-terminal domain of the σ3 subunit is also important for this interaction (Lefrancois et al. 2004). Interestingly, this C-terminal domain has also been shown to bind the δ appendage domain using three-hybrid mapping and so potentially provides a mechanism for regulating membrane binding. In support of this hypothesis, overexpression

of the appendage domain of δ adaptin caused AP-3 to become cytosolic and increase the trafficking of lysosomal membrane proteins over the plasma membrane.

The activity of ARF1 is regulated by GTP exchange factors and GTPase-activating proteins. It has been shown that ARF1 GEF BIG1 is recruited on to synthetic liposomes enriched in AP-3 and that depletion of BIG1 using siRNA causes the loss of AP-3 from membranes and an increase in the trafficking of lysosomal membrane proteins over the cell surface. The ARF1 GAP, AGAP1 has been shown to bind to AP-3 using the yeast three-hybrid assay (see Table 2). Overexpression of AGAP1 causes AP-3 to dissociate from membranes, and depletion of AGAP1 by siRNA makes AP-3 Brefeldin A insensitive (Nie et al. 2003). In addition, the GAP ARAP1 binds liposomes enriched in AP-3 complexes, and its depletion affects AP-3 binding to membranes (Baust et al. 2008). However, it is not known if ARAP1 directly interacts with AP-3.

PIP Binding

As mentioned earlier it has been shown that AP-2 recruitment to membranes is regulated by PIP_2 binding. The binding site on the trunk domain of the α subunit of AP-2 has been mapped and it is clear that the δ trunk domain of AP-3 also has a basic patch, although not as basic. However, it is not known whether phosphoinositides bind this patch. A good candidate is phosphatidylinositol 3-phosphate (PI3P) as studies using synthetic liposomes have shown that AP-3 preferentially binds to membrane enriched in PI3P. In addition, depletion of the enzyme PI-3KIIIC3, which generates PI3P, affects the recruitment of AP-3 to membranes and increases the trafficking of LAMPI over the plasma membrane (Baust et al. 2008). However, PI3P may not be the only lipid involved in AP-3 recruitment as PI-4KIIα is enriched in AP-3-derived vesicles and it can directly bind AP-3 via its dileucine motif (Craige et al. 2008). Depletion of PI-4KIIα blocks the recruitment of AP-3 to membranes, and like the loss of PI-3KIIIC3 also causes a LAMP1 trafficking defect. At present it is not known whether the binding of AP-3 to phosphoinositides might cause a conformational switch in the complex which allows it to bind cargo. In the case of AP-1, it is thought that this switch may be primarily regulated by the binding of ARF1 and not phosphoinositides.

Phosphorylation

The only subunits of the AP-3 complex to be significantly phosphorylated are β3A and β3B (Faundez and Kelly 2000). These subunits are phosphorylated on serine residues present in acidic patches in their flexible linker regions. In β3A approximately 31% of the hinge residues are acidic and a further 26% are serine residues. The linker regions of β3A and β3B contain many potential casein kinase I and II sites. It has been shown that a casein kinase 1α activity co-purifies with the AP-3 complexes isolated from cytosol. Inhibition of casein kinase activity reduces AP-3-dependent synaptic vesicle budding in vitro. However, it is unclear whether there are other substrates for casein kinase in the budding assay. KIF3A has recently been identified as a β3A linker domain interacting protein and its binding has been shown to be regulated by the phosphorylation state of the hinge domain (Table 2). In vitro assays using yeast extract have suggested that the acidic patches in the β3 linker domain may be substrates for IP7-mediated pyrophosphorylation and the levels of pyrophosphorylation may regulate the interaction (Azevedo et al. 2009).

Summary

Since its discovery over 15 years ago a substantial amount of progress has been made in elucidating the function of the AP-3 complex. It is now known that the complex is involved in the biogenesis of lysosome-related organelles, and loss of the complex in humans causes Hermansky–Pudlak syndrome type 2. The number of cargo molecules the complex traffics and the interacting proteins it binds is steadily increasing. Progress has been made in understanding how the complex is recruited onto membranes. However, several major questions/challenges remain. How many trafficking routes is the AP-3 complex involved in? Does AP-3 have any appendage domain binding proteins? What role does BLOC-1 have in AP-3 function? Why does AP-3 bind clathrin but not require it for its function? How do μ3B and β3B give AP-3 neuronal-specific functions when they appear to bind the same proteins as μ3A and β3A? How do AP-3-binding partners regulate its function? How are all these interactions coordinated within the cell?

Historical Background

In 1975, coated vesicles, which transport many membrane proteins, were purified and shown to include an ~180-kDa protein named clathrin (Pearse 1975). Later, other molecules involved in clathrin binding to the vesicles were also identified (Keen et al. 1979). In 1987, Keen et al. showed that these molecules formed heterotetrameric complexes, which were termed as adaptor protein complex (AP)-1 and AP-2 (Keen 1987). AP-1 and AP-2 are composed of two large subunits (γ and β1 for AP-1, α and β2 for AP-2), one medium subunit (μ1 for AP-1 and μ2 for AP-2) and one small subunit (σ1 for AP-1 and σ2 for AP-2). Later, another AP complex ▶ AP-3 was identified on the basis of its structural homology to AP-1 and AP-2 (Pevsner et al. 1994; Newman et al. 1995). The ▶ AP-3 complex, which consists of one molecule each of δ, β3, μ3, and σ3 subunits, is involved in protein trafficking and organelle biogenesis within the endosomal–lysosomal system. In 1997, Wang et al. identified a novel human protein termed μ-ARP2, which was homologous to the μ subunits of AP complexes (Wang and Kilimann 1997). Later studies identified three

additional proteins, ε, β4, and σ4, which form a novel adaptor protein complex AP-4, together with μ-ARP2 (renamed μ4) (Dell'Angelica et al. 1999; Hirst et al. 1999).

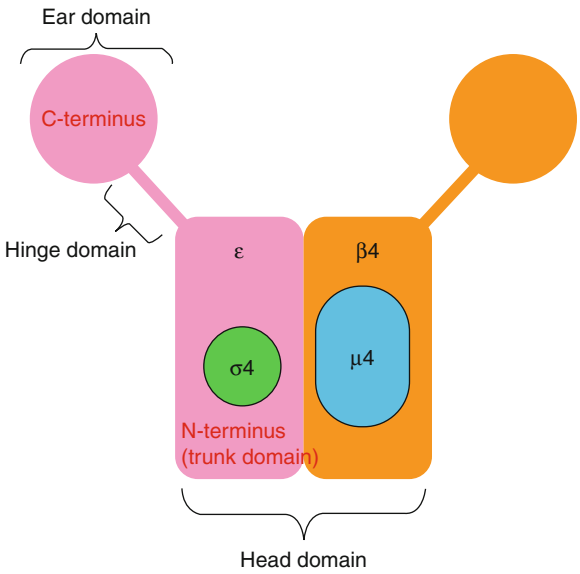
Basic Features

AP-4 is a heterotetrameric protein complex composed of two large subunits (β4 and ε), one medium subunit (μ4), and one small subunit (σ4). Because of the extensive similarities among the four AP complexes, AP-4 is likely to form a structure similar to AP-2 (Fig. 1). The C-terminal domain of two large subunits forms "ear domains," and the "head domain" is composed of the N-terminal domain (trunk domain) of two large subunits and medium and small subunits. The ear and head domains are connected by the flexible "hinge domains" of large subunits. The cargo proteins are thought to be recognized by the μ4 subunit.

Interestingly, AP-4 is found only in the mammals and plants, but the reason why other organisms have lost AP-4 during evolution is unknown. The all four subunits of AP-4 are expressed ubiquitously in almost all mammalian tissues. Immunocytochemical analysis using a Golgi stack maker mannosidase II and trans-Golgi network (TGN) markers TGN38 and furin indicates that the AP-4 complex is associated with the TGN (Dell'Angelica et al. 1999; Hirst et al. 1999; Simmen et al. 2002). Brefeldin A treatment caused dissociation of AP-4 from the TGN, suggesting that the recruitment of AP-4 to TGN membranes is regulated by a member of ADP ribosylation factor family protein (Dell'Angelica et al. 1999; Hirst et al. 1999). Immunoelectron microscopic analysis further indicated that AP-4 localized on the nonclathrin-coated vesicles in TGN (Hirst et al. 1999). Indeed, the hinge domains of the ε and β4 subunits lack clathrin-binding motifs conserved in other adaptor protein complexes. These results suggest that AP-4 is likely to be involved in sorting of nonclathrin-coated vesicles in post-Golgi compartments.

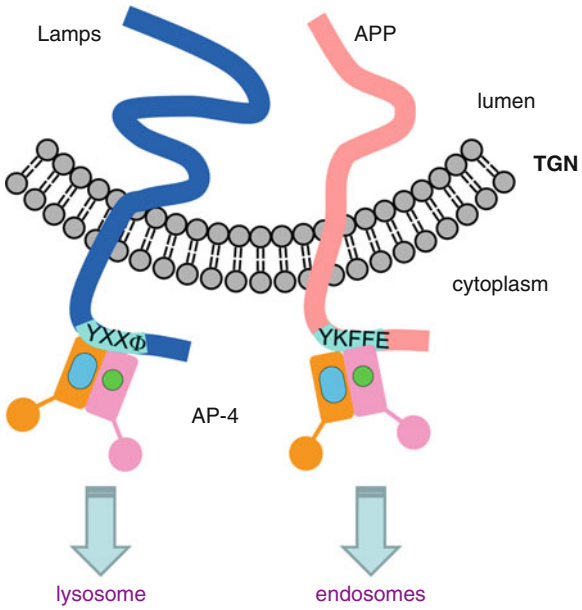
Function of AP-4: Transport to Lysosomes

The YXXØ (where Ø indicates a bulky hydrophobic residue) motif mediates targeting of vesicles at various intracellular transport steps, such as endocytosis, targeting from the plasma membrane to the TGN, targeting to lysosomal compartments, and basolateral sorting in polarized cells. Like μ subunits in other AP complexes, the μ4 subunit of AP-4 binds to the YXXØ



AP-4, Fig. 1 Schematic drawing of the AP-4 complex. AP-4 consists of two large subunits (ε and β4), one medium subunit (μ4), and one small subunit (σ4). The C-terminal domain of large subunits forms ear domains. Head domains are composed of two N-terminal trunk domains of large subunits, medium subunit and small subunit. Ear and head domain are connected by hinge domains of large subunits. The interactions between ε subunit and σ subunit, β4 subunit and μ4 subunit, and ε subunit and β4 subunit have been shown by yeast two-hybrid experiments

motif of several proteins, such as lysosomal membrane proteins Lamp-1 (Igp120) and CD-63 (Lamp-3) (Hirst et al. 1999; Stephens and Banting 1998). Screening of a combinatorial peptide library has shown that μ4 prefers aspartic acid at position Y+1, proline or arginine at Y+2, and phenylalanine at positions Y−1 and Y+3 (Aguilar et al. 2001). A signal that fits this preference is found in Lamp-2. Indeed, Tac chimeral proteins bearing a μ4-specific tyrosine-based sorting signal were targeted to the endosomal–lysosomal system. Nevertheless, knockdown of μ4 has no effect on the localization of these AP-4 interacting proteins to lysosomes (Janvier and Bonifacino 2005). This may be because the interaction between μ4 and the YXXØ motif is very weak (Stephens and Banting 1998) and Lamps are mainly trafficked to lysosomes by endocytosis from the plasma membrane via AP-2 (Janvier and Bonifacino 2005). However, approximately half of the Lamps still reach lysosomes in cells depleted with AP-2, indicating that AP-4 (and other APs) may also be involved in direct transport of Lamps from TGN to lysosomes under certain conditions (Fig. 2).



AP-4, Fig. 2 Schematic drawing of cargo protein recognition at the trans-Golgi network (TGN) and transport to lysosome and endosomes. AP-4 binds to the tyrosine-based sorting motifs (YXXΦ) in certain lysosomal membrane proteins (Lamps) and the sequence YKFFE located in the cytoplasmic region of the Alzheimer's disease amyloid precursor protein (APP) via the μ4 subunit. This association is essential for the transport of these cargo proteins from TGN to lysosome and endosomes

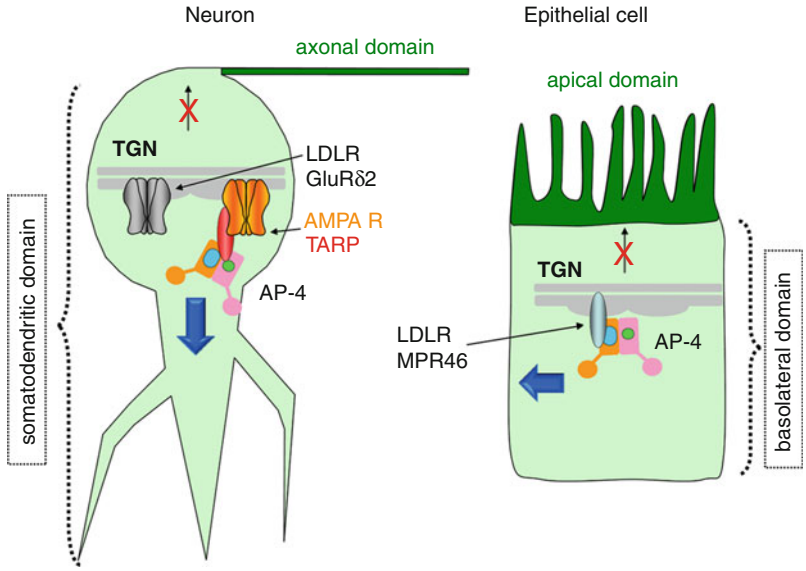
Function of AP-4: Endosomal Targeting of APP

Recently, the μ4 subunit has been reported to interact with the sequence YKFFE located in the cytoplasmic region of the Alzheimer's disease amyloid precursor protein (APP) (Burgos et al. 2010). The YKFFE motif encompasses a YXXØ motif, but it does not bind to μ subunits of other AP complexes. Interestingly, X-ray crystallographic structure determination shows that the YKFFE sequence binds to a site on μ4 that is different from the YXXØ-binding site on the μ2 subunit of AP-2. A mutation in the YKFFE sequence or depletion of μ4 shifted the distribution of APP from endosomes to the TGN, suggesting that AP-4 mediates transport of APP from TGN to endosomes. Impaired transport of APP to endosomes enhanced the generation of pathogenic amyloid β peptide by γ-secretase-catalyzed cleavage of APP. These findings indicate that the interaction between AP-4 and APP regulates APP trafficking at TGN or in the late secretory pathway. Furthermore, they suggest that defects in AP-4 could be a potential risk factor of Alzheimer's disease by producing excessive amyloid β peptide.

Function of AP-4: Polarized Sorting

The plasma membrane of epithelial cells is polarized: they are differentiated into apical and basolateral domains, containing distinctive sets of proteins and lipids. When AP-4 mRNA is disrupted, basolaterally transported proteins, such as the low-density lipoprotein receptor (LDLR) and 46 K cation-dependent mannose-6-phosphate receptor, were distributed nonselectively to both basolateral and apical domains (Simmen et al. 2002). Similarly, Tac chimeral proteins bearing a cytosolic domain of furin were missorted to apical domains. These results indicate that AP-4 mediates basolateral sorting of membrane proteins in epithelial cells (Fig. 3). However, basolateral sorting is also regulated by the AP-1 adaptor protein complex containing the μ1B subunit, which is specifically expressed in most epithelial cells (Ohno et al. 1999). Indeed, many basolateral proteins, such as LDLR and transferrin receptor, are missorted to the apical domain of the epithelial cell line lacking μ1B. Therefore, AP-1B and AP-4 may play complementary and sometimes redundant roles.

Neurons are also highly polarized cells composed of the somatodendritic domain and the axonal domain. The somatodendritic domain receives inputs from other neurons, and the axonal domain transports signals to other cells. Certain neurotransmitter receptors localize in the somatodendritic domain to receive signals from other neurons. For example, the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor is mainly transported to the dendrites where it mediates the majority of excitatory synaptic transmission. Disruption of the gene encoding the β subunit of AP-4 resulted in nonselective distribution of AMPA receptors in axons of hippocampal neurons and cerebellar Purkinje cells both in vitro and in vivo (Matsuda et al. 2008). Similarly, the δ2 subtype of glutamate receptor (▶ GluD2) and LDLR were missorted to axons in AP-4$\beta^{-/-}$ neurons. In contrast, the GluN1 subunit of *N*-methyl-D-aspartate (NMDA) receptors and metabotropic glutamate receptor (mGluR) 1α proteins was selectively targeted to the somatodendritic domain even in the AP-4$\beta^{-/-}$ neurons. These results indicate that AP-4 mediates the somatodendritic transport of AMPA receptors, ▶ GluD2, and LDLR. In addition, because neurons lack AP-1B, certain somatodendritic cargos, such as mGluR1 and GluN1, are likely recognized by unknown adaptor proteins other than AP-4 and AP-1B.



AP-4, Fig. 3 Polarized sorting in neuronal cells and epithelial cells by AP-4. α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors indirectly bind to the μ4 subunit of AP-4 via transmembrane AMPA receptor regulatory proteins (TARPs). LDL receptors (LDLR) and the δ2 glutamate receptor (GluD2) directly bind to μ4. These proteins are sorted to the somatodentritic domain at TGN (*left panel*). In epithelial cells, AP-4 binds to cargo proteins, such as LDLR and 46 K cation-dependent mannose-6-phosphate receptor (MPR46), via the μ4 subunit and regulates basolateral sorting at the TGN (*right panel*)

A motif containing FR and FTF in the C-terminus of the δ2 subtype of glutamate receptors was shown to bind to the μ4 subunit of AP-4 (Yap et al. 2003). In contrast, μ4 does not directly bind to AMPA receptors but associates with transmembrane AMPA receptor regulatory proteins (TARPs), which tightly bind to all subunits of AMPA receptors (Nicoll et al. 2006). An unconventional motif containing phenylalanine and tyrosine (YRYRF) was shown to be essential for the binding of TARP γ3 to μ4 (Matsuda et al. 2008). When TARPs are expressed in hippocampal neurons, they are excluded from axons in wild-type neurons, whereas they are missorted to the axons in AP-4$\beta^{-/-}$ hippocampal neurons. Furthermore, the specific disruption of the interaction between AP-4 and TARPs caused the mislocalization of endogenous AMPA receptors in the axons of wild-type neurons (Matsuda et al. 2008). These results indicate that AP-4 regulates proper somatodendritic-specific distribution of AMPA receptors by binding to TARPs in neurons (Fig. 3).

Human Diseases: AP-4 Deficiency Syndrome

Recently, autosomal recessive loss-of-function mutations in any one of the four subunits of AP-4 are shown to result in similar neurodevelopmental human disorders (Verkerk et al. 2009; Moreno-De-Luca et al. 2011; Abou Jamra et al. 2011). These include five patients in one family lacking the μ4 subunit, four patients in two families with disrupted ε, three patients in one family lacking σ4, and three patients in one family lacking β4. Commonly observed symptoms include an infantile muscular hypotonia that progresses to spastic tetraplegia and hypertonia, leading to inability to walk, severe intellectual disability, absent or markedly delayed speech, stereotypic laughter, and growth retardation. The disruption of any subunit generally destabilizes the entire AP complexes. Indeed, knockdown of μ4 or knockout of β4 results in depletion of the entire AP-4 complex in mice (Matsuda et al. 2008). Thus, these human disorders are now referred to as "AP-4 deficiency syndrome."

As observed in AP-4$\beta^{-/-}$ mice (Matsuda et al. 2008), postmortem brain histology showed irregular thickening of Purkinje cell axons and aberrant localization of ▶ GluD2 in a patient lacking the μ4 subunit (Verkerk et al. 2009). Nevertheless, symptoms of AP-4 deficiency syndrome are generally severer than those observed in AP-4$\beta^{-/-}$ mice. For example, although the mice exhibited a significantly poorer rotorod

performance than wild-type mice, they could walk along a straight line with regular steps throughout their lives. No significant differences in body weight or grip power were observed between the wild-type and AP-4$\beta^{-/-}$ mice. In addition, there seems to be a certain variation in the severity of symptoms in human patients. In a family lacking β4, some patient showed normal speech and could walk independently until the age of 2 (Abou Jamra et al. 2011). Thus, it remains to be determined what causes each symptom in human and what makes difference in phenotypes between human and mice.

Summary

AP-4 is the most recently identified AP complex, whose function has just started to be clarified. It mainly localizes in the TGN and mediates the trafficking of various membrane proteins. It binds to the certain types of tyrosine-based lysosomal trafficking motifs. It also mediates APP trafficking at TGN or in the late secretory pathway. Moreover, in polarized cells, such as the epithelial cells and neurons, AP-4 regulates the polarized sorting of several membrane proteins, such as AMPA receptors and ▶ GluD2. The loss-of-function mutations in any one of the four subunits of AP-4 result in similar neurodevelopmental human disorders called AP-4 deficiency syndrome. It remains to be determined how AP-4 mediated trafficking plays role in the brain development and symptoms in these disorders.

APO2L/TRAIL

Luis Martinez-Lostao, Alberto Anel and Javier Naval
Departamento de Bioquímica, Biología Molecular y Celular, Facultad de Ciencias, Universidad de Zaragoza, Zaragoza, Spain

Historical Background

Apo2 ligand/TNF-related apoptosis-inducing ligand (Apo2L/TRAIL) was independently identified by two different groups as the third member of the tumor necrosis factor (TNF) superfamily capable of inducing apoptosis in transformed cells while sparing normal cells (LeBlanc and Ashkenazi 2003). Apo2L/TRAIL is a type-II membrane protein, composed of 281 amino acids and its gene, designated as *TNFSF10*, has been located on human chromosome 3 at locus 3q26. Its C-terminal extracellular domain shares significant homology with other members of the TNF superfamily, whereas the N-terminal does not. The polypeptide moiety of the Apo2L/TRAIL monomer has a predicted molecular mass of 32.5 kDa but its mature, fully glycosylated form, has a molecular mass of around 41 kDa. There is a potential cleavage site in the extracellular domain of Apo2L/TRAIL at amino acid position 114 which would generate a soluble form of 24 kDa. Like other members of TNF superfamily, Apo2L/TRAIL is a homotrimer, with each monomer composed of two antiparallel β-sheets. Native Apo2L/TRAIL contains a central Zn atom buried at the trimer interface, which is important for the stability, solubility, and biological activity of the protein (Hymowitz et al. 2000).

Apo2L/TRAIL and Its Receptors

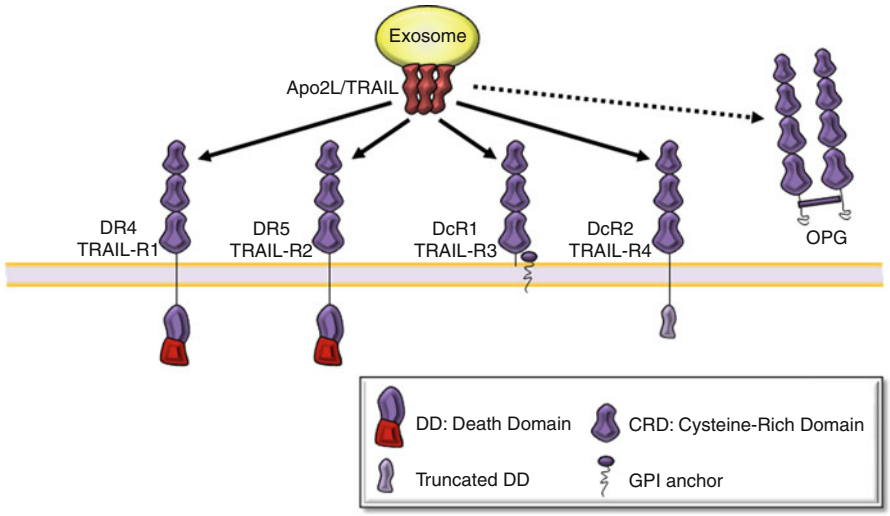
Apo2L/TRAIL can bind to a complex system of receptors with different affinities and distinct signaling outcomes. Five receptors for Apo2L/TRAIL are known in humans, called TRAIL-R1/DR4, TRAIL-R2/DR5, TRAIL-R3/DcR1, and TRAIL-R4/DcR2 (Fig. 1) (Ashkenazi and Dixit 1998). Finally, a soluble receptor termed osteoprotegerin (OPG) can also bind to Apo2L/TRAIL.

Only DR4 and DR5 possess a complete death domain (DD) in their intracellular moiety and can transduce apoptotic signals. Apo2L/TRAIL binds to DR4 or DR5 inducing their oligomerization and the subsequent formation of a multiprotein complex called death-inducing signaling complex or DISC (Walczak et al. 1999; Kischkel et al. 2000). DcR1 and DcR2 are two non-apoptotic membrane-bound receptors for Apo2L/TRAIL (Sheridan et al. 1997). DcR1 is a glycosylphosphatidylinositol (GPI)-anchored receptor and lacks a cytoplasmic domain. DcR2 contains a truncated DD, unable to transduce apoptotic signals. DcR1 and DcR2 seem to act as decoy receptors inhibiting Apo2L/TRAIL interaction with death receptors when overexpressed or, alternatively, interfering with the proper assembly of DR4 and DR5 prior to ligand binding. Alternative ways of inhibiting TRAIL apoptotic signaling by DcR1 and DcR2 have been reported. While DcR1 would prevent the assembly of the death-inducing signaling complex (DISC) by titrating Apo2L/TRAIL within lipid rafts, DcR2 would be co-recruited with DR5 within the DISC, thus preventing initiator caspase activation. Anyway, the physiological role of these receptors *in vivo* remains elusive. They might act more as regulatory molecules than decoy receptors.

Finally, Apo2L/TRAIL can bind, but with lower affinity, to a soluble receptor called OPG (LeBlanc and Ashkenazi 2003). The main function of OPG is the binding and modulation of the interaction of receptor activator of NF-κB ligand (RANKL), another TNF superfamily member, with its cell-surface receptor, RANK. RANKL-RANK interaction induces osteoclast activation, differentiation, and bone resorption. Since Apo2L/TRAIL- or DR5-deficient mice (the only TRAIL receptor expressed in mouse) are viable and exhibit normal bone density, it is unlikely that Apo2L/TRAIL may have a role in bone remodeling.

Apo2L/TRAIL Signaling

The initial step of apoptosis induced by Apo2L/TRAIL is the binding of the trimeric ligand to DR4 and/or DR5. Apo2L/TRAIL-DR4 or -DR5 interaction causes clustering of the death receptor followed by that recruiting of adaptor protein Fas-associated death domain (FADD), which in turn promotes the assembly



APO2L/TRAIL, Fig. 1 *Schematic representation of binding of homotrimeric exosome-bound human Apo2L/TRAIL to its receptors.* In humans, Apo2L/TRAIL binds to two pro-apoptotic receptors, TRAIL-R/DR4 (TNFRSF10A) and TRAIL-R2/DR5 (TNFRSF10B), which contain a death domain (DD). Apo2L/TRAIL can also bind to TRAIL-R3/DcR1 (TNFRSF10C), which is a GPI-anchored protein and lacks a cytoplasmic domain, and to TRAILR4/DcR2 (TNFRSF10D) which has a truncated DD. Similar to other TNFRs, TRAIL receptors possess cystein-rich extracellular domains (CRD). Apo2L/TRAIL also binds to the soluble protein osteoprotegerin (OPG)

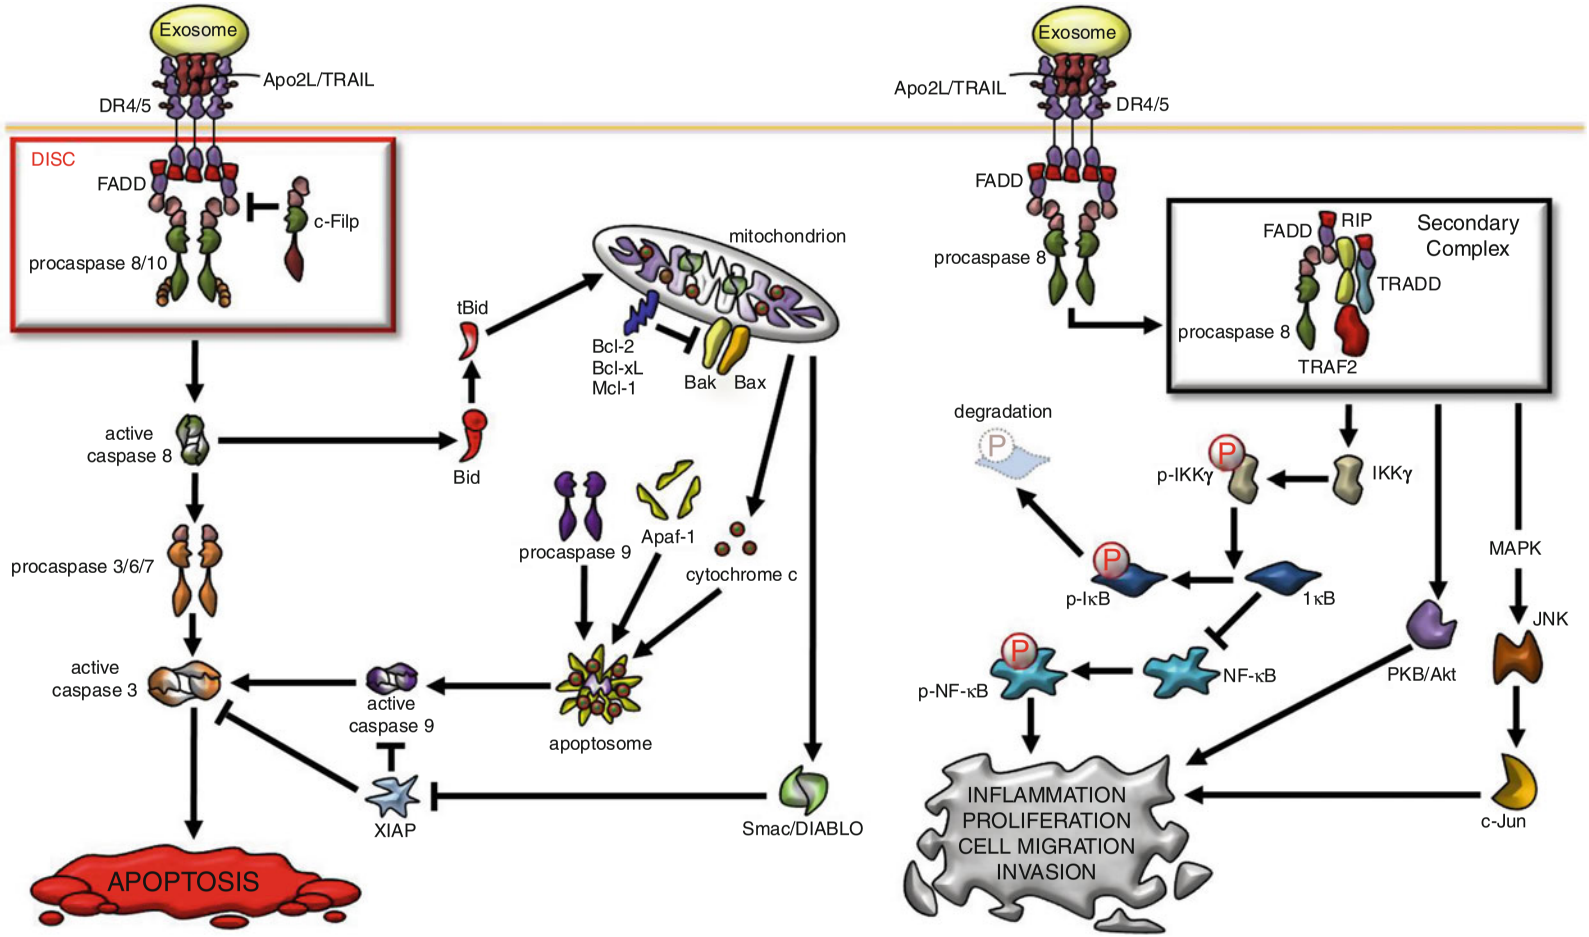
of DISC. The homotypic interaction of FADD with the DRs through their respective DDs exposes the death-effector domain (DED) of FADD and allows it to homotypically bind to procaspase-8 or -10 (Sprick et al. 2000). Recruitment of procaspase-8 to the DISC induces its activation by conformational change followed by autoprocessing and release into the cytosol. Active caspase-8 then cleaves and activates executioner caspases -3 and -7. Caspase-3 in turn cleaves a hundred of cell proteins, including caspase-6, and executes the apoptotic death program (Fig. 2).

DR4 and DR5 receptors may also recruit receptor-interacting protein (RIP) into the receptor complex upon Apo2L/TRAIL binding. RIP phosphorylates IκB kinase (IKK), leading to its degradation. Degradation of IκB promotes phosphorylation of transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). Apo2L/TRAIL also activates mitogen-activated protein kinase (MAPK) and protein kinase B (PKB) signaling.

Caspase-8 and -10 are recruited to and activated at DISC with similar kinetics and may function independently of each other. Some authors have reported that caspase-10 may substitute for caspase-8 but, in some cell types, caspase-10 do not restore the sensitivity to Apo2L/TRAIL in caspase-8-deficient cells and so this point remains controversial.

Depending on the cell type, activation of apoptosis through the extrinsic pathway may or not require help from the intrinsic pathway. In type I cells, the DISC-initiated caspase cascade is enough to activate effector caspases and hence the apoptosis induction. By contrast, in type II cells, in which less active caspase-8 seems to be generated, signal amplification through the mitochondrial pathway is needed. The link between the death receptor-triggered extrinsic pathway and the mitochondrial intrinsic pathway is the BH3-only protein, Bid. Upon DISC formation, Bid is cleaved by caspase-8 generating a truncated form of Bid (tBid) that translocates to mitochondrial outer membrane. There, tBid binds to and activates Bax and Bak leading to the release of cytochrome c and other proapoptotic factors from mitochondria. Cytochrome *c*, in the presence of (d)ATP binds to and induces heptamerization of apoptosis protease activating factor 1 (Apaf-1), forming the apoptosome, which recruits and activates by conformational change, procaspase-9. In his turn, activated caspase-9 cleaves executioner caspases (−3 and −7) leading to apoptosis. The mechanism of Apo2L/TRAIL apoptotic signal transduction is similar to that triggered by FasL, another death ligand from the TNF superfamily.

Apo2L/TRAIL apoptotic signaling pathway is regulated at different levels. Not all proteins present in the



APO2L/TRAIL, Fig. 2 *Schematic representation of Apo2L/TRAIL apoptotic and non-apoptotic signaling pathways.* Binding of Apo2L/TRAIL to their respective receptors induces receptor trimerization and formation of the death-inducing signaling complex (DISC), a multiprotein complex containing the adaptor FADD and procaspases-8 and -10. DISC-activated caspases-8 and -10 trigger a caspase cascade by cleaving caspase-3. cFLIP, another protein contained into the DISC can abrogate caspase-8 activation by competing with caspase-8 for the binding to FADD. In some cell types (type I cells), activation of the extrinsic pathway is sufficient to induce Apo2L/TRAIL-induced apoptosis whereas in other cell types (type II), the mitochondrial apoptosis pathway is engaged by the caspase-8 cleaving of proapoptotic Bid protein, leading to release of cytochrome *c* and Smac/DIABLO from mitochondria

DISC are proapoptotic. Cellular FLICE inhibitory protein (cFLIP), which shares high sequence homology with caspase-8 and -10, may inhibit caspase activation at the DISC by competing for binding to FADD. There are a number of splicing variants of cFLIP but only a longer ($cFLIP_L$) and a shorter version ($cFLIP_S$) can usually be detected at protein level. Both isoforms of cFLIP are recruited to the DISC by homotypic DED interactions. The C-terminal part of $cFLIP_L$ consists of two catalytically inactive caspase-like domains whereas the C-terminal portion of $cFLIP_S$ is neither homologous to procaspase-8 nor -10. $cFLIP_S$ can block caspase-8 processing and activation at the DISC. However, the role of $cFLIP_L$ depends on the molecular context: it may function as pro- or anti-apoptotic depending on the stoichiometry of the different cFLIP proteins and that of caspase-8. A recent model combining experimental data and mathematical modelization indicates that $cFLIP_L$, at moderate levels, may facilitate caspase-8 activation at DISC when the intensity of death signal is strong, but if death ligand concentration is low $cFLIP_L$ slows down induction of cell death.

Sensitivity to Apo2L/TRAIL-induced apoptosis may also be modulated by X chromosome-linked inhibitor of apoptosis (XIAP), a endogenous inhibitor of caspases-3, -7 and -9 which prevents inadvertent caspase activation in living cells. Interfering with XIAP expression renders cells highly sensitive to Apo2L/TRAIL bypassing the requirement for mitochondrial amplification in type II cells. Second mitochondrial activator of caspases/direct inhibitor of apoptosis-binding protein with low pI (Smac/DIABLO), a protein released from mitochondria during apoptosis, binds to and antagonizes XIAP. It has been proposed that the ratios of cFLIP to caspase-8 and XIAP to Smac/DIABLO together may determine whether the cells respond in a type I or type II way to DRs-Apo2L/TRAIL interactions (Fig. 2) (Gonzalvez and Ashkenazi 2010).

Several mechanisms of different nature have been described that may regulate Apo2L/TRAIL signaling. Posttranslational modifications of DR4 and DR5 by glycosylation or palmitoylation seem to be important modulators of the initial events of Apo2L/TRAIL signaling. *O*-glycosylation promoted ligand-stimulated clustering of DR4 and DR5, the first step in DISC formation, essential for recruitment and activation of the initiator caspase-8. Conversely, depletion of certain *O*-glycosylation enzymes attenuates caspase-8 activation at the DISC, whereas overexpression of GALNT14, the *O*-glycosylation-initiating enzyme, enhances the formation of the DISC and sensitizes cells to Apo2L/TRAIL (Wagner et al. 2007). Upon binding of Apo2L/TRAIL to its plasma membrane receptor(s), endocytosis of the ligand-receptor complex usually occurs. Both DR4 and DR5 are rapidly internalized in lipid vesicles after ligation through a dynamin-dependent mechanism. However, contrary to Fas signaling, internalization of the ligand-receptor complex is not required for Apo2L/TRAIL-mediated DISC formation and apoptosis signaling. Recently, ubiquitylation has been shown to be a crucial mechanism which regulates full activation of caspase-8. Death receptor ligation by Apo2L/TRAIL induces polyubiquitination of caspase-8, through an interaction of the DISC with a cullin3 (CUL3)-based E3 ligase (Jin et al. 2009).

Rather than inducing apoptosis, Apo2L/TRAIL can induce survival signals in some cell types. The signaling pathways mainly implicated in Apo2L/TRAIL non-apoptotic signaling are the ▶ NF-κB, MAPK and c-Jun N-terminal kinase (JNK) pathways (Fig. 2) (Falschlehner et al. 2007). Ligand engagement of DR5 quickly leads to formation of the DISC, which signals apoptosis. Subsequently, the primary complex dissociates and multiple proteins including RIP, TNF receptor–associated factor 2 (TRAF2), IKKγ and TNF receptor–associated DD (TRADD), organize into a secondary complex that lacks the ligand and the receptor but contains FADD and caspase-8. This secondary complex may be responsible for the activation of the ▶ NF-κB and MAPK pathways such as JNK and p38. The biological significance of ▶ NF-κB activation by Apo2L/TRAIL is not fully understood but it may serve to restrict apoptosis induction. However, ▶ NF-κB activation could act to increase the threshold of sensitivity to Apo2L/TRAIL-induced apoptosis. Since caspase activation following Apo2L/TRAIL stimulation occurs rapidly, the protection provided by ▶ NF-κB against apoptosis is probably insufficient except in cells that do not activate easily the caspase cascade. Accordingly, ▶ NF-κB activation by Apo2L/TRAIL has been implicated in proliferation, cell migration, and invasion in certain tumor cell lines resistant to Apo2L/TRAIL-induced apoptosis.

It has also been reported that Apo2L/TRAIL can lead to activation of Akt/PKB, a protein kinase typically involved in cell survival and migration. Finally, other studies have shown that Apo2L/TRAIL is able to promote cell proliferation and differentiation though activation of extracellular regulated kinase (ERK), other member of the MAPK family.

In summary, although the physiological relevance of the Apo2L/TRAIL-induced non-apoptotic signaling is not fully established, these observations must be considered in particular in cell types where Apo2L/TRAIL does not induce a rapid apoptosis.

Biological Role of Apo2L/TRAIL

Although the ability of Apo2L/TRAIL to kill certain transformed cells by apoptosis is well established, its physiological role is not fully understood. Studies with mice deficient for Apo2L/TRAIL or its apoptosis-inducing receptor (DR5/TRAIL-R), as well as experiments carried out with Apo2L/TRAIL-blocking agents have led to unraveling diverse functions of Apo2L/TRAIL in vivo. Apo2L/TRAIL deficient mice do not display any overt developmental defects. Similarly, TRAIL-R knockout mice are viable and normally develop indicating that Apo2L/TRAIL signaling in not essential for normal embryonic development (Falschlehner et al. 2009).

The major roles of Apo2L/TRAIL are exerted in the immune system, shaping and regulating the immune response. This was early suggested by the inducible expression of Apo2L/TRAIL in immune cells. At least in human-activated T cells, Apo2L/TRAIL is stored inserted in the inner membrane vesicles of cytoplasmic multivesicular bodies, also known as secretory lysosomes. When T-lymphocytes receive activation signals, native Apo2L/TRAIL is secreted to extracellular medium in the form of microvesicles (exosomes) after fusion of the outer membrane of secretory lysosomes with the plasma membrane. This membrane-bound form of Apo2L/TRAIL displays full pro-apoptotic activity (Anel et al. 2007) (Figs. 1 and 2).

The immunoregulatory role of Apo2L/TRAIL is dependent on two different mechanisms: (1) Apo2L/TRAIL can inhibit IL2-dependent human $CD8^+$ T cell blast proliferation through a cell-cycle arrest in G_2/M and (2) Apo2L/TRAIL is also able to induce apoptosis of $CD8^+$ T cell blasts but, in this case, an additional restimulation is needed. It has also been clearly demonstrated that Apo2L/TRAIL regulates $CD8^+$ T cell memory (Janssen et al. 2005; Anel et al. 2007). The key role of Apo2L/TRAIL in the regulation of T cell responses has been confirmed in Apo2L/TRAIL knockout mice, which are much more susceptible to develop experimentally induced autoimmune diseases, such as experimental autoimmune encephalomyelitis and collagen-induced arthritis, than wild-type mice (Lamhamedi-Cherradi et al. 2003). In fact, Apo2L/TRAIL has been proposed to be used as a treatment in several experimental models of those autoimmune diseases with good results, especially in the case of animal models of rheumatoid arthritis. The efficiency of Apo2L/TRAIL for the treatment of this inflammatory disease is greatly improved through its association with liposomes, mimicking its physiological released form in exosomes.

Apo2L/TRAIL is one of the effector arms of natural killer (NK) cells and plays a key role in NK cell-mediated, interferon (IFN)-γ-dependent, suppression of tumor cell growth and prevention of metastasis formation. Indeed, one of the physiological roles of Apo2L/TRAIL seems to be the tumor immune surveillance. TRAIL knockout mice are more susceptible to cell-inoculated and chemically induced tumors as well as to metastasis dissemination than wild-type mice. In addition, TRAIL-deficient mice show a high rate of spontaneous hematological tumors appearing at old age (Zerafa et al. 2005). The low systemic toxicity of Apo2L/TRAIL on normal cells, while exerting a potent pro-apoptotic activity on a variety of human tumors have led to the development of different recombinant versions of Apo2L/TRAIL and agonistic monoclonal antibodies to its signaling receptors (anti-DR4 or anti-DR5). These agents, alone or in combination with chemotherapeutic drugs, provide new and promising approaches to cancer treatment (Ashkenazi et al. 2008).

Summary

The membrane protein Apo2 ligand/TNF-related apoptosis-inducing ligand (Apo2L/TRAIL) is a cytokine which interacts with a complex system of membrane receptors and triggers the extrinsic pathway of apoptosis. The ability of Apo2L/TRAIL to kill tumor cells while sparing normal cells makes this cytokine a promising antitumor agent. In fact, numerous clinical trials using recombinant forms or Apo2L/TRAIL or agonistic antibodies are currently underway. During

the last decade, it has become apparent that Apo2L/TRAIL is key in the immune system function, mainly in tumor immune surveillance and in downregulation of immune response. Apo2L/TRAIL exerts immunosuppressive and immunoregulatory functions, important for immune homeostasis, tumor control, and prevention of autoimmunity. Hence, apart from the intended use of Apo2L/TRAIL as a chemotherapeutic agent, a recent body of evidence suggests that this cytokine may also be a promising therapeutic agent for autoimmune diseases. However, distinct aspects of the physiological role of Apo2L/TRAIL in cancer and autoimmunity need to be unraveled to fully understand the importance of this signaling pathway. Among these aspects for future research, it stands out to fully unravel the role of Apo2L/TRAIL in the immune system, as well as to establish the true role of non-apoptotic signaling by Apo2L/TRAIL in vivo.

Further investigations on the mechanism of action of this cytokine will unravel the complexities of its in vivo function and ultimately apply this knowledge to a better treatment of cancer and autoimmune diseases.

Historical Background

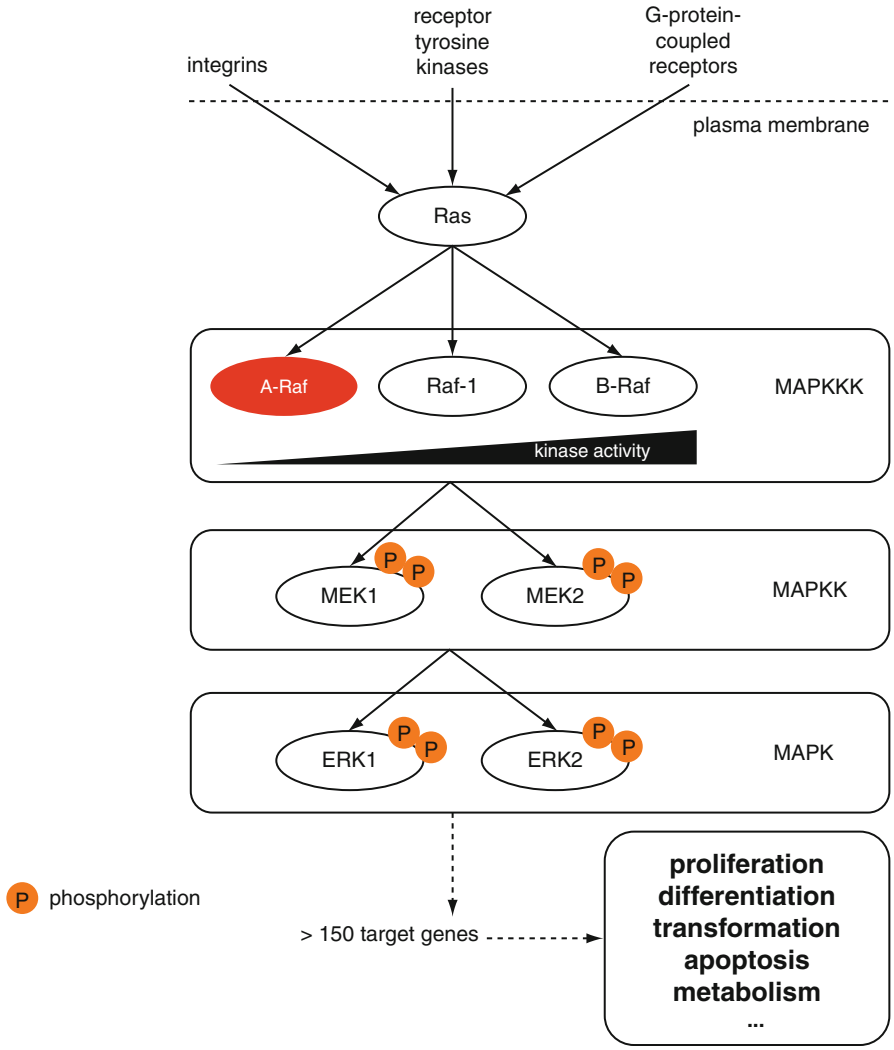
A-Raf is member of the Raf family of serine/threonine protein kinases comprising A-Raf, B-Raf, and ▶ Raf-1. In 1983 and 1986, viral homologues of RAF were isolated during experiments with the aim to identify novel transforming genes. Viral RAF (v-RAF) homologues were encountered in two different viruses, the avian retrovirus Mill Hill 2 (MH2) and the murine sarcoma virus (MSV) 3611. While MH2 contained the avian homologue of v-RAF, 3611-MSV was isolated from a mouse with lymphoma and lung adenocarcinoma. The name RAF derives from the observation that 3611-MSV increased the induction of fibrosarcoma in newborn NSF/N mice (*r*apidly *a*ccelerated *f*ibrosarcoma, or RAF). These initially identified viral RAF (v-Raf) genes originate from the mammalian counterpart of Raf-1 (or ▶ C-Raf) due to homologous recombination. After the discovery of the mammalian Raf-1 gene and initial functional characterization, additional C-RAF homologues were found in mammals, referred to as A- and B-RAF (Daum et al. 1994).

In the 1980s, several groups identified the ARAF gene as a paralogue of Raf-1. Mark et al. used low stringency hybridization techniques on human fetal liver cDNAs in order to identify v-Raf-related sequences and isolated ARAF, which was named PKS at that time (presumably for kinase sequence) (Mark et al. 1986). In the same year, Huleihel et al. isolated the A-Raf cDNA from a murine cDNA spleen library. They could show an 85% homology with Raf-1 and its expression in mouse tissues. Furthermore, incorporation of ARAF into a retrovirus showed that ARAF represents a new proto-oncogene (Huleihel et al. 1986). Later mouse and human ARAF genes were mapped to the X chromosome, and the complete A-RAF mRNA was sequenced from a human T-cell (Daum et al. 1994).

From an evolutionary point of view, there are no Raf kinases in yeasts, and B-Raf seems to be the phylogenetic oldest isoform of the three, which appears in invertebrates. In comparison, mammals possess three Raf isoforms (Raf-1, B-Raf, and A-Raf), with a shared modular structure. In comparison to Raf-1 and B-Raf, A-Raf is by far the least well-understood member of the Raf family (Rauch and Kolch 2010; Wellbrock et al. 2004; Zebisch and Troppmair 2006).

A-RAF and MAPK Signaling

Using genetic and biochemical approaches, A-Raf, like Raf-1 and B-Raf, was shown to be a component of the Ras-Raf-MEK-ERK pathway, also often referred to as the classic mitogen-activated protein kinase (MAPK) cascade. In this pathway Ras activates a three-tiered kinase module where Raf phosphorylates and activates ▶ MEK, and ▶ MEK phosphorylates and activates ERK. This pathway links receptor activation at the plasma membrane to >150 substrates in the cytosol and nucleus, which regulate many fundamental cellular functions such as proliferation, differentiation, transformation, apoptosis, and metabolism (Yoon and Seger 2006) (Fig. 1).



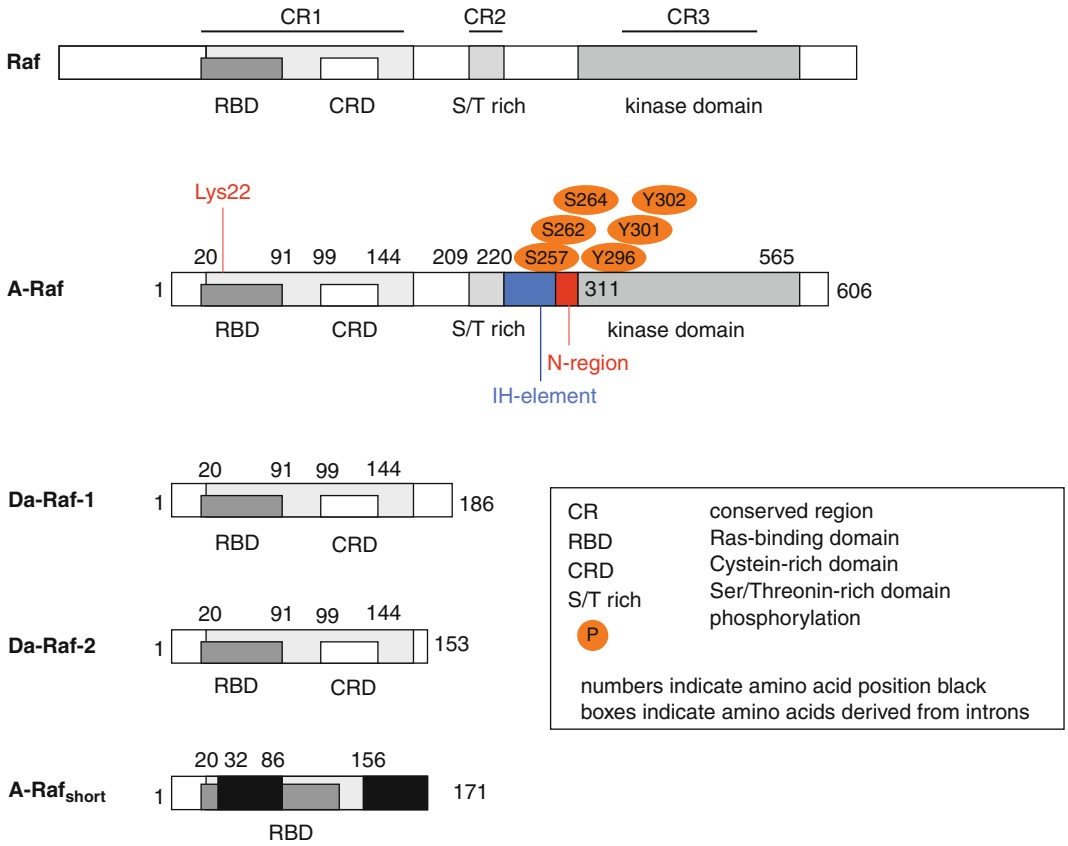
A-RAF, Fig. 1 Canonical Ras-Raf-MEK-ERK pathway

Regulation of Activity

The family of Raf serine/threonine protein kinases shares three conserved regions (CR) (Fig. 2). CR1 contains the Ras-binding domain and a cysteine-rich motif. CR2 features a short cluster of Ser and Thr residues, and CR3 contains the kinase domain. CR1 and CR2 restrain the function of CR3, and activation steps involve the release of this negative interaction as well as posttranslational modifications of CR3. The only bona fide substrates of Raf kinases are MEK1/2.

In general, A-Raf is regulated similar to Raf-1, although important differences have emerged over the years. While binding to active Ras suffices to activate B-Raf, Raf-1, and A-Raf require the presence of both activated Ras and Src, which is thought to phosphorylate tyrosines 301/302 in the negative-charge regulatory (N-) region upstream of the kinase domain (Marais et al. 1997). In B-Raf these tyrosines are replaced by aspartates, whose negative charge substitute for N-region phosphorylation normally induced by Ras binding.

A-Raf has a weak, hardly detectable kinase activity toward MEK. The reasons are (i) a substitution of a critical residue (arginine 22 for lysine) in the A-Raf RBD, which weakens the binding to Ras; and (ii) a non-conserved tyrosine 296 in the A-Raf N-region, whose mutation to glycine increases kinase activity (Baljuls et al. 2007). A-Raf is also positively regulated by phosphorylation (Baljuls et al. 2008). Serine 432 is crucial for the binding of MEK, while phosphorylation of serines 257, 262, and 264 in the



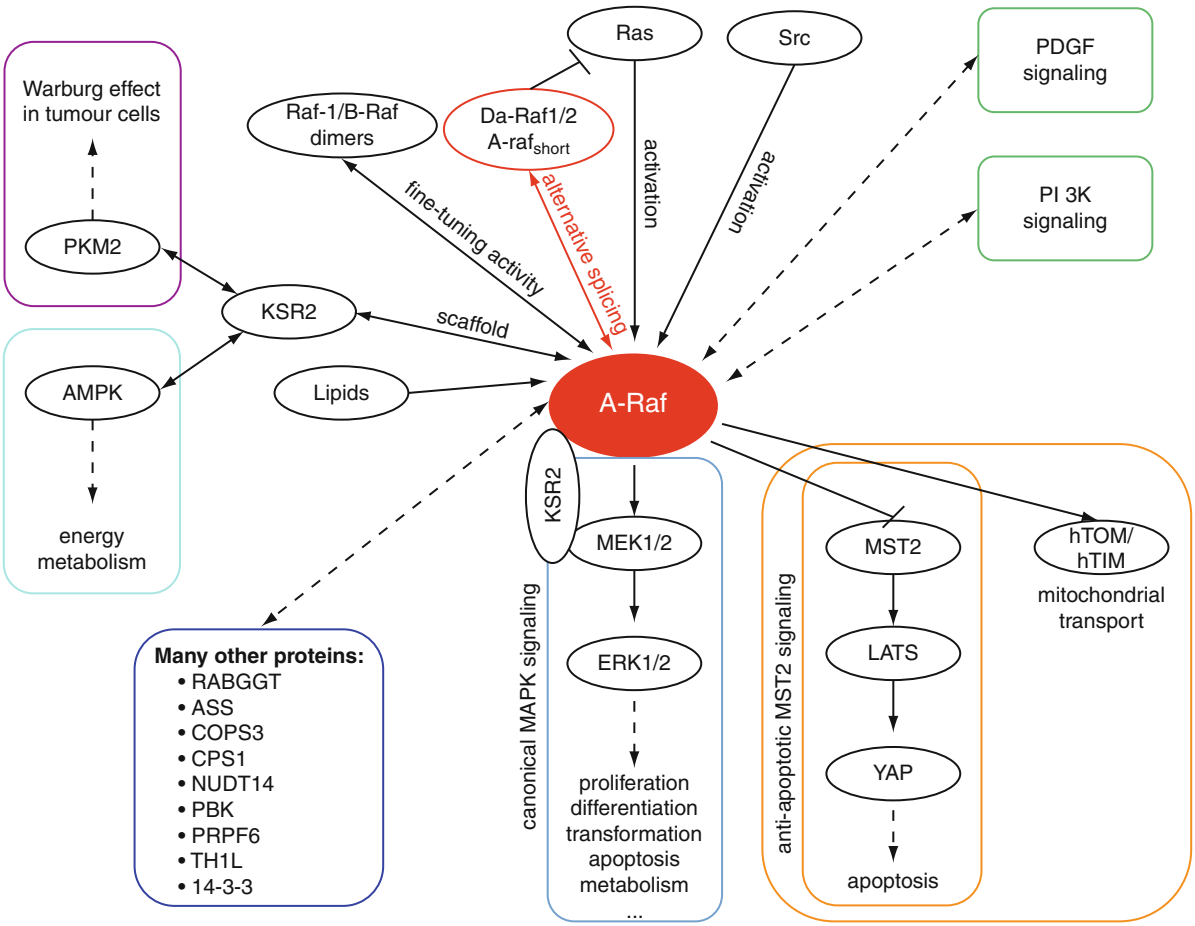
A-RAF, Fig. 2 Domain structure of Raf proteins (*top*). Comparison of domains and phosphorylation sites of the four A-Raf alternative splice forms

*I*soform-specific *H*inge (IH) segment stimulate A-Raf kinase activity. Full phosphorylation of the IH segment accumulates negative surface charges leading to the electrostatic destabilization of the interaction of A-Raf with the inner part of the plasma membrane and release into the cytosol. In addition, A-Raf like Raf-1 can bind lipids, such as phosphatidic acid and phosphoinositides (Johnson et al. 2005). Polyphosphorylated phosphoinositides, such as PI (4,5) and PI(3,4,5) suppress kinase activity. Thus, while sharing Ras as essential activator and MEK as substrate with other Raf isoforms, A-Raf shows unique mechanisms of regulation.

In addition to phophorylation and lipid binding A-Raf activity is also regulated by protein interactions, notably by heterodimerization with other Ras family members (Rushworth et al. 2006). B-Raf–Raf-1 heterodimerization dramatically elevates kinase activity. Heterodimerization is part of physiological Raf activation, but also an important "side effect" of Raf inhibitory drugs in cells harboring mutant Ras where these drugs promote Raf heterodimerization and thereby promote ERK pathway activation (Wimmer and Baccarini 2010). The regulatory subunit of ▶ casein kinase 2 (CK2β) binds and activates A-Raf when co-expressed in insect cells (Hagemann et al. 1997). However, the mechanism and physiological role of CK2β in A-Raf activation in mammalian cells remains to be proven. Other regulatory protein interactions are discussed below.

A-Raf Interacting Proteins

Apart from interacting with components of the ERK pathway, such as Ras, MEK, and other Raf isoforms, A-Raf also interacts with a number of other proteins. We recently summarized these interactions (Rauch and Kolch 2010), and therefore only discussed selected interactions here (Fig. 3).



A-RAF, Fig. 3 Overview about A-Raf interaction partners, cross talk to other signaling pathways, and processes where A-Raf is involved

A-Raf can associate with the p85 regulatory subunit of the phosphatidylinositide 3-kinase (PI3K) via the p85 SH2 domain. The interaction is constitutive and independent of growth factor stimulation or phosphorylation. A constitutively active A-Raf mutant inhibited p85 associated PI3-kinase activity, but it is unclear whether this interaction is a physiological connection between the ERK and ▶ PI3K pathways (Mahon et al. 2005). The hypothesis that A-Raf coordinates different signaling pathways is supported by the observation that A-Raf associates with the platelet-derived growth factor receptor (PDGFR), and specifically suppresses autophosphorylation and phosphorylation of the phospholipase C-γ (PLCγ) docking site, but not the phosphorylation of binding sites for other signaling molecules (Mahon et al. 2005). These functional effects were achieved by expression of an activated A-Raf mutant, while the role of endogenous A-Raf was not examined leaving it unclear whether A-Raf can regulate PDGFR signaling under normal conditions.

A physiological role of A-Raf was shown in the control of apoptosis. A-Raf binds and inhibits the proapoptotic kinase mammalian sterile 20-like kinase (MST2). A-Raf binds to MST2 constitutively, and seems to promote the survival of cancer cells (Rauch et al. 2010). By contrast, Raf-1 binding to MST2 is induced by stress and relieved by mitogens, while B-Raf does not detectably bind MST2 (O'Neill et al. 2004). This differential MST2 binding pattern inversely correlates with the kinase activity toward MEK and the evolution of the Raf family. B-Raf, the oldest member has the strongest MEK kinase activity and little affinity for MST2, while the youngest member, A-Raf, has poor MEK kinase activity but strong capacity to bind and inhibit MST2, suggesting that during evolution the role of Raf has shifted from

activating the ERK pathway to inhibiting the MST2 pathway. Interestingly, both A-Raf and MST2 localize to the mitochondria in tumor cell lines as well as primary tumors (Rauch et al. 2010). A-Raf associates with hTOM and hTIM, two proteins involved in the mitochondrial transport system (Yuryev et al. 2000). The biological function of A-Raf's mitochondrial location and interactions is unknown, but given A-Raf's poor MEK kinase activity the existence of alternative substrates, e.g., at the mitochondria, is likely.

Another intriguing A-Raf interaction partner is Kinase suppressor of Ras 2 (KSR2). In response to TNFα KSR2 recruits A-Raf rather than Raf-1 or B-Raf (Liu et al. 2009), suggesting that KSR2 may redirect A-Raf to the ERK pathway or nucleate other A-Raf specific signaling complexes. Interestingly, KSR2 also binds AMP kinase (AMPK) thereby mediating its stimulatory effects on glucose uptake and fatty acid oxidation (Costanzo-Garvey et al. 2009). The AMPK binding site overlaps the domain responsible for KSR2 membrane association suggesting the interesting possibility that AMPK binding to KSR2 could prevent the membrane translocation required for the efficient activation of the Raf-MEK-ERK module. Thus, metabolic requirements could restrain proliferation signals. A-Raf also may play a direct role in the cross talk between metabolism and proliferation by binding and inhibiting pyruvate kinase M2 (PKM2). PKM2 is the embryonic splice variant of PKM, which is reexpressed in tumors and responsible for the prevalence of anaerobic glycolysis (Warburg effect) typically observed in cancers (Christofk et al. 2008). A-Raf promotes the dimerization and inactivation of PKM2, whereas oncogenic A-Raf elevates the active tetrameric form of PKM (Mazurek et al. 2007). Thus, A-Raf may have a central role in coordinating proliferation via the ERK pathway, cell survival via the inhibition of MST2, and metabolic state in cancer cells via regulation of PKM2 activity.

Many more A-Raf binding partners have been reported, summarized in various interaction databases, e.g., String (http://string.embl.de), but their physiological roles and significance remain unexplored. An interesting dimension is added by the differential subcellular localization of A-Raf, which is found at the membrane, cytosol, and mitochondria. It is likely that A-Raf will engage with different binding partners in different compartments thus increasing the versatility and spatiotemporal coordination of A-Raf signaling.

A-Raf Splice Variants

Alternative splicing occurs in more than 90% of human genes, and greatly expands the information content and versatility of the transcriptome in generating tissue, stage, and development specific gene expression patterns.

For the ARAF1 gene so far, there are three reported alternative splice forms in addition to the wild-type mRNA (Fig. 2). Two of these splice forms, termed DA-Raf1 and DA-Raf2, contain the N-terminal Ras-binding domain, but lack the kinase domain due to preterminal stop codons. Therefore, they are still able to bind to activated Ras, but due to the lack of a kinase domain, act as dominant-negative antagonists of the Ras-ERK pathway (Nekhoroshkova et al. 2009; Yokoyama et al. 2007). Consistent with this functional role, DA-Raf1 promotes myogenic differentiation by binding to Ras and thereby inhibiting activation of the Raf-MEK-ERK pathway (Yokoyama et al. 2007). Similarly, DA-Raf2 binds and colocalizes with ARF6 on tubular endosomes and acts as a dominant effector of endocytic trafficking (Nekhoroshkova et al. 2009).

Recently, A-Raf$_{short}$, a third alternative splice form of the ARAF1 gene was reported. In comparison to DA-Raf1 and DA-Raf2, A-Raf$_{short}$ incorporates intronic sequences, and generates a shortened protein, which lacks the kinase domain. Consequently, A-Raf$_{short}$ acts as a dominant-negative antagonist by binding and blocking activated Ras and thus is a potent inhibitor of ERK signaling and cellular transformation. The expression of A-Raf$_{short}$ is reduced in several cancer entities suggesting that A-Raf$_{short}$ acts as a tumor suppressor protein.

Regulation in Cancer and Other Diseases

Initial studies in mice suggested a highly restricted tissue distribution of A-Raf with highest expression levels observed in epididymis, ovary, and intestine. In the meantime, however, A-Raf was found expressed in most normal tissues, but expression levels seem highly regulated and differ dramatically. While neuronal tissues, for example, express A-Raf only at low levels, the urogenital tract shows a high expression (Luckett et al. 2000). A-Raf mRNA and protein levels are elevated in a number of malignancies. Increased A-Raf mRNA levels were found in peripheral blood mononuclear

cells isolated from two patients with angioimmunoblastic lymphadenopathy with dysproteinemia (Mark et al. 1986). Elevated levels of A-Raf mRNA were also found in pancreatic ductal carcinoma (Kisanuki et al. 2005). In addition, enhanced A-Raf expression was also found in other tumor types, including astrocytic tumors, where high expression of A-Raf negatively correlated with patients' prognosis (Hagemann et al. 2009). Elevated A-Raf expression was also found in a number of head and neck squamous cell carcinomas as well as colon carcinomas.

Several publications addressed the mutational status of the ARAF1 gene. While B-Raf is a well-described target for mutations in human cancers, mutations in A-Raf, like Raf-1, are very rare to nonexistent. This poses the following question: How and why is A-Raf overexpressed in several malignancies although the gene is not altered at the genetic level? One mechanism is an increased expression of A-Raf due to chromosomal aberration. The human ARAF1 gene is situated on the X chromosome, and duplication of X chromosomes was found in testicular germ cell tumors leading to enhanced A-Raf levels. Furthermore, expression of wild-type A-Raf mRNA and protein requires the expression of the splice factor hnRNP H, whose levels are enhanced in several tumors including colon and head and neck cancers (Rauch et al. 2011). High levels of this splice factor ensure the expression of full-length A-Raf protein by suppressing alternative splicing of the *a-raf* mRNA, thus allowing the sufficient production of full-length A-Raf protein to counteract MST2-mediated apoptosis. Low levels of hnRNP H, as found in nonmalignant tissues, cannot suppress alternative splicing of the A-Raf wild-type mRNA, thus favoring the expression of the alternative splice form A-Raf$_{short}$. As mentioned already above, A-Raf$_{short}$ acts as a dominant-negative antagonist of the Ras-MAPK cascade, which seems to keep proliferation and transformation in nonmalignant cells in check.

Mouse Models and Phenotypes

In the 1990s, the first mouse model for the A-Raf gene was reported (Pritchard et al. 1996). It was shown that ablation of the A-Raf gene causes neurological defects. Interestingly, in an inbred mouse background, A-Raf ablation resulted in intestinal and neurological abnormalities. A-Raf knockout mice died 1–3 weeks after birth from megacolon which is reminiscent of Hirschsprung's disease in humans and was caused by a defect in the migration of visceral neurons controlling bowel contractions. In contrast, in an outbred background, A-Raf knockout animals survived to adulthood. In this genetic background, A-Raf ablation did not lead to intestinal abnormalities, but animals displayed a subset of neurological defects. Interestingly, the regulation of ERK and oncogene transformation is not impaired in A-Raf knockout cells. These results, together with the low kinase activity toward MEK suggest that A-Raf does not play a major role in MAPK signaling and that this function is fully compensated by the other two Raf family members. However, A-Raf seems to have a role in the development of the nervous system possibly by regulating neuronal migration. Comparing the knockout phenotypes of all three Raf isoforms in mice indicates that A-Raf and B-Raf may have more specialized functions, while Raf-1 seems to have a more general role in tissue formation.

Summary

What did scientists learn about A-Raf since its discovery in the early 1980s? A simple summary is that Raf proteins have distinct functions, and that A-Raf has more functions than initially expected. Details about its domain, phosphorylation sites, and functions are known in comparison with other Raf proteins and kinases. Furthermore, scientists made headway in deciphering in which pathways A-Raf might play a role. Science now has entered an era where the mapping of the components of signaling networks is rapidly accelerating producing even longer lists faster than ever before. However, these lists are like a telephone book full of names rather than an ordnance survey type of map that connects the names with pathway topologies. Undoubtedly, much more is known about Raf-1 and B-Raf and 25 years of research mainly focused on these two isoforms, as they play a bigger role in MAPK signaling and oncogenesis and are major targets for drug therapies. In comparison, A-Raf on its own seems to play only a minor role in the canonical MAPK pathway. Multiple studies over the last years have shown A-Raf's involvement in other processes, such as energy metabolism, the Warburg effect, mitochondrial transport, and anti-apoptotic signaling. However, it seems that these interactions with other

proteins and processes do not happen at the same time but are rather cell-, tissue-, and time-dependent. Furthermore, A-Raf is found at different localizations of the cell and this spatial regulation is another suitable explanation for the involvement in different pathways. Dissecting these micro-complexes and interacting proteins is a challenging endeavor on the experimental level. To add another level of complexity, three novel alternative splice forms were identified recently with functions that are even antagonistic to the wild-type form.

Despite a lot of research has already been done and had a huge impact on our understanding how A-Raf functions, there are still some unanswered questions:

- A-Raf was shown to bind to a plethora of proteins, which suggests A-Raf's involvement in many other signaling pathways outside the canonical MAPK pathway. However, if there is more than one function in signal transduction, how are these diverse functions coordinated in order to achieve the intended biological outcome and specificity? This question is also relevant for the other members of the Raf family.
- Similarly, A-Raf was found at different subcellular compartments. How does this localized expression impact on signaling pathways and networks?
- What is the impact of dynamic changes in the assembly of A-Raf signaling complexes on biochemical and biological outcome?
- A-Raf was shown to play a role in cancer and other diseases. Is this exploitable for the purpose of therapeutic intervention?

In summary, the current state of analysis of the "A-Raf network" offers a glimpse into a new world. New concepts and tools developed hopefully will widen this glimpse into a window overlooking the whole signaling network.

ARAP3

Siân-Eleri Owens and Venkateswarlu Kanamarlapudi
Institute of Life Science, School of Medicine, Swansea University, Swansea, Wales, UK

Synonyms

ARF-GAP, RHO-GAP, ankyrin repeat, and plekstrin homology domains containing protein 3; Centaurin delta 3; Centd3; Drag1; Expressed sequence AI851258.

Historical Background

Small GTPases of the Ras superfamily are binary switches that, by cycling between active GTP-bound and inactive GDP-bound conformations, regulate a wide variety of cellular and developmental events. They are grouped based on the sequence homology and function into five families: Ras, Rho, Ran, Rab, and ARF. The Rho and Arf family small GTPases are well-established regulators of cellular actin rearrangements and vesicular trafficking (Bos et al. 2007). Small GTPases are activated by guanine nucleotide exchange factors (GEFs), which catalyze the exchange of small GTPase-bound GDP to GTP, whereas GTPase-activating proteins (GAPs) inactivate small GTPases by stimulating hydrolysis of the small GTPase-bound GTP to GDP (Bos et al. 2007). In general, each small GTPase family has its specific GEFs and GAPs. However, the ARAP protein subfamily, which is composed of ARAP1, ARAP2, and ARAP3, is unique as its members act as GAPs for both Rho and Arf family small GTPases. The ARAP protein subfamily is included in the Arf GAP family in recent consensus nomenclature for the human Arf GAP-domain-containing proteins (Krugmann et al. 2002; Santy and Casanova 2002; Kahn et al. 2008). ARAP3 is a phosphoinositide (PtdIns) 3 kinase and Rap1- regulated GAP for RhoA and Arf6 (Krugmann et al. 2004).

ARAP3 was originally identified as a PtdIns(3,4,5)P_3 second messenger binding protein. It consists of a SAM domain, five PH domains, Rho GAP domain, an Arf GAP domain, and a RA domain (Krugmann et al. 2002). ARAP3 binding to PtdIns(3,4,5)P_3 depends on its amino-terminal tandem PH domains and adjacent sequences (Craig et al. 2010).

Protein Function and Regulation of Activity

The functions of ARAP3 that have been established thus far include regulation of the actin cytoskeleton, lamellipodia formation, and cell spreading (Raaijmakers et al. 2007). ARAP3 has been shown to increase the number of membrane projections, but it only weakly inhibits the migration of HEK293 cells (I et al. 2004). Overexpression of ARAP3 results in a loss of cell adhesion and cell retraction in platelet-derived growth factor (PDGF)-treated pig

aortic endothelial (PAE) cells (Krugmann et al. 2006). ARAP3 overexpression in PAE and NIH3T3 cells inhibits actin stress fiber formation by reducing RhoA activity (I et al. 2004).

ARAP3 Rho GAP activity is necessary for the suppression of cell spreading (I et al. 2004). The RA domain of ARAP3 is essential for the RhoA GAP activity (Krugmann et al. 2004). ARAP3 has also recently been identified as a host protein affecting cellular susceptibility to anthrax toxin (Lu et al. 2004).

It has been hypothesized that ARAP3 is constitutively active in monocytes. This is because unstimulated ARAP3 knockdown THP-1 cells (a monocyte-derived cell line) have increased RhoA activity. Additionally, platelet activating factor (PAF)-mediated inactivation of RhoA is reduced in ARAP3 knockdown THP-1 cells (Nandy et al. 2010).

Stimulation of PC12 cells with growth factors that induce PtdIns(3,4,5)P_3 formation such as EGF results in ARAP3 translocation from cytosol to the plasma membrane of PC12 cells (Krugmann et al. 2002). The dominant negative mutant of ARAP3 (which lacks both RhoGAP and ArfGAP acitivites) has been shown to inhibit significantly NGF- and bFGF-induced neurite outgrowth in PC12 cells, while overexpression of wild-type ARAP3 slightly increases the neurite outgrowth. This result suggests that RhoA inactivation by ARAP3 is required for NGF- and bFGF-induced neurite outgrowth in PC12 cells (Jeon et al. 2010a, b).

ARAP3 Arf and Rho GAP activities are dependent on its N-terminal PH domain binding to PtdIns(3,4,5)P_3 (Krugmann et al. 2004). Translocation of ARAP3 to lamellipodia of PAE cells is dependent on its first PH domain and PtdIns(3,4,5)P_3 produced by agonist-activated PtdIns 3-kinase (Krugmann et al. 2002).

Growth factor stimulation and cell adhesion to fibronectin leads to tyrosine phosphorylation of ARAP3 by Src-family kinases Lyn and Src when they are co-expressed in cells. Incubation with Src-family kinase and PtdIns 3-kinase inhibitors, or Src dominant interfering mutant, results in a decrease of adhesion-induced ARAP3 phosphorylation. Mutation of the two phosphorylation sites, Tyr 1399 and Tyr 1404, increases ARAP3 cellular functions, indicating that ARAP3 may be negatively regulated by the tyrosine phosphorylation. Moreover, both Lyn and Src have been shown to form stable bonds with ARAP3 (I et al. 2004).

ARAP3-dependent RhoA GAP activity is elevated in cells expressing Rap1A (Krugmann et al. 2004). The interaction of ARAP3 with PtdIns(3,4,5)P_3, has been shown to be vital for Rap-GTP to stimulate Rho GAP activity of ARAP3 in vivo, indicating the importance of PtdIns 3-kinase activity for this process (Krugmann et al. 2004). Moreover, Rho and ARF6 activities are increased in both basal and PDGF-stimulated ARAP3-knockdown cells (Krugmann et al. 2006).

Recent studies have shown that none of ARAP3 five PH domains are able to bind to PtdIns(3,4,5)P_3 in isolation. It has been suggested that binding to PtdIns (3,4,5)P_3 involves the formation of a complex mechanism whereby basic residues from two tandem PH domains, the N-terminal SAM domain, and basic residues within ARAP3 synergise in order to bind strongly and specifically to PtdIns(3,4,5)P_3 (Craig et al. 2010).

The small GTPase Rap1 has been shown to interact with the RA domain of ARAP3 and activate its Rho GAP activity (Raaijmakers et al. 2007).

ARAP3 has been shown to bind to the adaptor protein CIN85/CMS via its Pro-Arg motif. CIN85 has been implicated in the internalization of mono-ubiquinated membrane protein (Kowanetez et al. 2004), whereas CMS is involved in cytoskeletal rearrangements (Kirsch et al. 1999). ARAP3 binds to the secondary messenger PtdIns(3,4,5)P_3 through its PH domain(s) (Krugmann et al. 2002). The SAM domain of ARAP3 interacts with the SAM domain of the inositol 5'- phosphatase SHIP2 to form a heterodimer; however, binding of ARAP3 to SHIP2 is not required for SHIP2 activity. The binding of the two proteins seems to be constitutive, as the interaction does not require activation by PtdIns 3-kinase or Rap1. It has been shown that SHIP2, ARAP3, and CIN85/CMS form a mutimeric protein complex (Raaijmakers et al. 2007).

The NMR solution structure of ARAP3 SAM domain shows that it has the classical small five helix bundle. Chemical shift mapping studies have indicated that the interaction of SHIP2-SAM and ARAP3-SAM central regions are involved. ARAP3-SAM binding domain is made up of the carboxy-terminal α 5 helix and adjacent loop regions. It has been hypothesized that SHIP2-SAM and ARAP3-SAM binding is likely via the Mid-Loop/End-Helix Model that is common between SAM-SAM interactions (Leone et al. 2009).

Major Sites of Expression and Subcellular Localization

Studies have shown that ARAP3 expression is ubiquitous, albeit uneven. The strongest expression was detected in leukocytes and in the spleen (Krugmann et al. 2002).

ARAP3 is largely localized within the cytosol of unstimulated cells (Krugmann et al. 2002) and in the F-actin dense membrane ruffles and lamellipodia of some cells (I et al. 2004). ARAP3 binding of PtdIns $(3,4,5)P_3$ through its PH domain results in its translocation to the plasma membrane (Raaijmakers et al. 2007).

Stimulation of cells with growth factors that induce PtdIns$(3,4,5)P_3$ formation such as EGF resulted in ARAP3 translocation to the plasma membrane of PC12 cells. However, stimulation of PAE cells with PDGF, which also induces PtdIns$(3,4,5)P_3$ formation, led to ARAP3 translocation to lamellipodia (Krugmann et al. 2002).

All the subcellular localization studies were performed with exogenously overexpressed ARAP3. Therefore, it is possible that the endogenous protein may have a more specific localization, as is the case for both ARAP1 and ARAP2.

There are now commercially available polyclonal antibodies to ARAP3 raised against a carboxy-terminal peptide (1533–1544 amino acids of Human ARAP3). NZ white rabbits were immunized with purified GST-RAP3 fusion protein (residues 1278–1538) to raise ARAP3 polyclonal antibodies (I et al. 2004). An ARAP3 polyclonal antibody (T-16) is available from Santa Cruz Biotechnology, Inc. that can detect ARAP3 by western blot, immunofluorescence, and ELISA. An ARAP3 polyclonal antibody from Abcam can be used in ELISA. There is also a monoclonal ARAP3 antibody from Abnova (CENTD3 monoclonal antibody (MO3), clone ID6), which can be used for in ELISA and western blot assays.

Phenotypes, Splice Variants, and Disease

Two isoforms have been identified: ARAP3 and $ARAP3^{\Delta SAM}$, which does not possess the N-terminal SAM domain (I et al. 2004).

Knockdown of ARAP3 in PAE cells with RNA interference (RNAi) resulted in the alteration of their phenotype, including changes in cell shape with formation of numerous thin actin stress fibers. The ability of PDGF-stimulated PAE cells to produce lamellipodia and their polarizing ability during wound healing was also reduced upon ARAP3 knockdown (Krugmann et al. 2006).

It has been shown that ARAP3 knockout (KO) in the mice results in embryonic death in mid-gestation due to an endothelial cell-dependent defect in sprouting angiogenesis. Moreover, knock-in mice expressing an ARAP3 mutant (point mutation in its N-terminal PH domain) that cannot bind to PtdIns $(3,4,5)P_3$ showed angiogenesis defects comparable to those of the ARAP3 KO mice. These data suggest the involvement of ARAP3 signaling pathway downstream of PI3Kα in the regulation of embryonic angiogenesis (Gambardella et al. 2010).

Using conditional ARAP3 KO mouse model, it has been shown that ARAP3 regulates neutrophil adhesion-dependent processes. Loss of ARAP3 causes preactivation of neutrophil β2 integrins. ARAP3 deficiency has been shown to increase adhesion-dependent cellular functions such as reactive oxygen species (ROS) production, adhesion, spreading, and granule release in neutrophils. Loss of ARAP3 also interferes with integrin-dependent neutrophil chemotaxis. These studies show that ARAP3 regulates β2 intergrin activity, thereby retaining unstimulated neutrophils in their quiescent state (Gambardella et al. 2011).

An increase in the chemokine PAF in type 2 diabetics has been shown to accelerate atherosclerosis. PAF-stimulation enhances monocyte transendothelial migration *via* Rac-1 activation and RhoA inactivation. PAF-stimulated RhoA inactivation is reversed in ARAP3 knockdown monocytes, indicating that ARAP3 is responsible for PAF-mediated RhoA inactivation (Nandy et al. 2010).

ARAP3 has been shown to be expressed in normal fundic gland mucosa; however its expression in poorly differentiated carcinomas is reduced. Overexpression of ARAP3 has been shown to reduce cell-ECM attachment and cell invasion in vitro in the highly metastatic scirrhous gastric carcinoma cell line (58As9 cells). ARAP3 overexpression was also shown to inhibit peritoneal dissemination of 58As9 cells in vivo. Adhesion to and invasion through the ECM are necessary for peritoneal dissemination of scirrhous gastric carcinoma cells. Since ARAP3

regulates both cell-ECM adhesion and invasiveness, it may be a novel therapeutic target for preventing peritoneal dissemination of scirrhous gastric carcinoma (Yagi et al. 2011).

Summary

The subfamily of ARAP proteins includes three members: ARAP1, ARAP2, and ARAP3, which can act as GAPs for both Arf and Rho family small GTPases. ARAP3 was originally identified as a PtdIns(3,4,5)P_3 secondary messenger binding protein in porcine leukocyte cytosol. It consists of a SAM domain, five PH domains, Rho GAP domain and Arf GAP domain, and a RA domain. ARAP3 activity has been shown to be dependent on its N-terminal PH domain binding to PtdIns(3,4,5)P_3. It is largely localized within the cytosol of unstimulated cells and in the F-actin dense membrane ruffles and lamellipodia of some cells. ARAP3 binding to PtdIns(3,4,5)P_3 through the N-terminal PH domain leads to its translocation to the plasma membrane. It has been shown to play a role in the regulation of the actin cytoskeleton, lamellipodia formation, and cell spreading. ARAP3 also inactivates RhoA in response to NGF and bFGF leading to neurite outgrowth from PC12 cells. It has been shown to inhibit peritoneal dissemination of scirrhous gastric carcinoma cells by regulating cell adhesion and invasion. ARAP3 is tyrosine phosphorylated by Src, which negatively regulates its cellular functions. It forms a multimeric protein complex with CIN85/CMS and SH2-containing inositol phosphatase 2 (SHIP2) but the physiological significance of this interaction is not fully understood. ARAP3 interacts with CIN85/CMS through its proline–arginine motif and with SHIP2 using the SAM domain. It also binds to Rap1 through the RA domain. Studies have shown that ARAP3 expression is ubiquitous, albeit uneven with the strongest expression detected in leukocytes and in the spleen. ARAP3 knockdown with RNAi alters cell shape and reduces PDGF-induced lamellipodia formation in fibroblasts and increases RhoA activity in monocytes. Knockout of ARAP3 in mice results in embryonic death in mid-gestation due to defect in sprouting angiogenesis. ARAP3 inducible knockout studies revealed that it regulates chemotaxis and adehesion-dependent processes in neutrophils.

Synonyms

ADP-ribosylation factor; Arf-domain protein; Domain protein; Tripartite motif protein 23

Historical Background

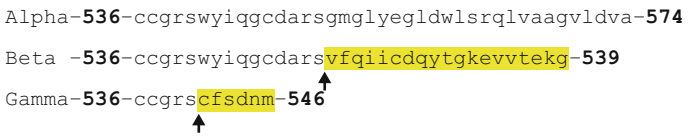
ARD1 was first described in 1993 as the deduced protein product of clones isolated from human and rat genomic cDNA libraries that encoded an about 18-kDa ▶ ADP-ribosylation factor (Arf) sequence at the C-terminus of a 64-kDa molecule (Mishima et al. 1993). Human ARD1 coding region cDNA hybridized with 3.7- and 4.1-kb mRNAs from all rat tissues examined. Both recombinant, full-length ARD1 and its Arf domain (M403-A574), activated cholera toxin ADP-ribosyltransferase activity, at that time a defining characteristic of Arf function, whereas the non-Arf (M1-K402) fragment of ARD1 did not. Using recombinant proteins on nitrocellulose membranes, only the Arf domain (and a recombinant ARF3), not the full-length ARD1, bound radio-labeled GTP (Mishima et al. 1993).

Further investigation of GTPase activity of the same recombinant proteins in solution provided evidence that the N-terminal non-Arf region of ARD1 acted as a GTPase-activating protein (GAP) domain for the Arf moiety (Vitale et al. 1996). Bound GDP dissociated from the Arf domain much more rapidly than it did from the full-length ARD1, but after addition of the non-Arf domain, GDP dissociation was slowed, essentially to that of GDP release from the intact ARD1. Thus, the ARD1 molecule comprises both GDI (GDP-dissociation inhibitor) and GAP domains that can influence biological activity of the Arf domain, although the extent to which these domains regulate its GTPase cycle in cells was not demonstrated.

The first several ARD papers contain more than one comment on its Zn^{2+}-finger structure near the N-terminus, but no mention of a potential E3 ubiquitin ligase activity, which was more widely recognized after ARD1 was described as TRIM23, a protein of the tripartite motif family (Reymond et al. 2001). The TRIM or RBCC structure comprises an N-terminal ring (R) followed by one or two B boxes (B1 and B2 in ARD1) and a predicted coiled-coil (CC) sequence. The B box, apparently found only in this protein family, was suggested as a useful identifier of TRIM molecules. Greatest diversity among TRIM proteins is in regions C-terminal to the CC domains, i.e., the Arf domain in ARD1, where it is compounded by alternative splicing. In addition to the full-length ARD1 initially cloned (Mishima et al. 1993), sequences of two more human ARD1 molecules that differ at the C-terminus (Fig. 1) are reported (Reymond et al. 2001; Venkateswarlu and Wilson 2011).

Regulation of ARD1 Activity

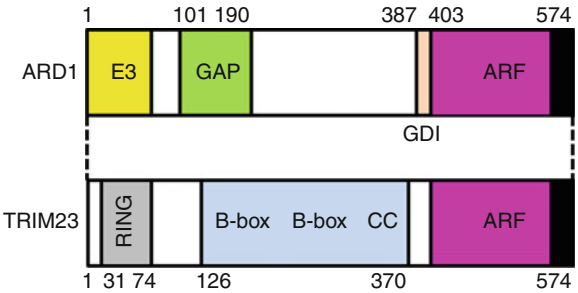
The Arf domain of ARD1 was not a substrate for a partially purified Arf GAP from rat spleen that enhanced GTP hydrolysis by ARFs 1, 3, 5, and 6 as well as Arf-like ARL proteins. Nor did the non-Arf part of ARD1 display GAP activity toward potential substrates other than its own Arf domain



ARD1/TRIM23, Fig. 1 C-terminal sequences of alternatively spliced ARD1α, β, and γ molecules. All three molecules are identical through position 540 in the Arf domain, with identity of α and β through 550. Accession numbers for human ARD1/TRIM23 are: ARD1-alpha (NP_001647), ARD1-beta (NP_150230), and ARD1-gamma (NP_150231)

(Ding et al. 1996). As often cautioned, the extent to which relationships of GAP (and GEF) activities assessed in vitro compare to those in living cells can be difficult to establish.

For more than a decade, limited research on ARD1 treated it simply as an Arf-domain protein of unknown function, even after its E3 ubiquitin ligase activity was described (Vichi et al. 2005). An ARD$^{-/-}$ mouse, generated to provide clues to physiological function(s), has been thus far only a source of murine embryo fibroblasts that proved useful for demonstration of contributions of Arf and E3 ligase actions to the regulation, respectively, of epidermal growth factor receptor (EGFR) degradation and of its own protein level (Meza-Carmen et al. 2011). The recognition of ARD1 as TRIM23, a member of the tripartite motif (TRIM) family of proteins (Reymond et al. 2001), which are critical for rapid innate immune responses to viral infection, introduces what may well be an even more intriguing chapter (Ozato et al. 2008). Relatively recent reports of TRIM23 involvement in NF-kB activation by HCMV (human cytomegalovirus) infection (Poole et al. 2009) and ubiquitination of NEMO (NF-kB essential modulator) catalyzed by TRIM23 (Arimoto et al. 2010) certainly present enormous numbers of intriguing questions to be answered. This entry summarizes, for the most part, findings from the earlier studies that are not yet meaningfully integrated with the important information now emerging. Domain structures as have been described for ARD1 and TRIM23 are aligned in Fig. 2 to facilitate reconciliation of the differently focused publications.



ARD1/TRIM23, Fig. 2 Domain structure of ARD1/TRIM23. The 574-amino-acid molecule contains an E3 ubiquitin ligase ring (*yellow*, E3, ARD1 or *gray*, 31–74, TRIM23) and a C-terminal ARF domain (*pink*, 403–574). At the extreme C-terminus, 34 amino acids (541–574, *black*) are involved in alternative splicing, as shown in Fig. 1. Positions 387–402 act as a GDI for the ARF domain. Intervening positions (126–370, *blue*, in TRIM23) contain B-boxes 1 and 2 plus the C-C region that make this a TRIM protein and overlap specific sequence (*green*) that can inactivate the ARF domain (101–190, GAP). We are grateful for the expert assistance of Dr. Gustavo Pacheco-Rodriguez, who prepared Figs. 1 and 2 and has made important contributions to many ARD1 studies

ARD1: Structure/Function

Structural requirements for functional interaction of the Arf and non-Arf domains of ARD1 were defined in some detail using site-specific mutagenesis and chimeric proteins (Vitale et al. 1997a). Replacement of seven Arf1 amino acids with those in the corresponding positions of the Arf domain in ARD1 enabled it to associate with the non-Arf domain that enhanced its GTPase activity. Further deletion of 15 amino acids from its N-terminus produced an Arf molecule structurally and functionally equivalent to the ARD1 Arf domain. Additional effects of numerous specific amino acid replacements in ARD1 and those of several phospholipids or detergents on interactions and/or activities of the GTP-binding Arf and regulatory non-Arf domains were also reported (Vitale et al. 1997a). Regions in the non-Arf domain responsible for acceleration of GTP hydrolysis by the intrinsic GTPase activity of the Arf domain, plus adjacent sequence necessary to establish the required physical interaction, were also identified. Evidence for interaction of acidic N427 and E428 (plus P432) in the Arf region

with basic R249 and K250 in the non-Arf domain was also obtained as regulated release of bound GDP and control of GTP hydrolysis are equally important for temporal continuity of the Arf domain GTPase cycling.

Structural elements of the ARD1 GDP dissociation-inhibitor (GDI) region were similarly characterized (Vitale et al. 1997b). Although both this action and the enhancement of GTPase catalytic activity involve intramolecular conformational changes, these might well differ in energetic costs and/or the effects on them of environmental changes. Early studies had shown that bound GDPβS was released more slowly from the recombinant Arf domain than from intact ARD1 (Vitale et al. 1996). Experiments with recombinant proteins and/or their fragments more clearly established the discrimination between GDP and GTP ligands. It was further demonstrated that 15 amino acids immediately preceding the Arf domain were responsible for slowing dissociation of GDP, but not GTP, and site-specific mutagenesis revealed importance of the hydrophobic amino acids for stabilization of ARD1-bound GDP (Vitale et al. 1997b). Even as our understanding of structure-function relationships in these actions of the ARD1 molecule continues to improve, their relationships to and integration with ARD1 functions in critical reactions of the innate immune system to viral infection appear to present more new and intriguing questions.

Cellular Localization of ARD1

After multiple attempts to identify endogenous ARD1 at intracellular sites in several tissues, Vitale et al. (1998b) were able to show single protein bands of about 64 kDa using antibodies immunoreactive with different parts of the ARD1 molecule in affinity-purified membranes from human liver presumed representative of lysosome or Golgi structures (Vitale et al. 1998b). Systematic microscopic observations of subcellular distribution of overexpressed EGFP-tagged ARD1 revealed perinuclear fluorescence consistent with Golgi localization in <5% of cells after 4 h, but present in almost 20% by 6 h and approaching 60% after 10 h. At the same time, fluorescence in widely dispersed vesicular structures, apparently lysosomes, was recorded in only <5% at 6 h and 40% of cells at 10 h. Between 12 and 50 h, both vesicular and perinuclear fluorescence was seen in about 60% of cells, suggesting the possibility of ARD1 cycling between Golgi and lysosomal organelles (Vitale et al. 1998b).

In attempts to identify appropriate localization signals in the ARD1 molecule, intracellular distribution of >20 overexpressed ARD1 fragments was evaluated microscopically with particular attention to YXXL motifs in the Arf domain thought to be potentially responsible for Golgi localization (Vitale et al. 2000b). Selective mutation of one or both of the sequences indicated that each could contribute to ARD1 presence in Golgi and that to reach the lysosomes, passage of ARD1 through the Golgi was required. A pentapeptide sequence, KFERQ, had been implicated as a targeting signal for lysosomes. Mutagenesis in 344KTLQQ348 and 369KQQQQ373 sequences of the non-Arf region of ARD1 demonstrated that the latter was critical for lysosomal localization (Vitale et al. 2000a).

ARD1: E3 Ubiquitin Ligase Activity and Arf Domain Function

E3 ubiquitin ligase activity of GST-ARD1 or its RING finger domain (residues 1–110) was demonstrated in vitro using the recombinant proteins plus pure mammalian E1, E2 (usually UbcH6), ATP, and ubiquitin (Vichi et al. 2005). Activity was abolished by deletion or mutation of the ARD1 ring structure. Like activities of the Arf and GAP domains, that of the E3 ligase was apparently independent of the rest of the molecule and was unaffected by addition of GTPγ*S* or GDP. Whether that is true also in the intracellular environment is not known. Although the ubiquitinated proteins failed to react with ARD1 antibodies, their increasing amounts and size during assays were paralleled by decreasing amounts of free ARD1 protein, consistent with auto-ubiquitination. Three bands of modified UbcH6 (E2) did react with UbcH6 antibodies as well as with those against ubiquitin (Vichi et al. 2005). Later studies of $ARD1^{-/-}$ mouse embryo fibroblasts stably expressing constructs for induced synthesis of ARD1 or a (C34A, H53A) mutant lacking E3 ligase activity supported the conclusion that auto-ubiquitination regulated ARD1 degradation and was responsible for maintaining its concentration at very low levels in all cells studied (Meza-Carmen et al. 2011). Mutant ARD1 without

E3 ligase activity accumulated in cells incubated with proteasomal inhibitors to levels sevenfold those usually seen.

Cytohesin-1 had been shown earlier to be a specific guanine nucleotide-exchange factor (GEF) activator for ARD1 (Vitale et al. 2000b). Since cytohesin-1 (and other cytohesins) had been reported to modify receptor tyrosine kinase action, effects of ARD1 or its mutants on EFGR were explored (Meza-Carmen et al. 2011). There was no evidence of E3 ligase involvement, but Arf domain function was clearly important. Actions in vesicular trafficking are probably the most extensively studied of all Arf functions. These require continuity of Arf cycling between inactive GDP-bound and active GTP-bound states. Overexpression of mutants with single amino acid replacements that abolish GTP binding (T418N), thereby blocking activation, or prevent GTP hydrolysis (K458I) both interrupt cyclic activation/inactivation, causing accumulation, respectively, of GDP or GDP-liganded proteins (thus referred to as ARD1-GDP or ARD1-GTP mutants). Amounts of EGFR were higher in ARD1-GDP and lower in ARD1-GTP cells than in those expressing wild-type (WT) ARD1 with a functional Arf domain, and without significant differences in RNA levels (Meza-Carmen et al. 2011). All findings were consistent with the conclusion that relatively rapid EGFR turnover enables more facile control of receptor protein levels and functions than would alterations in gene expression and necessary subsequent protein adjustments. Regardless of total levels, about 80% of the EGFR was on the cell surface. It was notable also that in ARD1-GDP and –GTP cells differences in total amounts of TGFβR III and insulin receptor (IR) were similar to those of EGFR, although the limited IR data did not reach statistical significance (Meza-Carmen et al. 2011). Potential functions of ARD1 in the regulation of these (and perhaps other) growth factor receptors, via internalization, signaling, and/or degradation, should be of considerable interest and importance.

ARD1: Action/Function as TRIM23

Description of TRIM 23 as a member of the TRIM protein family provided new perspective on ARD1 action (Reymond et al. 2001). Activation of transcription with induction of type I interferon production is critical for initiation of innate immune responses. Association of TRIM 23 (ARD1) with HCMV (human cytomegalovirus)-encoded protein UL144, which was known to activate NF-kB, was first recognized in a yeast two-hybrid screen undertaken to identify UL144-interacting proteins in human cells (Poole et al. 2009). Involvement of tumor necrosis factor receptor (TNFR)-associated factor 6 (▶ TRAF6) and/or TAK1 in HCMV-induced NF-kB activation was known, but the screen revealed no evidence of their direct interaction with the viral UL144 protein. Then, interaction of UL144 with TRIM23 was found and confirmed, showing direct interaction of the UL144 C-terminal Zn-finger with the TRIM23 N-terminal Zn-finger region. To verify those findings, tagged UL144, TRIM23, and TRAF6 or fragments thereof were overexpressed in human fibroblasts. All experimental data supported the conclusion that TRIM23 was required for NF-kB activation by UL144 (but not for its activation by TNF or dsRNA). TRIM23 was necessary for ubiquitination also of TRAF6, but it did not catalyze the modification (using ubiquitin lysine 63, not lysine 48 for both) that resulted evidently from TRAF6 auto-ubiquitination (Poole et al. 2009).

Rapid induction of the type I interferon response by viral infection is critical for an innate immune reaction. Involvement of several E3 ubiquitin ligases and their substrates provides complex feedback controls for the potentially harmful inflammatory reactions that result. To clarify some of these regulatory relationships, Arimoto et al. (2010) looked for effects of overexpression of one of the ligases, RNF-125, on gene expression and found a dramatic increase of >200% in TRIM23 mRNA. Exploration of TRIM 23 function revealed that it increased expression of an NF-kB-driven reporter gene in a NF-kB essential modulator (NEMO)-dependent manner. Direct interaction of the TRIM23 Arf domain with CC1 and LZ domains, which contain the sites of NEMO ubiquitination (via lysine 27), was demonstrated (Arimoto et al. 2010). Information regarding the role of UbcH5 as an E2 enzyme for TRIM23 ubiquitination of NEMO was notable, particularly perhaps the enhanced association of UbcH5 with NEMO after virus infection and the decreased NEMO ubiquitination by TRIM23 in UbcH5-depleted cells. Behavior of the alternatively spliced TRIM23 molecules (Venkateswarlu and Wilson 2011) in these interactions will surely be of interest, as an Arf domain contribution to intracellular trafficking might facilitate innate immune responses.

Summary

ARD1 was cloned because of its C-terminal Arf sequence (which lacks the first nine Arf amino acids). Initial investigation of the predicted 64-kDa protein was directed toward understanding how the Arf domain interacted with the non-Arf remainder of the molecule to accelerate hydrolysis of bound GTP using separately synthesized recombinant protein fragments. The region of the ARD1 molecule that serves as a GAP to terminate activation of the Arf moiety, including adjacent residues required for its functional interaction with Arf structure, appears to overlap B-box and C-C sequences of the TRIM23 molecule (Fig. 2). GDI action of 17 amino acids immediately N-terminal to the Arf domain mimics behavior of the N-terminal amphipathic α-helix of an Arf molecule that would precede the sequence designated Arf domain at ARD1 position 403 (Fig. 2). Both ARD1 and TRIM23 sequences assign E3 ubiquitin ligase actions to the same novel RING structure near the N-terminus. Generation of $ARD^{-/-}$ mouse embryo fibroblasts stably transfected with constructs for inducible expression of wild type or specifically mutated ARD1 molecules enabled demonstration that degradation of endogenous EGF receptor (EGFR) required continuity of the ARD1 GDP/GTP cycle. Cell content of TRIM23 was apparently maintained at low levels by auto-ubiquitination, with no TRIM23 contribution to EGFR ubiquitination. For auto-polyubiquitination of ARD1 in vitro with purified proteins, UbcH5a, 5b, 5c, and UbcH6 had been effective as E2 enzymes. UbcH5 was also involved in TRIM23 ubiquitination of NEMO. These and related findings may be a preview of the importance of only recently recognized antiviral actions of TRIM23.

Historical Background

ArfGAP1 is a 415 aa soluble protein that reversibly interacts with the Golgi apparatus (Cukierman et al. 1995). Originally isolated from rat liver cytosol (Makler et al. 1995), it is the founding member of the ArfGAP family of proteins, all characterized by a conserved catalytic domain containing a zinc finger model whose structure was solved by Goldberg (1999).

The substrate of ArfGAP1, Arf1, is a key regulator of the COPI system that mediates vesicular transport in the ER–Golgi shuttle. Upon GDP to GDP exchange, Arf1 associates with the Golgi membrane and recruits the heptameric COPI coat (coatomer), which in turn sorts cargo proteins and polymerizes to form the coat cage surrounding the vesicle. The subsequent hydrolysis of Arf-bound GTP is required for the release of coatomer from the membrane, a prerequisite for vesicle fusion. This reaction requires the action of a GAP. ArfGAP1 was the first Arf-directed GTPase-activating protein purified and cloned. Thirty one ArfGAP proteins are currently known in human, three of which – ArfGAP1, 2, and 3 – are thought to regulate COPI-mediated transport though the Golgi. Silencing of ArfGAP1 or a combination of ArfGAP2 and ArfGAP3 in HeLa cells does not decrease cell viability; however, silencing all three ArfGAPs causes cell death. In yeast, two ArfGAPs –GCS1, the orthologue of ArfGAP1, and Glo3, the orthologue of mammalian ArfGAP2/3 – have been implicated in COPI-mediated transport and were shown to function as an essential pair (Poon et al. 1999).

Function of ArfGAP1

Most published data implicate ArfGAP1 as a regulator of the COPI system. However, various and sometimes conflicting reports exist on the role of ArfGAP1 in the biogenesis and consumption COPI vesicles.

First indication for a role of ArfGAP1 in deactivation of Arf1 at the Golgi was provided by the finding that overexpression of ArfGAP1 in cells results in redistribution of the Golgi and its fusion with the ER (Huber et al. 1998), an effect that was known before to result from the deactivation of Arf1 by the drug brefeldin-A.

Reconstitution of COPI vesicles from Golgi membranes revealed that blocking GTP hydrolysis by the use of GTPγS (Serafini et al. 1991) or an activating mutant of Arf1 (Tanigawa et al. 1993) lead to the production of vesicles that cannot uncoat. These findings lead to the prediction that ArfGAP activity should trigger coatomer release from membranes. Subsequent studies, however, suggested that GTP hydrolysis on Arf1 is required for efficient uptake of cargo into vesicles (Lanoix et al. 1999; Nickel et al. 1998; Pepperkok et al. 2000), implying that GAP activity may also promote cargo sorting that occurs during vesicle formation. Lee et al. (2005) presented evidences for a role of ArfGAP1 in regulating the binding of coatomer to cargo proteins, indicating a direct role of ArfGAP1 in regulating cargo sorting. This study further demonstrated a requirement of

ArfGAP1 catalytic activity for vesicle formation from Golgi membranes suggesting that ArfGAP1 plays a central role in coupling cargo sorting and vesicle formation. An additional function of ArfGAP1 in the vesicle fission was also proposed (Kartberg et al. 2010; Yang et al. 2006). Finally, ArfGAP1 has been shown to be involved in the regulation of asymmetric tethering between flat and curved membrane mediated by the Arf1 effector, GMAP210 (Drin et al. 2008).

Regulation of ArfGAP1 Activity

Experiments in vitro have suggested two mechanisms for the regulation of ArfGAP1 activity: stimulation by the COPI coat and by regulated recruitment to membranes.

The first mechanism concerning the role of coatomer was first described by Goldberg (Goldberg 1999). Using the catalytic domain of ArfGAP1 and a truncated Arf1 lacking the first 17 residues that can be loaded with GTP in the absence of lipids or detergents, Goldberg reported that the activity of the ArfGAP1 can be stimulated by up to 1,000-fold by coatomer. In contrast, investigating ArfGAP1 catalytic activity in liposomal system (Szafer et al. 2000) or on Golgi membranes (Szafer et al. 2001) using myristoylated membrane-bound Arf1 revealed only moderate or no stimulation by the addition of coatomer, respectively. Examination of the enzymology of ArfGAP1 suggested that coatomer allosterically regulates ArfGAP1 activity, affecting the affinity of ArfGAP1 for Arf-GTP but not the catalytic rate constant. These results further support the idea that coatomer has a regulatory role on the activity of ArfGAP1 (Luo and Randazzo 2008).

The second mechanism concerns the role of lipids. Although there is no evidence for direct interaction of ArfGAP1 with specific lipids, binding of ArfGAP1 to membranes results in increase in GAP activity by bringing it into proximity with its membrane-bound substrate, Arf1-GTP. The binding of ArfGAP1 to liposomes and its catalytic activity are both increased by chemical or physical conditions that create open spaces in the outer leaflet of the membrane bilayer such as the presence of diacylglycerols, phospholipids containing monounsaturated fatty acids (Antonny et al. 1997; Bigay et al. 2005), and high membrane curvature. Curvature-dependent activity of ArfGAP1 in vitro is of particular interest as it offers a mechanism that may be employed in vivo to ensure efficient targeting of ArfGAP1 to coated vesicles and/or to the highly curved rim of the Golgi cisternae where budding of COPI vesicles takes place. Bigay et al. (2005) have identified a motif in the center of ArfGAP1 that mediates the interaction with loosely packed lipids. This domain, termed ALPS (for ArfGAP1 lipid packing sensor) is unstructured in solution but in the presence of loosely packed lipids, hydrophobic residues in ALPS are inserted between lipid residues and ALPS folds into an amphipathic helix with serine/threonine residues forming the hydrophilic face. A function for ALPS–lipid interaction in vivo is suggested by the findings that the hydrophobic residues in ALPS are required for the interaction of ArfGAP1 with the Golgi apparatus (Parnis et al. 2006). In subsequent studies a second amphipathic motif – ALPS2 – with similar physicochemical characteristics was identified in ArfGAP1 (Levi et al. 2008; Mesmin et al. 2007). The two amphipathic motifs are separated by a short break and function cooperatively conferring liposome interaction and Golgi localization of ArfGAP1.

Summary

Mounting evidence implicates ArfGAP1 as critical regulator of the COPI system, yet its precise role has remained uncertain, with suggested functions ranging from an uncoating factor to an essential coat component required for cargo sorting and vesicle formation. While most studies have focused on the role of ArfGAP1 in the COPI system, ArfGAP1 also interacts with components of clathrin-coated carriers (including clathrin, AP-1, and AP-2), although the functional consequences of these interactions remains to be established.

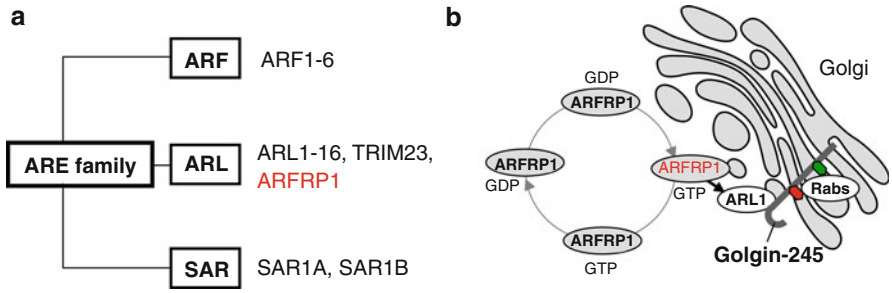
ARFRP1 (ADP-Ribosylation Factor Related Protein 1)

Deike Hesse, Alexander Jaschke and Annette Schürmann
Department of Experimental Diabetology, German Institute of Human Nutrition Potsdam-Rehbrücke, Nuthetal, Germany

Historical Background

Due to the remote similarity of the ADP-ribosylation factor related protein 1 (ARFRP1) to other members of the ARF family, it was designated as a distant ARF family member (Fig. 1a). Discovered by the screening of adipocytes with degenerated primers for ARF proteins, ARFRP1 was shown to be highly conserved among species (97% identical amino acids between rat and human, 79% identical to *Saccharomyces cerevisiae*, and 74% identical to *Drosophila melanogaster*) and closest related to ARL1 (33% identical) and ARL3 (39% identical) (Schürmann et al. 1995, 1999). In comparison to the membrane association motif of other members of the ARF family (myristoylation), membrane association of ARFRP1 is mediated by acetylation of the initial methionine and interaction with an integral membrane protein Sys1 (Behnia et al. 2004;



ARFRP1 (ADP-Ribosylation Factor Related Protein 1), Fig. 1 ARFRP1, a member of the ARF family is recruited to the *trans*-Golgi upon its activation. (**a**) The ARF family of small GTPases consists of ARF, ARF-like (ARL), and SAR proteins (Kahn et al. 2006). (**b**) Inactive, GDP-bound ARFRP1 is located in the cytosol, active, GTP-bound ARFRP1 associates with membranes of the *trans*-Golgi. Active ARFRP1 initiates recruitment of ARL1 and its effector Golgin-245 to this compartment (Zahn et al. 2006)

Setty et al. 2003). The *Arfrp1* gene consists of eight exons and is located on distal mouse chromosome 2 (human chromosome 20) with the transcriptional start codon in exon 2 (Mueller et al. 2002a). The gene product, ARFRP1, is a 25 kDa protein with a ubiquitous expression pattern and an intrinsic GTPase activity (Schürmann et al. 1995). In contrast, guanine nucleotide exchange is relatively slow in an in vitro system suggesting the existence of a so-far unidentified GEF (guanine nucleotide exchange factor) for ARFRP1 to act as a fast GTP-dependent molecular switch (Schürmann et al. 1995).

Molecular Function of ARFRP1

In the active GTP-bound form ARFRP1 is located at the *trans*-Golgi (Fig. 1b) (Zahn et al. 2006). The yeast homologue of ARFRP1, Arl3p, acts sequentially to recruit golgin proteins to the Golgi membranes. In yeast, Arl3p brings Arl1p, the yeast homolog of ARL1, to the Golgi apparatus which is then responsible for the recruitment of the yeast golgin Imh1p (Panic et al. 2003; Setty et al. 2003). Golgins are conserved proteins found in different parts of the Golgi stack, and they are typically anchored to the membrane at their carboxyl termini by a transmembrane domain or by binding a small GTPase (Rab and ARL1). They appear to have roles in membrane traffic and Golgi structure, but their precise function is in most cases unclear (Munro 2011). In cell culture as well as in murine embryos, ARFRP1 controls the targeting of ARL1 and its effector Golgin-245 to the *trans*-Golgi (Fig. 1b) (Zahn et al. 2006, 2008). Upon inhibition of the expression of *Arfrp1* in cells or deletion of *Arfrp1* in mice, the *trans*-Golgi structure appeared altered as several *trans*-Golgi markers (TGN38, ARL1, Syntaxin6, Golgin-245) showed a different distribution pattern or a dissociation from the Golgi membranes (Hommel et al. 2010; Zahn et al. 2006, 2008). However, other Golgi proteins located in the *cis*- and *medial*-region of the Golgi apparatus (giantin, GM130, 58 k) seemed less affected by the lack of ARFRP1 (Hommel et al. 2010; Zahn et al. 2006, 2008).

In mammalian cells, ARFRP1 seems to inhibit ARF1-regulated pathways such as the activation of phospholipase D (PLD) (Schürmann et al. 1999). ARFRP1 binds the Sec7 domain of the ARF-specific nucleotide exchange factor cytohesin in a GTP-dependent manner. This interaction does not modify the activity of ARFRP1 but results in the inhibition of the ARF/Sec7-dependent activation of PLD in a system of isolated membranes and in HEK-293 cells transfected with a constitutively active mutant of ARFRP1 (Schürmann et al. 1999).

Knockout Models Explaining the Physiological Role of ARFRP1

In order to characterize the function of ARFRP1 in a mammalian organism, its gene was disrupted by gene-targeting approaches. Homozygosity for the conventional transgene causes embryonic lethality, whereas tissue-specific deletion of *Arfrp1* resulted in growth retardation according to lipid and glycogen storage defects.

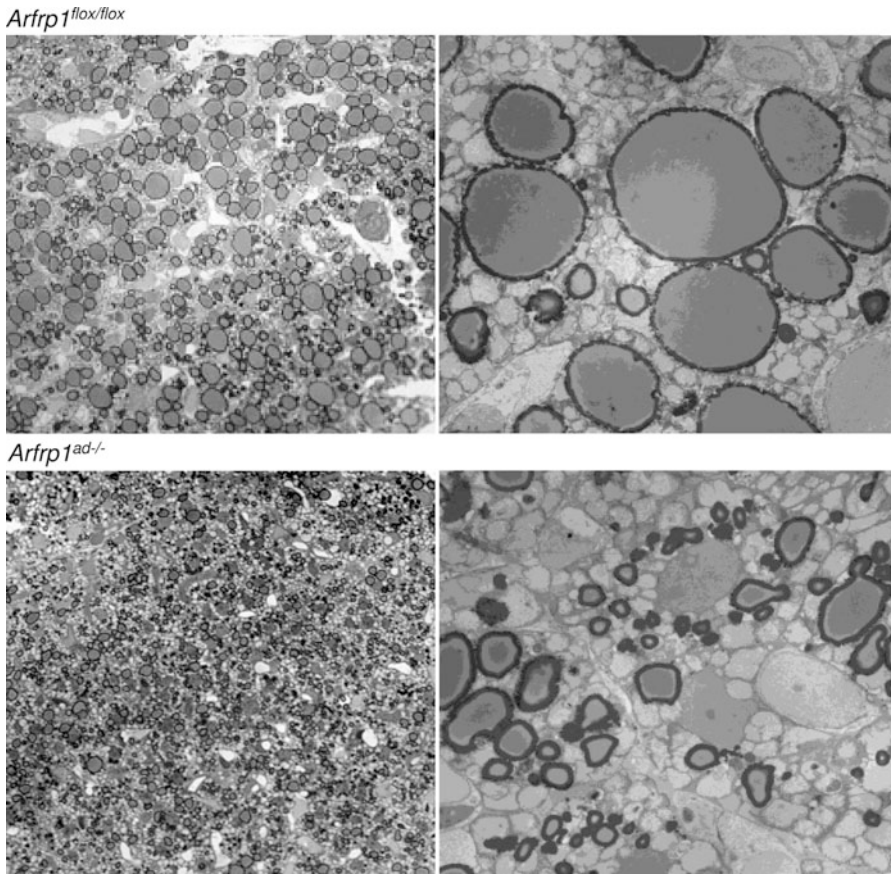
Adhesion Defects Responsible for Embryonic Lethality of Conventional *Arfrp1* Knockout Mice

Mueller et al. (2002b) showed that ARFRP1 is already important during early embryogenesis. The amount of *Arfrp1* mRNA was detectable from embryonic day 4.5 and increases during gastrulation and neurulation (Mueller et al. 2002b). The conventional deletion of *Arfrp1* in the mouse results in embryonic lethality during early gastrulation (Mueller et al. 2002b). *Arfrp1*-null mutant embryos seemed normal until embryonic day 5, but exhibited profound alterations of the distal part of the egg cylinder at day 6–6.5 due to a cell-adhesion defect (Mueller et al. 2002b; Zahn et al. 2008). Further investigations revealed that embryonic cells showed a mistargeting of E-cadherin to intracellular membranes which prevented epiblast cells to undergo an epithelial-to-mesenchymal transition, and resulted in a failure of mesoderm development (Mueller et al. 2002b; Zahn et al. 2008). This finding was confirmed in studies performed in intestinal epithelium of mice lacking *Arfrp1* specifically in the intestine (see below). Here retention of E-cadherin in intracellular membranes was observed, it was co-localized with a *cis*-Golgi marker (GM130) in epithelial intestinal cells. Moreover, a direct interaction of ARFRP1 with the E-cadherin/catenin complex was demonstrated by co-immunoprecipitation experiments (Zahn et al. 2008) indicating that ARFRP1 is essential for the correct trafficking of E-cadherin through the Golgi and finally for the correct cell surface localization of the E-cadherin complex.

Adipocyte-Specific Deletion of *Arfrp1* Resulting in Lipodystrophy and Reduced Survival

ARFRP1 is highly expressed in the adipose tissue of mice (Schürmann et al. 1995). Adipocyte-specific *Arfrp1*-deleted mice ($Arfrp1^{ad-/-}$) were generated with the Cre/loxP recombination system using the *Fatp4*/*aP2* promoter (He et al. 2003). Animals were born viable according to the expected Mendelian distribution but exhibited a markedly reduced survival with a mortality rate of 70% until weaning (Hommel et al. 2010). In addition, $Arfrp1^{ad-/-}$ mice showed a postnatal growth retardation accompanied by a reduced surface body temperature which presumably is responsible for the impaired survival. The most obvious phenotype of the $Arfrp1^{ad-/-}$ mice was a pronounced lipodystrophy indicated by the lack of subcutaneous and gonadal white adipose tissue depots as well as a significantly reduced amount of brown adipose tissue and an early hepatosteatosis. Oil-Red-O staining of brown adipose tissues of $Arfrp1^{ad-/-}$ and control littermates indicated an altered lipid storage associated with smaller lipid droplets in the brown fat cells (Hommel et al. 2010). One reason for the impaired lipid storage of $Arfrp1^{ad-/-}$ mice was shown to be a stimulation of lipolysis. The amount of phosphorylated hormone-sensitive lipase (HSL) was elevated, and the association of adipocyte triglyceride lipase (ATGL) with lipid droplets was enhanced in brown adipose tissue of $Arfrp1^{ad-/-}$ mice indicating that lipolysis was activated. In fact, siRNA-induced knockdown of *Arfrp1* in 3T3-L1 adipocytes increased basal lipolysis. A second cause for smaller lipid droplets in adipocytes lacking ARFRP1 was affiliated to a defective lipid droplet fusion. Electron microscopy showed that lipid droplets exhibited ultrastructural alterations such as a disturbed interaction of small lipid-loaded particles with larger lipid droplets (Fig. 2). The SNARE (soluble N-ethylmaleimide-sensitive-factor attachment receptor) protein SNAP23 (synaptosomal-associated protein) which is described to be involved in lipid droplet fusion (Boström et al. 2007) was predominantly located in the cytosol and plasma membrane in brown adipose tissue of $Arfrp1^{ad-/-}$ mice, whereas it was associated with small lipid droplets in controls. This suggested that ARFRP1 mediates lipid droplet growth via sorting of SNAP23. Thus, disruption of ARFRP1 in the adipose tissue led to a lipodystrophic phenotype by activating lipolysis and preventing the normal enlargement of lipid droplets via fusion events.

Since SNARE proteins (VAMP2, syntaxin-4, and SNAP23) have been implicated in the insulin-induced translocation of vesicles containing the glucose transporter GLUT4 to the plasma membrane of adipocytes (Hickson et al. 2000; Kawanishi et al. 2000; Bryant et al. 2002), subcellular distribution of GLUT4 in $Arfrp1^{ad-/-}$ adipocytes was studied. GLUT4 accumulated at the plasma membrane rather than being sequestered into an intracellular insulin-sensitive compartment as in control adipocytes (Fig. 3) (Hesse et al. 2010). A similar missorting of GLUT4 was produced



ARFRP1 (ADP-Ribosylation Factor Related Protein 1), Fig. 2 In the absence of *Arfrp1* in adipose tissues, the lipid droplets are much smaller as indicated in the ultrastructural analysis performed by electron microscopy (Hommel et al. 2010)

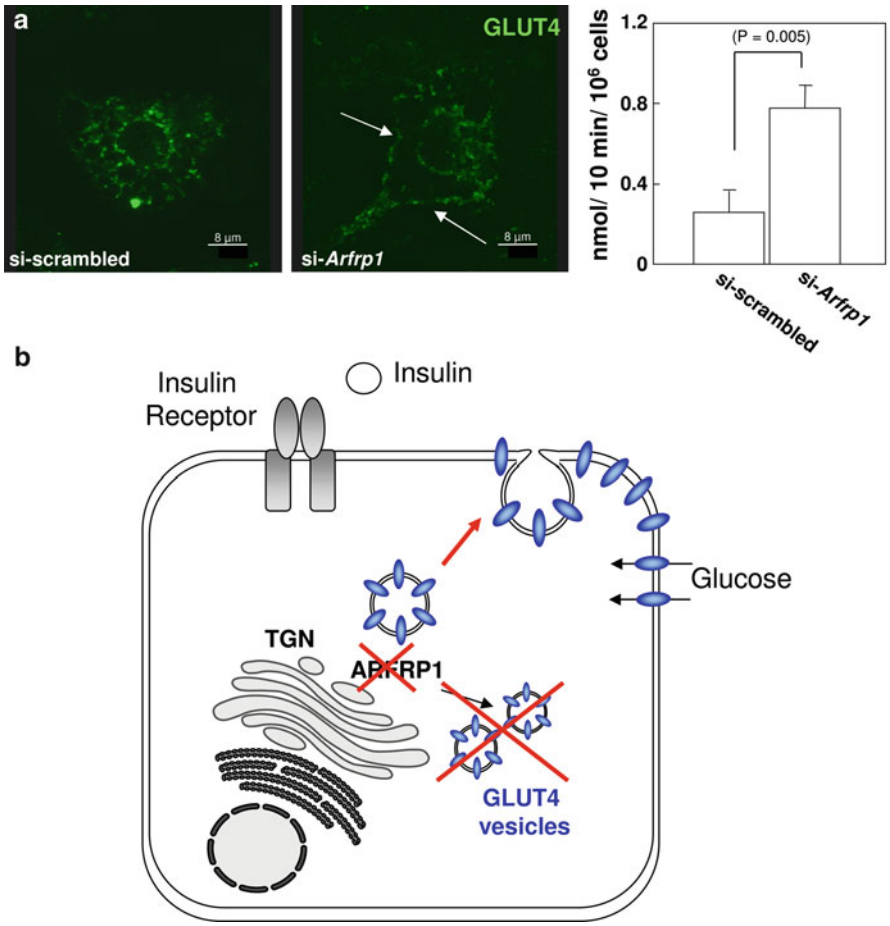
by siRNA-mediated knockdown of *Arfrp1* in 3T3-L1 adipocytes which led to a significantly elevated glucose transport. Thus, ARFRP1 appears to be involved in the sorting of GLUT4.

Deletion of *Arfrp1* in the Intestine Resulting in Fat Malabsorption

Conditional deletion of *Arfrp1* in the intestinal epithelium of mice ($Arfrp1^{vil-/-}$), as achieved by crossing $Arfrp1^{flox/flox}$ mice with transgenic mice expressing the Cre-recombinase under the villin promoter, resulted in an early postnatal growth retardation according to an impaired maturation and lipidation of chylomicrons (Jaschke et al., in revision).

$Arfrp^{vil-/-}$ mice revealed decreased levels of triglyceride and free fatty acid concentrations in the plasma, indicating that their growth retardation is the consequence of a malabsorption. Actually, lipid uptake elucidated by oral fat tolerance tests was impaired in $Arfrp1^{vil-/-}$ mice but fatty acids transport into the intestinal epithelium was normal and $Arfrp1^{vil-/-}$ mice accumulated lipid droplets in epithelial cells after an oil bolus. However, the release of resynthesized triglycerides was massively decreased, the apolipoprotein ApoA-I accumulated in the $Arfrp1^{vil-/-}$ epithelium, whereas its level in the plasma was reduced (Jaschke et al., in revision).

As stated above, ARFRP1 is required for recruitment of ARL1 and its effector, the golgin protein Golgin-245, to *trans*-Golgi membranes. Since several Rab proteins – involved in the regulation of vesicular trafficking – interact with Golgin-245, their subcellular distribution was studied in the $Arfrp1^{vil-/-}$ epithelium. Indeed Rab2 revealed a modified distribution in $Arfrp1^{vil-/-}$ epithelial cells as compared with $Arfrp1^{flox/flox}$ cells. Whereas Rab2 was predominantly located in the cytosol and only partially associated with membranes of the Golgi in control cells, it was mainly detected at large vesicular structures adjacent to the nuclei and co-localized with ApoA-I in



ARFRP1 (ADP-Ribosylation Factor Related Protein 1), Fig. 3 Downregulation of *Arfrp1* by siRNA results in a direct translocation of the glucose transporter GLUT4 to the cell surface without stimulation with insulin. (**a**) Immunocytochemical staining of GLUT4 in 3T3-L1 adipocytes that were transfected with scrambled or *Arfrp1*-specific siRNA (*left panel*). Glucose transport as detected by deoxyglucose uptake was significantly elevated in 3T3-L1 cells depleted for *Arfrp1* (*right panel*). (**b**) Predicted model of how GLUT4 vesicles are mistargeted to the plasma membrane in the basal unstimulated state when ARFRP1 is deleted (Hesse et al. 2010)

Arfrp1$^{vil-/-}$ cells (Fig. 4). These data indicated that an ARFRP1-ARL1-golgin-Rab2 cascade is required for intestinal chylomicron maturation in the Golgi.

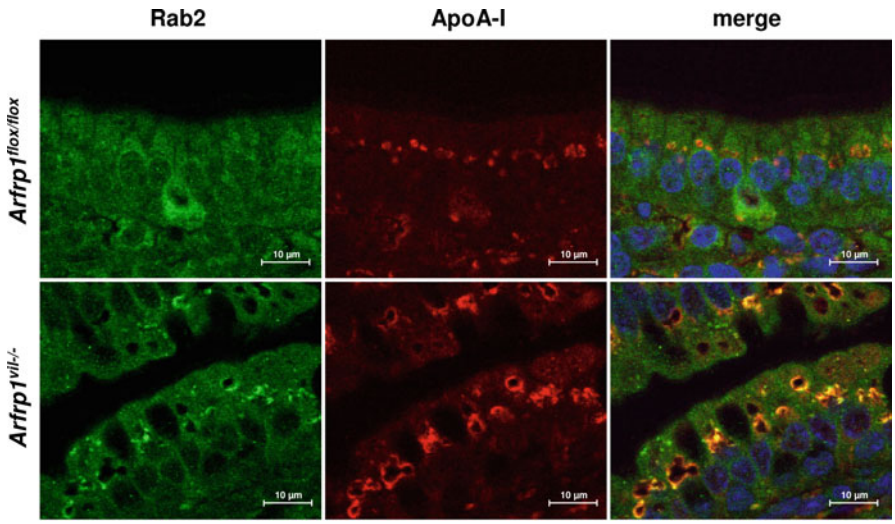
Deletion of *Arfrp1* in the Liver Impairing Glycogen Storage

The liver-specific deletion of *Arfrp1* resulted in a postnatal growth retardation accompanied by a significantly lower absolute and relative liver weight. The discrepancy between liver and body weight observed in *Arfrp1*$^{liv-/-}$ mice could at least partly be explained by the reduced glycogen storage which was reduced by 50% in knockout mice. This effect was referred to a reduced glucose uptake into the liver.

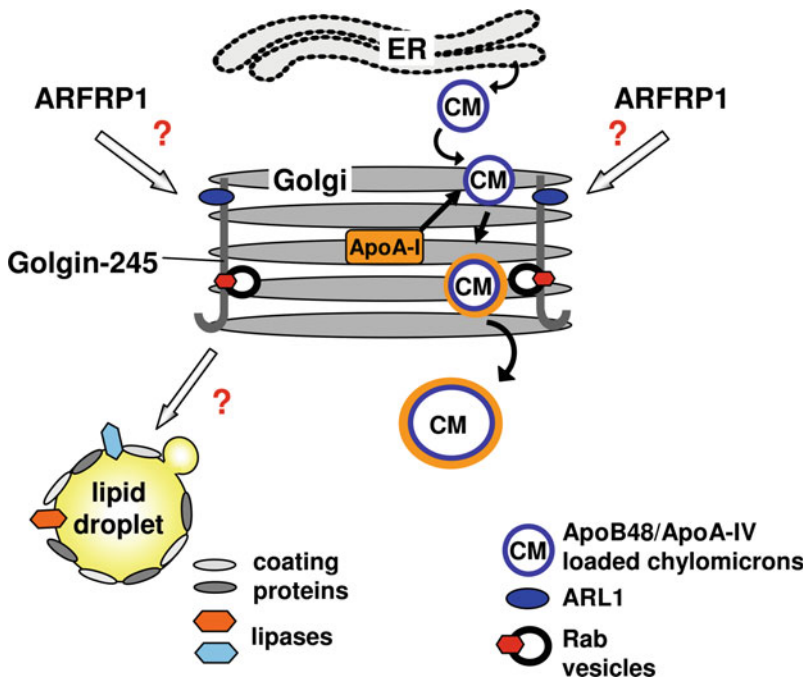
Immunohistochemical staining of the glucose transporter GLUT2 revealed a reduction of GLUT2 in the plasma membrane of *Arfrp1*$^{liv-/-}$ hepatocytes. In addition, total GLUT2 protein in lysates from livers of *Arfrp1*$^{liv-/-}$ mice was much lower compared to the controls. As the quantification of mRNA levels (*Slc2a2*) showed no alteration between the genotypes, it was speculated that a mistargeting of GLUT2 results in an advanced degradation of this transporter (Hesse et al., manuscript in preparation).

Suppression of ARFRP1 Expression in the Brain by Sleep Deprivation

ARFRP1 is not only expressed in peripheral tissues, it also shows a widespread distribution in the brain (Paratore et al. 2008). Highest expression levels of mRNA were determined by in situ hybridization and real-time PCR in the cerebral cortex, thalamic nuclei, colliculus, substantia nigra, and the granule cellular layer of the cerebellum. These brain areas show high



ARFRP1 (ADP-Ribosylation Factor Related Protein 1), Fig. 4 Co-localization of Rab2 with ApoA-I and its accumulation at Golgi membranes of intestinal *Arfrp1*$^{vil-/-}$ cells. Immunohistochemical detection of Rab2 (*left panels*), ApoA-I (*middle panels*), and the merged picture (*right panels*) in sections of the small intestine of 4-weeks old *Arfrp1*$^{flox/flox}$ and *Arfrp1*$^{vil-/-}$ mice that had free access to their diet



ARFRP1 (ADP-Ribosylation Factor Related Protein 1), Fig. 5 Proposed model of ARFRP1 action on lipid droplet formation and chylomicron maturation. ARFRP1 is necessary to recruit ARL1 to the Golgi, ARL1 binds to the scaffolding protein Golgin-245 which itself interacts with Rab proteins. *Left* part of the cartoon indicates that ARFRP1 is required for lipid droplet fusion and the regulation of lipases. *Right* part of the cartoon demonstrates the chylomicron formation in ER and Golgi. In the ER resynthesized triacylglycerol (TAG) is incorporated into ApoB48-containing pre-chylomicrons. Subsequently, ApoA-IV binds to the pre-chylomicrons which are then released to the *cis*-Golgi. ApoA-I is attached to the chylomicrons within the Golgi. ApoA-I loaded chylomicrons are then transported through the Golgi, released on the *trans*-site, and finally secreted into the lymph. Therefore, it is proposed that the ARFRP1-ARL1-golgin-Rab cascade is needed for an appropriate chylomicron assembly of ApoA-I and its transport through the Golgi

levels of neurotransmitter release, synaptic remodeling, and neuronal plasticity and therefore require extensive synaptic vesicle trafficking. Sleep deprivation alters the expression of genes involved in neuronal plasticity and synapse-related genes. In cerebral cortex the expression of *Arfrp1* was markedly reduced after sleep deprivation which could represent an adaptive response to the associated stress. Moderate levels of *Arfrp1* were detected in some amygdaloid nuclei, CA2 area, and dentate gyrus of the hippocampus, endopiriform nuclei, globus pallidus, striatum, molecular layer of cerebellum, and locus coeruleus. No expression of *Arfrp1* was observed in hypothalamic nuclei, CA1 and CA3 areas of the hippocampus and zona incerta.

Summary

ARFRP1 is a member of the family of ADP-ribosylation factors (ARFs) of GTPases which play a pivotal role in the regulation of membrane traffic. Activated, GTP-bound ARFRP1 associates with *trans*-Golgi membranes, and is required for the recruitment of ARF-like 1 (ARL1) and its effectors, specific golgin proteins to the *trans*-Golgi. ARFRP1 is essential for the correct targeting of several proteins (E-cadherin, GLUT4, GLUT2) but is also needed for the normal growth of lipid droplets (in adipose tissues) and the maturation of chylomicrons (in the small intestine) (Fig. 5). However, it is still not known how ARFRP1 is regulated, since no ARFRP1-specific GEF or GAP (GTPase-activating proteins) have been discovered so far. In addition, we did not solve the particular molecular action of ARFRP1 at the Golgi, how it initiates the ARL1-golgin-Rab cascade, and how this cascade finally modulates protein targeting, and lipid droplet and chylomicron maturation.

Synonyms

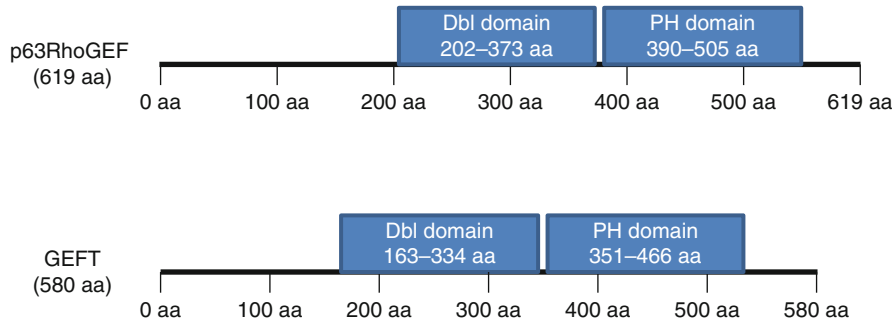
GEFT, p63RhoGEF; Rho Guanine Nucleotide Exchange Factor 25

Historical Background

The gene for ARHGEF25 is located on human chromosome 12q13.3, and its expression encodes a Rho-family guanine nucleotide exchange factor (GEF) protein composed of a Dbl homology domain and a pleckstrin homology domain flanked by short N- and C-termini (Souchet et al. 2002; Guo et al. 2003). ARHGEF25 belongs to a family composed of over 60 known human GEFs. This family of proteins serves as enzymes which catalyze the activation of the Rho family of small GTPases through stimulating the exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on Rho proteins, thus modulating a broad range of cellular processes in eukaryotic cells such as cell proliferation, gene expression, and actin cytoskeletal organization (Hall and Nobes 2000). Two known alternative splice variants of the ARHGEF25 gene have been identified (GEFT and p63RhoGEF) (Fig. 1), and these protein products share high homology with several other key Rho family GEFs including Trio, Kalirin, and MCF.2 cell line–derived transforming sequence (MCF2).

Regulation of Rho-Family GTPase Signaling by ARHGEF25 Proteins

Both GEFT and p63RhoGEF exhibit isoform specificity for the Rho-GTPases. p63RhoGEF appears to be ras homology gene family, member A (RhoA) specific, while GEFT has been shown to activate RhoA, ras-related C3 botulinum toxin substrate 1 (Rac1), and cell division cycle 42 (Cdc42) in a cell type–dependent manner. For instance, overexpression of GEFT in fibroblasts drives activation of Rac1 and Cdc42 leading to membrane protrusions (Guo et al. 2003); however, GEFT regulates gene expression and cell differentiation in skeletal muscle, neuronal cells, and lens epithelial cells through activation of multiple GTPases (Bryan et al. 2004, 2005, 2006; Mitchell et al. 2011). Rho-GTPase specificity of this nature is not at all surprising as similar isoform-specific regulation of Rho family members has been observed with the ARHGEF25 paralog MCF2 as well as other GEFs (Komai et al. 2002). p63RhoGEF induces RhoA-dependent stress fiber formation in fibroblasts and in H9C2 cardiac myoblasts (Souchet et al. 2002), while GEFT stimulates the formation of lamellipodia, actin



ARHGEF25, Fig. 1 *ARHGEF25 protein domains*. The ARHGEF25 protein isoforms p63RhoGEF (619 amino acids) and GEFT (580 amino acids) both contain Dbl homology domains and pleckstrin homology domains. These isoforms differ only at their N-terminus, where p63RhoGEF contains extra 39 amino acids not present in GEFT. With the exception of this N-terminal region, both isoforms share 100% amino acid identity

microspikes, and filopodia, similar to overexpression of constitutively active Rac1 and Cdc42 mutants (Guo et al. 2003; Bryan et al. 2004, 2006). p63RhoGEF has been shown to promote serum response factor (SRF) activity through a RhoA-specific pathway, while GEFT reportedly modulates the activity and/or subcellular localization of a number of transcription factors including SRF, activating protein 1 (AP1), nuclear factor kappa beta (NFkappaβ), myogenic differentiation 1 (MyoD), peroxisome proliferator-activated receptor gamma (PPARγ), and activating transcription factor 2 (ATF2) through RhoA, Rac1, and Cdc42 signaling (Bryan et al. 2004, 2005). Moreover, overexpression of GEFT stimulates the activation of numerous downstream kinases including Rho-associated, coiled-coil containing protein kinase (ROCK), p21 protein–activated kinase 1 (▶ PAKI), p21 protein–activated kinase 5 (Pak5), mitogen-activated protein kinase 14 (MAPK14), mitogen-activated protein kinase 8 (MAPK8), and ▶ p42/44 MAPK (Bryan et al. 2004, 2005) and promotes crystallin gene expression in lens epithelial cells (Mitchell et al. 2011). p63RhoGEF is expressed most highly in the heart and brain (Souchet et al. 2002). The expression of GEFT is detected at the highest levels in the excitable tissues (brain, heart, and skeletal muscle), while lower levels of protein expression are observed in a number of diverse tissues (Guo et al. 2003). An extensive analysis of GEFT expression in the developing and adult eye was recently performed by Mitchell et al. (2011), detecting high levels of the protein in the neuroblastic layer and differentiating lens fibers of the late-stage mouse embryo, and in the postnatal corneal epithelium, lens epithelium, and throughout the retina.

ARHGEF25 Protein Regulation of Muscle Physiology

Both p63RhoGEF and GEFT appear to play important roles in skeletal, cardiac, and smooth muscle function. For instance, p63RhoGEF is expressed highly in cardiomyocytes, where it strongly colocalizes with ▶ myosin at the sarcomeric I-band (Souchet et al. 2002). These data suggest the p63RhoGEF may be connected directly or indirectly to actin thin filaments and may play an important role in cardiac muscle contraction. In vascular smooth muscle cells, knockdown of endogenous p63RhoGEF ablates angiotensin II-mediated proliferation, actin stress fiber formation, longitudinal focal adhesion arrangement, and peripheral distribution of vimentin (Wuertz et al. 2010). Moreover, Wuertz et al. demonstrated that depletion of endogenous p63RhoGEF ablates angiotensin II-induced smooth muscle contraction using an in vitro collagen matrix assay. GEFT is expressed highly in the embryonic mouse limb bud, during differentiation of skeletal muscle precursors, and in established adult skeletal muscle (Bryan et al. 2005). Moreover, GEFT expression in cardiotoxin-damaged skeletal muscle is detected at high levels during the late phases of tissue regeneration, suggesting a role in the differentiation phase rather than the proliferative phase of muscle regeneration. Subcellular fractionation reveals that GEFT is wholly cytoplasmic, and fluorescence staining demonstrates that GEFT strongly colocalizes to the actin cytoskeleton in both undifferentiated skeletal muscle precursors and in differentiated multinucleated myotubes. Exogenous overexpression of GEFT in skeletal muscle precursors leads to

activation of RhoA, Rac1, and Cdc42 and their downstream effector proteins, and promotes myogenesis, inhibition of adipogenesis, and enhances in vivo tissue regeneration following skeletal muscle injury (Bryan et al. 2005).

ARHGEF25 Protein Regulation of Neuronal Physiology

p63RhoGEF expression has been detected in the cell bodies of astrocytes and oligodendrocytes localized in the cerebellar cortex (Souchet et al. 2002), while GEFT levels are observed throughout the adult brain, with prominent expression in the hippocampus, Purkinje cells, and granular region of the cerebellum (Bryan et al. 2005). Subcellularly, GEFT colocalizes to actin-rich regions, particularly those found in axons and dendrites (Bryan et al. 2006). Exogenous expression of GEFT promotes dendritic outgrown in cultured hippocampal neurons, resulting in a higher abundance and increased size of mature dendritic spines compared to the control (Bryan et al. 2005). GEFT activates RhoA, Rac1, and Cdc42 signaling in neuronal cells, and strongly enhances neurite outgrowth in neuroblastoma cells in a Pak1/Pak5-dependent manner, as well promotes axon and dendrite formation during neuronal cell differentiation (Bryan et al. 2005, 2006). Additionally, GEFT expression is highly upregulated during retinoic acid- or dibutyric cyclic adenosine monophosphate (cAMP)-induced neuronal cell differentiation (Bryan et al. 2006). During neuronal development, neural precursor cells migrate, differentiate, and extend axons and dendrites to specific regions to form synapses with appropriate target cells. Multiple GEFs have been implicated in neuronal morphonesis, growth cone guidance, and neuronal dendritic spines, and these data suggest that GEFT could play a strong role in neuronal guidance and pathfinding.

ARHGEF25 Protein Regulation of Ocular Development

High levels of Rho GTPase expression in the developing and adult eye suggest their importance in the morphogenesis and maintenance of ocular components (Mitchell et al. 2007). GEFT expression has been detected in mice as early as 9 days p.c. in the neuroepithelial tissue adjacent to the lumen of the optic vessel, and is notably expressed in differentiating lens fibers at later developmental stages (Mitchell et al. 2011). In the adult mouse eye, GEFT is observed in corneal and lens epithelium, and in the axons and cell bodies of the retinal ganglion cells of the optic nerve layer, the nerve fibers of the inner and outer plexiform layers, and the photoreceptor layer containing the rods and cones. In both in vitro and ex vivo systems, GEFT promotes lens epithelium differentiation through regulation of the expression of multiple lens crystallin and filensin genes through modulating the activation and subcellular localization of Rac1.

ARHGEF25 and Oncogenic Properties

In addition to normal physiological properties, GEFT has been shown to promote the oncogenic properties of transformed cells. The gene encoding GEFT was initially identified using an enhanced retroviral mutagen strategy selecting for foci-forming complementary DNAs (cDNAs) expressed in a human brain library (Liu et al. 2000), and its overexpression strongly induces foci-formation, proliferation, and migration in transformed fibroblasts (Guo et al. 2003). Moreover, expression of the ARHGEF25 gene is significantly elevated in approximately 4% of adenomas and carcinomas utilizing a large scale microarray study on 950 human tumor lines (https://array.nci.nih.gov/caarray/project/woost-00041).

Known Protein–Protein Interactions with ARHGEF Proteins

p63RhoGEF has been shown to physically interact with the activated G-protein coupled receptors (GPCR) G-alpha(q) and G-alpha11, but not with G-alpha12 or 13 (Lutz et al. 2005). This interaction occurs independently and in competition with the activation of the canonical G-alpha(q/11) effector phospholipase C beta, and strongly enhances the activity of p63RhoGEF. As has been reported for many GEF proteins, in the unbound state the C-terminal pleckstrin homology domain of p63RhoGEF folds over and autoinhibits its Dbl catalytic domain (Rojas et al. 2007; Lutz et al. 2007; Shankaranarayanan et al. 2010). This autoinhibition is relieved upon interaction

of the GPCR with the highly conserved C-terminal extension of the p63RhoGEF PH domain, thus coupling GPCR stimulation to Rho-GTPase activation. Alternatively, p63RhoGEF can serve as an inhibitor of GPCR function by forming a stable complex with activated G-alpha16 to inhibit its activation of phospholipase beta2, Ras, and ▶ Stat3 activation via competitive inhibition (Yeung and Wong 2009).

Several inhibitors of p63RhoGEF activity have been recently identified. p63RhoGEF, G protein coupled receptor kinase 2 (GRK2), and RGS GTPase activating proteins form a ternary complex with G-alpha(q)-coupled receptors (Shankaranarayanan et al. 2008). RGS 2 and RGS4 serve as negative allosteric regulators of G-alpha(q) binding to p63RhoGEF, thus inhibiting RhoA activation and downstream signaling. Moreover, the mixed lineage kinase 3 (▶ MLK3), a MAPK3 protein that normally activates the JNK-dependent MAPK pathways, binds directly to p63RhoGEF and prevents its G-alpha(q)-mediated activation of Rho-signaling pathways (Swenson-Fields et al. 2008). GEFT was recently identified as a protein that colocalizes and directly interacts with the cytoplasmic region of the Popdc family integral membrane protein Bves (blood vessel epicardial substance) in cardiac, smooth, and skeletal muscle (Smith et al. 2008). This interaction inhibits GEFT activity and leads to a reduction in cell movement and an increase in cell roundness via blocking of Rac1 and Cdc42 activity.

Summary

The ARHGEF25 gene encodes for two key GEF isoforms, p63RhoGEF and GEFT. These proteins are responsible for modulation of the activity of Rho-GTPases and their downstream signaling pathways in muscle and neuronal cell lineages. Future studies will likely uncover more roles and signaling cross talk for these protein products in a variety of tissues.

Historical Background

Arf (ADP-ribosylation factor) proteins were first discovered as a membrane-bound cofactor in the cholera-toxin-dependent ADP-ribosylation of Gα (Kahn and Gilman 1984). They are a family of Ras-related small GTP-binding proteins, approximately 21 kDa in size, and are expressed abundantly in all eukaryotic cells and some bacteria (Quinn 1995; Dong et al. 2007). Arfs regulate membrane trafficking and actin cytoskeleton dynamics, which are important for cellular events such as endocytosis, cell secretion, cell adhesion, cell migration, and neurite outgrowth (D'Souza-Schorey and Chavrier 2006). They act as molecular switches for many cellular pathways by cycling between inactive GDP-binding and active GTP-binding forms. Arf proteins are activated by guanine-nucleotide exchange factors (GEFs) and inactivated by GTPase-activating proteins (GAPs) (Donaldson and Honda 2005; Quinn 1995). Numerous Arf GEFs and GAPs have been identified and characterized (Gillingham and Munro 2007; Kahn et al. 2005). The Arf family consists of six mammalian Arfs (Arf1–Arf6) (Kahn et al. 2006). Arf1–Arf5 localize to and act at the Golgi, whereas Arf6 localizes to and acts at the cell surface (Donaldson and Honda 2005; Gillingham and Munro 2007). The biological functions of Arfs occur through their specific interactions with several downstream effectors (Kahn et al. 2006).

In addition to Arfs, the Arf family contains a number of Arf-like (Arl) proteins. Arl proteins are related to Arf proteins structurally but not functionally (Kahn et al. 2006). Arl proteins share 40–60% sequence identity with Arfs. In contrast to Arf proteins, Arls cannot act as cofactors in cholera-toxin-catalyzed ADP-ribosylation of Gαs; cannot activate ▶ phospholipase D (PLD); and cannot functionally complement Arf1 or Arf2 in *Saccharomyces cerevisiae* (Hong et al. 1998; Kahn et al. 2006; Price et al. 1988; Sebald et al. 2003; Stearns et al. 1990; Tamkun et al. 1991). These Arls contain an amino-terminal amphipathic helix and the "interswitch" region (Kahn et al. 2006; Li et al. 2004; Pasqualato et al. 2002). In humans, there are 22 Arls (Arl1–Arl22), which have been well conserved in evolution (Hofmann and Munro 2006). Generally, membrane binding of Arl proteins occurs via an N-terminal amphipathic helix that is inserted into the lipid bilayer once activated. In addition, this N-terminal amphipathic helix contains a myristoyl or an acetyl group (Gillingham and Munro 2007).

The Arl8 subfamily contains two isoforms, Arl8a and Arl8b, which share 92% amino acid identity in human, and there is a single homolog (Arl8) in *Drosophila* and *Caenorhabditis elegans* but none in yeast. This suggests that Arl8 is highly conserved in multicellular eukaryotes (Li et al. 2004; Kahn et al. 2006). Arl8b was originally identified in macrophages as a mycobacterial phagosome harboring protein

(Garin et al. 2001) and also as a lysosomal membrane protein in rat liver (Bagshaw et al. 2005). Arl8b is 186 amino acids in length and has a molecular weight of approximately 22 kDa (Okai et al. 2004; Kahn et al. 2006). The protein contains an N-acetylated amphipathic helix, a putative effector domain, and highly conserved GTP-binding domains (G1-G5) (Okai et al. 2004; Hofmann and Munro 2006).

Protein Function and Regulation of Activity

The main functions of Arl8b discovered so far include a role in lysosome motility (Hofmann and Munro 2006), delivery of endocytosed macromolecules to lysosomes (Nakae et al. 2010), axonal transport of presynaptic cargo (Klassen et al. 2010), neurite formation (Haraguchi et al. 2006), and chromosome segregation (Okai et al. 2004). Arl8b has been found to localize to lysosomes, and its overexpression resulted in a microtubule-dependent accumulation of lysosomes at the cell periphery (Hofmann and Munro 2006; Bagshaw et al. 2006). Wild-type Arl8 or a constitutively active (GTP-bound) mutant (Arl8-Q75L), but not a constitutively inactive (GDP-bound) mutant (Arl8-T34N), localize to lysosomes when expressed exogenously in mammalian cells, indicating that the lysosomal localization of Arl8b depends on its guanine-nucleotide-bound status (Bagshaw et al. 2006). As previously mentioned, membrane binding of the Arf family proteins generally occurs via an N-terminal myristoyl group. However, Arl8b does not contain this motif but instead contains an N-terminally acetylated Met-Leu, which is essential for its lysosomal localization (Hofmann and Munro 2006). RNA-interference-mediated knockdown of human Nα-terminal acetyl transferase complex C (hMak3), which acetylates Met-Leu protein N termini, alters the subcellular localization of Arl8b, supporting the hypothesis that Arl8b is a hMak3 substrate in vivo (Starheim et al. 2009).

Okai et al. (2004) believed Arl8b to be involved in microtubule-related functions based on co-immunoprecipitation of Arl8 with β-tubulin and chromosomal segregation defects in *Drosophila* cell lines following short interfering (si)RNA-mediated knockdown of Arl8. Overexpression of Arl8 mutants that lacked the putative effector domains but still contained tubulin-binding capabilities induced micronucleus formation. The authors concluded that Arl8b may act as a molecular switch to regulate chromosomal segregation by associating with microtubules (Okai et al. 2004).

A recent paper by Nakae et al. (2010) has demonstrated Arl8 localization to lysosomes and its involvement in late endosome-lysosome fusion in *C. elegans*. A loss of Arl8 in *C. elegans* caused an increase in number of late endosome-lysosome vesicles, which are smaller than those in worms expressing wild-type Arl8. In an Arl8 knockout (*arl8*) mutant, late endosomal vesicles are unable to fuse with lysosomes and thus a loss of Arl8 critically reduces late endosome-lysosome hybrid formation, which in turn affects the delivery of endocytosed macromolecules to lysosomes. These results suggest that Arl8 may be important in the biogenesis and function of lysosome-related organelles. In addition, homozygous *arl8* worms from heterozygous *arl8* mothers develop to fertile adults, whereas hermaphrodites homozygous for *arl8* produce no viable embryos, suggesting that Arl8 is required maternally for embryonic development. Introduction of wild-type Arl8 or a constitutively active Arl8-Q75L mutant, but not a constitutively inactive Arl8-T34N mutant, efficiently rescued the embryonic lethality of the *arl8* mutant, suggesting the importance of Arl8 in its GTP-bound active form for normal embryogenesis. Furthermore, expression of human Arl8 proteins in *C. elegans arl8* mutants could also rescue the embryonic lethality, indicating that Arl8 has a conserved role in multicellular animals.

As mentioned above, Arl8b has been shown to localize with microtubules to the spindle mid-zone in late mitosis and to be involved in chromosomal segregation (Okai et al. 2004). However, two later studies found no apparent mitotic spindle localization of Arl8b in mammalian cell lines other than PC12 cells tested (Nakae et al. 2010; Hofmann and Munro 2006). The authors concluded that this role may be important in certain cell types under specific conditions.

It has also been suggested that Arl8b may have an important role in neurite formation because Arl8b, when overexpressed, accumulates at the growth cones in primary neurons and greatly affects the morphology of human embryonic kidney HEK293 cells by inducing the formation of long protrusions (Haraguchi et al. 2006). In the absence of Arl8, presynaptic cargo prematurely aggregates in the axons in *C. elegans*,

indicating that Arl8 acts as a regulator of presynaptic assembly (Klassen et al. 2010).

A study by Salilew-Wondim et al. (2010) showed higher levels of *Arl8b* gene expression in bovine embryos that resulted in calf delivery than in those that resulted in no pregnancy. This study highlighted the potential of *Arl8b* gene expression pattern in embryos as a predictor of pregnancy success in cattle. *Arl8b* has recently been identified as an endogenous reference gene (ERG) using multi-platform expression data and validated for quantitative gene expression analysis (Kwon et al. 2009). ERGs are useful in normalization of mRNA levels, which is essential for an accurate comparison of gene expression between different samples. Several studies have reported the expression variability of traditional ERGs (tERGs) such as GAPDH and ACTB in various tissues or disease status. It has been suggested that Arl8 is better reference gene than tERGs owing to its greater expression stability.

A recent study by Korolchuk et al. (2011) has shown that knockdown of Arl8b (along with Arla) resulted in disruption of the centrifugal movement of lysosomes along microtubules and reduction in the nutrient-dependent activation of ▶ mammalian target of rapamycin (mTOR)-C1. In contrast, overexpression of Arl8b increased ▶ mTOR-C1 activity by increasing the number of lysosomes at the tip of cell protrusions. These findings suggest that the positioning of lysosomes regulates the ▶ mTOR-C1 activity. Inhibiting ▶ mTOR-C1 activity by restricting lysosomes transport to the cell periphery through downregulation of Arl8b and Arl8a increases the number of autophagosomes formed even when cells are maintained in nutrient-rich conditions. Moreover, an increase in the transfer of autophagic cargo from autophagosomes to lysosomes, known as autophagic flux, and its subsequent degradation was also observed in cells with simultaneous knockdown of Arl8b and Arl8a.

Arl8b activity is regulated through exchange of bound GDP for GTP and hydrolysis of the bound GTP to GDP. Arl8b is active when it is bound to GTP and inactive when it is bound to GDP (Okai et al. 2004). However, it is unknown currently whether Arl8b requires GEFs for its activation and GAPs for its inactivation. No GEFs or GAPs that are specific for Arl8b have been identified so far. In addition, it is currently unknown whether Arf GEFs and GAPs are active on Arl8b.

Arl8b is N-acetylated, which is necessary for its localization, and thereby its activity in intact cells. However, it is currently unknown whether N-acetylation is required for the GTP-binding or GTPase activity of Arl8b. Several members of the Arf family require membranes or lipid vesicles and micromolar concentrations of Mg^{2+} for an increase in their in vitro GTP binding (Pasqualato et al. 2002). However, it is currently unknown whether Arl8b requires any of these cofactors to promote GTP binding.

Arl8b interacts with GDP and GTP (Okai et al. 2004). Bagshaw et al. (2006) concluded that the localization of Arl8b to lysosomes may occur only when the protein is present in its GTP-bound active state. The authors made a constitutively GTP-bound active (Arl8-Q75L) and a constitutively GDP-bound inactive (Arl8-T34N) mutants of Arl8b. When these mutants were expressed in mammalian cells, the GTP-bound mutant localized to lysosomes whereas the GDP-bound mutant did not, indicating that the lysosomal localization of Arl8b depends on its guanine-nucleotide-bound status (Bagshaw et al. 2006).

Arl8b has been shown to associate with β-tubulin independent of its guanine-nucleotide-bound status or the absence of its effector domain (Okai et al. 2004). Interaction between Arl8b and β-tubulin was shown by co-immunoprecipitation from the extracts of HeLa cells overexpressing Arl8b.

In addition, several interacting proteins for Arl8b have been identified in the Biogrid, IntAct, HPRD, Bind, UniProtKB, MINT, and STRING databases. However, these interactions are yet to be confirmed.

Haraguchi et al. (2006) demonstrated that short-term feeding of a high beef-tallow diet in mice results in the downregulation of Arl8b mRNA in the brain.

Major Sites of Expression and Subcellular Localization

Arl8b is ubiquitously expressed in various tissues and cell lines. Expression in human tissues includes the brain, heart, skeletal muscle, colon, thymus, spleen, kidney, liver, small intestine, placenta, lung, and peripheral blood leukocytes. However, higher expression levels were observed in brain, heart, skeletal muscle, kidney, and placenta (Okai et al. 2004).

Arl8b has also been shown to be expressed in cell lines such as human HeLa and HEK293, rat PC12, mouse NIH3T3 and neuro2A, and mast cells (Okai et al. 2004).

Bagshaw et al. (2005) identified Arl8b as a lysosomal membrane protein by proteomic analysis. The lysosomal localization of Arl8b is supported by its colocalization with the lysosomal markers CD63, Lamp1, Lamp2, and NPC1 when expressed exogenously in mammalian cells (Hoffman and Munro 2006; Bagshaw et al. 2006; Nakae et al. 2010). In addition, Arl8b has been shown to change its localization from lysosomes to the mid-zone of spindle during mitosis (Okai et al. 2004). However, two later studies disproved this by showing Arl8b localization to lysosomes during mitosis (Hofmann and Munro 2006; Nakae et al. 2010). In neuronal cells, Arl8b localizes to the protruded core and the perinuclear regions (Haraguchi et al. 2006).

Arl8b is N-terminally acetylated, which is essential for its lysosome localization (Hofmann and Munro 2006). Arl8b becomes cytosolic when three hydrophobic amino acids in the N-terminal amphipathic helix are mutated (I5A, L8A, and F12A), which does not affect the N-acetylation of Arl8b (Hofmann and Munro 2006). This study indicates that the lysosomal localization of Arl8b may require not only the N-acetylation but also an intact N-terminal amphipathic helix region.

There are several anti-Arl8b antibodies that are commercially available, which could be used for studying Arl8b expression in tissues and cell lines. Two rabbit polyclonal antibodies raised against the C terminus (SAB1300305) and the center (SAB1300683) of Arl8 are available from Sigma and can be used for the detection of protein of human origin by Western blot, enzyme-linked immunosorbent assay (ELISA), and immunohistochemistry. Three rabbit polyclonal antibodies raised against synthetic peptide corresponding to internal regions of human ARL8b (LS-C102443, LS-C111980, and LS-C111981) are available from Lifespan Biosciences. These antibodies can be used for the detection of endogenous ARL8b by Western blot. Abnova supplies a mouse monoclonal antibody, clone 1A2 (H00055207-M01) raised against a full-length recombinant human ARL8, which can be used for the detection of recombinant protein by ELISA. An anti-Arl8b rabbit polyclonal antibody (13049-1-AP) available from ProteinTech group is suitable for recognition of Arl8b by Western blot and ELISA. Although no publications currently site any of these commercially available antibodies, the product data sheets supplied by companies contain evidence of their efficiency in the methods outlined above.

Phenotypes and Splice Variants

No studies on the phenotypic effects of Arl8b have been carried out in mammals because of the lack of *Arl8b* knockout mice. However, loss of Arl8 in *C. elegans* results in an increase in the number of late endosomal-lysosomal compartments that are small in size and inhibition of viable embryo production by hermaphrodites (Nakae et al. 2010). Knockdown of *Arl8b* in *Drosophila* S2 cells with siRNA resulted in chromosomal mis-segregation but no inhibition of mitotic progression (Okai et al. 2004). These abnormalities were also observed in HeLa cells following introduction of the dominant-negative mutants, Arl8b-T34N and Arl8b-N130I, into the cell. Therefore, the function of Arl8b in chromosome segregation must be conserved in animals. In addition, a recent study has shown that simultaneous knockdown of *Arl8b* and *Arl8a* additively enhanced autophagosome-lysosome fusion in HeLa cells (Korolchuk et al. 2011).

The human *Arl8b* gene is located on chromosome 3 and has eight exons. Nine splice variants have been predicted to be formed through alternative splicing of *Arl8b*, which differ from each other in length and amino acid sequence. However, it is not yet known whether the splice variants of *Arl8b* are functionally active or whether their expression levels differ.

Okai et al. (2004) raised a rabbit polyclonal antibody against the carboxy-terminal peptide (CLIQHSKSRRS) of human Arl8b and Arl8a and used in the recognition of Arl8 proteins by Western blot.

A rabbit antiserum raised against residues 18–186 of *Drosophila* Arl8 was used by Hoffman and Munro (2006) for the detection of endogenous *Drosophila* Arl8 by Western blot.

Nakae et al. (2010) generated an anti-Arl8 antibody by immunizing rabbits with a synthetic peptide (CDITLQWLIDHSKAQR) corresponding to the C terminus of *C. elegans* Arl8 and used it in the identification of Arl8 protein by Western blot.

Garin et al. (2001) have used a polyclonal antibody raised against the C-terminal region of Arl8b in Western blot analysis to indicate that the protein is highly enriched on phagosomes in macrophages. However, neither the immunogen sequence nor animal used for raising the antibody was reported in the publication.

Summary

ADP ribosylation factor (Arf)-like 8b (Arl8b) is a member of the Arf family of small GTP-binding proteins, which regulate membrane trafficking in eukaryotic cells. Arl8b is 186 amino acids in length and has a molecular weight of approximately 22 kDa. The protein contains an amino-terminally acetylated amphipathic helix, a putative effector domain, and GTP-binding domains. Like other small GTP-binding proteins, Arl8b acts as a molecular switch by cycling between the GDP-bound inactive and the GTP-bound active forms. Arl8b is primarily localized to lysosomes in its GTP-bound form. The N-terminal acetylation of Arl8b is also important for its localization to lysosomes. The main functions of Arl8b discovered so far include a role in microtubule-dependent accumulation of lysosomes at the cell periphery, delivery of endocytosed macromolecules to lysosomes, axonal transport of presynaptic cargo, neurite formation, and chromosome segregation. Recent studies also highlighted the potential of Arl8b as an endogenous reference gene for quantitative gene expression analysis and the use of its gene expression pattern in embryos as a predictor of pregnancy success in cattle. Arl8b has been shown to associate with β-tubulin independent of its guanine-nucleotide-bound status or the effector domain. It also interacts with several other proteins, but the interactions have not yet been confirmed. Arl8b is ubiquitously expressed in tissues and is especially high in brain, heart, skeletal muscle, kidney, liver, placenta, and lung and cell lines. Furthermore, *Arl8b* mRNA expression is downregulated in the brains of mice fed a high-fat diet. Studies on the phenotypic effects of loss of Arl8 in *Caenorhabditis elegans* revealed that Arl8 is required for embryonic development and late endosome-lysosome fusion. The human *Arl8b* gene is located on chromosome 3 and its alternative splicing is predicted to generate nine splice variants.

Historical Background

The term ATF was first used in 1987 to refer to a putative polypeptide with the activity to bind to the sites on the adenovirus E2, E3, and E4 promoters with sequences similar to the consensus TGACGT(C/A)(G/A) (Lee et al. 1987). However, it was later found that, instead of a single polypeptide, many polypeptides can bind to the sequence (Hai et al. 1988; Raychaudhuri et al. 1987). Cloning of the corresponding cDNAs using the consensus sequence to screen the expression library revealed seven different clones (Hai et al. 1989). These proteins were collectively called the ATF family of proteins. Over the years, identical or homologous cDNA clones have been isolated, expanding the size of this protein family (for previous reviews, see Hai and

Hartman 2001; Hai et al. 1999). Because the consensus ATF binding site is the same as the cAMP responsive element (CRE) (Montminy and Bilezsikjian 1987) and because ATF1 is 75% similar to the CRE-binding protein (▶ CREB) at the amino acid level (Hai et al. 1989), sometimes the ATF and ▶ CREB proteins are referred to as the ATF/▶ CREB or ▶ CREB/ATF family of proteins. ATF3 is a member of this family.

DNA Binding by ATF3

Both ATF and ▶ CREB proteins bind to DNA using their basic region/leucine zipper (bZip) motif and belong to a superfamily of bZip proteins that includes ATF, ▶ CREB, AP1 (Fos/Jun), C/EBP, and Maf families (see Hai 2006 for a dendrogram). These proteins can form cross-family heterodimers. In addition, many of these proteins can bind to each other's consensus sequences (which are similar to each other) or the composite sites (a previous review, Hai and Hartman 2001). Thus, their names reflect the history of discovery, rather than the differences (or similarities) between them. An unbiased way to view them is that they all belong to a superfamily of bZip transcription factors that form homodimers and selective heterodimers, with potentially overlapping DNA-binding sequences (for a few reviews on bZip proteins, see Amoutzias et al. 2007; Hurst 1995; Newman and Keating 2003; Vinson et al. 2002). Strictly speaking, there is no such site as the "ATF3 consensus binding sequence," since any sites bound by ATF3 are likely to be also recognized by other bZip proteins. When searching for potential ATF3 binding sites on a given promoter, one should scan the sequence not just for the consensus ATF sequence, but also the AP1 sequence (TGACTCA, one nucleotide deletion from the ATF site), and sequences with *several* deviations from either consensus. If potential sites are identified, it is necessary to test the binding experimentally. If no potential sites are identified, it does not necessarily mean that ATF3 does not regulate the promoters. It is possible that ATF3 can bind to the promoters at yet unidentified sites, or ATF3 can be recruited to these promoters via other proteins. Alternatively, ATF3 may regulate them indirectly via regulating other transcription factors that in turn regulate the promoters of interest. For more discussions on DNA binding by ATF3, see McConoughey et al. (2011).

Transcriptional Activity and Target Promoters of ATF3

Although the name "ATF" implies that the proteins are transcriptional activators, it is clear now that ATF3 can be an activator or repressor, depending on the promoter or cellular context (previous reviews, Hai 2006; Hai and Hartman 2001). Over the years, many potential ATF3 target genes (direct or indirect) have been identified. Table 1 lists some of the potential direct target genes that fulfill minimally two criteria: (a) ATF3 was shown to be recruited to their promoters in vivo by chromatin-immunoprecipitation (ChIP) assay; (b) their steady-state mRNA or protein levels are affected by ectopic expression or knockdown of ATF3. Note that changes in steady-state mRNA level could be due to change in transcription, or mRNA stability, or both, and the change in the steady-state protein level could be due to regulation at various steps. Thus, the second criterion by itself does not necessarily mean transcriptional regulation. In addition, it does not mean that the influence of ATF3 on the genes is direct or indirect. However, combined with the first criterion (recruitment of ATF3 to their promoters in vivo), it suggests that ATF3 may, at least in part, regulate their transcription. For some of the target genes listed in Table 1, ATF3 was shown to modulate their transcription in vivo by the indicated assay: pol II occupancy on the promoters/genes or the measurement of their pre-mRNA levels. Results based on transient transfection coupled with reporter assay were not included as evidence for in vivo transcription, because the assay does not address the issue of endogenous gene regulation. In addition, in vitro DNA binding (such as DNase footprint or electrophoretic mobility shift assay) were not included as evidence for ATF3 binding to the promoters. For potential ATF3 target genes identified using less stringent criteria, see McConoughey et al. (2011).

Biological Function of ATF3

ATF3 as a "Hub"

Overwhelming evidence indicates that the ATF3 mRNA level is low in many cell lines and tissues, but upregulated by a variety of signals, usually within 2 h of induction (see Hai (2006) for a short list, and see McConoughey et al. (2011) for more). One striking feature of ATF3 induction is that it is neither

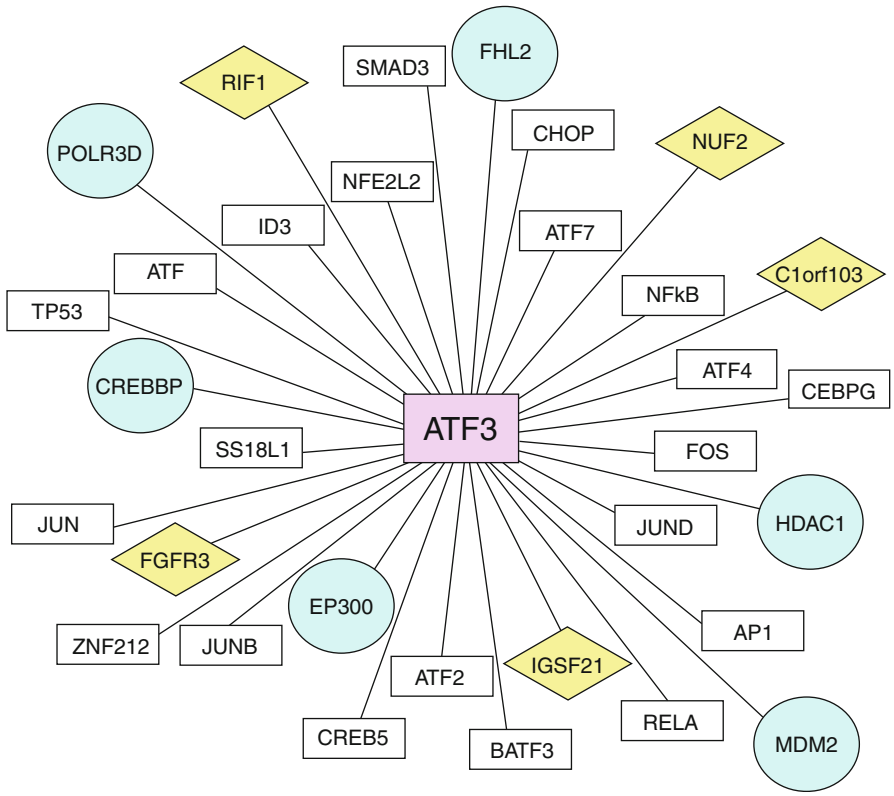
stimulus- nor cell type-specific. This lack of specificity raises an important question: What is the purpose of inducing ATF3? Previously, the idea that ATF3 is a hub of the cellular adaptive-response network to respond to signals perturbing homeostasis was put forth (Hai et al. 2010). This idea was based on the following observations (Amoutzias et al. 2007). A broad spectrum of stimuli can induce ATF3 (above) (Demidova et al. 2009). A variety of signaling pathways have been shown to induce ATF3, such as the JNK, Erk, p38, PKC, and NFκB pathways. This is consistent with the numerous binding sites on the



ATF3 Activating Transcription Factor 3, Fig. 1 Potential ATF3 interacting proteins

ATF3 promoters (ATF3 has at least two promoters, see a review, (Hai et al. 2010) that are recognized by transcription factors targeted by the above signaling pathways. (Gilchrist et al. 2006) Analysis of the amino acid sequence of ATF3 revealed many potential post-translational modification sites, again supporting the idea that ATF3 is a target for regulation by many signaling pathways. For detailed description and references, see Hai et al. (2010).

Additional observations to support the "hub" idea came from bioinformatics analysis. Using the Cytoscape program, Aderem and colleagues analyzed the known transcription factor protein–protein interaction network and found ATF3 to interact with a number of transcription factors, including AP1, CHOP, NFκB, and ▶ p53 (Gilchrist et al. 2006). As shown in Fig. 1, an expansion of this analysis to include all proteins – not just transcription factors – using the Ingenuity Pathway Analysis database revealed that ATF3 interacts with many proteins, further supporting the idea of ATF3 as a hub.

Figure 1 shows the potential ATF3-interacting proteins derived from the Ingenuity Pathway Analysis database. The level of evidence for their interaction varies, depending on the assays used in the studies. To address whether any interaction occurs in vivo in specific cell types, it is important to examine it using appropriate assays. White rectangle in the figure denotes classically defined sequence-specific transcription factors; blue circle denotes cofactors or regulators that modulate transcription factors; yellow diamond denotes other types of proteins.

ATF3 as a Cell–Cell Communication Gene

By its nature as an immediate-early gene, ATF3 has far-reaching effects. Immediate-early genes encode transcription factors and are known to turn on/off genes encoding transcription factors, which in turn regulate downstream genes, leading to a cascade of changes in transcriptional programs. Thus, to understand ATF3 function, an important task is to elucidate its target genes – either direct or indirect targets. Table 1 lists some genes that are likely to be direct targets (see above for criteria for inclusion). However, ATF3 has been shown to affect the expression of many more genes (see previous reviews, Hai et al. 2010; McConoughey et al. 2011; Thompson et al. 2009). Due to the lack of evidence for ATF3 recruitment to their promoters in vivo, it is not clear whether they are direct or indirect target genes of ATF3. Among the diversity of ATF3 targets, some can be grouped into functional pathways or groups. (a) ATF3 modulates the expression of numerous inflammatory genes – not only in immune cells (such as macrophages, mast cells, and T cells) but also in non-immune cells (see database (Knob et al. 2008) and a previous review Hai et al. 2010). (b) ATF3 functions as a co-transcription factor for Smad3 to regulate many TGFβ target genes, such as those that affect cell motility and cell cycle (Kang et al. 2003; Yin et al. 2008; Yin et al. 2010). Furthermore, ATF3 forms a positive feedback loop on TGFβ: *ATF3* gene is induced by TGFβ (Kang et al. 2003) and its gene product upregulates the expression of *TGFβ* gene (Yin et al. 2010). Thus, ATF3 appears to play an important role in TGFβ signaling.

TGFβ and the inflammatory gene products (such as cytokines and chemokines) are all soluble factors. This, combined with the "hub" idea above, supports the following view of ATF3. Upon the disturbance of homeostasis by extra- or/and intra-cellular signals, one of the key genes that the cells turn on is ATF3. After induction, ATF3 initiates a cascade of changes in gene expression with a key consequence of releasing various soluble factors, which in turn disturb the homeostasis of the cells receiving the signals. Thus, ATF3 is a key molecule for cell–cell communication, both as a gene to respond to the signals and as a gene to send out signals for communication. This proposed view of ATF3 is supported by a recent cRNA microarray data that cell–cell communication is within the top ten functional groups of genes regulated by ATF3 (Wolford et al. in preparation).

Other Functions

The above two proposed functions of ATF3 are based on literature with a perspective of viewing ATF3 from a broad angle. They are not meant to be comprehensive and do not include the function of ATF3 in various cellular processes, such as apoptosis, cell cycle, cell motility, metabolism, and DNA repair. For those functions, see previous reviews (Hai et al. 2010; McConoughey et al. 2011; Thompson et al. 2009). In this context, two points relevant to the understanding of ATF3 functions are of interest.

(a) Although ATF3 is a transcription factor, its subcellular localization is not limited to the nucleus. MacLeod and colleagues reported low levels of cytoplasmic ATF3 (in addition to nuclear ATF3) in human breast tumor samples by immunohistochemistry (Wang et al. 2008). Similar cytoplasmic localization of ATF3 has also been observed by other investigators (not published). The subcellular localization of ATF3 is likely a regulated event, as suggested by the observation that ATF3 localizes in the cytoplasm of Stat1 knockdown hepatocytes but in the nucleus of the control knockdown cells (Kim et al. 2009). These are potentially interesting observations. As shown in the literature, some proteins have unexpected functions outside their originally identified subcellular location, such as the mitochondrial function of the transcription factor ▶ p53 (a review, Vaseva and Moll 2009) and the nuclear function of the cytoplasmic membrane protein epidermal growth factor receptor (EGFR, Liccardi et al. (2011) and references therein). Clearly, further analysis for the subcellular localization of ATF3 is required. It is intriguing that FGFR3 – a cytoplasmic membrane receptor – is a potential ATF3-interacting protein based on a yeast two-hybrid screen

(Stelzl et al. 2005). If this interaction can be validated in mammalian cells, it would be important to address the subcellular localization of their interaction (nuclear or non-nuclear) and the functional consequences.

(b) Several isoforms of ATF3 have been identified (a review, McConoughey et al. 2011). However, the functional importance of these isoforms and the regulation of their expression are not well understood. When investigating ATF3 functions, this is an area to consider.

Potential Roles of ATF3 in the Pathogenesis of Diseases

Inflammation: A Potential Unifying Component for the Roles of ATF3 in Various Diseases

As detailed in a previous review (Hai et al. 2010), ATF3 modulates the expression of many inflammatory genes. Work by several groups clearly identified ATF3 to play a role in modulating inflammatory responses in macrophages (Gilchrist et al. 2006; Khuu et al. 2007; Whitmore et al. 2007). Furthermore, using systems biology approach combined with genome-wide ChIP-on-chip analyses, Aderem and colleagues identified a large array of ATF3 target genes (not just inflammatory genes) in macrophages and generated an interactive database (Korb et al. 2008). In addition to macrophages, ATF3 also regulates inflammatory genes in other immune cells (such as $CD4^+$-T cells, natural killer cells, mast cells, and dendritic cells) and nonimmune cells (such as fibroblasts and epithelial cells). See Table 2 in Hai et al. (2010) for a list and references. Considering the importance of inflammation in the pathogenesis of various diseases, it is reasonable to speculate that the ability of ATF3 to modulate inflammatory response genes – either in the immune cells or nonimmune cells – plays a key role in its potential implication in various diseases [for more discussions, see Hai et al. (2010)]. Below is a brief review of the data for ATF3 in cancer.

ATF3 in Cancer

Various mouse models have been used to investigate the potential roles of ATF3 in the pathogenesis of diseases. These include transgenic mice ectopically expressing ATF3 in selective tissues, knockout mice deficient in ATF3, and orthotopic injection of cells with modulation of ATF3 levels. See Table 3 in a previous review (Hai et al. 2010) for a brief description of the mouse models and phenotypes. Taking this set of literature together with the in vitro data that ATF3 affects many cellular processes relevant to cancer development (such as apoptosis, cell cycle progression, angiogenesis; for a review, see McConoughey et al. (2011)), it is reasonable to conclude that ATF3 most likely plays a role in the pathogenesis of cancer. However, ATF3 does not simply inhibit or promote cancer; rather, its function varies depending on the cellular context. As shown in the literature, ATF3 can either inhibit or enhance processes such as apoptosis, cell cycle progression, and tumor formation. Since these reports were derived from vastly different cell lines or models with different contexts (see McConoughey et al. (2011) for some examples), one idea is that the role of ATF3 is affected by cellular context. To address what specific features of the cells may affect the roles of ATF3 in cancer development, one study utilized isogenic cell lines. These cells share the same genetic background except the genetic and/or epigenetic alterations that allow them to have varying degrees of malignancy. Interestingly, ATF3 enhances apoptosis in normal or untransformed epithelial cells but has an opposite effect on a malignant cell line derived from them (Yin et al. 2008). Thus, ATF3 plays a dichotomous role, depending on the degree of malignancy of the cells. This concept explains the phenotypes of many transgenic mice models ectopically expressing ATF3 in selective tissues (see Table 3 in Hai et al. (2010) for specifics). In general, ATF3 has deleterious effects on the corresponding tissues, since the cells are untransformed. An exception is the CK5-ATF3 transgenic mice (which express ATF3 in the basal epithelial cells by the bovine cytokeratin promoter 5); the mice developed mammary carcinoma in biparous mice (Wang et al. 2007; Wang et al. 2008). Presumably, after cycles of proliferation and apoptosis, the mammary epithelial cells in biparous mice develop cellular context allowing ATF3 to be "co-opted" and become pro-oncogenic.

All the above data are derived from cell lines in culture dish or mouse models; a critical question is whether the conclusion that ATF3 affects cancer development can be extrapolated to human. At present,

ATF3 has been detected in various tumors, such as breast, prostate, squamous cell carcinoma, and Hodgkin lymphoma (see Table 4 in Hai et al. (2010)). Due to its nature of induction by various stress signals, it is not surprising that ATF3 is expressed within the tumors. The question is whether this has any functional relevance. Does ATF3 play a causal or preventive role? Can its expression be used as a predictive marker (positive or negative) for clinical outcomes? Since ATF3 can be induced in different cell types by various signals, it is likely to be expressed in both cancer epithelial cells and stromal cells. Does its expression in stromal cells have any functional relevance? Considering the complexity of ATF3 biology, these are challenging questions and much work is required to address them.

Summary

ATF3 is a member of the bZip superfamily of transcription factors. This review puts forth two potential functions of ATF3 from a broad perspective. (a) ATF3 as a hub: Overwhelming evidence indicates that ATF3 is induced by a variety of extra- and intra-cellular signals. This, combined with other clues (such as the involvement of various signaling pathways in its induction and its interaction with many proteins), prompted the proposal that ATF3 functions as a "hub" of the cellular adaptive-response network to respond to signals perturbing homeostasis. (b) ATF3 in cell–cell communication: Since ATF3 is a transcription factor, it exerts its actions at least in part by regulating downstream target genes. Analyses of its target genes – either direct or indirect targets – revealed that a consequence of inducing ATF3 is to turn on a variety of genes encoding soluble factors, which in turn disturbs the homeostasis of the cells receiving the signals. Thus, ATF3 is a key molecule for cell–cell communication, both as a gene to respond to the signals and as a gene to send out signals for communication. Various mouse models have been used to investigate the potential roles of ATF3 in the pathogenesis of diseases. A previous review put forth the idea that the ability of ATF3 to modulate inflammatory response genes is a key component for the potential implication of ATF3 in various diseases. This review highlights the evidence and clues that ATF3 most likely plays a role in the pathogenesis of cancer – in a context-dependent manner, not simply anti- or pro-cancer. A critical question is whether the findings from cell culture and mouse models can be extrapolated to human. This is a challenging question; in addressing this issue, it is important to consider the complexity of ATF3 biology.

Aurora Kinases Family Members

Aurora-A: AIK, ARK1, AURA, AURORA2, BTAK, MGC34538, STK15, STK6, STK7
Aurora-B: AIK2, AIM-1, AIM1, ARK2, AurB, IPL1, STK12, STK5
Aurora-C: AIE2, AIK3, ARK3, AurC, STK13, Aurora-C

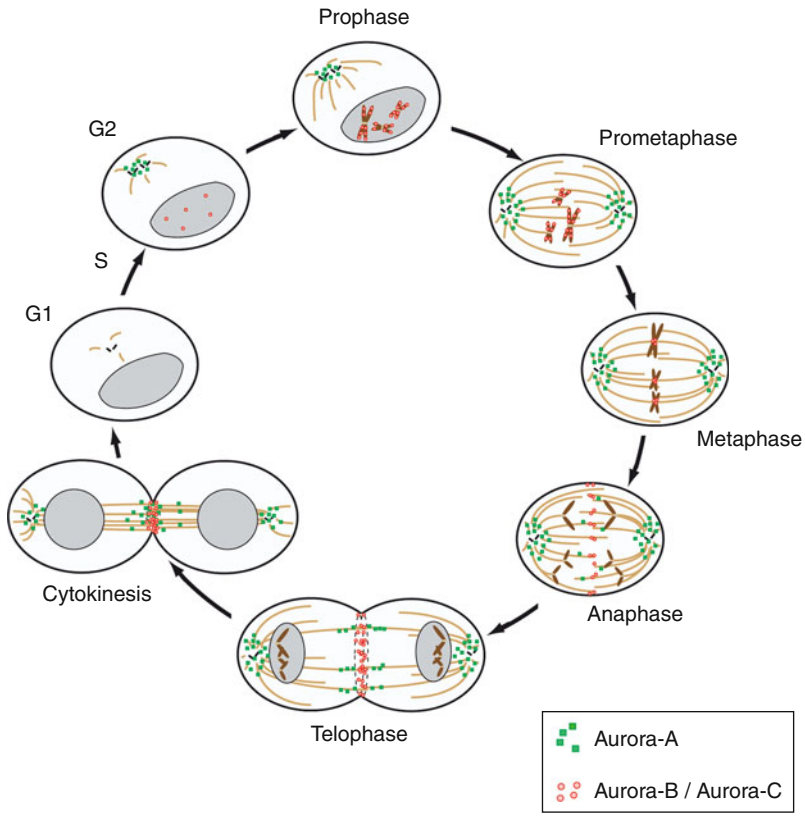
Historical Background

Every new cell is generated through division of an existing cell (one cell generates two cells) and survival of all organisms depends on reliable transmission of the genetic information from the mother cell to daughter cells. Consequently, all cellular components must be duplicated before cell divides, and these duplications must be achieved with extreme precision and reliability over generations. The eukaryotic cell (cell with a nucleus) has set up complex network of regulatory mechanisms to ensure a correct sequence of events that eventually leads to cell division. This network called the cell cycle control system consists mainly in a complex assembly of oscillating phosphorylation/dephosphorylation reactions. Several protein kinases and phosphatases are involved in these signaling cascades. Aurora kinases that belong to a family of serine/threonine kinases play such a role; they are critical for the establishment of mitotic spindle, centrosome duplication, and separation as well as maturation, chromosomal alignment, spindle assembly checkpoint, and cytokinesis. In the early 1990s, Chan and Botstein (1993) identified the first Aurora kinase in the budding yeast *Saccharomyces cerevisiae*. The kinase was originally named Ipl1 for Increase in Ploidy 1. Indeed, conditional temperature sensitive *ipl1*$^{ts-}$ mutant cells reveal abnormal ploidy induction, suggesting that the Ipl1 kinase is involved in controlling chromosomes segregation. Glover and colleagues (1995) then discovered a *Drosophila* homolog that they named Aurora. The kinase was identified during a search of mutants that affect centrosome cycle in *Drosophila*. The first human Aurora kinase was isolated simultaneously by two groups, one was searching homology with yeast Ipl1 and *Drosophila* Aurora in randomly sequenced cDNAs (They identified Aik "Aurora Ipl1–related Kinase") and the other one was mapping a chromosome region commonly amplified in breast cancer to search for potential oncogenes (they identified BTAK "breast tumor–activated kinase"). Rapidly, homology studies revealed several genes encoding Aurora kinases in the genome of multicellular organisms. They were first called AIRK for Aurora/Ipl1-related kinases. Thus, while yeast genome encodes only one Aurora kinase, a second gene was found in *D. melanogaster* through a genome sequencing program and simultaneously two new genes were found in *Homo sapiens*: STK12 and AIE2. Because all these kinases have been isolated simultaneously in different laboratories, they carried "esoteric" names strongly requiring a new nomenclature. This was achieved by dividing the Aurora family into three sub-members (Nigg 2001): Aurora-A, Aurora-B, and Aurora-C. Both Aurora-A and -B are expressed in proliferating cells, yet Aurora-A is associated predominantly with centrosomes and the spindle apparatus from prophase through telophase, whereas Aurora-B is prominent at the midzone during anaphase and in postmitotic bridges during telophase. Aurora-C seems to be restricted to germlines, is highly expressed in testis, but is also found overexpressed in tumors. Interestingly enough Aurora-C can fulfill Aurora-B function suggesting a close relationship. Chromosome localizations of Aurora kinase genes are as follows: Aurora-A (AURKA) on chromosome 20q13.2, Aurora-B (AURKB) on chromosome 17p13.1, and Aurora-C (AURKC) on chromosome 19q13.3.

Aurora Kinases Structure and Functions

Structure of Aurora Kinases

The catalytic domain of the Aurora kinases family is located in the carboxy terminus and is highly conserved among species. It contains 26 residues lining the ATP-binding active site that are characteristic of the Auroras. Interestingly, Aurora-A and Aurora-B

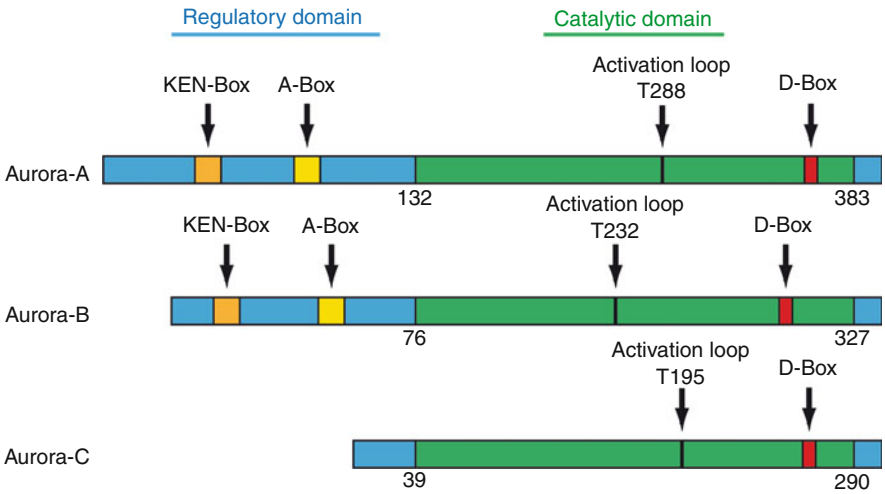


Aurora Kinases,
Fig. 1 Aurora kinases localization through cell cycle progression

sequences are so conserved that the mutation of a single residue in Aurora-A (G198N) is able to transform this kinase in a functional Aurora-B kinase (Hans et al. 2009). All Auroras possess a carboxyl terminal "destruction box" (D-box), but only Aurora-A has the amino terminal "D-box-activating domain box" required for the functional activation of D-box and subsequent degradation by the proteasome via the anaphase-promoting cyclosome complex (APC/c) pathway activated by CDH1. Aurora-B degradation also depends on proteasome and APC/c but needs a KEN-box and a A-box in the amino terminal part. Amino terminal extensions are of variable lengths and display little or no similarity (Fig. 1). Data suggest these domains may be involved in subcellular localization or substrate recognition for the proteins (Rannou et al. 2008).

Aurora-A Functions

Aurora-A is mainly localized at centrosome in interphase and at the poles of the spindle in mitosis (Fig. 2). Aurora-A first appears at centrosomes in G2, its targeting depends on several protein kinases also found at the centrosome, such as ▶ Pak1, Plk-1, and Cdk-11 (Vader and Lens 2008). At the centrosome Aurora-A participates in the recruitment of pericentrosomal materials (PCM), an event commonly called centrosome maturation. Aurora-A is for instance required for the centrosome localization and function of Centrosomin, NDEL1, LATS, TACC. Aurora-A depletion causes defects in centrosome maturation but also ch-TOG and MCAK mislocalization, two centrosomal proteins that are involved in microtubules polymerization and depolymerization, respectively, one of the major functions of the centrosome PCM. After maturation, the centrosomes migrate apart during late G2 to define the two poles of the bipolar mitotic spindle. This event requires Aurora-A function, since its invalidation leads to monopolar spindle formation. One hypothesis possibly explaining such phenotype could involve the Eg5 kinesin. Eg5, known to be involved in spindle bipolarity, is phosphorylated by Aurora-A. Yet the link between Eg5 phosphorylation and spindle bipolarity is still lacking.



Aurora Kinases, Fig. 2 Aurora kinases functions

Astral microtubules have also been implicated in centrosome's separation by connecting centrosomes to cellular cortex. One other hypothesis likely explaining involvement of Aurora-A in centrosome separation is that Aurora-A is implicated in astral microtubules formation by phosphorylating TACC on Ser863.

Aurora-A is involved in mitotic entry. On the first hand, Aurora-A phosphorylates and promotes the activation of the Cdc25B phosphatase at centrosomes. This event is dependent on the targeting of Aurora-A to the centrosome *via* the LIM protein Ajuba. Phosphorylation of CDC25B is required for initial centrosomal activation of Cyclin-B/Cdk-1. On the other hand, it was recently shown that Aurora-A promotes the G2 activation of Polo-like kinase-1 (Plk-1) through phosphorylation within the T-loop of Plk-1. Active Plk1 controls Cyclin-B/Cdk1 activity through phosphorylation of the Cdc25B phosphatase and degradation of the Cdk1 inhibitory kinase Wee1. Aurora-A might also be involved in both the DNA damage checkpoint and in the spindle assembly checkpoint. Marumoto et al. (2003) showed that loss of function of Aurora-A through microinjection of antibodies delays mitotic entry, while gain of function through overexpression leads to premature entry into mitosis in the presence of DNA damage. Anand et al. (2003) showed that overexpression of Aurora-A at levels equivalent to those observed in cancers leads to an override of the spindle assembly checkpoint (SAC). The function of this checkpoint is to prevent chromosome segregation until every one of them is bioriented through kinetochore/microtubule attachment. This is achieved by controlling the activity of the anaphase-promoting complex/cyclosome (APC/C). Once the checkpoint is satisfied, the inhibition is relieved on the APC/C that promotes anaphase and mitotic exit by targeting securin and cyclin-B for degradation by the proteasome.

In one word, in the presence of spindle defects induced by taxol treatment, cells should arrest in prometaphase because of the SAC. Cells overexpressing Aurora-A are resistant to taxol treatment, they exit mitosis despite an active SAC. This might explain centrosome amplification and polyploidy frequently observed after Aurora-A overexpression (Meraldi et al. 2002; Marumoto et al. 2003).

To fulfill its functions, Aurora-A needs to be activated. Several Aurora-A activators have been suggested, yet data are quite controversial. For example, Bora and Ajuba have been first described as Aurora-A activators. However, Bora turns out not to be a direct and general activator of Aurora-A but rather an intermediate stimulating PLK1 phosphorylation by Aurora-A. And Ajuba was demonstrated not to be an Aurora-A activator in *Drosophila*. TPX2, HEF1, and, more recently, CEP192 and Arpc1b were also described as Aurora-A activators. Activation mechanism through binding to TPX2 and CEP192 is well documented. TPX2 activates Aurora-A through conformational changes triggering protection of the T288 residue from dephosphorylation by PP1 phosphatase (Bayliss et al. 2003). CEP192 recruits Aurora-A to centrosomes and favors oligomerization leading to a strong activation.

Aurora-B

Aurora-B is a chromosome passenger protein, localized on chromosome and kinetochores in prophase, on kinetochores during prophase and metaphase, and at the midbody at the end of mitosis (Fig. 2). At the chromosome level, Aurora-B fulfills various functions. Aurora-B phosphorylates histone H3 at serine-10 during late G2/prophase thought to be required for chromosome condensation. Mutation of H3 serine-10 in *Tetrahymena thermophila* or *Schizosaccharomyces pombe* indeed caused chromosome condensation defects and subsequent segregation anomalies. Yet, the same mutation does not cause any similar defect in *Saccharomyces cerevisiae* and there is actually no evidence it could work in a similar way in human. Within condensin complexes, that play a major role in chromosomes condensation, the three non-SMC subunits are phosphorylated by Aurora-B. This phosphorylation is required for loading of condensin I complex on chromosomes.

Aurora-B is also involved in sister chromatid cohesion. This cohesion is maintained by a ring structure formed by the cohesin complex, that surrounds two sister chromatids. The ring is then broken at the metaphase-anaphase transition through a mechanism that involved both kinases Plk-1 and Aurora-B.

Aurora-B activity is required for the localization of the centromeric protein shugoshin-1 (Sgo1). In the absence of Aurora-B, instead of concentrating on centromeres, Sgo1 localizes diffusely along chromosome arms. The role of Sgo1 during mitosis is to protect centromeric cohesin from being degraded before the SAC has been satisfied. To protect cohesin, Sgo1 must bind to PP2A that locally counteracts PLK1 activity. Redistribution of Sgo1 from centromeres to chromosome arms in the absence of Aurora-B causes inappropriate cohesin protection along chromosome arms eventually inhibiting sister chromatids separation.

Aurora-B also participates in the SAC by regulating an enzyme involved in microtubule dynamics and that specifically controlled the biorientation of each chromosomes as well as the stability of the bipolar mitotic spindle. In a perfect spindle, each pair of every kinetochore is attached to microtubules emanating from different centrosomes building a bipolar spindle. Abnormal attachments can take various forms: (1) synthelic (in a kinetochore pair, both bind microtubules emanating from the same pole or centrosome) or (2) merothelic attachments (in a kinetochore pair, one binds to both centrosomes). Those two abnormal attachments are at the origin of a signal "lack of tension" in the spindle that will trigger a correction corresponding to an elimination of the abnormal attachment. The unattached kinetochores can then enter a new cycle of microtubule attachment until bipolar attachment is obtained. Two mechanisms involving Aurora-B in such corrections have been described. In the first one, Aurora-B phosphorylates the microtubule-depolymerizing enzyme MCAK and increases its recruitment to centromere. In the second one, Aurora-B phosphorylates kinetochore microtubule-capture factors such as Ncd80/Hec1 and Dam1. Phosphorylation reduces kinetochore affinity for microtubules whereas dephosphorylation stabilizes microtubule-kinetochore interactions. When biorientation is achieved, mitotic spindle comes under tension. This tension results in a movement of the kinetochores away from the kinase Aurora-B that is not able anymore to phosphorylate its target at the kinetochores. In summary, a single unattached kinetochore is sufficient to keep the SAC on in prometaphase. Aurora-B activity is required to arrest cell cycle progression in response to taxol that induces a lack of tension in the mitotic spindle. Attachments that do not generate tension are removed in an Aurora-B-dependent manner that triggers the recruitment of checkpoint proteins to kinetochores, resulting in inhibition of APC/C Cdc20.

After metaphase/anaphase transition, Aurora-B leaves kinetochores to concentrate at the spindle midzone and at the equatorial cortex to finally accumulates at the midbody. This protein localization from chromosome to midbody depends on microtubules and is characteristic of chromosome passenger protein essential for late mitotic events. Indeed, Aurora-B is the catalytic activity of the chromosomal passenger complex (CPC) consisting of Aurora-B itself, inner centromere protein (INCENP), borealin, and survivin. CPC plays an essential role in cytokinesis in a wide range of organisms. At the midbody Aurora-B phosphorylates the centralspindlin complex composed of the kinesin MKLP1/ZEN4 and the Rac GTPase–activating protein 1 (MgcRacGAP). This phosphorylation is required to signal the positioning of the cleavage furrow via phosphorylation. The centralspindlin complex then regulates events leading to RhoA activation positioning the actomyosin contracting ring. In budding yeast, Aurora-B (Ipl1) plays an additional role during cytokinesis by

controlling the NoCut pathway that prevents abscission (the final step of cytokinesis) when chromosomes have not been fully segregated and remain present at the site of abscission (Norden et al. 2006). Ipl1 controls the localization of the anillin-related proteins Boi1 and Boi2 to the ingression site, they both act as abscission inhibitors and prevent premature abscission and concomitant chromosome breakage.

Aurora-C

The third member of the Aurora family, Aurora-C, is a close relative to Aurora-B. Ectopically expressed Aurora-C shows the same mitotic localization pattern as Aurora-B. Aurora-C can also interact with INCENP and survivin, two CPC proteins. Overexpression of a kinase-dead mutant of Aurora-C interfered with Aurora-B function by displacing its binding partners. In normal physiological conditions, Aurora-C mRNA and protein were initially described to be expressed only in testis. Aurora-C is required for spermatogenesis and male fertility in mice. A recent study identified a homozygous mutation within the *Aurora-C* gene in a group of infertile men. The mutated *Aurora-C* gene yielded a truncated kinase activity-deficient Aurora-C protein. The spermatozoa in these men were polyploid, again indicating a role for Aurora-C in maintaining a stable karyotype during male meiosis. Aurora-C mRNA was detected in several human adult tissues, yet to significantly lower levels than in testis.

Aurora Kinases and Cancer

The chromosomal region in which *Aurora-A* gene is located is frequently amplified in human cancers. Many studies show a significant incidence of Aurora-A amplification and overexpression in human breast, bladder, ovarian, colon, and pancreatic cancers. Ectopic overexpression of Aurora-A transforms NIH3T3 cells and Rat 1 fibroblasts in vitro, and introduction of these transformed cells into nude mice results in tumor growth. Aurora-A mRNA and protein overexpression is not systematically correlated with the gene amplification (i.e., amplification of Aurora-A was detected in 3% of hepatocellular carcinoma (HCC), whereas more than 60% of HCCs overexpressed Aurora-A mRNA and protein). Apart from gene amplification, transcriptional activation and inhibition of protein degradation can also contribute to the elevated levels of Aurora-A expression. It is still unclear how Aurora-A triggers cellular transformation and tumorigenesis, and how important its kinase activity is during this process. For instance, two different studies showed contradictory results concerning the effect of overexpression of a kinase-dead version of Aurora-A (Meraldi et al. 2002; Anand et al. 2003). The oncogenic effect of Aurora-A overexpression is likely due to chromosome instability and directly due to its functions during mitosis. Aurora-A overexpression triggers centrosome amplification likely through a cytokinesis defect. Subsequent abnormal spindles (monopolar or multipolar) formation are precursors of aneuploidy that could contribute to genomic instability and to tumorigenesis. Also, abnormal spindle usually results in the maintenance of the SAC, which leads to abortive mitosis and cell death through apoptosis. Yet, in many tumor cells, there is a tight relation between Aurora-A overexpression and the tumor suppressor ▶ p53. Aurora-A directly phosphorylates p53 and controls its stability and transcriptional activity. Additionally, p53 directly inhibits Aurora-A function, potentially *via* its binding to the catalytic domain of Aurora-A. The effect of Aurora-A overexpression on tetraploidization and centrosome amplification thus depends on the p53 status. When Aurora-A is overexpressed in cells lacking p53, the newly generated tetraploid cells would continue their cell cycle progression, thus giving rise to polyploid cells with four centrosomes and finally leading to genomic instability. Aurora-A was also shown to physically bind to and phosphorylate BRCA1. BRCA1, like p53, is a tumor suppressor; its phosphorylation by Aurora-A causes a loss of function, making cells resistant to DNA damage and override checkpoint response.

Two recent studies in *Drosophila* and mouse showed that Aurora-A could yet function as a tumor suppressor. In *Drosophila*, Aurora-A is required for correct spindle orientation during asymmetric neuroblast division. Asymmetric stem cell division is required for the correct balance between stem cell self-renewal and differentiation. Disruption of asymmetric stem cell division through Aurora-A inactivation can give rise to stem cell overproduction and concomitant tumor growth. In mouse, Aurora-A heterozygosity results in a significant increased tumor incidence suggesting that Aurora-A may act as a haplo-insufficient tumor suppressor. Furthermore, Aurora-A heterozygous mouse embryonic

fibroblasts have higher rates of aneuploidy. These findings, together with the observation that Aurora-A levels are low in certain tumors, strongly suggest that a balanced Aurora-A level is critical for maintaining genomic stability. These data are important to keep in mind regarding the current efforts that are made to exploit Aurora-A inhibition by chemical inhibitors as an antitumor therapeutic.

The role of Aurora-B in tumorigenesis is not as clear as concerning Aurora-A. Only one study showed that overexpression of Aurora-B in CHO cells can promote aneuploidy and increase invasiveness in xenograft experiments. Yet, the chromosomal region containing Aurora-B has never been associated with amplification in tumors. Reports show that Aurora-B is overexpressed in certain tumor types, but it is not clear whether the observed overexpression of Aurora-B is due to the high proliferative index of cancerous cells or whether it is really related to tumorigenesis. Aurora-B overexpression was also shown to strongly enhance cellular transformation in cells expressing oncogenic Ras-V12. Thus, Aurora-B is probably not directly oncogenic but could participate in cell transformation in a particular cellular context.

Although the chromosomal region in which the Aurora-C gene is located is known to be deleted or translocated in certain human cancers cell lines, it is unclear whether Aurora-C deletion or overexpression plays a causative role in tumorigenesis even if a correlation was made between expression and aggressiveness of thyroid cancer.

Pharmacological Inhibitors of Aurora Kinases

The clearly established role for Aurora kinases in mitosis, accompanied by the evidence suggesting that deregulated Aurora-A and, to a lesser extent, Aurora-B expression is linked to tumorigenesis, raised the hypothesis that inhibiting these kinases might be a powerful antitumor strategy. The aim of this entry is not to give exhaustive data about Aurora kinase inhibitor (exhaustive details are given in these three excellent reviews: Boss et al. 2009; Katayama and Sen 2010; Karthigeyan et al. 2010) but to bring clear information important to know about pharmacological Aurora inhibition. Globally, and because the catalytic site is well conserved in Aurora kinases family, there does not exist any inhibitor to specifically target Aurora-A or Aurora-B. All inhibitors target the ATP-binding site to inhibit the catalytic activity of the kinase. Hesperadin and ZM447439 were the first proven small-molecule inhibitors of Aurora kinases. If Hesperadin is more effective on Aurora kinase B than on Aurora-A, ZM447439 inhibits both Aurora kinases A and B. Both compounds never entered clinical trials, probably due to the emergence of more potent and specific inhibitors of the Aurora kinases family. There are actually several new molecules that entered phase I and even phase II clinical trials. Some molecules are pan-Aurora inhibitors (i.e., VX-680, PHA-739358…), others are more selective for Aurora-B (i.e., AZD1152) or Aurora-A (i.e., MLN8054, MLN8237). Concerning pan-Aurora inhibitors, results suggest that effect is mainly directed against Aurora-B. Regarding these data, it is important to keep in mind that in vitro tests designed to assess inhibitor specificity do not take into account Aurora-interacting proteins (i.e., inhibitors or activators). Indeed, it is now known that binding of TPX2 to Aurora-A alters inhibitor interaction (Anderson et al. 2007). Specificity revealed in vitro thus does not reflect the real effect of the drug in vivo. Overall, the responses seen in the phase I studies reported to date in patients with solid tumors are rather disappointing. The majority of reports had only disease stabilization as best response, with very few exceptions. This highlights the fact that to increase the antitumor activity of the Aurora kinase inhibitors in the clinic, combination therapy with cytotoxic anticancer agents, radiotherapy, or other targeted agents might be used in the future. Regarding the possible role of Aurora-A as a tumor suppressor, one can also ask whether it is really judicious to specifically target the Aurora-A kinase or, in other words, whether there a risk to trigger tumorigenesis of noncancer cells in a patient treated with an Aurora kinase inhibitor. Further studies are needed to fully address these questions and there is a strong need to generate pertinent biomarkers to treat patients that really need these molecules.

Summary

Aurora proteins belong to a family of kinases involved in cell cycle regulation. In mammals, there exist three different Aurora kinases named Aurora-A, -B, and -C.

These proteins share a common structure but present different functions and subcellular localizations. Aurora-A is associated predominantly with centrosomes and the spindle apparatus from prophase through telophase and is mainly involved in mitotic spindle assembly. Aurora-B is prominent at the midzone during anaphase and in postmitotic bridges during telophase and participates in chromosomes segregation and cytokinesis. Aurora-C appears to possess functions similar to Aurora-B but its expression is restricted to testis. Due to their prominent roles in cell cycle regulation, Aurora kinases are frequently involved in tumorigenesis and are targets of pharmaceutical industry that aims at generating specific Aurora kinase inhibitors to treat cancer.

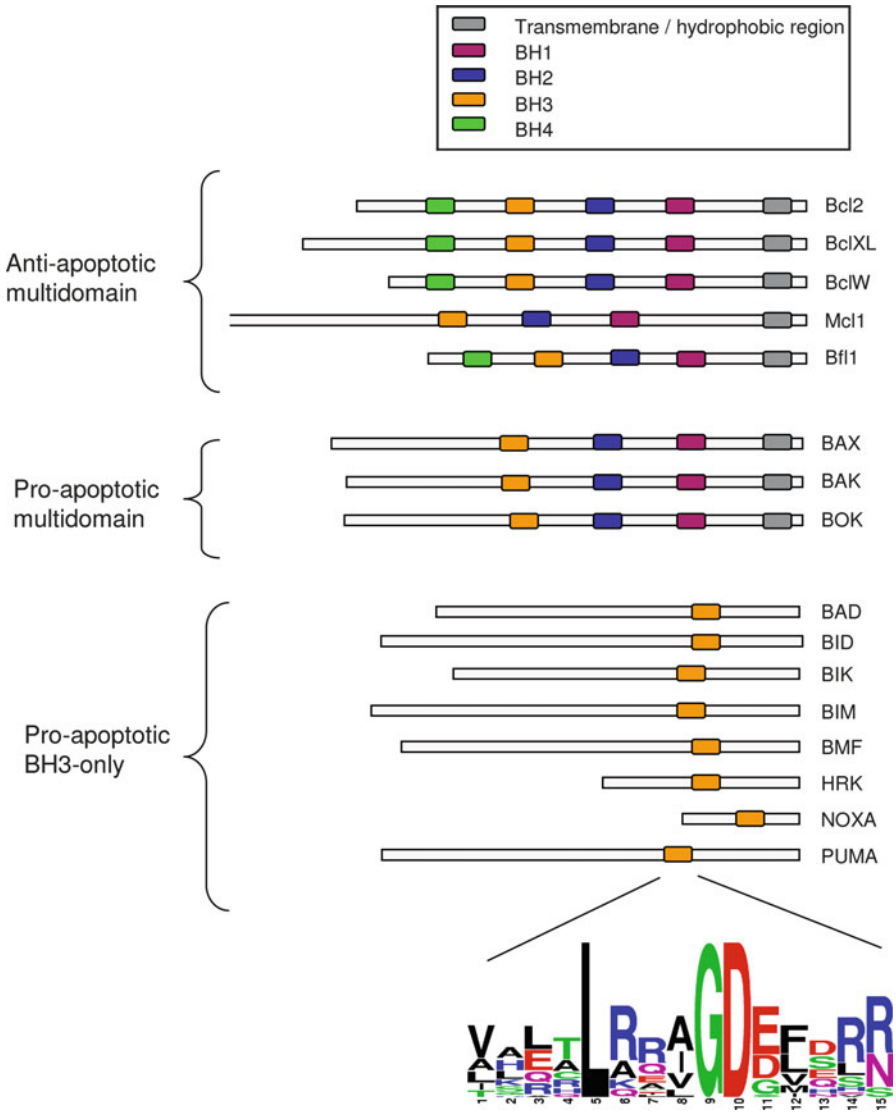
Historical Background

The BCL-2 protein, the founding member of this family of proteins, was discovered in 1985. The gene *BCL2* was identified as the main protagonist in the chromosomal translocation t(14;18) in a subset of B-cell lymphomas, placing it under the control of the promoter of the immunoglobulin heavy chain genes (Cotter 2009). In contrast to previously identified oncogenes that mainly promote cell proliferation, BCL-2 was the first oncogene shown to inhibit cell death (Vaux et al. 1988). Since then other members of the BCL-2 family have been discovered, and the family of BCL-2 proteins now consists of approximately 20 members. In mammalian organisms, BCL-2 proteins play an essential role in the control of programmed cell death, and in particular apoptosis. Recent investigations have helped to unveil some facets of their regulation and their molecular mode of action on membrane organelles and mitochondria.

Structure and Classification of BCL-2 Proteins

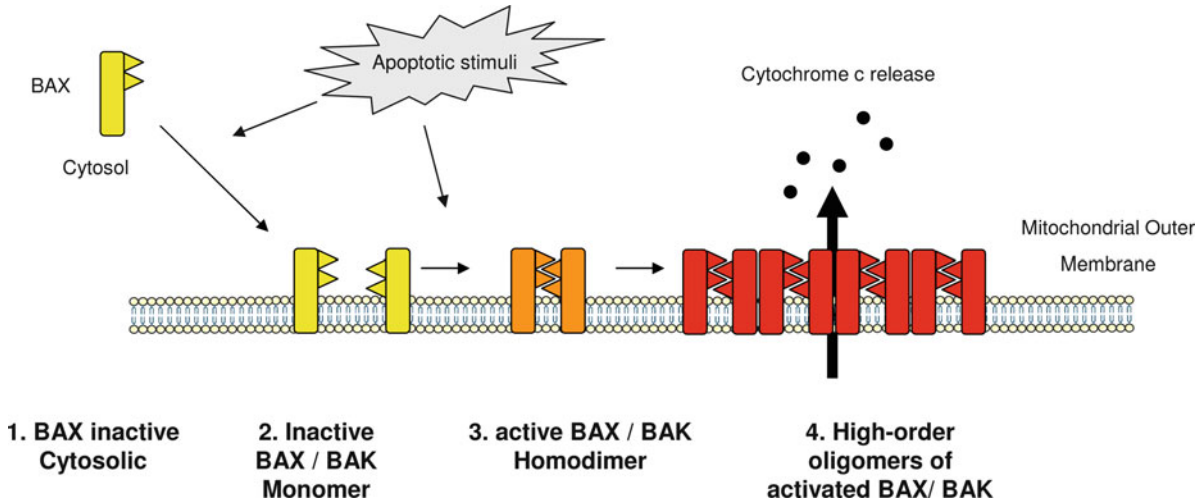
BCL-2 proteins are divided into three groups, based on functional as well as structural criteria (Chipuk et al. 2010): (1) functionally, depending on their effect on apoptosis – either pro- or anti-apoptotic; (2) structurally according to the presence of one or multiple homology domains – all members of the BCL-2 family share one or more regions of sequence homology, called the BCL-2 homology domains 1–4 (BH1 to BH4). The anti-apoptotic proteins of the BCL-2 family constitute the first group of proteins. They are multidomain proteins, usually containing BH1-BH4 domains. This group principally includes the proteins BCL-2, BCL-XL, MCL-1, and A1



BCL-2 Family,
Fig. 1 *Structural domains and organization of the BCL-2 proteins*. BCL-2 proteins can be classified according to their pro- or anti-apoptotic effects and the presence of one or multiple BCL-2-homology (BH) domains. The BH3 domain is the only domain of homology shared by all members of the family. It consists of 15 AA with a preference for the motif depicted in the sequence logo in the lower part of the figure (adapted from the server Prosite, http://expasy.org/cgi-bin/prosite/). While the membrane localization domains are indicated here for the multidomain BCL-2 proteins, several members of the BH3-only proteins also possess membrane targeting domains with an affinity for lipids

(Fig. 1). The corresponding proteins functionally counteract the pro-apoptotic proteins of the BCL-2 family. The pro-apoptotic proteins are divided into two groups: (1) the multidomain pro-apoptotic proteins (BAX, BAK, BOK) of the BCL-2 family, and (2) the BH3-only proteins, containing this sole homology domain (such as BID, BIM, PUMA, BAD, NOXA, BMF, HRK, BIK) (Fig. 1). The BH3 domain is, therefore, the only conserved region of homology among the proteins of the BCL-2 family. While this domain is an essential region for the activity of the BCL-2 proteins, it is short and consists of approximately 15 amino acids organized in an amphipathic helix (Fig. 1). The BH3 domain is also present in proteins that are only loosely connected to the BCL-2 family, such as the proteins MULE and Beclin-1.

Remarkably, despite important differences in their amino-acid sequences, all multidomain proteins of the BCL-2 family possess a similar secondary structure consisting mostly of α-helices and a similar overall fold (Chipuk et al. 2010). This similarity extends to the proteins that have opposing functions, either pro- or anti-apoptotic. In BCL-XL, the spatial juxtaposition of α-helices from the BH1-BH3 regions defines a globular structure with a hydrophobic groove on the surface of the molecule. This hydrophobic groove enables BCL-XL to interact with the BH3 domain of



BCL-2 Family, Fig. 2 *A model for the activation of BAX/BAK and the induction of MOMP*. The activation of the pro-apoptotic multidomain proteins BAX and BAK is an essential step that leads to mitochondrial membrane permeabilization and apoptosis. While BAK is constitutively present at the mitochondrial level, BAX is normally cytosolic. The first step in the activation of BAX consists of a cytosolic to membrane translocation, possibly occurring as a consequence of the release of the carboxy-terminal tail of BAX from an inhibitory internal interaction with the hydrophobic groove of this molecule. The second step consists of the activation of BAX/BAK per se and probably results in the shaping of the BH3 domains of BAX or BAK. Reciprocal interactions and homodimer formation are rendered possible once this shaping has allowed reciprocal interactions between their BH3 domains and hydrophobic grooves. Further interactions implicating other parts of BAX/BAK lead to higher order complex- and pore-formation, resulting in MOMP and apoptosis

pro-apoptotic proteins. In contrast to the multidomain proteins of the BCL-2 family, the BH3-only proteins are structurally diverse, with the exception of BID, which has an overall fold reminiscent of the multidomain proteins. Members of the BH3-only subset, such as BAD or BIM, tend to be intrinsically unfolded proteins and they probably acquire a stable fold only upon their interaction with other members of the BCL-2 family.

Mitochondrial Membrane Permeabilization by BCL-2 Proteins

In mammalian cells, mitochondrial outer membrane permeabilization (MOMP) is an early and crucial event during the induction of apoptosis (Tait and Green 2010). The MOMP leads to the release of pro-apoptotic factors, such as cytochrome c, into the cytosol. There, cytochrome c induces a cascade of biochemical events that lead to the activation of caspases, a family of proteases involved in the execution of the death sentence.

The proteins of the BCL-2 family are key players in the MOMP (Kuwana et al. 2002). The pro-apoptotic multidomain proteins of the BCL-2 family, i.e., BAX and BAK, play an essential role in the MOMP through their ability to form membrane-inserted oligomers (Chipuk et al. 2010; Westphal et al. 2010). How BAX and BAK insert and ultimately permeabilize mitochondrial membranes is a complex question and represents the focus of intense research. According to a commonly accepted model, several steps are required for BAX/BAX oligomerization and MOMP (Fig. 2). The first step consists of the mitochondrial recruitment of these proteins. While BAK is constitutively present at the mitochondrial level, BAX is cytosolic in healthy cells. In its cytosolic form, the C-terminal extremity of BAX is sequestered in its BH3-binding pocket and BAX is therefore locked in a monomeric, inactive form. The first step in BAX activation consists of the release of BAX from this intramolecular lock, and this step is a requisite for the insertion of BAX into the MOM. The next step is common to BAX and BAK, and consists of the direct activation of these proteins. Some proteins of the BH3-only subset, in particular BID, BIM, or PUMA, can directly activate BAX and BAK through direct contacts (Gavathiotis et al. 2008; Gallenne et al. 2009). The multimerization of BAX and BAK also requires the release of these molecules

from the inhibitory effect of anti-apoptotic proteins of the BCL-2 family, such as BCL-2, BCL-XL, or MCL-1. Anti-apoptotic proteins of the BCL-2 family negatively regulate the multimerization of BAX and BAK through two mechanisms: (1) the direct sequestration of BAX and/or BAK, and (2) indirectly, through the neutralization of the BH3-only proteins endowed with the ability to activate BAX/BAK, such as BID (Billen et al. 2008). Overall, the MOMP is a complex process that is intimately associated with the formation of complexes between proteins of the BCL-2 family. While the role of BCL-2 proteins in MOMP is well accepted, many questions about the precise mechanisms still remain, such as the exact nature of the pore formed by BAX and BAK and the contribution of accessory mitochondrial proteins to this process.

Regulation of the BCL-2 Network: Role of the BH3-Only Proteins

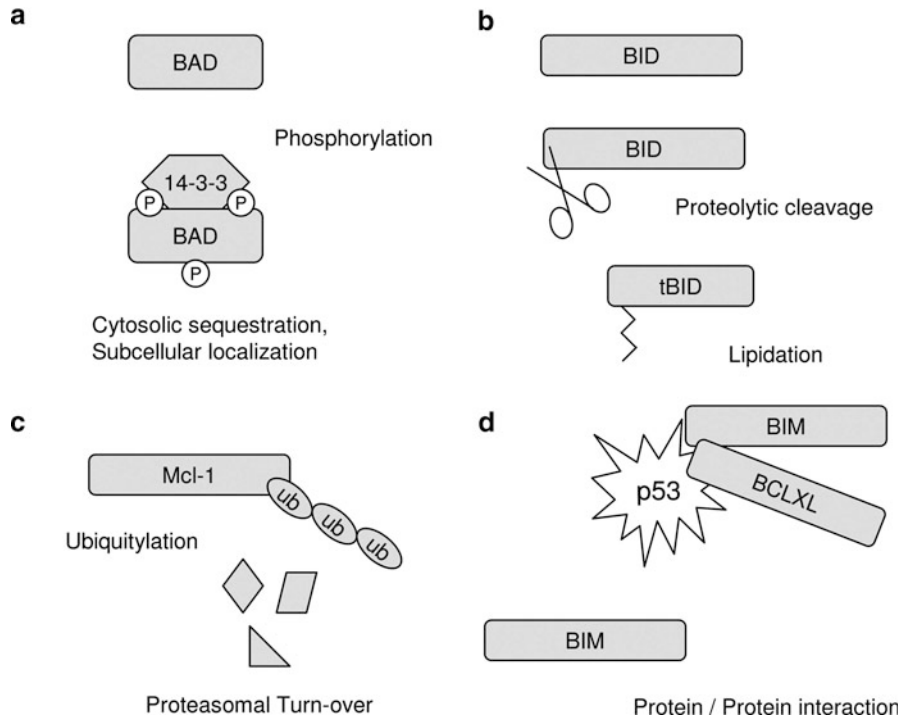
Cell survival is the result of a delicate balance between the activities of the pro- and anti-apoptotic proteins of the BCL-2 family. Apoptosis occurs when this balance is tipped over in favor of the pro-apoptotic signal. The BH3-only proteins play an upstream regulatory role in the BCL-2 network. While the proteins of this subset generally stimulate apoptosis, a complex picture of the mode of action of BH3-only proteins has recently emerged.

All BH3-only proteins are able to neutralize the anti-apoptotic proteins of the BCL-2 family, but the interaction of BH3-only proteins with anti-apoptotic BCL-2 proteins is characterized by its selectivity. There are large differences in the interaction spectra among BH3-only proteins (Chen et al. 2005; Certo et al. 2006). Some BH3-only proteins, such as BAD, neutralize selected anti-apoptotic proteins, such as BCL-2 and BCL-XL, while others, such as BIM and PUMA, bind all pro-survival proteins. Some BH3-only proteins, such as BIM, BID, and PUMA, do not only neutralize the anti-apoptotic proteins of the BCL-2 family, but can also activate the pro-apoptotic proteins BAX and BAK through labile interactions (Gavathiotis et al. 2008; Gallenne et al. 2009). These differences in terms of mode of action of the BH3-only proteins translate into differences in apoptotic potency, and proteins such as BAD behave more as sensitizers toward apoptosis rather than true inducers. The study of how the effector BCL-2 proteins are regulated in living cells has until now been a difficult task. New biochemical as well as functional approaches will certainly help to track the dynamic interactions between BCL-2 proteins, and to clarify the regulation of BCL-2 proteins during the life/death decision.

An important aspect of the regulation of BH3-only proteins is that they are kept under control by specific stimuli. Apoptosis-modulating stimuli operate on each BH3-only protein, via an array of regulations ranging from transcriptional to posttranslational (Fig. 3). For example, PUMA is induced transcriptionally following severe DNA damage, essentially through the activation of the transcription factor ▶ p53 (Yu and Zhang 2008). On the other hand, the BH3-only protein BAD is phosphorylated and thereby inactivated by pro-survival kinases, such as the kinase cascades RAF-MEK-ERK or PKB-mTOR. The survival of cells requires their constant exposure to trophic factors that activate these cascades, and BAD becomes activated by dephosphorylation in response to growth factor deprivation (Danial 2008). BID is another member of the BH3-only subset whose activity is under regulation through the engagement of a family of cell surface receptors known as death receptors. BID is activated by a proteolytic cleavage generating the truncated, active form of the molecule called tBID. Cellular studies have helped to establish the basics on the regulation of each BH3-only protein and the sentinel function of BH3-only proteins, but the regulation of BCL-2 proteins remains a complex topic, involving several protagonists with different tissue-specific expression patterns and partially redundant functions.

Various Physiological Functions

In addition to the regulation of programmed cell death, proteins of the BCL-2 family regulate several physiological processes. These processes are diverse, and range from the control of mitochondrial morphogenesis and Ca^{2+} fluxes in the endoplasmic reticulum to various aspects of cell metabolism. Cell proliferation and the integrity of the genome are also regulated by BCL-2 proteins, through interactions established with regulatory proteins of the cell cycle and DNA repair machinery. A detailed overview of these mechanisms is clearly beyond the scope of this chapter, but the



BCL-2 Family, Fig. 3 *Posttranslational regulation of proteins of the BCL-2 family*. The BCL-2 proteins are regulated through the direct modulation of their activation status, their subcellular localization, protein stability, or their functional sequestration. Posttranslational modifications, such as phosphorylations, proteolytic cleavage, ubiquitylation, lipidation, interaction with chaperones or with specific molecules are frequently encountered. For example, the protein BAD is regulated by phosphorylation and association with proteins of the 14-3-3 family (panel A). BID becomes active upon engagement of death receptors: A proteolytic cleavage by Caspase-8 creates a truncated version of this protein (tBID) and unmasks a site for N-myristoylation of this protein (panel B). The protein MCL-1 is regulated by ubiquitylation, a posttranslational modification that controls its turnover through proteasomal degradation (panel C). Finally, protein interactions can also regulate the activity of BCL-2 proteins. The protein p53 is able to functionally neutralize the anti-apoptotic proteins of the BCL-2 family, such as BCL-XL or MCL-1, despite the absence of a BH3 domain; by doing so, the cytosolic accumulation of p53 might release pro-apoptotic proteins of the BCL-2 family, such as BIM, from preexisting inhibitory interactions (panel D)

regulation of autophagy and inflammatory cytokine production by BCL-2 proteins provide two well-known examples. Autophagy is a process whereby cellular macromolecules or organelles become isolated inside cellular membrane and fuse with lysosomes to promote their elimination and recycling of their components. BCL-2 and BCL-XL have been shown to interact with Beclin-1, an essential regulator of autophagy. The interaction between Beclin-1 and BCL-2 is possible because Beclin-1 possesses a BH3 motif (Maiuri et al. 2007). BCL-2 and BCL-XL also play a role in the regulation of the metabolism of inflammatory cytokines, such as Interleukin-1, through molecular interactions established with the inflammasome, an intracellular protein complex involved in the regulation of Caspase-1, the enzyme responsible for the maturation processing of this cytokine (Bruey et al. 2007). The proteins of the BCL-2 family therefore exert pleiotropic effects that extend far beyond the regulation of programmed cell death.

BCL-2 Proteins and Cancer

Reduced sensitivity to apoptosis is one of the hallmarks of cancer cells. Deregulation of BCL-2 protein expression is frequently observed and it was shown to contribute to this disease (Yip and Reed 2008; Frenzel et al. 2009). Overexpression of the anti-apoptotic proteins of the BCL-2 family was the mechanism first reported to account for apoptosis resistance in cancer cells. While it is now well accepted that most

cancer cells present a reduced sensitivity to apoptosis due to modulation of the BCL-2 regulatory system, the mechanisms that lead to the altered regulation of BCL-2 proteins are complex. Alterations in the genome of cancer cells, epigenetic mechanisms, and posttranslational modifications often concur to shape the BCL-2 proteome in cancer cells (Yip and Reed 2008; Frenzel et al. 2009).

The regulation of the proteins of the BCL-2 family has attracted considerable attention as a possible approach for cancer treatment. Indeed, inducing tumor regression through the death of cancer cells is the main goal of cancer treatment, and most chemotherapeutic agents are apoptosis inducers in cancer cells (Fulda and Debatin 2006). In a growing number of situations, apoptosis of cancer cells induced by medical treatments was found to depend on the modulation of BCL-2 proteins: treatment-induced apoptosis could either be blocked by the overexpression of anti-apoptotic proteins, such as BCL-XL or MCL-1, or by the reduction of the expression of pro-apoptotic proteins of the BCL-2 family. For example, colorectal cancer cells with a BAX knockout were found to be insensitive to the commonly used chemotherapeutic agent 5-fluorouracil (Zhang et al. 2000). More recently, specific BH3-only proteins were found to account for cell death induced by specific targeted therapies. For example, the BH3-only protein BAD mediates the apoptotic response of liver cancer cells exposed to the kinase inhibitor sorafenib, currently the only medical treatment for this tumor (Galmiche et al. 2010).

The realization that BCL-2 proteins play a pivotal role in the response of cancers to medical treatments led to intense efforts aiming to identify compounds that would directly target these proteins and could be used as a new line of targeted therapies in oncology. In recent years great advancements have been made along this line, principally with the search for BH3-mimetic compounds that bind the hydrophobic groove formed by BH1-BH3 of the anti-apoptotic BCL-2 proteins, thus favoring apoptosis. To date, the compound with the best characterized BH3-mimetic activity is ABT-737 that was developed by the Abbott laboratories (Oltersdorf et al. 2005). ABT-737 binds with high affinity to the anti-apoptotic proteins BCL-2, BCL-XL, and BCL-W, but not to MCL-1, thus demonstrating a BAD-like reactivity. ABT-737 exerts a strong anticancer activity on Small Cell Lung Carcinoma cells, which frequently overexpress BCL-2 (Oltersdorf et al. 2005). An orally active derivative, ABT-263, has been developed. ABT-263 has shown promising effects in animal models with xenografted tumors, leading to sustained regression and demonstrating the safety of the inhibition of BCL-2 proteins in the entire organism. Studies aiming to test BCL-2 inhibitors in animal models that more closely mimic human tumors are now eagerly awaited. In parallel, the identification of compounds with reactivities that differ from those of ABT-737 as well as the understanding of cancer cell addiction to anti-apoptotic proteins of the BCL-2 family are the focus of future research. BCL-2 proteins have acquired the status of potential targets in oncology, and advances in this field are expected in the coming decade.

Summary

BCL-2 proteins are pivotal regulators of apoptosis. Over the past decade, intense research efforts have helped to better understand how these proteins mutually interact and regulate the mitochondrial membrane permeabilization, a critical step in apoptosis execution. In addition to their role as important effectors, BCL-2 proteins have also emerged as key integrators for the cell signaling pathways regulating programmed cell death. Extensive work still remains to fully understand the functionality of the intricate network of BCL-2 proteins, but recent advances have demonstrated the therapeutic potential of targeting BCL-2 proteins in cancer therapy. The introduction of drugs with a new mode of action, called BH3 mimetics, holds great promise in cancer research. It is also expected to facilitate the exploration of the physiological functions and the regulation of these important signaling molecules.

Historical Background

Beta-catenin (β-catenin) (Armadillo in *Drosophila*) is a multifunctional protein involved in two essential cellular events: cell–cell adhesion and the canonical Wnt signaling pathway (Takemaru 2006). β-Catenin/armadillo (Arm) was initially identified as a segment polarity protein in *Drosophila* in the early 1980s, and later recognized as a key downstream effector of the Wnt pathway. Meanwhile, β-catenin was shown to be

an integral component of cadherin-mediated cell adhesion complexes. Over the past two decades, interdisciplinary research has tremendously advanced our knowledge of β-catenin function and its involvement in human disorders (Takemaru et al. 2008; Cadigan and Peifer 2009; MacDonald et al. 2009). At cell–cell adhesion junctions, β-catenin interacts with type-I cadherins and α-catenin, which in turn associates with the actin cytoskeleton. In canonical Wnt signaling, β-catenin acts as a transcriptional coactivator through its interaction with transcription factors and cofactors to stimulate expression of target genes. In recent years, aberrant activity of β-catenin signaling has been linked to various diseases, especially cancer.

Structural Features of β-Catenin

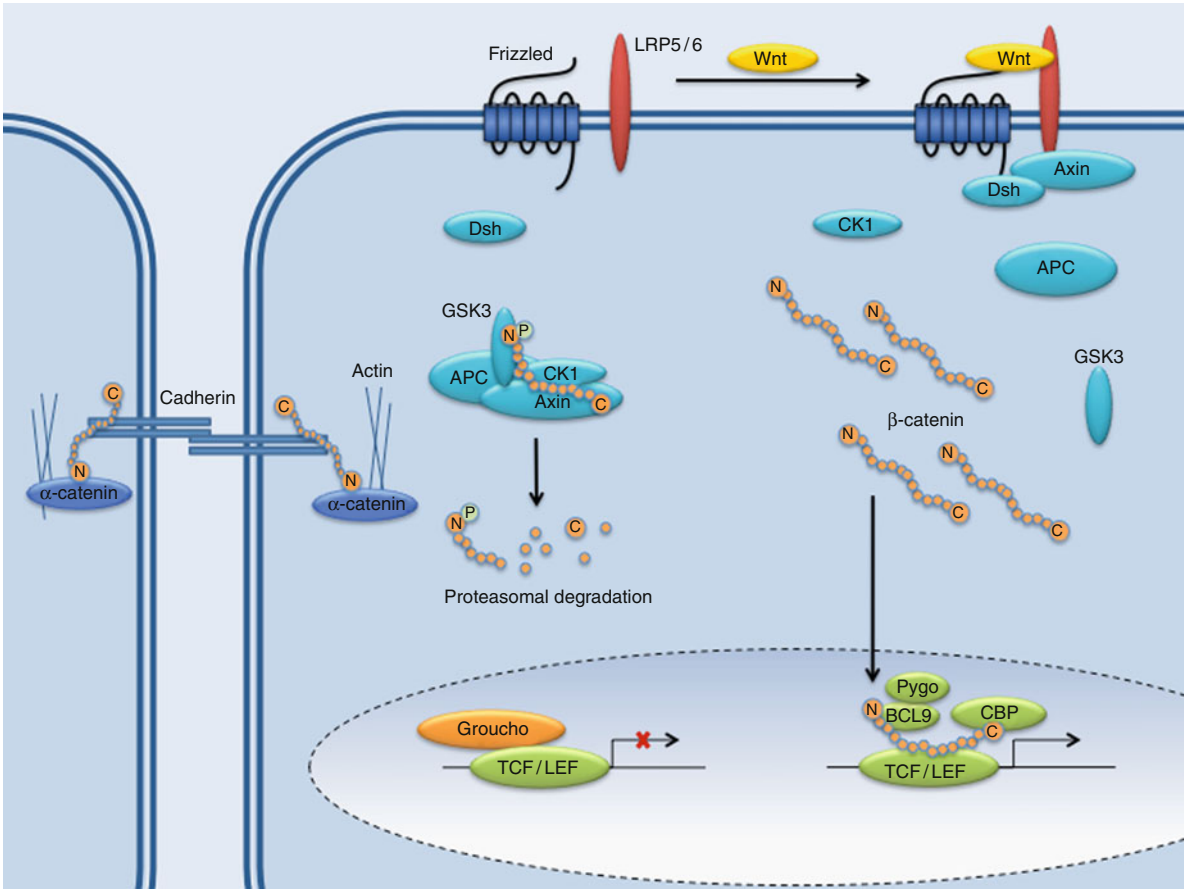
Human or mouse β-catenin consists of 781 amino acid residues, harboring a central structural core of 12 Arm repeats, flanked by unique N- and C-termini (Takemaru et al. 2008; Mosimann et al. 2009). The Arm repeat domain is highly conserved between vertebrates and other species but the terminal portions are diverged. The three-dimensional structure of the Arm repeat region has been determined, forming a twisted superhelical structure with a positively charged groove. Many β-catenin-binding partners bind to the Arm repeat domain. The precise structures of the N- and C-terminal tails remain unknown and may not form a rigid structure on their own. β-Catenin is subjected to posttranslational modifications such as ubiquitination, phosphorylation, and acetylation that control its protein stability, subcellular localization, and protein–protein interactions (Verheyen and Gottardi 2010). Plakoglobin (γ-catenin) is a close homologue of β-catenin in vertebrates and can fulfill some of the same functions (Zhurinsky et al. 2000).

β-Catenin as a Key Transcriptional Coactivator in the Canonical Wnt Pathway

β-Catenin is best known for its function as a transcriptional coactivator downstream of canonical Wnt signaling. Wnts are secreted extracellular proteins that play diverse roles in embryonic development and tissue homeostasis, including cell proliferation, cell fate decisions, and stem cell maintenance, as well as cell movement and polarity (Angers and Moon 2009; Cadigan and Peifer 2009; MacDonald et al. 2009). Core components of the Wnt/β-pathway are highly conserved in evolution from primitive cnidarians to humans.

Our current understanding of the Wnt/β-catenin signaling pathway is summarized in Fig. 1. In the absence of a Wnt ligand (Fig. 1, left), β-catenin is captured by the multi-protein "destruction complex," composed of the tumor suppressors Axin and adenomatous polyposis coli (APC), and the protein kinases casein kinase 1 (CK1) and glycogen synthase kinase 3 (GSK3). CK1 acts as a priming kinase and phosphorylates β-catenin at serine 45, allowing subsequent phosphorylation at threonine 41, serine 37, and serine 33 by GSK3. Phosphorylated β-catenin is then recognized by the E3 ubiquitin ligase receptor β-TrCP and targeted for ubiquitin-mediated proteasomal degradation. Therefore, under unstimulated conditions, cytosolic β-catenin is maintained at low levels. In the nucleus, the DNA-binding HMG-box T-cell factor/lymphoid enhancer factor (TCF/LEF) proteins keep Wnt target genes off by recruiting transcriptional corepressors such as Groucho (TLE). Extracellularly, the activity of Wnts is regulated by several secreted antagonists including Dickkopfs (DKKs), secreted frizzled-related proteins (sFRPs), and Wnt inhibitory factors (WIFs). Upon engagement with the seven transmembrane frizzled (Fz) receptors and the low-density lipoprotein receptor-related protein (LRP) coreceptors LRP5/6 (Fig. 1, right), Wnts trigger activation of the cytoplasmic protein disheveled (Dsh) and phosphorylation of the cytoplasmic tail of LRP5/6. This promotes recruitment of Dsh and Axin to the receptor complex at the plasma membrane, resulting in inhibition of β-catenin phosphorylation and degradation. Consequently, β-catenin accumulates in the cytoplasm and then translocates into the nucleus where it displaces Groucho and forms a complex with TCF/LEF transcription factors, leading to activation of Wnt target genes. Thus, activation of the Wnt pathway at the cell surface is ultimately translated into changes in gene expression through the TCF/β-catenin complex in the nucleus.

It is noteworthy that several negative regulators of β-catenin signaling, including APC, Axin, and Chibby (Cby), have been shown to contain both nuclear localization and nuclear export signals that enable them to shuttle between the nucleus and cytoplasm, and facilitate nuclear export of β-catenin (Willert and Jones



Beta-Catenin, Fig. 1 A simplified current model of the Wnt/β-catenin signaling pathway. β-Catenin has a dual function, acting in both cell adhesion and canonical Wnt signaling. See text for details

2006; Cadigan and Peifer 2009; MacDonald et al. 2009). In contrast, nuclear β-catenin interactors, such as TCF and BCL9/Pygopus (Pygo), appear to retain β-catenin in the nucleus. Detailed information on Wnt signaling can be found on the Wnt Homepage (http://www.stanford.edu/~rnusse/wntwindow.html).

Mechanisms of Target Gene Activation by β-Catenin

β-Catenin exerts its activation potential through assembly of coactivator and chromatin-remodeling complexes (Willert and Jones 2006; Takemaru et al. 2008; Mosimann et al. 2009). The C-terminal activation domain of β-catenin interacts with various positive cofactors such as the histone acetyltransferases CBP/p300, SWI/SNF ATPase subunit BRG1, and Parafibromin (Hyrax; a component of the RNA polymerase II-associated PAF1 complex). On the other hand, the N-terminal portion of β-catenin directly binds to the bridging molecule BCL9 (Legless), which in turn recruits the PHD-finger protein Pygo. Other β-catenin coactivators include TIP49 (Pontin), MED12, TRRAP, MLL1/2, and TBL1/TBLR1. The signaling activity of β-catenin is negatively regulated by its antagonists such as ICAT and Cby. There is also evidence that the TCF/β-catenin complex can function as a transcriptional repressor (Cadigan and Peifer 2009; MacDonald et al. 2009).

A considerable number of direct target genes of the TCF/β-catenin complex have been identified in various model systems including c-Myc, cyclinD1, Axin2, and TCF/LEF (for a comprehensive list of Wnt target genes, see the Wnt homepage). In general, cellular responses to Wnt signals vary significantly among

different cell types, and many Wnt/β-catenin target genes are regulated in a cell-type specific manner. There are a number of reagents/tools available to monitor β-catenin signaling activity including cell-based reporters, transgenic reporter animals, and direct β-catenin target genes (Moon et al. 2004; Barker and Clevers 2006; Chien et al. 2009).

β-Catenin at the Crosstalk with Other Signaling Pathways

Besides the canonical Wnt pathway, β-catenin signaling activity is positively or negatively regulated by a variety of other signaling pathways including Akt (protein kinase B), Src, PTEN, p53, NF-κB, epidermal growth factor (EGF), integrin-linked kinase (ILK), insulin-like growth factor (IGF), and prostaglandin E2 (PGE2) (Moon et al. 2004; MacDonald et al. 2009).

In addition to TCF/LEF factors, β-catenin has been shown to serve as a coactivator or, in some cases, a corepressor for many DNA-binding transcription factors including members of the nuclear hormone receptor family and HMG-box-containing Sox proteins (Takemaru et al. 2008; MacDonald et al. 2009). For instance, the vitamin A, vitamin D, and androgen receptors physically interact with β-catenin in a ligand-dependent fashion to potentiate activation of their target genes, while suppressing expression of TCF/β-catenin-dependent genes. Thus, it is apparent that β-catenin, via these transcription factors, could impact a broader range of gene expression programs.

β-Catenin in Development and Disease

The Wnt/β-catenin pathway has been studied extensively in a wide spectrum of model organisms including *C. elegans*, *Drosophila*, zebrafish, *Xenopus*, and mouse, and proven to be essential for numerous aspects of embryonic development such as segmentation, axis formation, and brain patterning (Cadigan and Nusse 1997; Chien et al. 2009). In mice, β-catenin deficiency results in embryonic lethality at the gastrulation stage (Grigoryan et al. 2008). Over the last decade, through the use of conditional mouse models, β-catenin has been activated and inactivated in various tissues in a temporal and tissue-specific manner (Grigoryan et al. 2008). These studies revealed important roles of Wnt/β-catenin signaling in development and homeostatic maintenance of many organs. In adults, Wnt/β-catenin signaling is crucial for maintaining self-renewal of pluripotent stem cells in skin, blood, intestine, and brain, and for tissue regeneration and repair following injury (Reya and Clevers 2005; Clevers 2006; Stoick-Cooper et al. 2007). Remarkably, recent studies identified the Wnt/β-catenin target and orphan receptor Lgr5 (GPR49) as a marker for stem cells in the adult intestinal epithelium and hair follicle (Barker and Clevers 2010).

More recently, dysregulation of Wnt/β-catenin signaling activity has been linked to the pathogenesis of a wide range of human diseases such as bone density defects and cancer (Logan and Nusse 2004; Clevers 2006; MacDonald et al. 2009).

Loss-of-function mutations in the Wnt coreceptor LRP5 are associated with osteoporosis-pseudoglioma syndrome (OPPG) characterized by low bone mass and loss of vision. Conversely, activating mutations in LRP5 cause increased bone density. These findings clearly demonstrate that Wnt/β-catenin signaling positively regulates bone formation.

Constitutively activated β-catenin signaling, due to loss-of-function mutations in APC or Axin or gain-of-function mutations in β-catenin itself, is associated with a variety of human malignancies including melanoma and colon and hepatocellular carcinomas (Polakis 2000; Takemaru et al. 2008). Remarkably, greater than 70% of colon cancers show aberrant Wnt/β-catenin signaling activity. Mutations in APC or Axin compromise their function within the β-catenin destruction complex, while oncogenic mutations in the N-terminal regulatory domain of β-catenin block its degradation via the ubiquitin-proteasome pathway. In addition, some tumor types show loss of expression of the secreted Wnt antagonists sFRPs and WIF1 due to epigenetic silencing by hypermethylation (Barker and Clevers 2006; Takemaru et al. 2008). All of these alterations ultimately lead to stabilization and nuclear translocation of β-catenin, followed by activation of target gene expression. Hence, β-catenin is an attractive molecular target for cancer therapeutics as well as other Wnt-related diseases. To date, small molecules that disrupt TCF/β-catenin or CBP/β-catenin interaction or stabilize Axin protein and therefore inhibit β-catenin-dependent transcription have been reported (Moon et al. 2004; Barker and Clevers 2006; Takemaru et al. 2008).

Summary

β-Catenin plays crucial roles in diverse biological processes as a pivotal component of cell–cell adhesion and Wnt signaling. It serves as a protein network hub by mediating numerous protein–protein interactions to ensure proper development and homeostasis of multiple tissues. Recent advances in genome-wide RNAi screens and proteomics approaches greatly facilitate the identification of novel β-catenin regulators (Angers and Moon 2009). The realization that β-catenin signaling is perturbed in various human diseases continues to fuel worldwide research efforts in the future. Certainly, a better understanding of β-catenin functions has broad impact on human diseases, stem cell biology, and regenerative medicine.

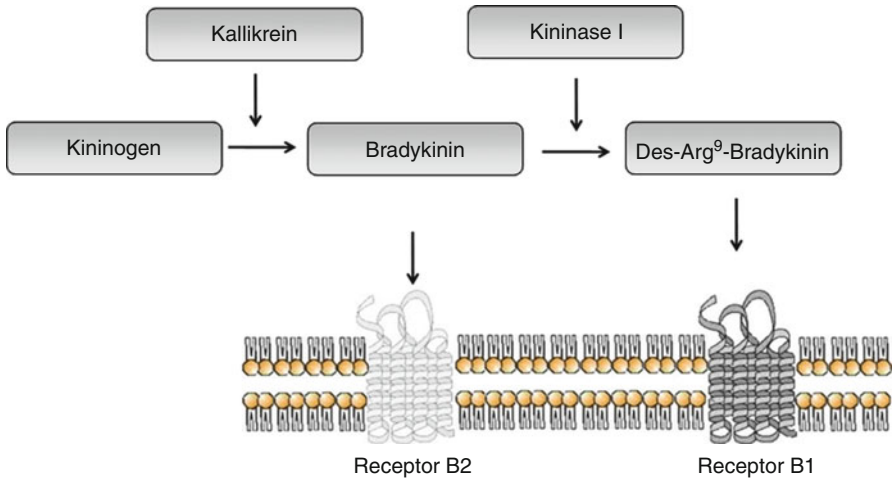
Historical Background

A primary mediator of inflammation, the nonapeptide bradykinin (BK) is a pharmacologically active peptide of the kinin group released in tissues and circulation as a consequence of coagulation cascade activation, more specifically by the kininogen cleavage by kallikrein. The enzyme kallikrein was described in 1930 by Werle and Frey. It was the first component of the kallikrein-kinin system (KKS) discovered, followed by the identification of bradykinin (BK) by Rocha e Silva and colleagues in 1949. In 1970s Regoli and coworkers characterized molecularly the two subtypes of kinin receptors B_1 and B_2, based in their pharmacological and expression profiles differences (Fig. 1). These findings enabled the subsequent development of different agonists and antagonists for these receptors (Leeb-Lundberg et al. 2005). The genes encoding these receptors were cloned in 1990s and after that, animal models for the study of this system were generated: the B_2 knockout



Bradykinin Receptors, Fig 1 Kallikrein-kinin system

mice (Borskowki et al. 1995), the B_1 knockout mice (Pesquero et al. 2000), and the knockout mice for both kinin receptors (Cayla et al. 2002).

Structural Aspects

The BK receptors are typical G protein coupled receptor (GPCR), consisting of a single polypeptide chain that spans the membrane seven times, with the N-terminal domain being extracellular and the C-terminal domain being intracellular. These receptors are present in different species of mammals like human, monkey, rats, mice, rabbit, and others.

In humans both receptors, B_1 and B_2, are homologues preserving 36% of identity at the amino acid level (Leeb-lundbeerg et al. 2005). These receptors are encoded by three-exon genes. B_1 receptor gene is in tandem with the B_2 receptor gene, located sequentially (5′ direction) separated by only 12 kb at cromossome 14q32 in humans. This composition can vary between species like the deletion of exon 2 in mice (Cayla et al. 2002).

Knockout animal models of each kinin receptor gene by homologous recombination have been done. The B_2 receptor knockout mice are fertile, apparently healthy, and when smooth muscle or neurons of these mice are stimulated with bradykinin they failed to produce response (Borkowski et al. 1995). The B_1 receptor knockout mice are healthy, fertile, normotensive, and they are analgesic in behavioral tests of chemical and thermal nociception (Pesquero et al. 2000). The generation of a knockout mouse of both receptors ($B_1B_2^{-/-}$) was also done. Due to the fact that both genes are in close chromosomal position, $B_1B_2^{-/-}$ mice could not be obtained by simple breeding of the single knockout lines. The B_1 receptor gene was inactivated in embryonic stem cells derived from B_2-deficient animals. These animals are normotensive and protected from endotoxin-induced hypotension (Cayla et al. 2007). Recently, another model of double-knockout of kinin receptors was generated by complete deletion of the gene locus (Kakoki et al. 2010).

Pharmacological Aspects

Kinins are locally released from their origin molecules, the kininogens, as a result of limited proteolysis by a class of serine proteases called kallikreins. The metabolite generated is the nonapeptide bradykinin or a decapeptide, kallidin (Lys-BK). Kinins cleavage by the kininase II also named angiotensin converting enzyme (ACE) generates inactive metabolites terminating bradykinin activity. The action of carboxipeptidases on kinins generates des-Arg^9-BK (DBK) or Lys-des-Arg^9-BK (Lys-DBK). The B_2 receptor has high affinity for the intact kinins, those generated by either plasma or tissue kallikreins, BK and Lys-BK, in all mammalian species. B_1 receptor responds to different kinin metabolites, either DBK or Lys-DBK, generated by arginine carboxypeptidases, such as carboxypeptidase N and M. In humans, plasma

kallikrein forms BK, whereas tissue kallikreins form kallidin. In rodents, both plasma and tissue kallikrein generate BK. Receptor affinity for agonist ligands: B_2 receptor, BK ≈ Lys-BK >> des-Arg^9-BK and Lys-des-Arg^9-BK; B_1 receptor, Lys-des-Arg^9-BK > Lys-BK ≈ des-Arg^9-BK >>BK (Leeb-Lundberg et al. 2005).

Peptide antagonists for the kinin B_1 receptor were the first antagonists generated based on modifications of the agonist structure, such as [Leu8]des-Arg^9-BK and Lys-[Leu8]des-Arg^9-BK. The search for antagonists showed that the spatial orientation of the C-terminal region of the peptide molecule is critical for antagonism. Many antagonists the for B_2 receptor have been generated. The most known peptide antagonist is the icatibant or HOE-140. Non-peptide ligands for the kinin receptors have been designed and are yet a great field of study, since peptides are generally poor drugs for oral bioavailability and brain penetration (Leeb-Lundberg et al. 2005).

Signaling Pathways

In different species both kinin receptors are identified as seven transmembrane G protein coupled receptor. Various signal transduction mechanisms have been described for kinins depending on the cellular type. BK or DBK stimulates B_2 or B_1 receptors, respectively. Through the phospholipase C pathway (by Gq activation), kinin signaling leads to inositol 3-phosphate (IP_3) generation and intracellular calcium mobilization, whereas through the ▶ phospholipase A_2 pathway (activated through Gi or calcium-dependent mechanisms) it leads to arachidonic acid release, also by activating the endothelium nitric oxide synthase (eNOS) and producing nitric oxide (NO). B_2 receptor has also been found to directly interact with other eNOS in a G protein-independent manner (Leeb-Lundberg et al. 2005).

BK also transiently promotes tyrosine phosphorylation of ▶ MAP Kinases and activates a Janus-activated kinase/STAT (JAK-STAT) pathaway. This involves tyrosine phosphorylation of both the Janus-activated kinase family tyrosine kinase Tyk2 and STAT3 followed by STAT3 nuclear translocation. B_2 activates multiple transcription factors that regulate the induction of several cytokines involved in tissue injury and inflammation as well as B_1 receptor induction. Besides these classical pathways, IL-1β and ▶ TNF-α can stimulate the expression of B_1 and B_2 receptors by pathways involving activation of ▶ NF-κB and MAPKs. Although the B_1 and B_2 receptors seem to couple to similar cellular signal transduction pathways, the patterns of signaling are different (Leeb-Lundberg et al. 2005; Brechter et al. 2008).

B_1 and B_2 receptor form homodimers and these receptors were found to spontaneously heterodimerize. Heterodimerization was associated with a specific proteolytic degradation of the participating B_2 receptor and an increase in both agonist-dependent and -independent signaling of the heterologous receptor complex. The existence of a B_2 receptor and angiotensin receptor 1 (B_2/AT1) heterodimeric complex may have implications for blood pressure. The B_2/ACE interaction modulates ACE activity (Sabatini et al. 2008).

B_2 receptor function is controlled by short-term mechanisms involving fast ligand dissociation, receptor desensitization and internalization, and, after long-term stimulation, downregulation of the receptor occurs. In contrast, B_1 receptors elicit persistent responses and signaling that are subjected to very limited desensitization and receptor internalization with very slow ligand dissociation (Couture et al. 2001).

Kinins and Disease

The kallikrein-kinin system (KKS) is present in numerous pathologies and the role it plays may vary. It can maintain the danous state of disease or play a protective role, as summarized below in Table 1.

Generated during inflammation and tissue injury, bradykinin contributes to the initiation and maintenance of inflammation, to exciting and sensitizing sensory nerve fibers, thus producing pain as reviewed by Couture and coalleagues in 2001. Thus the B_2 receptor is involved in acute inflammation, including increased vascular permeability, venoconstriction, arterial dilatation, and pain through the activation of sensory nerve terminals. This receptor has a limited role in the cellular component of the inflammatory response involving leukocyte recruitment within the microcirculation. The activation of B_2 receptors in sensory neurons promotes hyperalgesia. Bradykinin can sensitize nociceptors following the release of prostaglandins, cytokines, and

Bradykinin Receptors, Table 1 Kinin receptors' presence in various diseases

Disease	Effect
Inflammation	Pro-inflammatory[a]
Pain	Hyperalgesia[a]
Infection	BK increase:

nitric oxide either from sensory neurones, endothelial and immune cells or fibroblasts in addition to its interaction with mast cell mediators. The blockade of B_2 receptors located on sensory neurons may be responsible for the analgesic property of B_2 receptor antagonists. The pro-inflammatory effects of B_1 receptors include promotion of blood-borne leukocyte trafficking, edema and pain. B_1 receptors are primarily involved in persistent inflammatory pain and are expressed in macrophages, fibroblasts, or endothelial cells, where they may be responsible for inflammation mediators releasing (prostaglandins, cytokines, and nitric oxide) that sensitize or activate the nociceptors.

Because of its multicellular location and the mode of persistent signaling mechanism, the B_1 receptor is likely to exert a strategic role in inflammatory diseases, particularly those with an immune etiology (asthma, rheumatoid arthritis, multiple sclerosis, and diabetes). In addition to the pro-inflammatory effects of kinin receptors, B_1 receptors may exert a protective effect in brain inflammatory diseases such as multiple sclerosis by reducing T-lymphocyte infiltration into the brain (Schulze-Topphoff et al. 2009).

Kinins exert influence on multiple players of the immune system (i.e., macrophages, dendritic cells, T and B lymphocytes). BK is capable of modulating the activation, proliferation, migration, and effector functions of immune cells. Kinin receptors seem to be important in autoimmune conditions, such as rheumatoid arthritis, lupus, and myasthenia gravis (Schulze-Topphoff et al. 2008).

Kinin receptors are present in osteoblasts, osteoclasts, and fibroblasts, linking the kallikrein-kinin system with rheumatoid arthritis, periodontitis, and bone resorption. They can stimulate bone resorption through prostaglandins. Kinin B_1 and B_2 receptors synergistically potentiate IL-1β and TNF-α-induced prostaglandin biosynthesis in osteoblasts by a mechanism involving increased levels of cycloxygenase-2 (Brechter et al. 2008).

Many studies have demonstrated increased kinin generation associated with asthma, allergic rhinitis, and during viral rhinitis (Proud 1998). The first studies began with the analysis of the presence of kinins after allergen stimulation in allergic subjects and absence of them in non-allergic subjects. The inflammatory infiltration and relation between kinins and the chronic phase of the disease were then observed. Kinins are also associated with the release of the mast cell granule constituents, histamine, and tryptase, major mediators of acute phase. The kinin concentration increase during asthma is associated with the augment in histamine

and other inflammatory markers, including eicosanoids. The administration of bradykinin by nasal spray to the upper airways of normal, nonatopic subjects, or of asymptomatic atopic individuals has been shown to result in the dose-dependent induction of symptoms of nasal obstruction, modest rhinorrhea, nasal irritation, and sore throat, but not sneezing (Proud 1998).

Kinin receptors are involved with brain damage in different forms. They act in multiplus sclerosis, epilepsy, and Alzheimer's disease. Kinin B_2 receptor promotes survival and protects against brain injury by suppression of apoptosis and inflammation induced by ischemic stroke. In epilepsy, the kinin B_2 receptor also plays a neuroprotector effect and the kinin B_1 receptor plays a deleterious, pro-epileptogenic action in animal models (Leeb-Lundberg et al. 2005). Kinin receptors are involved in neurodegeneration and increase of amyloid-b concentration, associated with Alzheimer's disease (Lemos et al. 2010). More recently it was shown that during the aging process, the B_1 receptor could be involved in neurodegeneration and memory loss. Nevertheless, the B_2 receptor is apparently acting as a neuroprotective factor (Lemos et al. 2010). In inflammatory brain disease, like sclerosis, kinin B_1 receptors are important in limitating migration of lymphocytes through the central barrier and inflammation in the brain (Schulze-Topphoff et al. 2009).

Kinins receptors are present in the kidney and are involved with kidney disease, such as renal failure and nephropathy. Since kinin receptors are present in patients in end stage of renal failure, treatment with a B_1 receptor antagonist reduces both glomerular and tubular lesions and improve renal function trough the reduction of renal chemokine expression and macrophage accumulation in glomerulonephritis (Klein et al. 2010). Genetic association between B_1 receptor polymorphisms and end-stage renal failure have been reported, as the B_2 receptor polymorphism is associated with diabetic nephropathy (Leeb-Lundberg et al. 2005).

Lack of B_1 and B_2 receptors exacerbates diabetic complications, enhances the nephropathy (glomerulonephritis), neuropathy (decrease the time of nervous impulse), and bone mineral loss caused by insulin-dependent diabetes in mice (Kakoki et al. 2010). The development of diabetic retinopathy increases vascular permeability, neovascularization, inflammation and B_2 activation contributes to vascular permeability and edema, which suggests the correlations between the KKS and microvascular complications of diabetes. Studies performed in diabetic mice demonstrated that the absence of B_2 receptor in these animals increases indicators of senescence like alopecia, skin atrophy, kyphosis, osteoporosis, testicular atrophy, lipofuscin accumulation in renal proximal tubule and testicular Leydig cells, and apoptosis in the testis and intestine (Kakoki et al. 2006).

The kinin B_2 receptor agonist BK may participate in the regulation of substrate utilization by several tissues by improving blood flow and substrate delivery to the tissues and also by promoting translocation of glucose transporters. It appears to improve the release of insulin and improve insulin sensitivitiy. Furthermore, insulin may activate the kallikrein-kinin system, which consequently may increase its metabolic effects. However, in experimental diabetes mellitus, BK may participate in the inflammatory reaction leading to Langerhans islets destruction (Damas et al. 2004). Kinin B_1 receptor is involved in obesity, as shown by Mori et al. The absence of B_1 receptor in mice decreases plasma leptin levels, increases leptin sensibility, protects mice from diet-induced obesity (diet with 45% of fat), and augments energy expenditure.

The KKS has importante role in various pathological processes of the cardiovascular system, such as hypertension, cardiac failure, ischemia, left ventricular hypertrophy, and endotoxemia. There is activation of BK activity in endotoxemia. On the other hand, it seems that there is deficient activity of the KKS in hypertension, cardiac ischemia, and development of left ventricular hypertrophy. These pathological states might be due to a genetic abnormality of the KKS or downregulation of the BK receptors (Sharma 2003). Several studies have detected a significant association between the B_2 receptor 58 C/T polymorphism and hypertension (Leeb-Lundberg et al. 2005). Kinin B_1 receptor deficiency aggravates atherosclerosis and aortic aneurysms in mice under cholesterolemic conditions, supporting an antiatherogenic role for the kinin B_1 receptor (Merino et al. 2009).

The KKS is also present in the liver and is related to liver disease. BK can induce portal hypertensive response when injected in the liver. This hepatic hypertensive response to BK is mediated by the B_2 receptor and modulated by the L-Arg/nitric oxide pathway. There is also evidence of the participation of BK in

the pathogenesis of vasodilatation and ascites formation in cirrhotic patients (Kouyoumdjian et al. 2005).

Finally, the ability of BK to stimulate vessel growth and increase vascular permeability may contribute to the biological behavior of tumors. Evidence for increased generation of kinins and kinin receptors detection in different types of cancer has been reported (Leeb-Lundberg et al. 2005).

Summary

Considering the knowledge gathered since the classical pharmacological models were established and the more recently gene target animal models, much has been changed concerning the kinin receptors function. In the beginning, the kinin receptors were first implicated with pain and inflammation. Nowadays they are still important in this area of study; however, they have been implicated with different diseases like asthma, arthritis, sepsis, kidney disease, hypertension, cardiopathy, diabetes, and cancer among others. In the last years, new implications of kinin receptors in obesity and immunology are described, as well as interaction of kinin receptors and other proteins like ACE and AT1 receptor. These implications will bring new possibilities for therapies involving kinin ligands (agonists and antagonists). Moreover, ongoing tests with new drugs affecting the KKS are on the way. The main goal is to develop more potent and tissue specific ligands, with increased disposability, central permeability, and reduced collateral effects. The field of study of these receptors is wide and promising.

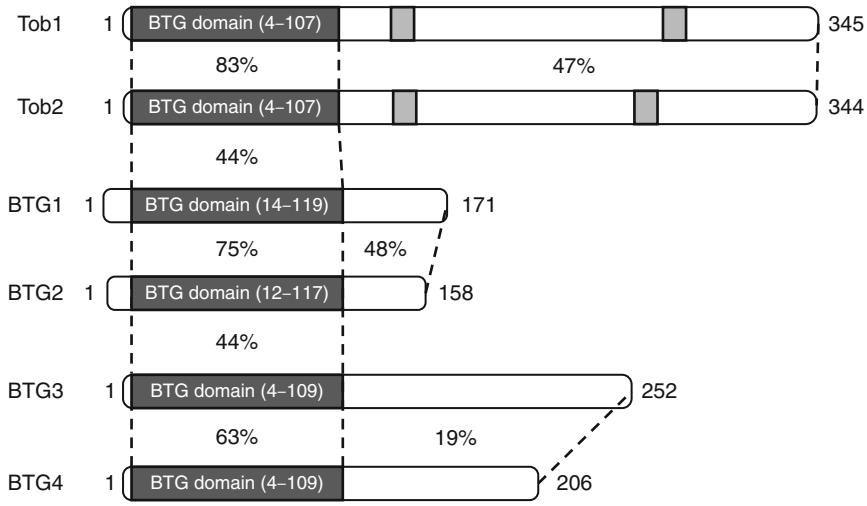
Historical Background

The human BTG/TOB proteins form a small family of six proteins, which share a conserved N-terminal domain and anti-proliferative activity (Matsuda et al. 2001; Tirone 2001; Winkler 2010). BTG2 was discovered first by two laboratories: as the immediate/early response gene PC3 in rat PC12 cells stimulated with nerve growth factor and as TIS21 in mouse 3T3 fibroblasts in response to treatment with 12-O-tetradecanoylphorbol-13-acetate (TPA). The discovery of BTG1 (B-cell translocation gene 1), as a gene involved in a chromosomal translocation associated with chronic lymphocytic leukemia, suggested the presence of a new family of anti-proliferative genes. These findings were extended by the discovery of TOB1, which was found as an interacting protein of the ErbB2 tyrosine kinase receptor (HER2). The remaining three members, BTG3 (ANA), BTG4 (PC3B), and TOB2, were identified based on sequence homology of the conserved N-terminal domain. The preferred gene names by the Human Genome Nomenclature Committee are BTG1, BTG2, BTG3, BTG4, TOB1, and TOB2.

Regulation of Gene Expression: mRNA Deadenylation

The conserved N-terminus is known as the BTG domain (Pfam number PF07742) and comprises 104–106 amino acids. The C-terminal regions are less conserved and confer additional functions to the family members. Sequence analysis of both the BTG



BTG/TOB, Fig. 1 Schematic overview of the human BTG/TOB protein family. The approved gene names used by the human genome nomenclature committee are used. Indicated are the N-terminal BTG/TOB domains (*dark gray*) and PAM2 motifs (*gray*). The pair-wise percentage identities were determined using the Clustalw2 multiple sequence alignment program. The length of the proteins (amino acids) and the position of the BTG domain are also indicated

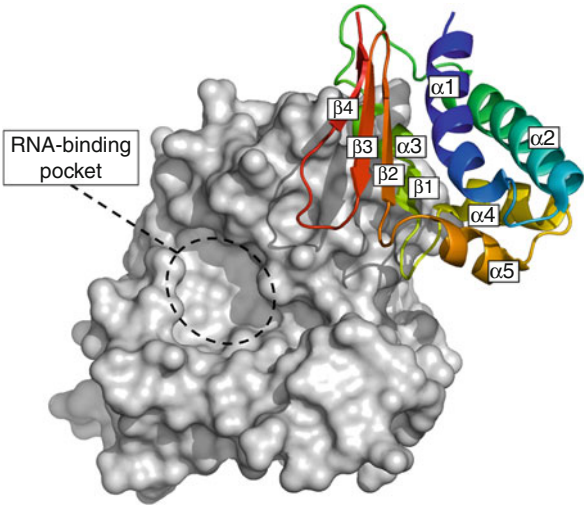
domain and the C-terminal regions suggests that TOB1 and TOB2, as well as BTG1 and BTG2, are highly similar, whereas BTG3 and BTG4 are more distantly related (Fig. 1). The BTG/TOB proteins are implicated in the regulation of gene expression by at least two distinct mechanisms.

The best characterized role of the BTG/TOB proteins in gene expression is mediated via the BTG homology domain, which interacts with the CNOT7 (Caf1a) and CNOT8 (Caf1b) subunits of the Ccr4-Not complex (Mauxion et al. 2009; Bartlam and Yamamoto 2010; Wiederhold and Passmore 2010; Winkler 2010). The highly similar CNOT7 and CNOT8 proteins are deadenylase enzymes, which shorten and remove the poly(A) tails of cytoplasmic mRNA resulting in translational repression and mRNA degradation (Bartlam and Yamamoto 2010; Wiederhold and Passmore 2010; Winkler 2010). The interaction of all BTG/TOB proteins (except BTG4) with either CNOT7 and/or CNOT8 is experimentally confirmed, and a specific role in the regulation of deadenylation and mRNA degradation was demonstrated for BTG2, TOB1, and TOB2. Both TOB1 and TOB2 contain PAM2 motifs in their C-terminal regions, which allow them to interact with poly(A)-binding protein 1 (PABPC1). During termination of translation, several proteins containing a PAM2 motif are consecutively recruited to the mRNA by PABPC1: following binding of the translation termination complex eRF1-eRF3 and the PAN2-PAN3 deadenylase, TOB1 recruits the Ccr4-Not deadenylase via interactions between the conserved BTG domain and the CNOT7 and CNOT8 deadenylase subunits. This sequence of events implicates TOB1 – as well as the related TOB2 protein – in mRNA deadenylation coupled to termination of translation. Alternatively, TOB1 can be recruited to specific mRNAs by sequence-specific RNA-binding proteins. For example, cytoplasmic polyadenylation element-binding protein 3 (CPEB3) binds TOB1 resulting in mRNA destabilization (Hosoda et al. 2011).

Several protein structures illuminate the molecular details of the interaction between BTG/TOB proteins and the CNOT7/CNOT8 deadenylase enzymes. The BTG domain is characterized by two long anti-parallel α-helices in the N-terminus of the domain that are part of a four-helix bundle and three β-sheets at the C-terminus of the domain (Fig. 2). Comparison of the structure of the free BTG domain of TOB1 with the domain in complex with the CNOT7 deadenylase indicates that the BTG domain does not undergo significant rearrangements upon binding. The RNA-binding catalytic site of the CNOT7 deadenylase appears to be separated from the residues important for binding to the BTG domain. In agreement with this, binding of the BTG domain of TOB1 does not influence the catalytic activity of the CNOT7 deadenylase.

Regulation of Gene Expression: Transcription

In addition to their role in mRNA deadenylation, BTG/TOB proteins can regulate gene expression at the level



BTG/TOB, Fig. 2 Structure of the BTG domain of TOB1 in complex with the CNOT7 (Caf1a) deadenylase enzyme. The representation was generated using structure 2d5r deposited in the Protein Data Bank (PDB) using Pymol (www.pymol.org). The BTG domain of TOB1 is represented by a multicolored cartoon. Indicated are the five α-helices and four β-sheets. The surface of the CNOT7 (Caf1a) deadenylase enzyme is represented in gray. Circled is a deep pocket that binds poly(A) RNA and corresponds to the catalytic center

of transcription (Matsuda et al. 2001; Tirone 2001; Winkler 2010). Several reports point to the ability of the BTG/TOB proteins to interact with DNA-binding transcription factors and modulate their ability to bind their cognate DNA sequence elements. Both BTG1 and BTG2 can interact with Hoxb9, a homeobox DNA-binding transcription factor, through their extreme N-terminus (residues 1–14). This interaction enhances the ability of Hoxb9 to bind to its consensus DNA sequence. Thus, this may increase the transcription rates of Hoxb9 target genes, which may contribute to the anti-proliferative function of BTG1 and BTG2. TOB1 and TOB2 have the most extensive C-terminal regions within the protein family. This region of TOB1 mediates interactions with a number of Smad transcription factors, altering their ability to bind to DNA. As a consequence, TOB1 regulates the expression of Smad target genes, such as the cytokine IL-2 promoter in quiescent T cells. BTG3 presents a third example of this mode of action: BTG3 can interact with E2F1, a transcription factor important for S-phase entry and cell-cycle progression. BTG3 binds E2F1 through its N-terminal region, which, in this case, inhibits DNA binding of the E2F1, thereby reducing the overall transcription rate of E2F1-responsive promoters and cell proliferation.

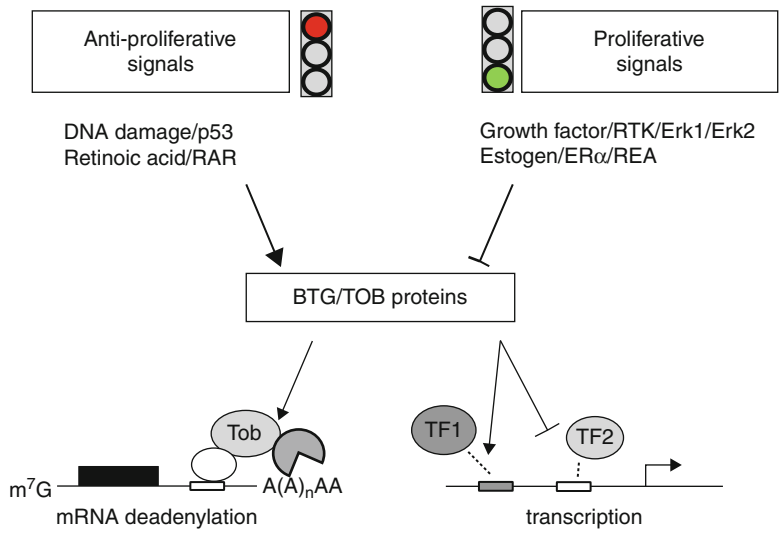
Finally, BTG1 and BTG2 can interact with protein arginine methyltransferase 1 (PRMT1) through a short β-sheet region (also known as Box C) just outside the BTG domain, which is not conserved in other BTG/TOB proteins. PRMT1 specifically methylates the arginine 3 residue of histone H4 in vitro and in vivo, which facilitates subsequent acetylation of histone H4 tails by p300 and gene activation. Thus, this raises the possibility that BTG1 and BTG2 could be involved in the regulation of chromatin modifications.

Effectors of Signaling Pathways

There are a variety of different signaling pathways that exploit the anti-proliferative properties of BTG/TOB proteins either positively or negatively by regulating the cellular levels of these proteins by transcriptional and post-translational mechanisms (Fig. 3). Both TOB1 and BTG2 are phosphorylated upon stimulation with growth factors by the Erk1/Erk2 kinases at serine residues in the C-terminus. This results in subsequent deactivation, which – in the case of TOB1 – leads to increased cyclin D1 expression and enhanced activation of CDK4, driving cell proliferation forward.

In MCF7 cells (an estrogen receptor–expressing breast cancer cell line), BTG2 mRNA can be regulated both positively and negatively by signaling through nuclear receptor transcription factors. BTG2 expression is activated when MCF7 cells are treated with retinoic acid through direct binding of the ▶ retinoic acid receptor (RAR)/RXR heterodimers to three retinoic acid response elements (RARE) in the BTG2 promoter region. Conversely, BTG2 expression is reduced when MCF7 cells are treated with estrogen through ▶ estrogen receptor ERα and its co-repressor REA.

BTG2 and BTG3 are both downstream targets of the ▶ p53 signaling pathway. Both proteins are direct transcriptional targets for p53 and play a role in the p53-mediated response to DNA damage (Rouault et al. 1996; Ou et al. 2007). In embryonic mouse fibroblasts, BTG2 plays critical role in suppressing transformation through oncogenic Ras by acting as a downstream effector of p53 (Boiko et al. 2006). BTG2 expression downregulates cyclin D1, cyclin E1, and the phosphorylation of retinoblastoma (Rb), slowing the cell cycle rate and preventing cellular transformation.



BTG/TOB, Fig. 3 Signaling pathways impinge on BTG/TOB proteins. Both antiproliferative and proliferative signals impinge on BTG/TOB family members by upregulation/activation or inhibition, respectively. In turn, BTG/TOB proteins can participate in the regulation of gene expression by deadenylation (left) or transcriptional mechanisms (right). See text for further details

Finally, TOB1 and BTG2 are implicated in signaling of TGF family members through Smad transcription factors. This was demonstrated in both quiescent T cells activated by CD28, which impinges on TGF-β signaling, and in bone-forming osteoblast cells upon stimulation by bone morphogenic protein (BMP) 2, a TGF family member.

Bone Formation: TOB1 and TOB2

The generation of mice containing null alleles of TOB1, TOB2, BTG2, and BTG3 uncovered a role for these proteins in bone formation and resorption (Yoshida et al. 2003; Park et al. 2004; Ajima et al. 2008; Miyai et al. 2009). The contrasting phenotypes observed in TOB1 and TOB2 knockout mice are of particular interest. Mice lacking TOB1 are apparently normal, but display increased bone volume and bone density. Interestingly, in a mouse model for estrogen-deficiency-induced osteoporosis, the increased bone mineralization in TOB1 null mice can compensate for bone loss associated with induced osteoporosis since ovariectomized TOB1 knockout mice have a bone mineral density and volume comparable to (sham operated) control mice (Usui et al. 2004). The increased bone density in TOB1$^{-/-}$ mice is due to enhanced bone formation, and osteoclast parameters are unchanged as compared to control mice. A similar increase in bone density is observed in mice lacking the CNOT7 deadenylase (Washio-Oikawa et al. 2007). As observed in TOB1 null mice, CNOT7 knockout mice do not display altered osteoclast parameters, suggesting that the role of TOB1 in bone formation is mediated via its interactions with the CNOT7 deadenylase subunits of the Ccr4-Not complex.

By contrast, mice lacking TOB2 display decreased bone mass due to an increased number of differentiated osteoclast cells. TOB2 interacts with the ▶ vitamin D receptor and reduces expression of RANKL, a vitamin D–induced gene. In agreement with this notion and the observation that osteoclast parameters are unaltered in CNOT7 knockout mice, TOB2 is a repressor of vitamin D–induced osteoclast formation (Ajima et al. 2008).

Cancer and Tumorigenesis

The discovery of BTG2 as an effector of the tumor suppressor function of p53, as well as the critical role of TOB1 in Ras-mediated transformation, strongly implicates these BTG/TOB proteins as important cellular components that contribute to the prevention of tumorigenesis (Rouault et al. 1996; Suzuki et al. 2002; Boiko et al. 2006). In agreement with this notion, expression of BTG/TOB genes is reduced or undetectable in a variety of clinical cancer samples (Table 1). In particular, the presence of increased levels of phosphorylated, inactive TOB1, and the absence of TOB1 protein levels correlate with tumor

BTG/TOB, Table 1 Relationship of BTG/TOB expression and cancer. To date, no changes in TOB2 expression are reported in human cancer samples

BTG/TOB, Fig. 4 Mutations identified in BTG1 and BTG2 in non-Hodgkin lymphoma. Mutations in BTG1 and BTG2 identified by RNA-sequencing data from over 100 non-Hodgkin lymphomas (Morin et al. 2011. Nature; doi: 10.1038/nature10351). In some cases, both alleles contained mutations. Indicated are schematic representations of BTG1 and BTG2, the location of the BTG domain, and the presence of secondary structure elements based on the crystal structure of BTG2 (PDB structures 3dju, 3djn and 3e9v)

grade in a panel of lung cancer samples. Similarly, expression of BTG3 is reduced in the majority of lung cancer cell lines and clinical samples derived from lung cancer patients. Furthermore, BTG1 and BTG2 are frequently found to be mutated in non-Hodgkin lymphomas (Fig. 4). Such mutations are seemingly present in a mutually exclusive manner as compared to p53 mutations, suggesting a causative role as a component of the p53 pathway in this type of cancer. It is yet unknown how the identified mutations in BTG1 and BTG2 interfere with the function of the encoded gene products.

An important role for BTG/TOB proteins in the suppression of tumorigenesis is further evident from mouse knockout models. Disruption of TOB1 in mice results in susceptibility to a variety of cancers, including lung tumors, which is also observed in mice lacking BTG3 (Table 1). Thus, a direct role of several BTG/TOB proteins in the suppression of tumorigenesis and cancer development is now clearly established.

Summary

The understanding of the function and mechanisms through which the BTG/TOB proteins act have rapidly advanced in the past few years. The best characterized role of the BTG/TOB proteins is mediated by the interaction of the BTG homology domain with the CNOT7 and CNOT8 deadenylase subunits of the Ccr4-Not complex, which impacts on mRNA deadenylation. In addition, BTG/TOB proteins are also involved in the regulation of transcription and, possibly, the establishment of histone H4 modifications through the interactions of BTG1 and BTG2 with the PRMT1 methyltransferase. Mouse models have uncovered the importance of these proteins in the biology of bone and cancer. Reduced expression of BTG/TOB proteins is observed in a variety of clinical samples, and mutations in BTG1 and BTG2 are found in non-Hodgkin lymphoma. It remains to be determined whether BTG/TOB proteins regulate cell proliferation through mRNA degradation or transcriptional mechanisms, or both. Furthermore, there are still many questions with respect to unique and/or redundant roles of the individual BTG/TOB proteins.

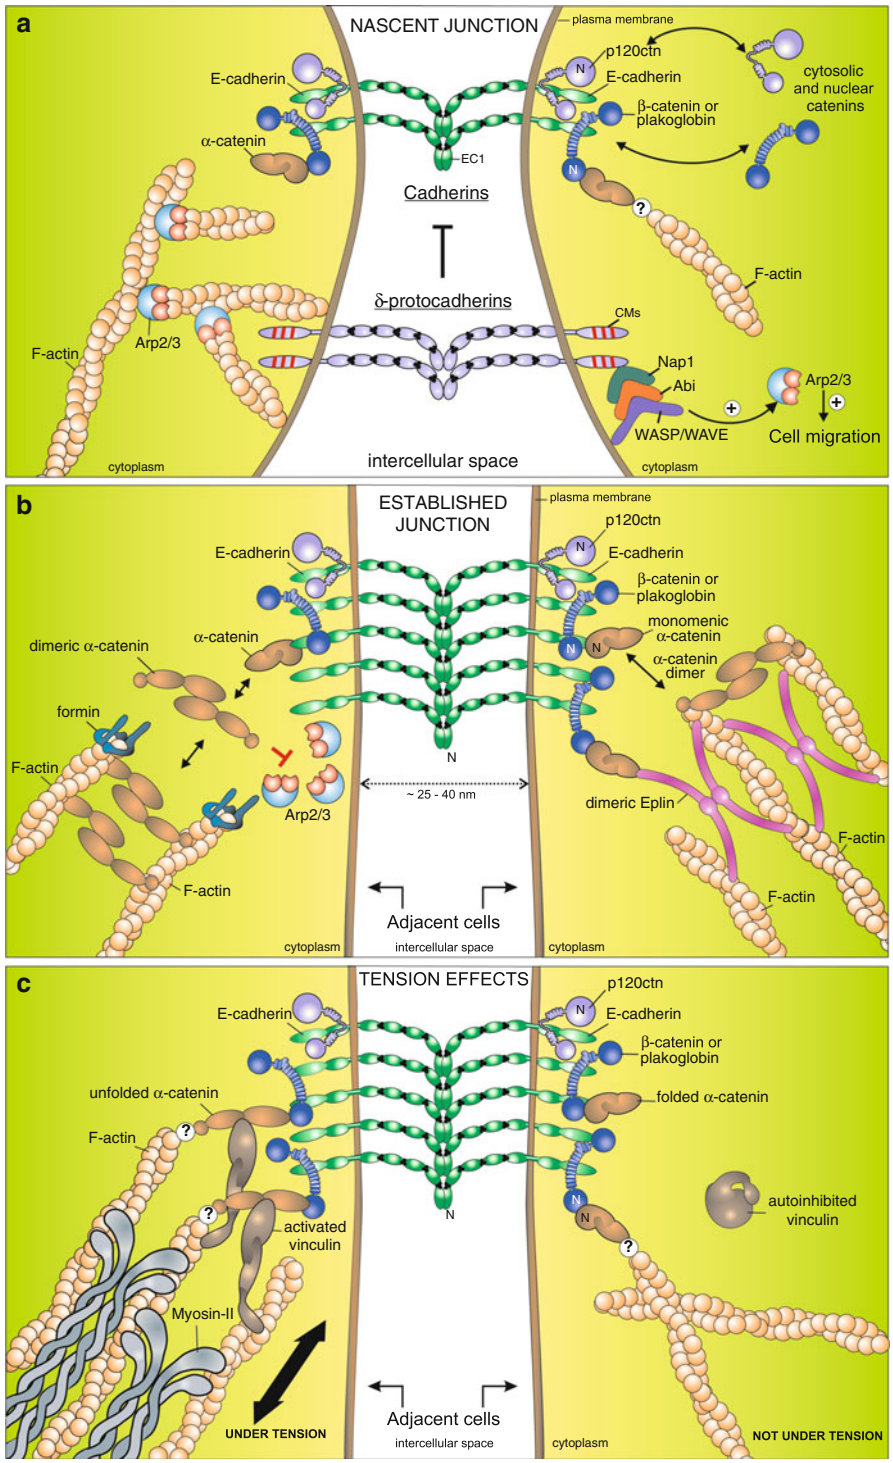
Historical Background: The Larger Cadherin Superfamily

Cadherins comprise a large protein superfamily of calcium-dependent proteins associated with the plasma membrane. They are hallmarked by at least two consecutive extracellular cadherin repeats (ECs) in their extracellular domain. Epithelial cadherin (E-cadherin or cadherin-1) is the founding family member and represents the classic or type-I cadherins. These cadherins mediate specific and strong cell-cell adhesion and play key roles in local organization of cytoskeletal structures and in signaling cascades, as documented below. The mature E-cadherin contains an ectodomain of about 550 amino acids (AA) comprising five ECs, a single transmembrane (TM) domain, and a cytoplasmic domain (CD) of about 150 AA. The CD has two highly conserved domains for binding p120ctn and related protein family members, as well as β-catenin and the homologous plakoglobin (γ-catenin), all of which belong to the armadillo protein family (reviewed by van Roy and Berx 2008) (Fig. 1). Association of p120ctn with the juxtamembrane domain (JMD) of cadherins protects them from premature endocytosis and hence stabilizes the junctions. On the other hand, in a classical cadherin-catenin complex (CCC), β-catenin forms a molecular bridge between the cadherins and α-catenins, the latter of which are vinculin-related proteins that bind F-actin. However, recent data reported by the groups of Nelson and Weis have cast doubt on this model (reviewed in Nelson and Fuchs 2010). These authors showed that monomeric α-catenin can integrate into the CCC but does not associate with F-actin, whereas homodimeric α-catenin dissociates from the CCC but binds F-actin. In contrast, other actin-binding linker molecules, such as α-actinin and Eplin, might be involved in anchoring cadherin-dependent junctions to the cytoskeleton (Fig. 1).

Cadherins were originally discovered as mediators of specific cell-cell adhesive structures, often called adherens junctions (AJ) (Gumbiner 2005; Nelson and Fuchs 2010). The basic and well-documented model for this function involves two modes of interaction

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,



Cadherins, Fig. 1 Alternative states of the classic cadherin-catenin complex (CCC) at the junction between two neighboring epithelial cells (see text for details and references). (**a**) Nascent junction: Transmembrane classic cadherins form zipper-like intercellular junctions based on homophilic molecular interactions between their EC1 and EC2 domains. Their cytoplasmic domains contain conserved binding sites for the armadillo proteins p120ctn and β-catenin (although not drawn that way, p120ctn and β-catenin can interact simultaneously with a single cadherin molecule). p120ctn and β-catenin also have

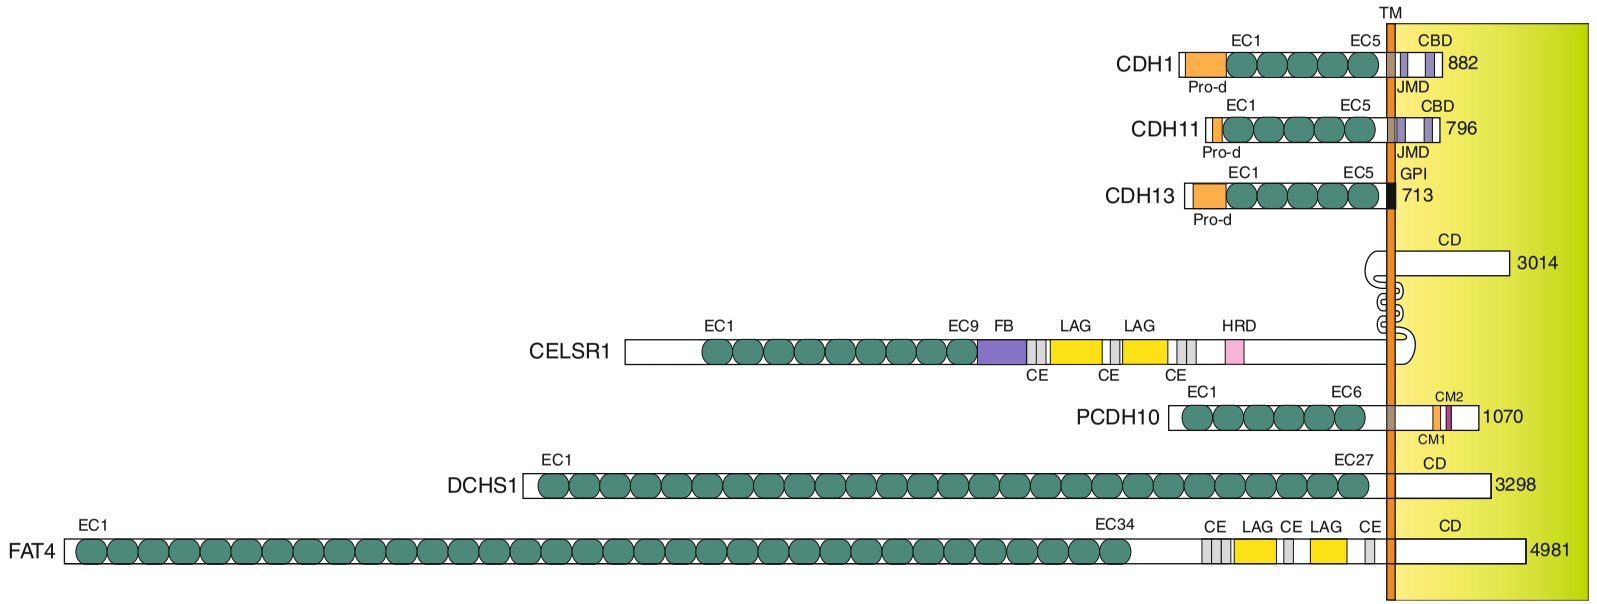
between the most amino-terminal ECs (called EC1): homophilic (between identical cadherin species) and homotypic (between identical cell types). Both *cis* (between neigboring cadherin molecules in the same plasma membrane) and *trans* interactions (between apposing cadherin molecules) have been described in considerable detail (van Roy and Berx 2008). Cell-cell adhesion mediated by classic cadherins is considered the basis of cell sorting out during both embryonic development and the morphogenesis of most organs (Gumbiner 2005; Halbleib and Nelson 2006; Nelson and Fuchs 2010). Although the cadherin activity during these important processes might be explained by cadherins serving as cell-type specific molecular glues, it is increasingly clear that signaling by and to cadherins plays major roles. Indeed, cadherins are required not only for rigid, static cell-cell contacts, but also for regulation of dynamic morphogenetic cell movements by active remodeling of intercellular junctions and the associated cytoskeletal structures (Nishimura and Takeichi 2009; Harris and Tepass 2010).

Presently, mammalian genomes are known to contain over 100 genes encoding cadherins or cadherin-related proteins (Hulpiau and van Roy 2011). Some of them are more recent evolvements, such as desmogleins and desmocollins, which form the backbone of desmosomes (strong cell junctions in tissues under high physical stress, like epidermis and heart). The so-called clustered protocadherins form another recently evolved cadherin subtype. Protocadherins seem to be less involved in tight cell-cell adhesion and may play greater roles in cell recognition and signaling. On the other hand, recent phylogenetic analyses have shown the existence of six ancient types of cadherins and cadherin-related proteins (Hulpiau and van Roy 2011) (Fig. 2). These are the classical cadherins (CDH), the FAT cadherins, the FAT-like cadherins, the Dachsous cadherins (DCHS), the flamingo (Fmi) or CELSR cadherins, and several cadherin-related proteins, such as cadherin-related 23 (CDHR23). Several of these cadherin family members were originally discovered in the fruit fly, and their genetic analyses have revealed important functions in signaling. The protocadherins emerged slightly later in evolution. They were originally thought to be specific for deuterostomes, but recent studies revealed their presence in cnidarians but not in the fruit fly or the nematode, which probably lost them during evolution.

From these studies, several hallmarks became clear: ancient family members always have long ectodomains with numerous ECs, which during evolution became progressively shorter (Hulpiau and van Roy 2011). Current classic and desmosomal cadherins have five ECs whereas protocadherins have six to seven ECs (Fig. 2). This, together with the finding of many long cadherin-like proteins in unicellular choanoflagellates, indicates that the cadherin family members originally served in extracellular sensing and cell-cell recognition rather than in specific cell-cell adhesion.

Cadherins characteristically have an ectodomain that is largely or exclusively composed of ECs, but their TM domains and in particular their CDs are much more diverse (Fig. 2). Quite often, cadherins have their own subfamily-specific CD, often with one to several motifs. These CDs are conserved within the same subfamily, but apparently they are not related to each

Cadherins, Fig. 1 (continued) roles in the cytoplasm and nucleus (not detailed here). Further, the CCC contains monomeric α-catenin, which via partly unknown intermediate proteins (?) links the CCC to the actin cytoskeleton. In a nascent junction, F-actin grows and branches by the action of the Arp2/3 protein complex. Certain δ-protocadherins (including protocadherin-10/OL-protocadherin) interfere with formation of tight CCC-dependent junctions and induce cell migration by (strong?) activation of Arp2/3, leading to formation of lamellipodia. This is because the cytoplasmic domain of δ-protocadherins, which has conserved motifs (CMs), recruits a Nap1-Abi-WASP/WAVE complex. (**b**) Molecular interactions in an established CCC-dependent junction. Monomeric α-catenin in the CCC can associate with the actin-bundling protein Eplin. On the other hand, it can dissociate from the CCC, dimerize, and locally bundle F-actin. Dimeric α-catenin is thought to inhibit the Arp2/3 complex, so that F-actin grows merely linearly by the action of formins. (**c**) Recently, evidence was obtained for tighter cadherin-dependent junctions in cells under mechanical tension, for example, during morphogenetic movements and wound repair. While in cells not under tension (depicted on the *right*) both vinculin and α-catenin are in a less active, folded configuration, they become unfolded when tension is applied. Local tension is generated by the action of myosin-II on F-actin (depicted on the *left*). This stretches α-catenin to a configuration that recruits and activates vinculin. Vinculin in turn binds the actomyosin complex. In this way, the reinforced mechanical coupling between the CCC and the cytoskeleton protects the junction against the tension while transmitting the force over the tissue. Modified after (van Roy and Berx 2008), and after (Yonemura et al. 2010)



Cadherins, Fig. 2 Domain structure of representative members of the cadherin superfamily in man (*Homo sapiens*). All proteins are drawn to scale and aligned at their transmembrane domains (TM). They are depicted as precursor proteins with their extracellular N-terminal ends on the left. Sizes (number of AA) are indicated on the right and range between about 800 and 5,000 AA. The cadherin families are exemplified as follows (from top to bottom). The CDH family is represented by E-cadherin (CDH1), cadherin-11, and cadherin-13. The latter has an atypical glycosyl phosphatidyl inositol anchor (GPI). The CELSR/Flamingo family is represented by CELSR1. These proteins have a seven-TM domain. The protocadherin (PCDH) family is represented by protocadherin-10. The Dachsous family is represented by DCHS1. Finally, the FAT family is represented by FAT4. The following protein domains are annotated: *CBD* (conserved cadherin-specific) β-catenin-binding domain; *CD* unique cytoplasmic domain; *CE* Cysteine-rich EGF repeat-like domain; *CM1* and *CM2* conserved motifs in the CDs of particular protocadherins; *EC* extracellular cadherin repeat; *FB* Flamingo box; *HRD* Hormone receptor domain (in CELSR/Flamingo proteins); *JMD* (conserved cadherin-specific) juxtamembrane domain, binding p120ctn; *LAG* laminin A globular domain; *Pro-d* prodomain. Modified after Berx and van Roy (in Nelson and Fuchs 2010)

other and often not at all to the "standard" CD of classic cadherins. Cadherin-13, also called T-cadherin (truncated), stands out because it is the only known cadherin lacking a TM domain. Instead, it is linked to the cell surface by a glycosylphosphatidylinositol (GPI) anchor (reviewed by Berx and van Roy in Nelson and Fuchs 2010). Moreover, the recently resolved structure of its EC1 domain is unusual. The flamingo/CELSR cadherins have, besides an ectodomain of nine ECs, a 7-TM domain, which is exceptional for cadherins.

Signaling by Classic Cadherin-Catenin Complexes

Many major mechanisms are known to influence the roles of classic cadherins in cell structure and function. (1) Specific interactions between cells are influenced by the generation and stabilization versus destabilization and internalization of junctions composed of cadherins. This also has consequences for other types of junctions, such as tight junctions and gap junctions, which are not composed of cadherins. (2) By forming either static or dynamic cell-cell junctions, cadherins have a flexible influence on cytoskeletal structures, such as cortical F-actin/myosin-II (actomyosin) networks as well as microtubules, which in turn influence the form, polarity, and behavior of cells. (3) Either by physically sequestering β-catenin and p120ctn in stable junctions at the cell surface or by functional control of these armadillo proteins, cadherins can modulate the signaling roles of these key proteins in the cytoplasm and/or nucleus. Reciprocally, stable exposition of classic cadherins at the cell surface is due to p120-mediated inhibition of endocytosis, and stable association of β-catenin is needed for a functional CCC. (4) Cadherin ligation by itself is an excellent inhibitor of cell proliferation and a stimulator of cell polarity and differentiation, because cadherins engaged in adhesion serve as a hub in various signaling pathways, particularly in those involving small GTPases. A selection of published studies illustrates and consolidates these various signaling possibilities.

1. During both normal embryogenesis and pathological processes, such as invasive cancer, cadherin-type switching is a frequent occurence that forms the basis for the migration of particular cells and for generation of new structures with new functions (reviewed by Berx and van Roy in Nelson and Fuchs 2010). A notable example is the dynamic but highly controlled behavioral change of cells derived from the neural crest.
2. On the one hand, junctional p120ctn stabilizes the cadherins, but on the other hand, cadherins counteract cytoplasmic p120ctn, which can modulate members of the Rho GTPase family (reviewed by Pieters et al. 2012). Also, it has recently become clear that junctional αE-catenin can serve as a tension transducer for the CCC (Yonemura et al. 2010) (Fig. 1c). When an external force is applied to epithelial cells, for instance during wound healing, actomyosin-driven tension induces an unfolded conformation in αE-catenin so that it can recruit vinculin to the CCC. This serves as a positive feedback because it reinforces mechanical coupling between actomyosin networks and the CCC. At the same time, the force-dependent αE-catenin/vinculin interaction strengthens the intercellular junctions and contributes to tissue integrity despite the external force.
   On the other hand, αE-catenin dimers were shown to preferentially dissociate from the CCC and to locally block the binding of the actin nucleating and branching factor ARP2/3 complex (reviewed in Nelson and Fuchs 2010) (Fig. 1b). At the same time, binding of αE-catenin to formin is promoted in a way that facilitates the formation of elongated F-actin fibers that can associate effectively with myosin-II (Fig. 1b and c). More recently, it was demonstrated that AJs interact also with microtubules, either the plus ends of microtubules via β-catenin or the minus ends via p120ctn (reviewed by Harris and Tepass 2010). Association of the AJ with microtubules facilitates junctional assembly and also allows the AJ to influence intracellular structuring. For instance, the orientation of both symmetric and asymmetric cell divisions are influenced by AJs (reviewed by Harris and Tepass 2010).
3. By sequestering β-catenin in the junctions, this important signaling molecule is prevented from entering the nucleus and activating LEF/TCF-dependent gene activation (▶ Beta-Catenin). Similarly, p120ctn in complex with classic cadherins cannot shuttle into the nucleus, where it would

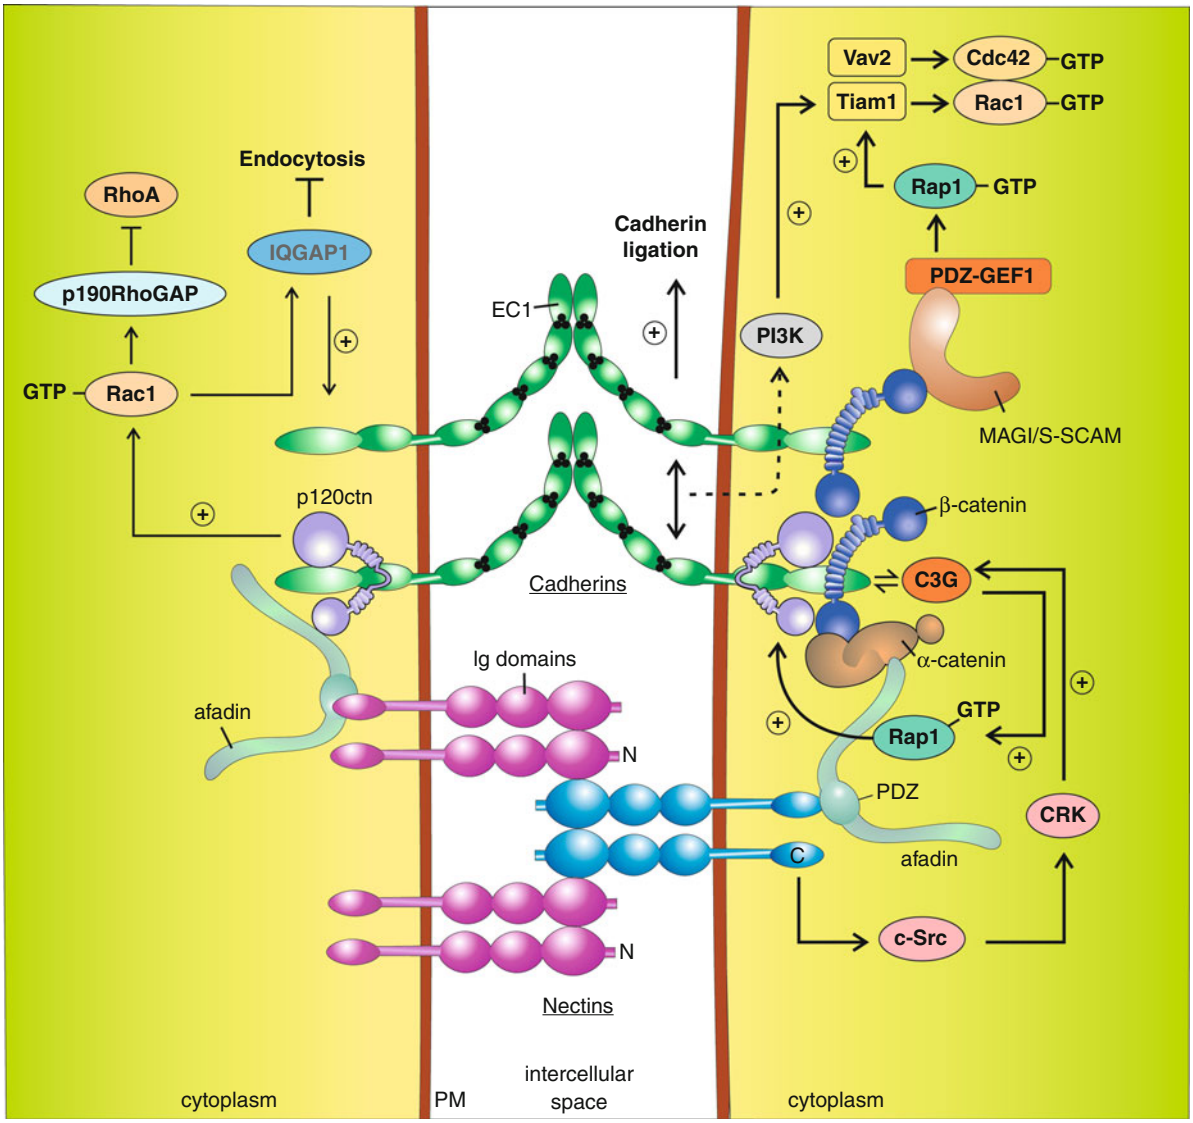
contribute to Wnt signaling by retrieving the transcriptional inhibitor Kaiso to the cytoplasm. In the case of E-cadherin, p120ctn binding to the JMD of classic cadherins shields both a di-leucine motif required in mammalian cells for clathrin-mediated endocytosis and a Tyr residue that, when phosphorylated, is recognized by Hakai, an E3 ubiquitin ligase (reviewed by Niessen et al. 2011) (see next section).

4. Native cadherin ligation, that is, the interaction in *trans* between cadherins across cell-cell boundaries, can result in two types of signaling: increased juxtacrine signaling by neighboring non-cadherin molecules, and a direct effect on cadherin-mediated signaling. To dissociate the first type of adhesion-dependent processes from the second type, researchers trigger cell-associated cadherins with, for instance, beads coated with recombinant cadherin ectodomains. Studies of this type have revealed a major role for small GTPases of the Rho family (Kooistra et al. 2007; Watanabe et al. in Nelson and Fuchs 2010; Niessen et al. 2011; Pieters et al. 2012). Although the effects seen are complex and much dependent on the cadherin type involved, as well as on cell type and cell activation status, several useful models have emerged. For instance, E-cadherin ligation induces local and transient activation of Rac1 and Cdc42 GTPases (Fig. 3). This might occur by activation of appropriate GEFs (guanine nucleotide exchange factors) such as Tiam1 and Vav2, and it appears to be dependent on association of p120ctn with cadherin. Two potential mediators of cadherin-induced GTPase activation are PI3K, which is stimulated upon E-cadherin ligation and leads to Tiam1 activation, and Rap1, a Ras-like small GTPase that has numerous effectors, including Vav2 and Tiam1 (Kooistra et al. 2007).

   Rap1 by itself can be activated upon cadherin ligation in at least four possible ways (Fig. 3). (a) The E-cadherin cytoplasmic domain transiently recruits the Rap-GEF C3G in nascent junctions. (b) Junctional β-catenin recruits MAGI scaffold proteins and PDZ-GEF1, and this macromolecular complex activates Rap1. (c) Nectins, which are immunoglobulin-like adhesion molecules, promote cadherin-dependent junction formation (reviewed by van Roy and Berx 2008) and also induce Rap1 activation by a process involving c-Src, Crk, and C3G (Hoshino et al. 2005). (d) Various RTKs can associate with classic cadherins (see below) and trigger signaling pathways leading to Rap1 activation. Interestingly, afadin (AF6), an actin-binding adaptor protein, couples the cytoplasmic domains of nectins to junctional p120ctn and α-catenin (van Roy and Berx 2008) (Fig. 3). Afadin has a Rap1-binding domain and is indeed recruited to nascent junctions through the action of Rap1. There, it strengthens the binding of p120ctn to E-cadherin, what counteracts the endocytosis of unligated E-cadherin and hence contributes to maturation of cadherin-based and nectin-based junctions (Hoshino et al. 2005).

   When and where are such cadherin-modulated signals important? Nascent epithelial junctions show a restricted membrane zone with active GTP-Rac1, recruitment of Arp2/3, and increased lamellipodial activity at the site of the expanding intercellular contacts (reviewed by Nelson and Fuchs 2010; Niessen et al. 2011). Subsequent expansion and completion of cell-cell adhesion is dependent on RhoA activation at the distal edges of the intercellular contacts, which locally induces actomyosin contractility. The cadherin-induced activation of Rac1 (and also Cdc42) can have different consequences, including actin nucleation through activation of WASP-WAVE family proteins and the Arp2/3 complex, local inhibition of RhoA by activation of p190RhoGAP, and inhibition of E-cadherin endocytosis through IQGAP1, which is an F-actin cross-linking protein and a downstream target of Rac and Cdc42 (Izumi et al. 2004) (Fig. 3).

   Interestingly, similar signaling molecules are at play also in neural synapses (reviewed by Brigidi and Bamji 2011). Postsynaptic spine morphology is indeed dependent on modulation of small GTPases by p120ctn, the related neural δ-catenin, and α-catenin. So, clustering of postsynaptic N-cadherin with associated p120ctn and α-catenin leads to recruitment of afadin, which in turn recruits the Rac-GEF kalirin-7, promoting Rac1-dependent widening of the spine head. Moreover, p120ctn and δ-catenin can inhibit RhoA, which regulates spine length and density. These findings collectively show that functional interactions of catenins, be it β-catenin, p120ctn, or α-catenin, with small GTPases and actin remodeling proteins is a recurrent theme that has evident implications for correct tissue morphogenesis (reviewed by Harris and Tepass 2010).



Cadherins, Fig. 3 Interactions between ligation of nectins, ligation of classic cadherins and activation of small GTPases. Nectins are members of the immunoglobulin(Ig)-like family of adhesion proteins. They homopolymerize in *cis* and heteropolymerize in *trans*. Their C-terminal ends bind to the PDZ domain of afadin. Afadin binds to a variety of proteins, including α-catenin, p120ctn, and Rap1, a Ras-like small GTPase. Rap1 is converted into its GTP-bound active form by the action of either Rap-GEF C3G or PDZ-GEF1. This occurs initially in nascent E-cadherin-containing junctions as C3G binds transiently to the cytoplasmic domain of E-cadherin (where it competes with β-catenin). Nectins promote C3G activation and junctional maturation via a c-Src/CRK signaling pathway. In this macromolecular complex, strengthening of the binding of p120ctn to E-cadherin stimulates activation of Rac1, which leads to inactivation of RhoA and activation of IQGAP1. The latter is an F-actin cross-linking protein counteracting E-cadherin endocytosis and in that way stimulating junctional maturation. Cadherin ligation by itself stimulates PI3K, leading to activation of the GEF proteins Vav2 and Tiam1, which in turn activate Rac1 and Cdc42. Upon junctional maturation, C3G on the cadherin tail is displaced by β-catenin, which interacts with scaffold proteins of the MAGI/S-SCAM family. Interaction of these scaffold proteins with PDZ-GEF1 further increases the local concentration of active Rap1-GTP, which in turn further activates Vav2 and Tiam1. Modified after (van Roy and Berx 2008), and after (Pieters et al. 2012)

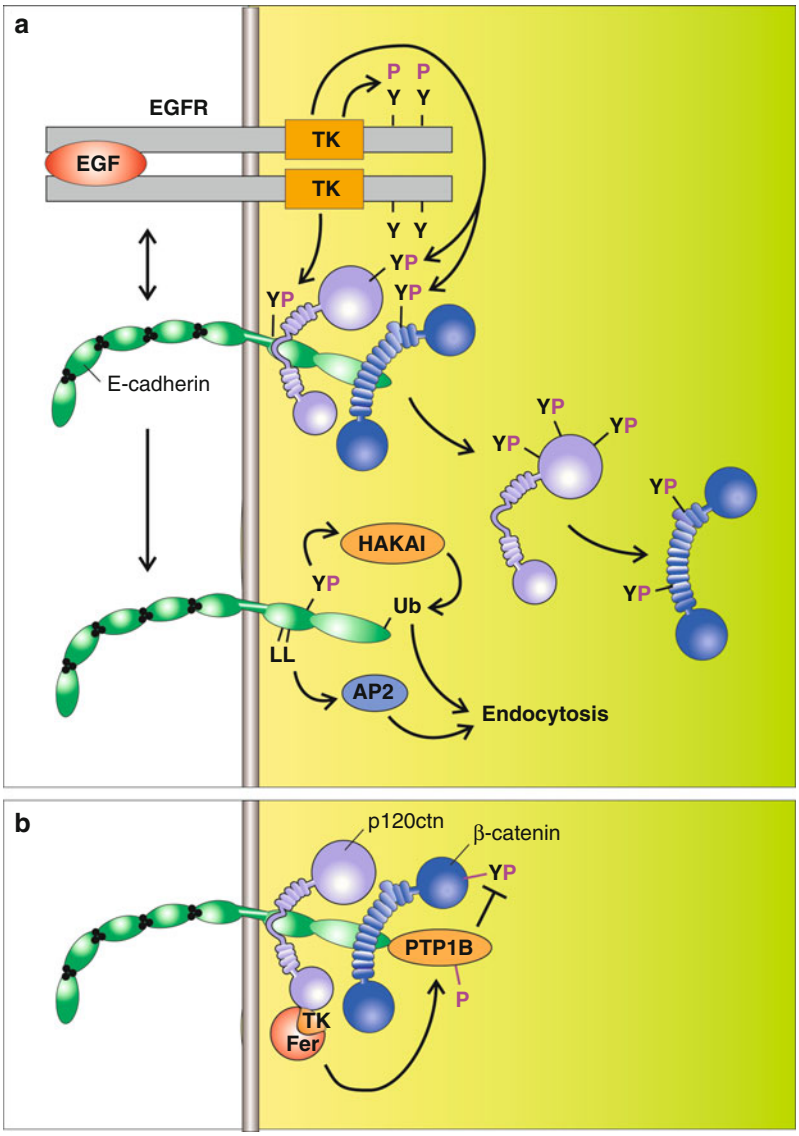
Signaling by Posttranslational Modification of Classic Cadherins

Of the wide variety of possible posttranslational modifications that might affect and modulate classic cadherins and associated proteins, (de)phosphorylation and proteolytic processing have been studied in most detail. For instance, the cytoplasmic domains of classic cadherins as well as the associated armadillo proteins p120ctn and β-catenin are efficient substrates for various tyrosine kinases, both receptor tyrosine kinases (RTKs) and non-receptor tyrosine kinases such as Src, Fyn, and Fer (reviewed by Niessen et al. 2011; Pieters et al. 2012). Tyrosine phosphorylation of cadherin and catenin is generally thought to perturb their functions, but there is ample evidence that weak or transient phosphorylation under physiological conditions stimulates cadherin-mediated adhesion. Ligation of E-cadherin stimulates the c-Src signaling pathway in a delicate biphasic way: weak signals are supportive of E-cadherin-based cell-cell contacts in a positive feedback, whereas strong signals inhibit E-cadherin functionality in a negative feedback (reviewed by Niessen et al. 2011).

Interestingly, cadherins can interact, in a cadherin-type specific way, with transmembrane signaling proteins like RTKs and phosphotyrosine phosphatases, and this influences both transcellular and intracelluar signaling. For instance, the E-cadherin ectodomain interacts physically with the ectodomains of EGFR and the HGF-receptor c-Met (Fig. 4a). These interactions either stimulate or inhibit ligand-induced receptor activities, through co-recruitment of RTKs by E-cadherin to the cell surface or by co-endocytosis of E-cadherin with the receptor (reviewed by van Roy and Berx 2008). On the other hand, the associated RTKs can negatively affect E-cadherin functionality by tyrosine phosphorylation of E-cadherin and the associated catenins. In the case of N-cadherin, the ectodomain has been demonstrated to interact molecularly and functionally with the FGF-receptor ectodomain to prevent FGFR internalization and allow sustained receptor activation and downstream signaling (reviewed by Berx and van Roy in Nelson and Fuchs 2010). In endothelial cells, VEGFR2 associates with the CD instead of the ectodomain of VE-cadherin (cadherin-5). This interaction also prevents receptor internalization and signaling, and this ultimately inhibits cell growth (reviewed by Niessen et al. 2011). VE-cadherin is tyrosine phosphorylated in response to a wide spectrum of signals, including triggering by VEGF and various inflammatory mediators.

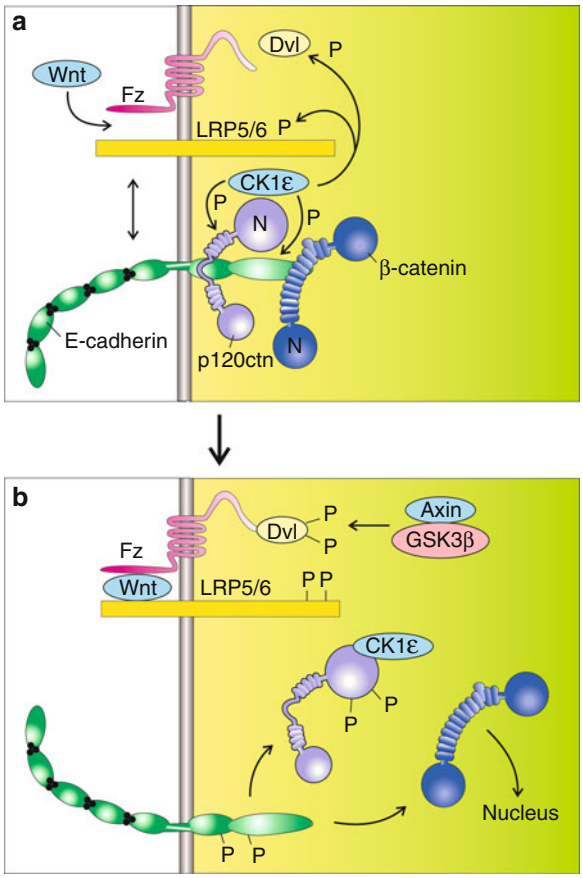
Generally, the cellular response to cadherin/catenin phoshorylation appears to be much influenced by the cadherin type, the cell type, and the microenvironment. Therefore, the following interactions serve as representative examples rather than as rules of thumb. In adherent cells expressing N-cadherin, the cadherin-associated p120ctn recruits the non-receptor tyrosine kinase Fer, which activates the protein Tyr phosphatase PTP1B (PTPN1) when this is complexed to junctional β-catenin (Fig. 4b). This promotes junctional integrity (reviewed by Pieters et al. 2012). Interestingly, a similar mechanism of junctional stabilization occurs in excitatory synapses, where junctional p120ctn at the presynaptic membrane recruits Fer, leading to activation of the Tyr phosphatase SHP2 (PTPN11), which in turn dephosphorylates β-catenin and promotes junctional integrity at synapses (Lee et al. 2008) (Fig. 4b). Further, synaptic functionality is promoted by the following specific molecular interactions with junctional β-catenin (reviewed by Brigidi and Bamji 2011). The PDZ-binding motif at the C-terminus of β-catenin acts as a scaffold for recruitment of various proteins to the cadherin/catenin complex, including the presynaptic scaffolding protein Scribble and the postsynaptic scaffolding protein S-SCAM (Magi2). Synaptic vesicles (SVs) are recruited via Scribble to the presynaptic membrane, whereas at the postsynaptic side, junctional S-SCAM recruits the cell adhesion protein neuroligin-1 (NL1) to the synapse. NL-1 engages in trans-synaptic binding with neurexin and this enhances the clustering of SVs in the presynaptic compartment (reviewed by Brigidi and Bamji 2011). Likewise, δ-catenin binds several PDZ-domain-containing proteins, including postsynaptic receptor scaffolding proteins. δ-catenin is a p120ctn homolog exclusively expressed in the brain. Moreover, the ectodomain of N-cadherin also associates with the AMPA receptor GluR2, and this interaction appears to be essential for GluR2-mediated spine maturation.

When RTKs or oncogenic tyrosine kinases are active, phosphotyrosine sites on p120ctn and cadherin cytoplasmic domains recruit SH2-containing kinases and phosphatases. These enzymes act in a complex and concerted manner on junctional, cytoskeletal, and signaling protein substrates. A major consequence can be

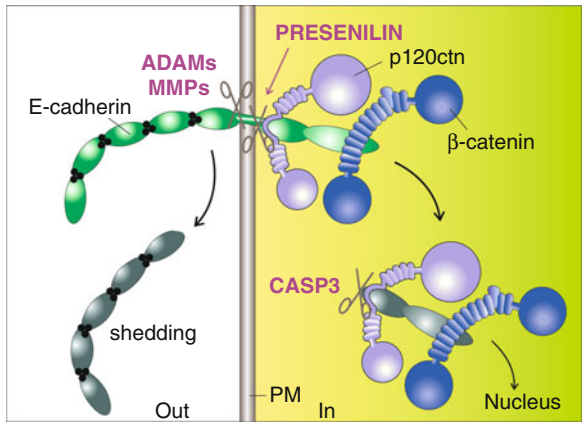


Cadherins, Fig. 4 Tyrosine phosphorylation of the cadherin/catenin complex (CCC) influences its stability. (**a**) The ectodomain of E-cadherin forms a complex (*bidirectional arrows*) with the epidermal growth factor receptor (EGFR). Triggering of dimeric EGFR by its ligand EGF activates its tyrosine kinase (TK) activity, leading to cross-phosphorylation of EGFR and phosphorylation of several components of the CCC on Tyr (Y) residues (arrows and -YP annotations). This leads to release of catenins from the CCC, which exposes a di-Leu motif on the cytoplasmic domain of E-cadherin. Recognition of this motif by the clathrin adaptor AP2 induces endoctysosis of E-cadherin. Moreover, the P-Tyr on the cytoplasmic domain of E-cadherin is recognized by the E3 ubiquitin ligase Hakai. Ubiquitinated E-cadherin is quickly endocytosed. (**b**) On the other hand, junctional p120ctn can associate with the non-receptor tyrosine kinase Fer. This leads to activation of the protein Tyr phosphatase PTP1B in complex with junctional β-catenin, which counteracts the action of other tyrosine kinases, including EGFR, on β-catenin. Not shown here is that increased Fer activity leads to Tyr phosphorylation also of β-catenin, stimulating its release from the CCC. Modified after (Pieters et al. 2012)

phosphorylation of critical Tyr residues on β-catenin, leading to disassembly of β-catenin from cadherin tails on the one hand and from α-catenin on the other hand (Fig. 4a). Moreover, junctional p120ctn can also recruit the Ser/Thr kinase CK1ε, which upon activation (for instance, by Wnt signaling) phosphorylates and activates several Wnt receptor components, which form a macromolecular complex with the



Cadherins, Fig. 5 Action of casein kinase-1ε (CK1ε) on a macromolecular complex of E-cadherin with the Wnt receptor modulates the Wnt signaling pathway. (**a**) In the absence of the ligand Wnt, the Ser/Thr kinase CK1ε associates with junctional p120ctn, whereas E-cadherin associates with the Wnt co-receptor LRP5/6 (*bidirectional arrows*). Upon binding of Wnt, the complex grows by association between LRP5/6 and the Wnt receptor Frizzled (Fz), followed by recruitment of Dishevelled (Dvl). By then, CK1ε becomes activated and phosphorylates LRP5/6, Dvl, p120ctn, and the cytoplasmic tail of E-cadherin (*arrows*). (**b**) On the one hand, these phosphorylation events trigger Wnt signaling by recruiting (and thus inhibiting) Axin and GSK-3β, while β-catenin is released from the CCC and can shuttle to the nucleus, where it stimulates transcription. On the other hand, phosphorylated E-cadherin dissociates from both LRP and p120ctn, which increases its turnover. Modified after (Casagolda et al. 2010)



Cadherins, Fig. 6 Junctional E-cadherin is sensitive to proteolytic processing. Action of metalloproteases (MMPs) and ADAMs (A Disintegrin and Metalloprotease) can lead to shedding of the ectodomain of cadherins. This reduces intercellular adhesion directly, as well as indirectly by interfering elsewhere in the tissue or organism with the clustering/signaling by full-length cadherins. The remaining cell-associated cadherin fragment is released from the plasma membrane by the actions of presenilin (γ-secretase) and then caspase-3. The final C-terminal fragment, which is still bound to the armadillo catenins, might shuttle as a complex to the nucleus, or it might first release these catenins, which then might translocate separately to the nucleus. In either case, transcription of specific target genes would be activated. Modified after (van Roy and Berx 2008)

E-cadherin/catenin complex (Casagolda et al. 2010) (Fig. 5). However, CK1ε also phosphorylates the cadherin tail and p120ctn. This leads to dissociation of both β-catenin and p120ctn/CK1ε from E-cadherin. Wnt signaling is then terminated for two reasons: CK1ε is released from the signalosome, and the release of p120ctn from the JMD of the E-cadherin tail removes Fer and PTP1B from the complex and exposes Tyr residues in the cadherin tail. When these residues become phosphorylated, they serve as docking sites for the E3 ubiquitin ligase Hakai; this results in ubiquitination and internalization of E-cadherin (Fig. 4a) (Pieters et al. 2012). Whether this scenario is valid for all cell types that are responsive to Wnt signals is an open question.

Posttranslational processing is another means for modulating the adhesive and signaling functions of cadherin-catenin complexes. Briefly, furin-mediated removal of a prodomain is essential for initiating adhesion by classic cadherins (reviewed by van Roy and Berx 2008). Moreover, the ectodomain of classic cadherins is shed upon cleavage by various metalloproteases, including transmembrane ADAMs. This phenomenon is probably relevant to cancer progression (reviewed by Berx and van Roy in Nelson and Fuchs 2010). In turn, the remaining membrane-associated cadherin fragments can be further cleaved by presenilin-1/γ-secretase or by caspase-3 (Fig. 6).

The final C-terminal fragments can retain biological activity by binding various proteins, including armadillo-family catenins, and by translocation into the nucleus (reviewed by Berx and van Roy in Nelson and Fuchs 2010; Niessen et al. 2011).

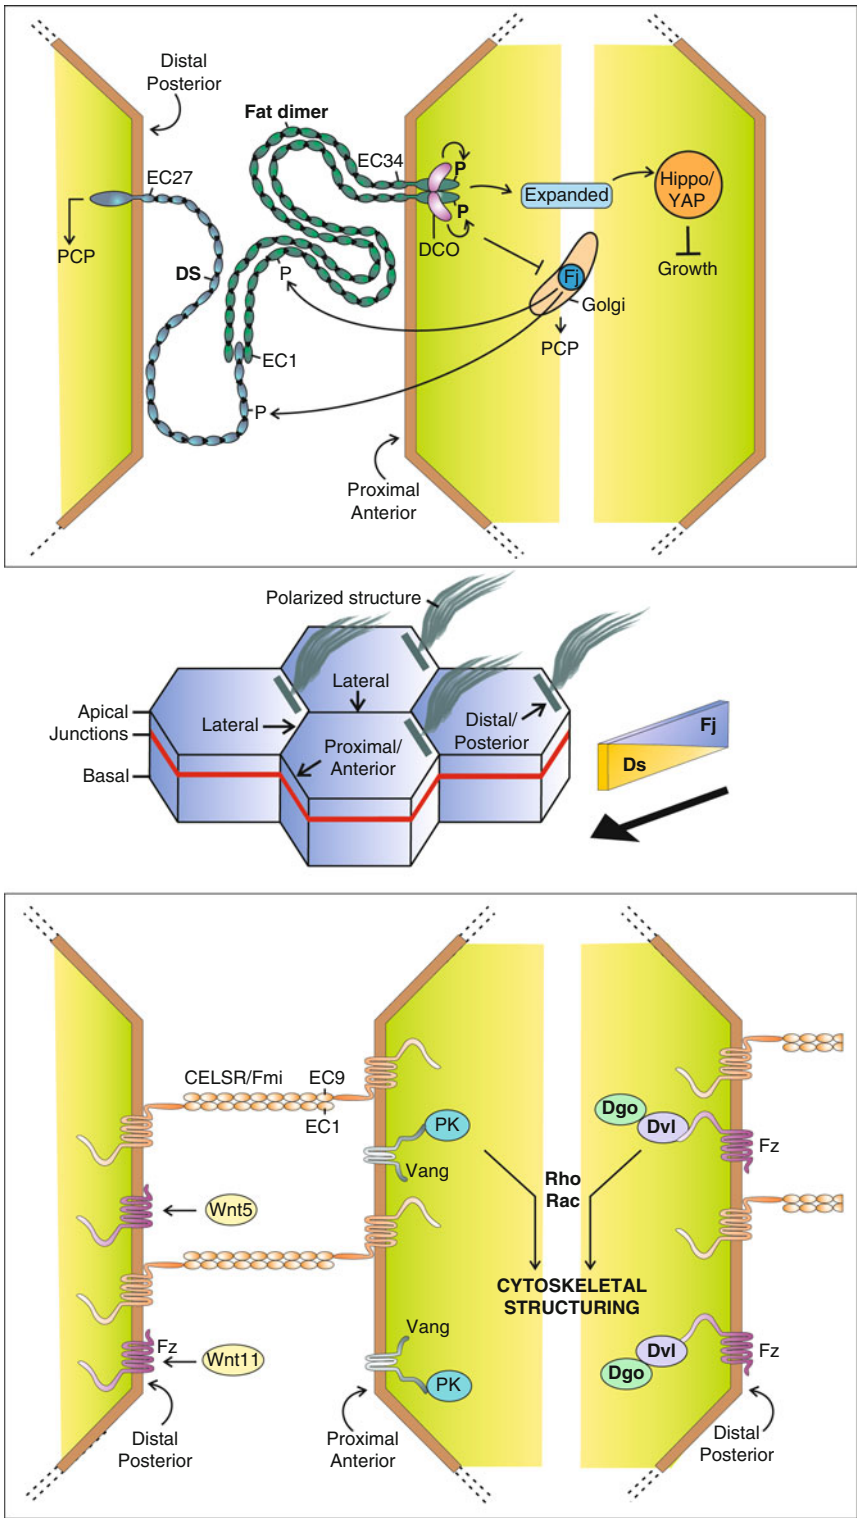
Signaling by Nonclassic Cadherins

Compared to classic cadherins, knowledge on nonclassic and cadherin-related atypical cadherins is still sparse. Nevertheles, it points to multiple signaling functions.

Cadherins with atypical membrane association are the GPI-anchored cadherin-13 and flamingo/CELSR with 7-TM domains. Upon homophilic ligation to endothelial cell surfaces, cadherin-13 becomes linked to Grp78/BiP. The latter is normally ER-retained but can be secreted under particular conditions. Formation of this complex with Grp78 triggers the anti-apoptotic Akt kinase pathway. This has important consequences for tumor-associated angiogenesis (reviewed by Berx and van Roy in Nelson and Fuchs 2010). The flamingo (Fmi)/CELSR proteins are particularly well known for their roles in planar cell polarity (PCP), both in fruit fly (where flamingo is also called starry night or stan) and in vertebrates (Gray et al. 2011). PCP (Fig. 7, middle) has turned out to be central for a variety of important biological processes: convergence and extension movements during embryonic development, inner ear development, hair follicle and cilia polarization, tangential neuronal migration, and development of heart, kidney, and lung (Gray et al. 2011). At the distal side of polarized cells, Fmi/CELSR forms a molecular complex with Frizzled receptors preferentially, while at the proximal side a complex of Fmi/CELSR with Van gogh (Vang, also called strabismus or stan), is preferred (Fig. 7, bottom). In addition to these heterophilic interactions, Fmi/CELSR molecules interact homophilically in *trans* across distal-proximal membrane boundaries, but not at lateral cell boundaries. Unfortunately, the structures of these various molecular interactions have not been reported. Anyhow, cellular asymmetry is assumed to be generated on the basis of the heterophilic interaction partners of Fmi/CELSR. Outside these asymmetric junctional complexes, Fmi/CELSR is unstable due to a high rate of endocytosis.

While Fmi/CELSR is considered a core protein that mediates PCP at the cellular level, two other atypical cadherin proteins, Fat and Dachsous (Ds), are considered either upstream or parallel signaling proteins for PCP, as they mediate PCP at a more global embryonic or organ level (Gray et al. 2011). In mammals, Fat4 is the true ortholog of fly Fat, and DCHS1 is the ortholog of Ds (Hulpiau and van Roy 2011). It is noteworthy that the cytoplasmic domain of FAT4 deviates completely from those of FAT1 to FAT3. Both Fat and Ds have very long ectodomains with numerous EC repeats, and they interact heterophilically with each other at cell junctions. Unfortunately, the structure of these ectodomains is not resolved. Polarity across embryos/organs is mediated both by increased Ds expression at the proximal side and by increased four-jointed (Fj) at the distal side (Sopko and McNeill 2009) (Fig. 7, middle). Fj is a kinase that phosphorylates the ectodomains of Fat and Ds. In fly, strong triggering of Fat by Ds leads to *cis*-dimerization of Fat and to phosphorylation by the associated Dco (Disc Overgrown, the fly homolog of CK1ε) (Fig. 7, top). Importantly, actively signaling Fat not only mediates PCP but, at least in *Drosophila*, also activates the Hippo signaling pathway by a complex, multistep and still incompletely understood mechanism (Badouel and McNeill 2011). The Hippo or Yap pathway is an emerging signaling network with critical importance for controlling organ size, and its derangement is being reported in an increasing number of human cancer types (Badouel and McNeill 2011).

Genuine protocadherins comprise more than half of the cadherin species in mammals and have typical cytoplasmic domains completely different from those of classic cadherins. Reportedly, they have much weaker or even undetectable adhesion potential compared to classic cadherins (for instance, Biswas et al. 2010). Consequently, they are believed to have a signaling function rather than an adhesive function. Unfortunately, analyses of protocadherins are fairly few, and functional studies have been performed only on a few protocadherins and mostly in *Xenopus* (Nishimura and Takeichi 2009). The cytoplasmic domain of arcadlin, which corresponds to the rat protocadherin-8, interacts in synaptic junctions with N-cadherin. Excitation of hippocampal neurons upregulates arcadlin, and this promotes N-cadherin internalization, which is accelerated by the homophilic



Cadherins, Fig. 7 Role of various members of the cadherin superfamily in planar cell polarity (PCP). *Central panel*: Scheme of a typical tissue with established PCP. Cells are arranged in a sheet with a polarized structure (for instance, sensory bristles on a fly wing). Besides having lateral membranes, cells thus have a proximal (anterior) membrane and a distal (posterior)

interaction of arcadlin ectodomains and involves an associated MAPKKK named TAO2β (reviewed by Nishimura and Takeichi 2009). A similar observation of cross-inhibition involves the induction by activin of PAPC expression in *Xenopus*, which is linked to decreased adhesion activity of C-cadherin, a classic cadherin in frog. For protocadherin-10 (OL-protocadherin), a specific interaction between its CD and the actin-organizing complex Nap1/WAVE has been reported (Nishimura and Takeichi 2009). Protocadherin-10 is enriched at sites of cell-cell contact and it recruits Nap1/WAVE, which in turn leads to weakening of the classic cadherin-catenin complex and upregulation of the cell motility machinery (Fig. 1a). These molecular interactions might explain the aberrant migration of particular neurons in mice in which protocadherin-10 is knocked out. One could therefore conclude that a general function of protocadherins is to negatively regulate the activity of classic cadherins. However, protocadherin-19 in zebrafish acts synergistically with N-cadherin to control cell migration during anterior neurulation (Biswas et al. 2010). This protocadherin is also thought to be linked to WAVE regulation. It will thus be challenging to unravel in detail the underlying mechanisms of protocadherin functions.

Summary

This entry deals with selected examples of intra- and cross-cellular signaling by members of the large cadherin superfamily. Much attention is paid to E-cadherin, which as founder of the superfamily, is an extensively studied "classic" cadherin. As a mediator of specific intercellular junctions, both static and dynamic ones, it has a pivotal role in epithelial cell behavior, tissue formation, and suppression of cancer. Compelling evidence has been gathered that E-cadherin is much more than "molecular glue," because it serves as a hub for several signaling pathways. On the one hand, association of the armadillo protein p120ctn with the juxtamembrane domain of classic cadherins, as well as activation of various small GTPases, contribute to junctional stability. On the other hand, cadherin ligation generates signals that contribute to cell differentiation and inhibit growth stimulatory signaling, in part by binding via its C-terminal domain the proto-oncogenic β-catenin. Important modulators of cadherin-associated signaling are cytoskeleton components, such as actomyosin, and several enzymes, in particular receptor tyrosine kinases and counteracting phosphatases. E-cadherin is also processed by several proteases to generate various fragments with signaling activity. The many other members of the superfamily include protocadherins, which may act negatively on classic cadherins in various ways. The flamingo/CELSR cadherins and the very extended Dachsous and Fat cadherins play important roles in the signaling toward planar cell polarity. In conclusion, signaling by cadherins is a rapidly growing research field with multiple proven or proposed links to mammalian pathologies. Recent investigations on cadherin-linked signaling raised many interesting questions that remain to be addressed by multidisciplinary approaches.

Cadherins, Fig. 7 (continued) membrane. A spatial gradient of Dachsous (Ds) and an inverse gradient of four-jointed (Fj) contribute to long-range polarity (indicated by the *arrow*). This is further detailed in the *top panel*, showing a speculative model of *Drosophila* cells with PCP. The very long Ds protein in the apical region of a distal membrane interacts with Fat in a proximal membrane of a juxtaposed cell (the interaction via the EC1 domains of these two cadherin family members is speculative). This induces *cis*-dimerization of Fat, followed by phosphorylation of their Fat cytoplasmic domains by the recruited kinase Discs Overgrown (Dco). This leads to inhibition of Fj, which is a Golgi-localized kinase that can phosphorylate the ectodomains of both Ds and Fat. Inverse spatial gradients of Ds and Fj over the tissue (*middle panel*) are believed to direct PCP. Moreover, the activated Fat dimer triggers, via complex signaling (not shown here), the growth inhibitory Hippo/YAP signaling pathway. One of the mechanisms involved is recruitment of Expanded, a FERM-domain-containing protein, to the apical side of the membrane. *Bottom panel*: Polarized expression pattern of the core polarity proteins Frizzled (Fz) and Van Gogh (Vang, also named Strabismus/Stbm) in juxtaposed plasma membranes. At the extracellular side, Fz becomes activated by Wnt5 or Wnt 11. At the cytoplasmic side, Fz is associated with Dishevelled (Dvl) and Diego (Dgo), whereas Vang is associated with Prickle (Pk). The assymetric distribution of these proteins leads to a polarized cytoskeleton structure via modulation of Rho and Rac signaling. Fz and Vang interact heterophilically across the intercellular space in a poorly understood way to which homophilic interaction of Flamingo (CELSR/Fmi) cadherins contribute (the interaction between EC1 and EC9 domains of overlapping Flamingo molecules is speculative). Modified after Berx and van Roy in (Nelson and Fuchs 2010), and after (Badouel and McNeill 2011)

Historical Background

Calpains are a family of non-lysosomal cysteine proteases that are activated by calcium. Calcium-dependent protease activity has already been detected in 1964 in brain tissue from rats, and this activity was later related to calpain. Yet, the identification of the protein started off with structural analysis of muscle tissue and its alteration by *post mortem* degradation (history broadly reviewed by Goll et al. 1990, 2003): In the late 1960s, Wayne Busch and Darrel Goll studied the physiological effects of Ca^{2+} in tissue specimen of rabbit muscle. When muscle strips were left overnight in a 1 mM Ca^{2+} buffer solution, it became apparent that the Z-line (a structural element separating sarcomers in skeletal muscle) had completely disappeared. Busch and Goll subsequently incubated the stripes in EGTA, thereby preventing degradation of the Z-line. With the help of Marvin Stromer, they performed electron microscopy studies showing that the degradation process was completely restricted to the Z-line, leaving other structural elements unaltered. In 1972, Busch and colleagues isolated a protein fraction from muscle fibers which caused removal of the Z-disk in a preparation of rabbit skeletal muscle at Ca^{2+} concentrations higher than 0.1 mM. The Z-line remained intact when Ca^{2+} was substituted by EGTA, strengthening the view that this activity required calcium. In 1976, Bill Dayton joined this group to isolate the protein (at that time called "Ca^{2+}-activated factor"). There was need for larger tissue quantities which required a switch of species from rabbit to pigs. From this preparation, Dayton and colleagues could isolate a sufficient amount of protein with Ca^{2+}-dependent proteolytic activity, which showed Z-disk removing characteristics. They also revealed that this protease contained two subunits, an 80-kDa subunit and a 30-kDa subunit. The protein was later named m-calpain, and is now mainly referred to as calpain 2. The name calpain was given to indicate that this is a *cal*cium-dependent protease with pa*pain*-like activity.

Ron Mellgren identified a second Ca^{2+}-dependent protease eluting at a different salt concentration than m-calpain. The Ca^{2+} concentration necessary for activation was in the μM range, and this protein was later named μ-calpain (now called calpain 1). This protein is also a heterodimer consisting of a catalytic 80-kDa subunit and a small 30-kDa subunit. The cDNAs for the large subunit of the two calpains have been cloned in the 1990s, and described as gene products of CAPN1 (coding for calpain 1) and CAPN2 (coding for calpain 2). The gene encoding the 30-kDa subunit has also been cloned and referred to as CAPN4. In 1989, further calpains beyond calpain 1 and calpain 2 were discovered, and over the last two decades 15 calpain-like genes have been identified in various tissues, and implicated with a variety of diseases. Only nine of them have the typical calmodulin-like EF-hand sequence and are commonly called "typical calpains," as opposed to the "atypical calpains," which do not contain an EF-hand domain (Saez et al. 2006).

Since the mid-1970s it was suspected that there must be a natural inhibitor of calpain in purified fractions of the enzyme and, in 1982, the first detailed report on an intrinsic inhibitor of calpain from human erythrocytes, called calpastatin, was published. Calpastatin is specific for calpain 1 and calpain 2, and does not appear to inhibit any other protease (Rachel et al. 2008). A number of synthetic calpain inhibitors, mostly of peptidic nature, are now commercially available. However, none of them is specific to calpain (Pietsch et al. 2010).

In the late 1980s, it was discovered that calpain dysfunction underlies muscular dystrophies. Since then, calpains have been suggested to be involved in a number of different pathologies, and the information on the pathophysiology of the calpain system has been increasing tremendously in the last two decades (Zatz and Starling 2005). Yet, the physiological role of calpains remains to a large extent unclear.

Biological Properties and Regulation

The "classical" calpains (1 and 2) are heterodimers comprising an 80-kDa subunit (catalytic subunit) and a common 30-kDa subunit (regulatory subunit). The catalytic domains of both calpains share about 60% sequence homology, and are comprised of four domains (I–IV). Domain II is further divided into two subdomains, IIa and IIb. In the absence of calcium, the catalytic triad consisting of Cys105 in domain I and His262 and Asn286 in domain II is separated, indicating that a conformational change is required for activation. Domain IV shares some sequence identity with calmodulin and contains five EF-hand Ca^{2+}-binding sites. The regulatory subunit constitutes two domains (V and VI), with EF-hand binding sites in domain VI (Strobl et al. 2000).

The cellular regulation of calpain and its inhibition by calpastatin is rather complex (Khorchid and Ikura 2002). Structural analysis revealed that the Ca^{2+}-free enzyme is catalytically inactive. A rise in the Ca^{2+} concentration above 1 mM induces a conformational change in the calpain molecule, inducing its proteolytic properties. Calcium appears to bind to more sites of the protein than just the EF-hand motifs, and it is not yet resolved which binding sites are required for activation of proteolytic activity. Interestingly, the concentration of 1 mM for the activation of calpain is not reached under physiological conditions, as the total intracellular Ca^{2+} concentration normally does not exceed 500 nM. It is likely that calpain can only be activated in cellular subdomains with increased Ca^{2+} concentration (e.g., in proximity to Ca^{2+} channels, synaptic terminals, etc.). Phospholipids appear to modulate the Ca^{2+} requirements of calpain, and it is possible that localization of calpain to the plasma membrane would enhance catalytic activity. Recent studies in fibroblasts have revealed that calpain 2 can be activated independently of calcium. Mitogen-activated protein kinase (▶ MAP Kinases), for example, activates calpain 2 by phosphorylation. As a result, calpain 2 is rapidly activated in dendrites and dendritic spines, thereby participating in cytoskeletal reorganization. Calpain 2 is also phosphorylated by the serine/threonine protein kinase ERK, leading to an activation of calpain and subsequent changes in tau cleavage, cell motility, and adhesion.

The contribution of the small "regulatory" subunit to calpain regulation is not fully understood. It has initially been speculated that the catalytic subunit is activated by dissociation of the small subunit from the core molecule. However, it appears that proteolytic activity is also present when the subunits are associated. The 30-kDa subunit may also be involved in folding of the 80-kDa subunit (as a molecular chaperone), thereby regulating function.

Physiological Function

The last decades have revealed the involvement of calpain in several pathological conditions. In contrast, less is known about the exact physiological function of calpain. It likely fulfills multiple roles, which is indicated by its great number of cellular substrates. It is therefore surprising that inhibition of calpain in animals by synthetic inhibitors is largely harmless.

Probably the best described function of calpain is its contribution to the (re)organization of the cytoskeletal system during a number of cellular events. The involvement of calpains in cell movement is well documented (Glading et al. 2002). Some cytoskeletal proteins including those assembling into intermediate filaments (vimentin, desmin, neurofilament protein) are cleaved by calpain and may allow adaptation of cellular architecture. Spectrin, a building block of the sub-membraneous cytoskeleton as well as cross-linkers of cytoskeletal filaments (e.g., talin) are also substrates for calpain, further underlining its involvement in structural modulation. Notably, a number of muscular elements including myosin and titin (which anchors actin and myosin to the Z-disk) are calpain substrates and possibly mediate the involvement of calpain in muscle diseases. Calpain also degrades dystrophin, a protein anchoring actin to the plasma membrane of muscle cells. Proteins of the microtubular system (MAP1 and MAP2) are also cleaved, as well as cell adhesion molecules (e.g., N-cadherin). In addition, calpain appears to be involved in cytoskeletal protein cleavage in platelet aggregation. Finally, calpain modulates cytoskeletal organization during myoblast fusion.

It is generally thought that calpain is central to a number of signaling pathways (Vosler et al. 2008). For example, RhoA activity is directly affected by calpain, thereby inhibiting cell spreading. Calpain also appears to be involved in apoptosis. Calpain inhibitors reportedly block proliferation at the G1 phase

suggesting that calpain contributes to cell cycle. In some tissues calpains may have highly specialized functions. In neurons, for example, calpains appear to play a central role in regulating synaptic function and plasticity (Wu and Lynch 2006), and may mediate long-term potentiation (LTP), a cellular form of learning and memory.

Calpains and Disease

Calpains have been suggested to be involved in a number of CNS diseases, especially those accompanied by chronic neurodegenerative processes (Liu et al. 2008). Excessive stimulation of NMDA receptors leads to calpain-mediated neurodegenerative cascades, which can be prevented by inhibition of calpain in several in vivo models. Calpain is activated in a number of CNS disorders, including Alzheimer's disease, Parkinson's disease, and Huntington's disease. It was recently shown that amyloid-β-induced nucleus basalis degeneration (a brain region affected during Alzheimer's disease) can be prevented by calpain inhibition in rats. At the cellular level, calpain mediates amyloid-β-induced cleavage of the presynaptic protein dynamin, thereby causing deficits in synaptic function. Calpain exacerbates tau pathology in Alzheimer's disease by cleaving p35, thereby activating cdk5, one of the kinases hyperphosphorylating tau protein. Calpain-mediated cdk5 activation also contributes to dopaminergic cell death in Parkinson's disease. A dysfunctional calpain system is also present in Huntington's disease, where active calpain directly cleavages the protein huntingtin, leading to a toxic accumulation of a protein fragment.

Beside chronic neurodegenerative diseases, calpain contributes to cell death in traumatic brain injury (Saatman et al. 2010) and cerebral ischemic processes (Bevers and Neumar 2008). Both pathologies involve excitotoxic cascades, which are prevented by calpain inhibition. For example, knockdown of calpain 1 increases long-term survival and protects hippocampal function in transient forebrain ischemia. Calpain is activated in the penumbra of the ischemic injury site and some calpain inhibitors have been shown to be neuroprotective. Similarly, calpain inhibition was effective in rat models of traumatic brain injury. Interesting, brain damage in both ischemia as well as traumatic brain injury can be prevented, when calpain inhibitors are given after the insult, indicating that calpain is involved in part of the downstream cascade of the excitotoxic process.

Calpain activation also facilitates degeneration of cardiac tissue after myocardial ischemia/reperfusion injury (Inserte et al. 2009). Both calpain 1 and calpain 2 are increased in ventricular muscle after coronary artery ligation in rats, and inhibition of calpain protects from ischemic cardiac muscle degeneration in animal models of myocardial infarction or in isolated rabbit heart. In an ischemia/reperfusion model in pigs, calpain inhibition decreased infarct size and improved ventricular contractility, and improved overall hemodynamic function.

Finally, there is strong evidence for the involvement of calpains in myopathies of skeletal muscle (Zatz and Starling 2005). Mutations in the gene encoding calpain 3 are responsible for the autosomal recessive disorder limb-girdle muscular dystrophy type 2A. Recent data suggest that mitochondrial abnormalities in calpain 3 deficient muscles may be the underlying mechanism.

Summary

Ubiquitously expressed and with numerous known substrates, calpain plays a significant role in cellular physiology. When activated, calpain cleaves various membrane components, cytosolic enzymes, and regulatory and structural proteins. Interaction with its substrates may lead to rapid changes in cellular functioning. While calpain activation is critically involved in numerous diseases including degenerative changes in the brain, muscles, retina, kidney, and other tissues, the physiological role is less understood. For an activity-regulated system like the calpain system, parameters like duration, intensity, and localization set the course for either a physiological or a pathological process. For example, activation of NMDA receptors activates calpain, leading to a cleavage of synaptic NMDA receptor subunits thereby preventing overexcitation. In contrast, excessive stimulation (possibly involving extrasynaptic NMDA receptors) induces calpain overactivation leading to downstream excitotoxic cascades and neurodegeneration. Analysis of the conditions which turn calpain activation from physiological function into pathophysiological offense is important not only for a full appreciation of the

signaling role of this molecule, but also for the development of novel therapeutics exploiting the biological significance of the calpain system.

10 (BCL10) and MALTL translocation gene 1 (MALT1), form a complex and play an essential role in nuclear factor κB (NF-κB) activation through immunoreceptor tyrosine-based activation motif (ITAM)-coupled receptors and some G-protein-coupled receptors (Hara and Saito 2009). CARMA1 is a member of CARD-containing membrane-associated guanylate kinase (MAGUK) family and was found to be a binding partner of BCL10 via CARD-CARD interaction (Bertin et al. 2001; Gaide et al. 2001), similar to CARD9 and the other member of CARD-MAGUKs, CARMA2 and CARMA3. Among the CARD-MAGUK families, only CARMA1 is highly and selectively expressed in lymphoid organs such as thymus, lymph node, and spleen. It is thought that CARMA1 binds to BCL10-►MALT1 complex following triggering through lymphocyte antigen receptors to form a signaling complex referred to as CARMA1-BCL10-MALT1 (CBM) complex (Fig. 1).

CARMA1 in the Development and Function in T and B Lymphocytes

Immunoreceptors such as T-cell receptors (TCRs), B-cell receptors (BCRs), some members of Fc receptors (FcRs), and activating ►NK receptors (NKRs) transduce activation signals by associating with signaling chains (e.g., CD3s, Igα, Igβ, FcRγ, and DAP12) containing ITAM (consensus; YxxL-x6-8-YxxL) in their cytoplasmic domains (Fig. 2). Upon engagement of ITAM-coupled

receptors, an activation signal cascade is initiated with phosphorylation of specific tyrosines in ITAMs, culminating in the activation of transcription factors including NF-κB, nuclear factor-activated T cells (NFAT), and activating protein-1 (AP-1).

Genetic studies using knockout mice of CARMA1, BCL10, and MALT1 as well as a CARMA1-deficient Jurkat cell line have demonstrated an essential role of CBM complex in antigen receptor signaling (Fig. 2a). The T-cell phenotype of CARMA1-deficient (*CARD11*$^{-/-}$) mice closely resembles that of BCL10-deficient (*BCL10*$^{-/-}$) and of MALT1-deficient (*MALT1*$^{-/-}$) mice (Hara et al. 2003; Ruefli-Brasse et al. 2003; Ruland et al. 2001, 2003). Peripheral mature T cells from these knockout mice show almost complete abrogation of proliferation and cytokine production upon stimulation through TCR or with a direct protein kinase C (PKC) activator, PMA plus Ca^{2+}-ionophore (P/I). Accordingly, these mice exhibit severely impaired T-cell immunity. The loss of CBM molecules abrogates TCR-or P/I-induced NF-κB activation owing to defective activation of I-κB kinase (IKK), whereas calcium mobilization and proximal tyrosine phosphorylation are unaffected. In addition, CARMA1 and MALT1 deficiency affect the activation of the MAPK JNK, particularly JNK2, but not the other MAPKs, Erk, and p38.

The CBM deficiency does not affect overall development of thymocytes, with normal numbers of the $CD4^+CD8^+$, $CD4^+CD8^-$, and $CD4^-CD8^+$ cells, but increased $CD4^-CD8^-$ cells for unclear reasons (Hara et al. 2003; Ruland et al. 2001). No overt developmental defects in conventional CD4 and CD8 T cells are observed in the peripheral lymphoid organs of these knockout mice; however, the number of natural-occurring regulatory T cells (nTregs) is markedly reduced both in the thymus and periphery (Molinero et al. 2009; Schmidt-Supprian et al. 2004). This phenotype is likely attributed to the reduced expression of the transcription factor Foxp3, the master regulator of Treg development, in thymic nTreg precursor cells in *CARD11*$^{-/-}$ mice because the TCR-induced NF-κB activation directly promotes the transcription of Foxp3 (Long et al. 2009).

Deficiency of CBM molecules in B cells, similar to that in T cells, results in abrogated BCR-induced NF-κB activation and thereby defects in B-cell proliferation and survival, although one line of *MALT1*$^{-/-}$ mice has exhibited only mild defects in B-cell activation (Fig. 2a) (Hara et al. 2003; Ruefli-Brasse et al. 2003; Ruland et al. 2001, 2003). Reduced follicular (FO) and marginal zone (MZ) B cells in spleen and an almost complete absence of peritoneal B-1 B cells have been

consistently observed in *CARD11*$^{-/-}$, *BCL10*$^{-/-}$, and *MALT1*$^{-/-}$ mice. CARMA1 and probably BCL10 control JNK activation through BCRs, whereas MALT1 might be dispensable for it. ▶ CD40-induced proliferation is also defective in splenic B cells with CBM deficiency, possibly owing to the defective development of MZ B cells, which are the major cells responding to CD40 stimulation.

The involvement of CBM complex in toll-like receptor (TLR) signaling in B cells has been suggested, although it remains a controversial issue. *CARD11*$^{-/-}$ whole splenic B cells show impaired proliferation in response to LPS (Hara et al. 2003). A study that compared FO and MZ splenic B cells revealed that BCL10 deficiency affected only MZ B cells responding to LPS due to impaired NF-κB activation (Fig. 2a) (Xue et al. 2003).

In addition to the essential role of CBM complex in canonical NF-κB signaling downstream of TCRs and BCRs, it also acts in the noncanonical NF-κB pathway through B-cell activation of the TNF family (BAFF) receptor, which regulates the survival of MZ B cells (Fig. 2a). Lack of MALT1 impairs BAFFR-induced phosphorylation and degradation of NF-κB2 precursor p100 (Tusche et al. 2009). The *MALT1*$^{-/-}$ MZ but not FO B cells exhibit reduced survival and anti-apoptotic gene induction in response to BAFF in vitro, likely owing to the elevated expression and defective BAFFR-induced downregulation of TRAF3, a negative modulator of the BAFFR-induced survival signal particularly in MZ B cells. The phenotypes of BAFF-Tg mice, including increased basal serum Ig, MZ B cells and B1 B cells, spontaneous germinal center formation, and Ig deposition in the kidney, all disappear in the absence of MALT1 or BCL10.

CARMA1 in NK-Cell Development and Function

Upon triggering of activating NKRs, NK cells attack targets through two defined effector functions: the cytotoxicity and the production of pro-inflammatory cytokines and chemokines. Studies have revealed that CARMA1, BCL10, and MALT1 are essential for production of cytokines and chemokines induced by multiple activating NKRs, including FcγRIII, NK1.1, Ly49H, Ly49D, and NKG2D; in contrast, the cytotoxicity of NK cells induced by these activating NKRs is not affected by CBM deficiency (Fig. 2b) (Gross et al. 2008; Hara et al. 2008). CBM deficiency does not influence either maturation or the repertoire formation of peripheral NK cells. The loss of CBM results in impaired NF-κB activation following activation of NKRs, whereas ▶ Vav1 phosphorylation and Ca^{2+} mobilization, both of which regulate exocytosis of lytic granules, are unaffected. Contribution of CBM to MAPK activation remains controversial. Similar to T cells, PKCθ activity is required for NF-κB activation through activating-NKR. TNF- or IL-18R-mediated NF-κB activation does not require CBM in NK cells.

Signaling Regulation of CBM

Multiple regulation mechanisms, involving phosphorylation, ubiquitylation, oligomerization, caspase activation, and recruitment to plasma membrane, have been proposed to control CBM-signaling (Fig. 1) (Hara et al. 2010).

Upon activation of antigen receptors, CARMA1 and BCL10 are phosphorylated by several kinases. Phosphorylation of CARMA1 by PKCθ (mainly in T cells) and PKCβ (mainly in B cells) in the PKC-regulated domain (PRD) likely transform CARMA1 to an active one that is accessible to BCL10 and other downstream molecules. Phosphorylation of CARMA1 by CaMKII facilitates the interaction between CARMA1 and BCL10. CaMKII also phosphorylates BCL10 but this phosphorylation is involved in the attenuation of the signaling. ▶ HPK1 phosphorylates CARMA1 within the PRD and is involved in both JNK and NF-κB activation although the precise mechanism is unclear. Phosphorylation of CARMA1 by IKKβ promotes signaling activation by enhancing the assembly of CBM complex. IKKβ also phosphorylates BCL10 within the MALT1-interacting S/T-rich domain and within CARD upon TCR stimulation. The former interferes with IKK ubiquitination by causing disengagement of BCL10 from MALT1, and the latter induces BCL10 degradation in the proteasome, thus negatively regulating the signaling. CK1α associates with the PRD of CARMA1after TCR stimulation and contributes to initial NF-κB activation; however, subsequent phosphorylation of the PRD by CK1α contributes to the negative feedback of the signaling.

Upon receptor stimulation, CARMA1 recruits downstream molecules and triggers oligomerization and ubiquitination cascades. BCL10-dependent MALT1

oligomerization induces activation of the E3 ubiquitin ligase ▶ TRAF6, which in turn activates the IKK complex through lysine (K) 63-linked ubiquitylation of the regulatory subunit of IKK NEMO. BCL10 and MALT1 also undergo K63-linked ubiquitination in the CARD domain and the C-terminal region, respectively, upon T-cell activation, which provide docking surfaces for the recruitment of NEMO. MALT1 itself has an E3-ligase activity and targets MALT and NEMO for ubiquitination. In contrast, ubiquitination also acts for signaling inhibition. CARMA1 is K48-linked-polyubiqutinated after receptor stimulation, leading to degradation of CARMA1 in the proteasome, which is dependent on the phosphorylation by PKCs on PRD. cIAP likely targets this ubiquitination of CARMA1. The E3 Cbl-b promotes mono-ubiquitination of CARMA1, which is involved in the anergy induction in NK T cells. BCL10 undergoes degradation following ubiquitination of CARD after receptor stimulation, which contributes to the termination of signaling. NEDD, cIAP, β-TrCP, and Itch have been suggested as E3 ubiquitin ligases of BCL10. The CNS5 and CNS2 of the COP9 signalosome fine-tune IKK activation by interfering with the polyubiquitination and degradation of BCL10. The deubiquitinating enzyme A20 catalyzes the removal of the K63-linked ubiquitin chains on MALT1 and therefore regulates the duration and strength of signals.

MALT1 and CARMA1 interact with Caspase-8 and thereby regulate the Caspase-8-c-FLIPL-mediated NF-κB activation pathway. Paracaspase activity of MALT1 fine-tunes CBM-signaling by cleaving BCL10 and A20. The BCL10 cleavage is required for TCR-induced cell adhesion to the extracellular matrix protein fibronectin. The cleavage of A20 by MALT1 disrupts the inhibitory effect of A20.

Membrane recruitment of signaling components is a crucial event in CBM-mediated NF-κB activation. BCL10, PKCθ, PKCβ, MALT1, pro-caspase-8, c-FLIPL, and the IKK complex are recruited into lipid rafts after antigen receptor stimulation. CARMA1 resides in both the cytoplasm and lipid rafts in resting cells, but the amount in lipid rafts increases after activation. CARMA1 controls the recruitment of PKCθ, BCL10-MALT1, and IKK complexes to lipid rafts. The adapter protein ▶ ADAP acts as a linker between the TCR-ZAP-70-SLP-76 signaling complex and CBM by binding to CARMA1. PDK1 recruits PKCθ and CARMA1 to lipid rafts upon TCR stimulation.

CBM in Lymphomas

The chromosomal translocations, t(11;18)(q21;q21), t(1;14)(p22;q32) and t(14;18)(q32;q21), have been well characterized in MALTL. MALT1 gene was originally identified in the break point of t(11;18)(q21;q21) (Du 2007). This translocation generates API2-MALT1 fusion products comprising the N-terminus of API2 and the C-terminus of MALT1. The fusion product, but neither API2 nor MALT1 alone, is capable of activating NF-κB. The translocations, t(1;14)(p22;q32) and t(14;18)(q32;q21), bring the BCL10 and MALT1 genes under the regulatory control of the Ig heavy chain (IgH) enhancer, respectively, leading to dysregulated expression of these genes and aberrant NF-κB activation. In addition, BCL10 gene amplification has been reported in pancreatic cancer and nodal diffuse large B-cell lymphoma (DLBCL). Similarly, MALT1 gene amplification was found in cell lines of MZ B-cell lymphoma and DLBCL. While normal B cells express BCL10 in the cytoplasm, MALTL cells bearing t(11;18)(q21;q21) and t(1;14)(p22;q32) express the protein predominantly in the nucleus, indicating a possible relationship between aberrant BCL10 nuclear localization and tumorigenesis.

Among the subtypes of DLBCL, the least curable activated-B-cell-like (ABC) subtype DLBCLs, but not the germinal center B-cell-like (GCB) subtype, rely on constitutive NF-κB signaling for survival (Hara et al. 2010). A loss-of-function RNA interference screen for genes required for survival of ABC DLBCLs revealed that CARMA1 is a key upstream signaling component responsible for the constitutive IKK activation in ABC DLBCLs but not GCB DLBCLs (Ngo et al. 2006). In line with this, oncogenic missense mutations of CARMA1 gene, all within exons encoding the C-C, have been found in ABC DLBCLs (Lenz et al. 2008). These mutations constitutively activate the NF-κB pathway and enhance antigen receptor signaling to NF-κB, possibly owing to aggregate the formation of the mutant proteins. The oncogenic forms of CARMA1 promote proteolytic activity of MALT1. Inhibition of MALT1 activity with the inhibitor z-VRPR-fmk specifically affects the growth and survival of ABC DLBCLs.

The CBM-regulated BAFFR signaling also contributes to the development of B lymphomas. BCL10-transgenic mice elevate BAFF expression

and specifically promote survival of MZ B cells, and some mice develop splenic MZ lymphomas (MZL) (Li et al. 2009). BAFF overexpression, with concomitant nuclear expression of BCL10 and NF-κB activation, is associated with *Helicobacter pylori*-independent growth of gastric DLBCL with histological evidence of MALTL (Kuo et al. 2008).

Summary

NF-κB plays a central role in the activation and survival of lymphocytes. CARMA1 is a CARD-MAGUK family adaptor protein originally found as a binding partner of BCL10 via CARD-CARD interaction. CARMA1 and the MALTL-related proteins BCL10 and MALT1 form so-called CBM complex following receptor stimulation. CBM complex is essential for the canonical NF-κB activation signaling through TCRs, BCRs, and activating NKRs, as well as for the noncanonical NF-κB signaling through BAFF, thereby regulating proliferation, survival, and effector functions of T, B, and NK cells. Multiple regulation mechanisms involving phosphorylation, ubiquitylation, oligomerization, caspase activation, and recruitment to plasma membrane have been proposed to control NF-κB activation signaling through CARMA1. The chromosomal translocations and the amplification of MALT1 and BCL10 genes are associated with the development of MALTL and DLBCL. ABC DLBCLs, but not GCB DLBCLs, rely on constitutive NF-κB activation via CBM-signaling for its survival. Oncogenic missense mutations of CARMA1 gene within the coiled-coil domain, leading to constitutive activation of the NF-κB pathway and enhancing antigen receptor signaling to NF-κB, have been found in ABC DLBCL. The CBM-regulated BAFF signaling also contributes to the development of MALTL, MZL, and DLBCL. Thus, CBM-signaling may be a promising therapeutic target of specific B lymphomas.

Historical Background

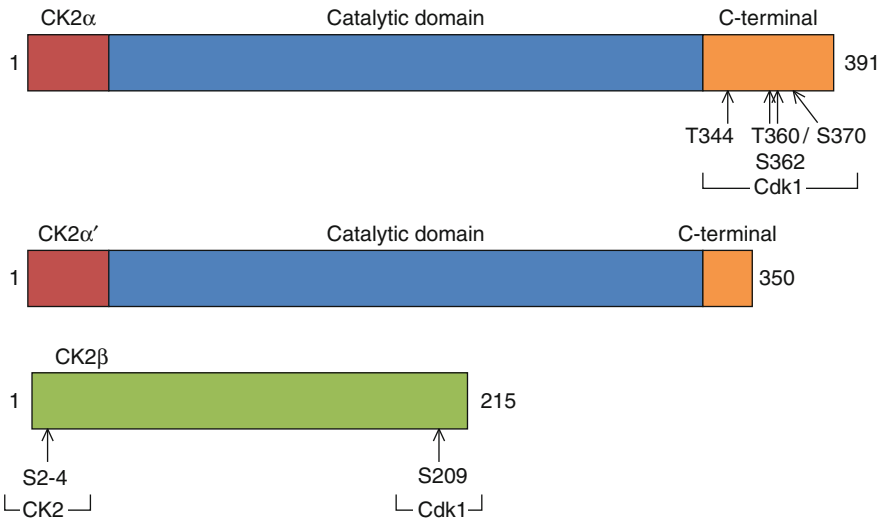
Protein kinase CK2 was isolated almost 60 years ago on the basis of its ability to phosphorylate the milk protein Casein (Allende and Allende 1995). As a result, it was originally designated "Casein kinase II," though this misnomer is less frequently used because of the lack of physiological significance for the phosphorylation of Casein by CK2. Ironically, the enzyme/substrate relationship between CK2 and Casein illustrates somewhat of a recurring theme. In this respect, over 50 years of research on CK2 has resulted in a compilation of a very large number of putative CK2 substrates while the functional analysis of these phosphorylation events has lagged comparatively behind. In large part, the identification of many CK2 substrates has been promoted by its relatively simple and somewhat unique preference for acidic specificity determinants (S/T – X – X- E/D/pS/pY) (Meggio and Pinna 2003). Even before the onset of the large-scale identification of phosphorylation sites, there were more than 300 candidate substrates identified with thousands of potential CK2 substrates now predicted on the basis of global phosphoproteomics and computational analyses (Pinna and Allende 2009). The promiscuity of CK2 in both its number of substrates and the cellular functions in which it has been implicated comes as little surprise when considering its lack of strict regulation (Litchfield 2003; Olsten and Litchfield 2004). Work to date has not yielded a unifying mechanism to explain the regulation of CK2 in cells. In this respect, it has been suggested that CK2 is constitutively active, although there is evidence that there are changes in the phosphorylation of some of its substrates in cells suggesting that its activity could in fact be regulated. Despite the uncertainties about its cellular regulation, evidence for pathogenic misregulation of CK2 in various human malignancies was observed over 20 years ago; CK2 activity and expression are elevated in a number of human cancers, while inhibition of CK2 results in cellular death (Duncan and Litchfield 2008; Trembley et al. 2009). This entry will outline structural and enzymatic features of CK2 and will highlight some of the mechanisms that may contribute to its physiological regulation. Also outlined is an overview of its cellular functions and its emergence as a candidate for molecular-targeted therapy.

Structural and Enzymatic Features of CK2

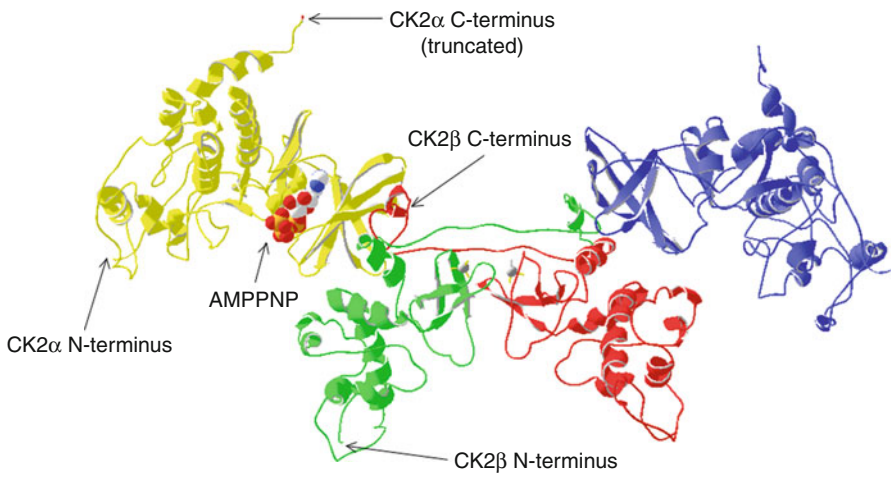
Protein kinase CK2 is ubiquitously expressed in eukaryotes and has generally been considered to be composed of two regulatory CK2β subunits and two catalytic subunits (CK2α and/or CK2α′) (Litchfield 2003). CK2α and CK2α′ are 90% similar within their catalytic domains, but differ substantially in their C-terminal domains (Fig. 1). The close similarity of CK2α′ and CK2α results in an inability to distinguish them on the basis of their catalytic properties as they appear to share the same enzymatic features. For example, the substrate specificity of CK2α and CK2α′ appears to be indistinguishable, with both proteins exhibiting a minimal consensus motif of S/T – X – X – D/E/pS/pY. The regulatory CK2β subunit is a 25 kDa protein in humans that displays little sequence homology with any other protein, but with exceptional conservation between species. While CK2 was traditionally considered to be a tetrameric enzyme, there are indications that its catalytic and regulatory subunits may also exist in cells independent of tetrameric complexes (reviewed in Olsten and Litchfield 2004; Bibby and Litchfield 2005). Although some of the enzymatic characteristics of tetrameric CK2 can be distinguished from that of the free catalytic subunits, a striking feature of CK2 is that both of these forms of CK2 are catalytically competent. In this respect, CK2 is distinct from Cyclin-dependent kinases where catalytic activity is strictly dependent on the presence of an activating Cyclin or from second messenger-dependent kinases such as PKA or PKC where catalytic activity is suppressed by an auto-inhibitory subunit or domain.

Although CK2β is not strictly required to turn on or turn off the catalytic activity of CK2α or CK2α′, it is apparent that it can affect the activity of the catalytic subunits and modulate substrate selectivity (Meggio and Pinna 2003; Olsten and Litchfield 2004; Bibby and Litchfield 2005). While the majority of CK2 substrates can be effectively phosphorylated by either tetrameric CK2 or free catalytic CK2 subunits, the regulatory CK2β subunit generally enhances thermal stability of the catalytic subunits and confers a modest increase (typically 3–5 fold) in catalytic activity toward most substrates. By comparison, there are other proteins such as eIF2β, where CK2β is required to enable efficient phosphorylation, or Calmodulin, where the presence of CK2β leads to complete inhibition of phosphorylation. The demonstration that Calmodulin is phosphorylated at its CK2 sites in cells was amongst the first evidence provided to suggest that free catalytic subunits exist, and are functionally active, in cells. In a similar vein, CK2 independent functions and regulatory mechanisms of CK2β have been explored (reviewed by Bibby and Litchfield 2005). In this respect, it is interesting to note that CK2β is synthesized in excess of the catalytic subunits. Though it is believed that CK2β is quickly degraded when it is not incorporated into tetrameric CK2 complexes, a number of reports highlight potential CK2-independent interactions of CK2β including interactions with a number of other protein kinases (e.g., c-Mos, Chk1, and A-Raf). Collectively, these findings illustrate not only the ability of CK2β to control the substrate specificity of CK2, but also raise the specter that individual CK2 subunits exist outside the holoenzyme and are governed by unique modes of regulation. At this point however, the precise mechanisms that drive tetramer formation and dissociation in cells remain unclear.

Structural studies have yielded many insights into the unique features of protein kinase CK2 (Niefind et al. 2009). First, its constitutive activity is apparent in virtually all of its more than 30 solved structures. In many instances, protein kinases contain an activation loop that can exist in either an open or closed confirmation that governs kinase activity. In the case of MAPKs, for example, phosphorylation of this loop by upstream protein kinases results in the open confirmation, thus activating the MAPK and promoting downstream phosphorylation of pathway constituents. By comparison, structures of CK2 provide evidence for its permanently open conformation and constitutive activation. Second, the structure of the CK2 holoenzyme, consisting of both catalytic and regulatory subunits, revealed the tetrameric configuration of CK2 (Fig. 2). CK2β dimerizes to form the core of the tetramer, and individual catalytic subunits bind to the regulatory subunit dimer. Interestingly, the interaction surface between CK2β and the catalytic subunits is considered strikingly small given the extremely tight interactions that have been measured between the two subunits. Lastly, structures of CK2 in complex with purine analogues revealed unique features of its ATP binding domain in relation to the ATP binding domain of other protein kinases. In CK2, the



Casein Kinase II, Fig. 1 Schematic representation of CK2 subunits. Linear representation of the catalytic isoforms CK2α and CK2α′ and the regulatory subunit CK2β. In vivo phosphorylation sites are indicated, including the four mitotic phosphorylation sites on the extended C-terminal of CK2α. Also noted are the mitotic and autophosphorylation sites located on CK2β



Casein Kinase II, Fig. 2 Crystal structure of tetrameric CK2. Catalytic subunits are shown in *blue* and *yellow* and regulatory subunits are shown in *green* and *red*. Also indicated is a non-hydrolyzable ATP analog, AMPPNP, in the active site of one of the catalytic subunits. Note that the C-terminal tail of CK2α is truncated in this structure (missing amino acids 337–391). The structure of the C-terminus is unknown. This representation of the CK2 tetramer was generated using Swiss PDB Viewer; PDB File 1JWH (Niefind et al. 2001)

ATP binding domain is collapsed and relatively thin in one plane, while being wider in the second plane. The widening allows for utilization of GTP as a phosphate donor, a relatively unique characteristic amongst protein kinases, while the thinning in the other plane provides the opportunity for the rational design of specific, small molecule ATP competitive inhibitors that exploit van der Waals interactions in CK2. A more detailed discussion of strategies for the development of CK2 inhibitors will be presented later.

Physiological Regulation of CK2

As mentioned previously, the activity of CK2 in cells is not subject to absolute "on/off" regulation by individual events such as posttranslational modifications, protein/protein interactions, or small molecule secondary messengers that are observed with other major protein kinase families such as MAPKs, CDKs, and PKCs, respectively. Rather, on the basis of structural characteristics (discussed above), the ability to isolate active, recombinant enzyme from bacterial sources and, most

importantly, the observation that activity is neither turned on nor turned off in response to a variety cellular stimuli that modulate a large number of other protein kinases, CK2 is considered to be constitutively active. While it is apparent that CK2 lacks strict on-off regulation, it is conceivable that a number of more subtle mechanisms may contribute to its regulation in cells, including protein interactions and temporal or stimulus specific changes in function that are discussed below.

The observation that CK2 phosphorylates proteins in multiple cellular compartments supports the hypothesis that interacting proteins regulate CK2 function by directing it to specific locations within the cell (Olsten and Litchfield 2004; Filhol and Cochet 2009). In this way, specific subpopulations of CK2 could be regulated by interacting proteins that permit spatial access to substrates, much the same way that AKAPs modulate the localization and function of PKA. One protein that may regulate CK2 in this manner is ▶ CKIP-1, a PH-domain containing protein that localizes CK2α, but not CK2α′, to the plasma membrane (Canton and Litchfield 2006). Changes in the expression of CKIP-1 induce alterations in cell morphology and the actin cytoskeleton. Since CKIP-1 interacts with CPα, a subunit of the heterodimeric actin capping protein that can be phosphorylated by CK2, these observations are consistent with a working model suggesting that CKIP-1 could participate in the regulation of the actin cytoskeleton by modulating the CK2 catalyzed phosphorylation of CPα. In addition to CKIP-1, CK2 has a large number of other potential interaction partners. Again, given the large number of CK2 substrates that are located in numerous cellular locations, further elucidation of its interaction partners and investigation of their spatial distribution could reveal important new insights into the regulation and physiological functions of CK2.

Though not necessarily responsible for global changes in CK2 activity, it has been demonstrated that discrete populations of CK2 are modulated in response to specific stimuli (Filhol and Cochet 2009). For example, in response to UV radiation, CK2 interacts with the FACT complex, which consists of SSRP1 and hSPT16. Binding of CK2 to the FACT complex results in increased phosphorylation of ▶ p53 by CK2 at Ser 392, an event believed to increase the transcription of apoptotic and cell cycle regulatory genes. Likewise, the regulation of specific CK2 protein interactors and substrates has been observed in nocodazole-arrested cells where CK2α has been shown to be phosphorylated at four proline-directed phosphorylation sites that can be phosphorylated by CDK1 in vitro (Fig. 1) (St-Denis and Litchfield 2009). Phosphorylation of these sites within its unique C-terminal domain promotes interactions between CK2α and the peptidyl-prolyl isomerase ▶ Pin1. Interactions with Pin1 modulate the ability of CK2 to phosphorylate Topoisomerase IIα in vitro at sites that are known to be phosphorylated in mitotic cells. Collectively, the examples of FACT and Pin1 illustrate mechanisms by which the ability of CK2 to phosphorylate specific proteins can be modulated by interactions with other cellular proteins. Given the large number of protein interactions that have been reported for CK2, it is likely that other proteins will exert similar effects to modulate discrete populations of CK2 in cells.

The isoform-specific interactions of proteins such as CKIP-1 and Pin1 also reveal independent forms of regulation for CK2α as compared to CK2α′, an observation consistent with the demonstration of distinct phenotypes for CK2α and CK2α′ knockout mice (Dominguez et al. 2009). CK2α′ knockout mice are viable but exhibit defects in spermatogenesis in males which results in infertility. By comparison, CK2α knockout mice are embryonic lethal with embryos exhibiting significant defects in heart development. Taken together, these contrasting phenotypes suggest unique functions for both catalytic subunits, though CK2α appears more able to compensate for a loss of CK2α′. Furthermore, it is conceivable that unique regulatory mechanisms of CK2α are responsible for its greater importance to murine viability.

Though some progress has been made regarding the regulation of CK2 via posttranslational modifications and protein/protein interactions, relatively little is known about the transcriptional regulation of CK2. As previously noted, the expression of CK2 is elevated in rapidly dividing cells and a number of human cancers. The precise mechanism by which the expression of CK2 isoforms, apparent housekeeping genes, are upregulated in cancers has not been thoroughly characterized, though a number of putative binding sites for various transcription factors have been identified (Pyerin and Ackermann 2003). For example, it is intriguing that all of the human CK2 genes contain response elements for the Ets1 transcription factor that is regulated by mitogen-activated pathways.

Other factors that may contribute to the regulation of CK2 levels include ubiquitination and degradation by the proteasome (Zhang et al. 2002).

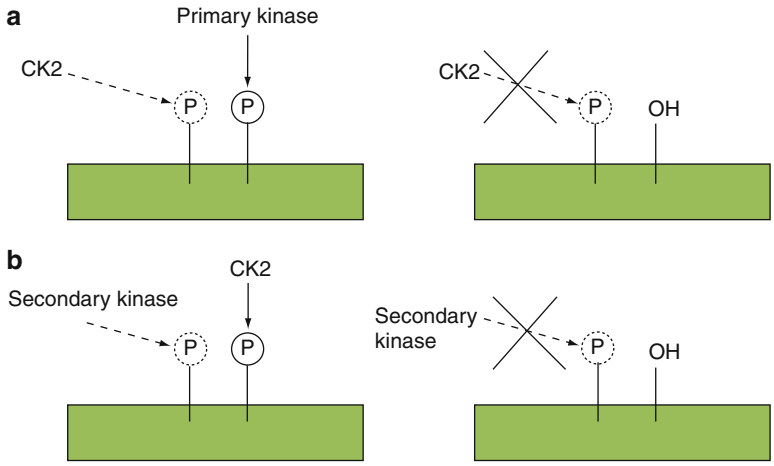
Cellular Functions of CK2

In consideration of its large number of documented substrates (and the ever-expanding list of prospective substrates that are appearing in rapidly populating phosphoproteomic databases), it is not surprising that CK2 has been implicated in a broad range of cellular processes including cell proliferation and survival, apoptosis, circadian rhythms, viral infection, and transcriptional control (Duncan and Litchfield 2008; St-Denis and Litchfield 2009; Mizoguchi et al. 2006). Of particular interest to human disease are the observations that CK2 is over-expressed in a number of human cancers, including kidney, mammary gland, lung, head and neck and prostate, and that targeted over-expression of CK2 in mice T-cells and mammary glands results in lymphoma and mammary adenocarcinomas (Duncan and Litchfield 2008). Furthermore, synergistic effects in tumor formation are observed in mice when over-expressing CK2 in concert with the ▶ Myc or Tal-1 oncogenes or in p53 (−/−) backgrounds (Xu et al. 1999). Conversely, short hairpin RNA (shRNA) knockdown and pharmacological inhibition studies in a variety of model systems results in cell death, reinforcing the notion that targeted inhibition of CK2 represents a promising therapeutic strategy for the treatment of human cancers (Trembley et al. 2009; Ruzzene and Pinna 2010). Though it is clear that global changes in CK2 activity regulate processes pertaining to cellular proliferation and survival, the precise molecular mechanisms by which CK2 exerts these functions are still incompletely understood. In the following discussion, some of the recent advances made in dissecting the specific role of CK2 in these cellular processes will be highlighted.

CK2 has been implicated in many signaling pathways directly involved in controlling the rate of cellular proliferation (Duncan and Litchfield 2008). As noted above, coordinated overexpression of CK2 and Myc in murine T-cells results in lymphoma development. Supporting the pathogenic synergism between CK2 and Myc is the observation that CK2 phosphorylates Myc and prevents its proteasome-dependent degradation, allowing increased transcriptional activity of proliferative and survival genes. Similarly, CK2 is believed to function at many levels within the Wnt signaling pathway, ultimately promoting ▶ Beta-Catenin stability, dissociation from APC, and the transcription of pro-survival and proliferative genes.

In a related vein, evidence for the direct involvement of CK2 in the control of cell cycle progression is continually mounting (St-Denis and Litchfield 2009). Knockout studies in genetically tractable organisms such as yeast highlight a requirement for CK2 in G1/S and G2/M transitions. Similarly, knockdown and pharmacological inhibition of CK2 in mammalian cells results in attenuation of cell cycle progression. A specific role for CK2 in mitosis has also been revealed in mammalian cells, where disruption of mitotic phosphorylation of CK2α leads to multiple mitotic defects, including chromosome missegregation and induction of mitotic catastrophe, a form of cell death. CK2 substrates involved in mitotic progression have also been identified, including the aforementioned Topoisomerase IIα, whose phosphorylation is regulated by mitosis-specific interaction of Pin1 with CK2α, and the cell cycle regulatory protein kinase Wee1. The phosphorylation of Wee1 reveals the intricate relationships between protein kinases since prior phosphorylation of Wee1 by CDK1 generates a consensus phosphorylation motif for CK2, which leads to the degradation of Wee1 and entry into mitosis. Wee1 is a prime example of the participation of CK2 in hierarchical phosphorylation (Fig. 3a). Given its preference for acidic determinants, including phosphoserine and phosphotyrosine, there will undoubtedly be other substrates that are phosphorylated by CK2 only after prior phosphorylation by other protein kinases. It is also noteworthy that CK2 can participate in hierarchical phosphorylation by enabling subsequent phosphorylation by another protein kinase (Fig. 3b). For example, the CK2-catalyzed phosphorylation of glycogen synthase is a prerequisite for its subsequent phosphorylation by ▶ GSK-3. Overall, the participation of CK2 in hierarchical phosphorylation, both as a primary and as a secondary protein kinase, reveals its capacity to participate in complex regulatory events with other protein kinases.

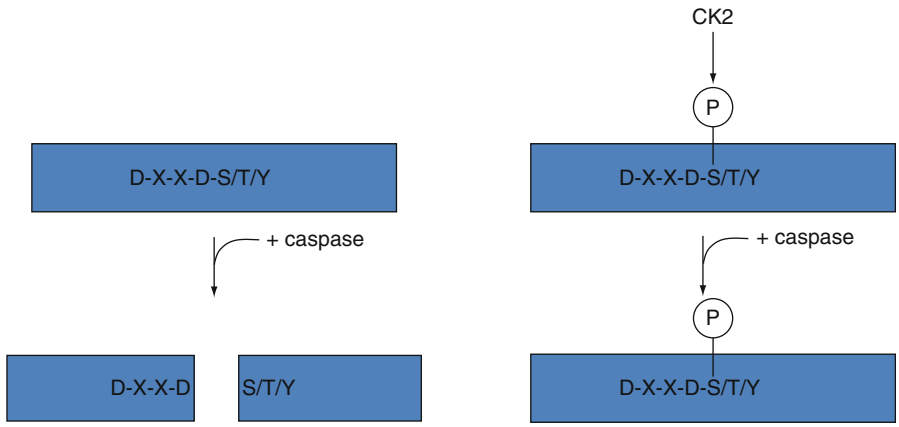
The observation that shRNA-mediated knockdown and pharmacological inhibition of CK2 results in cell death has accelerated the identification of CK2 functions within apoptotic pathways (Duncan and Litchfield 2008). One provocative example involves



Casein Kinase II, Fig. 3 Hierarchical phosphorylation events involving CK2. (**a**) A hypothetical example of CK2 acting as a secondary kinase in a hierarchical phosphorylation event whereby previous phosphorylation of a protein renders it a substrate of CK2. One example of this hierarchal phosphorylation, as discussed in the text, is observed when CDK1 primes Wee1 for phosphorylation by CK2. (**b**) A depiction of CK2 phosphorylating and priming a protein for subsequent phosphorylation by a secondary kinase is shown. This form of regulation is observed, for example, on glycogen synthase, where phosphorylation by CK2 creates a phosphorylation site for GSK-3

the CK2-dependent regulation of PML – a tumor suppressor protein responsible for the formation of PML bodies in the nucleus, which acts to promote senescence and apoptosis (Scaglioni et al. 2006). Interestingly, phosphorylation of PML by CK2 results in its proteasome-mediated degradation. Moreover, CK2 activity and PML protein levels are inversely correlated in non-small cell lung cancers. The fact that PML overexpression induces senescence and apoptosis underscores the potential importance of CK2 in PML regulation and, ultimately, cell survival. A role for the direct regulation of apoptotic machinery by CK2 has also recently been observed (reviewed in Duncan et al. 2010). Bid, a member of the Bcl-2 family of apoptotic signaling molecules, functions to permeabilize the mitochondrial membrane upon cleavage by Caspase-8 and, therefore, promote the activation of downstream caspases. However, phosphorylation of Bid at CK2 phosphorylation sites proximal to the caspase-8 cleavage site blocks processing, mitochondrial permeabilization, and the progression of apoptosis. Notably, the strict requirement for acidic residues in both the caspase recognition site and the CK2 minimal consensus motif may illustrate a more widespread apoptotic regulatory mechanism for CK2 than is currently appreciated (Fig. 4). Along these lines, other substrates with overlapping CK2 and caspase regulation motifs have been identified (including Connexin 45.6, murine Caspase-9, Max, HS-1, ▶ PTEN, and Presenilin-2). In all of these instances, phosphorylation by CK2 confers protection from caspase cleavage. These observations may provide at least a partial explanation for the enhanced survival that is observed in cancer cells with elevated levels of CK2. In this respect, given its constitutive activity, elevated levels of CK2 could result in increased phosphorylation of caspase substrates to attenuate caspase-mediated death pathways.

It is important to reiterate the vast repertoire of cellular functions involving CK2 and the diversity of its substrates. Even before the inception of predictive analyses that probe phospho-proteomic databases for putative CK2 substrates, CK2 was believed to have over 300 substrates, including over 60 transcription factors, 80 signaling molecules, and 40 viral proteins (Meggio and Pinna 2003). However, as a result of the constitutive activity of CK2 and its relatively simple consensus motif determinants, some analyses of phospho-proteomic databases have predicted the number of CK2 substrates to number in the thousands (Pinna and Allende 2009). While the systematic identification of all CK2 substrates remains a daunting task, a more complete evaluation of substrates will undoubtedly uncouple the pathogenic and physiological functions of CK2. Along these lines, an important avenue of future research will involve validating putative substrates. One appealing approach will



Casein Kinase II,
Fig. 4 Modulation of caspase cleavage by phosphorylation. Shown here is an example where phosphorylation within a caspase degradation motif renders a substrate refractory to caspase cleavage

certainly employ bioinformatic consensus motif analyses of phosphoproteomic databases to identify likely physiological targets of CK2, followed by in vitro phosphorylation assays that test the ability of CK2 to directly phosphorylate these sites (Turowec et al. 2010). In this sense, demonstration of direct phosphorylation of putative substrates by CK2 as well as the existence of these phosphorylation sites in cells should be adopted as the gold standard for classifying substrates as bona fide. Furthermore, sorting of biologically relevant CK2 substrates by GO designations will not only act to further clarify the physiological function of CK2, but may streamline the identification of substrates with pathological significance. Likewise, the demonstration that CK2 can participate in complex hierarchical regulatory mechanisms, such as protection of caspase substrates from degradation or acting as a primary or secondary kinase in hierarchical protein phosphorylation, may also be exploited by bioinformatics and/or high-throughput analyses that attempt to expand upon the role of CK2 in signaling pathways pertaining to cellular proliferation (Figs. 3 and 4) (St-Denis and Litchfield 2009; Duncan et al. 2010).

Emergence of CK2 as a Candidate for Molecular-Targeted Therapy

The overexpression of CK2 in a number of human malignancies and its participation in multiple pro-survival signaling pathways has driven the development of pharmacological inhibitors of CK2 for use as candidate lead compounds for molecular-targeted therapy (Sarno and Pinna 2008). Rational development of specific ATP competitive inhibitors using structural information, as well as virtual screening of chemical libraries has led to the identification of a number of CK2 inhibitors with inhibitory constants (Ki) in the micromolar range (Sarno et al. 2005). Preclinical studies of a number of these inhibitors, including DRB, Emodin, TBB, TBBz, DMAT, IQA, and TBCA, resulted in the induction of apoptosis in a number of cancer cells (Duncan and Litchfield 2008; Ruzzene and Pinna 2010). Despite these advances, the challenge of developing ATP competitive specific protein kinase inhibitors is exacerbated by the high degree of conservation exhibited amongst all human protein kinases, and to a lesser extent even other ATP binding proteins (Prudent and Cochet 2009; Prudent et al. 2010). Indeed, off-target effects of CK2 inhibitors are apparent and remain relatively uncharacterized.

To address concerns of off-target effects that result from ATP binding domain conservation, the development of CK2 inhibitors that bind at allosteric sites has recently been pursued (Prudent and Cochet 2009; Prudent et al. 2010). Using high-throughput screening of chemical libraries, polyoxometalates have been identified as a class of compounds that bind outside of both the ATP binding domain and the CK2α/β interface, and may function by docking in the vicinity of the activation loop and locking it in the closed confirmation. Another intriguing mode of modulating CK2 function is to regulate tetramer formation by blocking the ability of CK2β to bind the catalytic subunits. Preventing holoenzyme formation is predicted to decrease the cellular half-life of CK2 due to the relative instability of

individual subunits. Furthermore, it should also reduce catalytic activity by three- to fivefold, as CK2β has a generally stimulatory effect toward catalytic activity, but may also stimulate phosphorylation of substrates that are negatively regulated by CK2β. While the physiological consequences of inhibiting tetramer formation remain unknown, the prospect that it could function to block CK2 functions related to cellular proliferation and apoptosis remain plausible.

One limiting aspect pertaining to the characterization of CK2 inhibitors as being effective cellular pharmacological agents is the lack of bona fide biomarkers. As noted earlier, the preclinical utility of CK2 inhibitors to date has generally been measured by gross phenotypic changes, such as apoptosis, as opposed to a decrease in phosphorylation of a particular biomarker (Ruzzene and Pinna 2010). By developing tools that directly monitor the phosphorylation status of specific cellular substrates, the distinction between off-target effects and specific CK2 inhibition would be more easily clarified as biomarker status could be correlated to gross phenotypic changes. Furthermore, the use of phosphospecific antibodies, for example, as markers for CK2 activity would also be useful in identifying pathological samples that exhibit hyperactive CK2 activity and thus, are most likely to respond to treatment with CK2 inhibitors.

Summary

Since its discovery in 1954, much has been learned regarding the enzymatic characteristics, physiological regulation, and cellular functions of protein kinase CK2. Structural studies have yielded many insights into the unique features of CK2, such as its constitutive activity and ability to use GTP as a phosphate donor. While CK2 appears to be constitutively active, it is likely that a number of distinct mechanisms such as spatial regulation through protein interactions and possibly the regulated assembly or disassembly of tetrameric CK2 will govern how the phosphorylation of many of its substrates is controlled in cells. However, on the whole, many details regarding the precise manner by which CK2 is regulated in cells remain to be defined. Though the expanding list of CK2 substrates has illuminated many cellular functions, including roles pertaining to cell survival, proliferation, and involvement in diseases such as cancer, it is clear that CK2 has many undefined substrates whose phosphorylation status dictates unknown roles. In this sense, future endeavors should involve the use of phosphoproteomic databases, which contain a tremendous resource of physiological protein phosphorylation sites, to guide the identification of bona fide CK2 substrates. In expanding our knowledge of CK2 substrates, it is more likely that the physiological and pathogenic functions of CK2 will be uncoupled and that the generation of convenient biomarkers capable of monitoring CK2 activity in cells will be established. Tools such as these will greatly accelerate the development and benchmarking of current and future generations of inhibitors, which in turn will feedback and drive the discovery of CK2 functions and benefit the treatment of cancers where CK2 hyperactivity may be an oncogenic driver.

Caspase Family

Dave Boucher and Jean-Bernard Denault
Department of pharmacology, Université de Sherbrooke, Sherbrooke, QC, Canada

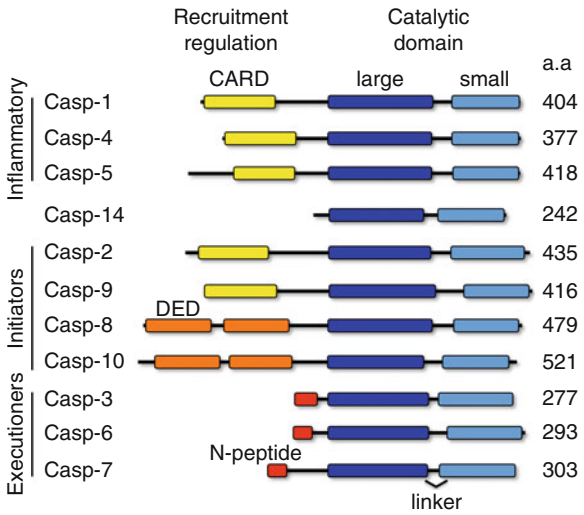
Historical Background

The importance of proteases in cell signaling is well established. This chapter presents the protease family of caspases, which performs limited proteolysis on a wide range of substrates, with molecular consequences ranging from inactivation to gain-of-function to accelerated degradation. It is important to emphasize that caspases are signaling proteases and not degrading enzymes, akin to lysosomal cathepsins or digestive enzymes. The first family member, caspase 1, was identified in 1989 (Black et al. 1989). Caspases are principally implicated in inflammation and apoptosis.

The term "programmed cell death" (PCD) was coined in 1964 by Lockshin and coworkers and originally designated the breakdown of tissues during development, especially in insects. Later, in 1972, Ker and colleagues described apoptosis for the first time. However, both concepts (PCD and apoptosis) are now considered synonymous. The first genetic evidence of "programming" in apoptosis came with works by H. Robert Horvitz's group in 1986. They reported the identification of genes required for the execution of cell death in the roundworm *Caenorhabditis elegans*. Finally, it took the work of Black and coworkers, who identified the mammalian cysteine protease caspase 1 as responsible for the maturation of pro-IL (interleukin)-1β, to realize that one of the genes found by Horvitz's group, *CED-3* (*C. elegans* cell death), encoded a cysteine protease homologous to caspase 1. These groundbreaking works paved the way for the identification of caspases responsible for apoptosis in mammals and other family members with roles in inflammation and keratinization of epithelia.

Caspases

Caspase stands for *c*ysteine *asp*artyl-specific prote*ase*. They are members of clan CD peptidases, i.e., with



Caspase Family, Fig. 1 *Schematic representation of the human caspase family*. Human caspases are grouped according to their main in vivo role: cytokine activators (inflammatory), initiator, and executioner apoptotic caspases. The five known domains of caspases are color coded: CARD (*yellow*) and DED (*orange*) are involved in recruitment, regulation, and activation; the N-peptide of executioner caspases (*red*) that is removed during apoptosis; the large subunit (*blue*), and small subunit (*light blue*) forming the catalytic domain are separated by a linker of variable length. Caspases are drawn to scale and the number of amino acids of the longest known isoform of each protein is shown on the right

a cysteine nucleophile and catalytic residue in the order His-Cys in the protein sequence. They form the C14 family of cytosolic cysteine peptidases, which is defined by strict specificity for the hydrolysis of aspartyl bonds. Their structure is highly conserved and composed of two domains: the N-terminal domain and the catalytic domain (Fig. 1). The catalytic domain, or unit, is defined as having one large and one small subunit separated by a flexible interdomain connector of variable lengths (hereafter referred to as the linker). This segment is sensitive to proteolysis and is always cleaved during activation. Cleavage of the catalytic domain gives rise to fragments often referred to as p20/p10. The catalytic unit is structured by 6 β-strands and 5 α-helices assembled in an open α/β barrel fold (Fig. 2a). The large subunit contains the catalytic dyad His-Cys that controls the hydrolysis of the peptide bond. The small subunit possesses most residues that form the substrate binding pocket, including a critical arginine, a residue involved in aspartate recognition by the substrate binding pocket. Based on the available literature, catalysis follows the same steps as serine and other cysteine peptidases. Fuentes-Prior and Salvesen have described in great depth the topology of the substrate binding site and catalytic cycle of caspases (Fuentes-Prior and Salvesen 2004a). Due to space limitations, we will not discuss it further. Importantly, active caspases are obligate dimers, and this feature is at the root of the activation mechanism.

Caspases are classified in three main categories based on their functions (Fig. 1): apoptotic caspases (caspases 2, 3, 6, 7, 8, 9, and 10), inflammatory caspases (caspases 1, 4, and 5), and caspase 14 which is involved in epithelial differentiation. However, accumulating evidence has clearly demonstrated roles of some caspases outside their traditional realm (Yi and Yuan 2009).

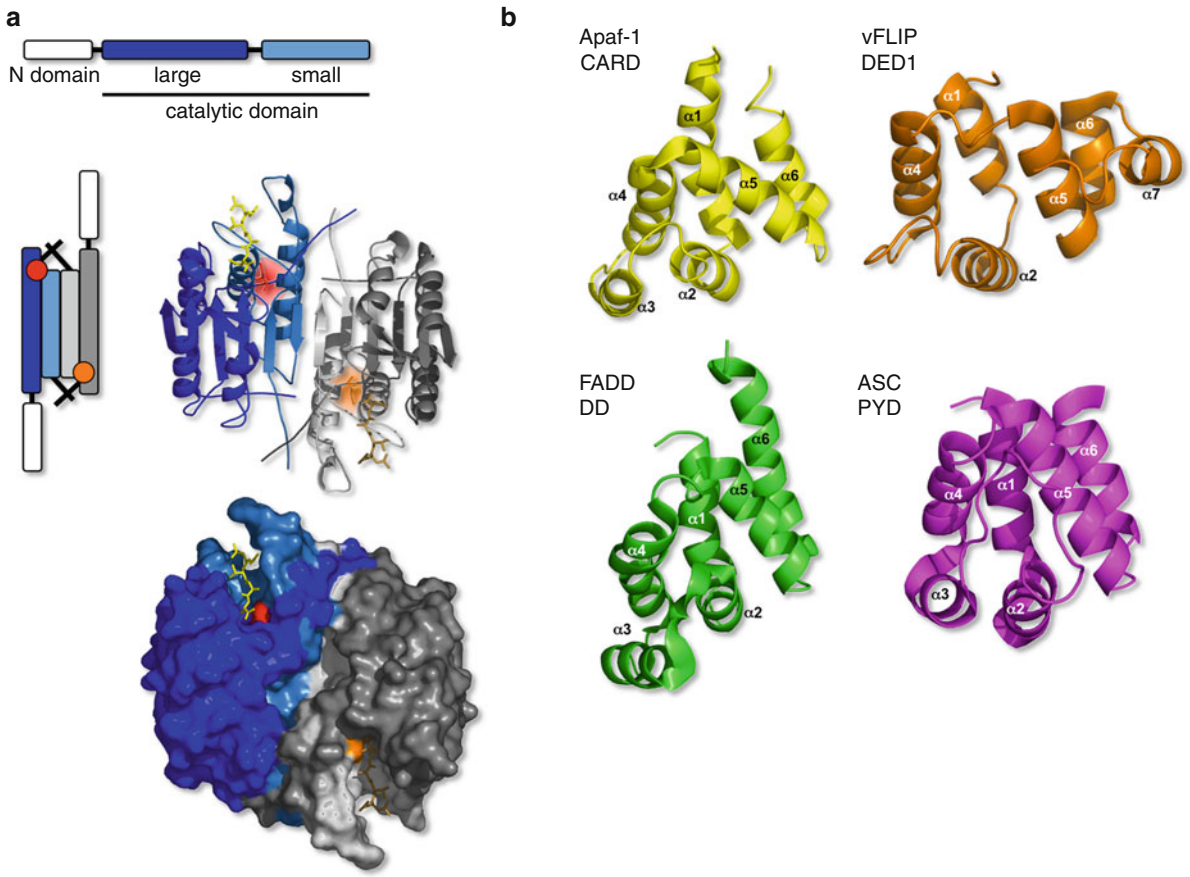
Inflammatory Caspases

In humans, three inflammatory caspases (caspases 1, 4, and 5) coexist, caspase 1 being the prototypical member of this group. The similar domain organization and the fact that their genes are all located on chromosome 11 suggest a rather recent evolution. These caspases are expressed in most, if not all, tissues, but mRNA levels are higher in inflammatory cells, such as monocytes (Martinon and Tschopp 2007).

Inflammasomes

In healthy cells, inflammatory caspases rest as cytosolic monomeric inactive enzymes. It is through recruitment by their N-terminal CARD (caspase-recruitment domain) to multimeric platforms named inflammasomes that they gain activity. Similar to other homotypic interaction domains, DD (death domain) and DED (death effector domain), CARD is a member of the death domain superfamily, and all of its members share a similar fold (Fig. 2b) (Park et al. 2007). The function of an inflammasome is to bring enough caspase molecules in close proximity to provoke their dimerization and activation [the so-called induced-proximity model (Salvesen and Dixit 1999)]. Subsequently, cleavage of the linker occurs, which further stabilizes the dimer.

Inflammasomes are multimeric complexes composed of several different proteins (Schroder and Tschopp 2010). At their core, they contain a NLR (NOD [nucleotide-binding oligomerization domain]-like receptor): a NOD protein, a (NOD)-like



Caspase Family, Fig. 2 *Caspase domain structures.* (**a**) General structure of caspases. Caspase structure is highly conserved and composed of two domains: the N-terminal domain and the catalytic domain. The catalytic domain (*red*/*orange*), or unit, is defined as having one large (*blue*/*gray*) and one small subunit (*light blue*/*gray*) separated by a flexible linker of variable lengths. This segment is sensitive to proteolysis and is always cleaved during activation. Cleavage of the catalytic domain gives rise to fragments often referred to as p20/p10. The catalytic unit is structured by six β-strands and five α-helices assembled in an open α/β barrel fold. The large subunit contains the catalytic dyad His-Cys that controls the hydrolysis of the peptide bond. The cleaved linker interacts with the other end of the other catalytic unit and stabilizes the active site. Active caspase 3: PDB 1CP3. (**b**) CARD, DED, DD, and PYD share similar fold of the death domain family. *CARD* caspase-recruitment domain, *DED* death effector domain, *DD* death domain, *PYD* pyrin domain are members of the DD superfamily, all members share a globular helicoidal structure made of six antiparallel α-helices. Homophylic interactions between each domain are dictated by specific residues. Apaf-1 CARD: PDB 1C15; vFLIP DED1: PDB 2F1S; FADD DD: PDB 1E3Y; ASC PYD: PDB 1UCP

receptor protein (NLRP) family member or an Ipaf (ICE [IL-1β converting enzyme]-protease activating factor) protein. The complex also includes ASC (apoptosis-associated speck-like protein containing a CARD) and caspase 1 (Bryant and Fitzgerald 2009). Caspase 5, but not caspase 4, has also been reported as part of inflammasomes (Martinon et al. 2002). In humans, 22 NLRs have been identified; thus, at least as many different inflammasomes may exist (Schroder and Tschopp 2010). With the exception of NLRP10, all NLRs are composed of an LRR (leucine rich-repeat), a central NOD, and one to three variable homotypic protein-protein interaction domains involved in protein recruitment. LRRs recognize a wide range of pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (LPS), muramyl dipeptide, lethal toxin, crystalline factors, and endogenous damaged-associated patterns (DAMPs). By a mechanism that is still poorly understood, a specific LRR recognizes a particular PAMP or DAMP, a macromolecular platform assembled via the NOD, and ASC is recruited. Subsequently, caspase 1

monomers join the complex and dimerize (Bryant and Fitzgerald 2009). Despite little information, the current view is that the many NLRs exist to detect various bacterial, viral, or other chemical entities, and most, if not all, lead to caspase 1 activation. To add to the complexity of multiple NLRs, several decoy CARD-only proteins (COPs) have been described that can compete with caspases at the activation platforms (Stehlik and Dorfleutner 2007).

Like caspase 1, caspase 4 activation requires its dimerization and cleavage of its linker domain. By analogy, caspase 5 activation likely resembles that of caspases 1 and 4, but further studies are needed to clarify this point.

Inflammatory Caspases Functions

Active caspase 1 cleaves cytosolic cytokine precursors to their mature form. Based on small peptidic substrate libraries, caspase 1 prefers (W/Y)XXD↓ motifs (Thornberry et al. 1997) with a small residue in P1', a motif that is found in caspases 1, 4, and 5 and in pro-IL-1β. Pro-IL-1β and pro-IL-18 are the only caspase 1 inflammatory mediators identified to date. Recent proteomic data suggest that caspase 1 is responsible for the bulk of cleavage events versus other inflammatory caspases (Agard et al. 2010). Caspase 4 cleaves caspase 3, IL-1β, and IL-1F7B (Luthi and Martin 2007). The transcription factor Max is a substrate of caspase 5, and cleavage occurs at an unconventional glutamate residue instead of aspartate (Luthi and Martin 2007).

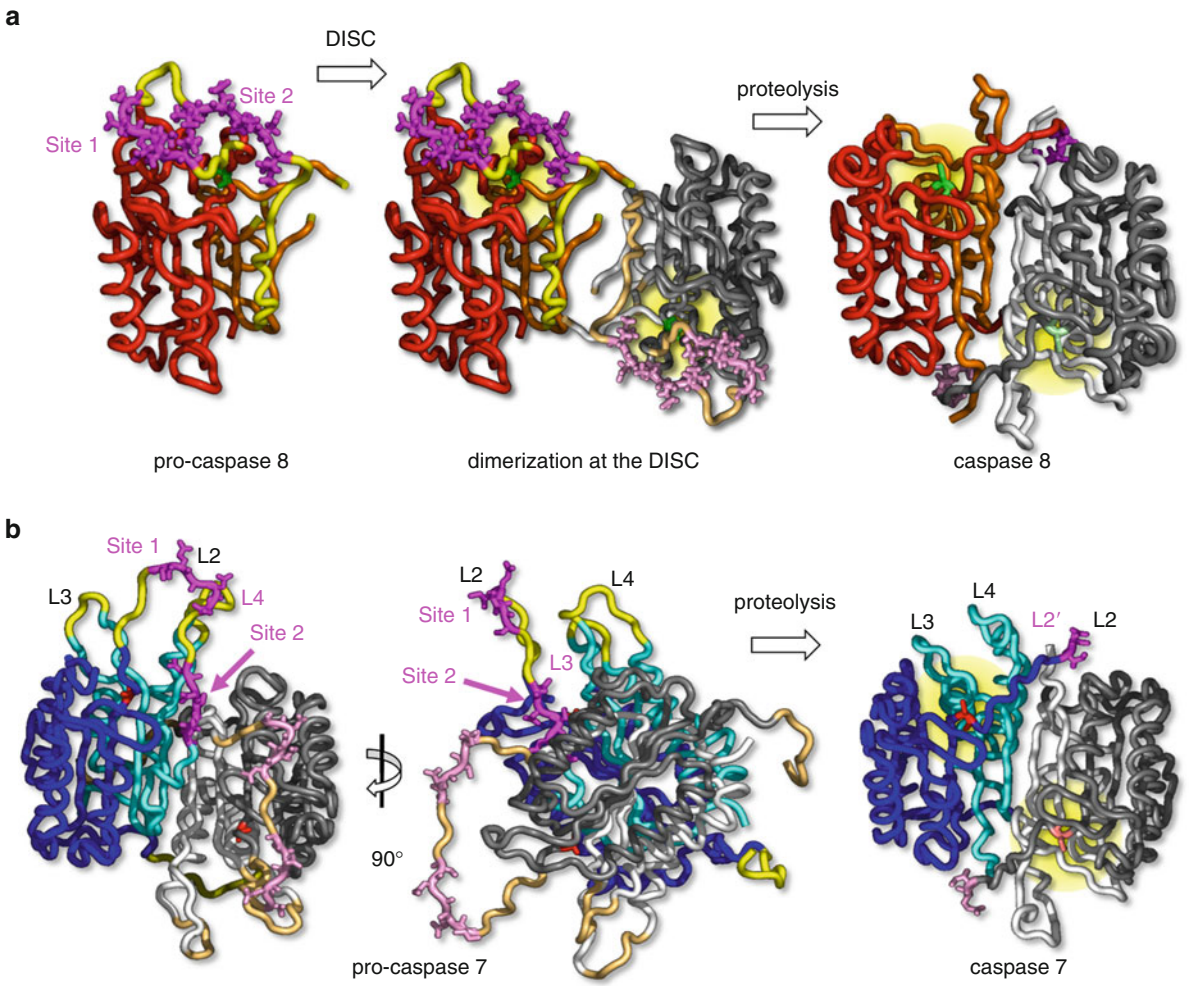
Other substrates of caspase 1 include caspase 7 and PARP (poly[ADP-ribose] polymerase), which are cleaved during pyroptosis (Lamkanfi 2011). This process is a peculiar form of cell death related to inflammation and macrophage death, thus providing a link between inflammation and part of the apoptotic machinery (Lamkanfi 2011).

Apoptotic Caspases: The Initiators

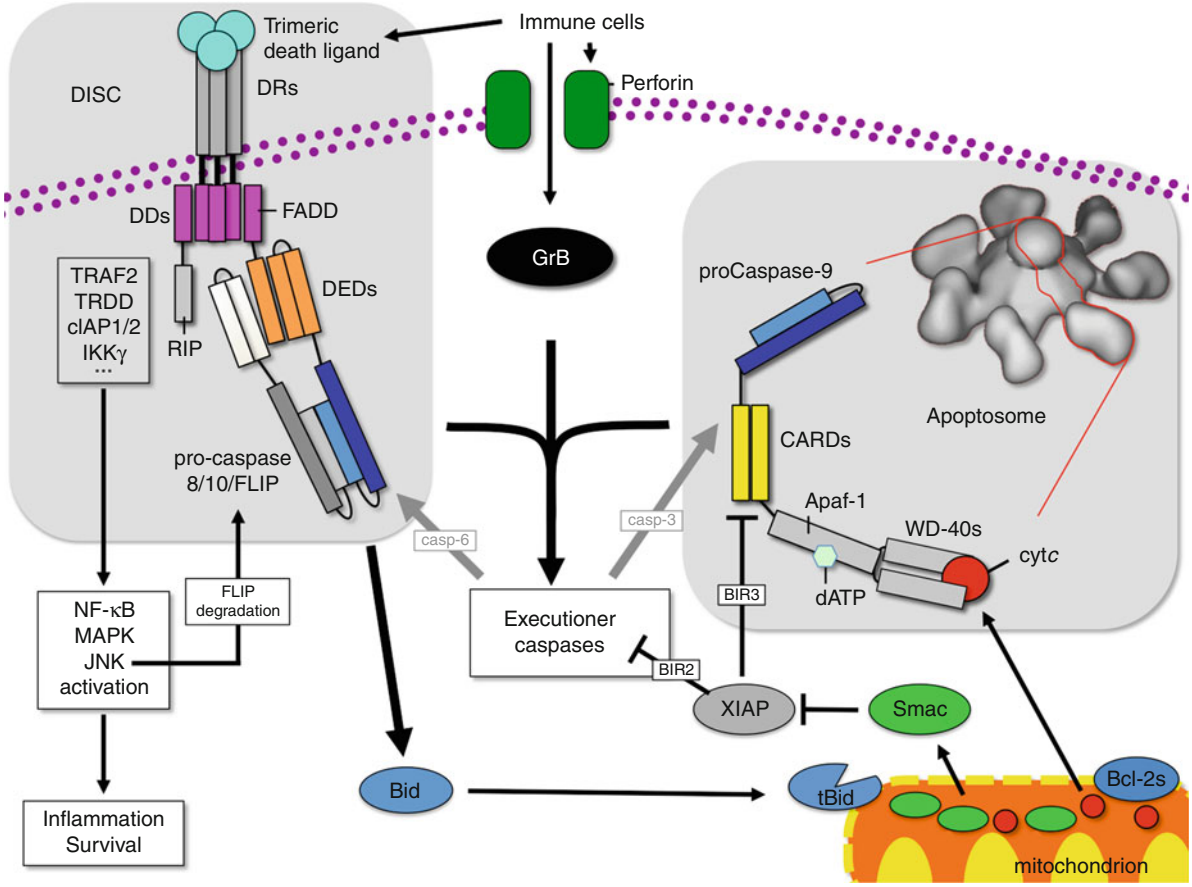
Apoptotic caspases are expressed in all tissues and cell types. They are integrators of apoptotic stimuli, and their activity is required for the activation of executioner caspases, their main substrates (Fig. 4). Like inflammatory caspases, initiators possess a protein-protein interaction domain at the N-terminus (Fig. 1), and they are activated by dimerization on macromolecular platforms (Mace and Riedl 2010a) (Fig. 3a). For a long time, cleavage of initiators has been viewed as synonymous to activation. However, the picture is far more complex than this model. Cleavage of the linker, which gives rise to the characteristic large and small subunits, always occurs during apoptosis. However, in a reconstituted system, uncleavable caspase 9 sustains caspase activation to the same extent as the fully cleaved protease. In vitro proteolysis is not necessary for initiator activation (Boatright and Salvesen 2003). Consequently, cleavage of an initiator caspase does not equate to activation. However, recent work has shown that cleavage is necessary for caspase 8-driven apoptosis *in cellulo* (Oberst et al. 2010). Therefore, cleavage seems to play a role not in activation per se, but rather in modulating the activity of the active caspase. Interestingly, executioner caspase 6 can cleave caspase 8, and caspase 3 cleaves caspase 9. The role of cleavage of caspase 9 by caspase 3 is to relieve it from the inhibition set by the endogenous XIAP (X-linked IAP [inhibitor of apoptosis protein]) caspase inhibitor. In contrast, cleavage of caspase 8 produces a more stable caspase dimer (Pop et al. 2007). Because mice do not have caspase 10, little attention has been paid to this caspase in humans. Nevertheless, it is known that, similar to other initiators, this caspase is activated by dimerization (Wachmann et al. 2010). Importantly, unprocessed caspase 10 possesses high activity on Bid (BH3 interacting domain death agonist), but efficient cleavage of its other targets requires linker proteolysis (Wachmann et al. 2010). Initiator caspases activate two major intracellular pathways to drive apoptosis: the extrinsic and the intrinsic pathways.

The Extrinsic Pathway

The extrinsic pathway (Fig. 4) drives the activation of caspases 8 and 10. It is initiated by ligation of preassembled trimeric death receptors by their cognate ligand (Guicciardi and Gores 2009). These ligands are membrane bound in their more potent form and are normally produced by cytotoxic lymphocytes and natural killer cells, which play a crucial role in immunosurveillance against viral infection and cancer. Based on X-ray crystallography, ligation of death receptors would enable the opening of the cytoplasmic region of the receptor and exposed DD. This would signal the recruitment of the adaptor FADD (Fas [fibroblast associated]-associated with death domain)



Caspase Family, Fig. 3 *Conformational changes during caspase activation.* (**a**) Initiator caspase activation: caspase 8. The NMR structure of pro-caspase 8 catalytic domain shows a monomeric (*left*) entity and has the general fold of an active catalytic unit (*right*). However, the dimer interface provided by the small subunit (*orange*) is disorganized. Interestingly, and contrary to executioner pro-caspase 7, the rather long linker is structured and sits over the unformed catalytic domain where it contacts several residues from loop L1. Recruitment at the DISC brings molecules in close proximity and caspase 8 dimerizes. The activity gained by this process allows cleavage of caspase 8, which further stabilizes the active form. However, it is not clear whether proteolysis occurs in *cis* (self-cleavage) or *trans* (cleavage by a neighboring molecule). Zymogen: PDB 2K7Z; active caspase 8: PDB 1QDU. (**b**) Executioner caspase activation: caspase 7. The zymogen (*left* and *middle*) and the active form (*right*) of caspase 7 adopt a similar fold, a globular arrangement of two catalytic units (*one blue*, *one gray*), each of which is composed of two subunits, the large and small (*dark* and *light colors*). The main differences between them involve three flexible loops (L2–L4, *yellow*) surrounding the unformed catalytic site and substrate binding pocket of the zymogen. The transition to the active form is driven by proteolysis at one of the two cleavage sites (*magenta*) found in the L2 loop. It is noteworthy that in the zymogen dimer, L2 loops adopt different conformation. The L3 loop, which is implicated in the formation of substrate binding pocket, is reoriented following cleavage of the caspase linker, allowing the formation of the substrate binding pocket in the mature form. The L4 loop turns 60° toward the opposite direction and flattens the catalytic groove. Together with loop L2, loop L4 forms a loop bundle, a structure implicated in the stabilization of the active site in the active form of caspase 7. The L2 loop changes drastically upon its cleavage and interacts with the same loop (L2') of the other catalytic unit and stabilizes the active site by crucial interactions. The cleavage of L2 loops leads to the reorientation of the catalytic cysteine in a solvent accessible conformation and enables the catalytic activity of caspases. Zymogen: PDB 1GQF; active caspase 7: PDB 1F1J



Caspase Family, Fig. 4 *Apoptotic pathways*. There are two fundamental pathways leading to caspase activation. The intrinsic pathway depends on the cell's internal control mechanisms, which are integrated at the mitochondrion by Bcl-2 family members (*blue ovals*). If proapoptotic members dominate, the mitochondrion then releases, among others, cyt*c* (*red*) and Smac. With dATP (*lime*), cyt*c* causes Apaf-1 protein oligomerization into an heptameric structure, the apoptosome, that regroups caspase-recruitment domains (CARD; *yellow*) at its apex. This allows the gathering of initiator caspase 9 by virtue of its CARD and its activation by dimerization. Smac (*light green*), which is co-released along with cyt*c*, relieves the inhibition of caspases by XIAP (BIR2 domain inhibits caspase 3 and 7 whereas BIR3 inhibits dimerization of caspase 9) and amplifies the signal initiated by cyt*c*. The second pathway, called extrinsic, originates from outside the cell and requires the ligation of death receptors (DRs) such as Trail-Rs, CD95/Fas, or TNF-Rs. Their ligands are produced by natural killer cells and cytotoxic T lymphocytes. Their activation provokes the assembly of a death-inducing signaling complex (DISC) that will recruit the adaptor protein FADD and initiator caspase 8 and 10 (and also FLIP) by virtue of DEDs (*orange*) and DDs (*magenta*) homotypic interactions. The high concentration of initiator caspases recruited at the DISC allows their activation through dimerization, which can be prevented by excess FLIP. Once active, the initiators cleave executioner caspases 3 and 7 (Fig. 5) to activate them. Depending of the DR, the DISC has the possibility to activate inflammatory and survival pathways through the recruitment of various proteins. The Bcl-2 family member Bid is proteolyzed by initiator caspase 8 and 10 to give tBid (truncated Bid), which provides a way for the extrinsic pathway to activate the intrinsic pathway. Some immune cells can inject in the cytosol of doomed cells using perforin pores the serine protease granzyme B (GrB) complementing the extrinsic pathway. GrB directly activate executioner caspases. Finally, some regulating steps are provided by executioner caspases through their ability to cleave the initiator caspases (*gray arrows*), although these events do not activate the initiators

by homophilic interactions between the newly exposed DD and FADD's DD. On the contrary, NMR (nuclear magnetic resonance) studies have proposed a model that does not involve structural opening, but instead the sandwiching of Fas and FADD's DDs into a pentameric organization of Fas/FADD heterodimer. Interestingly, this latter arrangement is similar to the one observed for the proposed caspase 2 activation platform (Hymowitz and Dixit 2010). No matter which model prevails, both highlight the importance

of receptor clustering for death-inducing signaling complex (DISC) formation. The other domain found on FADD is a DED that is also present in initiator caspases 8 and 10. This four-component complex, ligand-receptor-adaptor-caspase, constitutes the basis of the extrinsic pathway. DISC composition and signaling varies greatly depending on the initiating ligand-receptor pair (reviewed in Guicciardi and Gores 2009a). All assemblies use FADD adaptor protein to link the death receptor to caspase 8, but the tumor necrosis factor (TNF) receptor type 1-associated DD (TRADD) is also used as an adaptor by TNFα receptor.

Bound receptors cluster in lipid rafts and are internalized. Subsequently, the cytosolic side of the DISC becomes a micro-domain of DED and recruits caspases 8 and 10. The locally high concentration of initiator caspase molecules causes its dimerization through induced proximity (Salvesen and Dixit 1999), activation and cleavage of the caspase. A layer of regulation is provided by cFLIP (cellular FLICE [full-length ICE] inhibitory protein) (Thome et al. 1997). The long form of FLIP ($FLIP_L$) is a catalytically disabled caspase 8-like protein and competes with initiator caspases at the DISC at high level of expression, thus damping the death signal. Alternatively, low levels of $cFLIP_L$ can serve as a caspase 8 dimer partner and support caspase activation. In general, death signaling is strong during or after internalization, but weak when receptors are at the plasma membrane, where likely all of them generate pro-survival signals through the NFκB (nuclear factor κB) or mitogen-activated protein (MAP) pathways (Varfolomeev et al. 2005). A key mediator of the pro-survival effect is the kinase RIP1 (receptor-interacting serine/threonine-protein 1) that binds to all death receptors and FADD using its own DD. Post-translational modifications, such as phosphorylation, proteolytic cleavage by caspase 8, and ubiquitination, dictate the various effects of this kinase (Cho et al. 2009). Some particularities of each complex are briefly summarized below (reviewed in (Guicciardi and Gores 2009a)).

The Fas/CD95 DISC

Fas/CD95 (fibroblast associated) was discovered as the antigen to an antibody recognizing T lymphocytes and B cells (Oehm et al. 1992) and is considered a tumor suppressor. Compared to TNF-R1 (TNF receptor 1) and to a lesser extent Trail-R1/2 (TNF-related apoptosis-inducing ligand receptor 1/2; see ▶ APO2L/TRAIL), Fas does not display strong pro-survival effects unless its proapoptotic signaling is masked. For example, tumor cells with disabled Fas-mediated apoptosis will activate the pro-survival NFκB and MAP kinase pathways (Shikama et al. 2003; Barnhart et al. 2004). In non-pathological conditions, Fas signaling via extracellular signal-regulated kinase (ERK) is critical for neuronal regeneration, stellate cell proliferation after hepatic injury, and is required for activated T-cell and thymocyte proliferation. However, despite these few examples, Fas is essentially a death receptor.

The mechanism by which Fas is activated is the best understood among death receptors. After ligation by FasL (Fas ligand), the adaptor FADD is recruited, and the receptor gets palmitoylated, which constitutes the signal for receptor clustering in the lipid raft. Subsequently, Fas is internalized in endosomes in a clathrin-dependent manner, where it continues to recruit and promote caspase 8 and 10 activation. In some cells (so-called type II cells, e.g., hepatocytes, pancreatic β-cells), direct Fas-driven caspase activation is insufficient to cause apoptosis. Consequently, the intrinsic pathway also contributes via the cleavage of Bid by caspases 8 and 10 (Wachmann et al. 2010), which will engage the mitochondrion to release cytochrome *c* (cyt*c*). The discriminating difference between type I and II cells is the level of XIAP, which needs to be overcome for apoptosis to proceed (Jost et al. 2009). Although this dichotomy was initially described for Fas, it also applies to the other death receptors.

The TNFα DISC

The TNF receptor system is comprised of two receptors, TNF-R1 and TNF-R2, but only TNF-R1 is considered a true death receptor because TNF-R2 does not have a DD. Three ligands bind TNF-R1: the membrane bound and soluble form of TNFα and TNFβ, also known as the lymphocyte-derived cytokine α (LTα). However, the focus will be on TNFα signaling because it is the most studied. TNFα is produced by many immune cell types, hepatocytes, and fibroblasts, and plays a crucial role in inflammation, proliferation, and differentiation. The complex formed after TNFα ligation to TNF-R1 is peculiar in that its primary signaling is pro-survival (complex I) rather than apoptotic. It involves the recruitment of RIP1, TRAF2

(TNF receptor-associated factor 2), cIAP1/2 (cellular inhibitors of apoptosis protein 1/2), and maybe TRADD, although the presence of the latter is controversial. This complex also includes IKKγ (inhibitors of κB kinase)/NEMO (NFκB essential modulator). The association of RIP1 and TRAF2 activates two signaling routes. First, it promotes differentiation, proliferation, and inflammation via NFκB activation (Wajant and Scheurich 2001), and second, it stimulates JNK (c-Jun N-terminal kinase) activity. Together, both routes counteract each other because, despite the fact that at a low level of activity the JNK pro-death signal is counteracted by NFκB activation, sustained JNK activity leads to the activation of caspases 8 and 10, and apoptosis.

The pro-death DISC efficiently assembles only after internalization of the receptor, following which FADD and both initiators are recruited to promote cell death. Until now, there is no specific event that switches signaling by TNF-R1 from pro-survival to apoptosis. Instead, the build-up of pro-survival signaling before pro-death signaling strikes the balance between life and death by TNFα signaling.

The Trail-R1/2 DISC

Signaling via Trail-R1/2 seems to follow a mechanism similar to the one used by Fas to activate initiator caspases 8 and 10. However, internalization is dispensable for efficient apoptosis induction in type I cells but seems necessary for type II cells (Guicciardi and Gores 2009a). Trail can also initiate pro-survival signaling by a secondary complex, which is initiated at the receptor but works independently afterward. It contains FADD and initiators, but this complex does not support caspase activation. The complex also contains the kinase RIP1, TRAF2, the adaptor TRADD, and IKKγ/NEMO in a manner reminiscent of TNF-R1 signaling. Furthermore, this complex can lead to MAP kinase pathway activation. The role of this complex is not clear because it antagonizes the death pathway, but it may explain why many cancer cells retain Trail receptor expression.

Caspases 8 and 10 Substrates

Initiator caspases 8 and 10 have few substrates. They cleave themselves at the DISC and proteolyze executioner pro-caspases 3 and 7 and Bid (Luthi and Martin 2007). Because both caspases are recruited to the DISC, it is not surprising that some substrates are part of this complex. Indeed, initiators cleave proteins that are part of pro-survival signaling assemblies with a net result of promoting death. For example, caspase 8 proteolyzes RIP1, shifting TNFα signaling toward cell death. TRAF1, which participates with TRAF2 in NFκB signaling, is cleaved by caspase 8. It was shown that the C-terminal fragment of TRAF1 can displace TRAF2 from a TNF-R/TRADD complex and sensitize cells to apoptosis. Consequently, cleavage of TRAF1 would have the same functional role as RIP1 proteolysis.

$FLIP_L$ is cleaved by caspase 8. Its ability to compete with initiators at the DISC, to heterodimerize and activate caspases 8 and 10 (Yu et al. 2009) and even alter caspase 8 substrate preference make it a key player in DISC signaling. To illustrate this, recent work by Oberst and colleagues showed that uncleaved caspase 8-$FLIP_L$ heterodimer abrogates RIP kinase 3-dependent necrosis during development without inducing apoptosis (Oberst et al. 2011), suggesting a different activity of this dimer compared to the cleaved version. Taken together, both the protein composition of the DISC and the specific form of each of its constituents is crucial in determining the substrate repertoire of caspases 8 and 10, and therefore, the cell's fate.

Aside from DISC components, extrinsic initiators cleave few other proteins. HDAC7, a class II histone deacetylase that represses gene transcription, is cleaved by caspase 8, which changes its subcellular localization and its ability to repress gene transcription.

Regulators of Caspase 8/10

Few other caspase 8- and 10-activating platforms have been proposed in recent years. One of them promotes limited activation of caspase 8 and is controlled by the paracaspase MALT1 (mucosa-associated lymphoid tissue; see ▶ MALT1) during lymphocyte proliferation (Kawadler et al. 2008). Independently of its protease domain, MALT1 can associate with caspase 8 and direct its activation. However, the activity of caspase 8 in this complex seems limited to FLIP.

Several proteins regulate extrinsic initiator caspases, among them kinases such as src (sarcoma) and ERK1/2 (Kurokawa and Kornbluth 2009). The specifics of each phosphorylation event will not be discussed here, but the general effect of phosphorylation is to inhibit activity or activation.

The Intrinsic Pathway

Caspase 9 drives an intracellular apoptotic pathway called the intrinsic/mitochondrial pathway (Fig. 4). This route is used in response to various stresses and developmental cues. Indeed, the critical role of caspase 9 during mouse development is exemplified by the fact that knockout mice die perinatally and show severe brain malformation. The intrinsic pathway integrates signals such as DNA damage, reactive oxygen species (ROS) generation, and metabolic cues, and can also be activated by the extrinsic pathway through the cleavage of Bid. The detailed mechanisms by which these stimuli lead to caspase activation are out of the scope of this chapter, but a basic understanding of the major players is necessary. The mitochondrion is central to this pathway in that it amalgamates cues on its outer membrane through a delicate balance of pro- and anti-apoptotic proteins of the Bcl-2 (B-cell lymphoma 2) family. At the resting state, the anti-apoptotic subgroup (A1, Bcl-2, Bcl-W, Bcl-X_L, and Mcl-1) keeps the proapoptotic members Bak, Bax, and Bok in check by forming a heterodimer with them. A third group, named BH3 (Bcl-2 homology 3)-only proteins (Bad, Bid, Bik, Bim, BMF, BNIP3, HRK, Noxa, and Puma), works to destabilize the equilibrium set by the other two groups by either binding to anti-apoptotic members, thus freeing proapoptotic proteins, or by directly binding to proapoptotic members to activate them. Either model leads to mitochondrion outer membrane permeabilization (MOMP) and leakage of key proteins including cyt*c* and Smac (second mitochondria-derived activator of caspases). The latter protein neutralizes IAPs (Fuentes-Prior and Salvesen 2004a) including XIAP, a direct inhibitor of caspases 3, 7, and 9.

Caspase 9 Activation and Regulation

Once released into the cytosol, cyt*c* binds to Apaf-1 (apoptotic peptidase activating factor). In brief, Apaf-1 contains a CARD domain at its N-terminus, a central NOD and C-terminal WD-40 repeats. The latter inhibits the oligomerization of Apaf-1, which is relieved by cyt*c* binding, enabling the formation of a heptameric wheel-shaped structure, the apoptosome (Mace and Riedl 2010a). This complex also requires dATP/ATP ligation to the nucleotide-binding domain (NOD), a feature also found in NLRs. Subsequently, the apoptosome recruits caspase 9 through homophilic CARD interaction into a central hub where it dimerizes. Recent studies have proposed that only a single dimer of caspase 9 is at the apoptosome at any given time (Malladi et al. 2009) and that it is active only when bound to Apaf-1. This creates a molecular timer for executioner caspase activation regulated in part by caspase 9, which stays on the apoptosome. Caspase 9 autoproteolysis is dispensable for the proper execution of apoptosis.

The crystal structure of dimeric caspase 9 has been published. It reveals only one active catalytic unit whereas the other domain has a distorted active site. The biological implication of this half-active dimer remains unclear and may be due to the presence of the inhibitor, which may be fixing the protein in a particular conformation.

Recently, Bratton and Salvesen surveyed regulators of caspase 9 activation and activity in details (Bratton and Salvesen 2010). Therefore, only the most relevant and best-characterized ones will be addressed. First and foremost, cleaved caspase 9 is inhibited by XIAP, which prevents dimerization via its BIR3 (baculovirus inhibitory repeat) domain. The strength of inhibition relies partly on the N-terminus of the cleaved small subunit of caspase 9 that contains a motif reminiscent of the mature Smac N-terminus. Interestingly, caspase 3, but not caspase 7, can remove this epitope by cleaving downstream of it, thus promoting caspase 9 activity by removing the influence of XIAP.

Another way by which caspase 9-driven apoptosis is modulated is through phosphorylation (Kurokawa and Kornbluth 2009). Representative examples include phosphorylation by ERK2 and Akt, both of which prevent caspase 9 activation. Notably, cancer cells rely heavily on the MAP kinase (MAPK) pathway led by ERK1/2 and growth factor phosphatidylinositol 3-kinase (PI3K)-Akt pathway to survive, thus showing a clear path to damper the suicidal tendencies of tumor cells. Interestingly, and contrary to most kinases, c-Abl (Abelson murine leukemia viral oncogene homolog 1)-mediated phosphorylation promotes caspase 9 processing in response to DNA damage.

Caspase 9 Substrates

There are only three well-established caspase 9 substrates: itself and pro-caspases 3 and 7 (Luthi and Martin 2007). By analogy to DISC proteins that are substrates of caspases 8 and 10, proteins that are in

close proximity to the apoptosome may be cleaved by caspase 9. Few other substrates have been proposed (less than 15) for caspase 9, but for many of them, experimental evidences are circumstantial at best.

Based on peptidic substrate library screens, caspase 9 cleaves the preferred LEHD↓ motif (Thornberry et al. 1997). There is no data on residue preference at the prime sites of the scissile bond. Remarkably, none of the reported substrate cleavage sites, including those on pro-caspases 3 and 7 and caspase 9 itself, match the preferred site. Similar to most caspases, the rule of a "good-enough site" seems to prevail. Indeed, no more that twofold improvement can be attained by substituting the primary pro-caspase 7 activation site for the preferred motif recognized by caspase 9 or caspase 8. Even the work-horse of apoptosis, caspase 3, does not have most of its substrates matching its preferred motif, i.e., DEXD↓(S/A/G).

Caspase 2

Caspase 2 is the most conserved member across species and the closest homolog to the unique *C. elegans* caspase ced-3 (Vakifahmetoglu-Norberg and Zhivotovsky 2010). However, it is also the least understood of the initiators. Opinions over its roles in the cell are controversial, with demonstrated pro-survival and apoptotic functions. It is present in the cytoplasm and the Golgi apparatus, and it is the only caspase found in the nucleus of some cell types.

Caspase 2 is activated in response to acute DNA damage by a mechanism involving p53. In this context, p53 promotes the expression of the CARD-containing adaptor RAIDD (RIP1 domain containing adaptor with DD) and PIDD (p53-induced protein with a death domain). Following a two-step autoproteolysis process, which converts PIDD from a pro-survival to a proapoptotic protein, PIDD relocalizes to the nucleus and forms an activation complex with RAIDD called the PIDDosome. However, Bouchier-Hayes and colleagues have localized the PIDDosome only in the cytosol, contradicting previous findings. Irrespective of the definitive location of this complex, it is responsible for the recruitment and activation of caspase 2 by dimerization in a manner reminiscent of other initiator caspase-activating platforms. X-ray crystallization showed that the PIDDosome has a ring-like shape composed of 5 PIDD and 7 RAIDD molecules (Mace and Riedl 2010a). Caspase 2 activation seems to be upstream of mitochondria, but the real requirement for this pathway remains unknown. Interestingly, PIDD-deficient cells display normal caspase 2 cleavage and no abnormalities, which suggests that another pathway can activate this caspase.

Contrary to other caspases, the caspase 2 substrate binding pocket seems to extend beyond the S4 pocket because it is relatively inactive on tetrapeptidic substrates but fairly active on pentapeptides. Caspase 2 substrates are limited compared to other caspases. Unlike the other initiators, caspase 2 cannot process executioner caspases, but it processes itself and cleaves Bid.

Apoptotic Caspases: The Executioners

Caspases 3, 6, and 7 are classified as executioner caspases based on their position in the activation cascade, i.e., downstream of initiator caspases (Fig. 4). Caspase 6 is often omitted from this group. However, because of its crucial role in cleaving nuclear lamins, it earned its status among executioners. They are responsible for the execution of apoptosis by cleaving many cellular substrates critical for the apparition of apoptotic features (Table 1). These caspases are expressed in all cell types and exist as obligate dimers at cellular concentrations.

Unlike the others, executioner caspases possess an N-terminal peptide of 23–28 amino acids instead of a protein-protein interaction domain. This segment is always cleaved during apoptosis. However, the role of this peptide remains unclear. For caspases 3 and 6, the N-peptide seems to silence the enzyme *in cellulo*. Also, the N-peptide removal of caspase 7 allows efficient activation by the serine protease granzyme B (GrB), at least in some cells (Fig. 5).

Cleavage of the linker that separates the large and small subunit of the catalytic domain is the driving force of executioner caspase activation (Fig. 2d). Cleavage occurs at conserved aspartate residues and is performed by initiator caspases or granzyme B. Other proteases can activate executioner caspases, further demonstrating the sole requirement for cleavage of the linker for activation. Proteolysis allows the formation of the substrate binding pocket and the reorientation of the catalytic cysteine. Cleavage is required for the executioners and not for the initiators possibly due to the relatively short length of the

Caspase Family, Table 1 Death substrates cleaved by caspases that result in an apoptotic hallmark

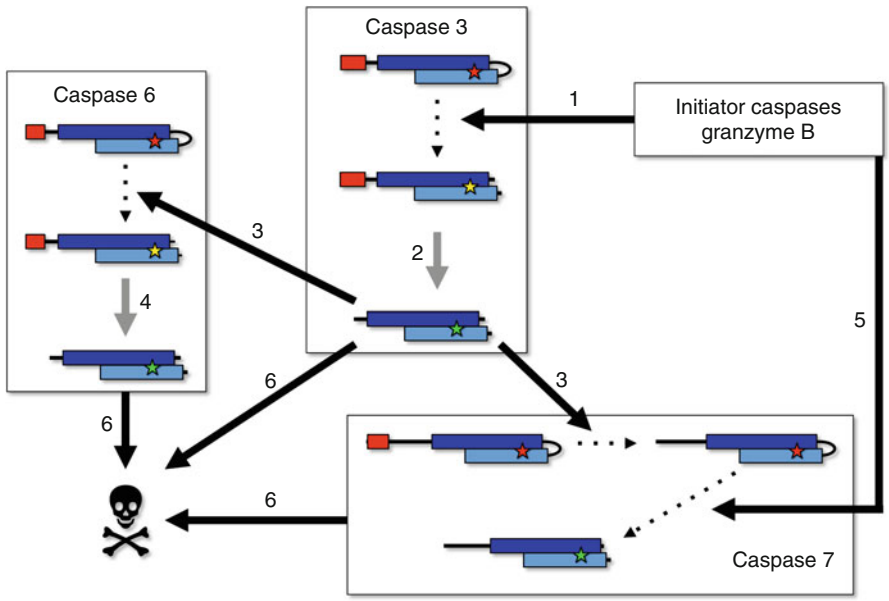
Death substrates	Description	Main role	Hallmark
Vimentin	Intermediate filament networking protein	Structural, cytoskeleton component	Intermediate filament dismantling/ blebbing
iPLA2[a]	Calcium-independent phospholipase A2	Generation of arachidonic acid and lysophosphatidylcholine	Find-me signal, healing response, phagocyte recruitment
Mst-1[b]	Human serin/threonine kinase	Phosphorylate many substrates like JNK, p38 MAPK and H2B histone, Akt1 inhibition	Chromatin condensation via histone H2B phosphorylation
Grasp65[c]	Receptor of GM130	RE and Golgi dynamics	RE and Golgi disruption
Bid[d]	Proapoptotic Bcl-2 family member	Transmit extrinsic death signal to the intrinsic pathway	Extrinsic pathway activation
PARP[e]	Poly(ADP-ribose) polymerase	Signal breaks in double-stranded DNA	PARP cleavage and ATP level maintenance
ICAD[f]	Inhibitor of caspase-activated DNAse	Inhibits and assists the folding of caspase-activated DNAse	Internucleosomal DNA fragmentation
ROCK I/II[g]	Serine/threonine kinase, Rho effector kinase	Phosphorylation of myosin light chain	Membrane blebbing, apoptotic bodies formation, nuclear fragmentation
PKCδ[h]	Protein kinase C, isoform delta	Serine/threonine kinase involved in cell signaling	Amplify apoptosis signal by promoting degradation of Mcl-1
p75 (NDUFS1)	p75 subunit of complex I	Participate in the respiratory chain of mitochondria	Loss of mitochondrial potential and ROS generation
Nuclear lamins	Nuclear structural protein	Nuclear morphology	Chromatin condensation, nuclear fragmentation
Gelsolin	Calcium-dependant regulator of actin filament dynamic	Regulator of actin organization	Cell round-up, matrix detachment
Pannexin 1	Ion channel	ATP and UTP release	Find-me signal

[a]Intracellular phospholipase A2
[b]Mammalian sterile 20-like 1
[c]Golgi reassembly and stacking protein of 65 kDa
[d]BH3 interacting domain death agonist
[e]Poly(ADP-ribose) polymerase
[f]Inhibitor of CAD
[g]Rho-associated protein kinase
[h]Protein kinase C δ

executioner's linker. However, this can hardly be reconciled with the linker of caspase 6, which is longer than that of caspase 8, and still requires cleavage for activation.

Caspase 7 is the best-understood executioner caspase at a structural level. Many structures provided information on executioner activation mechanism and substrate catalysis. The first reported structure of caspase 7 revealed a globular arrangement of two catalytic units and the presence of interdigitation between units by the so-called L2-L2' loops (Fig. 3b). Caspase 3 has a similar structure. The zymogen and the active form of caspase 7 adopt a similar fold. The main differences between them implicate three flexible loops surrounding the unformed catalytic site and substrate binding pocket (Fig. 3a). The unliganded form of caspase 7 exhibits an unformed substrate binding pocket, suggesting that substrate recognition is key to the formation of the fully active enzyme (induced fit process). However, these data remain conflicting, as some groups have reported no differences between unbound and inhibitor-bound caspases 3 and 7. More recently, many studies on the activation mechanism of caspase 6 were published. Globally, conformational changes occurring during the passage from the zymogen to the active state resemble the changes described for caspase 7 (Wang et al. 2010).

As mentioned, the removal of their respective N-terminal peptides seems an important step during *in cellulo* activation of executioners. Once activated, caspase 3 cleaves its own N-terminal peptide and then



Caspase Family, Fig. 5 *Executioner caspases activation cascade*. Within the executioners, a proteolytic cascade exists and is started by the cleavage of pro-caspase 3 by the initiator caspases or, to a lesser extent, granzyme B (step 1). Caspase 3 gains full activity after self-removal of its own N-peptide (step 2). Subsequently, caspase 3 cleaves pro-caspase 6 in its linker and the N-terminal peptide of pro-caspase 7 (step 3). In a manner reminiscent of caspase activation, caspase 6 removes its own N-peptide (step 4). Alternatively, caspase 8 can perform this step. Removal of caspase 7 N-peptide renders this caspase available to initiators and granzyme B for activation (step 5). GrB-mediated cleavage of pro-caspase 7 is one of the fastest proteolytic event known. Afterward, active executioners cleave their repertoire of death substrates (step 6) and cause apoptosis. *Trans* cleavage events are indicated by black arrows whereas gray arrows indicate *cis* proteolysis. The activity status of each protease is indicated by color-coded stars (inactive, *red*; silenced, *yellow*; active, *green*)

cleaves that of caspase 7. Because caspase 3 has higher enzymatic activity than caspase 7 and is present at a higher concentration in cells (~100 nM), it is considered to be the major executioner. Current studies suggest that caspase 6 is activated by caspase 3, not by an initiator caspase.

Caspase activation is regulated by IAPs. Executioner caspases 3 and 7 (and initiator caspase 9) are directly inhibited by XIAP. This IAP, which is often upregulated in cancer cells, provides a unique way to adjust sensitivity to apoptosis, and is responsible for defining type I and type II cells (Jost et al. 2009). Based on work by Scott et al. the second BIR of XIAP uses two binding sites to achieve low nanomolar affinity toward caspase 7 (Scott et al. 2005). Interestingly, the region N-terminal to BIR2 binds in reverse orientation over the substrate binding pocket, whereas the BIR2 domain binds further away from the catalytic site. Through its C-terminal RING (really interesting new gene) domain, XIAP can ubiquitinate caspases and hasten their proteasomal degradation. Moreover, a recent report suggests that executioner caspases and proteasome activity levels are strongly linked (Gray et al. 2010).

Cell Death by Caspases

Many phenotypic hallmarks resulting from caspase activation can be recapitulated, at least in some form, without caspase activity (e.g., DNA fragmentation, mitochondrial depolarization, and cleavage of some death substrates). Caspase activation is thought to be a means to an end more than it is thought to be a part of apoptosis, and this is still being debated. Some have argued that apoptosis should be defined as "caspase-mediated cell death," which contradicts formulations such as "caspase-independent apoptosis," as is often suggested in the literature.

Activation of any of the three executioner caspases is sufficient to induce apoptosis (Gray et al. 2010). For example, overexpression of caspase 7 results in cell

rounding and detachment, PARP and protein kinase C δ (PKCδ) cleavage, and DNA fragmentation without the activation of any other caspases, but no lamin B_1 cleavage and cyt*c* release from the mitochondria. Because the "good" cleavage motif recognized by caspases 3 and 7 is simple (i.e., DXXD↓(G/A/S)), this motif is common in mammalian genomes. Indeed, over 1000 caspase substrates have been identified covering the whole gamut of protein types and cellular functions (Luthi and Martin 2007). Interestingly, only a handful of them other than caspases have been shown to be necessary to produce full-blown apoptosis (Table 1). Notably, genetic studies in mice on the requirement for DNA fragmentation by CAD (caspase-activated DNAse), a hallmark of apoptosis, revealed that this endonuclease is dispensable for apoptosis and proper cell removal by professional phagocytes. Conversely, mice carrying a caspase 3- and 7-resistant PARP, whose cleavage is a characteristic hallmark of apoptosis, are resistant to endotoxic shock and to intestinal and renal ischemia reperfusion. PKCδ cleavage seems essential for apoptosis mediated by some genotoxic reagents. Despite these few examples, it is difficult to clearly establish that a given protein is truly an important death substrate. Here, death substrates are divided into three categories: death substrates in which cleavage (1) is absolutely required, (2) helps the process, or (3) is an accessory to apoptosis (bystander substrates). Thus, for each category – stimulus, cell, or tissue – specificities may exist. For example, cleavage of Bid illustrates group 1 proteins in type II, but not in type I cells, in which proteolysis would only help apoptosis. With the exception of caspases themselves, required cleavage events are quite rare, and most cleavage events are probably of the bystander-type, especially if they occur later during apoptosis. Recently, Timmer and Salvesen have addressed this issue and proposed simple steps, at least in theory, to discriminate true death substrates (likely few) from bystanders (many) (Timmer et al. 2007).

The timeline of hallmark's appearance may be different from one cell to another, may depend on the stimulus that initiates apoptosis, and may be dictated by sensitivity of the assay used. However, it is clear that there are early, intermediate, and late events. The earliest event is likely the exposure of phosphatidyl-serine (PS) on the external leaflet of the plasma membrane, occurring within 1 h in some cells. This "eat-me" signal originates from the downregulation of an amino phospholipid translocase and the activation of scramblases, which are activated by various signals. At the other end of the timescale, the packaging of cell components into small apoptotic bodies would be considered a late event. The other hallmarks find their place somewhere in between early and late events.

Apoptotic Caspases Beyond Death

Recently, acute attention has been paid to non-apoptotic roles of caspases (Yi and Yuan 2009). Caspase 8 is implicated in the immune network by modeling the proliferation and the differentiation of many cell types (monocytes, B and T cells). Reports also ascribe a role to this protease in cell migration and metastasis. Furthermore, caspase 3 activation has been linked to differentiation of some cell types. Skeletal muscles need cleavage of Mst-1 (mammalian sterile 20-like 1) and ICAD (inhibitor of CAD) (Larsen et al. 2010) for myoblast differentiation. In mice, caspases 3 and 7 are implicated in the generation/secretion of factors that promote wound healing and tissue regeneration. This role is concomitant with the execution of apoptosis and seems important for compensatory proliferation during normal tissue apoptosis. Besides, caspase 3 has a role in the maturation of erythrocytes and embryonic stem cell differentiation driven by Nanog proteolysis. Many non-apoptotic roles of caspases are probably hidden by the crude phenotypes of caspase knockout mice, and many other non-apoptotic roles are possibly masked by the compensatory phenotype observed in viable mice lineages.

Caspase and Disease

Multiple attempts to identify mutations in genes encoding caspases in cancers have been made, but no mutation hotspot has emerged. However, in some cancers, mutation rates are relatively high, with many of them having an effect on caspase protein level. Intuitively, any mutation diminishing caspase activity or its expression could contribute to tumorigenesis. However, there is currently little evidence suggesting that caspase gene mutations are early events in tumorigenesis, and the impact of mutations to establish their

relevance in promoting cancer development has not been studied. Nevertheless, at least two publications have suggested that caspases 2 and 8 are tumor suppressors.

Human genomic mutations in extrinsic initiators have been reported and cause divergent but related diseases. For example, an inactivating mutation in human caspase 8 (Arg^{248}->Trp in the large subunit) leads to immunodeficiency, whereas mutation in caspase 10 (Ile^{406}->Leu in the small subunit) produce autoimmune lymphoproliferative syndrome (ALPS). In addition to caspase mutations, cancer cells have many other ways to control caspase activation and activity to escape apoptosis. Indeed, the upregulation of XIAP and some anti-apoptotic Bcl-2 family members are well-known mechanisms by which caspase regulation is altered in tumor cells.

Many pathogens use proteins that target caspases to counteract their action and alter the normal cell response (Best 2008; Faherty and Maurelli 2008). For example, the viral serpin CrmA (cytokine response modifier A) encoded by the cowpox virus is a potent inhibitor of caspases 1 and 8 and granzyme B (a serine protease injected by cytotoxic lymphocytes and natural killer cells into the cytosol of target cells), thus preventing the inflammatory response and apoptosis. Viral FLIP-like protein (vFLIP) encoded by many viruses (e.g., Kaposi's sarcoma-associated herpesvirus) binds the DED-containing proteins FADD and initiator caspases 8 and 10, thus blunting the action of the extrinsic pathway. Viral FLIP also contributes to tumor development by promoting NFκB pathway activation.

Some neurological illnesses are linked to deregulation in caspase activation. In mice, Huntington, which is a caspase 6 substrate, needs cleavage for Huntington disease to occur. Caspase 7 is implicated in spinocerebellar ataxia type 7, a neurological polyglutamine disease. This caspase cleaves Ataxin-7, leading to specific neurological degeneration. A mutation in the cleavage site of DJ-1, normally recognized by caspase 6, is responsible for a subset of familial Parkinson's disease.

Summary

Since their discovery more than 20 years ago, caspases have drawn intense scrutiny. The role of caspases as mediator of inflammation, apoptosis, and skin maturation is relatively well understood, but their involvement in nontraditional processes remains unclear. The mechanisms by which other activities of caspases are selected over the traditionally recognized ones remain elusive.

Despite all the work done, many questions linger. Few of them have been mentioned throughout this chapter. An exciting topic in caspase biology is currently to delineate the substrate repertoire of each of them during apoptosis (Gray et al. 2010) and non-apoptotic processes. A corollary to this is to understand how caspases "know" which subset of proteins needs cleavage in a particular setting. Timmer and Salvesen have proposed that caspases use exosites to "select" their substrates (Timmer et al. 2007). It can be proposed that selectivity toward substrate subsets could be provided by exosite modulation, which are more amenable to regulation than the primary substrate binding pocket. The ability of caspase 10 cleavage status to dictate proteolysis of Bid versus other substrates exemplifies this issue (Wachmann et al. 2010). Irrespective of the death substrate repertoire of each caspases, another outstanding question regards the relevance for apoptosis of a given cleavage event: Is there a need to cleave all ~1,000 proteins for apoptosis to work? It is unlikely, but which cleavage events are important? Finally, caspase therapeutical potential is largely untapped. Although it is not expected that caspase inhibitors will be used for chronic treatments, their acute use can potentially be useful in ischemia reperfusion and acute hepatic failure. Direct caspase activators are, at least for now, more problematic in their design.

Precerebellin

Historical Background

In 1984, the cerebellum-specific hexadecapeptide "cerebellin" was identified and shown to be concentrated in the synaptosomal compartment (Slemmon et al. 1984). Although "precerebellin" was originally identified as a precursor of cerebellin, the cerebellin peptide is not flanked by the classical dibasic amino acids observed in many neuropeptide precursors (Urade et al. 1991). In addition, precerebellin clearly belongs to the C1q family, whose members, such as C1q, adiponectin (Adipoq), and collagen X, are secreted and are involved in various intercellular functions (Yuzaki 2008). Indeed, full-length, uncleaved precerebellin is secreted from cerebellar granule cells (Bao et al. 2005; Iijima et al. 2007). Therefore, it is now evident that precerebellin is the actual signaling molecule itself, which should be referred to as Cbln1, although the cerebellin peptide may have additional functions.

Basic Features

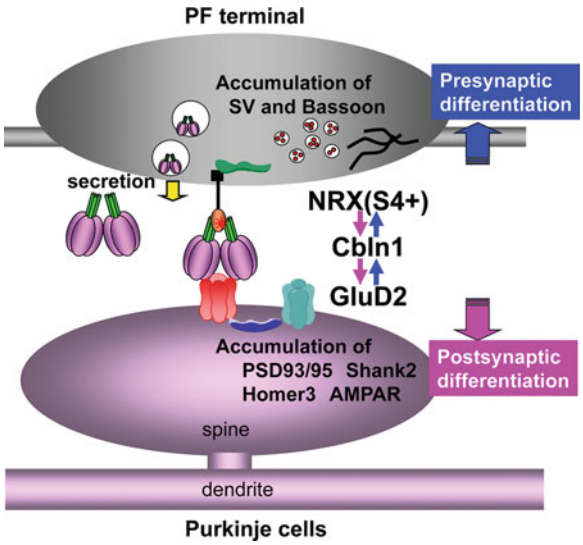
Cbln1 is predominantly expressed in cerebellar granule cells. Analysis of *Cbln1*-null mice revealed two essential functions of Cbln1 at synapses formed between parallel fibers (PFs; axons of granule cells) and Purkinje cells in the cerebellum (Hirai et al. 2005). The number of PF-Purkinje cell synapses is markedly reduced, and as many as 80% of the dendritic spines of Purkinje cells remains uninnervated in *Cbln1*-null mice. In the remaining PF-Purkinje cell synapses in $Cbln1^{-/-}$ mice, the postsynaptic densities (PSDs) are frequently longer than the presynaptic active zones, whereas the length of the active zones completely matches that of PSDs in wild-type mice. In addition, the long-term depression (LTD) of synaptic transmission at PF-Purkinje cell synapses, which is thought to underlie motor coordination and information storage in the cerebellum, is completely abrogated in *Cbln1*-null cerebellum. These unique phenotypes indicate that Cbln1 functions as a synaptic organizer that regulates matching and the maintenance of pre- and postsynaptic structures and proper synaptic functions at PF-Purkinje cell synapses.

Interestingly, *Cbln1*-null mice precisely phenocopy mice lacking a gene encoding the δ2 glutamate receptor (▶ GluD2; ▶ GluRδ2) (Yuzaki 2009). Indeed, ▶ GluD2, which is predominantly expressed in Purkinje cells, has been recently identified as a postsynaptic receptor for Cbln1 (Matsuda et al. 2010). Furthermore, neurexin (NRX), which is located at the presynaptic site of PF-Purkinje cell synapses, has been shown to serve as another receptor for Cbln1 (Uemura et al. 2010; Matsuda and Yuzaki 2011). These findings indicate that Cbln1 released from PFs forms a tripartite complex NRX/Cbln1/▶ GluD2 by binding to its presynaptic receptor NRX and postsynaptic receptor ▶ GluD2 at synaptic junctions and serve as a unique synaptic organizer (Fig. 1).

Cbln1 as a C1q Family Protein

Cbln1 belongs to the C1q family, which is characterized by the globular C1q domain (gC1q) at the C-terminus.All C1q family proteins are thought to form trimers via the C-terminal gC1q domain, and this unit trimer is often further organized into a higher-order multimeric complex via various motifs located at the N-terminus. Indeed, Cbln1 forms a hexamer via the disulfide bond at the N-terminal two cysteine residues (Bao et al. 2005; Iijima et al. 2007). A mutant Cbln1, which could not form a hexamer, does not exhibit any synaptogenic activities (Ito-Ishida et al. 2008). Thus, like other C1q family proteins, such as adiponectin and collagen X, the oligomeric status of Cbln1 is crucial for its functions.

The C1q family proteins including Cbln1 are completely absent in plants (*Arabidopsis thaliana*), yeasts (*Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*), nematodes (*Caenorhabditis elegans*), and insects (*Drosophila melanogaster*). The Cbln family consists of four members, Cbln1–Cbln4, which share 57–79% amino acid similarity with each other. All Cbln proteins are highly conserved among mammals. Indeed, 96–100% of the amino acid sequences of Cbln1–Cbln4 are identical between mice and humans.



Cbln1, Fig. 1 A schematic diagram summarizing synaptic signaling mediated by the tripartite complex NRX/Cbln1/GluD2. Cbln1 serves as a bidirectional synaptic organizer by binding to the presynaptic receptor NRXs containing the splice site #4 (S4+) and the postsynaptic receptor GluD2 at PF-Purkinje cell synapses. At the presynaptic site, NRXs accumulate synaptic vesicles (SVs) and bassoon to induce presynaptic differentiation. At the postsynaptic site, Shank2, PSD93/95, homer3, and AMPA receptors are accumulated by direct or indirect binding to GluD2's C-terminus

In contrast, Cbln3 is absent in frog (*Xenopus laevis*), fish (*Danio rerio*), and birds (*Gallus gallus*). These findings suggest that the Cbln family, especially Cbln3, may have emerged relatively late in the evolution to overcome the requirement for complex synaptic wiring (Yuzaki 2008; Yang et al. 2010).

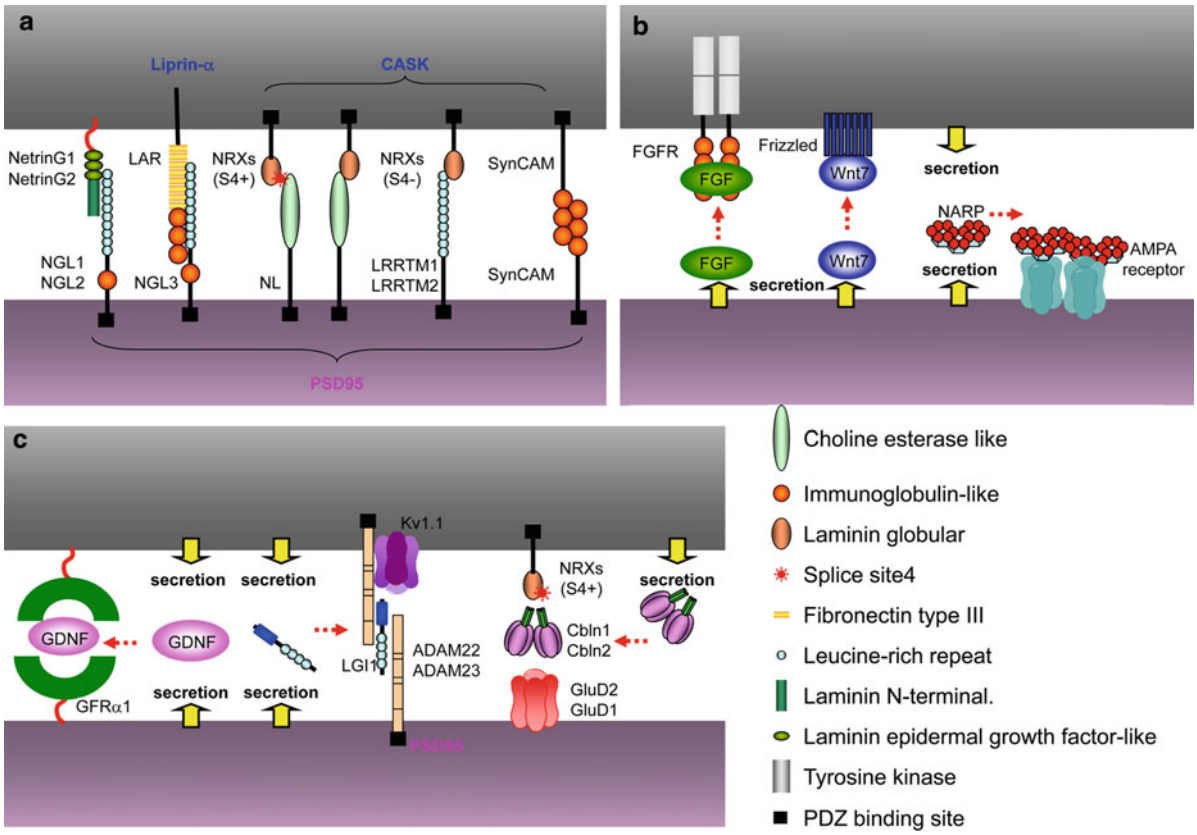
Cbln1, Cbln2, and Cbln4 are expressed in various brain regions outside the cerebellum (Miura et al. 2006). Interestingly, Cbln1 and Cbln2 but not Cbln4 can bind to NRX and induce the presynaptic differentiation of hippocampal and cortical neurons in vitro (Matsuda and Yuzaki 2011). Since Cbln4 is coexpressed with Cbln1 or Cbln2 in many brain regions (Miura et al. 2006), Cbln4 may modulate the synaptogenic activities of Cbln1 and Cbln2 by forming a heteromeric complex. Although ▶ GluD2 is predominantly expressed in the cerebellum, its family protein GluD1 is expressed in various brain regions and binds to Cbln family proteins (Matsuda et al. 2010; Matsuda and Yuzaki 2011). These findings suggest that GluD1 may form a tripartite complex with NRXs and Cbln1/2/4 to exert synaptic functions similar to those achieved by the NRX/Cbln1/▶ GluD2 complex.

A New Comer to the World of Synaptic Organizers

A growing number of synaptic organizers have been identified (Fox and Umemori 2006). They are generally classified into two categories, cell adhesion molecules and secreted factors (Fig. 2). A pair of cell adhesion molecules located at pre- and postsynaptic sites directly link pre- and postsynaptic elements. These include NRXs/neuroligins (▶ NLS (Nuclear Localization Sequence)), NRXs/leucine-rich repeat transmembrane proteins (LRRTMs), synaptic cell adhesion molecules (SynCAMs)/SynCAMs, netrin G–ligand (NGL)/leukocyte common antigen-related (LAR), and NGL/netrin G (Fig. 2a). Upon association, these pairs induce bidirectional synaptic differentiation. On the other hand, most secreted factors, such as Wnt7a, fibroblast growth factors (FGFs), and a pentraxin NARP, work on either the pre- or postsynaptic site, depending on the location of their receptors (Fig. 2b).

In contrast to these conventional synaptic organizers, Cbln1 secreted from PFs is sandwiched between the presynaptic receptor NRXs and the postsynaptic receptor ▶ GluD2 (Figs. 1, 2c). Similarly, glia-derived neurotrophic factor (GDNF) is reported to serve as a synaptic adhesion molecule being sandwiched by its receptor GFRα1 located at both pre- and postsynaptic neurons (Ledda et al. 2007). In addition, leucine-rich glioma inactivated 1 (LGI1) is also secreted from neurons and bind to its pre- and postsynaptic receptors ADAM22 and ADAM23, respectively, to accumulate potassium channels and AMPA receptors at synapses (Fukata et al. 2010). Thus, Cbln1 and these molecules may constitute the third category of synaptic organizers, a sandwich type (Fig. 2c) (Yuzaki 2011).

Cell adhesion molecules, such as cadherins, protocadherins, NRXs/NLs, and NRXs/LRRTMs, generally require extracellular Ca^{2+}. Thus, the second unique feature of the NRX/Cbln1/▶ GluD2 complex is that the binding between these molecules does not require Ca^{2+} (Matsuda and Yuzaki 2011). Indeed, Cbln1 specifically binds to NRXs containing an alternatively spliced exon known as "splice site #4," suggesting that Cbln1-binding properties for NRXs are distinct from those of ▶ NLS (Nuclear Localization Sequence) or LRRTMs. Since synaptic adhesion itself is independent of Ca^{2+}, Ca^{2+}-resistant binding of the NRX/Cbln1/▶ GluD2 complex is consistent with the function of the complex as synaptic glue, connecting pre- and postsynaptic elements.



Cbln1, Fig. 2 A schematic diagram showing three types of synaptic organizers. (**a**) Cell adhesion molecules. Cell adhesion molecules form transsynaptic complexes by their extracellular regions. NGL3 binds to the first two fibronectin type III repeats in LAR. NGL1 and NGL2 bind Netrin-G1 and Netrin-G2 anchored to the plasma membrane by glycosylphosphatidylinositol, respectively. Unlike Cbln1, which specifically binds to NRXs containing the splice site #4 (S4+), LRRTM1/2 binds to NRXs that lack the splice site #4 (S4–). NLs bind NRXs (S4–) and NRXs (S4+). SynCAM forms a homophilic complex through IgG-like domains. (**b**) Secreted molecules. FGF and Wnt7a, secreted from postsynaptic neurons bind to FGFR and Frizzled, respectively, on presynaptic terminals and induce presynaptic differentiation. Narp, secreted from pre- and postsynaptic sites, causes clustering of the AMPA receptors (GluA1 and GluA4 subunits) at the postsynaptic site. (c) Sandwich-type molecules. GDNF binds to GFRα1 located on both pre- and postsynaptic sites. The GFRα1/GDNF/GFRα1 complex induces cell adhesion. LGI1 binds to presynaptic ADAM22 and postsynaptic ADAM23 and accumulate presynaptic potassium channels (Kv1.1) and postsynaptic AMPA receptors, leading to enhanced synaptic transmission. Secretion sites of GDNF and LGI are not well understood. Cbln1 are secreted from presynaptic sites, acting on both pre- and postsynaptic sites by forming the tripartite NRX/Cbln1/GluD2 complex

Summary

Cbln1 is one of the most recently identified synaptic organizers that belong to the C1q family. Unlike other synaptic organizers, a deficiency in Cbln1 causes a severe reduction in the number of synapses between PFs and Purkinje cells in the cerebellum. Cbln1 released from PFs binds to NRXs expressed on the presynaptic PFs and ▶ GluD2 at the postsynaptic site. The NRX/Cbln1/▶ GluD2 tripartite complex is resistant to low extracellular Ca^{2+} levels and serves as a unique sandwich-type synaptic organizer. The mechanism by which the NRX/Cbln1/▶ GluD2 complex activates synapse formation/maintenance remains to be determined in future studies. In addition, the signaling mediated by other family members, such as Cbln2, Cbln4, and GluD1, remains to be clarified in vivo. Interestingly, members of other C1q family, such as the classical complement C1q and C1ql, are also shown to regulate the elimination of synaptic connections (Stevens et al. 2007; Bolliger et al. 2011). Thus, characterization of C1q family

proteins is expected to provide new insights into the mechanisms by which synapses are formed and modified in the CNS.

Synonyms

Macrophage inflammatory protein-1 alpha

Historical Background

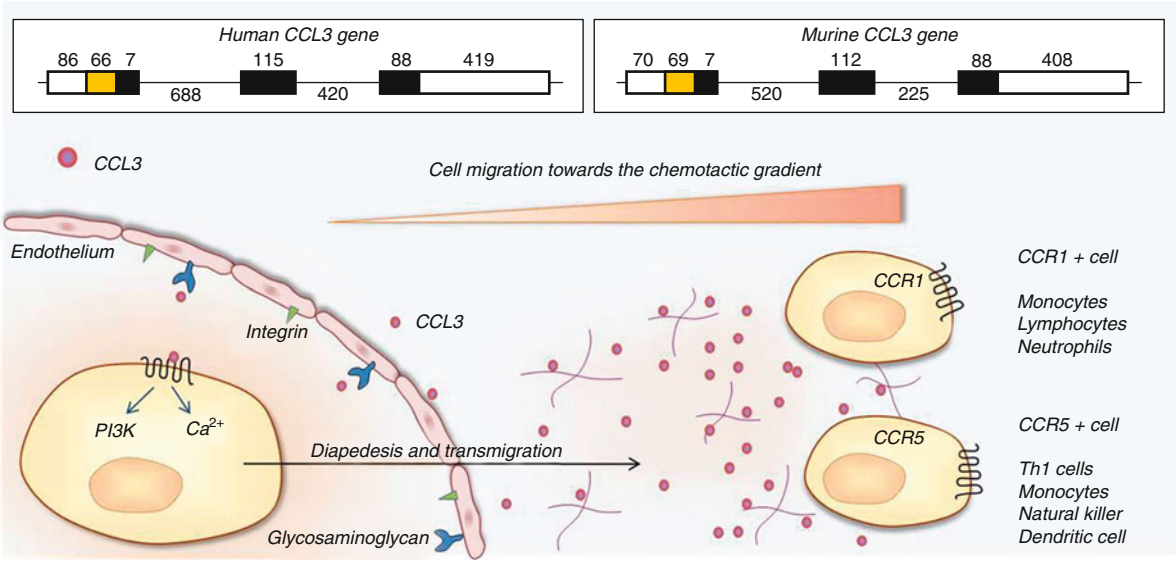
CCL3 was initially described in 1988, as a partially purified 8-kDa protein doublet from conditioned medium of endotoxin-stimulated mouse macrophages. In the view of its prominent proinflammatory chemotactic role, characterized both in vivo and in vitro at that time, this protein was denominated "macrophage inflammatory protein-1 alpha" (MIP-1α). Subsequently, a high nucleotide sequence similarity (69%) was found between the murine MIP-1α cDNA and a reported human cDNA cloned from stimulated lymphocytes, initially called LD78α or GOS19, assuming to be the human counterpart to murine MIP-1α (Wolpe et al. 1988; Menten et al. 2002; Maurer and von Stebut 2004). Interestingly, human and murine MIP-1α has been independently isolated in many laboratories in relatively short time spam, and has been named differently by each group. Similarly, several other cytokines with chemotactic abilities were identified, leading to the introduction of a new classification and nomenclature introduction for the designation of the chemokines, in which, murine MIP-1α and human MIP-1α/LD78α have been renamed CCL3 (Zlotnik and Yoshie 2000).

Collectively, chemokines are defined as small (8–14 KDa) proteins of cytokine family that have a broad range of activities involved in the recruitment and function of specific population of leukocytes at site of inflammation, presenting therefore important roles in the initiation and maintenance of host inflammation. These chemoattractive cytokines are subdivided into four groups based on a cysteine (C) motif, CXC, CC, C, and CX3C (Menten et al. 2002; Maurer and von Stebut 2004; Rollins 1997). In the view chemokine classification, CCL3 is characterized structurally and functionally as an inducible and secreted proinflammatory chemokine of the CC subfamily.

CCL3 Gene and Production

Both murine and human CCL3 are encoded by genes comprising three exons and two introns located on chromosome 11, which code for a 92 amino acids pre-protein. During secretion process a signal peptide of the precursor protein is cleaved off to yield their corresponding mature protein. Mature murine CCL3 contains 69 amino acids and has a theoretical M_r of 7883.9 *Da*. For human CCL3 precursor protein, the recognition site for the signal peptidase may present slight variations (still unclear), and hence the exact length of the mature protein between 66 and 70 residues is still a matter of debate (Fig. 1) (Menten et al. 2002; Hirashima et al. 1992).

While some chemokines expression is characteristically constitutive, CCL3 gene expression is basically inducible in most mature hematopoietic cells, being only very low levels expressed constitutively. In fact, while monocytes and macrophages present just low levels of CCL3 mRNAi, upon stimulation with a relatively wide range of stimuli, including PAMPs (pathogen-associated molecular patterns) such as LPS from Gram-negative bacteria and lipoteichoic acids from Gram-positive bacteria, superantigens such as the lectin phytohemagglutinin (PHA), or innate and adaptive cytokines such as IL-1β



CCL3, Fig. 1 *Schematic illustration of CCL3 structure and function*. The structures of human and murine CCL3 gene comprise exons divided in untranslated sequences (*light boxes*), translated leader sequences (*yellow boxes*) and translated mature protein sequences (*dark boxes*), and two intron sequences presented as *horizontal lines*; the lengths of the segments are indicated in bp. In the CCL3 gene structure, a cell migration toward a chemotactic gradient by diapedesis transmigration and the signaling pathways triggered by CCL3 in leukocyte are represented. On the *right side* of the panel are represented the cells chemoattracted by CCL3 by means of specific chemokine receptors, namely CCR1 and CCR5

and ▶ IFN-γ, a significant CCL3 secretion was observed in human monocytes/macrophages. Neutrophils have been shown to secrete CCL3 when stimulated by microbial antigens. Not only phagocytes, but also lymphocyte populations have been showed to secrete CCL3 when stimulated with PAMPs or superantigens. In addition, it was reported that antigen binding to B cell receptors (BCR) induced CCL3 production by B cells. Natural killer cells were also shown to efficiently produce CCL3 upon stimulation with IL-12 and IL-15. Interestingly, the co-stimulation provided by cytokines increases the stability of the LPS-induced CCL3 mRNA, demonstrating a convergence of proinflammatory signals toward an augmented CCL3 production. In contrast, inhibition of the LPS-mediated CCL3 production in monocytes was reported upon addition of anti-inflammatory and/or Th1-type cytokines such IL-4, IL-10, IL-13, and also by the classic anti-inflammatory and immunosuppressant glucocorticoid dexamethasone. Indeed, IL-10 suppressed the LPS-induced release of CCL3 via an accelerated degradation of CCL3 mRNA (Menten et al. 2002; Maurer and von Stebut 2004; Cook 1996).

CCL3 Receptors

To discover the role of determined chemokine, the researchers started by looking at the receptor usage and the biological responses of the cell types. Chemokine receptors characteristically are G protein-coupled receptors containing seven transmembrane domains that are found predominantly on the surface of leukocytes, being the 19 different chemokine receptors characterized to date expressed by leukocyte subpopulations with distinct degrees of selectiveness and specificness. Indeed, although chemokine receptors share high amino acid identity in their primary sequences, they typically bind a limited number of ligands.

As a CC-family member, CCL3 chemokines mediate their biological effects by binding to cell surface CC chemokine receptors (3×10^4 to 5×10^5 receptors per cell). Receptor binding involves high affinity interactions and a subsequent cascade of intracellular events that rapidly leads to a wide range of target cell functions including chemotaxis, degranulation, phagocytosis, and mediator synthesis. Signal transduction events are initiated by G protein complex leading to its dissociation into Gα and Gβ subunits. Gα induces ▶ phosphoinositide 3-kinase (PI3K) pathway

activation, and Gβγ subunits activate phospholipase C and induce Ca^{2+} influx resulting in the protein kinase C isoform activation. It has also been shown that ▶ MAP kinases as well as the JAK/STAT signaling cascade are involved (Maurer and von Stebut 2004; Proudfoot et al. 2003). The overall effect of chemokine receptor signaling involves the activation of specific cellular mechanisms related to leukocyte migration (such as changes in the avidity of cell adhesion molecules [called integrins] and activation of mechanisms involved in diapedesis) and activation (such as degranulation, polarization, and effector functions) (Maurer and von Stebut 2004).

Human chemokine CCL3 can bind in two specific chemokine receptors, namely, CCR5 and CCR1; while murine CCL3 is able to bind to the CCR1, CCR3, CCR5, and D6 receptors (Fig. 1) (Menten et al. 2002). From a therapeutic point of view it is more interesting to identify the chemokine receptors involved in the control of recruitment of the principal cell type responsible for the initiation and resolution of inflammatory immune responses in lymphoid and peripheral tissues (Horuk 2001).

Analysis of chemokine receptors has revealed using chemokines radiolabeled to demonstrate the presence of specific cell surface binding sites on many cell types. Not different, the first human CC chemokine receptor was isolated using several labeled chemokines, including LD78α. This receptor was designed CC-CKR1, but it has been renamed CCR1 to fit with the new nomenclature (Menten et al. 2002; Zlotnik and Yoshie 2000; Neote et al. 1993). The gene encoding human CCR1 has been mapped to chromosome 3p21, in a cluster with several other chemokine receptor genes (CCR2, CCR3, CCR4, CCR5, CCR8, CCR9, XCR1, CX3CR1). Using polyclonal antibodies to CCR1 the receptor has been shown to be predominantly expressed on monocytes and lymphocytes. On neutrophils, CCR1 can be expressed upon induction with specific cytokines. However, mouse neutrophils express CCR1 constitutively. Furthermore, CCR1 mRNA has been detected in human dendritic cells and eosinophils. CCR1 is expressed in leukocytes from a broad range of species including rhesus, rabbit, rat, and mouse, and there is a high degree of sequence homology among all these sequences. The CCR1 seven-membrane protein consists of 355 amino acid residues and belongs to the peptide subfamily of Class A GPCR family. This chemokine receptor is thought to predominantly signal through Gi/o couple pathway to regulate calcium flux, inhibit adenyl cyclase, and is thought unable to signal via Gq/11 protein. In addition, at least 11 different ligands (chemokines) interact with CCR1, including CCL3 (Cheng and Jack 2008).

In 1996, a second receptor for CCL3 was cloned and, as it was the fifth CC chemokine receptor cloned, named as CC-CKR5 (Samson et al. 1996). This name has been replaced by CCR5 in the new nomenclature; however, it is also called CD195 (Zlotnik and Yoshie 2000). The human CCR5 receptor is encoded by CCR5 gene, located on the short arm at position 21 on chromosome 3. Interestingly, CCR5 is a member of GPCR superfamily and shares 55% identical amino acids with CCR1, the firstly identified CCL3 receptor (Menten et al. 2002). CCR5 is one of the most studied chemokine receptor by the fact that, soon its discovery, CCR5 was shown to function pathologically as a key cell entry co-receptor for HIV-1. Certain population (approximately 20%) has a genetic deletion of a portion of the CCR5 gene (CCR5 Δ32) resulting in a frameshift at amino acid 185 and produces a mutant protein which is not expressed on the cell surface, which may result in distinct functional outcomes regarding inflammatory immune responsiveness (Carrington et al. 1999). In fact, CCR5 play important roles, not only in HIV infection, but also in the elaboration of a specific immune response against a series of pathogens. Lipopolysaccharide, proinflammatory cytokines, and various other stimuli can stimulate the CCR5 expression. This increase of CCR5 expression can influence in the selection of the appropriate effector T cell (i.e., Th1 or Th2) by the way CCR5 is expressed on both Th1 and Th2 lines. Although, it was absent in several Th2 clones markedly influenced by interleukin 2 (Maurer and von Stebut 2004). In addition, CCR5 expression has been detected on primary and secondary lymphoid organs, neurons, capillary endothelial cells, as well as epithelium, endothelium, vascular smooth muscle, fibroblast, Langerhans cells, macrophages, dendritic cells, CD34+ progenitor cells, and thymocytes (CD4+ and CD8+ cells) (Menten et al. 2002; Maurer and von Stebut 2004; Horuk 2001).

In addition to binding to the chemokine receptors, chemokines (including CCL3) characteristically present a carboxyl terminus stretch of positively charged residues that recognize heparan sulfate (HS) glycosaminoglycan (GAGs). Interestingly, chemokines can signal through cognate G protein-coupled receptors

(GPCRs) either at their soluble or immobilized (i.e., glycosaminoglycan associated) states. Recent evidences demonstrate that GAGs are indispensable for immobilization and function of major chemokines required for leukocyte adhesion to and crossing through blood and lymphatic vessels. In fact, chemokines stably immobilized on GAGs at the luminal surface of endothelium prevent their dilution by blood flow, but also to facilitate localized signaling to rolling leukocytes, while GAGs at inflamed tissue contribute to establish a chemotactic gradient that guides the influx of the leukocytes within the tissue. In spite of these versatile functions of HS GAGs in different types of endothelial cells and basement membranes, it is still possible that many extravasation processes involve HS-GAG-independent mechanisms. Interestingly, the presence of HS GAGs on leukocytes do not contribute to their migratory and inflammatory properties, subsets of antigen presenting cells may need to immobilize the chemokines they secrete within particular immune synapses, resulting in local activities essential for adhesion, motility, and survival of the cells involved.

CCL3 Activities

The proinflammatory activities of CCL3 overlap with, but not identical to, the activities of other CC chemokines (Menten et al. 2002; Maurer and von Stebut 2004; Repeke et al. 2010). For example, both CCL3 and ▶ CCL4 induce migration of monocytes and T lymphocytes, but they differ in their effects on different T cell subsets. Thus, while CCL3 is considered primarily chemotactic for B lymphocytes and activated CD8+ T cells, CCL4 is chemotactic for activated CD4+ cells (Fig. 1). Differently of CCL4, CCL3 is able to induce natural killer chemotaxis (Menten et al. 2002; Maurer and von Stebut 2004).

The wide role of CCL3 suggests that this chemokine has an important role in inflammation. In fact, CCL3 participates in the recruitment of monocytes and T cells into the inflamed synovium in rheumatoid arthritis. Furthermore, elevated levels of CCL3 are present in the synovial fluid and tissues of arthritis patients (Patel et al. 2001). High levels of CCL3 are also been detected in the cerebrospinal fluid of patients with bacterial meningitis (Lahrtz et al. 1998). Not different, the upregulation of CCL3 in glomeruli was observed in patients with glomerulonephritis and can be responsible for the part of leukocytes recruitment (Segerer et al. 2000). In addition, CCL3 has been shown to be implicated in many blood cell diseases, such as myeloid leukemia and T cell leukemia (Menten et al. 2002).

To understand the exact role of CCL3, the researchers used embryonic stem cell technology to generate mice homozygous for a disrupted CCL3 gene, called CCL3 knockout (CCL3-KO) or MIP-1KO mice. The homozygous mutant (−/−) mice were born in Mendelian proportions and had no obvious gross or histological abnormalities, indicating that CCL3 is not required for normal development (Cook 1996). The absence of CCL3 in CCL3-KO mice have reduced, but not eliminated influenza virus-induced pneumonitis and presented highly resistence to CVB3-induced myocaditis (Cook 1996). Furthermore, CCL3-KO presented reduced scores of autoimmune encephalomyelitis, arthritis rheumatoid, *Trypanosoma cruzi*, and other inflammatory diseases (Cook 1996; Machado et al. 2005). However, the absence of CCL3 had no significant effect in the ability to decrease the effects on the inflammatory response in some chronic diseases, such as periodontal disease. Although, CCL3 is the most abundantly expressed chemokine in diseased periodontium, its absence probably is supplied by a overlap role of the homologous chemokines CCL4 and ▶ CCL5 (Repeke et al. 2010; Silva et al. 2007).

Summary

In conclusion, CCL3 plays an important role in the induction and maintenance of inflammatory immune responses, in the context of both autoimmune reactions and host defense. In this way, this interest chemokine has shown as an important protein in the body operation, still not appears such as an essential life protein. In addition CCL3 might therefore play an important role in the pathogenesis of inflammatory diseases, such as arthritis, pneumonitis, leukemia, AIDS and others, which would have implications for design of new therapeutic strategies.

Synonyms

Macrophage inflammatory protein-1 beta

Historical Background

CCL4 was initially described in 1988, as a partially purified 8-kDa protein doublet from conditioned medium of endotoxin-stimulated mouse macrophages. In the view of its prominent proinflammatory chemotactic role, characterized both in vivo and in vitro at that time, this protein was denominated macrophage inflammatory protein-1 (MIP-1). Further biochemical experimentation resulted in the separation and characterization of two distinct but highly related proteins, then renamed as MIP-1α and MIP-1β. Also in 1988, the human equivalent of MIP-1β (Act-2, AT 744) was independently cloned by different groups and similarly, several other cytokines with prominent chemotactic properties were identified, leading to the introduction of a new classification and nomenclature introduction for the designation of the chemokines, in which, murine MIP-1β and human MIP-1β have been renamed CCL4 (Zlotnik and Yoshie 2000).

Collectively, chemokines are defined as small (8–14 kDa) proteins of cytokine family that have a broad range of activities involved in the recruitment and function of specific population of leukocytes at site of inflammation, presenting therefore important roles in the initiation and maintenance of host inflammation. These chemoattractive cytokines are subdivided into four groups based on a cysteine (C)

motif, CXC, CC, C, and CX3C (Rollins 1997; Menten et al. 2002; Maurer and von Stebut 2004). In the view of chemokine classification, CCL4 is characterized structurally and functionally as an inducible and secreted proinflammatory chemokine of the CC subfamily.

CCL4 Gene and Production

Murine CCL4 is encoded by a single gene on chromosome 11, which consists of three exons and two introns (Widmer et al. 1993). In addition, murine CCL4 gene also codes for a pre-protein of 92 amino acids with a theoretical M_r of 7826.9 Da and has a sequence homology of 60% with murine CCL3, a homologous CC family chemokine.

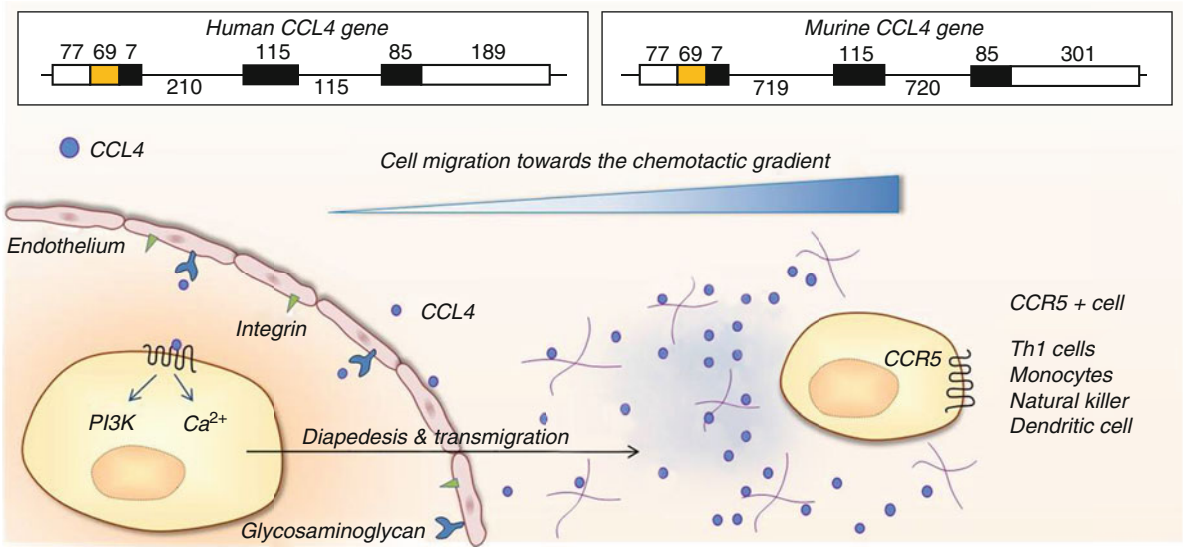
The human CCL4 gene (AT 744.1) is closely linked to human CCL5 gene on chromosome 17. The human CCL4 gene contains three exons and two introns, and codes a pre-protein of 92 amino acids, similar to the murine CCL4 (Fig. 1). The 3′untranslated regions of the murine and human CCL4 cDNAs contain a polyadenylation site (AATAAA) and several AT-rich sequences (Menten et al. 2002; Widmer et al. 1993).

The three-dimensional structure of human CCL4 has been defined by heteronuclear magnetic resonance analysis. It has shown that CCL4 exists as a symmetrical homodimer. Within each human CCL4 subunit (monodimer), the main secondary structure elements comprise a triple-stranded antiparallel β sheet arranged in a Greek key structure on top of which lies an α-helix. The NH_2-terminus consists of an irregular strand and a series of non-classical turns that form a long loop. This loop is followed by a four-residue helical turn, which leads into strand β_1. The two disulfide bridges, present in CCL4, have a left-handed spiral conformation (Menten et al. 2002; Lodi et al. 1994).

About CCL4 cell production, it have been demonstrated that monocytes produce high amounts of CCL4 when stimulated with LPS or IL-7 (Menten et al. 2002; Lukacs et al. 1995). This CCL4 production is counteracted by addition of IL-4, which reduces level of CCL4 mRNA expression. Activated T- and B- cells which have been triggered by antigen binding also secrete CCL4. Furthermore, NK cells are a good source of CCL4 by physiological activation signals, such as cross-linking of their Fc receptors or lysis of target cells (Menten et al. 2002; Oliva et al. 1998). In addition, brain microvessel endothelial cells were found to release CCL4 following stimulation with LPS, TNF-α, IFN-γ, or IL-1β, and pulmonary vascular smooth muscle cells–secreted CCL4 after addition of IL-1β, TNF-α IL-4, IFN-γ, and IL-10 (Menten et al. 2002; Lukacs et al. 1995; Shukaliak and Dorovini-Zis 2000). Finally, dendritic cells have also been shown to produce CCL4 in response to LPS, TNF-α, or CD40 ligand (Menten et al. 2002).

CCL4 Receptors

In 1996, the first receptor for CCL4 was identified as CC-CKR5, the fifth CC chemokine receptor cloned (Samson et al. 1996). This name has been replaced by CCR5 in the new chemokine system nomenclature, however, it is also still called CD195 (Zlotnik and Yoshie 2000). The human CCR5 receptor is encoded by CCR5 gene, located on the short arm at position 21 on chromosome 3. Interestingly, CCR5 is a member of GPCR superfamily and shares 55% identical amino acids with CCR1, the firstly identified CCL3 receptor (Menten et al. 2002). CCR5 is one of the most studied chemokine receptor by the fact that, soon its discovery, CCR5 was shown to function pathologically as a key cell entry co-receptor for HIV-1. Certain population (approximately 20%) has a genetic deletion of a portion of the CCR5 gene (CCR5 Δ32) resulting in a frameshift at amino acid 185 and produce a mutant protein which is not expressed on the cell surface, which may result in distinct functional outcomes regarding inflammatory immune responsiveness (Carrington et al. 1999). In fact, CCR5 plays important roles, not only in HIV infection, but also in the elaboration of a specific immune response against a series of pathogens. Lipopolysaccharide, proinflammatory cytokines, and various other stimuli can stimulate the CCR5 expression. This increase of CCR5 expression can influence in the selection of the appropriate effector T-cell (i.e., Th1 or Th2) by the way CCR5 is expressed on both Th1 and Th2 lines. Although, it was absent in several Th2 clones markedly influenced by IL-2 (Maurer and von Stebut 2004). In addition, CCR5 expression has been detected on primary and secondary lymphoid organs, neurons, capillary endothelial cells, as well as epithelium, endothelium, vascular smooth muscle, fibroblast, Langerhans cells, macrophages, dendritic cells,



CCL4, Fig. 1 *Schematic illustration of CCL4 structure and function*. The structures of human and murine CCL4 gene comprise exons divided into untranslated sequences (*light boxes*), translated leader sequences (*yellow boxes*) and translated mature protein sequences (*dark boxes*) and two intron sequences presented as horizontal lines; the lengths of the segments are indicated in bp. Below CCL4 gene structure, a cell migration toward a chemotactic gradient by diapedesis transmigration and the signaling pathways triggered by CCL4 in leukocyte are represented. On the *right* side of the panel are represented the cells chemoattracted by CCL3 by means of specific chemokine receptors, namely, CCR5

CD34+ progenitor cells, and thymocytes (CD4+ and CD8+ cells) (Fig. 1) (Menten et al. 2002; Maurer and von Stebut 2004; Horuk 2001).

In addition to binding to the chemokine receptors, chemokines (including CCL3) characteristically present a carboxyl terminus stretch of positively charged residues that recognize heparan sulfate (HS) glycosaminoglycan (GAGs). Interestingly, chemokines can signal through cognate G protein coupled receptors (GPCRs) either at their soluble or immobilized (i.e., glycosaminoglycan associated) states. Recent evidences demonstrate that GAGs are indispensable for immobilization and function of major chemokines required for leukocyte adhesion to and crossing through blood and lymphatic vessels. In fact, chemokines stably immobilized on GAGs at the luminal surface of endothelium prevent their dilution by blood flow but also facilitate localized signaling to rolling leukocytes, while GAGs at inflamed tissue contribute to establish a chemotactic gradient that guides the influx of the leukocytes within the tissue. In spite of these versatile functions of HS GAGs in different types of endothelial cells and basement membranes, it is still possible that many extravasation processes involve HS-GAG-independent mechanisms. Interestingly, the presence of HS GAGs on leukocytes do not contribute to their migratory and inflammatory properties, and subsets of antigen-presenting cells may need to immobilize the chemokines they secrete within particular immune synapses, resulting in local activities essential for adhesion, motility, and survival of the cells involved.

CCL4 Activities

When analyzed in vitro in a microchamber chemotaxis assay, CCL4 was shown to be potent lymphocyte chemoattractant. Lymphocyte migration from blood into tissues depends on the integrin-mediated adhesion of lymphocytes to the endothelium. Adhesion requires not only the presence of integrins on the surface of leukocytes, but also the activation of these molecules by chemokines. CCL4 was shown to be effective in augmentation adhesion of T lymphocytes to the integrin vascular cell adhesion molecule 1 (VCAM-1, or CD106) (Menten et al. 2002; Tanaka et al. 1993). In addition, CCL4 is potent chemoattractant for immature dendritic cells, but appears to be totally inactive on basophils (Fig. 1).

A series of studies demonstrate that CCL4 has an important role in inflammation. In fact, CCL4 participates in the recruitment of monocytes and T-cells into the inflamed synovium in rheumatoid arthritis. Furthermore, elevated levels of CCL4 are presented in the synovial fluid and tissues of arthritis patients (Patel et al. 2001). High levels of CCL4 have also been detected in the cerebrospinal fluid of patients with bacterial meningitis (Lahrtz et al. 1998). No difference, the upregulation of CCL4 in glomeruli was observed in patients with glomerulonephritis and can be responsible for the part of leukocytes recruitment (Segerer et al. 2000). Furthermore, CCL4 has been detected during rejection of liver transplant, and CCL4 has been associated with chronic hepatitis C infection (Adams et al. 1996).

Interestingly, since CCL4 shares the binding to CCR5 with the analogous chemokines CCL3 and CCL5, these factors are thought to operate in a complex network that regulates cell traffic in a given tissue. Interestingly, the redundancy (more than one chemokine can ding the same receptor) and the promiscuity (one chemokine can bind to more than one receptor) are characteristics that confer a robustness to the chemokines/chemokine receptors system. Indeed, the robustness is a common feature of many cytokine and growth factor networks that assure their proper performance, since the outputs of these cytokine networks may be retained to a sufficient extent, even if genetic or epigenetic alterations affect qualitatively or quantitatively individual network components. However, robustness, redundancy, and promiscuity also difficult, the study of individual factor roles within these systems, being the role of chemokine receptors, usually more easily unraveled in details than its chemokine ligands.

Summary

In conclusion, CCL4 plays an important role in the induction and maintenance of inflammatory immune responses, in the context of both autoimmune reactions and host defense. In addition, CCL4 might therefore play an important role in the pathogenesis of inflammatory diseases than previously thought, which would have implications for design of new therapeutic strategies.

RANTES

Historical Background

CCL5 was initially described in 1988 and this new protein was named for its characteristics: Regulated upon Activation expressed by Normal T cells and presumably Secreted (RANTES) (Schall et al. 1988). A relatively new technology, at the time, was used to indentify RANTES, subtraction cDNA libraries, which help to distinguish genes expressed in one cell and not in another. This genetic approach has since led to the uncovering of close to 50 other chemokines and, in order to clarify the nomenclature of all chemokines and their receptors, a new nomenclature has been introduced, in which, RANTES has been renamed CCL5 (Zlotnik and Yoshie 2000). CCL5 was first discovered in T cell–specific cDNA, and this initial report on CCL5 placed further attention on a new family of chemotactic proteins that proved to be important in influencing a series of biologic and pathological processes (Levy 2009).

Collectively, chemokines are defined as small (8–14 kDa) proteins of cytokine family that have a broad range of activities involved in the recruitment and function of specific population of leukocytes at site of inflammation, presenting therefore important roles in the initiation and maintenance of host inflammation. Four classes of chemokines have been discovered, based on the conserved cysteine (C) residues on the mature protein CXC, CC, C, and CX3C. In the view chemokine classification, CCL5 is characterized structurally and functionally as an inducible and secreted proinflammatory chemokine of the CC subfamily (Conti and DiGioacchino 2001).

CCL5 Gene and Production

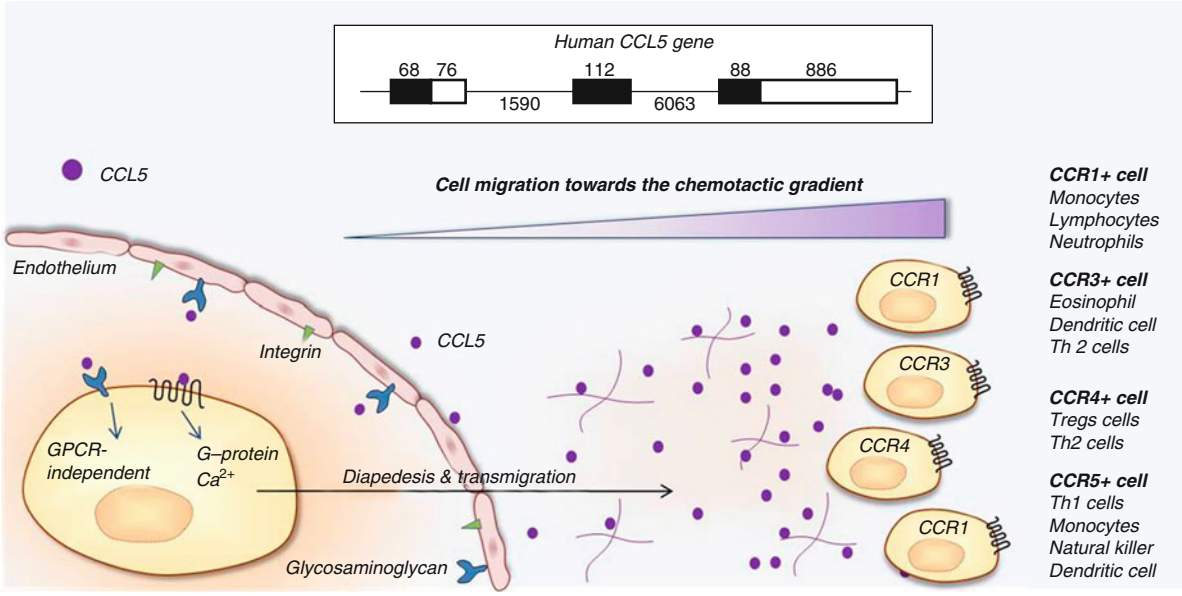
The CCL5 gene is located on the short arm of chromosome 17 (17q11.2); this gene product is predicted to be 10 kDa and, after cleavage of the signal peptide, approximately 8 kDa. Of 68 residues of CCL5, four are cysteines, and there are no sites for N-linked glycosylation (Fig. 1).

Initially, this chemokine was considered a T cell–specific protein; however, it was demonstrated that CCL5 can be produced by many cells in the vertebrate body including platelets, macrophages, eosinophils, and fibroblasts, as well as endothelial, epithelial, and endometrial cells. Interestingly, while stimulation of T cells inhibits the expression of CCL5, whereas as a general rule in the other cells mentioned, synthesis of CCL5 is induced by TNF-α and IL-1α but not by TGFβ, IFNγ, and IL-6 (Graziano et al. 1999).

CCL5 increases the adherence of monocytes to endothelial cells. It selectively supports the migration of monocytes and T lymphocytes expressing the cell surface markers CD4 and UCHL1. These cells are thought to be pre-stimulated helper T cells with memory T cell functions. CCL5, although activating human basophils and causing histamine release from some donor cells, has also been found to inhibit the release of histamine from basophils induced by several cytokines (Graziano et al. 1999). In addition, CCL5 is a potent eosinophil-specific activator of oxidative metabolism, and it also changes the density of eosinophils, making the hypodense, which are thought to represent a state of generalized cell activation. These cells are most often associated with diseases such as asthma and allergic rhinitis (Graziano et al. 1999; Appay and Rowland-Jones 2001).

CCL5 Receptors

Analysis of chemokine receptors using radiolabeled chemokines has the presence of specific cell surface binding sites on many cells type. Interestingly, CCR5 was one of the chemokines used to characterize the first human CC chemokine receptor isolated. This receptor was initially designated CC-CKR1, but it has been renamed CCR1 to fit with the new chemokine system nomenclature (Fig. 1) (Zlotnik and Yoshie 2000; Menten et al. 2002; Neote et al. 1993).



CCL5, Fig. 1 Schematic illustration of CCL5 structure and function. The structures of human and murine CCL5 gene comprise exons divided in untranslated sequences (*light boxes*), translated leader sequences (*yellow boxes*) and translated mature protein sequences (*dark boxes*), and two intron sequences presented as *horizontal lines*; the lengths of the segments are indicated in bp. Below the CCL5 gene structure, a cell migration toward a chemotactic gradient by diapedesis transmigration and the signaling pathways triggered by CCL5 in leukocyte are represented. On the *right side* of the panel are represented the cells chemoattracted by CCL3 by means of specific chemokine receptors, namely, CCR1, CCR3, CCR4, and CCR5

The gene encoding human CCR1 has been mapped to chromosome 3p21, in a cluster with several other chemokine receptor genes (CCR2, CCR3, CCR4, CCR5, CCR8, CCR9, XCR1, CX3CR1). Using polyclonal antibodies to CCR1, the receptor has been shown to be predominantly expressed on monocytes and lymphocytes. On neutrophils, CCR1 can be expressed upon induction with specific cytokines. However, mouse neutrophils express CCR1 constitutively. Furthermore, CCR1 mRNA has been detected in human dendritic cells and eosinophils. CCR1 is expressed in leukocytes from a broad range of species including rhesus, rabbit, rat, and mouse, and there is a high degree of sequence homology among all these sequences. The CCR1 seven-membrane protein consists of 355 amino acid residues and belongs to the peptide subfamily of Class A GPCR family. This chemokine receptor is thought to predominantly signal through Gi/o couple pathway to regulate calcium flux, inhibit adenyl cyclase, and is thought unable to signal via Gq/11 protein. In addition, at least 11 different ligands (chemokines) interact with CCR1, including ▶ CCL3 (Cheng and Jack 2008).

The second CCL5 chemokine receptor cloned is named CCR3, which is primarily expressed by eosinophils and appears to play an important role in regulating the migration of these cells. After the initial report of the first CCR3 clone, the same group showed that eotaxin, an eosinophil-selective CC chemokine and currently named CCL11, was a potent agonist for CCR3. Finally, in 1996, it was demonstrated that the CC chemokine CCL5 was also functional CCR3 agonist. Having noted the importance of CCR3 for eosinophil responses, subsequent studies demonstrate that this receptor and its cognate ligands such as CCL5 are directly involved in Th2-type responses and play an important role in allergy including asthma and atopic dermatitis. Furthermore, CCR3 was shown by several groups to be a HIV-1 co-receptor, and it is expressed on microglial cells of the brain, promoting disease like AIDS dementia, and also expressed in dentritic cells, play a role there in HIV-1 infection.

Another CCL5 chemokine receptor is called CCR4, and it was originally cloned from a human basophilic leukemia cell line library (Power et al. 1995; Horuk 2001). Nowadays, current literature describes that

CCR4 and its ligands are important for regulating immune balance and is known to be expressed selectively on Th2 cells and Treg cells; with special regard to the relationship between CD4 + CD25 + FOXp3+ Treg subset and CCR4 (Horuk 2001; Ishida and Ueda 2006). In a subset of patients with CCR4+ T cell leukemia/lymphoma, the tumor cells themselves function as Treg cells, contributing to tumor survival in the face of host antitumor immune responses. In other types of cancer, the specific ligand chemokines for CCR4 such as CCL5 that are produced by tumor cells and the tumor environment, attract Tregs cells to the tumor, where they create a favorable environment for tumor escape from host immune response (Ishida and Ueda 2006). In addition, CCR4 is known to modulate T cell migration to several sites of inflammation in the body and play a central role in T cell migration to the thymus, and T cell maturation and education (Ishida and Ueda 2006).

In 1996 was cloned the fifth CC chemokine receptor, named CC-CKR5 (Samson et al. 1996). This name has been replaced by CCR5 in the new nomenclature; however, it is also still called CD195 (Zlotnik and Yoshie 2000). The human CCR5 receptor is encoded by CCR5 gene, located on the short arm at position 21 on chromosome 3. Interestingly, CCR5 is a member of GPCR superfamily and shares 55% identical amino acids with CCR1, the firstly identified CCL5 receptor (Menten et al. 2002). CCR5 is one of the most studied chemokine receptor by the fact that, soon its discovery, CCR5 was shown to function pathologically as a key cell entry co-receptor for HIV-1. Certain population (approximately 20%) has a genetic deletion of a portion of the CCR5 gene (CCR5 Δ32) resulting in a frameshift at amino acid 185 and produces a mutant protein which is not expressed on the cell surface, which may result in distinct functional outcomes regarding inflammatory immune responsiveness (Carrington et al. 1999). In fact, CCR5 play important roles, not only in HIV infection, but also in the elaboration of a specific immune response against a series of pathogens. Lipopolysaccharide, proinflammatory cytokines, and various other stimuli can stimulate the CCR5 expression. This increase of CCR5 expression can influence in the selection of the appropriate effector T cell (i.e., Th1 or Th2) by the way CCR5 is expressed on both Th1 and Th2 lines. Although, it was absent in several Th2 clones markedly influenced by interleukin 2 (Maurer and von Stebut 2004). In addition, CCR5 expression has been detected on primary and secondary lymphoid organs, neurons, capillary endothelial cells, as well as epithelium, endothelium, vascular smooth muscle, fibroblast, Langerhans cells, macrophages, dendritic cells, CD34+ progenitor cells, and thymocytes (CD4+ and CD8+ cells) (Menten et al. 2002; Horuk 2001; Maurer and von Stebut 2004).

In addition to the binding to the chemokine receptors, chemokines (including CCL5) characteristically present a carboxyl terminus stretch of positively charged residues that recognize heparan sulfate (HS) glycosaminoglycan (GAGs). Interestingly, chemokines can signal through cognate G protein coupled receptors (GPCRs) either at their soluble or immobilized (i.e., glycosaminoglycan associated) states. Recent evidences demonstrate that GAGs are indispensable for immobilization and function of major chemokines required for leukocyte adhesion to and crossing through blood and lymphatic vessels. In fact, chemokines stably immobilized on GAGs at the luminal surface of endothelium prevent their dilution by blood flow but also to facilitate localized signaling to rolling leukocytes, while GAGs at inflamed tissue contribute to establish a chemotactic gradient that guides the influx of the leukocytes within the tissue. In spite of these versatile functions of HS GAGs in different types of endothelial cells and basement membranes, it is still possible that many extravasation processes involve HS-GAG-independent mechanisms. Interestingly, the presence of HS GAGs on leukocytes do not contribute to their migratory and inflammatory properties, subsets of antigen presenting cells may need to immobilize the chemokines they secrete within particular immune synapses, resulting in local activities essential for adhesion, motility, and survival of the cells involved (Horuk 2001).

On T cells, CCL5 can act by two quite separate signaling pathways. At nanomolar concentrations, CCL5 acts as a typical chemokine, by the GPCR-mediated pathway, as described above. And, at micromolar concentrations, CCL5 also triggers a distinct herbimycim A-sensitive ▶ protein tyrosine kinase (PTK)-mediated pathway (GPCR independent), leading to prolonged calcium influx, hyperphosphorylation, and generalized cell activation. The exact signaling pathways of CCL5 on T cells appear to be very complex and are not yet fully characterized,

especially as the same kinases can be induced within both the GPCR and GPCR-independent signaling pathways (e.g., ZAP-70 and p125). The ability of CCL5 to induce the GPRC-independent pathway and activate leukocytes is a distinct and important feature of the biology of this unusual chemokine. However, because high, and perhaps non-physiological, concentrations of CCL5 are required to demonstrate this phenomenon, its relevance remains unclear (Appay and Rowland-Jones 2001).

CCL5 Activity

CCL5 is a potent chemoattractant for memory T lymphocytes, monocytes, and eosinophils (Fig. 1). It was found highly expressed in activated T lymphocytes, macrophages, fibroblasts, platelets, mesangial cells, epithelial cells, megakaryocytes, and some tumors (Graziano et al. 1999; Appay and Rowland-Jones 2001). The activity of the chemokine CCL5 is not restricted merely to chemotaxis. It is a powerful leukocytes activator, a feature potentially relevant in a range of inflammatory disorders (Conti and DiGioacchino 2001). In fact, increased CCL5 expression has been associated with a wide range of inflammatory disorders and pathologies, including allogeneic transplant rejection, atherosclerosis, arthritis, atopic dermatitis, inflammatory airway disorders such as asthma, delayed-type hypersensitivity reactions, glomerulonephritis, endometriosis, some neurological disorders (such as Alzheimer's disease), and certain malignancies. In all these pathologies, CCL5 is thought to act by promoting leukocytes infiltration to site of inflammation (Appay and Rowland-Jones 2001).

At high concentration, CCL5 is able to induce the activation of T cells. This activation induced by CCL5 is followed by many diverse effects, including T-cell proliferation and apoptosis and the release of proinflammatory cytokines such as Interleukin 2 (IL-2), IL-5, interferon (IFN) –γ, and ▶ CCL4. CCL5-induced activation is not only restricted to T cells, but can also extend to monocytes and neutrophils, where similar dual-signaling pathways are induced (Graziano et al. 1999; Appay and Rowland-Jones 2001). Furthermore, CCL5 not only play a key role in cells activation and inflammatory diseases but also in the immune response to viral infection. In 1995, CCL5 was shown to be the most potent member of a trio CC chemokines (CCL3-5) release by CD8+ T cells that were able to suppress the replication of non-syncitium-inducing (NSI) HIV-1 strains in vitro (Appay and Rowland-Jones 2001; Cocchi et al. 1995).

In the view of the relative unspecificity of CCL5, a modified version of this chemokine was developed by the removal of the two N-terminal residues of CCL5 in order to create a partial agonist of chemokine receptors, and consequently therapeutically interfere with chemokine-based cell migration. This compound, named Met-RANTES, was described to function as a chemotaxis inhibitor and more effectively blocks CCR5-mediated HIV 1 infection of monocytes. Met-RANTES was initially produced during the synthesis of recombinant RANTES by the extension of the product with a single methionine residue, and its treatment was extensively studied in inflammatory bone diseases, such as arthritis rheumatoid (AR) and PD (Doodes et al. 2009; Repeke et al. 2010; Proudfoot et al. 1996). Furthermore, studies demonstrated the ability of met-RANTES treatment to extenuate tissue injury in models of arthritis, renal inflammation, and experimental colitis, among other (Doodes et al. 2009). Similarly, met-RANTES was able to decrease the experimental periodontal disease scores such as alveolar bone loss and inflammatory cell influx (Repeke et al. 2010). Interference with this homologous chemokine production or activity by blocking target receptors represents a potential novel therapeutic strategy in chronic inflammatory disease (Wells et al. 1999).

Summary

In summary, CCL5 plays a key physiological role in T cell migrations and in the inflammation disorders, inducing leukocyte infiltration and activation. CCL5 might therefore play an important role in the pathogenesis of inflammatory diseases than previously thought, which would have implications for design of new therapeutic strategies.

Historical Background

In the early 1990s, three gene products with novel structural similarity were identified. The first member was discovered as a factor induced upon growth factor stimulation and was designated as cysteine-rich 61 (Cyr61), based on its structural characteristics. The second member was purified as a platelet growth factor–related molecule with a mitogenic effect on fibroblasts and, thus, it was initially named connective tissue growth factor (CTGF). Subsequently, a gene with structural similarity to the above two genes was found to be overexpressed in nephroblastomas, which provided the name nephroblastoma-overexpressed (NOV) gene to this third member. Based on these findings, the acronym of the names of these three genes, CCN, was given for the first time as the family name by Bork (1993). Thereafter, the other three members were identified as tumor suppressor–like gene products, or Wnt-inducible secreted proteins, in 1998; however, no CCN-related names were assigned to them (Perbal and Takigawa 2005). As such, a number of different names were confusingly given to the six genes encoding structurally quite similar proteins. In order to solve this problem, a unified nomenclature was proposed at the second International Workshop on the CCN Family of Genes and was approved by major researchers in this field in 2002. This proposal

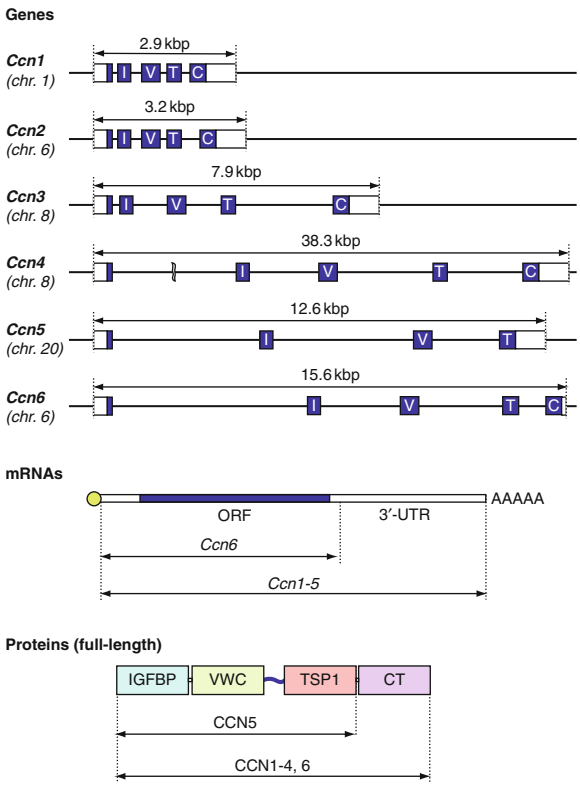
was published in 2003 to encourage comprehensive progress in the research on this novel family of genes and their products (Brigstock et al. 2003).

Structure

In the human genome, the six CCN family members are distributed on five chromosomes. Only *ccn2* and *ccn6* share the same chromosome, number 6, with a significant distance between them. The transcribed area of each gene consists of the first exon with a 5′-untranslated region (UTR) and a small portion encoding the signal peptide for secretion, a few intermediate exons corresponding to the amino-terminal and intermediate modules, and the last exon encoding the carboxy-terminal module with the 3′-UTR, together with the interspersed introns of diverse sizes. It should be noted that the exon-intron boundaries in these genes exactly correspond to those between the modules in their proteins, suggesting that these genes were established through exon shuffling during animal evolution (Kubota and Takigawa 2007a; Chen and Lau 2009). The prototypic gene of the six members is anticipated to be either *ccn1* or *ccn2* since these genes are quite compact with short introns. The genetic promoter for *ccn2* has been profoundly characterized, as described later on; whereas investigation of those promoters in the others is currently not (Leask and Abraham 2006).

Except for *ccn6*, the typical forms of the mRNAs of the CCN family members are characterized by the retention of the 3′-UTR of significant lengths, which suggests the functional significance of these 3′-UTRs. Indeed, the regulatory function of the 3′-UTR of *ccn2* was exclusively analyzed, and its role in posttranscriptional gene regulation was uncovered (Kubota and Takigawa 2007a). Splicing variants lacking 1 or 2 module-encoding exons were reported in the case of *ccn4* and *6* (Perbal and Takigawa 2005).

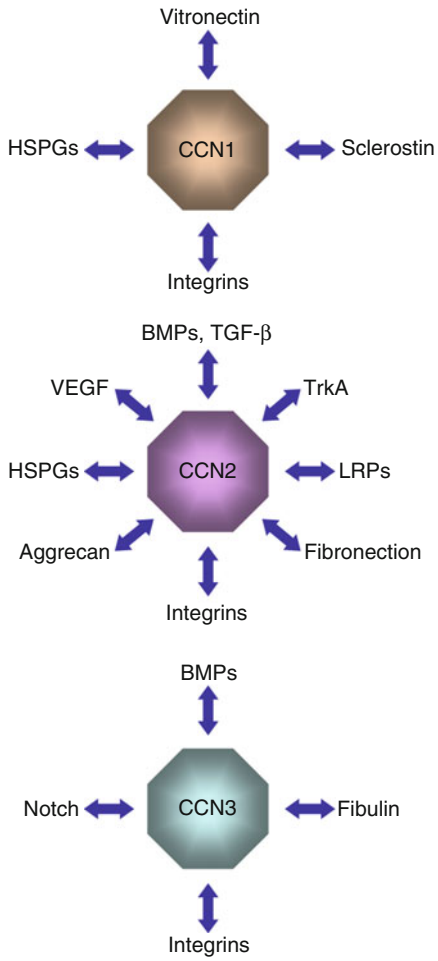
The structures of the resultant proteins encoded by these genes are novel and distinctly analogous. All of the members have four conserved modules referred to as insulin-like growth-factor-binding protein-like (IGFBP), von Willebrand factor type C repeat (VWC), thrombospondin type 1 repeat (TSP1), and C-terminal cystine knot (CT) modules, except for CCN5, which lacks the fourth one (Fig. 1). In addition, as many as 30 cysteine residues are present in each member, which also provides the structural basis for the functional property of CCN family proteins. Indeed, 38 cysteine residues are strictly conserved among mammalian CCN1, 2, 3, and 4. Internal VWC and TSP1 modules are connected by an amino acid stretch designated as the "hinge region" having a variety of lengths. This region is generally susceptible to cleavage by proteinases, which occasionally yield subfragments of the corresponding CCN family proteins. In silico prediction suggests remarkable similarities in the tertiary structures among the IGFBP modules of CCN1, 2, 3, and 6 and IGFBP4; among the VWC modules of all members and chordin; among the TSP1 modules of all members and thrombospondin; and among the CT modules of CCN1, 2, and 3 and BMP-7 (Holbourn et al. 2008).



CCN, Fig. 1 Gene and protein structure of the CCN family members. Abbreviations I, V, T, and C represent IGFBP, VWC, TSP1, and CT module-encoding regions, respectively

Molecular action

As summarized above, CCN family proteins comprise four modules, which may be compared to "hands" since all four modules are highly interactive with other molecules. All they have are four hands; however, CCN family proteins can manipulate a number of biomolecules via multiple interactions with these



CCN, Fig. 2 Interaction of CCN family member proteins with other biomolecules. Abbreviations are defined in the text

hands. Therefore, CCN family proteins are able to play central roles in orchestrating the extracellular signaling network in a variety of microenvironments.

The known interacting counterparts of the classical CCN family members are illustrated in Fig. 2. As stated above, such multiple interactions indeed provide the basis of the molecular behavior and multiple effects of CCN family proteins. Owing to the interaction with extracellular matrix (ECM) components and its biological significance, CCN family proteins are frequently called "matricellular proteins." It should be noted that interaction with integrins is a common property of all of the classical members, which eventually induces certain cellular responses, such as migration and adhesion through the adhesion signaling cascade under collaboration with cell-surface proteoglycans (Chen and Lau 2009). Interaction with other receptor molecules on the cell surface, including low-density lipoprotein receptor-related proteins (LRPs), ▶ Notch, and TrkA receptor protein kinase, also promote or modulate intracellular signal transduction (Kubota and Takigawa 2007b; Katsube et al. 2009). Moreover, CCN family proteins are known to modify the signal emission/transduction by other growth factors through direct binding. The effects of CCN2 on the action of transforming growth factor (TGF)-ß, bone morphogenetic protein (BMP)s, and vascular endothelial growth factor (VEGF) are classical examples, whereas interaction with other growth factors and its biological significance are currently being investigated as well. To date, the biological significance of the mutual interaction between CCN family members themselves has also been indicated (Perbal et al. 2010). As a result of such interplay, a number of major intracellular signaling cascades, which include Wnt, JNK, ▶ p38MAPK, ERK, ▶ PI3K, and PKC-mediated pathways, are modulated by CCN family proteins (Chen and Lau 2009).

In other words, CCN family protein function is highly dependent upon the coexisting molecules in the microenvironment. Thus, the same CCN family member may exert apparently opposite biological effects under different local situations, as typically represented by the differential roles of CCN family proteins in the development of malignancies. On the other hand, it is widely recognized that CCN2 and CCN3 are functionally quite counteractive in skeletal development and renal fibrosis (Perbal et al. 2010). The fundamental difference between CCN2 and CCN3 functions may be established by the preference for their functional counterparts, which is determined by the property of their modules.

Physiological Function

Based on the molecular actions stated, several CCN family proteins, particularly three classical ones, are already known to mediate a variety of biological events occurring throughout tissue and organ development, especially in mesenchymal tissues. A major part of these functions, as represented by the angiogenic function common to all of the classical members, is thought to be the outcome of the common and prominent cell biological effects of promoting adhesion, migration, and proliferation of cells of mesenchymal origin, whose promotion is exerted by the integrin-mediated

matricellular action of these proteins (Kubota and Takigawa 2007b; Chen and Lau 2009). Interestingly, CCN5 is the only member that shows functionality opposite to that described above. Probably, this functional property of CCN5 can be ascribed to its structural property of lacking the CT module since binding sites for proteoglycans, such as heparan sulfate proteoglycan (HSPG)s, including perlecan, have been identified in the CT module in CCN2. Although CCN1, 2, and 3 are functionally quite similar in vitro, as stated below, their role in tissue/organ development significantly differs. These differences can be ascribed to their different temporospatial distribution during development, which is enabled by the proper action of their regulatory machinery for gene expression.

CCN1, 2, and 3 are commonly characterized by their angiogenic functions. However, according to the phenotypic analysis of mutant mice, CCN1 appears to play the most critical part in the angiogenic developmental events. In fact, CCN1-null mice display severe defects in embryonic cardiovascular development. Even the disruption of a single *ccn1* locus was reported to cause defects in the atrial septum of the mutant mice. Compared with that of CCN1, the phenotypic change induced by CCN2 or CCN3 deletion is relatively mild; but it should be noted that CCN3 deficiency induces cardiac septal defects in mice (Chen and Lau 2009).

Concerning the classical members, their involvement in skeletal development can be specified as another common property of these molecules, although the quality of contribution differs for each member. CCN1 is known to promote chondrogenesis, whereas CCN2 plays a central role in endochondral ossification by promoting all of the stages of this process. CCN2 is produced predominantly by growth-plate chondrocytes at late differentiation stages, and is supplied and acts on the cells involved in a matricrine manner. The target cells include osteoblasts and vascular endothelial cells in addition to chondrocytes; hence, intramembraneous ossification also requires CCN2 (Kawaki et al. 2008). The regenerative effects of CCN2 on damaged articular cartilage were also confirmed in vivo. These findings are overall supported by the phenotype of CCN2-null mice (Perbal and Takigawa 2005). Such a profound and multiple functionality of CCN2 in osteogenesis is supposed to be based on the interaction of CCN2 with TGF-ß, BMPs, and other growth factors in the microenvironment. The contribution of CCN3 to skeletal development has been also indicated by previous studies on mutant mice. Overexpression of CCN3 in osteoblasts resulted in osteopenia; and, more interestingly, CCN3 deficiency causes severe joint malformation with appendicular skeletal defects. These findings suggest a critical role of CCN3 in joint formation and morphogenesis (Katsube et al. 2009; Chen and Lau 2009).

In addition to these functional characteristics shared by several members, the cell biological activities unique to each member have been revealed through recent investigations, as summarized in Table 1. The most outstanding of them is the action and effects of CCN3 on the hematopoetic system. It has been recently shown that CCN3 is produced by hematopoietic progenitors, regulates hematopoietic stem cell renewal, and induces clonal expansion of progenitors, in which the latter two actions are based on the interaction of CCN3 with Notch and BMPs (McCallum and Irvine 2009; Katsube et al. 2009). In contrast to those of the classical members, the distinct roles of the other three members in certain tissue/organ development are not yet certain, albeit their significant activities are observed in vitro. A contribution of CCN family members to aging is suggested as well. According to a recent study (Perbal et al. 2010), the expression of *ccn3, 4, 5*, and *6* is elevated in human skin upon aging, suggesting their significant roles in biological processes long after development.

Roles in Pathological Conditions and Wound Healing

Up to the present, a vast number of malignant tumor tissues and cells from a variety of origins have shown increased expression of CCN family members. Particularly, cumulative findings indicate the involvement of classical CCN family members in multiple types of malignancies. Indeed, overexpression of *ccn1* is observed in breast cancer, pancreatic tumors, and other tumors, as shown in Table 2. In the case of *ccn2*, basic and clinical investigations have revealed its overexpression in skin cancer, gallbladder cancer, chondrosarcoma, lymphoblastic leukemia, glioma, hepatocellular carcinoma, and melanoma, as well as in other cancers (Table 2), as based on functional evidence (Perbal and Takigawa 2005; Kubota and Takigawa 2007a; Chen and Lau 2009). Also for *ccn3*, osteosarcoma, renal cell and prostate carcinomas, Ewing sarcoma, Wilms' tumor, and rhabdomyosarcoma have been shown to overexpress this particular

gene. Even 2, 3, or more CCN family members can be overexpressed simultaneously in the same tumor cells. These findings represent the association of CCN family members with malignant tumors. However, whether such overexpression is a causative or inducing factor of malignant tumors, or an anti-tumorigenic response, is not easy to determine; and further experimentation is needed to clarify the situation. Moreover, even if specific effects were experimentally confirmed, the role of CCN1 and CCN2 in tumor development and metastasis still would remain quite controversial, for the forced expression of CCN1 or CCN2 in tumor cells occasionally yields apparently opposite outcome, depending upon the cell type. As discussed above, this functional variation may be conferred by the difference in the composition of the functional counterparts among those cells/tissues. In contrast, experimental evidence indicates the anti-tumorigenic functions of the other four members (Perbal et al. 2010). It is also of great interest that CCN1 induces epithelial-mesenchymal transition (EMT), whereas the loss of CCN6 triggers EMT (Perbal and Takigawa 2005; Chai et al. 2010). The structural basis to account for the difference in behaviors between CCN1/2 and CCN3–6 has not yet been established.

Probably the best-known CCN family-related disorder at present is fibrosis, in which CCN2 is believed to play a central role. Elevated CCN2 gene expression

is observed in most of the fibrotic lesions of various organs. Unlike cancer cases, CCN2 always act positively on fibrosis. In general, such fibrotic changes are hardly reversible; and thus, the establishment of anti-CCN2 molecular therapy is desired. The utility of plasma CCN2 as a diagnostic marker for the fibrotic change in kidney and heart has also been suggested (Kubota and Takigawa 2007a; Koitabashi et al. 2008; Chen and Lau 2009). It is noteworthy that the actions of structurally and functionally similar CCN1 and CCN2 are contrastive in fibrotic kidney disease. CCN2 is known to be a promoter of diabetic nephropathy, whereas CCN1 expressed in podocytes enhances glomerular reconstruction by inhibiting the migration of mesangial cells and promoting neovascularization (Perbal and Takigawa 2005).

Fibrosis can be regarded as a failure in tissue repair after injury. Therefore, it is reasonable for CCN2 to participate in both fibrotic lesion formation and the wound healing process during which transient fibrosis occurs. In contrast, regarding the events in the kidney, CCN1 and CCN2 collaborate therein. Immediately after wounding, CCN2 is rapidly supplied by platelets; and *ccn2* induction is also initiated in the cells around

the injured tissue (Kubota and Takigawa 2007a). During this initial step, both CCN1 and CCN2 support the adhesion of platelets and migration of monocytes (Chen and Lau 2009). After clotting, the migration of fibroblasts and granulation tissue formation are thought to be mediated by the abundant CCN2. The contribution of the other members is currently unknown.

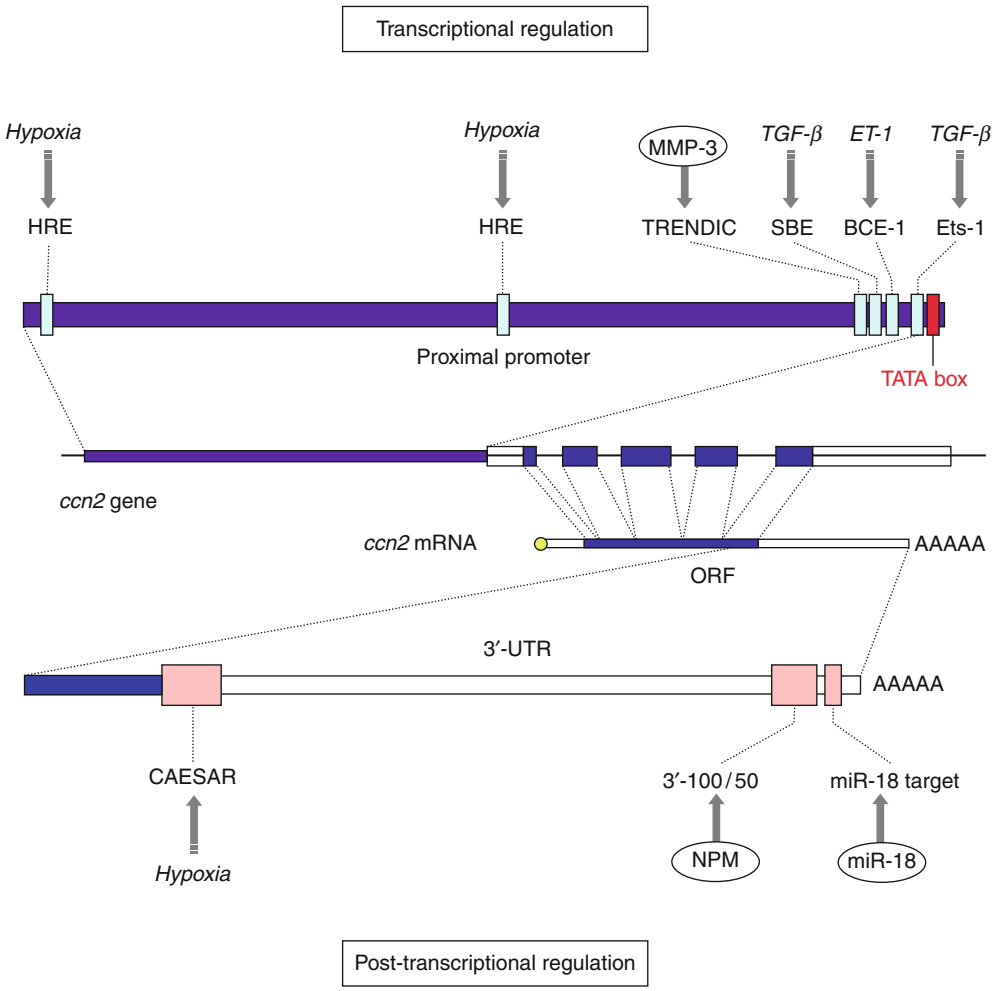
Other specific and relevant association between CCN family members and corresponding disorders is also summarized in Table 2. The genetic linkage between a CCN6 missense mutation and pseudorheumatoid dysplasia in humans is clearly indicated; however, *ccn6*-null mice show no appreciable phenotypic changes. This discrepancy may represent a significant difference between primates and rodents (Chen and Lau 2009).

Gene Regulation

Since the biological outcome caused by CCN family members is highly dependent on the other molecules surrounding them in the microenvironment, it is a critical determinant as to when and where CCN family proteins are produced in vivo. Therefore, the molecular function of each CCN family protein is determined by its gene regulatory system as well as by its molecular architecture itself. Nevertheless, in general, the gene regulatory system of CCN family members has not been sufficiently investigated yet. In fact, little is known about the structure and function of the genetic promoters of *ccn3, 4, 5*, and *6*.

In the case of *ccn1*, several reports have revealed particular regions in the *ccn1* gene that are responsible for the transcriptional upregulation elicited by certain stimuli. A serum response element was identified within a <2 kb region upstream of the TATA-box in murine *ccn1*; and this element was shown to be essential for the transcriptional induction of *ccn1* by serum and platelet-derived growth factor (PDGF) in fibroblasts (Chen and Lau 2009). Also, hypoxic induction of *ccn1* is conducted by well-known mediators of hypoxic gene upregulation, such as hypoxia inducible factor (HIF)-1α (Chen and Lau 2009). This transcriptional regulation is mediated not by a few HIF-1α binding site-like sequences, but through a c-jun/AP-1 binding sequence located at approximately 620 bp upstream of the transcription initiation site in *ccn1*. In addition, transcription of *ccn1* is induced in response to mechanical stretch by the binding of early growth response (Egr)-2 factor to an element located within a 200 bp region upstream of the TATA-box. In contrast to such knowledge about transcriptional regulation, the posttranscriptional regulation of *ccn1* is still left to be explored to date.

Transcriptional and posttranscriptional regulatory systems of *ccn2* have been extensively investigated (Fig. 3), and a number of valuable findings have been reported (Leask and Abraham 2006). According to these studies, the proximal promoter of *ccn2* contains several functional *cis*-regulatory elements. Within the same region and in close proximity, 3 *cis*-elements are located in tandem, all of which mediate *ccn2* induction by TGF-ß, either directly or indirectly. The one closest to the TATA-box and the third one accept the signal from TGF-ß via binding of Ets-1 and Smad transcription factors, respectively, whereas the second one in the middle mediates the signal from endothelin 1 (ET-1), a TGF-ß-inducible extracellular signaling molecule. It was recently revealed that Krupel-like factor 15 (KLF-15) negatively regulates *ccn2* transcription by counteracting Smad 3 signaling (Perbal et al. 2010). This second element was initially referred to as the TGF-ß responsive element (TbRE) since it was characterized by TGF-ß-responsiveness and interaction with nuclear protein(s). Nowadays, the TGF-ß-responsiveness of this element is regarded as being indirect, which is mediated by the induction of ET-1 production; and so, an alternative name, basal control element −1 (BCE-1), has been given. Adjacent to them, another element with a novel protein counterpart has been built into the *ccn2* promoter. This element, named transcriptional enhancer dominant in chondrocytes (TRENDIC), is a target of matrix metalloproteinase 3 (MMP-3), which is widely known to be an extracellular matrix-degrading enzyme. Surprisingly, MMP-3 is distributed also in the nuclei of chondrocytes and drives the transcription of *ccn2*, probably under the collaboration with chromatin remodeling molecules (Perbal et al. 2010). Hypoxia is an effective stimulant to cause the induction of *ccn2* as well as *ccn1* at both transcriptional and posttranscriptional levels. Transcriptional induction of *ccn2* upon hypoxia is mediated by two typical hypoxia responsive element (HRE)s, located relatively distant from the TATA-box in the proximal promoter; and the involvement of forkhead transcription factors, which are also mediators of *ccn1* gene regulation, has been suggested (Chen and Lau 2009; Samarin et al. 2010). Additionally, hypoxic signaling is also mediated by



CCN, Fig. 3 Transcriptional and posttranscriptional gene regulation of a CCN family member, CCN2. Abbreviations are defined in the Gene Regulation subsection in the text

a posttranscriptional element, *cis*-acting element of structure-anchored repression (CAESAR) in the 3′-untranslated region of *ccn2* mRNA.

CAESAR is the first identified posttranscriptional regulatory element in *ccn2*, which is located at the junction of the open reading frame and the 3′-UTR (Leask and Abraham 2006; Kubota and Takigawa 2007a; Chen and Lau 2009). This structured RNA segment exerts dual functions: one is to retain the basal expression level by repressing translation, and the other is to alter the steady-state mRNA level by controlled RNA degradation in response to hypoxia. Subsequently, another element, 3′-100/50, was discovered in the 3′-UTR of chicken *ccn2* mRNA as a regulatory element of mRNA stability in chondrocytes during endochondral ossification. Onto this element, nucleophosmin (NPM)/B23 specifically binds and accelerates the selective degradation of *ccn2* mRNA in the cytoplasm (Perbal et al. 2010). More recently, a functional target of miR-18a, one of the micro RNAs (miRNAs) that posttranscriptionally repress gene expression, was experimentally confirmed (Ohgawara et al. 2009). Of interest, the miR-18a target is located quite close to the 3′-100/50 element, suggesting a mutual interaction between regulatory complexes.

Although genetic targets and precise regulatory mechanisms remain unclarified, a number of other extracellular/intracellular factors are known to regulate *ccn* family gene expression. The expression of the *ccn1* gene is enhanced by angiotensin II, estrogen, the active form of vitamin D, mechanical stress, and UV

light irradiation. CCN2 protein is induced by glucocorticoids, nicotine, inflammatory cytokines, and mechanical stress, occasionally in a cell-type-dependent manner (Kubota and Takigawa 2007a; Chen and Lau 2009; Takeuchi et al. 2010). Repressive regulation of *ccn2* by several miRNAs other than miR-18a has also been reported. It should be noted that TGF-ß enhances the transcription of as many as 4 CCN family members, *ccn1*, *2*, *4*, and *5*, whereas it contrarily represses that of *ccn3*. As represented by the initial names given, *ccn4* and *5* expression is induced by Wnt-1, which led to the discovery of these gene products (Perbal and Takigawa 2005).

Summary

The CCN family consists of six members in vertebrates, all of which are composed of 3–4 highly interactive protein modules. Using these modules as "hands," CCN family proteins harmonize the extracellular signaling network via multiple interactions with molecular counterparts in the microenvironment. Therefore, the function of CCN family proteins is altered by the location and time point of gene expression, both of which are determined by their proper gene regulatory machinery. Physiologically, CCN family proteins enable harmonized development of the tissues involved and thus promote adequate tissue regeneration and wound repair. Conversely, aberrant expression of CCN family genes occasionally causes fibrotic disorders and frequently accompanies malignant transformation and invasion by tumor cells. Based on these unique properties, the medical utility of CCN family proteins and their derivatives is to be expected, and the development of anti-CCN family therapeutic strategy is currently being considered.

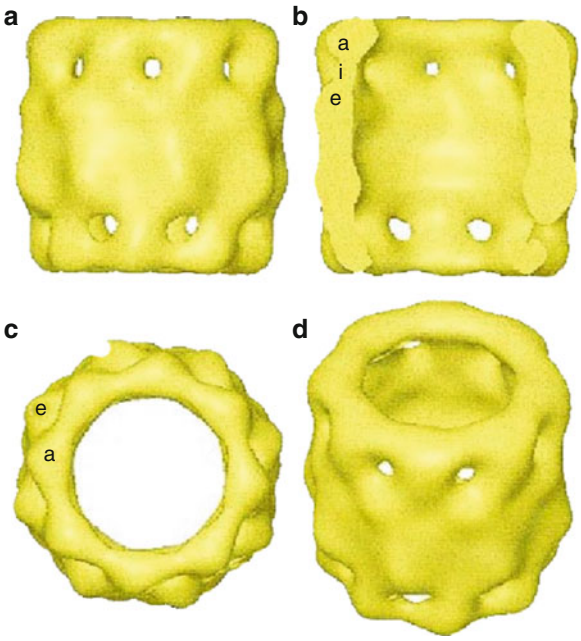
Historical Background

In the cell, the correct folding of many proteins depends on the function of preexisting ones known as Molecular Chaperones (for a review see Hartl and Hayer-Hartl 2009). These, were defined as proteins that bind to and stabilize an otherwise unstable conformation of another protein, and by controlling binding and release, facilitate its correct fate in vivo, be it folding, oligomeric assembly, transport to a particular subcellular compartment, or disposal by degradation. Molecular chaperones do not convey steric information specifying correct folding: instead, they prevent incorrect interactions within and between nonnative peptides, thus typically increasing the yield but not the rate of folding reactions.

Molecular chaperones are ubiquitous and comprise several protein families that are structurally unrelated (Hartl and Hayer-Hartl 2009). The Hsp70s and the Chaperonin families have been extensively studied. **Hsp70** homologs are widespread in prokaryotes and eukaryotes where they occur in the cytosol, mitochondria, chloroplasts, and endoplasmic reticulum. Their expression can be induced by a variety of cellular stresses but they have also essential functions under normal cellular conditions. Chaperonins are large oligomers and have ring-like or toroidal structures with central cavities. The group I chaperonins are found in Eubacteria (the chaperonin of *E. coli* GroEL and

its co-chaperonin GroES), and their close homologs in mitochondria (Hsp60-Hsp10) and chloroplasts (cpn60-cpn10) eukaryotic organelles of endosymbiotic origin. The eukaryotic cytosol also contains a more distantly related chaperonin known as TRiC (TCP-1-ring-complex), TCP-1 complex, cytosolic chaperonin (c-cpn), chromobindin A, or CCT (Chaperonin-containing-TCP-1) that is a member of the group II chaperonins (for review Valpuesta et al. 2002). Although related, both groups of chaperonins are distinct. In the group I chaperonins are homo-oligomeric complexes composed of seven-membered rings, whereas group II chaperonins are hetero-oligomeric complexes consisting of eight- or nine-membered rings. Another important difference between the two groups relies in the fact that group I chaperonins act in combination with a co-chaperonin during protein folding. These co-chaperonins are also oligomeric proteins that cap the central cavity of the chaperonin. The co-chaperonins are absent in chaperonins of group II but their function is mimicked by helical protrusions formed by an extra sequence localized at the tip of the apical domain (for review Hartl and Hayer-Hartl 2009).



CCTα, Fig. 1 Several views of the three-dimensional reconstruction of apo-CCT. ***a***, and ***b***, are side views, with (*b*) representing a cut along the longitudinal axis of the oligomer, where half of the particle has been removed. ***c***, A *top* view and ***d***, a side view tilted 35° toward the viewer. The locations of the apical (a), intermediate (i), and equatorial domains (e) are indicated (figure from Llorca et al. 1999 with permission)

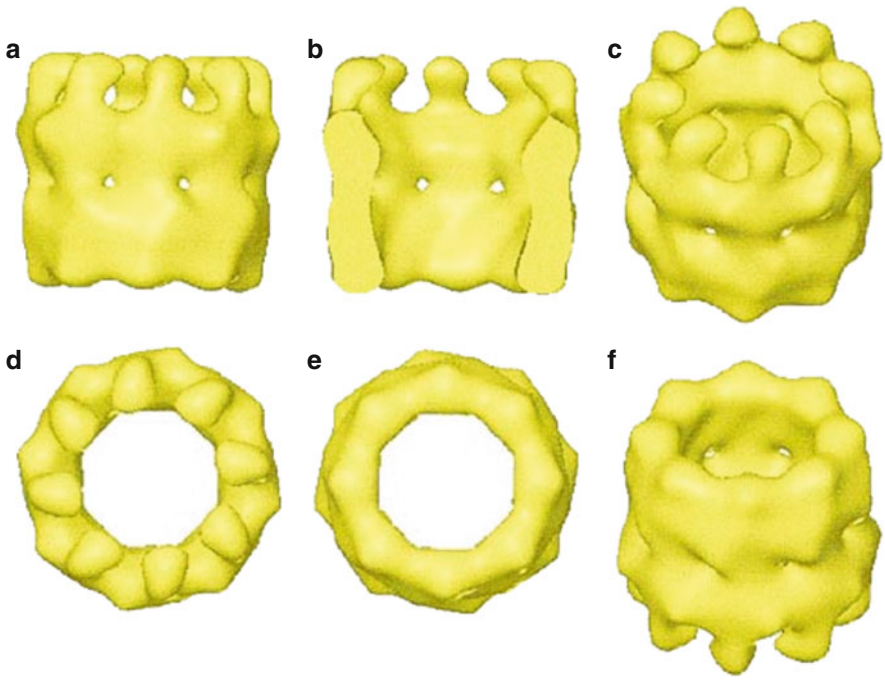
The CCT Complex, Its Interacting Proteins and Folding Mechanism

CCT exists as a hetero-oligomeric complex of about 900 kDa composed of two back-to-back stacked rings of eight different, though related, gene products that were designated as CCTα to CCTζ (for review Kubota et al. 1995). T-complex polypeptide-1 (TCP-1) was the first identified subunit of the chaperonin-containing TCP-1 CCT complex. TCP1 was renamed CCTα, whereas the other CCT subunits were designated by CCTβ, CCTε, CCTδ, CCTγ, CCTη, CCTθ, and CCTζ (Cct1 to Cct8 in yeast). The CCTα encoding gene was first cloned from mouse and humans. The mouse gene is highly expressed in the testis and is located in the mouse t-complex region on chromosome 17, which is involved in the transmission ratio distortion of t-complex-carrying mice (Kubota et al. 1995).

CCT complex forms a barrel-shaped cylinder with a diameter of about 150 Å and a height of 160 Å. Within the complex each subunit interacts with one subunit of the opposite ring and it has been shown that CCTα subunits are opposite, or nearly opposite, to each other in opposing rings (for a review see Valpuesta et al. 2002). The arrangement of subunits in the ring moving clockwise is α/1, ε/5, ζ/6, β/2, γ/3, θ/8, δ/4, and η/7. This unique arrangement in which each subunit occupies a well-defined position seems to be universal throughout eukaryotes (for review Valpuesta et al. 2002).

CCT subunits consist of three domains: an equatorial domain containing an ATP-binding site, an apical domain responsible for target protein interaction, and the intermediate domain connecting the other two. The apical domain contains a helical protrusion, which is involved in opening and closing the central cavity of the chaperonin (Llorca et al. 1999) (Figs. 1 and 2).

Phylogenetic analyses revealed that the sequence differences between CCT subunits from different species are located mainly in their apical domains. Although they contain several highly conserved motifs for ATP binding, the overall amino acid sequence identities are only about 30% (for review Kubota et al. 1995).



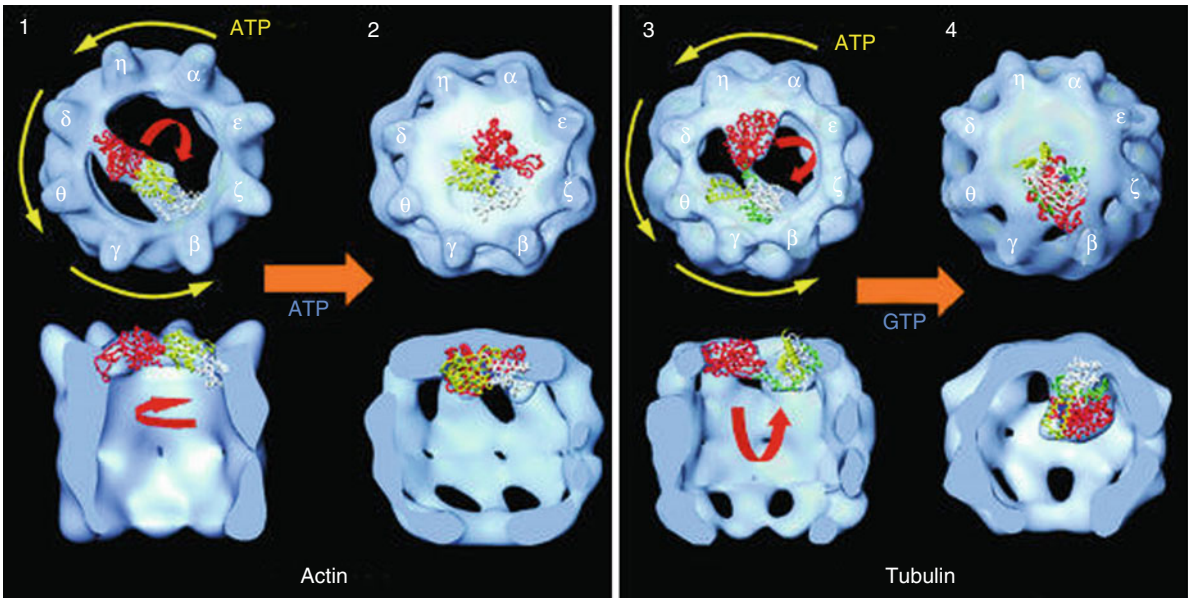
CCTα, Fig. 2 Several views of the three-dimensional reconstruction of ATP-CCT. *a*, and *b*, are side views, with (*b*) representing a cut along the longitudinal axis of the oligomer. *c*, and *f*, are side views tilted 35° toward the viewer showing the *top* and *bottom* ring of the volume in (*a*), respectively. *d*, and *e*, are top views showing the *top* and *bottom* ring of the volume in (*a*), respectively (figure from Llorca et al. 1999 with permission)

Smaller complexes of CCT-subunit subsets have also been detected in several cell types and were proposed to be intermediates in the assembly of the intact chaperonin (for review Valpuesta et al. 2002). Additionally, CCT subunits have functional differences in vivo which is reflected in the fact that the overexpression of each CCT subunit is not able to rescue mutations in the other CCT subunits, indicating CCT-subunits specificity of function (for a review see Gonçalves et al. 2007).

CCT assists the folding of approximately 5–10% of the cellular proteome being tubulins and actin quantitatively the major substrates (for a review see Lundin et al. 2010). Therefore, the chaperonin is implicated in several processes related to cytoskeleton systems, cell cycle control, nuclear pore complex assembly, chromatin remodeling, and protein degradation. Although most of these proteins do not seem to present a sequence signature which identifies them as CCT interacting proteins many present WD40 domains, which contain the WD repeat (a weakly conserved sequence motif of ~31 amino acids ending with conserved tryptophan and aspartate residues) and share a β-propeller fold (for a review see Valpuesta et al. 2002). Among the proteins that require CCT for their biogenesis we find centractin (actin-related protein), septin, von Hippel–Lindau tumor suppressor, histone deacetylases (HDAC3, Set3p, and Hos2p), and cell cycle regulators (Cyclin E, Cdc20p, and Cdc55p) (for reviews see Valpuesta et al. 2002; Dekker et al. 2008). However, not all CCT interacting proteins are chaperonin substrates and are probably involved in the regulation of its activity. For example, proteins such as phosducin-like 1, 2, and 3 (PhLP1-3) bind to CCT in their native forms and were described as modulators of CCT function by competing with CCT substrates or modulating its ATPase activity (for review Willardson and Howlett 2007). In contrast, caveolin-1 (a protein that is a major component of caveolae and membrane lipid rafts) also interacts directly with CCT, modulating the folding of actin through the protein filamin (Doucey et al. 2006).

The whole CCT complex mediates protein folding, driven by ATP binding and hydrolysis. The CCT folding mechanisms have been studied mainly for actin and tubulins.

Newly synthesized tubulins and actin are delivered to the CCT complex by prefoldin, a hetero-hexameric complex also referred to as Gim C, which interacts directly with the chaperonin (for a review see Hartl and Hayer-Hartl; Lundin et al. 2010). Actin and tubulin interact with CCT in a quasi-native conformation



CCTα, Fig. 3 Model of the structural changes undergone by the actin and tubulin molecules during the CCT functional cycle. Docking models with the atomic structures of actin and tubulin have been overimposed to the volume of the same proteins complexed with CCT. Quasi-folded actin (1) and tubulin (3) molecules bind to apo-CCT. The N-terminal domains of both cytoskeletal proteins (*colored red*) bind to CCT with less affinity than the corresponding C-terminal domains. ATP binding induces large movements of the CCT apical domains that seal the cavity. These movements occur sequentially, starting in CCTα, and move in an anticlockwise direction (see *yellow arrows* in 1 and 3). Following this sequence, the N-terminal domains of both actin and tubulin molecules are the first ones to respond to the rearrangement of the apical domains, resulting in their release and movement toward the C-termini, giving rise to a more native conformation (2 and 4). The C-terminal domains bind to CCT with a higher affinity than the N-terminal domains, and this interaction is maintained after nucleotide binding and hydrolysis. Nucleotide release induces the return to the nucleotide-free, open state and the liberation of the folded substrate. Only one of the possibilities for actin and tubulin binding to CCT is shown, although the other fits equally well with the model proposed (figure from Llorca et al. 2001 with permission)

through specific interactions between the apical domains of specific CCT subunits and defined regions of these proteins (Llorca et al. 2001).

It was proposed that actin and tubulin molecules bind to the nucleotide-free (apo-CCT), open conformations of CCT, and are thus stabilized in quasi-native conformations that correspond to a high degree of secondary and tertiary structure (Llorca et al. 2001). On binding ATP, the central ring cavity of the ATP-ring expands slightly and is closed by the helical extensions of the apical domains (Llorca et al., 2001). These movements are coupled to the folding movements of actin and tubulin and force the substrate molecules to achieve their quasi-native structures. Llorca and colleagues (2001) proposed that after ATP binding and hydrolysis the target proteins maintain their interaction with the chaperonin, and the release of the nucleotide leads to the substrate discharge and the regeneration of apo-CCT open conformation (Fig. 3).

CCT: The Cytoskeleton and Cell Cycle Progression

Since the first studies, it was clear that the cytosolic chaperonin CCT was intimately connected with the formation of the cytoskeleton in vivo. For example, in the budding yeast mutations in the CCTα gene caused both abnormal microtubular structures and disruption of actin microfilaments (for review Kubota et al. 1995).

Subsequently, TCP-1/CCTα and CCTζ were identified in centrosomes. Furthermore, the incubation of these microtubule organizing centers with an antibody against TCP-1/CCTα in vitro prevents microtubule growth, indicating that TCP-1/CCTα may assist in microtubule nucleation (for review Brackley and Grantham 2009).

CCTα, CCTγ, CCTζ, and CCTθ subunits associate with microtubules polymerized in vitro behaving as

typical microtubule-associated proteins. In addition, TCP-1/CCTα associates with the microtubules of the manchette, a highly specialized microtubule structure of male germ cells (for review Brackley and Grantham 2009).

In addition, Stephens and Lemieux (1999) reported the progressive appearance of TCP1/CCTα in cilia during the final stages of cilia regeneration in the sea urchin. In agreement, CCTα, CCTε, CCTδ, and CCTη subunits localize at cilia tips, basal bodies, and other complex microtubule structures in the ciliate protozoa *Tetrahymena pyriformis* (Seixas et al. 2003). In, *T. thermophila*, CCTα or CCTδ knockouts caused a loss of cell body microtubules, failure to assemble new cilia, and cell death (Seixas et al. 2010). Additionally, the loss of CCTα subunit activity leads to axoneme shortening and splaying of cilia tips.

Recently, CCT-subunits (CCTα-ε and CCTθ) were shown to form a complex with the chaperonin-like BBS6, BBS10, and BBS12 proteins (vertebrate specific BBS genes) (Seo et al. 2010) required for BBSome assembly. The BBSome is an oligomeric complex of BBS (BBS1-2, BBS4-5, BBS7-9) proteins that have been directly implicated in ciliogenesis by promoting vesicle trafficking to the cilia membrane (Nachury et al. 2007). In fact, several studies have shown that mutations in BBS proteins underlie the Bardel Biedl Syndrome (BBS), a genetically heterogeneous disorder associated with defects in primary cilia (Seo et al. 2010).

The interaction of CCT subunits with membranes was already reported. The adrenal medullary form of CCT (chromobindin A) binds efficiently to chromaffin granule membranes (Kubota et al. 1995). Furthermore, in human erythrocytes, CCTα is translocated to the plasma membrane where it binds by a specific association with actin cytoskeleton proteins following a heat shock (Wagner et al. 2004).

CCT has been also implicated in the assembly of the actin cytoskeleton, by acting at filament ends. In fact, the CCT chaperonin interacts in vitro with filamentous actin and decreases the initial rate of actin polymerization (for review Brackley and Grantham, 2009). Accordingly, the depletion of CCT levels in vivo by CCT-subunit specific siRNA inhibits cell cycle progression and alterations in microtubule and actin cytoskeleton organization and cell motility (for review Brackley and Grantham, 2009).

The fact that CCT subunits do not always colocalize strongly suggest that they might have other functions as free entities or as part of microcomplexes. For example, the CCTα-subunit is more abundant in growing neurites than other CCT-subunits and in yeast the CCTθ subunit appears to play a role in the Ras signaling pathway (for review Kubota et al. 1995; Brackley and Grantham 2009).

The involvement of specific CCT subunits with actin and microtubule networks seems to indicate that they have in fact specific functions outside the whole complex. However, the oligomerization state and the mechanism/s by which CCT-subunits are involved in the assembly and regulation of these dynamic filaments are far from being completely understood and deserve further investigation.

CCT subunits are mainly cytoplasmic; however, CCTα and CCTγ have also been observed to be localized in the nucleus (for a review see Gonçalves et al., 2007). TCP-1/CCTα was also described to associate with heterochromatin in both somatic and germ cells during mammalian spermiogenesis and was suggested that CCT assists in the folding of nuclear matrix proteins and proteins involved in DNA remodeling (for review Brackley and Grantham, 2009). The presence of the whole CCT complex in the nucleus has not yet been demonstrated. However, it has been suggested that CCTα may have a specific nuclear role because it translocates into the nucleus upon the induction of apoptosis (for a review see Gonçalves et al., 2007). Recently, an extensive study of the CCT interactome showed that, besides SET3 and histone deacetylase complex other enzymes responsible for histone post-translational modifications interact with CCT which definitively implicates the chaperonin in chromatin remodeling and consequently in gene expression regulation (Dekker et al. 2008).

Numerous evidences suggest an involvement of CCT in cell cycle-regulated events. For example, reducing CCT levels by siRNA assays in mammalian cultured cells leads to cell cycle arrest (for review Brackley and Grantham, 2009). Additionally, CCT subunits expression is regulated during cell cycle. For example, the expression of TCP-1/CCTα messenger RNA is strongly up-regulated during cell growth especially from the G1/S transition to early S phase (for review Brackley and Grantham, 2009). This idea is supported by observations in the mouse showing that highly proliferative tissues (such as testis, spleen, thymus, and bone marrow) and cultured cells express much higher levels of TCP-1/CCTα and the other CCT subunits than those

with low proliferation rates (such as heart, kidney and lung) (for a review see Gonçalves et al. 2007).

The abundance of CCT varies during the cell cycle which seems to reflect the requirements of the cell for specific cell cycle regulators that are known to interact with such as cyclin E, cdk-2, cdc20 and Plk1. Besides the alterations in abundance it was shown that CCT complexes in M-phase-arrested cells have less ability to bind α- and β-tubulin in vivo and for binding and folding β-actin in vitro when compared with the CCT complexes in S phase-arrested cells (for a review see Gonçalves et al. 2007). Thus, the regulation of CCT activity correlates with a fine tuning of the cell cycle by defining the precise moment of folding/assembly of proteins/complexes involved in cell cycle progression.

CCT in Stress Response and Disease

Many molecular chaperones are stress-inducible, making it interesting that the levels of TCP-1/CCTα decrease in *S. cerevisiae* submitted to hyperthermic stress. However, the levels of TCP1/CCTα were unaffected when mammalian cells were subjected to heat shock (for review Kubota et al. 1995). Nevertheless, it was also shown that TCP-1/CCTα, as well as the other CCT subunits, are up-regulated in several mammalian cell lines during recovery from chemical stress (sodium arsenite or a proline analogue, l-azetidine-2-carboxylic acid) (for a review see Kubota, 2002), suggesting that they respond to protein damage and have a function in the recovery of cells from specific stresses.

Taking into account the different observations concerning the response of CCT genes to stress/environmental stimuli it is plausible that the induction of TCP-1/CCTα by stress conditions may be dependent on the type of stress, cell type, organism, or environmental conditions. Moreover, in some of these studies the corresponding protein levels were not investigated. The mouse TCP-1/CCTα gene contains in its first intron a heat-shock element that is recognized by the heat-shock transcription factors HSF1 and HSF2, whose overexpression in HeLa cells activates the TCP-1/CCTα gene (for review Kubota 2002). However, no significant increase in CCT subunits in HeLa cells was detected by western blot analysis after heat treatment at 42–45°C, whereas **Hsp70** protein was induced (for review Kubota 2002). HSF2 is also known to be important in the tissue-specific and developmental-stage-specific expression of HSPs. This transcription factor is highly expressed in embryos and in testis, and this could indicate that this factor is involved in the regulation of TCP-1/CCTα under non-stress conditions.

Many molecular chaperones, e.g., **Hsp70**, have been extensively implicated in the pathogenesis of misfolding diseases. Indeed, the inability of an essential protein to form its native structure under physiological conditions may be the basis of a variety of human diseases.

In the case of CCT, a relationship has been found with neurodegenerative diseases. The Huntington's disease is caused by the misfolding and aggregation of proteins with expanded polyglutamine (polyQ) repeats. CCT interacts with polyglutamine-expanded variants of the neuronal huntingtin (Htt) protein and prevents their aggregation and the resulting formation of toxic polyQ fibrils. Depletion of CCT enhances polyglutamine aggregation, whereas its overexpression has the opposite effect, preventing neurotoxicity. In this context, this chaperonin may be a key component in the pathway leading to the progression of Htt to pathogenic conformations. Interestingly it was shown that, in this process, the CCT chaperonin acts synergistically with **Hsp70** and Hsp40 on initial oligomer forms of huntingtin promoting the formation of nonpathogenic oligomers (for a review see Broadley and Hartl 2009).

The altered expression of some genes encoding CCT subunits were also reported in other pathological processes. For example the TCP-1/CCTα was shown to present altered patterns of expression in the brain in the early stages of developing Down syndrome (for review Gonçalves et al. 2007).

Increased levels of TCP-1/CCTα were also reported associated with human hepatocellular and colonic carcinoma and in a cisplatin-resistant ovarian cancer cell line (for review Lundin et al. 2010).

Summary

CCT is an abundant cytosolic chaperonin composed of two hetero-oligomeric stacked rings arranged back to back, with a central cavity that interacts with a large number of distinct cellular proteins as shown by the recent characterization of the CCT interactome. Among these interacting proteins some will constitute true substrates while others will be co-chaperones or

regulators. Tubulins and actin are the most prominent cytoskeletal CCT substrates, but proteins involved in various cellular processes, such as cell cycle regulation and chromatin remodeling, have also been described. CCT is therefore a key player in the maintenance of cellular homeostasis. Many evidences, supported by cellular localizations and by the presence of different oligomeric forms of CCT subunits, have also indicated that CCT subunits may play additional functions outside of the chaperonin complex. For example, it has been proposed that CCT subunits behave as microtubule-associated proteins or regulate actin polymerization. Important is also the fact that some CCT subunits have been found in centrosomes, basal bodies, and cilia axonemes and are essential for the maintenance of the ciliary structure. This places the CCTcomplex/CCT subunits in a new cellular compartment and in the middle of the very exciting field of cilia biology. In conclusion, the misregulation of CCTcomplex/CCT subunits might be in the basis of a myriad of human diseases from cancer to ciliopathies.

Historical Background

NK lymphocytes recognize abnormal or aberrant cells through multiple receptors that detect normal host molecules, as well as stress-induced or pathogen-expressed motifs (Lanier 2005). Individual NK cells express both activating and inhibitory receptors, which together drive the specificity toward target cells.

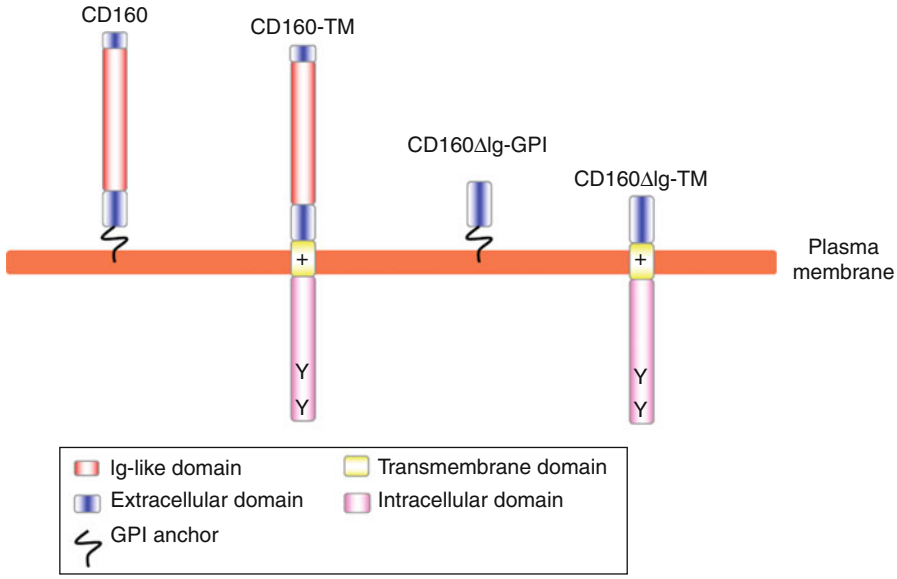
The NK cell inhibitory receptors have been classified into three groups, namely, the heterodimeric CD94/NKG2A, the Ig-like transcript (ILT) receptors, and the members of the killer cell Ig-like receptors (KIRs). All of them bind to classical or nonclassical MHC-class I molecules. A common characteristic of the inhibitory receptors is the presence of immunoreceptor tyrosine-based inhibition motif(s) (ITIM) within their intracellular tail. Following engagement by their ligands, the inhibitory receptors become phosphorylated on the tyrosine residue(s) present in the ITIM(s), creating docking sites for the SH2-domains of the cytoplasmic protein tyrosine phosphatases, SHP1 and SHP2. Their recruitment further results in the down-regulation of the intracellular activation cascade. In contrast, activating receptors recognize a large variety of ligands, mostly distinct from MHC-class I molecules, and exhibit more complex but well-characterized signaling pathways. Natural cytotoxicity receptors (NCRs) and ▶ NKG2D are the major receptors involved in NK cytotoxicity. The NCRs (namely, ▶ NKp46, NKp44, and NKp30) belong to the Ig superfamily and represent non-MHC-class I-specific receptors whose cellular ligands still have to be confirmed (Arnon et al. 2006). In contrast to NKp46 and NKp30, constitutively expressed on circulating NK lymphocytes, NKp44 expression is activation-dependent (Vitale et al. 1998). The NCRs transduce signals through their association with ITAM-containing molecules such as CD3ζ, FcεRIγ, and DAP12 (Moretta et al. 2000; Vivier et al. 2004). Besides the NCRs, NKG2D is a C-type lectin-like receptor shown to recognize the MHC-class I homologues MICA and MICB, and the family of UL16-binding proteins (ULBPs) (Gonzalez et al. 2006). NKG2D uses the transmembrane polypeptide DAP10 for signaling, which interacts with the ▶ PI 3-kinase once phosphorylated. Interestingly NKp80, an additional C-type lectin-like activating receptor exclusively expressed by human NK cells, has been identified. A search for NKp80 ligands led to the identification of activation-induced C-type lectin (AICL) (Welte et al. 2006). However, NKp80 signaling pathway remains enigmatic as this receptor does not contain a transmembrane charged residue (a feature allowing association with ITAM-containing adaptor proteins) or any intracellular consensus activation motifs. Finally, besides these MHC- class Ia/Ib molecule-independent activating receptors, it is important to mention the well-characterized DAP12-associated CD94/NKG2C and KIRs activating isoforms (Lanier et al. 1998; Olcese et al. 1997), although the precise events leading to their specific recruitment still have to be better defined. Here we review our knowledge on a unique NK cell receptor, named CD160, which is expressed by circulating $CD56^{dim}CD16^{bright}CD3^{-}$ NK lymphocytes.

Subheadings

Structure, Specificity, and Function of CD160

CD160 receptor was initially identified by the monoclonal antibody (mAb) BY55 generated following immunization with YT2C2, a human leukemia cell line with NK activity. BY55 mAb was shown to immunoprecipitate an 80 kDa cell surface structure expressed mainly on a subset of circulating NK and T lymphocytes and on all intestinal intraepithelial T lymphocytes (Anumanthan et al. 1998; Maiza et al. 1993). Subsequently, CD160 expression was detected on mast cells (Ortonne et al. 2011), activated endothelial cells (Fons et al. 2006), and found increased in activated T lymphocytes (Abecassis et al. 2007; Nikolova et al. 2009). The increased expression of CD160 during T cell activation was found to be inhibited in $CD4^{+}CD25^{bright}$Fox $P3^{+}$ lymphocytes.

The molecular cloning of CD160 molecule recognized by BY55 mAb revealed that it is a glycosylphosphatidylinositol (GPI)-anchored receptor, unique in its nucleotide and aminoacid sequences, which has a single Ig-like extracellular domain (Anumanthan et al. 1998). The *CD160* gene was found to be located on human chromosome 1q21.1. The mature molecule corresponds to a cysteine rich 134-aminoacids polypeptide, with six cysteines, that has two potential sites for *N*-linked glycosylation. The size predicted for the mature CD160 polypeptide plus two for *N*-linked glycosylations would be approximately 25 kDa indicating

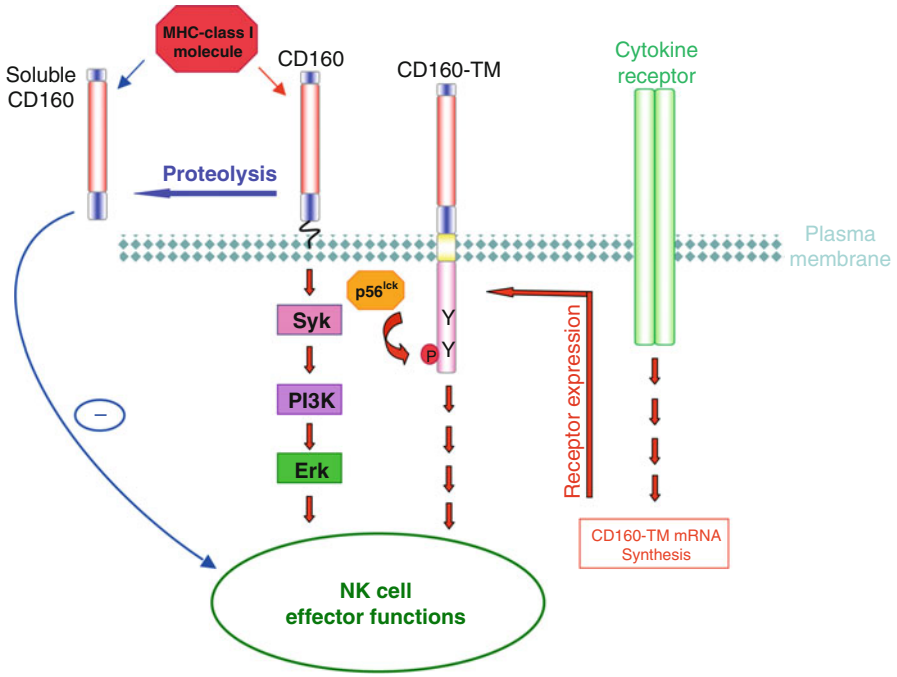


CD160, Fig. 1 Schematic representation of monomeric CD160 isoforms. Two types of receptors can be distinguished according to their mode of insertion to the plasma membrane (GPI-anchored or transmembrane molecule) and the presence or absence of an Ig-like domain within the extracellular part. All isoforms have in common the signal peptide and the membrane proximal moiety. Transmembrane isoforms are characterized by a transmembrane charged lysine residue (+) and the presence of two putative intracellular phosphorylation sites on tyrosine residues (Y)

that the 80 kDa cell surface structure immunoprecipitated by BY55 mAb corresponds to multimers (most likely trimers).

CD160 Ig-like domain is related to a number of Ig superfamily members, with the highest degree of homology being to Ig-V domains of the pregnancy-specific glycoprotein and the first Ig-C2 domain of KIR. This homology is weak, with 29% identity between CD160 and KIR2DL4/CD158d. The 68-aminoacids distance between the Ig cysteines at positions 44 and 112 is more characteristic of an Ig-V domain than an Ig-C domain. The CD160 structure is unusual for an Ig superfamily member as it has an additional cysteine immediately following the 112 Ig cysteine. This dicysteine is found only in few other Ig superfamily members with three Ig-V domains. Similar to CTLA4, CD160 has two cysteines between the Ig cysteines that potentially promote the looping out of a short region between aminoacids 61 and 68. CD160 receptor binds to MHC-class Ia/Ib molecules (Agrawal et al. 1999; Le Bouteiller et al. 2002) and to HVEM (Cai et al. 2008).

Functionally, CD160 behaves as an activating receptor on $CD56^{dim}CD16^{+}$ NK lymphocytes (Fig. 1) as demonstrated by the induction of their cytotoxic potential upon engagement (Le Bouteiller et al. 2002). Furthermore, its engagement with its physiological ligand or with specific mAbs triggers a unique profile of cytokine secretion, with the release of ► TNF-α, ► IFN-γ, and IL-6 (Barakonyi et al. 2004). The CD160-mediated signaling molecules recruited upon specific crosslinking on NK lymphocytes upstream and downstream of PI3-kinase correspond to Syk and Erk, respectively (Rabot et al. 2007). Importantly, in isolated CD160-enriched peripheral blood $CD8^{+}$ T lymphocytes CD160 ligation by itself does not provide activation but enhances their CD3-induced proliferation. Thus, its co-triggering with ► CD3 results in its association with $p56^{lck}$ and tyrosine phosphorylated CD3-ζ chains (Nikolova et al. 2002). Besides its activating receptor function in NK cells and $CD8^{+}$ T lymphocytes, CD160 is found to exhibit inhibitory features in other cell types. Thus, on activated endothelial cells, engagement of CD160 with its physiological ligand HLA-G1 results in inhibition of the endothelial tube formation and induction of apoptosis (Fons et al. 2006). Similarly, CD160 interaction with the herpes virus entry mediator



CD160, Fig. 2 CD160 and CD160-TM signaling in NK cells. Upon ligand recognition, CD160 mediates positive signals with the recruitment of Syk, PI3-kinase, and Erk that result in the generation of an NK cell effector response. Short-time cell activation (addition of cytokines for 1–3 days) leads to the proteolysis of CD160 through a phospholipase-dependent mechanism and to the release of soluble CD160. This latter promotes the down-modulation of NK cell functions, most likely by acting as a blocking molecule that competes with other activating NK cell receptors for the binding of MHC-class I molecules. This step is followed by the synthesis of CD160-TM mRNA and receptor expression at the plasma membrane (day 3–10 following activation). Upon phosphorylation by $p56^{lck}$, CD160-TM initiates a cascade of still undefined activating signals that enhances the NK cell killing activity

(HVEM) is described as inhibiting $CD4^+$ T lymphocytes activation (Cai et al. 2008). However, the mechanisms leading to the arrest of proliferation remain to be elucidated.

In NK lymphocytes or mast cells the GPI-anchored CD160 is down-modulated upon activation with cytokines. Indeed IL-15 treatment converts the membrane-bound receptor to a soluble form through a proteolytic cleavage involving a metalloprotease (Giustiniani et al. 2007). The CD160 transcript remains highly synthesized during the process of protein shedding, its synthesis being even induced in $CD56^{bright}$ NK cells upon interleukin-treatment. The soluble CD160 that is released by NK lymphocytes or mast cells impairs the MHC-class I-specific cytotoxic $CD8^+$ T lymphocytes and NK cells function. This observation is most likely related to the ability of soluble CD160 to interact with MHC-class I molecule (Giustiniani et al. 2007) and to eventually compete with activating NK receptors for ligand binding, resulting in the down-modulation of NK cell cytotoxic activity (Fig. 1).

CD160 Transmembrane Isoform (CD160-TM): Structure and Function

Later on, three additional RNA encoding putative CD160 isoforms were identified in NK cells. These transcripts originate from the alternative splicing of the *CD160* gene, and their translation would lead to the synthesis of proteins sharing high level of homology with CD160 (Fig. 2; Giustiniani et al. 2009). The first one corresponds to a CD160 mRNA that lacks the coding region for the Ig domain; this deletion would therefore result in a GPI-anchored molecule devoid of extracellular Ig domain (CD160ΔIg-GPI). The second transcript presents a high level of identity with the CD160ΔIg-GPI coding sequence and would lead to a CD160 molecule with no extracellular Ig domain

but possessing a transmembrane and an intracellular domain (CD160ΔIg-TM). The third mRNA is the larger one and codes for a putative receptor having the complete extracellular moiety of CD160, as well as a transmembrane and an intracellular part, and would thus corresponds to a transmembrane isoform of the original GPI-anchored molecule (CD160-TM). CD160-TM encompasses a transmembrane charged aminoacid, a feature usually found in activating KIRs and allowing their interaction with DAP10 or DAP12, as well as two potential tyrosine phosphorylation sites within its intracellular domain. The two transcripts coding for the GPI-linked molecules are detected in resting NK cells, while the synthesis of the transmembrane receptors mRNA is only induced upon NK cell activation (Giustiniani et al. 2009). While the proper expression of the two isoforms lacking an Ig domain cannot be assessed because of a lack for the appropriate antibodies, the translation of the CD160-TM isoform is specifically detected in activated NK cells but not activated T lymphocytes, mast cells, or endothelial cells. In fact, the appearance of CD160-TM at the plasma membrane parallels the disappearance of the GPI-bound isoform that occurs through a phopholipase-dependent proteolysis (Giustiniani et al. 2007).

Biochemical analyses further reveal that CD160-TM is expressed as a multimeric molecule with an apparent molecular weight of 100 kDa. Its cellular ligands remain to be identified, but given the complete homology of its extracellular domain with the one of CD160, they may share the same ligands, namely, MHC-class I molecules and HVEM. However, conformational changes induced by the presence of a transmembrane and an intracellular domain may also drive a different ligand specificity for CD160-TM. This possibility is sustained by the observation that CD160-TM isoform is not recognized by the anti-CD160 mAb BY55 (Giustiniani et al. 2009).

Functionally, CD160-TM behaves as an activating receptor on NK cells (Fig. 1). Indeed, its triggering leads to the generation of cytotoxic activity toward target cells and enhances NK cells degranulation. This activating function is under the control of an intracellular tyrosine residue located within the intracellular domain of CD160-TM and requires the expression of the Src-family kinase $p56^{lck}$, as assessed by the loss of function upon tyrosine mutation or kinase depletion (Giustiniani et al. 2007). However, the proteic intermediates involved in the downstream signaling pathways remain to be identified.

Conclusions

Among the NK receptors, CD160 and the NK cell lineage highly restricted CD160-TM present unique structural and functional characteristics. Work performed so far suggests that the tightly regulated expression of CD160 isoforms might be an important step in the cascade of events leading to a specific and efficient NK cell response. The existence of at least a GPI-linked and a transmembrane CD160 receptor, each expressed at different stage of NK cell activation and signaling through a distinct intracellular pathway, together with the generation of a soluble form of CD160 that mediates immunoregulatory functions open new perspectives regarding the cellular events involved in the regulation of NK cell functions. Finally, while the transmembrane CD160 receptor does not exist in mice, the GPI-anchored CD160 is expressed but only as a dimeric molecule (Maeda et al. 2005). Therefore, it remains to consider the functional specificity of CD160 according to its various structural features.

Summary

CD160 is a multimeric Ig-like 134-aminoacid glycoprotein expressed as a GPI-anchored receptor on $CD56^{dim}CD16^{+}$ circulating NK lymphocytes, T lymphocyte subsets, endothelial cells, and mast cells. Upon activation, only in NK lymphocytes, an additional transmembrane CD160 isoform, with two putative tyrosine phosphorylation sites within its cytoplasmic tail, is expressed. Both isoforms share identical extracellular region with an Ig-like V-domain, that is weakly homologous to the one of KIR2DL4/CD158d, and behave as activating NK receptors upon engagement. MHC-class I molecules have been shown to bind with low affinity to CD160 in mice and humans. The two receptors are described as participating in the generation of an appropriate NK cell effector response. Thus, while the transmembrane CD160 isoform is exclusively expressed on NK cells upon activation, the GPI-anchored receptor is cleaved and the resulted soluble CD160 molecule exhibits immunoregulatory function.

Introduction

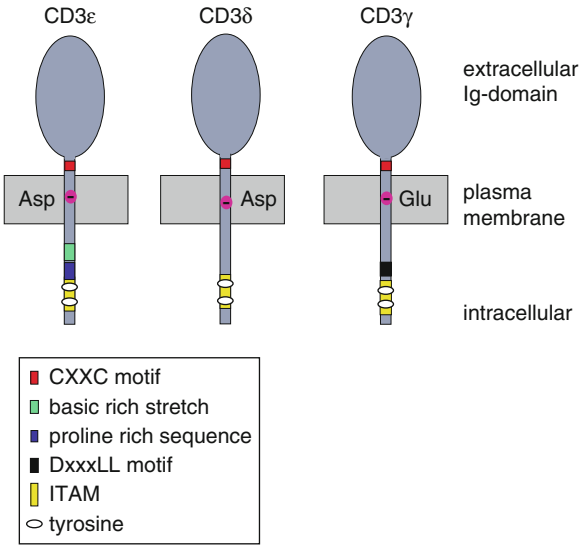
CD3 is a complex of three type 1 transmembrane (TM) proteins expressed exclusively in T cells: CD3γ, CD3δ, and CD3ε. ▶ CD3ζ (▶ CD247) is described in a separate chapter due to significant differences compared to CD3γ, CD3δ, and CD3ε. The CD3γ and CD3δ chains are glycoproteins, each of which forms a heterodimer with a non-glycosylated CD3ε chain. These chains associate with TCRαβ and a CD3ζζ dimer to form the αβ T cell antigen receptor (TCR-CD3) complex in αβ T cells (Figs. 1 and 2). The CD3 chains and CD3ζζ also associate with pTα and TCRβ to form the pre-TCR-CD3 and with TCRγδ to form the γδTCR-CD3 in the case of pre-T cells and γδ T cells, respectively. Each of the CD3 subunits possesses an immunoreceptor tyrosine-based activation motif (ITAM) in its cytoplasmic tail which becomes phosphorylated upon antigen binding to TCRαβ. Hence, the TCR-CD3 is responsible for activation of a T cell upon antigen encounter, and thus, initiation of the immune response. In addition, CD3 and CD3ζ subunits bring TCRαβ to cell surface. As the CD3 subunits, CD3γ, CD3δ, and CD3ε, are expressed exclusively on T cells, they are used as T cell markers in clinical and basic research studies using flow cytometry.

Historical Background

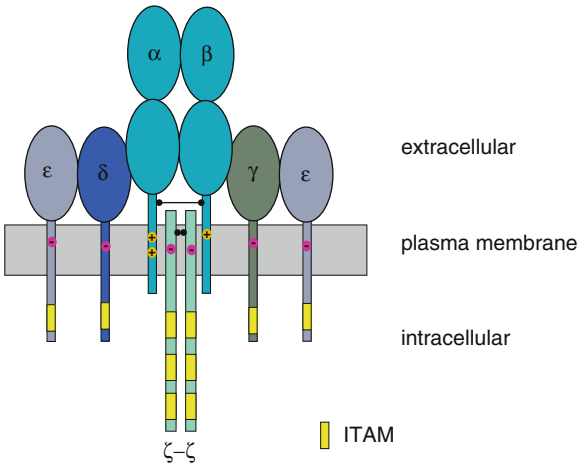
In the late 1970s, monoclonal antibodies against T cells were generated. One such antibody, OKT3, was generated in 1979 by P. Kung and G. Goldstein (Kung and Goldstein 1979). Later it was recognized that OKT3 binds to proteins involved in T cell activation and therefore the proteins were named T3. With the introduction of the immunological CD nomenclature in 1982, the proteins were renamed CD3. Now it is known that OKT3 binds to properly folded CD3ε expressed on the T cell surface and the interaction has been characterized in detail using X-ray crystallography.

Genomic Organization and Protein Structure

The CD3 genes are clustered in a 50-kb region of chromosomes 11 and 9 in humans and mice, respectively (Tunnacliffe et al. 1988). CD3δ is located in the



CD3, Fig. 1 Schematic representation of the CD3 subunits. CD3ε, CD3γ, and CD3δ are shown with their structural features highlighted



CD3, Fig. 2 The TCR-CD3 complex. CD3γ and CD3δ, each form a heterodimer with CD3ε. These heterodimers associate with TCRαβ and CD3ζζ to generate the TCR-CD3 complex that is expressed on T cells of the immune system. TCRαβ are the ligand-binding subunits, while the CD3 chains aid in receptor assembly, transport to the cell surface, and in signal transmission. Important for assembly are the potentially charged amino acids in the TM region of the TCR-CD3

central position of the cluster and flanked on either side by the oppositely transcribed CD3γ and CD3ε gene loci. CD3γ is less than 2 kb apart from CD3δ, and CD3ε is located about 22 kb downstream of CD3δ. CD3δ is encoded by five exons, whereas seven exons encode CD3γ and seven or eight exons encode CD3ε depending on the presence of two and three miniexons in human and mouse, respectively (Fig. 3). A model for the evolution of the CD3 gene family predicts that a single CD3 gene first duplicated to form CD3γ/δ and CD3ε, and a second duplication of the CD3γ/δ gene subsequently generated the CD3γ and CD3δ genes as found in mammals (Gobel and Dangy 2000).

At protein level, the CD3γ, CD3δ, and CD3ε subunits share a similar structure, comprised of an extracellular immunoglobulin (Ig) domain, a stalk region, a TM region of 27 amino acids, and a cytoplasmic domain of 45–55 amino acids. The Ig domains of the CD3εγ and CD3εδ dimers have been characterized by X-ray crystallography and nuclear magnetic resonance (NMR). Like all proteins that enter the secretory pathway, the CD3 chains contain an N-terminal signal peptide that targets protein translation to the endoplasmic reticulum (ER). Since this peptide is cleaved co-translationally, it is not present in the mature proteins.

The structure of these subunits can be described as follows.

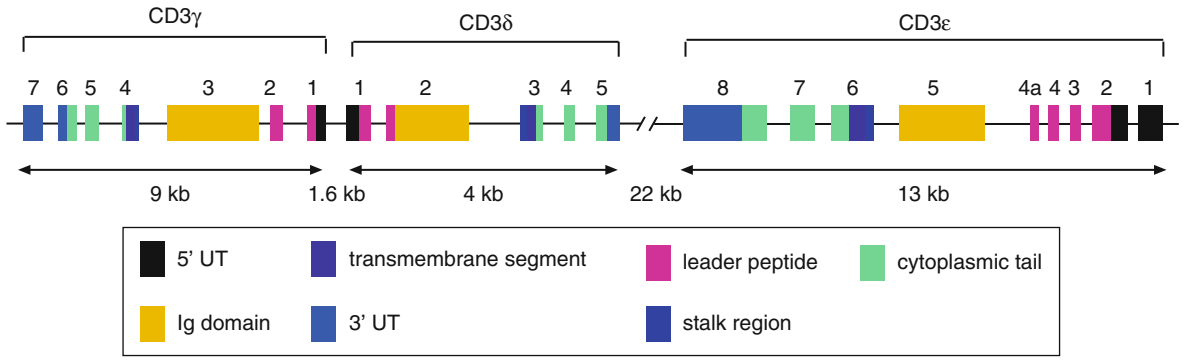
Ectodomains

The solution structure of the Ig domains of the mouse CD3εγ heterodimer showed that CD3ε and CD3γ both have C2-set Ig domains that interact with each other to form an unusual side-to-side dimer configuration. Crystal structures of the Ig domains of human CDεγ in combination with the OKT3 Fab fragment and human CD3εδ in combination with a single-chain fragment of the anti-CD3ε antibody UCHT1 have been solved (Arnett et al. 2004; Kjer-Nielsen et al. 2004). In contrast to mouse, human CD3ε contains a C1-set Ig fold. Human CD3γ has the C2-set Ig fold. Although the sequence identity between CD3ε and CD3γ is only 20%, the subunits share significant structural homology. Human CD3δ contains a C1-set Ig fold (Fig. 4).

In addition, CD3ε possesses several negatively charged residues in the N-terminal region before the Ig domain, which can be cleaved by metalloproteases. This results in two CD3ε isoforms with different molecular weights and isoelectric points.

Stalk Region

CD3ε, CD3γ, and CD3δ molecules each contain a CXXC motif in their short stalk region connecting the Ig-like domains to their TM regions. Some reports have suggested that the CXXC motif is involved in the dimerization of CD3ε to CD3γ or to CD3δ, or in the



CD3, Fig. 3 Genomic organization of the human CD3 cluster. Approximate sizes of CD3 genes and the intervening sequences are shown

binding of CD3 dimers to TCRαβ. However, other studies did not find significant impairment of assembly either of CD3 dimers or of the TCR-CD3 complex by mutating those cysteines in CD3ε. Molecular dynamics studies have suggested that the β strands of CD3ε become more rigid upon anti-CD3 antibody binding. This stiffening effect can be transmitted to the stalk region. The CXXC motif seems to participate in the transmission of the stiffening effect to the TM and cytoplasmic parts. In accordance with this, mutation of these cysteines in CD3ε prevented both the transmission of an antigen-induced conformational change to the cytoplasmic tail of CD3ε and the activation of T cells (Martinez-Martin et al. 2009). Thus, the stalk region might be important in transmitting the information that antigen has bound from TCRαβ to the cytoplasmic tails of CD3.

Transmembrane Region

CD3ε and CD3δ each possess an aspartic acid residue in its TM region, while CD3γ possesses a glutamic acid residue. These four acidic amino acids, along with two acidic residues of CD3ζζ dimer and three basic TM residues on TCRαβ (Fig. 1), play an important role in the assembly of TCRαβ with CD3εγ, CD3εδ, and CD3ζζ dimers. However, to date it is not known whether these TM residues are charged or not.

Cytoplasmic Region

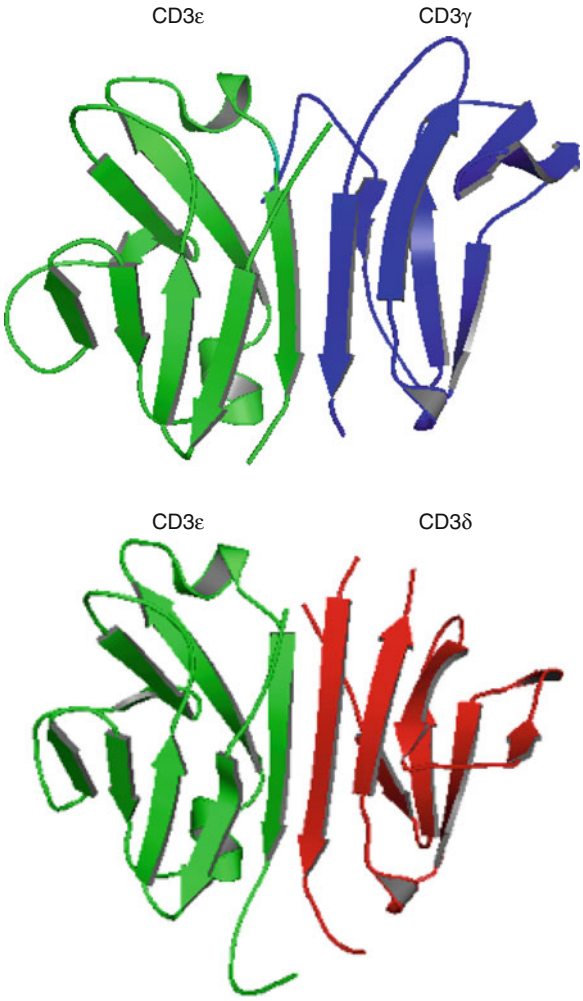
In the cytoplasmic portion, the CD3 subunits possess the signaling motifs discussed below.

Immunoreceptor Tyrosine-Based Activation Motifs

ITAMs have a consensus sequence of Yxx(L/I)$x_{6–8}$ Yxx(L/I) (Reth 1989). This motif was also known as TAM, ARH1, ARAM, YXXL, and Reth motif and occurs in a variety of proteins that include CD3ε, CD3δ, CD3γ, ▶ CD3ζ (3 ITAMs on each ▶ CD3ζ chain), Ig-α, Ig-β, FcεR1β, FcεR1γ, DAP12, and some viral proteins, e.g., the LMP2A protein from the Epstein–Barr virus. The ITAM tyrosine residues of CD3 are necessary for ITAM signaling activity and, when both are phosphorylated, bind to the tandem Src homology 2 (SH2) domains of ▶ ZAP70. Each TCR-CD3 complex contains 10 ITAMs. The exact role of each ITAM is still not defined due to the possibility of redundancy. The non-conserved amino acid sequences within the ITAMs, particularly at positions Y + 1 and Y + 2, might facilitate the association of signaling proteins through SH2 domain-containing domains. Indeed, in addition to ZAP70, phosphorylated ITAMs bind to Syk, Fyn, Lck, p85, Shc, ▶ SHIP, and other signaling proteins. The first tyrosine of the CD3ε ITAM lies within a proline-rich region. CD3 proteins do not contain non-ITAM tyrosines.

Di-Leucine-Based Motif

The di-leucine-based motif (DxxxLL) of CD3γ binds to the clathrin-coated vesicle adaptor proteins AP-1 and AP-2 and is involved in down-regulation of the TCR-CD3 (Dietrich et al. 1994). Phosphorylation of serine 126 induces a conformational change in the context of complete TCR-CD3. The DxxxLL motif is then exposed for AP-1/2 binding, a mechanism required for down-regulation. In an incompletely assembled TCR-CD3 lacking ▶ CD3ζ, the DxxxLL motif is directly accessible and recognized by AP-1 at the trans-Golgi network, leading to sorting of TCRαβCD3εγεδ to lysosomes for degradation. In contrast, in the fully assembled TCR-CD3 complex,



CD3, Fig. 4 Crystallographic structures of the immunoglobulin domains of CD3εγ and CD3εδ. Crystal structures were obtained from the protein data bank (human CD3γε heterodimer in complex with antibody OKT3 Fab fragment, PDB ID: 1SY6 and human CD3δε heterodimer in complex with UCHT1 single-chain antibody fragment, PDB ID, 1XIW) and figures generated using the software MacPymol. For simplicity, the antibody fragments are omitted

the DxxxLL motif is inaccessible, and the receptor follows the default transport route to the plasma membrane. Thus, ▶ CD3ζ masks the CD3γ DxxxLL motif in the fully assembled TCR-CD3 and this effect relies more on the length of the cytoplasmic tail than on the primary sequence (Lauritsen et al. 2004).

Proline-Rich Sequence

Proline-rich sequences (PRS) bind to Src homology 3 (SH3) domains. In CD3ε, the evolutionarily conserved PRS (RPPPVPNPDYEP) binds to the first SH3 domain of the adaptor protein Nck upon a conformational change induced by antigen binding to TCR-CD3 (Gil et al. 2002). The precise function of this interaction is not clear. According to some observations, the CD3ε PRS is necessary for peptide-MHC-induced phosphorylation of CD3ε, and for recruitment of protein kinase Cθ to the immune synapse in differentiated cytotoxic T lymphocytes. It is speculated that the PRS amplifies weak TCR signals by promoting synapse formation and CD3ε phosphorylation. This interaction is also used as a readout for the CD3 conformational change. In addition, Eps8L1 (epidermal growth factor receptor pathway substrate 8-related protein 1) binds to the CD3ε PRS but the functional consequence of this interaction has yet to be determined.

Basic Rich Stretch

The basic rich stretch (BRS, also called phospholipid binding motif) locates to the juxtamembrane portion of the CD3ε cytoplasmic tail (Deford-Watts et al. 2009). Positively charged residues of the BRS enable this part of CD3ε to bind to acidic phospholipids in vitro. The BRS is also shown to be important for localization of CD3ε to the immunological synapse and binding to signaling proteins GRK2 (G protein-coupled receptor kinase2) and CAST (CD3ε associated signal transducer).

Serine Residues

Unique to the cytoplasmic tail of CD3γ are three serine residues which represent potential phosphorylation sites that can subsequently interact with proteins containing phospho-serine binding domains such as 14-3-3, WW, and MH2 domains.

Retention Motif

All subunits of the TCR-CD3 contain ER retention/retrieval motifs. These motifs are important for sequential assembly of the TCR-CD3 components and assure that only a fully assembled TCR-CD3 is expressed on the cell surface. Different subunits contain different numbers of retention motifs. The CD3ε retention motif (an elongated α-helix followed by βI' turn and contains three closely spaced residues, tyrosine, leucine, and arginine) seems to be dominant as the CD3δε and CD3γε heterodimers reach the cell surface when the CD3ε retention motif is mutated. The CD3ε retention motif is overridden only when CD3ζ is incorporated in the TCR-CD3 complex.

Assembly and Membrane Organization

Assembly in the ER begins with the formation of CD3εδ and CD3εγ heterodimers. CD3εδ then associates with TCRα using the potentially charged TM residues (see above). CD3εγ dimers associate with TCRβ in a similar manner (Alarcon et al. 1988). Once TCRαβCD3εγεδ has formed, the CD3ζζ homodimer is the last subunit to join. The CD3ζζ homodimer requires the aspartic acids at position six in the TM regions of CD3ζ for interaction with the arginine residue in TCRα and upon its incorporation, the whole TCR-CD3 complex is transported to the plasma membrane (Sancho et al. 1989). In addition, the ectodomains of CD3δ and CD3γ play a role in selective association of CD3εδ to TCRα and CD3εγ to TCRβ.

No structural data have been obtained for the entire TCR-CD3 complex yet. However, mutagenesis studies suggest that CD3εγ and CD3εδ are located on the same side in the TCR-CD3 complexes, so that the other side can mediate homotypic TCRαβ interactions. Using electron microscopy and Blue Native-PAGE studies, it was shown that TCR-CD3s exist both as monovalent receptors with a stoichiometry of TCRαβCD3εγεδζζ (see below) and pre-clustered multimers of the monovalent receptor (Schamel et al. 2005).

Functions

Together with ▶ CD3ζ, the CD3 subunits are the main signaling units in the TCR-CD3. Upon antigen binding to TCRαβ, a conformational change in CD3ε exposes the PRS where the adaptor protein Nck can bind as discussed earlier. Antigen binding also leads to the phosphorylation of the ITAM tyrosines by the Src family kinases Lck and Fyn, which results in association of ▶ ZAP70 to phospho-tyrosines with its tandem SH2 domains. ▶ ZAP70 phosphorylates the adaptor protein ▶ LAT on several sites, which act as the hub for initiation of downstream signaling. The CD3 subunits also regulate surface TCRαβ expression. Knock-out mice and humans that lack individual CD3 chains show impairment in TCR-CD3 expression. CD3δ associates with the co-receptor CD8 and couples the TCR-CD3 to CD8 for signaling by the CD8-associated kinase Lck (Doucey et al. 2003) and for enhanced apparent affinity to peptide-MHC. As CD3 subunits are also associated with the pre-TCR-CD3 on developing thymocytes, CD3-mediated signaling is required toward progression of the double-positive thymocytes and TCRα gene rearrangement. Pro-T cells express low levels of CD3 possibly in association with calnexin in the absence of TCRαβ at their surface. Anti-CD3ε antibody-induced cross-linking of the CD3 molecules on pro-T cells of RAG-$1^{-/-}$ mice in vivo induces differentiation of these pro-T cells into pre-T cells. This suggests that CD3 has a functional role in pro-T cells.

Various transfection studies, genetic knock-out mice, and natural mutations have revealed the importance of individual CD3 subunits in T cell development. In the absence of intact CD3ε, thymocytes do not progress beyond the $CD44^{-/low}CD25^{+}$ triple-negative stage in the CD3ε knock-out mouse. CD3γ is essential for development of both the αβ and γδ T cell lineages in mice, whereas human patients lacking CD3γ develop αβ and γδ T cells in which CD3γ is replaced by CD3δ. CD3δ-deficient mice develop γδ T cells but no αβ T cells. Human patients lacking CD3δ, on the other hand, fail to develop either αβ or γδ T cells (Dadi et al. 2003). These observations can be explained by the distinct stoichiometries of human and mouse γδTCR-CD3s. While the stoichiometry of human γδTCR-CD3 is TCRγδCD3εγεδζζ, mouse γδTCR-CD3 has a stoichiometry of TCRγδCD3εγεγζζ (Siegers et al. 2007). Also the individual CD3 subunits have partially different roles in T cell development at distinct stages of development. CD3ε-deficiency blocks the T cell development at a triple-negative stage whereas CD3δ is more important for positive selection as evident by the mice lacking CD3δ in which T cells progress from a $CD4^{-}CD8^{-}$ double-negative to a $CD4^{+}CD8^{+}$ double-positive stage but fail to undergo positive selection.

Pathophysiological and Clinical Roles

Absence of individual CD3 subunits causes immunodeficiencies of varying severity. As discussed earlier, CD3δ- and CD3ε-deficient humans fail to develop either αβ or γδ T cells, resulting in severe combined immunodeficiency (SCID) (Dadi et al. 2003; Soudais et al. 1993). Deficiency in CD3γ results in a milder form of SCID, since T cells are present in which CD3γ is replaced by CD3δ (Arnaiz-Villena et al. 1992). Table 1 summarizes the effect of the deficiencies in individual CD3 subunits in human and mouse.

CD3, Table 1 Immunological disorders associated with different CD3-deficiencies in human and mouse

CD3ε	–		–	Malissen et al. (1995)

In addition, anti-CD3 antibodies are used in the clinic for treatment of various immunological disorders. In fact, OKT3 was the first monoclonal antibody to be approved by the US Food and Drug Administration (FDA) in 1986 for clinical use. OKT3 is an immunosuppressant given to reduce acute rejection in patients with organ transplants such as allogeneic renal, heart, and liver transplants. Anti-CD3 antibodies are also used for the treatment of T cell acute lymphoblastic leukemia. Immediately after administration of anti-CD3 antibodies, T cells are depleted from circulation. OKT3 appears to kill CD3 positive cells by inducing Fc-mediated apoptosis, antibody-mediated cytotoxicity, and complement-dependent cytotoxicity. In addition, removal of the TCR-CD3 from the cell surface by internalization is thought to be a mechanism of action. Due to their mitogenic activity and release of cytokines, Fc receptor (FcR)-binding antibodies such as OKT3 induce flu-like symptoms in treated patients. Thus, in 1994 the first humanized non-FcR-binding antibodies specific for human CD3 were produced and by late 1990s successfully used in the clinic. Teplizumab and Visilizumab are some of the non-FcR-binding anti-CD3 antibodies used to date (Chatenoud and Bluestone 2007).

Summary

The three CD3 subunits CD3γ, CD3δ, and CD3ε form an integral part of the TCR-CD3 complex and, together with ▶ CD3ζ, provide TCRαβ (and TCRγδ) with the signal transmission ability upon antigen binding. The CD3 proteins are type 1 TM proteins that form dimers, CD3εγ and CD3εδ, containing diverse cytoplasmic signaling motifs for inducible interaction with kinases, adaptor proteins, and other signaling proteins. In addition, CD3 is important for the assembly and surface transport of the TCR-CD3. Thus, CD3 subunits are crucial for both normal T cell development and their function in the periphery. Lack of any of these subunits causes immunodeficiencies. Anti-CD3 antibodies are being used in the clinic as immunosuppressants to reduce acute transplant rejection and in the treatment of T cell acute lymphoblastic leukemia.

ADP-ribosyl cyclase; cADPr hydrolase; Cyclic ADP-ribose hydrolase; T10 antigen

Historical Background

As with many molecules, CD38 was first identified in the early 1980s through the pioneering work of E. L. Reinherz and S. F. Schlossman. It was identified by the monoclonal antibody OKT10, and for this reason, the molecule was initially called T10 antigen (Reinherz et al. 1980). Through the production of many monoclonal antibodies, this research team identified numerous molecules associated with the T cell receptor (TCR) and many others that eventually produced lineage markers initially used to define clusters of differentiation (CDs). Several years later, using a cloning system designed by B. Seed and A. Aruffo, D. G. Jackson and J. I. Bell cloned and identified the T10 antigen (Jackson and Bell 1990). *This molecule had been defined as CD38 by the panel of the 4th International Conference on Human Leukocyte Differentiation Antigens*. The preliminary interest in this molecule was due to the distinctive discontinuous expression revealed during the maturation of both T and B lymphocytes. The identification and cloning of murine CD38 opened new avenues to investigate its biological role not only because a closer look was feasible using rodents but also because it was possible to manipulate its expression to analyze its roles in many different biological processes.

CD38 Gene and Protein

CD38 was the prototype of a new family of molecules that includes both CD157 and the enzyme ADP-rybosil cyclase, identified in the sea slug *Aplysia californica* (GeneCards®; Human Genome Organisation (HUGO)). Throughout the years, other members have been cloned or predicted in mammals, birds, amphibian, and fish (Fig. 1) (Malavasi et al. 2008). Due to the homology, chromosome location, and gene organization between CD38 and CD157, it is thought that both molecules came from a common ancestor that was duplicated around 300 million years ago. The CD38 gene is located on chromosome 4p15 in humans and chromosome 5 (23.85 cM) in mice. The gene spans more than 80 kb and consists of eight exons and seven introns. Intron 1 is about 37 kb and interrupts the 5-prime coding region. Exon 1, the largest exon, encodes intracytoplasmic, transmembrane, and membrane proximal (33 aa) regions (GeneCards®; Human Genome Organisation (HUGO); OMIM ®). Exons 2–8 are smaller and encode the rest of the extracellular domains. Gene expression is regulated by retinoic acid, TNF (Tumor necrosis factor), and IFNβ among other factors (Malavasi et al. 2008; OMIM ®).

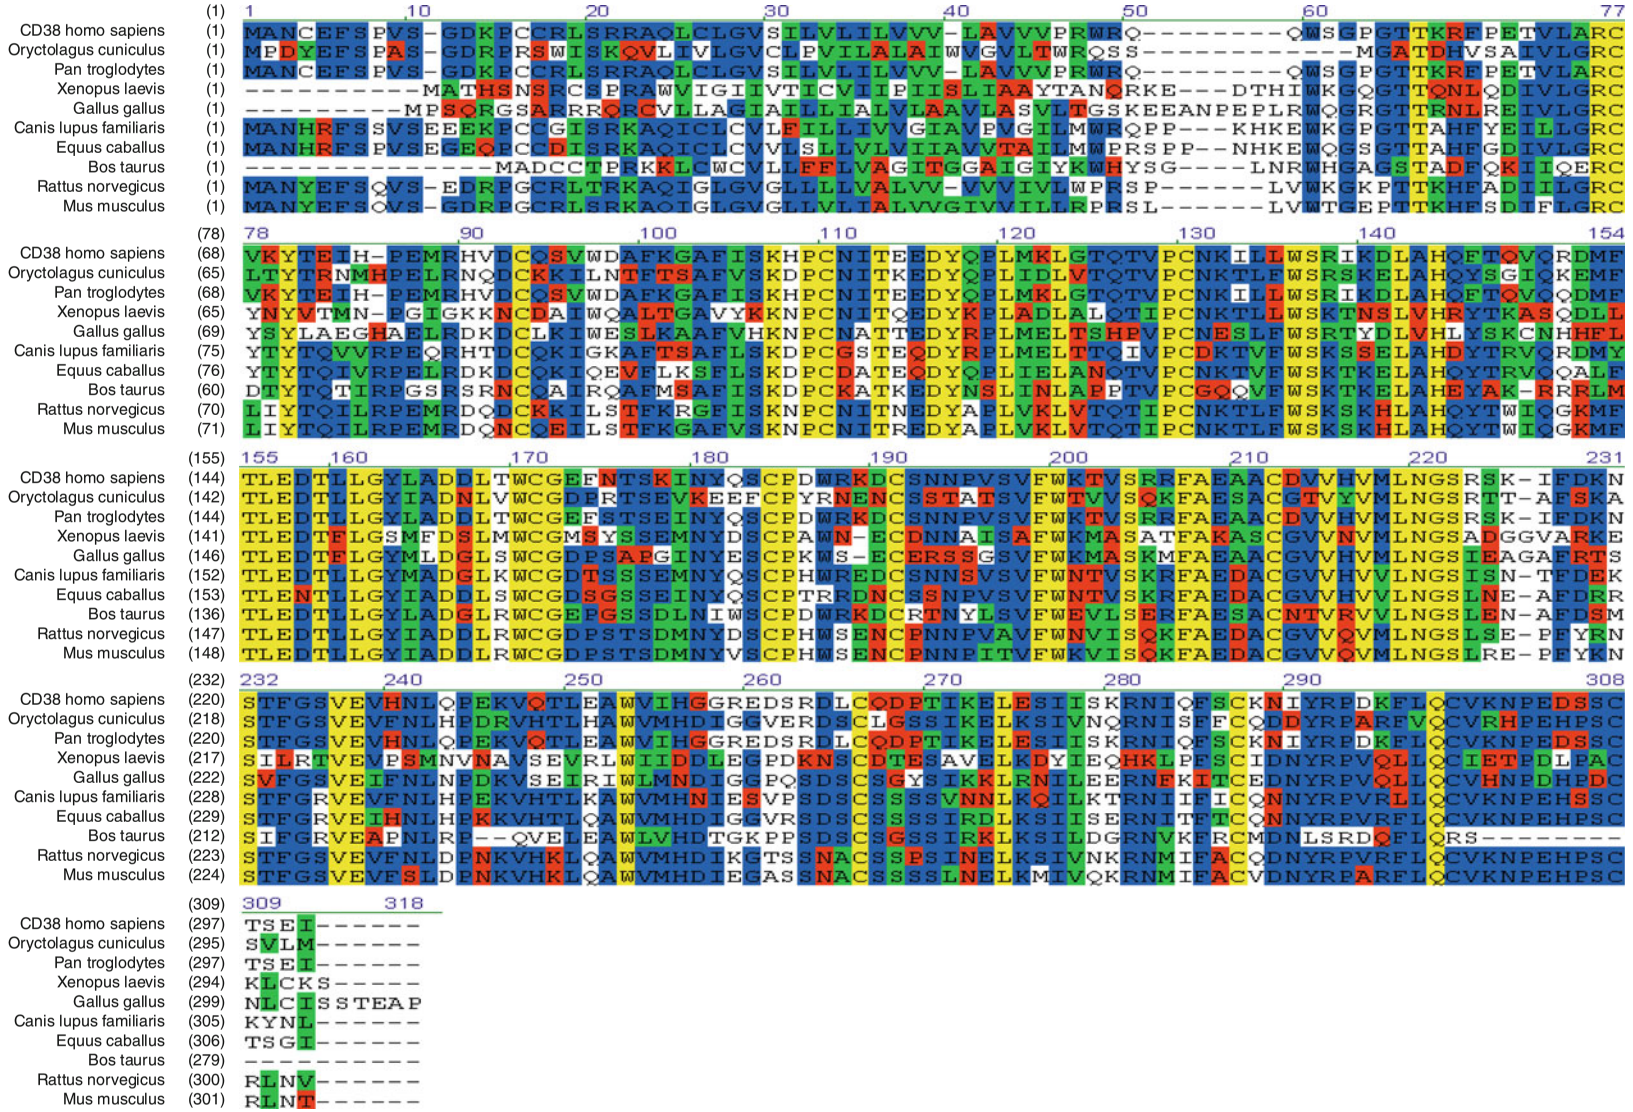
CD38 protein is a 45 kDa type II glycoprotein. It contains an intracytoplasmic (∼21 aa), transmembrane (∼22 aa), and extracellular (∼257 aa) region. The extracellular domain contains four glycosylation sites and is divided into two domains: the NH2 (amino membrane proximal) domain, which is comprised of a bundle of five α-helices and two short β-strands (residues 45–118 and 144–200) and the COOH (membrane distal) domain, which is comprised of four parallel β-sheets, two long, and two short α-helices (residues 119–143 and 201–300). The NH2 and COOH domains are connected by a hinge region composed of three peptide chains (residues 118–119, 143–144, and 200–201). CD38 is an ectoenzyme whose catalytic activity depends on the disulfide bonds that stabilize the conformation of the enzyme (Lee 2006).

CD38 Distribution

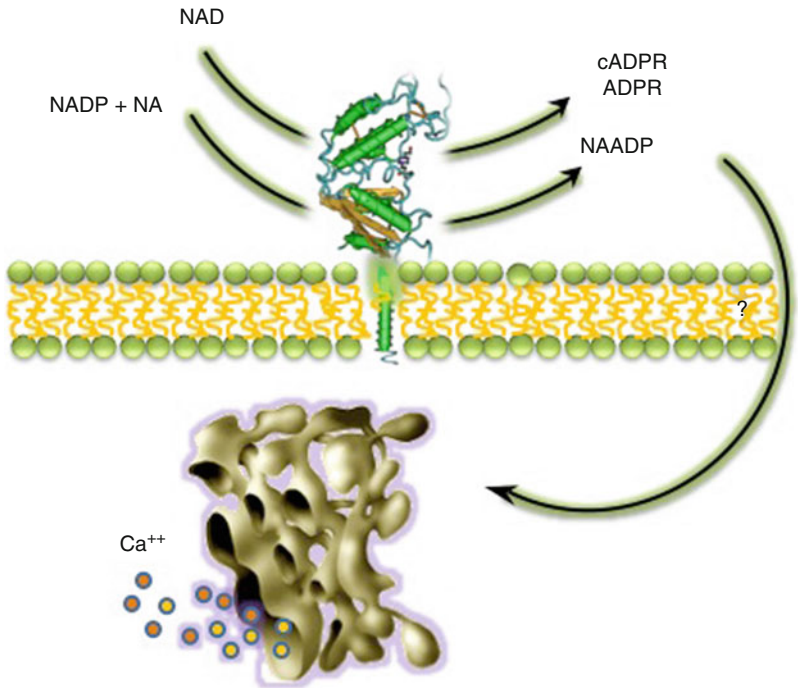
Historically, CD38 was first identified as a leukocyte marker, expressed in both T and B lymphocytes. However, CD38 is widely distributed in myeloid, bone marrow, pancreas, prostate, brain, kidney, muscle, and eye cells (GENATLAS; Higashida et al. 2007; Human Genome Organisation (HUGO); Malavasi et al. 2008; Okamoto et al. 1997; OMIM ®). Some reports of the distribution outside the immune system have found CD38 in the cytoplasm and the nucleus of these cells (Malavasi et al. 2008; Okamoto et al. 1997). In lymphocytes, the expression of CD38 is tightly regulated, and its expression fluctuates during the different stages of the development and differentiation of these cells (Campana et al. 2000; Malavasi et al. 2008).

CD38 as an Enzyme

The analysis of the CD38 sequence showed a low homology (∼30%) with an enzyme cloned from the sea slug *Aplysia*; however, the gene structure was similar, and more importantly, 10 out of 12 cysteines were fully conserved indicating that CD38 may have a similar conformation and function. As predicted, CD38 showed enzymatic activity within its extracellular domain (Howard et al. 1993). CD38 uses nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP) plus nicotinic acid to produce cyclic ADP ribose (cADPr), ADP ribose (ADPr), and nicotinic acid adenine dinucleotide phosphate (NAADP). This finding is important because it highlights that cADPr, and later NAADP, can mobilize Ca++ by an IP3-independent mechanism. The Ca++ mobilization requires ryanodine sensitive channels (RyR) (Lee 2006; Schuber and Lund 2004). Conversely, one of the difficulties with this finding is that the substrates are not usually found in the extracellular milieu, and the products of the enzymatic reaction reach the internal compartments, where these ryanodine Ca++ compartments are located. Mechanisms have been suggested that resolve these discrepancies, including specific channels that transport the products of the enzymatic reaction inside the cell. A second suggestion elaborated in several papers is that the CD38 active site may also face the cytosol or that there may even be a cytosolic isoform; however, neither genetic nor clear biochemical evidence for these isoforms has yet been published. An intermediate argument is that CD38 may be found in vesicles, but still the substrate would need to enter the vesicle and the products would need to be transported into the cytosol. For immune cells, it has been suggested that inflammation, including cell destruction, may provide



CD38, Fig. 1 Alignment of CD38 from ten species. Indicating the conserved amino acids, the colors indicate black = non-similar; red = weakly similar; green = similar; blue = conservative; and yellow = identical; respectively

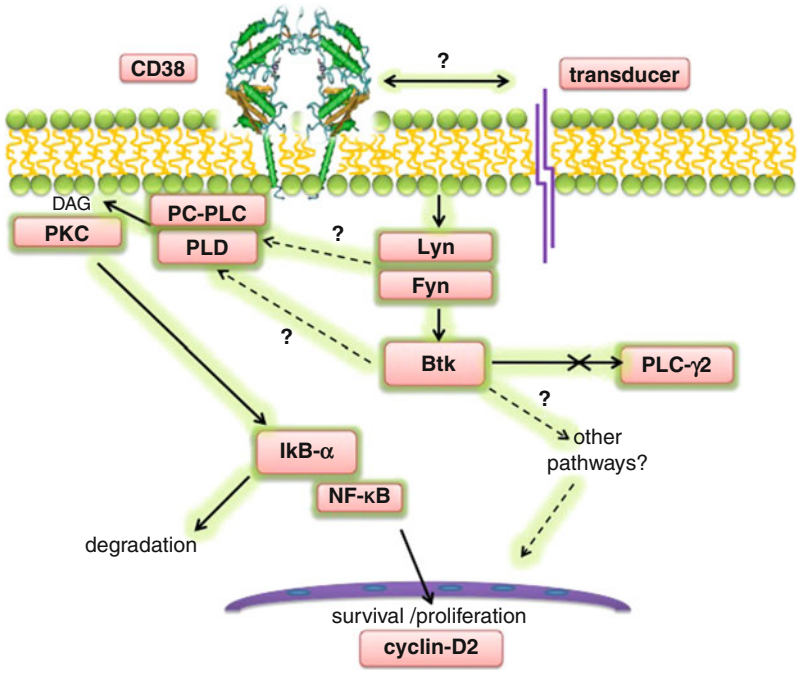


CD38, Fig. 2 CD38 as an enzyme. CD38 uses nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP) plus nicotinic acid (NA) to produce cyclic ADP ribose (cADPr), ADP ribose (ADPr), and nicotinic acid adenine dinucleotide phosphate (NAADP). NAADP and cADPr mobilize Ca++ by an IP3-independent mechanism

the necessary substrates, but the transfer of the products still requires the identification and characterization of specific channels that facilitate their transport through the plasma membrane (Schuber and Lund 2004). Although enzymatic activity has been described as important for the functions of CD38 in immunity, CD38 has also demonstrated a variety of functions outside the immune system. For example, CD38 has been shown to participate in the regulation of insulin and oxytocin secretion and to have roles in diabetes and social behavior (Higashida et al. 2007; Okamoto et al. 1997). It has also been shown that CD38 participates in resorption of bone. All these activities depend on the enzymatic activity of this molecule (Fig. 2) (Malavasi et al. 2008; Schuber and Lund 2004).

CD38 as a Receptor

Most of the work characterizing CD38 as a receptor has come from studies using agonistic antibodies (usually monoclonal) for the activation of lymphocytes. The first set of evidence used the monoclonal antibody (mAb) A10/1B4. This mAb induced the proliferation of human peripheral blood mononuclear cells (PBMC). Stimulation of CD38 in human T lymphocytes induced the phosphorylation of different substrates (CD3-ε, PLC-γ1, c-Cbl, ZAP-70, LAT, and Shc) and the initiation of canonical signaling pathways shared by other receptors, such as CD3, even though there are differences between stimulation through CD38 and TCR (Malavasi et al. 2008). Mature B lymphocytes also respond to CD38 crosslinking through proliferation and differentiation (Lund 2006; Moreno-Garcia et al. 2005). Agonistic antibodies include clones of rat anti-mouse mAbs NIM-R5, Ab 90, and CS/2. Interestingly, both human and murine B lymphocytes respond differentially to the engagement of CD38 depending on their maturation status. Thus, immature B cells become apoptotic, while more mature cells proliferate and differentiate (Campana et al. 2000; Moreno-Garcia et al. 2005). This dual response has also been described for stimulation through the B cell antigen receptor (BCR). The signaling pathways involved with these responses in B cells have not been completely elucidated, but they include the recruitment and activation of BTK (Bruton's Tyrosine Kinase), as well several canonical proteins previously described in activation via the BCR. Interestingly, the signaling of murine B cells through CD38 seems to be



CD38, Fig. 3 CD38 as a receptor in murine B lymphocytes. CD38, probably associates with some transduction signaling subunits, activates Lyn and Fyn, which in turn activates Btk. Btk does not activate PLC-γ2 and instead may participate in the activation of PC-PLC/PLD. Activation of PC-PLC/PLD then promotes the production of DAG, activation of PKC, and NF-kB translocation to nucleus, providing signals that promote cell survival, cyclin-D2 expression, and cell proliferation

independent of PLCγ2 participation and IP3 production (Moreno-Garcia et al. 2005). To date, this represents the main difference between the activation triggered by CD38 and the activation triggered by BCR, whose requirement of PLCγ2 seems to be essential. There is, however, an increase of cytosolic Ca++ that has been linked to the enzymatic activity of CD38, as described earlier. Protein Kinase C (PKC) recruitment and activation, which require diacylglycerol (DAG), are downstream of the CD38/BTK pathway, and other phospholipases must participate to generate this metabolite. Both phosphorylcholine-PLC (PC-PLD) and PLD have been shown to participate in the generation of DAG, but the connections among CD38, BTK, and these two phospholipases are still missing (Fig. 3) (Moreno-Garcia et al. 2005).

The cytoplasmic tail of CD38 is very short and does not contain canonical motifs involved in signal transduction. There is some literature suggesting a direct link between CD38 and Lck; however, most of the studies assessing the receptor properties of CD38 support an indirect association with the transduction machinery. One of the strongest arguments against a direct link is the finding that the cytoplasmic tail is unnecessary for signaling, suggesting instead that CD38 associates laterally with other molecules to transmit its signal. For T lymphocytes, it has been described that CD38 uses the CD3/TCR module, while there is evidence of participation of both the BCR and the complex CD19/CD21/CD81 in B cells. For NK cells, monocytes, and dendritic cells studies indicate the modules CD16/CD81, MHC-II/CD81, and CD11b/CD81/CD83, respectively (Lund 2006; Malavasi et al. 2008).

As described previously, some functions of CD38 activity may be attributed to its enzymatic activity; however, there is also clear evidence that enzymatically dead mutants can transmit signals. Therefore, for at least for some biological functions of CD38, its receptor activities are completely independent of its enzymatic activity (Lund 2006).

The only CD38 ligand identified so far is CD31, a molecule present in endothelial cells as well several leukocytes and platelets. There is at least one other possible candidate described in murine dendritic cells that may participate in the engagement of CD38 present on the surface of T and B lymphocytes. This is an interesting possibility because it has been shown that CD38 is recruited to the immunological synapse during the interaction of T lymphocytes with antigen presenting cells (Malavasi et al. 2008).

CD38 in Health and Disease

For more than a decade, CD38 has been used to classify tumors from patients suffering from different types of leukemia. CD38 on CD8 T cells have also been used extensively to evaluate AIDS progression in patients infected with HIV. During the mid-1990s, it was clear that CD38 had a dual function as both an enzyme and a receptor, but there was no association between its dysfunction and any disease. After the development of CD38 deficient mice (CD38−/−), it was possible to evaluate its function in the general health of these rodents. From the results of various studies, it was possible to speculate about human diseases in which CD38 may be involved. The first results indicated that although CD38−/− mice have no major defects in hematopoiesis, they have difficulties in the production of antibodies. Later, it was shown that these mice also have deficiencies in innate immunity, especially in the ability of their neutrophils to migrate to sites of infection. Additionally, dendritic cells from CD38−/− mice showed deficiencies in migration, affecting the priming of specific T cells and, as a consequence, affecting T-B cell collaboration for the adequate production of antibodies. Although these deficiencies are mild, they have an important impact, making the animals more prone to some infections (Lund 2006; Malavasi et al. 2008).

Outside of the immune system, the results from CD38−/− mice have also been very enlightening. For example, it was demonstrated that these mice have lower insulin levels than their wild-type counterparts. Because it is known that NAD is important in controlling insulin secretion, these results can be linked to CD38 enzymatic activity. This effect can be explained by the CD38-dependent production of cADPr that controls the Ca++ release from internal stores, which regulates insulin secretion (Okamoto et al. 1997). There is evidence in the literature about the role of CD38 in the development of human diabetes, and it is clear that CD38 is one of the many factors controlling the development of this complex and multigenic disease. Related to the control of caloric metabolism, CD38−/− mice are also shown to be resistant to developing obesity when fed high fat diets, in contrast with their wild-type counterparts that became significantly obese; this result is an exciting phenomenon that has yet to be fully explained.

Finally, CD38 has also been implicated in the regulation of oxytocin secretion, which has an important role in social behavior. CD38−/− female mice have defects in maternal nurturing and male animals fail to develop social memory. The role of enzymatic activity of CD38 in this phenomenon was demonstrated with the administration of enzyme antagonists in wild-type mice to mimic the effect of the absence of CD38. Therefore, it is possible to speculate that some human neurodevelopmental disorders may relate to the defective expression or function of CD38, thus opening the possibility for a pharmacological approach to treat these diseases (Higashida et al. 2007).

Summary

Despite the fact that there are more than 20 years since the initial description and cloning of CD38, its biological role is just emerging, revealing unexpected surprises. Most studies investigate the role of CD38 in leukocytes, but knowledge of its role outside of the immune system is growing greatly and unveiling many of its undisclosed roles. Due to its wide distribution in organisms, it is reasonable to expect more discoveries about the biological roles of this molecule, and there is still much work to be done to fully understand the many ways in which CD38 participates in the control of many diverse biological activities.

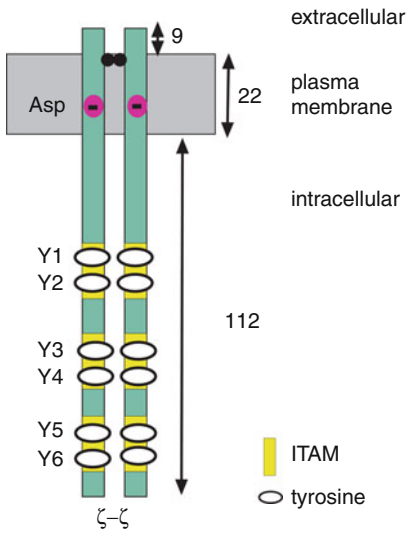
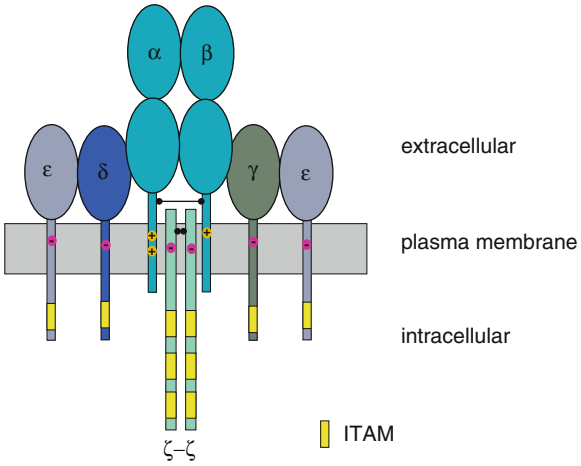
Introduction

CD3ζ is a homodimer-forming type 1 transmembrane (TM) protein and is part of the T-cell antigen receptor (TCR-CD3) complex along with TCRαβ, CD3γε, and CD3δε dimers expressed on the surface of T cells (Figs. 1 and 2). T cells are an important component of the vertebrate adaptive immune system that are activated via TCR-CD3 by the peptides generated from infectious agents and presented on major histocompatibility complex (MHC) molecules on the surface of cells. CD3ζ possesses a small extracellular part, a TM region, and a long cytoplasmic part that contains three immunoreceptor tyrosine-based activation motifs (ITAMs), which correspond to the six tyrosines that get phosphorylated upon antigen binding to the extracellular part of TCRαβ. Phosphorylation subsequently activates several downstream signaling cascades. Hence, CD3ζ plays a vital role in the activation of a T cell. CD3ζ is also part of the pre-TCR-CD3 in pre-T cells and the γδTCR-CD3 in γδ T cells that contains TCRγδ instead of TCRαβ. In addition, CD3ζ



CD3ζ, Fig. 1 Schematic representation of CD3ζ. CD3ζ possesses a small nine amino acid ectodomain, a TM region, and a long cytoplasmic domain (112 amino acids in human) with three ITAMs, each of which contains two tyrosines. The two CD3ζ chains are joined by a disulphide bond at the border of the extracellular and the TM regions



CD3ζ, Fig. 2 Structure of the TCR-CD3 complex. The CD3ζζ dimer is a component of the TCR-CD3 complex, which in addition contains CD3γε, CD3δε, and TCRαβ and is expressed on T cells of the immune system. TCRαβ are the ligand binding subunits, while the CD3 chains aid in receptor assembly, transport to the cell surface, and in signal transmission. Important for assembly are the potentially charged amino acids in the TM region of the TCR-CD3

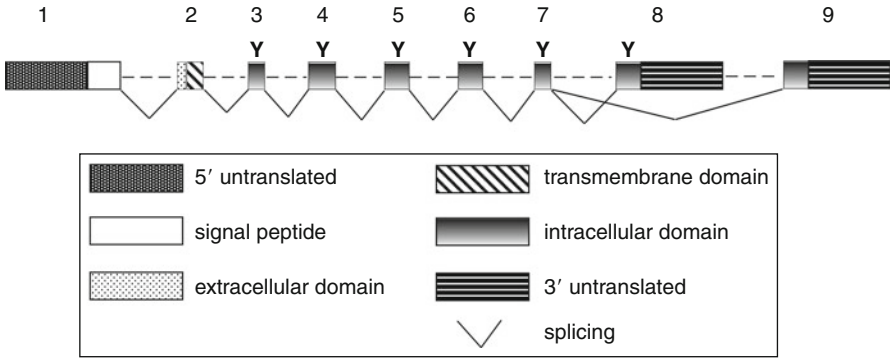
is also expressed in other cell types and as a member of other receptor complexes. In experimental studies, CD3ζ is often tagged with fluorescent proteins for the study of TCR-CD3 dynamics in the immune synapse.

Historical Background

CD3ζ was first discovered in T cells as a component of the TCR-CD3 in 1985 (Samelson et al. 1985) (and was the last subunit of TCR-CD3 to be discovered) and as a part of the pre-TCR-CD3 complex where it was shown to play an important role in T cell development. Later, it was also found to be a component of the activating receptors NK-cell protein 46 (▶ NKp46), NKp30, and the low affinity Fc receptor for IgG (FcγRIII), which are expressed by NK cells (Lanier et al. 1989). It was recently found expressed in retinal ganglion cells, where it regulates neuronal development (Xu et al. 2010).

Evolution, Genomic Organization, and Protein Structure

The CD3ζ gene is evolutionarily related to other ITAM-containing proteins as highlighted by analysis of its exon–intron organization. The nucleotide sequence corresponding to each of the three CD3ζ ITAMs is encoded by two exons that are interrupted by a phase 0 intron at the same position (one amino acid after the first tyrosine of the ITAM). This indicates that these repeated motifs probably derive from triplication of an ancestral pair of exons, the product of which participates in the intracellular signaling by binding to tandem SH2 domain–containing proteins. Such exon–intron structure is also present in most of the other sequences coding for ITAMs. Therefore, a primitive two-exon set has probably undergone multiple rounds of duplication and transposition through evolution to give rise to the gene for CD3ζ by triplication and to various Ig-like (Ig-α, Ig-β, CD3γ, CD3δ and CD3ε) or non-Ig-like (FcεRI-β, FcεRI-γ, DAP-12/KARAP) ectodomain-containing proteins through exon shuffling. It is speculated that the CD3ζ, FcεRI-γ, and DAP-12/KARAP polypeptide set might have branched off from the ancestor of the CD3εγδ set and lost the exon corresponding to the extracellular Ig domain. Therefore, CD3ζ probably shares both a common origin (an ancestral two-exon set) and a common function (recruiting SH2-containing signaling proteins) with the other ITAM-containing proteins found associated with immunoreceptors (Malissen 2003).



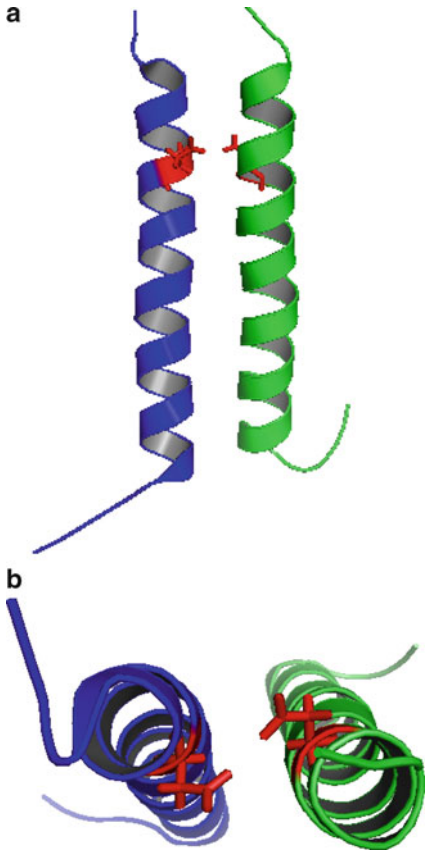
CD3ζ, Fig. 3 Genomic organization of the human CD3ζ gene. The gene encoding CD3ζ is localized to the distal part of chromosome 1 and comprises a total of nine exons. CD3ζ is translated from the first eight exons while in an alternatively spliced form, CD3η, exon 8 is replaced with exon 9. The nucleotides location corresponding to each ITAM tyrosine is marked by Y in exons 3–8

However, the CD3ζ chain differs from other TCR-CD3 subunits in its genetic organization, chromosomal localization, and protein structure. The gene encoding the CD3ζ chain is found in the distal part of chromosome 1 in humans and mice. There is an alternatively spliced form, CD3η, in which exon 8 (zeta specific exon) is replaced with exon 9 (η specific exon) (Ohno and Saito 1990) (Fig. 3). In some circumstances, the TCR-CD3 complex can contain heterodimers of CD3ζ/η or FcRγ. For example, following activation of the γδ T cells, FcRγ is expressed and is included in the γδTCR-CD3 complex (Hayes and Love 2002), and in $CD4^{-}CD8^{-}$ double negative $NK1.1^{+}$ T cells, FcRγ forms a heterodimer with CD3ζ which may drive these cells along NK cell lineage (Curnow et al. 1995).

At its N-terminus CD3ζ contains a signal peptide that targets protein translation to the endoplasmic reticulum. Since this peptide is cleaved co-translationally, it is not present in mature CD3ζ. Unlike the other ▶ CD3 subunits, CD3ζ has a very short ectodomain of nine amino acids and a long cytoplasmic tail (112 amino acids in human and 113 in mouse) and does not belong to the Ig supergene family. The short CD3ζ ectodomain is buried within the TCR-CD3 complex and its length, but not primary amino acid sequence, is highly conserved across orthologs. When this domain is artificially enlarged, the resulting TCR-CD3 complex is distorted leading to a hyperactive phenotype and enhanced T cell activation (Minguet et al. 2008). So far, only the three-dimensional structure of the TM part of the CD3ζζ dimer has been solved by NMR studies (Call et al. 2006), which showed that the TM domain of CD3ζ adopts an α-helical structure (Fig. 4). The TM dimer interface is composed of both hydrophobic packing interactions and intermolecular hydrogen bonds and a potentially charged aspartic acid on each CD3ζ. A disulfide bond between the cysteine residues in the TM portion stabilizes the dimer, although it is not absolutely required for dimerization or assembly with the TCR. In its cytoplasmic domain, CD3ζ contains three ITAMs, which get phosphorylated upon antigenic stimulation. In contrast, CD3η contains 155 amino acids and only two ITAMs in its cytoplasmic domain.

Assembly and Membrane Organization

Only a fully assembled TCR-CD3 complex is transported to the T cell plasma membrane, while individual subunits are most likely degraded in the endoplasmic reticulum. Thus, in T cells lacking CD3ζ, a TCRαβCD3εγεδ complex is only expressed at low levels on cell surface. CD3ζ is the last subunit to be associated with TCR-CD3 complex and may only assemble to the other subunits in the Golgi, where it shields the lysosomal targeting sequence in CD3γ. Each of the CD3ζ, CD3ε, and CD3δ molecules possess an ionizable aspartic acid in their TM region, while CD3γ possesses a glutamic acid residue. Together, this gives six acidic residues in the TM region of the TCR-CD3 complex. TCRβ and TCRα possess one and two basic residues, respectively, in their TM



CD3ζ, Fig. 4 NMR structure of CD3ζ transmembrane region. The TM domain of CD3ζ adopts an α-helical structure. The NMR structure was downloaded from protein data bank (PDB ID: 2HAC) and images prepared using the software MacPymol. The acidic residue aspartic acid is shown in the stick form. (**a**) is rotated by approximately 90° compared to (**b**)

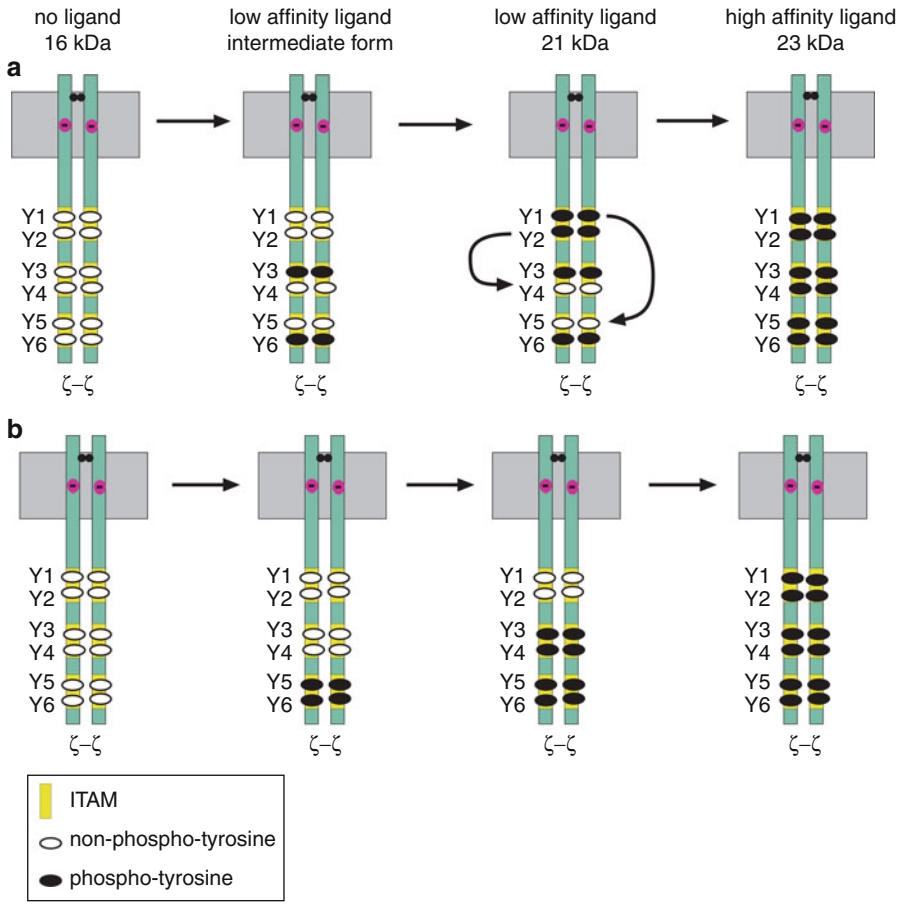
region. This gave rise to the speculation that each TCR-CD3 complex might contain two TCRαβ dimers to balance the six acidic residues in the CD3εγεδζζ. However, several studies have now confirmed a stoichiometry of TCRαβCD3εγεδζζ (Schamel et al. 2005). Indeed, assembly of each of the three CD3 dimers with TCRαβ involves a trimeric interface between one basic and two acidic TM residues where CD3ζ associates with TCRα. So the basic TCR–CD3 complex is monovalent, which then associates with other TCR-CD3 complexes to give rise to TCR-CD3 nanoclusters. The exact role of these TCR-CD3 nanoclusters is still a question under study but it might provide the T cell with high sensitivity to detect minute numbers of antigenic peptides (Schamel et al. 2005).

Phosphorylation and Internalization of CD3ζ

Following receptor ligation, CD3ζ is the most heavily tyrosine phosphorylated subunit of the TCR-CD3. The phosphorylation pattern of CD3ζ has been a topic of intense debate. In Western blot experiments, several forms of CD3ζ can be observed depending upon its phosphorylation status. Among these, forms with an apparent molecular weight of 16, 21, and 23 kDa are the most prominent in reducing SDS-PAGE. The 16 kDa form represents non-phosphorylated CD3ζ. The 21 kDa form most likely represents CD3ζ phosphorylated at four tyrosines and is generated upon stimulation of T cells by low affinity self pMHC ligands or altered peptide ligands. The 23 kDa form results from phosphorylation of all the six tyrosines upon stimulation with high affinity foreign pMHC ligands. The order of phosphorylation of the different tyrosines and which four tyrosines are phosphorylated in 21 kDa form is not clear, as the results from different studies are contradictory. According to one study (Kersh et al. 1998), tyrosine 3 (Y3) and tyrosine 6 (Y6) are phosphorylated in resting T cells (Fig. 5a), most likely by the interaction of TCRαβ with low affinity self-peptides presented on MHC. Upon stimulation by high affinity foreign peptides on MHC, the phosphorylation of tyrosines follows a specific order as indicated in Fig. 5a. In a second study (van Oers et al. 2000), a different order of phosphorylation was proposed (Fig. 5b). The four membrane distal tyrosines are phosphorylated by low affinity self-pMHC interactions (the 21 kDa form of CD3ζ) and all tyrosines are phosphorylated only upon high affinity interaction with foreign pMHC (the 23 kDa form) as in the earlier study.

CD3ζ has not been reported to undergo serine or threonine phosphorylation.

How the binding of pMHC ligand to the ectodomains of TCRαβ transmits the signal to the cytoplasmic tail of CD3ζ has not been resolved yet. In aqueous solution, the cytoplasmic tail of CD3ζ is unstructured, whereas in the presence of liposomes it exhibits a helical secondary structure. This lipid binding-dependent conformational change in CD3ζ could be one activation mechanism. In the pre-activation state when CD3ζ is bound to the inner leaflet of the plasma membrane, it is resistant to phosphorylation by the ► Src family tyrosine kinases. TCR-CD3 engagement by pMHC ligands might force cytoplasmic tails



CD3ζ, Fig. 5 Phosphorylation pattern of CD3ζ. After different stimulation of the TCR-CD3, several distinct molecular weight forms of CD3ζ can be distinguished by reducing SDS-PAGE. There are two models (a and b) that explain to which phosphorylation forms they correspond. (**a**) In one model, tyrosine 3 (Y3) and tyrosine 6 (Y6) are phosphorylated in resting T cells. Upon stimulation by antigen, the phosphorylation of tyrosines follows a specific order as indicated. Only the high affinity agonist ligand results in full phosphorylation and generates 23 kDa CD3ζ form. (**b**) In another model, CD3ζ undergoes a stepwise phosphorylation that is initiated at Y6. Tyrosines 3–6 are phosphorylated by low affinity self-peptide-MHC interactions (21 kDa form) and all tyrosines are phosphorylated upon high affinity interaction with foreign peptide loaded on MHC (23 kDa)

to be released from the membrane, which now are accessible for phosphorylation by the kinases (Aivazian and Stern 2000). Another possibility is that the TCR-CD3 is in equilibrium between open and closed conformations. CD3ζ tyrosines are only accessible for phosphorylation in the open conformation. In resting state, equilibrium favors the closed, inaccessible conformation. pMHC binding stabilizes the open conformation, hence makes the tyrosines accessible for phosphorylation (Minguet and Schamel 2008).

TCR-CD3 is constitutively internalized and recycled to the plasma membrane in naïve and activated T cells. Phosphorylation of TCR-CD3 upon activation by antigen binding leads to enhanced TCR-CD3 down regulation from surface. Cell surface TCR-CD3s lacking CD3ζ are endocytosed more rapidly than completely assembled receptors. CD3ζ may stabilize TCR-CD3 expression on cell surface by blocking access to the internalization motifs on other CD3 subunits (D'Oro et al. 2002). On the other hand phosphorylated CD3ζ targets internalized TCR-CD3 for ubiquitin-dependent degradation. Src-like adapter protein (SLAP) binds to internalized and phosphorylated CD3ζ via its SH2 domain in the endosomal compartment and mediates recruitment of the E3 ubiquitin ligase CBL (Casitas B-lineage lymphoma; also known as c-CBL), resulting in ubiquitylation of CD3ζ, thereby targeting the TCR-CD3 for

degradation. A recent study suggests that phosphorylated CD3ζ accumulates in endosomes (Yudushkin and Vale 2010). This endosomal CD3ζ remained signaling competent and could possibly help to sustain long term signaling in T cells.

Functions

The TCR-CD3 complex plays a critical role in the immune response by activating the T cells which then help in the activation of B cells by releasing helper cytokines (helper T cells) or kill the target cell directly by inducing apoptosis. CD3ζ has two important functions: (1) assembly of the TCR-CD3 complex in the ER/Golgi and transport to the cell surface, as a TCR-CD3 complex lacking CD3ζ is mostly subjected to lysosomal degradation, (2) signaling, as the TCRαβ or TCRγδ dimer itself lacks the signaling motifs and relies on the CD3ε, CD3γ, CD3δ, and CD3ζ components for intracellular signaling. Each CD3ζ contains six tyrosines, helping in signal amplification. The tyrosines of the ITAM are phosphorylated by the Src family kinases Lck and Fyn. This leads to the recruitment of the tyrosine kinase ► ZAP70 to the phosphotyrosines via its tandem SH2 domains. This initiates further downstream signaling and ultimately activation of the T cell. A similar sequence of events takes place in the signal transduction downstream of pre-TCR-CD3 in the developing pre-T cells. The signals are required for TCRα gene arrangement and further development of these cells. In addition, CD3ζ is expressed on pro-T cells. In pro-T cells CD3ζ was phosphorylated upon anti-CD3ε antibody stimulation, although no direct association between CD3ζ and other CD3 subunits was observed. CD3ζ-deficient mice have a decreased number of peripheral T cells, as will be discussed later.

Several studies have been performed to explore the role of the individual ITAMs in the different CD3 proteins in T-cell development and function. According to one study, together the ITAMs in CD3ε, CD3γ, and CD3δ can provide normal TCR-CD3 signal transmission in mature, peripheral T cells, and CD3ζ ITAMs play mainly a role in positive selection in the thymus (Pitcher et al. 2005b). However, in another study, expression of the mutant CD3ζ, which lacked Y1 and Y2, so that the 23 kDa form of CD3ζ could not be generated (Fig. 5), partially impaired negative selection and promoted the emergence of potentially autoreactive T cells (Pitcher et al. 2005a). Furthermore, contradicting results were obtained in a comprehensive study of all CD3 ITAMs (Holst et al. 2008). Mice with fewer than seven ITAMs (any of the seven) developed a lethal, multiorgan autoimmune disease due to breakdown in central tolerance. The proliferation potential of cells was directly proportional to the number of ITAMs, whereas cytokine production was independent of the ITAM number. Thus, a high number of ITAMs in TCR-CD3 (independent of which subunit) amplifies the signaling that effects proliferation and ensures negative selection to prevent autoimmunity.

In resting human T cells, a portion of CD3ζ associates with the actin cytoskeleton. This interaction, mediated by a sequence in the C-terminus of CD3ζ, may be involved in the localization of the TCR-CD3 into lipid raft structures and/or in TCR-CD3 recycling. Some viral proteins, such as simian immunodeficiency virus Nef, bind the CD3ζ and downmodulate TCR-CD3. Such interaction seems to have evolved as an immune escape strategy for the virus. CD3ζ is also shown to interact with the transferrin receptor (TfR) and plays a role in T-cell activation via TfR stimulation. The TfR/CD3ζ complex is expressed on the cell surface independent of the expression of the other subunits of the TCR-CD3, and activation of this complex might be a signal-amplifying mechanism for T cells. Phosphorylated CD3ζ can bind to several SH2 domain–containing proteins which include adaptor proteins Shc and Grb2 and the p85 subunit of PI3K. SLAP-2, an SH2 domain–containing protein related to SLAP, binds to CD3ζ upon ligand binding and is a negative regulator of downstream signaling. CTLA-4, another negative regulator of the T-cell activation, binds to phospho-CD3ζ and prevents accumulation of the TCR-CD3 in lipid rafts upon antigen binding.

In addition, CD3ζ is also expressed in cells other than T cells, for example, NK cells and neurons. In NK cells, CD3ζ is associated with NK FcγRIII (CD16) and may be necessary for efficient cell surface expression of this receptor complex. Activation of NK cells with an anti-FcγRIII antibody induces tyrosine phosphorylation of CD3ζ and FcγRIII-associated CD3ζ might be downregulated in patients with cancer due to chronic inflammation (Eleftheriadis et al. 2008). CD3ζ is also associated with NKp46 and NKp30 receptors on NK cells, and its phosphorylation is required for

transmission of activating signals upon antigen binding to these receptors. CD3ζ is also expressed in retinal ganglion cells and brain neurons, where it regulates neuronal development by reducing the size of the dendritic arbor.

Pathophysiological Roles

Under normal circumstances, only the fully assembled TCR-CD3 complex is displayed on the T-cell surface. Partially assembled TCR-CD3s are retained in the endoplasmic reticulum or targeted for degradation. However, certain pathologies might be associated with downregulation of CD3ζ. In these cases, despite the absence of CD3ζ, normal TCR-CD3 numbers are expressed on the surface of T cells, for example, the tumor infiltrating T cells (Baniyash 2004). Downregulation of CD3ζ is also reported in autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis, and infectious diseases such as HIV and leprosy (Baniyash 2004). These reports have given rise to speculation over a role for downregulation of CD3ζ chain as an immune escape mechanism induced by various pathologies. Pregnancy is also associated with suppression of immunity, including downregulation of CD3ζ expression (Taylor et al. 2002). There are several mutations identified in the human CD3ζ gene (listed in Table 1) that are associated with primary immunodeficiencies and systemic lupus erythematosus. In mouse, elimination of the CD3ζ gene from the genome results in a drastically reduced thymus due to the lack of T cells and T-cell precursors. These cells express low level of a TCRαβCD3εγεδ complex. The number of single positive cells detected in the thymus is very low, which could be because of a failure to transition from double positive to single positive cells. In contrast to the thymus, spleen and lymph nodes contain large numbers of TCR-CD3^{low} T cells (Malissen et al. 1993). Also, the number of γδ intestinal intraepithelial T lymphocytes are not significantly affected by deletion of the CD3ζ (Ohno et al. 1993). These studies indicate that CD3ζ is required for T-cell development but it is not absolutely essential.

CD3ζ, Table 1 Immunological disorders associated with mutations in CD3ζ

Mutation	Immunological disorder	Reference
Q70X	Primary immnunodeficiency	(Rieux-Laucat et al. 2006)
−76 T insertion in the promotor	SLE	(Nambiar et al. 2001)
344 bp insertion in 3′ UTR	SLE	(Nambiar et al. 2001)
Splice mutation deleting of exon 7	SLE	(Takeuchi et al. 1998)

Summary

CD3ζ is a type 1 TM protein and a subunit of the TCR−CD3 and pre-TCR-CD3 complexes. It forms a dimer and is necessary for assembly and expression of these receptors on the cell surface. CD3ζ possesses three ITAMs with six tyrosines, which are phosphorylated upon receptor engagement. Once phosphorylated, these tyrosines recruit SH2 domain–containing proteins for downstream signaling which ultimately leads to the development of pre-T cells in the thymus, and activation of mature T cells in the periphery, which then initiate an immune response. The phosphorylation pattern of the six CD3ζ tyrosines is still under debate, but it is commonly accepted that all tyrosines are phosphorylated only by the high affinity agonist ligands, whereas low affinity ligands lead to partial phosphorylation without T-cell activation. CD3ζ is also part of several other receptors on T cells and NK cells. It is also expressed and has a function in neurons. Downregulation of CD3ζ has been noticed in tumors and autoimmune and infectious diseases, and further investigations of the molecular mechanism of this downregulation might offer better therapeutic options for treatment of these diseases.

Historical Background

CD40, a 50 kDa transmembrane member of the tumor necrosis factor (TNF) receptor (TNFR) superfamily of molecules, plays a key role in adaptive immune responses. This includes contact-mediated signals to B cell from activated T lymphocytes, as well as costimulatory interactions between T cells and other antigen-presenting cells (APC), such as dendritic cells (DC) and macrophages. CD40-mediated interactions between B and T cells contribute to the development of an optimal humoral memory response (Bishop and Hostager 2001a).

CD40 lacks intrinsic enzymatic activity and therefore depends on cytoplasmic adaptor molecules referred to as TNF receptor associated factors (TRAFs) for delivery of signals to the cytoplasm. CD40 engagement on B cells stimulates the binding of TRAFs to the CD40 cytoplasmic domain and the stimulation of kinase activity and gene expression pathways that lead to a variety

of responses including B cell survival and expansion, immunoglobulin (Ig) production, isotype switching and affinity maturation, B cell memory, and the production of various cytokines (Bishop and Hostager 2001a, 2003; Graham et al. 2010).

CD40 was identified in 1984 as an antigen associated with transitional cell carcinoma of the human urinary bladder. CD40-specific mAbs bind in vitro transformed B lymphocytes and 5–10% of peripheral lymphocytes (Koho et al. 1984). The first signaling role of the CD40 receptor was suggested by experiments in which an anti-human CD40 agonistic mAb induced in human B-lineage lymphoid cells the tyrosine phosphorylation of cellular proteins, activation of phospholipase Cγ2, and activation of specific Ser/Thr protein kinases (Uckun et al. 1991). The natural ligand for CD40, now known as CD154, was discovered via the complementary methods of in vitro mouse cell experiments and the study of a human immunodeficiency disease, X-linked Hyper IgM syndrome (HIGM). Plasma membrane fractions from activated T helper (Th) cells induce B cell cycle entry, a process that requires de novo protein synthesis. Ultimately, the identity of the Th membrane protein responsible was elucidated by the cloning of CD154 in 1992 (previously referred to as CD40L, gp39, TRAP, or TRAM) (Schönbeck and Libby 2001; Graham et al. 2010).

It was subsequently discovered that defects in CD154 expression or its CD40 binding site cause HIGM, in which patients are susceptible to recurrent extracellular bacterial infections as well as certain intracellular pathogens. HIGM does not affect T cell–independent immune responses, but features a decrease in the production of "switched" isotypes of IgG, IgA, and IgE, as well as defects in antigen presentation. CD40- and CD154-deficient mice display defects in T cell–mediated immunity, including immune responses to parasites, due to defects in T cell–APC interactions (Bishop and Hostager 2001b; Bishop 2004). CD40- and CD154-deficient mice also display defective germinal center formation and B cell memory development in response to antigenic challenge. Together, these findings show that CD40/CD154 interactions are needed for successful T-dependent B cell activation, promoting B cell proliferation, antibody production, isotype switching, germinal center formation, B cell memory, upregulation of costimulatory and adhesion molecules, and cytokine production (Bishop and Hostager 2003; Graham et al. 2010).

Although CD40–CD154 interactions are important for appropriate immune responses, recent studies have revealed a more diverse role of this receptor and its ligand in physiological and pathological processes due to its broad expression pattern. While constitutive expression of CD40 is generally restricted to B cells, dendritic cells, and macrophages, it has also been reported to be expressed under specific conditions on epithelial cells, monocytes, basophils, eosinophils, T cells, vascular endothelium, neuronal cells, and smooth muscle cells. Additional studies have also demonstrated CD40 expression on fibroblasts, keratinocytes, and platelets. CD154, originally thought to only be expressed on CD4+ T helper cells has also been shown to have inducible expression on CD8+ T cells, mast cells, basophils, eosinophils, epithelial cells, monocytes, fibroblasts, NK cells, and platelets. Further studies also reveal that low constitutive levels of CD154 are expressed and can be upregulated after cell activation on endothelial cells, smooth muscle cells, marcrophages, and dendritic cells (Graham et al. 2010).

This unique receptor–ligand pair has been implicated in chronic inflammation and immune responses in transplantation rejection and diseases including cancer (both in tumor-promoting and growth-inhibitory roles depending on the tumor), Grave's disease, type 1 diabetes, atherosclerosis, neuroinflammatory disease, systemic lupus erythematosus, psoriasis, arthritis, and inflammatory bowel disease (Schönbeck and Libby 2001; Peters et al. 2009). Therefore, a detailed understanding of CD40 signaling pathways in normal immunity and disease is important for manipulation of this important player for potential therapeutic benefits.

CD40 and TRAFs

Although CD40 itself lacks intrinsic enzymatic activity, it delivers a variety of important signals to cells. Due to space constraints, this review will focus upon studies performed in B lymphocytes; the reader is referred to other recent reviews of CD40 function in other cell types (Bishop 2009). Human CD40's short 62 amino acid (aa) cytoplasmic (CY) domain has a highly conserved protein sequence, which is almost identical in human and mouse (73 aa long CY). The human CD40 CY domain does not contain tyrosine residues, and thus is devoid of motifs for tyrosine kinases or phosphatase-binding motifs common to other immune receptors. The CY domain does contain serine and threonine residues

which could serve as sites of phosphorylation, and initial structure–function studies determined that T234 in human (T254 in mouse) CD40 plays an important role in growth inhibition of certain transformed B and T cell lines (Bishop and Hostager 2003). However, phosphorylation of the CY domain of CD40 has not been shown to have a major functional role. Rather, proximal signaling events appear largely dependent upon specific sequences in the cytoplasmic domain of CD40 that mediate binding to adapter proteins called TNFR-associated factors (TRAFs) (Bishop and Hostager 2001b).

Although death receptors, such as CD95, do not appear to bind TRAFs, most other members of the TNFR superfamily (TNFRSF) utilize distinct but overlapping sets of TRAFs to transduce intracellular signals. TRAFs 1 and 2 were isolated as proteins physically associating with the CY tail of the tumor necrosis factor receptor type II (TNFR-2/CD120b). In the same year, TRAF3 was initially dubbed CD40-binding protein, as it was first isolated via association with both mouse and human CD40. Within several years TRAFs 4–6 were isolated (Bishop and Hostager 2003; Bishop 2004). CD40 directly binds TRAFs 2, 3, 5, and 6, and also can recruit TRAF1 via a heterotypic interaction with TRAF2. TRAFs 1, 2, and 6 play important positive roles in CD40-mediated signaling, while TRAF3 plays an inhibitory role, and TRAF5 appears to play only a modest role (Bishop and Hostager 2001b; Bishop et al. 2003). CD40 has three known TRAF binding sites: (a) a membrane proximal region for direct TRAF6 binding; (b) a more medial site for overlapping binding of TRAFs 1, 2, 3, and 5; and (c) a second distal TRAF2-binding region (Graham et al. 2010).

All TRAFs contain a conserved C-terminal domain which mediates direct binding to TNFRSF members (Bishop and Hostager 2001b). The six known TRAFs also contain a coiled-coil, leucine-zipper domain known as TRAF-N, shown to mediate homo- and hetero-trimerization of TRAFs. All TRAF molecules except TRAF1 have a zinc-binding Really Interesting New Gene (RING) domain and multiple zinc finger domains at the N-terminus. The RING domain appears to mediate TRAF involvement with the process of ubiquitin modification, an important regulatory mechanism for TRAFs and TNFRSF signaling (Bishop 2004). Removal of the zinc RING domains abolishes TRAF-mediated signaling and creates a "dominant negative" (DN) molecule (Bishop and Hostager 2003).

To fully understand the complex details of CD40-mediated signaling pathways in B cells, the specific contributions of each TRAF, and their interactive functions in CD40 signaling, must be elucidated. There are many approaches to determine TRAF roles. The utilization of DN TRAF molecules which can still associate with CD40, but no longer initiate downstream signals, can provide hints about the biological roles of their full-length counterparts in CD40 signaling. A similar alternative to this approach is the use of CD40 molecules that contain mutations in the CY domain for the study of TRAF binding properties. Application of these approaches in cell lines and transgenic mouse models has yielded useful information about TRAF association and CD40 functions. However, DN versions of TRAFs (especially TRAFs 2 and 3) can alter the binding of other TRAFs due to the overlapping nature of the TRAF 1, 2, 3, and 5 binding site of CD40, a concern that also arises for mutations of the CD40 CY tail in this region (Bishop and Hostager 2001a, 2003; Graham et al. 2010).

Many studies have used the 293 transformed epithelial cell line in which both CD40 and certain TRAFs (wild type and DN) have been transiently overexpressed. However, 293 cells are not a physiologically relevant cell type to determine CD40 functions specific to immune cells. Additionally, studies in such systems do not always accurately reflect binding requirements seen in the cells' physiological levels of both CD40 and relevant signaling proteins (Bishop and Hostager 2001b, 2003; Bishop 2004).

The application of gene targeting by homologous recombination, in which the expression of specific gene products has been disrupted, has facilitated the creation of mice deficient in many known signaling proteins. This powerful technology provides many valuable new insights into the function of various proteins. However, because many signaling molecules mediate multiple pathways involved in normal development and physiology, removal of such proteins from the entire animal results in early lethality of many of these strains. This approach has limited the usefulness in studies of receptor signaling in mature cell types expressing CD40, as has been the case for mice deficient in TRAFs 2, 3, and 6. Although these first efforts to understand TRAFs yielded many clues about TRAF binding and function, much of the information gained from these approaches cannot be clearly interpreted (Bishop and Hostager 2001a; Bishop 2004; Graham et al. 2010).

Advances in gene targeting techniques led to the production of "conditional" knockout mice, in which a gene flanked by bacterial recombinase recognition sequences is removed from specific cell types in the targeted mouse by breeding with a strain expressing the recombinase behind a promoter specific for expression in the desired cell type(s). This technology holds great promise in gaining new insights into TRAF function; however, it is a high-cost, time-consuming, and labor-intensive process (Bishop et al. 2007).

To overcome these obstacles, TRAF deficient B cell lines were created by targeting the TRAF genes via homologous recombination. This system allows transfection of the cells with mutant CD40 molecules as well as wild-type and mutant TRAFs, and avoids the interpretation complications of mutant TRAF or CD40 molecules affecting other TRAFs. This approach has revealed valuable information about roles of TRAF proteins in CD40-mediated signals in B cells. Through information gained from the various complementary approaches, a more detailed picture of CD40-mediated molecular signaling events is emerging (Graham et al. 2010).

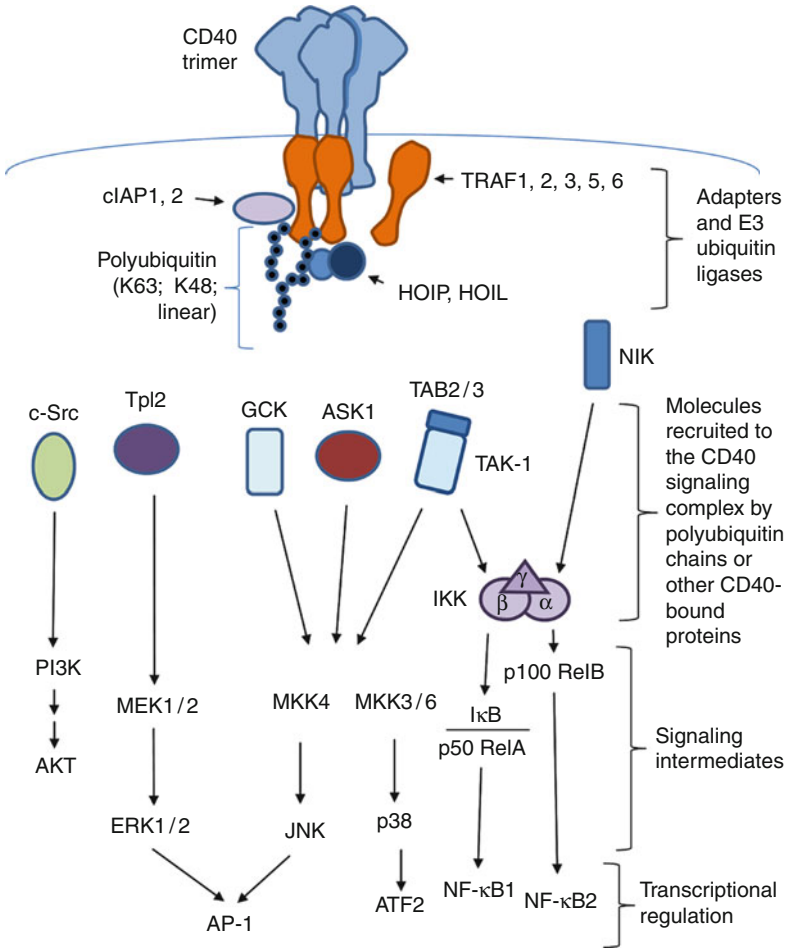
TRAF Recruitment and Degradation

Following ligation, CD40 redistributes into membrane lipid rafts and recruits TRAFs to the membrane signaling complex (Bishop and Hostager 2001b; Bishop 2004). The degree of receptor aggregation regulates downstream TRAF-dependent signaling in a complex manner. Most CD154-mediated signals can be initiated by agonistic antibodies, which can be used as a ligand substitute in many signals. However, CD40-mediated production of interleukin-6 (IL-6) in B cells requires a membrane-bound form of CD154. CD154 ligation leads to enhanced activation of c-Jun amino-terminal kinase (JNK) which binds to and activates c-Jun. The pairing of c-Jun with the protein c-Fos results in the formation of the transcription factor AP-1. The cooperation of AP-1, nuclear factor-kappa B (NF-κB), and C/EBP-β leads to induction of Il-6 gene transcription. Strength and duration of CD40 engagement in B cells can also alter TRAF binding. Agonistic antibody binding to CD40 is sufficient to initiate TRAF2 and 3 recruitment, but CD154-mediated engagement is required for optimal recruitment of TRAF6 (Bishop 2004). This may explain the CD154-dependent nature of CD40-mediated IL-6 production, which is itself TRAF6-dependent (Hostager 2007).

The Zn-binding RING domains of TRAFs 2 and 3 are required for optimal raft recruitment, as their removal or incubation with a membrane-permeable Zn-chelating agent inhibits this process, suggesting that the TRAF RING domain interacts with an unidentified raft-localized protein (Bishop and Hostager 2001b; Bishop et al. 2002). Following recruitment to CD40, TRAFs 2 and 3 are polyubiquitinated and degraded. CD40 association does not mediate degradation of TRAFs 1 or 6. Studies have also shown that TRAF6 association requires greater CD40 cross-linking and its recruitment to rafts is slower than that of TRAFs 2 and 3, a recruitment process that might be enhanced by the degradation of TRAFs 2 and 3 (Bishop 2004). TRAFs 2 and 6 have activity as E3 ubiquitin ligases in various contexts (Bishop et al. 2007).

CD40 signals need to be tightly regulated because CD40 plays a central role in the activation of multiple facets of immune responses. CD40-mediated degradation is important in limiting downstream signaling activation, for dysregulation of CD40 or CD40-like signals can contribute to autoimmunity and/or malignancies. The Epstein-Barr virus key transforming latent membrane protein (LMP1), is a CD40 mimic that provides an amplified and sustained signal. Unlike CD40, however, LMP1 appears able to bypass the activation of negative regulatory mechanisms that otherwise help to control TRAF activity. Avoidance of these regulatory mechanisms may contribute to the oncogenic activity of the virus (Graham et al. 2009).

CD40 signaling is tightly regulated by ubiquitination (Ub) of TRAFs 2, 3, and 6. Ub events appear to be critical for the proper assembly of the CD40 signaling complex and for the signals which it delivers (Fig. 1). This two-phase transduction mechanism starts with the covalent modification of signaling proteins with branched polyubiquitin chains in which ubiquitin molecules are covalently attached at lysine 63 (K63) of the preceding ubiquitin in the chain. This type of ubiquitin chain has been associated with the activation of various signaling pathways. TRAF2 and TRAF6 appear to undergo self-modification with K63-linked polyubiquitin, a RING-dependent process that mediates recruitment of TRAF3 and cellular Inhibitor of Apoptosis Proteins 1 and 2 (cIAP1 and cIAP2). TRAF2 and TRAF6 subsequently serve as E3 ubiquitin ligases for cIAP1/2 leading to their K63 polyubiquitination (K63 polyUb) and activation. These K63



CD40, Fig. 1 CD40 signaling pathways. Molecules shown as symbols are those for which there is evidence of direct interactions with CD40, members of the TRAF family, or polyubiquitin. See text for details of these interactions

polyubiquitin chains may provide docking sites for a number of additional components of the signaling complex including important MAPKKK (Karin and Gallagher 2009). These proteins include the Inhibitor of Kappa B (IκB) Kinase γ (IKKγ; also called NF-κB essential modulator – NEMO) and the transforming growth factor-β-activated kinase (TAK1), whose recruitment is mediated by the TAK1-binding proteins 2 and 3 (TAB2 and TAB3) (Hostager 2007). TRAF2 also mediates recruitment of MEKK1 (MAPK/ERK kinase kinase 1), a MAPKKK (Karin and Gallagher 2009). A newly identified component, heme-oxidized IRP2 ubiquitin ligase-1 (HOIL-1L) interacting protein (HOIP), may also be recruited by K63-linked polyubiquitin chains. HOIP, likely in a complex with another ubiquitin ligase, HOIL-IL, may serve to promote the activation of IKKγ through the addition of linear polyubiquitin to proteins in the CD40 signaling complex (Hostager et al. 2010).

The second phase of CD40-mediated signal transduction targets TRAFs 2 and 3 for proteasomal degradation by chains of Ub molecules linked through lysine at position 48 (K48). CD40 regulation was first observed when a decrease in the amount of TRAF2 in B cell lysates over time was noted during CD40 signaling; a similar trend was later observed for TRAF3. CD40-induced TRAF2 and TRAF3 degradation has been associated with the two Ub ligases cIAP1 and cIAP2 (Bishop and Hostager 2001b). After cIAP1/2 are activated by K63 polyUb as stated above, they may act as E3 ligases for TRAF3, promoting its K48 polyUb and proteasomal degradation (Karin and Gallagher 2009; Graham et al. 2010). TRAF3 is a negative regulator of CD40-mediated signals and acts as a brake on MAPK activation. TRAF3 degradation is thought to release signaling complexes into the cytosol where MAPKKKs can undergo autophosphorylation and activate downstream events (Graham et al. 2009, 2010).

Other ubiquitin ligases also interact with CD40 via TRAF interactions and include Casitas B lymphoma-b (Cbl-b), an E3 ubiquitin ligase that has been implicated in negatively regulating CD40 signaling. Cbl-b is recruited to CD40 via TRAF2, and Cbl-b deficient splenic B cells display decreased CD40-stimulated TRAF2 and TRAF3 Ub and degradation (Graham et al. 2010). Negative regulatory proteins such as A20 are also recruited to sites of polyUb and are likely involved in switching off signaling at the appropriate time, as A20 inhibits NF-κB activation (Bishop 2004).

Early CD40 Signals

Clustering of CD40 upon engagement leads to TRAF aggregation and the subsequent activation of downstream kinase cascades, including a variety of proteins in mitogen-activated protein kinase (MAPK) and stress-activated protein kinase (SAPK) pathways. There are several distinct CD40-signaling pathways linked to TRAF proteins. These pathways lead to the activation of SAPK/MAPKs including JNK, p38, NF-κB, and ERK1/2 (Fig. 1; Bishop 2004).

CD40-mediated activation of SAPK/MAPK JNK and p38 has been attributed to various kinases including members of the MAPKKK family. Mechanisms that have been confirmed in B cells include interactions of germinal center kinase (GC kinase) and related enzymes with the TRAF domain of TRAF2, which contribute to the induction of JNK activation. TRAF2 may also activate another MAPKKK, ASK-1 (apoptosis-signaling kinase 1) which is also upstream of JNK and p38 (Bishop 2004). Other MAPKKKs associated with JNK and p38 activation in B cells include MEKK1 and the TRAF6-dependent TAK-1. MAPKKs that have been demonstrated to participate in CD40-mediated activation of JNK and p38 include MKK4 and MKK3/6 respectively. The E2 ubiquitin-conjugating enzyme Ubc13 is also required for CD40-mediated activation of the JNK and p38 pathways (Karin and Gallagher 2009; Graham et al. 2010).

CD40 signaling activates both the canonical (NF-κB1) and noncanonical (NF-κB2) pathways. Direct TRAF–protein interactions for NF-κB1 activation include the TRAF6-dependent activation of TAK1. TAK1 can mediate activation of the downstream IKK complex which phosphorylates IκB proteins. This leads to their polyUb and proteasome-mediated degradation, followed by release and nuclear translocation of NF-κB1 which is composed of p50 and the transcription factor protein encoded by v-rel reticuloendotheliosis viral oncogene homolog A gene (RelA) to activate transcription. Unlike the rapid response of the canonical NF-κB1 pathway, the noncanonical NF-κB2 pathway requires new protein synthesis and is activated with much slower kinetics (Bishop and Hostager 2001a, b). In the NF-kB2 pathway, p100 is processed to p52, which complexes with the transcription factor protein encoded by v-rel reticuloendotheliosis viral oncogene homolog B gene (RelB) and translocates to the nucleus. It was initially thought that the first kinase to initiate TRAF-mediated NF-κB activation was NF-κB -inducing kinase (NIK) a serine-threonine MAPKKK. NIK activates the IKK complex, and although NIK enhances NF-κB activation in 293 cells, there is no direct evidence that it specifically mediates CD40-mediated NF-κB activation in B lymphocytes (Bishop and Hostager 2003). It is important to note that the interactions of TRAFs with NIK have mostly been demonstrated under non-physiological conditions in which both TRAFs and candidate kinases were transiently overexpressed in epithelial cells (Bishop et al. 2003). One study suggests that NIK is degraded rapidly in non-stimulated splenic B cells (and is therefore difficult to detect) and that CD40 engagement leads to stabilization of NIK via accumulation of newly synthesized protein that can finally activate the noncanonical NF-κB pathway (Karin and Gallagher 2009).

Another MAPK regulated by CD40-mediated signaling is the extracellular signal-regulated kinase (ERK). There are many factors upstream of ERK activation, including MAPKAPK-2, implicated in ERK and p38 activation and MEK1/2 phosphorylation, an event that requires tumor progression locus 2 (Tpl2) (Bishop et al. 2007). CD40 signals can also activate the Src-family kinase Lyn, and the phosphorylation of both phosphatidylinositol 3-kinase (PI3K)/Akt and phospholipase Cγ2 in human B cells (Bishop 2004). CD40-mediated signals have been shown to activate the serine-threonine kinase Pim-1 in mouse B cells and Janus kinase JAK3 in a human B cell line (Bishop et al. 2003; Graham et al. 2010).

Kinases are not the only proteins believed to interact with TRAFs during early CD40-mediated signals. The adaptor proteins Act1 and the B-cell scaffold protein with ankyrin repeats (BANK) have been identified as negative regulators of CD40-mediated signaling. Act1 (an adaptor protein that interacts with TRAF3) and BANK both negatively regulate

CD40-mediated kinase activation. Act1-deficient primary mouse splenic B cells display increased CD40-mediated ERK and NF-κB activation. CD40-mediated activation of another kinase, Akt, is also enhanced in BANK-deficient mouse splenic B cells, resulting in enhanced B cell proliferation and survival. However, it is important to note that a different Act1-deficient mouse strain shows only increases in Interleukin-17 (IL-17) production without an impact on CD40 signaling. Similar to the elusive kinase NIK, Act1's role in regulating CD40 signaling needs further investigation (Graham et al. 2010).

Intermediate CD40 Signals

CD40-mediated signaling to B cells causes increased production of surface molecules, lymphokines, and immunoglobulins, and plays a critical role in the activation of Ig isotype switching. Upstream of these events, CD40 can affect transcriptional regulation of the involved genes (Bishop and Hostager 2003). NF-κB mediated transcriptional regulation participates in a large number and variety of cellular functions, so studies of mice deficient in the various proteins associated with NF-κB transcription (RelA, RelB, p52, p50) cannot provide clearly interpretable information on the role of NF-kB in CD40-mediated effects. B cells from these mice develop in an altered environment and are not ideal models. An inducibly expressed mutant form of the inhibitory protein IκBα that cannot be phosphorylated and degraded in mouse B cell lines revealed that CD40-mediated NF-κB1 activation is critical for some, but not all, CD40 effector functions (Bishop and Hostager 2001b). Functions dependent on NF-κB1 include upregulation of the costimulatory CD80 molecule, Pim-1 kinase activation, IgM secretion, and isotype switching to IgE. There is also a partial dependence upon NF-κB1 for upregulation of CD23, CD95, and CD54. NF-κB1-independent functions include upregulation of LFA-1 and CD11a, and JNK activation (Bishop and Hostager 2001b; Bishop 2004).

Basal levels of NF-κB1 subunits in the nucleus, together with induced AP-1 and C/EBP-β activation, are required for maximal CD40-incuded IL-6 promoter activity as well as maximal IL-6 protein production in B cells (Bishop 2004). An important contributor to this cooperation is also the need for CD40-mediated activation of c-Jun, which can form the transcription factor AP-1 by pairing with c-Fos. However, the protein complex binding of the canonical AP-1 site in the mouse IL-6 promoter can be mediated by a transcriptionally active c-Jun homodimer. In addition to regulating IL-6, AP-1 and C/EBP-β transcription factors also play a role in CD40-mediated B cell IgM secretion and CD80 surface expression (Baccam et al. 2003; Bishop 2004).

Additional transcription factors that contribute to CD40-dependent functions include the B cell-specific activator protein (BSAP) and Stat6. In B cells, these factors appear to play roles in the transcription of the germ line ε gene that precedes class switch recombination to IgE. Furthermore, Stat6 and NF-κB can interact, with a potential contribution toward the synergy between CD40 and IL-4 signals in the induction of germline ε transcription. NF-AT, Stat5, and E2F are also activated in B cells following CD40 ligation. However, the causative roles of each of these factors in B cell functions have not been fully explored. Both the germline ε and CD23 promoters may contain yet unidentified regulatory elements specific to CD40-mediated gene expression (Bishop and Hostager 2001a, b, 2003; Bishop 2004).

Late CD40 Signals

Several biological functions of CD40 in the immune response were discussed above. The production of cytokines and chemokines is also an important function of B cells. These factors help regulate many CD40-mediated processes, including Ig switching, and antigen presentation. CD40 signaling has been shown to induce the production of various cytokines and chemokines including IL-2, IL-6, IL-7, IL-10, IL-12, IL-15, IL-17, IFNγ, lymphotoxin-α (TNF-β), and TNF-α (Graham et al. 2010). As discussed above, CD40-mediated signals play an important role in antigen presentation, a process that requires the upregulation of the costimulatory molecules CD80, CD86, and MHCII. The CD40-mediated upregulation of adhesion molecules including CD23, CD30, CD54, Fas, ICAM, and LFA-1 (Graham et al. 2010) is also important for enhancing T cell–B cell interactions during an immune response.

Summary

CD40 engagement results in downstream signaling events that include the activation of MAPK/SAPK kinase cascades and many transcription factors that enhance and regulate a number of biological processes.

Studies in both mouse and human cells from many laboratories have established that CD40 signaling pathways play a key role in mediating adaptive immune responses and are implicated in the pathogenesis and progression of many inflammatory and autoimmune diseases, as well as malignancies. A more accurate and detailed understanding of CD40-mediating molecular signaling may offer many new molecular targets for the development of new vaccines and new molecular therapies for the treatment of immune-mediated disorders. However, much remains to be learned, including how CD40 regulates transcriptional activation of a variety of genes. Other questions include the specific contributions of each of the known TRAFs and the specific mechanisms mediating their regulatory interactions with CD40. TRAFs can initiate signaling cascade via directly interacting with receptors, or alternatively, with intracellular signaling proteins to regulate downstream pathways. The activities of the TRAF proteins involved in CD40 signaling are, as yet, only partially defined. It is also quite likely that additional signaling molecules both directly and indirectly associate with the CY domain of CD40; CD40-mediated signaling cascades can also interact with other receptors' signaling pathways. Addressing these questions will elucidate CD40 functions and also provide important principles governing the regulation of signaling by other TRAF-utilizing receptors.

Synonyms

Leukosialin; Sialophorin, galactoglycoprotein

Historical Background

CD43, also called sialophorin or leukosialin was first identified as a defective molecule of leukocytes and

platelets of patients affected with the Wiskott-Aldrich syndrome. It was thought that expression of this heavily glycosylated, mucin-type membrane protein was restricted to hematopoietic cells. However, recent advances in the field, evidence that CD43 is present in non-lymphoid tissues, particularly tumor cells. Here we reviewed the most important features about this molecule, highlighting the recent advances that have contributed to our understanding of the roles of CD43.

Gene Expression and Protein Structure

CD43 is a type I cell surface glycoprotein abundantly expressed on almost all hematopoietic cells, except for erythrocytes and resting B cells. Although initially considered an immune cell molecule, recent reports evidence a much broader distribution, as epithelial cells, and a range of tumors of epithelial origin are CD43 positive. Expression of CD43 has also been documented in the normal brain and in the uterus. The gene encoding human CD43 is located in chromosome 16; it has two transcription initiation sites and it is composed of two exons and a single intron within the untranslated 5′ region, although the entire protein is encoded only by the second exon. Alternative polyadenylation signals generate two mRNAs that differ from each other in the length of the 3′ untranslated region (Pallant et al. 1989).

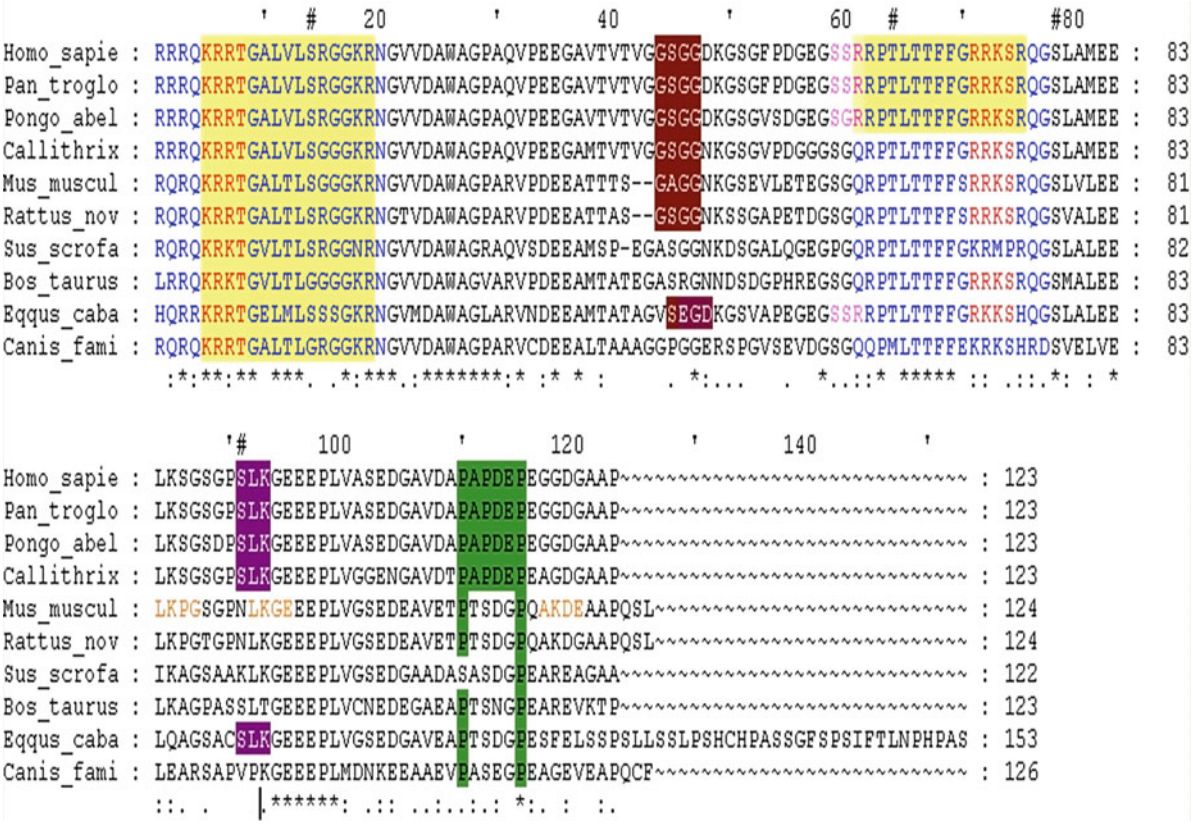
CD43 is a bulky and extended cell surface mucin that protrudes 45 nm from the cell surface. Its 239 amino acids long extracellular domain comprises five tandem repeats of 18 amino acids each (^{116}Ile–^{205}Ser), rich in serines and threonines modified by O-GalNAc glycosylation. As a result of the timely controlled activity of core 2 β-1,6-N-acetylglucosaminyltransferase (C2GnT), two isoforms of CD43 that define cell interaction affinities and functional cell states have been characterized. A 115 kDa isoform is expressed preferentially in thymocytes, resting CD4 T lymphocytes and monocytes, and a 130 kDa isoform is detected in resting CD8, CD4 activated T lymphocytes, neutrophils, platelets, B lymphocytes and macrophages, as well as tumor cells. The low molecular isoform contains almost exclusively the tetrasaccharide NeuAc(α2-3)-Gal(β1-3)[(NeuAc(α2-6)]GalNAc (Core1) and the high molecular isoform exhibits mainly the branched hexasaccharide NeuAc(α2-3)-Gal(β1-3[NeuAc(α2-3)Gal(β1-4)GlcNAc(β1-6)]Gal-NAc (Core2) (Fukuda 2002). The intracellular domain has 123 amino acids with a highly conserved sequence among primates, mouse, and rat; it includes different motifs (Fig. 1) that allow CD43 to participate in different signaling pathways, supporting a functional role for this molecule.

CD43 Expression is Tightly Controlled

The levels and relative abundance of CD43 on the cell surface are controlled through several mechanisms: expression regulation, molecular density, or processing, evidencing a regulatory role for CD43 in cell function.

Aside from a tissue-specific gene transcription regulation, the relative abundance of CD43 at a specific location of the cell membrane is tightly controlled. As T lymphocytes and neutrophils migrate to inflammatory lesions, CD43, together with PSGL-1, ICAM-3 and CD44, moves from the leading edge to the rear end (uropod) of the cell through its association with members of the ERM family of molecules, while chemokine receptors relocate at the leading edge. Likewise, and through a similar mechanism, during the encounter of an antigen-specific T cell with the appropriate antigen-presenting cell, CD43 is excluded from the immunological synapse (intimate contact zone between the two cells), and relocates partially to the distal pole, where it plays a yet to define role. Interestingly, it is excluded from the inhibitor natural killer (NK) cell synapse, but not from the activating one (Reviewed in Ostberg et al. 1998; Aguilar-Delfín et al. 2006).

In addition, CD43 expression can be regulated by proteolysis and shedding. Processing of CD43 has been described in human neutrophils, murine T lymphocytes, as well as in human carcinoma cell lines (Lopez et al. 1998; Seo and Ziltener 2009; Andersson et al. 2004). The enzymatic cleavage of CD43 by a γ secretase-dependent intramembrane processing mechanism leads to the shedding of the extracellular domain, known as galactoglycoprotein and present in high concentrations in normal serum, and to the translocation of the intracytoplasmic domain to the nucleus, where it has been found to protect cells from apoptotic signals, promoting cell survival (Andersson et al. 2004; Seo and Ziltener 2009). Lastly,



CD43, Fig. 1 Multiple alignment of the intracellular region of CD43. Sequences are the reported on NCBI or were obtained by a BLAST analysis and picking the hits with at least 80% identity. The *Pan troglodytes, Pongo abelii, Rattus novergicus, Canis familiaris, Callithrix jacchus* and *Equus caballus* sequences are computational predictions. Two binding sites for ERM family proteins (ezrin, radixin, moesin) are highly conserved between species (blue letters, aminoacids 1–20 and 61–77). Two nuclear localization signals (NLS, yellow-shaded residues), comprising residues 5–19 and 61–75 of the intracellular domain respectively, overlap with the ERM binding domains. Potential phosphorylation sites are also located within the NLS and ERM binding regions. Serine/threonine residues experimentally confirmed to be phosphorylated in human, and well conserved, are marked with a "#" symbol. Red colored letters represent predicted cAMP- and cGMP-dependent protein kinase phosphorylation sites (residues 5–8 and 71–74). Pink letters and purple shaded letters tag predicted Protein kinase C phosphorylation pattern sites (residues 59–61 and 91–93). Between the two ERM binding domains, potential casein kinase II phosphorylation sites are predicted (brown shaded letters, residues 44–47, and 45–48 in Equus caballus). In addition, three potential SUMO modification consensus sequence sites (ψKXE) located close to the C terminus (orange letters) have been identified in the murine CD43 protein (residues 84–87, 92–95, 117–120, as you can see the middle one is well conserved across species). Finally, a proline rich region (green shaded letters, residues 110–115) at the C-terminus allows SH3-domain containing proteins to bind and participate in CD43 signaling pathways (Reviewed in Aguilar-Delfin et al. 2006; Seo and Ziltener 2009)

secretion of intracellularly stored CD43 is yet another mechanism through which CD43 expression levels are regulated: following LPS exposure, the intracellular levels CD43 present in intestinal epithelial cells have been found to augment, and correlate with an important secretion of CD43 to the intestinal lumen, underscoring a role for this mucin as a defense mechanism against infection in the intestinal epithelium (Amano et al. 2001).

A Multifunctional Protein

The abundance of CD43, its elongated structure, and the sequence homology of its intracytoplasmic domain between species indicate that this molecule transduces information from the cell surface to the intracellular milieu in order to modulate the decisions of the cell. In line with the fact that CD43 has been found to partner with a seemingly ever-growing list of membrane

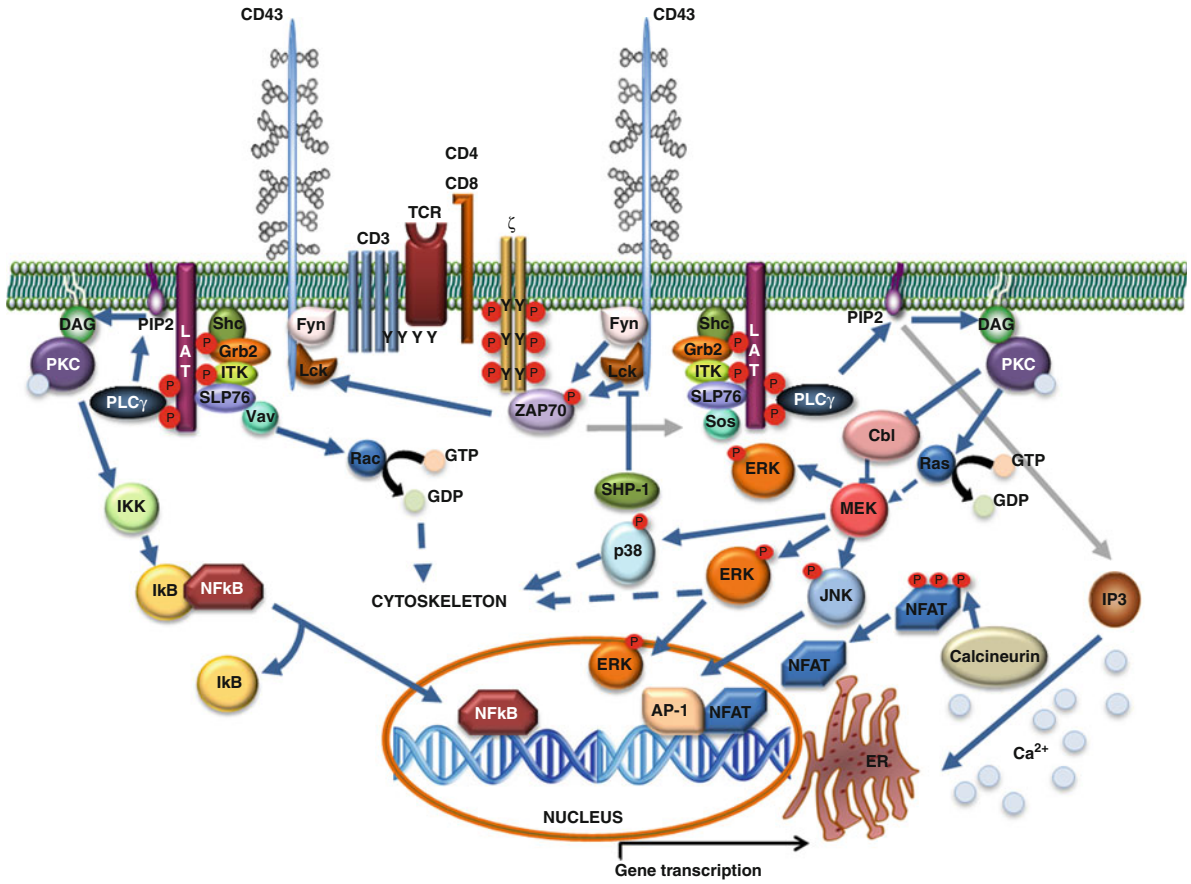
molecules, multiple, but often opposing functions have been described for CD43. The capacity of CD43 to transduce activation signals that regulate these multiple functions relies on its intracytoplasmic domain. Depending on the cell, and most probably on the ligand it encounters, CD43 must activate different signaling pathways that ultimately fine-tune the decision-making process of the cell, although little is known about this.

The net negative charge of CD43, resulting from the elevated glycosylation and sialic acid content, led to first propose that the role of this abundantly expressed cell surface mucin was to provide the cells with a repulsive force to limit cell contacts. Further attempts to understand the role of CD43 have been undertaken in vivo, with the $CD43^{-/-}$ mice, in different disease models where T lymphocytes are pivotal. In a model of vaccinia virus infection, despite the fact that CD8-dependent cytotoxic response is more robust in the knockout mice, viral clearance is less efficient in these mice as compared to wild-type animals (Manjunath et al. 1995). Likewise, infiltration of naïve CD8+ T cells to the brain following intracranial infection with Lymphocytic Choriomeningitis Virus (LCMV) is impaired in $CD43^{-/-}$ mice, resulting in prolonged survival of the animals. In an experimental model of autoimmune encephalomyelitis (EAE), $CD43^{-/-}$ mice have a lower incidence rate of the disease and milder symptoms due to a defective migratory capacity of antigen-specific CD4 T cells to the central nervous system. In addition, and consistent with a reduced inflammation, these animals have higher levels of IL-4 rather than of IFNγ. The LCMV model also provides evidence that, in addition to regulate the migration of T lymphocytes, CD43 participates in the contraction phase of the response, as antigen-specific CD8+ T cells numbers remain higher in the knockout mice, due to enhanced levels of ▶ Bcl-2 and hence decreased apoptosis (Onami et al. 2002; Ford et al. 2003). Altogether, these results highlight a positive role of CD43 in regulating the migration of naïve T cells to inflammation sites, and in regulating cell number and homeostasis. This in turn determines the development and the outcome of the disease and correlates with the fact that anti-CD43 antibodies prevent the migration of T cells to pancreatic islands, and the development of diabetes (Johnson et al. 1999). However, all these studies were done in the mixed background BL6.129, and care should be taken in the interpretation of the data, as a mixed genetic background can influence the outcome of the experiments. Also, it should be taken into account that these animals are completely deficient for CD43. It will be interesting to valuate the function of this mucin in mice where CD43 deficiency is limited to a specific cell type.

In addition to interact with cytoskeletal elements and to participate in directing cell migration, CD43 regulates cell–cell interactions and activation (Fig. 2). In vitro, CD43 engagement has been shown to induce homotypic cell adhesion, dendritic cell maturation, monocyte respiratory burst, increased T and B cell proliferation, and cytokine and chemokine secretion in NK cells, mast cells, dendritic cells, and T cells. CD43 engagement can induce apoptosis of Jurkat T cells and bone marrow cells; however, constitutive expression of CD43 in B cells promotes cell survival. Only expressed on a small proportion of naive B cells, CD43 expression is upregulated upon stimulation through the BCR or pokeweed mitogen and it contributes to cell proliferation; moreover, forced expression of CD43 was shown to inhibit B cell G1 arrest, extending B cell survival. Consistent with the fact that expression of CD43 on B cell lymphomas correlates with a bad prognosis, uncontrolled proliferation and enhanced survival capacity, two hallmarks of cancer cells, are positively regulated by CD43 in B cells (Reviewed in Aguilar-Delfín et al. 2006 and Pedraza-Alva and Rosenstein 2007).

Multiple Ligands for a Multifunctional Protein

The diversity of the physiological ligands identified for CD43 evidences a dynamic role for this cell-surface mucin in regulating intercellular interactions. The fact that ICAM-1 and MHC-1 molecules have been found to act as receptors for CD43 (Reviewed in Pedraza-Alva and Rosenstein 2007), together with the recent finding that CD43 interacts with LFA-1 and CD147 in two distinct complexes (Khunkaewla et al. 2008), indicates that CD43 plays a role in cell–cell adhesion, in concert with, and probably regulating, other adhesion molecules. Consistent with this possibility, splenocytes and thymocytes from CD43-deficient mice exhibit enhanced homotypic adhesion to ICAM-1 and fibronectin (Manjunath et al. 1995). Paradoxically, in contrast with this anti-adhesive function, a number of anti-CD43 mAbs block homotypic cell–cell interactions or lymphoid cell binding to lymph



CD43, Fig. 2 The signaling pathway of CD43 has been best characterized in T cells, where it functions as a co-receptor of the TCR and its co-stimulatory function is independent of CD28 (Sperling et al. 1995). Additional to its role as a costimulatory molecule, CD43 also signals by itself. CD43 engagement in human T cells induces its association to the ▶ Src family kinases Lck and Fyn, through the interaction of their SH3 domains and the proline-rich region of CD43. This then leads to the phosphorylation of the CD3 ς chain and the assembly of macromolecular complexes that include adaptor proteins such as Shc, Grb2, ▶ SLP-76, and the guanine exchange factor ▶ Vav. These signaling complexes promote ERK MAPK activation, leading to regulation of actin cytoskeleton and a positive feedback loop for Lck signaling as a result of an ERK-dependent serine phosphorylation of Lck, which inhibits its association to the phosphatase SHP-1. CD43 engagement also induces calcium fluxes and Protein kinase C activation, necessary for Cbl serine phosphorylation and its interaction with 14-3-3. Moreover, T cell pre-stimulation by the CD43 co-receptor molecule before TCR engagement inhibits the TCR-dependent c-Cbl tyrosine phosphorylation and interaction with the adapter molecule Crk-L and promotes Cbl-b ubiquitination and degradation in a Protein kinase C θ dependent manner. The inhibition of these E3 ubiquitin ligases results in prolonged tyrosine phosphorylation and delayed degradation of ▶ ZAP-70 and of the CD3 ς chain, leading to enhanced MAPK activation and robust T cell response. These data indicate that CD43-mediated signals lower the threshold for T cell activation by restricting the c-Cbl and Cbl-b inhibitory effects on TCR signaling (Reviewed in Pedraza-Alva and Rosenstein 2007)

nodes and high endothelial venules (Reviewed in Ostberg et al. 1998, and in Aguilar-Delfín et al. 2006). Moreover, E-selectin has been found to interact with CD43, favoring neutrophil and B cell leukemia cell lines rolling, further evidencing the participation of CD43 as a pro-adhesive molecule that regulates the infiltrating ability of cells (Matsumoto et al. 2008; Nonomura et al. 2008). CD43 also interacts with Siglec-1 (sialoadhesin), a regulator of lymphoid and myeloid cell adhesion, probably consolidating physical contacts between cells. On the contrary, the putative association of CD43 to human serum albumin inhibits neutrophil function by limiting cell spreading as well as CD43 proteolysis by elastase (Reviewed

in Aguilar-Delfín et al. 2006). Altogether, these data support the idea that CD43 triggers signaling pathways that modulate other conventional adhesion mechanisms.

In human dendritic cells, galectin-1-CD43 interaction primes the cells and results in cytokine production, upregulation of metalloproteases, and increased migration, through signaling pathways that depend on calcium fluxes as well as on Syk and Protein kinase C activation. However, through its interaction with galectin-1, CD43 promotes T cell apoptosis, possibly by recruiting galectin-1 molecules to the cell surface and making them accessible to CD7, which is directly responsible for galectin-1-induced cell death (Hernandez et al. 2006; Fulcher et al. 2009). Interestingly, through the interaction of membrane nucleolin with capped CD43, macrophages recognize apoptotic cells (Miki et al. 2009).

The myriad of ligands underscores a regulatory role for CD43, ultimately favoring homeostasis of the immune system. It is clear that, since most of these molecules are also ligands for other receptors, and different functions have been associated to each of them, CD43 participates in the fine-tuning of cell fate. However, information about the cellular responses and the intracellular signals that result from the interaction of CD43 with each of its ligands is very fragmentary, and this is undoubtedly a question that needs to be addressed.

CD43 is a Pathogen Recognition Receptor

The complex glycosylation pattern of CD43 functions as bait for multiple pathogens. During HIV infection, as a result of increased Core2 enzyme activity, more O-Core2 glycans and lactosamine residues decorate CD43, ultimately leading infected cells to apoptosis, presumably as a result of the interaction of galectin-1 with CD43 and CD45. Moreover, it was suggested that this pathway can contribute to the death of infected as well as noninfected cells, and thus to a decrease in T cell counts (Lanteri et al. 2003). What is more, the combination of CD43 and TCR-▶ CD3 complex signals lowers the signaling threshold for HIV LTR-driven gene activity, promoting the activation of NFκB and ▶ NFAT, ultimately favoring viral replication (Reviewed in Pedraza-Alva and Rosenstein 2007). In addition, the alternative glycosylation of CD43 promotes the production of autoantibodies against hyposialylated isoforms, although their role in HIV pathogenesis is not understood.

Influenza A virus (IAV) was also found to interact with polymorphonuclear leukocytes through the specific interaction of CD43 with the IAV hemagglutinin. In addition to lessen the oxidative burst of these cells, IAV modifies the expression level of adhesion-related molecules: while it reduces that of CD43 and L- and P-selectins, it augments that of integrins CD11b and CD11c, subtly modulating the adhesive interactions of polymorphonuclear cells (Hartshorn and White 1999). It is presently not known if this is the result of the signals transduced by the CD43–hemagglutinin A interaction or if it reflects the activation of additional, CD43-independent pathways.

Several pathogenic bacteria also use CD43 as a docking molecule. Recent reports have defined Cpn60.2 (Hsp65, GroEL), a molecular chaperone and an adhesin of the capsule of *Mycobacterium tuberculosis* as a ligand for CD43 (Hickey et al. 2010). This is consistent with the fact that, on macrophages, CD43 was previously identified as a receptor for *M. tuberculosis*, taking part in bacillus uptake and limiting its intracellular growth through the production of TNF α (Fratazzi et al. 2000). *Streptococcus gordonii*, the causative agent of infective endocarditis, has also been found to specifically interact with CD43 through Has, another adhesin (Ruhl et al. 2000). More recently, CD43 was reported to be the substrate of StcE, a metalloprotease that cleaves mucin-like glycoproteins, and is secreted by enterohemorrhagic *Escherichia coli*, the enteric pathogen that causes hemorrhagic colitis. The net balance of this proteolytic activity is the cleavage of the extracellular domain of CD43 from neutrophils, increased oxidative burst, but impaired neutrophil motility (Szabady et al. 2009).

In addition, CD43 is a counter-receptor for the trans-sialidase of *Trypanosome cruzi*, the causal agent of Chagas disease. This enzyme transfers sialic acid from β-galactopyranosil donors to β-galactopyranosil acceptors with α2–3-linkages providing the parasite with a disguise to avoid recognition by the host immune system. Furthermore, it restores the glycosylation status of CD43 to a Core1 glycans expression pattern, similar to that of resting T cells, thus compromising the T cell-dependent response, ensuring parasite replication. Interestingly, *T. cruzi* produces large amounts of an inactive and soluble form of the trans-sialidase that is also

recognized by CD43, although the biological significance of this is not understood presently (Freire-de-Lima et al. 2010).

On non-lymphoid cells, CD43 retains the capacity to function as a pathogen recognition receptor (PRR). Together with the glycolipid GM1, CD43 has been described as a receptor for the heat-labile enterotoxin of enterotoxigenic *E. coli* in the microvilli of enterocytes (Zemelman et al. 1989). Interestingly, in CaCo2 cells differentiated into enterocytes, CD43 is not exposed on the cell surface, but stored in intracellular granules from where it is released and secreted to the extracellular compartment upon exposure of the cells to bacterial lipopolysaccharides (Amano et al. 2001).

Altogether, these data suggest that through the pathogen receptor function of CD43, PAMPS initiate signal transduction pathways that modulate the activation of target cells and the onset of an inflammatory response and inflammation-related diseases. A better knowledge of the specific role of CD43 in the pathogen recognition and the cell-surface association processes will provide a clue to identify key target molecules both on the pathogen and on the host's cells.

CD43 and Noninfectious Diseases: A Poorly Understood Function

In addition to function as a PRR, CD43 has been associated to diverse diseases. CD43 was first described as the molecule responsible for the Wiskott-Aldrich Syndrome (WAS), an immunodeficiency characterized by frequent infections, skin eczema, decreased platelet numbers, and defective T-cell function (Remold-O'Donnell et al. 1984). However, it was later demonstrated that this X-linked disease was caused by mutations in the gene encoding WASP, a protein involved in signal transduction from cell receptors to the actin cytoskeleton. Yet, the link between WASP and CD43 is still unclear.

Although the participation of CD43 in several autoimmune diseases is documented, we are still lacking the full picture regarding the mechanisms of pathogenesis associated to this. Decreased expression of CD43 on the cell surface of synovial fluid polymorphonuclear cells of rheumathoid arthritis patients (Humbria et al. 1994) while an enhanced expression on the T cells infiltrating the synovium of osteoarthritis patients (Sakkas et al. 1998) have been reported. In systemic lupus erythematosus (SLE) patients, anti-CD43 and anti-galectin-1 autoantibodies, together with high levels of soluble galectin-1 were found to correlate with the time of disease evolution and low levels of complement (Montiel et al. 2010). A role for CD43 in Type I diabetes has been suggested, as preventing T cell migration and possibly that of other CD43+ cells such as monocytes and dendritic cells from bloodstream to inflammation sites (lymph nodes, pancreas, and salivary glands) with exogenous anti-CD43 antibodies, inhibits the progression of the disease (Johnson et al. 1999). Thus, reflecting the dual nature of CD43, anti-CD43 antibodies could function in two ways: favoring the inflammatory response, exacerbating the disease (SLE and arthritis), or preventing the establishment of the disease (diabetes).

CD43: A New "Kid on the Block" in Tumor Development

CD43 function has been mostly studied in hematopoietic cells and hence in an immunological context. However as mentioned, this molecule is no longer considered solely as an immune protein. It has been detected in normal and transformed tissues. In addition to hematopoietic tumors, non-hematopoietic tumor-derived cells from breast, lung, colon, bladder, cervix, and prostate express CD43 (Reviewed in Aguilar-Delfin et al. 2006) pointing to a role for this molecule in cell transformation, raising the question as to whether CD43 could be used as a marker for malignancy and prognosis.

The contribution of CD43 to tumor development is slowly emerging. CD43 is expressed in approximately 30% of low-grade B-cell lymphomas and 90% of T-cell lymphomas, B-cell lymphoblastic lymphomas, and of T-cell lymphoblastic lymphomas (Leong et al. 2003). Since CD43 expression in B cells is restricted to early B-cell ontogeny and activation of peripheral B cells, expression of CD43 suggests a state of malignancy. In fact, when expressed in a $CD43^{-}$ murine B-cell lymphoma, CD43 was found to provide the cells with increased viability and proliferation when cultured under serum deprivation conditions. Interestingly, expression of a CD8/CD43 chimera did not result in cell proliferation, indicating that the intracellular domain of CD43 is not sufficient to protect the cells from apoptosis and to promote cell cycle entry and, that the interaction of the extracellular domain of the

molecule with its ligands generates intracellular signals necessary for cell survival and proliferation (Misawa et al. 1996). Accordingly, T-cell lymphomas that test positive for the expression of the c-Maf protooncogene, also express CD43 together with high levels of cyclins D1 and D2 (Murakami et al. 2007). Moreover and consistent with these findings, in the absence of the tumor suppressors ▶ p53 and/or ARF, overexpression of CD43 in a human carcinoma cell line protects the cells from FAS-mediated apoptosis, ultimately favoring cell proliferation (Kadaja et al. 2004). In addition, it is now clear that the proteolytic cleavage of the CD43 cytoplasmic domain through a regulated intramembrane proteolysis (RIP) process exposes a nuclear localization signal that promotes the translocation of the truncated protein to the nucleus, where it interacts with ▶ beta-catenin, resulting in increased expression of the c-Myc and cyclin D1 genes (Andersson et al. 2004). Furthermore, CD43 was recently shown to participate in tumor cell-peritoneum interaction, through a metalloprotease-dependent mechanism activated by the interaction with ICAM-1, one of its putative ligands (Alkhamesi et al. 2007). Altogether, these data demonstrate that CD43 participates in the coordinated regulation of cell adhesion and cell motility as well as in the control of cell cycle entry, ultimately favoring cell transformation, tumor formation, and invasiveness. A deeper understanding of the CD43-mediated signals involved in tumor cell proliferation or survival will be critical for the rational development of drugs aimed to reduce malignancy.

Summary

CD43 is a mucin that modulates the response of all cells of the immune system as well as that of other cells. Because of its elongated structure and its abundance on the cell surface, it serves as an antenna that senses the environment, and prepares the cells for future actions. CD43 signals help the cell progress toward differentiation and maturation, as it regulates cell migration and cell contact. In addition, through the interaction with its numerous physiological and pathological ligands, CD43 actively participates in the onset of an inflammatory response and of inflammation-related diseases, underscoring the possibility to consider this molecule as a potential therapeutic target. An effort should be undertaken to identify those regions of the extracellular domain that are important for ligand recognition as well as to understand the rules that dictate selectivity of the different isoforms of CD43 for a given ligand. Unraveling the signals that follow interaction with a given ligand will help to untangle the multiple intracellular signals generated through this molecule. Understanding the role soluble CD43 is also a challenge. A better comprehension of the functions regulated by the interaction of CD43 with each of its multiple ligands in different cells in diverse contexts of activation will provide a sharper picture of the roles this molecule plays in cell physiology in different organs, under normal and pathological scenarios.

Historical Background

CD45 was first identified by antisera and then by monoclonal antibodies (mAbs) as a major lymphocyte cell surface glycoprotein. CD45 is leukocyte specific, expressed on all hematopoietic cells except red blood cells and this has led to the clinical use of pan-specific CD45 mAbs to identify leukocytes and cells of hematopoietic origin. Some mAbs identify specific isoforms of CD45 that are expressed in a cell type and developmentally regulated manner and are referred to as CD45R mAbs. CD45 isoforms range from 180 to 220 kDa and cloning of the CD45 gene revealed that these isoforms arise by alternative splicing of at least three exons (ABC) that encode a region near the amino terminus of the extracellular domain of CD45 (Thomas 1989; Johnson et al. 1997). The B220 (CD45RABC) isoform of CD45 is expressed primarily on B cells and the CD45RA and RB isoforms are expressed on T cells and downregulated on T cell activation whereas the CD45RO isoform, which does not include any of the alternatively spliced exons, is upregulated on T cell activation. Thus CD45 isoform expression is a useful parameter to monitor the activation state of the T cell and has been particularly useful for human cells. The PTPRC gene, which encodes CD45, was cloned in the 1980s, revealing significant sequence identity of the cytoplasmic domain of CD45 with the protein tyrosine phosphatase, PTP1B. This led to the identification of CD45 as a receptor-like protein tyrosine phosphatase (Trowbridge and Thomas 1994). The phosphatase activity of CD45 was subsequently shown to be important for antigen receptor signaling in T and B lymphocytes where it regulates the phosphorylation state and activity of specific Src family kinases (Alexander 2000). In addition, work with CD45-deficient cells and mice has implicated CD45 in regulating leukocyte adhesion, cytokine signaling, and immune receptor signaling involving Fc, NK, and Toll-like receptors.

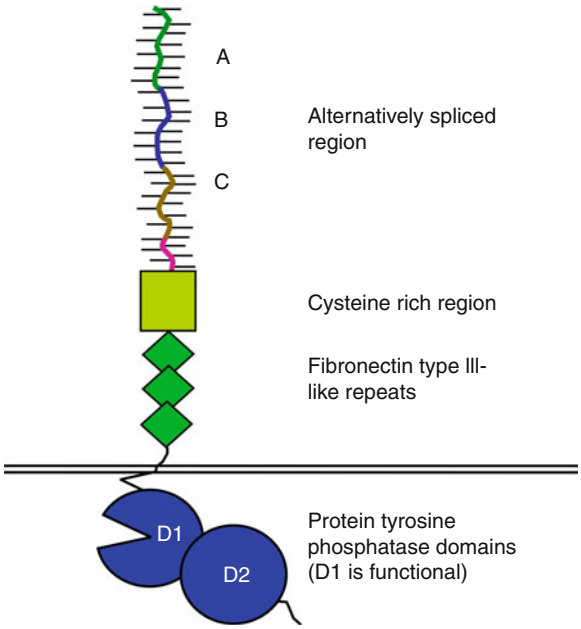
CD45 is a Transmembrane Protein Tyrosine Phosphatase

The PTPRC gene is conserved across several vertebrate species, from zebra fish, lamprey, and shark to chickens, cows, and humans. It spans over 50 MB and is located on chromosome 1q31-32 in humans and chromosome 1 at 74 cM in mice. Further information on the *PTPRC* gene, the protein sequences from the different species, and the crystallographic structure of the cytoplasmic domain of CD45 can be found at the National Center for Biotechnology Information, NCBI (http://www.ncbi.nlm.nih.gov). CD45 is a type I transmembrane protein, which is abundantly expressed on leukocytes. By electron microscopy, CD45 has a globular cytoplasmic domain of 12 nm and a rod-like extracellular domain of 28 nm, which extends to 51 nm when the alternatively spliced exons are included (Johnson and Felberg 2000). This makes CD45 one of the largest molecules on the lymphocyte membrane, being considerably larger than the cell surface molecules involved in antigen recognition that are estimated to extend approximately 8 nm from the cell surface. CD45 is heavily glycosylated with 25% of its mass attributed to carbohydrate. N-linked glycosylation sites are interspersed throughout the extracellular domain whereas O-linked sites are enriched in the amino terminal and alternatively spliced regions. The rest of the extracellular domain is relatively cysteine rich and may contain up to three fibronectin type III-like domains (Fig. 1).

CD45 has a single transmembrane region and a large intracellular domain of over 700 amino acids that has been shown by crystallographic studies to contain two protein tyrosine phosphatase domains. Only the membrane proximal phosphatase domain (D1) has catalytic activity but the second domain is required for optimal activity (Johnson and Felberg 2000). Since basal phosphotyrosine levels in naive lymphocytes are low, CD45 is thought to be a constitutively active phosphatase, whose activity can be regulated by its level of expression and by access to substrate. No specific ligands have been identified for CD45 but the carbohydrates of CD45 can bind lectin molecules such as galectin 1, which cluster CD45 and modulate its activity. Serine phosphorylation and the interaction of CD45 with other proteins (such as CD45AP, the CD45 associated protein) may also regulate its ability to dephosphorylate substrates, but these mechanisms are not well understood.

CD45 is a Major Regulator of the Src Family Kinases, Lck and Lyn

The ▶ Src family tyrosine kinase, Lck, was identified as a key substrate for CD45 in T cells and Lyn was

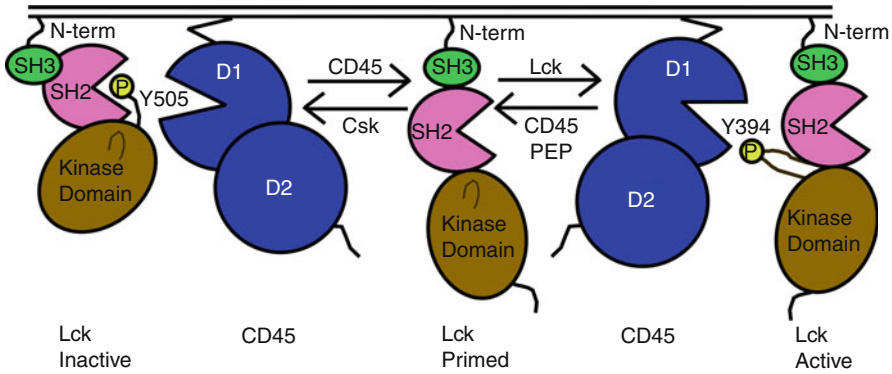


CD45 (PTPRC), Fig. 1 *Schematic of CD45 structure*. CD45 is a type I transmembrane glycoprotein. The extracellular domain is relatively large and heavily glycosylated with several N-linked carbohydrate sites interspersed throughout the region whereas the majority of O-linked glycosylation sites are localized in the amino terminal region and the alternatively spliced regions (designated *A*, *B*, and *C*) of CD45. The cytoplasmic region of CD45 consists of a membrane proximal wedge region followed by two protein tyrosine phosphatases (*D1* and *D2*), with the catalytic cysteine residing in *D1*, and then a short C-terminal region

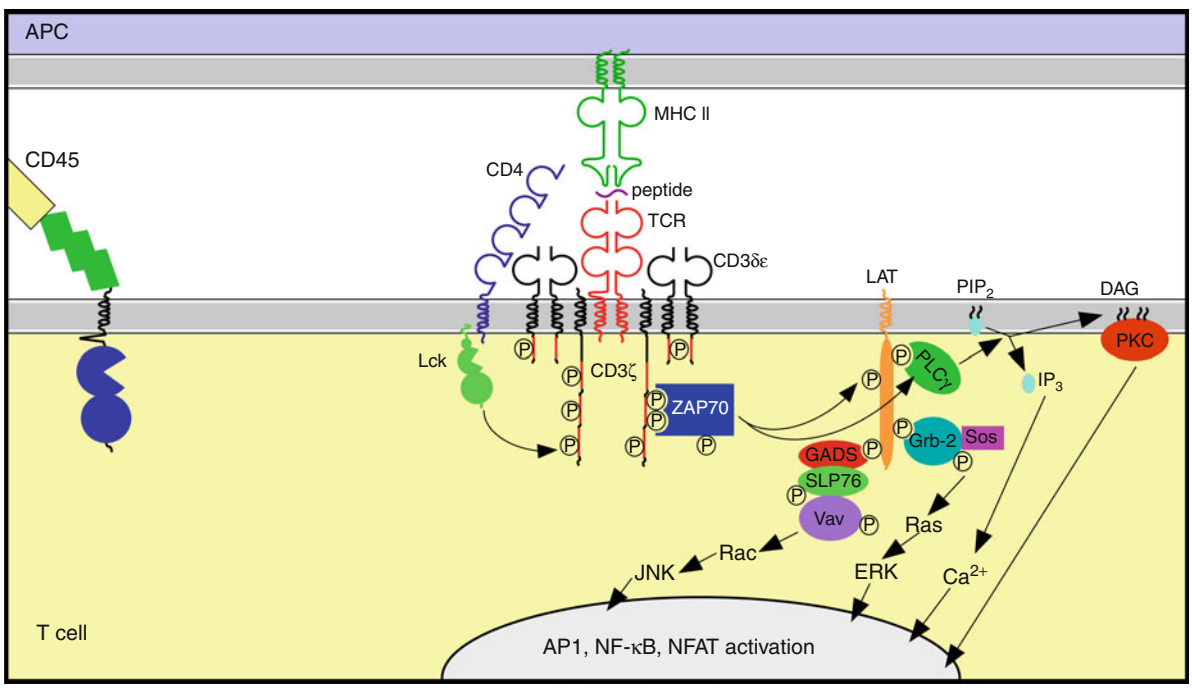
identified as a major substrate in B cells. Fyn may also be a CD45 substrate in T cells, but is less affected by the absence of CD45. In macrophages, the Src family tyrosine kinases Lyn and Hck have been identified as substrates for CD45 (Alexander 2000; Hermiston et al. 2003; Saunders and Johnson 2010). The Src family tyrosine kinases are regulated by two major tyrosine phosphorylation sites: a negative regulatory site close to the C-terminus of the protein and a positive regulatory site in a loop close to the active site of the kinase which, when phosphorylated, moves the loop away from the catalytic site thereby allowing substrate access (Williams et al. 1998). CD45 was shown to dephosphorylate Lck at the negative regulatory site in T cells, thus priming Lck for activation. However, subsequent work showed that CD45 could also dephosphorylate the positive regulatory site that is normally autophosphorylated in the active kinase. Thus CD45 has the ability to both upregulate and downregulate Lck activity in T cells and has the ability to maintain Lck in the primed, dephosphorylated state (Fig. 2). Although CD45 has been identified as a significant regulator of Src family kinase phosphorylation in hematopoietic cells, it is not the only regulator, as other tyrosine phosphatases such as CD148 can dephosphorylate the negative regulatory site and SHP-1 and Lyp/PEP can dephosphorylate the positive regulatory site (Hermiston et al. 2009).

CD45 and T Cell Antigen Receptor Signaling

The distribution of CD45 in the membrane, as well as the recruitment of Lck to the membrane either by myristoylation or by association with the CD4 or CD8 transmembrane proteins influences the ability of CD45 to access and dephosphorylate Lck. The basal activity of CD45 in naïve T cells primes Lck so it is ready to effectively participate in T cell receptor (TCR) signaling. Recognition by the TCR of peptide antigen presented by MHC class I or II molecules together with the binding of CD4 or CD8 co-receptor molecules to MHC molecules brings Lck into close proximity with the TCR associated ▶ CD3 chains. Antigen recognition is thought to induce clustering of these TCR complexes, which excludes CD45 and allows Lck to phosphorylate the ▶ CD3 chains at specific immunoregulatory tyrosine activation motifs (ITAMs) (van der Merwe and Dushek 2011). This results in the recruitment of the SH2 domain–containing tyrosine kinase ▶ Zap-70 that further propagates the phosphorylation cascade and the recruitment of signaling proteins (Tomlinson et al. 2000 and Fig. 3). Signaling from these microclusters leads to T cell activation and proliferation. These microclusters also aggregate to form the center of an immune synapse (cSMAC), which is surrounded by a ring of adhesion molecules referred to as the pSMAC (Dustin et al. 2010). CD45 is dynamically regulated during this process; it is initially excluded from the microclusters and the initial cSMAC then accumulates at the cSMAC at later time points, where it may play a role in downregulating Lck kinase activity and terminating the phosphorylation-induced signals. In the absence of CD45, Lck is constitutively phosphorylated in T cells, which leads to inefficient TCR signaling and



CD45 (PTPRC), Fig. 2 *Regulation of Src family kinase phosphorylation by CD45*. CD45 can dephosphorylate both the negative (Y505) and positive (Y394) regulatory tyrosines of the Src family kinase, Lck in T cells. In its dephosphorylated state, Lck is maintained in a primed state. CD45 acts reciprocally to the ▶ Csk kinase to dephosphorylate Lck at Y505. This releases the intracellular binding of phosphorylated Y505 to the SH2 domain to create an open, primed Lck. Lck either autophosphorylates or transphosphorylates Y394 which displaces the loop from the catalytic site, and creates an active kinase. CD45, as well as other phosphatases such as PEP, downregulate Lck activity by dephosphorylating Y394



CD45 (PTPRC), Fig. 3 *Function of CD45 in TCR signaling*. In the unactivated T cell, CD45 dephosphorylates Lck on the negative regulatory site and maintains Lck in a primed, dephosphorylated state. On engagement of peptide-MHC on the antigen-presenting cell (APC) by the TCR, costimulatory molecules (CD4 or CD8) are recruited along with Lck and signaling clusters are formed that exclude CD45. Active Lck then phosphorylates tyrosine residues in the ITAMs on CD3 molecules (δ, ε and ζ), which leads to the recruitment and phosphorylation of the kinase ZAP-70. Activated ZAP-70 then phosphorylates signaling molecules and initiates a downstream signaling cascade that leads to T cell activation. Later in the signaling process, TCR clusters form an immune synapse and CD45 moves into the synapse where it is thought to inactivate Lck and terminate TCR signaling

an increased threshold for T cell activation. This disrupts both positive and negative selection in the thymus, leading to reduced numbers of peripheral T cells in CD45-deficient mice that do not respond appropriately on antigen recognition (Alexander 2000; Hermiston et al. 2003; Saunders and Johnson 2010).

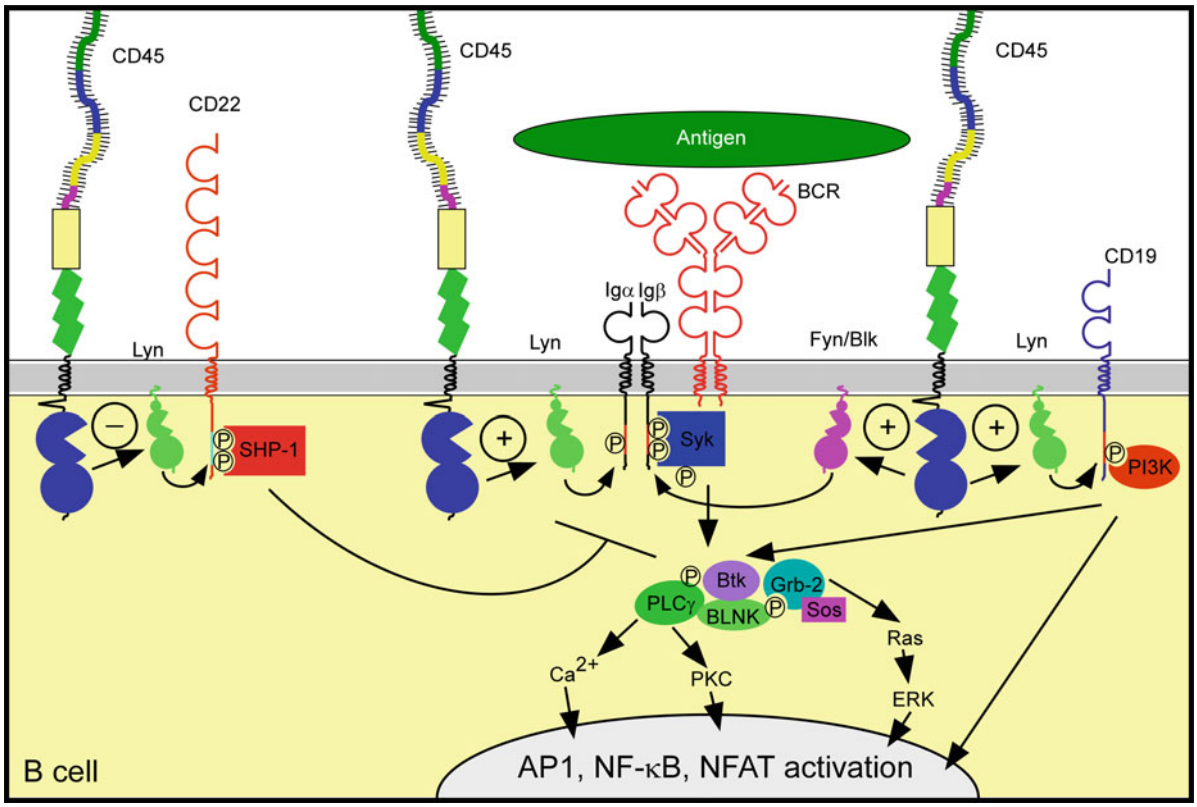
CD45 and B Cell Antigen Receptor Signaling

B cell antigen receptor (BCR) signaling, like TCR signaling, requires protein tyrosine kinase cascades to propagate signals required for B cell development and function. However the BCR is less dependent on CD45 and Src family kinases and is instead more dependent on the Syk tyrosine kinase. Syk is not as dependent on CD45 for activation as some BCR signaling events do occur in the absence of CD45. As a result, B cell development occurs in CD45-deficient mice but with increased numbers of immature IgM^{hi} cells and marginal zone B cells in the spleen and decreased numbers of circulating mature B cells (Hermiston et al. 2005). In CD45-deficient B cells, Syk and Btk are activated to some extent, Lyn is hyperphosphorylated and Fyn and Blk are not activated upon BCR engagement. This results in Igα and Igβ tyrosine phosphorylation but reduced ERK phosphorylation and diminished calcium signaling, which is insufficient to induce B cell proliferation in response to IgM cross-linking and points to a role for CD45 in enhancing BCR signaling strength. This reduced BCR signaling, as well as reduced phosphorylation of the costimulatory molecule, CD19, implicates CD45 in the positive regulation of Lyn, Fyn, and Blk (Fig. 4). However, CD22 was hyperphosphorylated in a CD45-deficient B cell line and Lyn was hyperphosphorylated at both the negative and positive regulatory sites and was more active in an in vitro assay, suggesting that CD45 may also negatively regulate Lyn (Huntington and Tarlinton 2004; Saunders and Johnson 2010). In B cells and myeloid cells, Lyn has the unique ability to phosphorylate immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in key negative regulatory molecules such as CD22, PIR-B, and FcγRIIB1 (Xu et al. 2005; Scapini et al. 2009). This non-redundant role for Lyn became evident through studies of Lyn-deficient mice where B cells are hyperresponsive to BCR ligation and resistant to signal inhibition induced by inhibitory receptor BCR co-ligation. Lyn-deficient mice also showed diminished tyrosine phosphorylation of key inhibitory phosphatases such as SHP-1 and SHIP-1. Many of these effects were opposite to those observed in CD45-deficient B cells, consistent with the loss of CD45 having an activating effect on Lyn. This view is strengthened by analysis of Lyn gain-of-function (Lyn^{up}) mice, which have enhanced BCR-induced calcium mobilization and tyrosine phosphorylation of both stimulatory (PLCγ, Syk) and inhibitory proteins, impaired B cell proliferation, and reduced circulating B cells in vivo. Thus there are many similarities between the CD45-deficient and Lyn^{up} B cells, with the minor differences perhaps being explained by the effect of CD45 on Blk and Fyn. It is also possible that CD45 has a dual effect on Lyn in B cells, downregulating its unique role activating inhibitory receptors and promoting Lyn's role in BCR signaling (Fig. 4), but exactly how this occurs is not known. Overall, the data indicate a clear role for CD45 in regulating BCR-induced signaling by regulating Lyn kinase.

Regulation of Additional Signaling Pathways by CD45 in Leukocytes

CD45 regulates other signals that are associated with ITIM or ITAM containing signaling molecules such as the Fc and NK receptors (Hermiston et al. 2009; Saunders and Johnson 2010). These receptors associate with ITAM-containing signaling proteins such as DAP12, FcRγ and ▶ CD3ζ chains, which are phosphorylated by Src family kinases and recruit Syk or ▶ Zap-70; thus, a similar pattern to antigen receptor regulation by CD45 is thought to exist. CD45 is required for IgE-mediated degranulation and IgE-mediated anaphylaxis in mast cells; however, FcRγ-mediated events such as IgG-mediated phagocytosis and antibody-dependent cytotoxicity in NK cells are not CD45 dependent. Interestingly, cytokine production induced by cross-linking NK cell receptors is CD45 dependent and correlates with impaired calcium mobilization and Syk and ERK activation. Thus the effect of CD45 may depend on the relative importance of Src family kinases in the response.

CD45 can also regulate cytokine signaling in hematopoietic cells (Saunders and Johnson 2010). CD45 can either upregulate or downregulate IFNα signaling in



CD45 (PTPRC), Fig. 4 *Function of CD45 in BCR and inhibitory protein* (*CD22*) *signaling*. Antigen binding cross-links the BCR, which activates the Src family kinases (Lyn, Fyn, and Blk) to phosphorylate ITAMs on Igα and Igβ. This leads to the recruitment and activation of Syk, which can then phosphorylate signaling molecules propagating a downstream signal that leads to B cell activation and proliferation. CD45 dephosphorylates and positively regulates these Src family kinases involved in BCR signal transduction. However, Lyn also negatively regulates BCR signaling by phosphorylating ITIMs present on inhibitory receptors such as CD22. This recruits the SHP-1 tyrosine phosphatase which downregulates BCR signaling. The data suggest that in this situation, CD45 negatively regulates Lyn activity, thereby promoting BCR signaling. Thus the net effect of CD45 is a partial inhibitory effect on BCR signaling

T cells and downregulates IL-3-induced proliferation in bone marrow–derived mast cells. CD45 can also negatively regulate erythropoietin-stimulated bone marrow progenitors to produce erythroid colony-forming units (CFU), although others see no difference in CFU after IL-3 stimulation. Penninger's group showed that the Janus kinase, JAK2, was hyperphosphorylated in IFNα-stimulated CD45-deficient thymocytes, Jurkat T cells, and in IL-3-induced bone marrow–derived mast cells. This led the authors to conclude that CD45 is a JAK phosphatase (Penninger et al. 2001). Interestingly, Lyn-deficient mice have increased splenic CFUs in response to IL-3, GM-CSF, and CSF-1, illustrating that Lyn may also negatively regulate cytokine signaling (Hibbs and Harder 2006). Thus it is possible that CD45 may activate Lyn to downregulate cytokine signaling by phosphorylating inhibitory receptors. The receptors recruit inositol (SHIP-1) and tyrosine (SHP-1) phosphatases that inhibit cytokine signaling through the attenuation of the PI3K pathway or by dephosphorylation of Janus kinases, respectively.

In CD45-deficient macrophages, autophosphorylation and activation of Hck and Lyn kinases leads to dysregulated $\alpha_M\beta_2$-mediated adhesion. In CD45-deficient T cells, enhanced $\alpha_5\beta_1$ integrin- and CD44-mediated adhesion leading to enhanced signaling and sustained Src family kinase activity is observed. Thus the negative regulation of Src family kinases by CD45 also impacts leukocyte adhesion.

In dendritic cells, CD45 can modulate pro-inflammatory cytokine production in response to Toll-like receptor (TLR) stimulation. The effect depends on the type of TLR activated and may be explained by a differential effect of CD45 on the ▶ MyD88 dependent and independent TLR signaling pathways. Although Btk as well as Hck and Lyn have been implicated in TLR signaling, tyrosine phosphorylation is not considered a major component of the TLR signaling pathway and exactly how signals from these kinases are integrated into the TLR signaling pathway is not well understood. TLR signals can also be modulated by signals derived from other receptors such as integrins, cytokine, and inhibitory receptors, raising the possibility that CD45 may also impact TLR signaling by modulating this cross talk (Johnson and Cross 2009).

Summary

CD45 is a protein tyrosine phosphatase, conserved throughout the evolution of vertebrates. CD45 is leukocyte specific and dephosphorylates specific Src family kinases, namely, Lck and Fyn in T cells and Lyn and Hck in B cells and myeloid cells. As CD45 can both positively and negatively regulate Src family kinases, it is challenging to determine whether Src kinase substrates are also direct CD45 substrates or whether their phosphorylation state is indirectly determined by the effect of CD45 on the kinase. Although the lack of CD45 in leukocytes significantly affects the phosphorylation state and activity of these Src family kinases, it is not the only regulator of these kinases. Specific regulators of Src family kinases may operate in specific locations under specific circumstances or some may have overlapping roles. Understanding when and where CD45 regulates Src family kinases will also provide a better understanding of immune cell activation. One of the main functions of CD45 is to help maintain specific Src family kinases in a primed, dephosphorylated state, preventing both hyperactivation and inactivation, which both lead to severe immune dysfunction. Indeed, the loss of CD45 in humans and mice results in severe combined immunodeficiency, illustrating the importance of CD45 in leukocyte function.

Historical Background

CD47 was first identified in 1987 as an antigen that is missing in red blood cells of patients with Rhesus (Rh)-null hemolytic anemia (see the following reviews for CD47 source references unless otherwise cited: (Brown and Frazier 2001; Frazier et al. 2010)). Loss of CD47 is not the primary cause of this disease, but CD47 closely associates with the Rh complex on red blood cells. Independently, the same protein was identified as an antigen, OA3, that is overexpressed in ovarian carcinoma and as a protein that co-purified with certain integrins and named integrin-associated protein (IAP). IAP and OA3 were shown in 1994 to be identical to CD47. CD47 is a type I integral membrane protein with an extracellular immunoglobulin variable (IgV)-like domain, five membrane-spanning segments, and a short alternatively spliced carboxy-terminal cytoplasmic tail. CD47 is widely expressed in higher vertebrates. In addition to its lateral association with certain integrins and the Rh complex, three extracellular ligands have been identified for CD47: thrombospondin-1 (TSP1), SIRPα (also known as ► Src homology 2 domain containing protein tyrosine phosphatase substrate-1 or SHPS1), and SIRPγ. TSP1 is a secreted protein and is the most studied ligand for regulating signaling through CD47. SIRPs are integral membrane proteins with important signaling functions, so CD47 is technically a counter-receptor for SIRPs. Most studies of SIRP-CD47 interactions regard CD47 as the ligand that regulates signal transduction through SIRPα (Barclay and Brown 2006), which will not be discussed here. However, there is growing evidence that this signaling is bidirectional (Sarfati et al. 2008), and more research is needed to clarify the role of SIRPs as signaling ligands for CD47.

Early studies of CD47 function as a signaling receptor focused on its role in integrin activation, and peptides derived from TSP1 that bind to CD47 were shown to enhance the activation of specific integrins. Ligation of CD47 by these peptides in different cell types also stimulated calcium influx and changes in cAMP levels, ► MAP kinase activities, and Giα activation. The central function of CD47 in cardiovascular physiology was first revealed by an enhanced angiogenic response to nitric oxide (NO) in muscle explants from TSP1 and CD47 null mice. TSP1 binding to CD47 inhibited NO-mediated activation of soluble guanylate cyclase (sGC) in endothelial cells. Subsequent studies extended this inhibition of NO signaling to other vascular cells, including smooth muscle cells, platelets, and T lymphocytes. Functional studies showed that this inhibitory signaling by TSP1 through CD47 acutely controls vascular tone, blood pressure, and platelet hemostasis (Isenberg et al. 2009). Subsequent biochemical studies expanded the intracellular targets of this inhibitory signaling to include cGMP-dependent protein kinase (cGK), endothelial nitric oxide synthase (eNOS, NOS3), and vascular endothelial growth factor receptor-2 (VEGFR2) (Bauer et al. 2010; Kaur et al. 2010). Thus, CD47 signaling is now recognized as a highly redundant inhibitor of the NO/cGMP signaling cascade in vascular cells.

A second major function that has emerged for CD47 is to control cell survival. Early studies showed that some CD47 antibodies can induce apoptosis of T cells. Studies in mice lacking CD47 have extended this more broadly to survival of ischemic stress, ischemia reperfusion, and radiation injury. Mechanistic studies show some involvement of the NO/cGMP cascade and regulation of SIRPα-mediated phagocytosis, but

additional pathways have been identified through which CD47 signaling controls mitochondrial-dependent cell death.

Proximal Targets of CD47

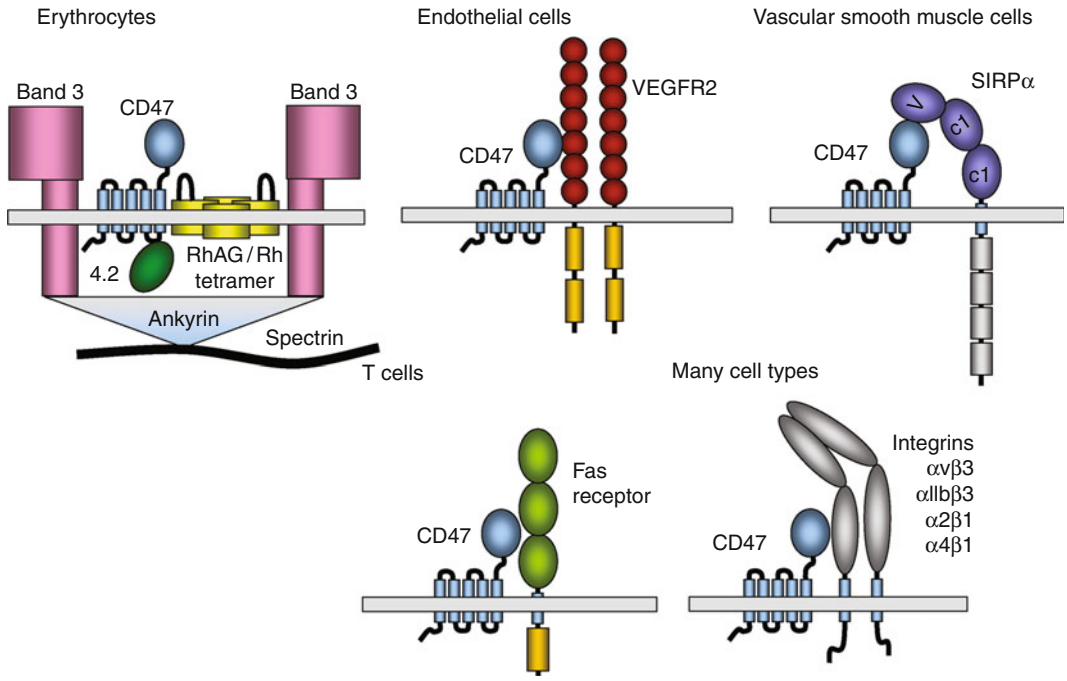
CD47 has a only a short C-terminal cytoplasmic tail, so signal transduction through CD47 is generally believed to be mediated by its interactions with other cellular proteins, either laterally in the plasma membrane or by recruiting cytoplasmic proteins to the complex of CD47 with its membrane binding partners (Fig. 1). The first direct interaction partner identified for CD47 was the integrin $\alpha_v\beta_3$ based on their co-purification. This is a lateral interaction between two integral membrane proteins, and the extracellular IgV domain of CD47 is necessary and sufficient to mediate integrin binding and to activate αvβ3 to bind its ligand vitronectin. Ligation of CD47 by TSP1 or certain TSP1 peptides leads to activation of this and some other integrins, including $\alpha_{IIb}\beta_3$, $\alpha_2\beta_1$, and $\alpha_4\beta_1$. These integrins were also shown to interact with CD47 based on co-immunoprecipitation, although it is not clear that all of these integrins are direct binding partners of CD47. In red blood cells, the Rh complex replaces integrins as the major lateral binding partner of CD47. Although the composition of this complex is well known, the proximal interactions of CD47 within the complex remain unclear, and potential effects of CD47 ligands on functions of the Rh complex remain to be determined. SIRPα has been implicated as a lateral binding partner of CD47 in smooth muscle cells (Fig. 1), but the alternative possibility that the extracellular domain of SIRPα is shed and then binds to CD47 on the same cell has not been excluded. In T cells, CD47 laterally associates with Fas, and this association is increased by Fas ligation. Finally, colocalization, co-precipitation, and fluorescence resonance energy transfer studies recently identified VEGFR2 as a proximal binding partner of CD47 (Kaur et al. 2010). This interaction is specifically disrupted when VEGF and TSP1 bind simultaneously to their respective receptors.

Several cytoplasmic binding partners of CD47 have been identified. CD47 was shown to coprecipitate with some heterotrimeric G proteins. Ligation of CD47 leads to dissociation of Giα from Gβγ. The ability of cyclodextrin to dissociate Giα from CD47 suggests that this interaction is not direct. Yeast two-hybrid studies revealed that protein linking IAP and cytoskeleton-1 (PLIC-1, ubiquilin-1) and the related PLIC-2 (ubiquilin-2) are proximal cytoplasmic ligands of CD47. The latter may be a general negative regulator of G protein–coupled receptor endocytosis (N'Diaye et al. 2008). Another yeast 2-hybrid screen identified Bcl2 homology 3-only protein 19 kDa interacting protein-3 (BNIP3) as an interaction partner of CD47 (Lamy et al. 2003).

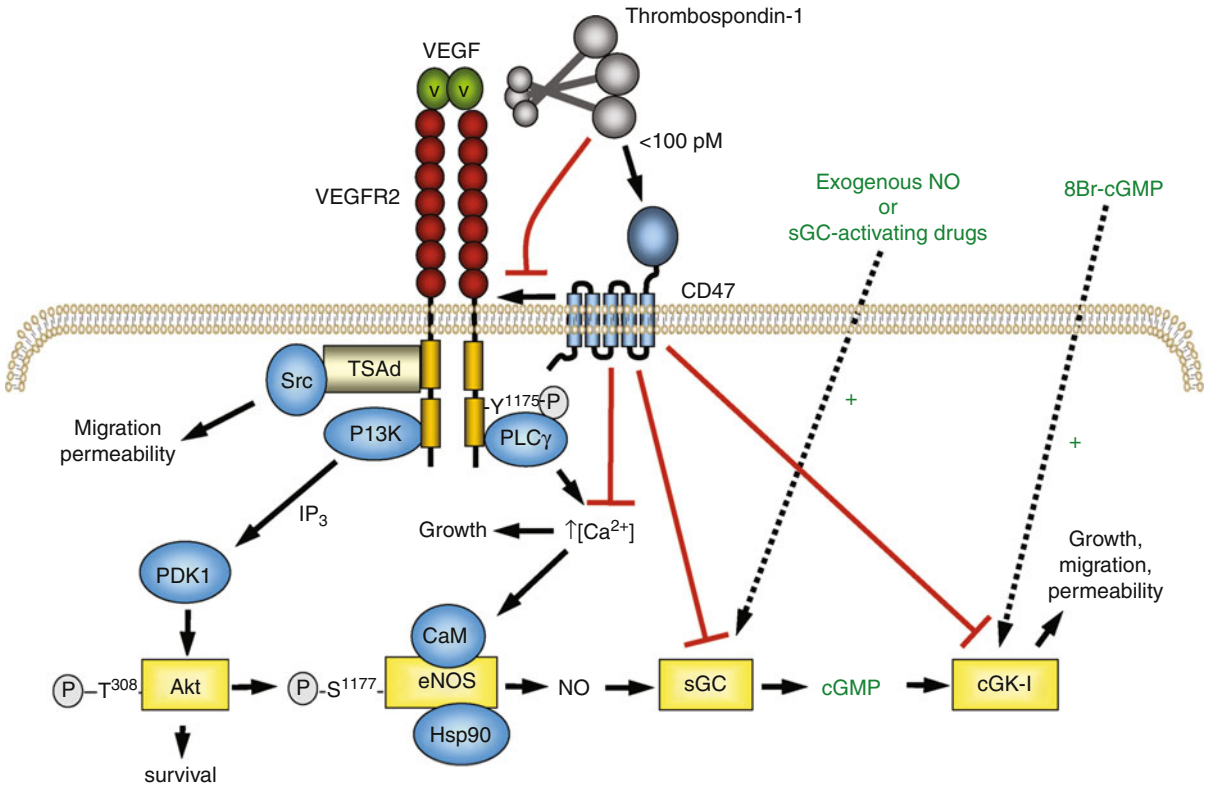
NO/cGMP Pathway

NO is a central regulator of cardiovascular function, hemostasis, immunity, and neural processing. Three NO synthases (eNOS, nNOS, and iNOS) convert L-arginine to L-citrulline and NO. NO freely traverses cell membranes to rapidly activate its intracellular targets and so can mediate intercellular signaling between endothelium and arterial smooth muscle. NO binds to heme proteins, including ▶ sGC, which is the primary sensor of physiological NO levels (Fig. 2). NO binding increases cGMP synthesis, which in turn activates cGMP-dependent protein kinases and cyclic nucleotide-gated ion channels to suppress inflammation and platelet aggregation, inhibit leukocyte recruitment, dilate blood vessels, and stimulate angiogenesis. A majority of cardiovascular diseases are associated with loss of endogenous NO production and decreased sensitivity to NO. Conversely, several cardiovascular therapeutics enhance NO signaling, including nitroglycerine and other nitrovasodilators and phosphodiesterase inhibitors. NO signaling can be modulated through control of NO production and phosphodiesterases that degrade cGMP. However, CD47 signaling mediates a more profound control of this pathway.

TSP1 binding to CD47 potently limits sGC activation by NO in endothelial and vascular smooth muscle cells and platelets. TSP1 also potently inhibits sGC activation by heme-dependent and nonheme-dependent chemical activators such as YC-1 and Riocuguat (BAY 63-2521) in vascular cells (Miller et al. 2010). Physiological circulating concentrations of TSP1 in blood (0.1–0.2 nM) are sufficient to inhibit sGC activation. This is consistent with the observation that endothelial and vascular smooth muscle cells and platelets from TSP1 and CD47 null mice have elevated basal levels of cGMP. In wounds and some chronic



CD47, Fig. 1 Membrane complexes containing CD47



CD47, Fig. 2 Thrombospondin-1 interaction with CD47 redundantly inhibits VEGFR2 and NO/cGMP signaling

disease states, much greater levels of TSP1 can be demonstrated in tissues and blood. These findings suggest that TSP1 functions in both health and disease to inhibit NO-stimulated activation of sGC. At higher concentrations (>10 nM), TSP1 also inhibits sGC activation via engaging the cell receptor CD36, but this inhibitory activity still requires the presence of CD47.

TSP1 limits activation of cGK in platelets stimulated by NO or by cell permeable analogs of cGMP (Fig. 2). Furthermore, assay of cGK activity using a defined peptide substrate in lysates of platelets pretreated with TSP1 showed inhibition of in vitro activation of the enzyme by cGMP. Therefore, cGK is a second direct target of CD47 signaling (Fig. 2).

eNOS is the major NO synthase expressed in vascular endothelium. eNOS is activated by hormonal or mechanical stimulation of the endothelium through modulation of intracellular calcium and phosphorylation of eNOS. TSP1 also inhibits eNOS activation in endothelial cells, thereby limiting endothelial-dependent arterial dilation (Bauer et al. 2010). This inhibitory activity on eNOS requires interaction with endothelial CD47. Importantly, CD47 null mice are hypotensive at rest compared to wild type controls, demonstrating a role for the cell surface receptor as a mediator of arterial tone and vascular resistance. In vivo circulating TSP1 was found to limit endothelial activation and associated decreases in blood pressure. Thus, physiologic levels of circulating TSP1 function as a hypertensive by limiting eNOS activation and endogenous NO production, and in this capacity TSP1 functions to support blood pressure. Targeting the TSP1-CD47 ligand receptor interaction can acutely lower blood pressure, suggesting possible therapeutic opportunities in the treatment of systemic hypertension.

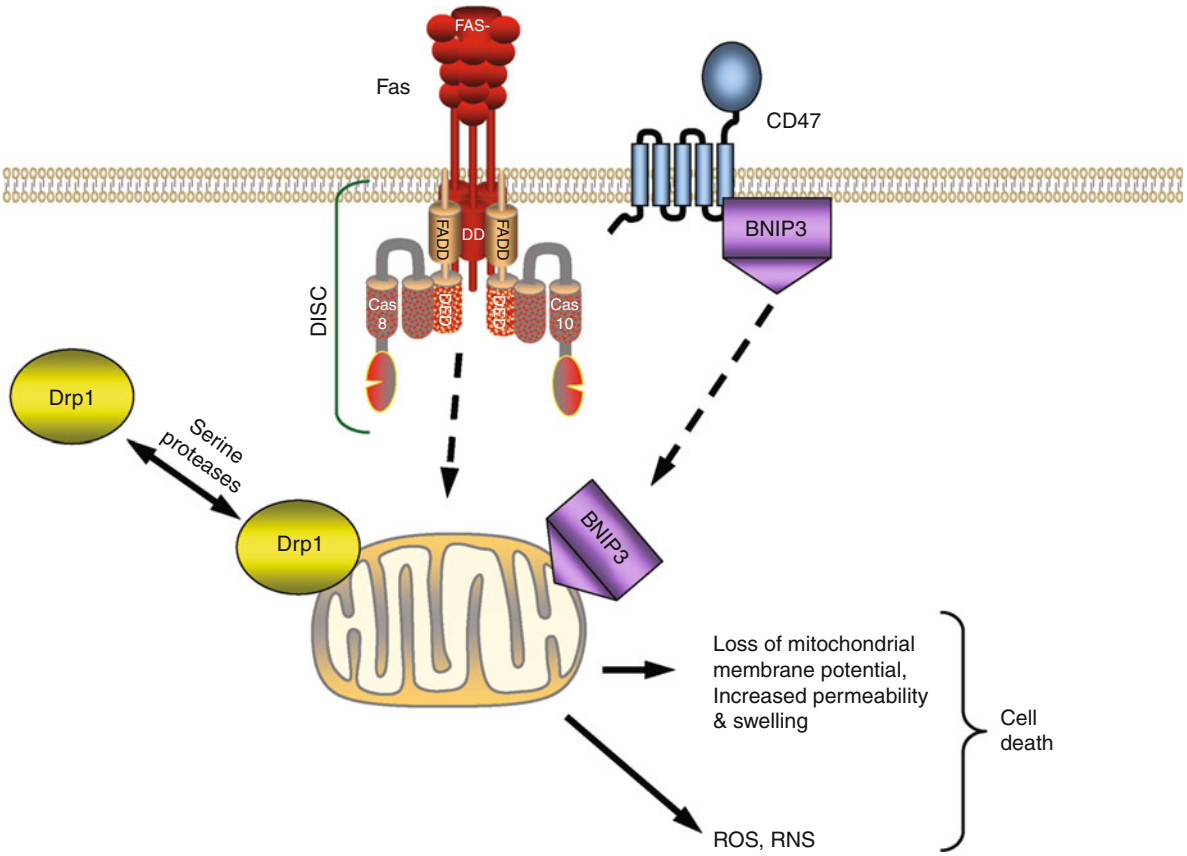
Phosphorylation of eNOS activates the enzyme and can be stimulated in endothelial cells by VEGF binding to its receptor VEGFR2 (Fig. 2). Recently, CD47 was found to interact with VEGFR2 in endothelial cells (Kaur et al. 2010). Ligation of CD47 in the presence of VEGF dissociates CD47 from VEGFR2 and prevents autophosphorylation of VEGFR2 at Tyr^{1175}. This is a necessary phosphorylation for downstream signaling. Therefore, CD47 ligation by TSP1 can globally inhibit signaling downstream of VEGFR2, which includes Src kinase and phospholipase Cγ pathways important for cell migration and proliferation in addition to blocking Akt and subsequent eNOS activation (Fig. 2).

Cell-Survival Signaling

Antibody ligation of certain epitopes on CD47 induces death of activated T cells independent of Fas and TNFR signaling (Sarfati et al. 2008). Cell death induced via CD47 does not involve DNA fragmentation, suggesting activation of CD45 and HLA class I signaling. Moreover, Jurkat T cells lacking CD47 are relatively resistant to Fas-mediated death but are efficiently killed by Fas ligand or anti-Fas antibody upon re-expression of CD47 (Sarfati et al. 2008). Cells lacking CD47 exhibit impaired downstream responses to Fas activation, including caspase activation, poly-(ADP-ribose) polymerase cleavage, cytochrome C release from mitochondria, loss of mitochondrial membrane potential, and DNA cleavage (Fig. 3). Treatment with an anti-Fas antibody induces an association of Fas with CD47. Antibody binding to CD47 enhances Fas-dependent apoptosis in Jurkat T cells and in primary mouse T cells. The expression of CD47 causes Fas to cluster and associate with the extracellular IgV of CD47, affecting Fas function upstream of caspase activation.

Cell death involving CD47 is not exclusive to T cells. Treatment with an immobilized monoclonal antibody or TSP1 induces apoptosis in B-cell chronic lymphocytic leukemia (B-CLL) cell clones from patients. As observed in T cells, CLL cell death occurred without nuclear features such as chromatin condensation and DNA fragmentation. However, cytoplamic changes, such as cell shrinkage, and decrease in mitochondrial membrane potential were observed (Sarfati et al. 2008). Moreover, electron microscopy revealed swelling of the mitochondria, indicating an increase in permeability of the mitochondrial membrane. This indicates that CD47 may regulate mitochondrial function to control cell survival. In activated T-cells, treatment with the CD47 antibody B6H12 disrupts mitochondrial transmembrane potential, followed by the release of reactive oxygen species (Roue et al. 2003). This dysfunction in the mitochondria is not accompanied by the release of cytocrome C or AIF, indicating an alternate mechanism for programmed cell death (Roue et al. 2003).

One possible mediator of CD47-dependent cell death is BNIP3, a member of the Bcl2 interacting proteins that translocates to the mitochondria to induce apoptosis (Lamy et al. 2003). BNIP3 contains a BH3 domain and a transmembrane domain that are associated with pro-apoptotic functions. BNIP3 interacts



CD47, Fig. 3 CD47 regulation of cell survival

with the transmembrane domains of CD47 (Lamy et al. 2003). Antisense suppression of BNIP3-inhibited, CD47-mediated induction of apoptosis, indicating that binding of antibody or peptides mimicking TSP1 induces BNIP3 to translocate from the plasma membrane to the mitochondria to execute cell death (Lamy et al. 2003). This regulation of mitochondrial function by CD47 implicates other forms of cell death.

CD47 ligation also regulates dynamin-related protein 1 (Drp1), a mayor regulator of type III programmed cell death (Bras et al. 2007). CD47 ligation induces Drp1 translocation from the cytosol to mitochondria, a process controlled by chymotrypsin-like serine proteases. Once in mitochondria, Drp1 blocks the mitochondrial electron transport chain, which dissipates the mitochondrial transmembrane potential, increases reactive oxygen species generation, and produces a drop in ATP levels (Bras et al. 2007). This process is reversed upon ligation of CD47 in conjunction of with Drp1 blockade, suggesting that this protein is essential for the CD47 regulation of mitochondrial function and induction of type III–programmed cell death.

CD47 also controls cell survival independent of controlling programmed cell death by allowing senescent or damaged cells to escape phagocytosis. CD47 is up-regulated in a number if cancers, including ovarian and bladder carcinomas and myeloid leukemia and in migrating hematopoietic progenitors. Increased CD47 expression correlates with an ability to evade phagocytosis by macrophages and cytolysis by NK cells (Jaiswal et al. 2010). Conversely, CD47 expression limits survival of many cells types under conditions of stress (Lamy et al. 2003; Isenberg et al. 2008b). In fixed ischemic stress generated by surgically creating myocutaneous flaps, tissue blood flow and perfusion were dramatically increased in CD47 null animals (Isenberg et al. 2008). These animals experienced 100% tissue survival, whereas WT flaps underwent close to 50% necrosis, indicating that CD47 enhances tissue necrosis during ischemic injury (Isenberg et al. 2008). Similar observations have been made for other

fixed ischemic insults or ischemia/reperfusion injuries in mice, rats, and pigs (Isenberg et al. 2008). In a model of cerebral focal ischemia, CD47 null mice show reduced brain damage after ischemic insult. These activities of CD47 to limit tissue survival are based on its inhibition of NO/cGMP-mediated maintenance of tissue perfusion and vascular remodeling. In addition, CD47 expression promotes neuroinflamation by promoting MMP-9 upregulation, neutrophil extravasation, allowing the progression of ischemic brain injury and death (Jin et al. 2009). Treatment with antibodies to CD47 or antisense morpholino oligonucleotides that suppress CD47 mRNA translation increase recovery from ischemic insults in several animal models (Isenberg et al. 2008). Together, these data suggest that therapeutic blockade of CD47 could be clinically useful to restore blood flow and improve tissue survival after ischemic injuries.

The cytoprotective effects of decreased CD47 expression extend to ionizing radiation (IR) injuries. IR acutely damages cellular DNA and other cellular macromolecules, eliciting stress responses that ultimately lead to cell death. CD47 null and TSP1 null mice show enhanced skin, muscle, and bone marrow preservation after radiation injury (Isenberg et al. 2008). Vascular cells cultured from the null mice showed enhanced cell-survival and proliferative capacity after IR injury, demonstrating that this acute radioprotection of vascular cells is cell-autonomous (Isenberg et al. 2008). In a follow-up study, treatment with a CD47-binding peptide or antisense suppression of CD47 protected human endothelial cells in vitro and protected soft tissue, bone marrow, and tumor-associated leukocytes in irradiated hindlimbs of mice (Maxhimer et al. 2009). Although NO is a known radioprotectant, enhanced NO signaling is not sufficient to account for radioprotection by CD47 blockade. Treatment with DETA/NO or a cell permeable cGMP analog does not result in a significant survival advantage to irradiated endothelial cells (Maxhimer et al. 2009). Conversely, inhibition of endogenous NO production does not prevent the protective effects of CD47 morpholino (Maxhimer et al. 2009). Therefore, the radioprotection observed by CD47 targeting occurs in a largely NO-independent manner.

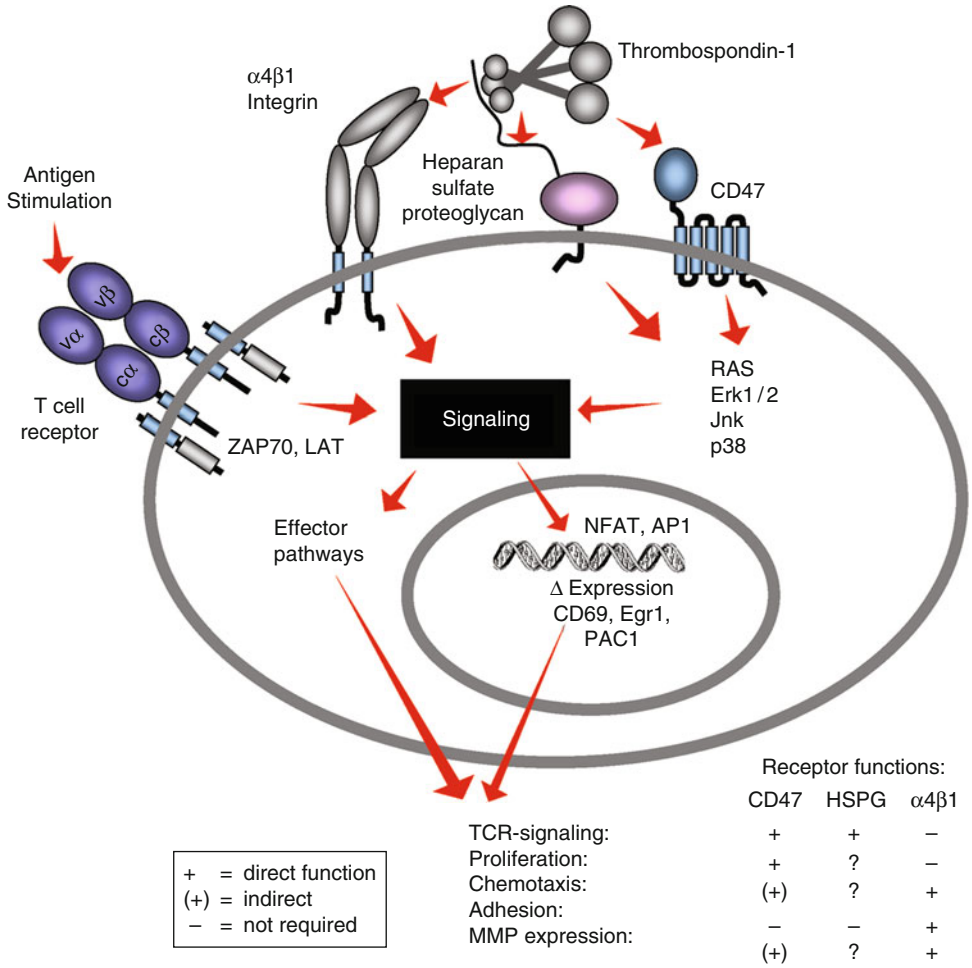
Because therapeutic irradiation is employed in treating a majority of cancer patients, the suppression of CD47 was studied in tumor-bearing mice in combination with radiation treatment. Treatment with IR alone resulted in the expected tumor regrowth delay. However, CD47 morpholino treatment followed by IR dramatically delayed tumor regrowth (Maxhimer et al. 2009). In vitro, CD47 blockade conferred minimal radioprotection to tumor cells, suggesting that suppression of CD47 enhances tumor growth delay after irradiation through enhancing host antitumor immunity (Maxhimer et al. 2009). Although details of this mechanism remain to be elucidated, it is clear that the expression of CD47 is a critical regulator of survival for several cell types. This regulation is important for normal tissue homeostasis, such as clearance of aging erythrocytes and limiting inflammation, but is also essential in the protection of tissues subjected to stress or pathologies that dysregulate programmed cell death.

T-Cell Signaling and Differentiation

Ligation of CD47 in T cells results in transient activation of Ras and the MAP kinases ERK, JNK, and p38 (Wilson et al. 1999). However, engaging CD47 in conjunction with TCR signaling globally inhibits T-cell activation (Sarfati et al. 2008). This occurs downstream of the TCR signaling molecules ▶ LAT and ▶ ZAP70 (Fig. 4). This inhibitory signaling limits induction of interleukin-2 and CD69. Because the CD47 ligand TSP1 also regulates T-cell behavior via integrin and proteoglycan receptors, T-cell responses integrate signals from these three receptors. Signaling through CD47 also drives T cells toward Treg differentiation. As discussed above, CD47 signaling can induce T-cell apoptosis, and CD47-deficient mice consequently exhibit T cell–mediated inflammatory responses due to maintaining excessive numbers of activated inflammatory cells (Lamy et al. 2007).

Other Second Messengers

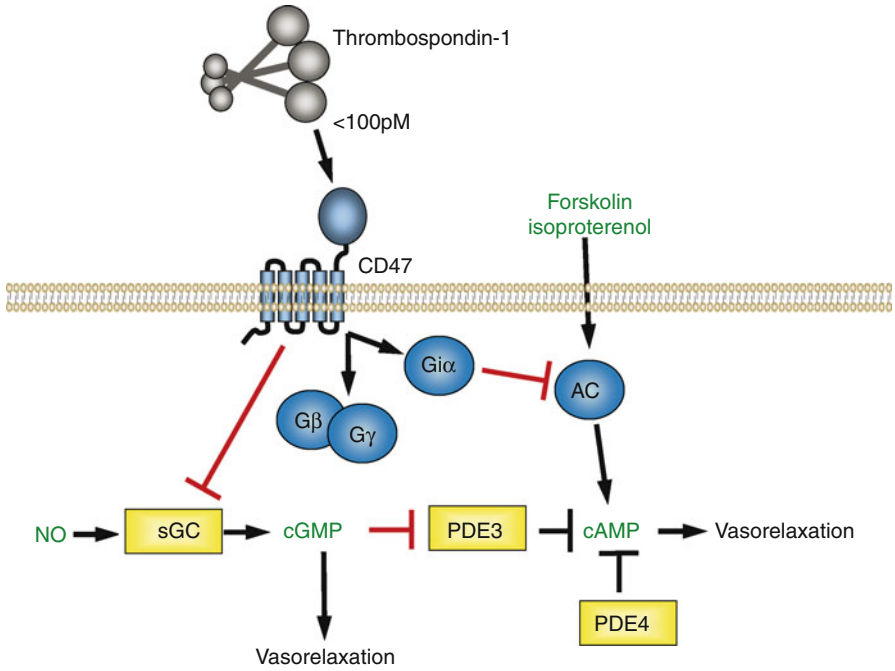
Cyclic AMP is a ubiquitous second messenger that promotes relaxation of airway and arterial smooth muscle cells, in part through lowering intracellular calcium. In platelets, cAMP inhibits aggregation. These activities of cAMP parallel those of cGMP, and the levels of both intracellular second messengers trend in the same direction. cAMP is produced by the enzyme ▶ adenylyl cyclase when activated by G protein–coupled receptor signaling. cAMP is



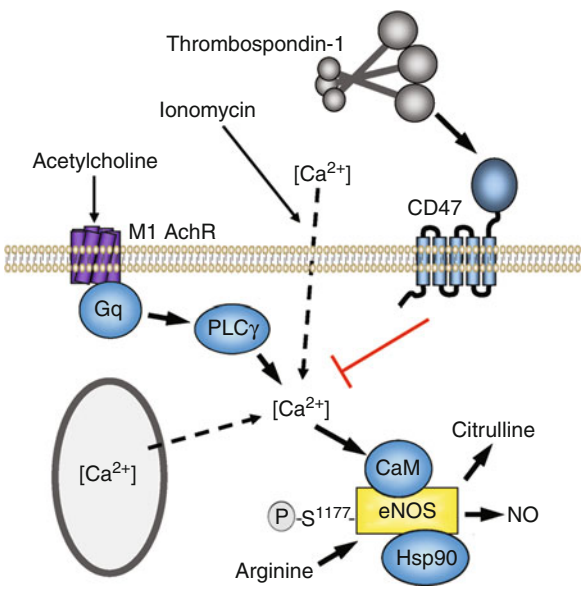
CD47, Fig. 4 CD47 regulation of T-cell signaling

hydrolyzed by several phosphodiesterases (PDEs), which are themselves controlled through cGMP-dependent cross talk. CD47 ligation alters cAMP levels in several cell types. In thyroid cells, a TSP1 peptide specific for CD47 maintains cAMP levels. Conversely, in T cells, vascular smooth muscle cells, and platelets CD47 ligation lowers cAMP levels, in part, through cGMP-mediated control of PDEs. cAMP levels are inherently higher in vascular cells, skeletal and cardiac muscle from TSP1, and CD47 null mice, suggesting that in the absence of ligand engagement CD47 modulates cellular cAMP (Isenberg et al. 2009). Ligation of CD47, though both NO-dependent and NO-independent signaling, inhibits vascular smooth muscle cell cAMP (Yao et al. 2010). In vascular smooth muscle cells, the TSP1-CD47 axis inhibits direct activation of adenylyl cyclase and, in this manner, blocks cAMP-stimulated vasorelaxation. These latest findings support a role for CD47 in limiting both cGMP and cAMP driven vasorelaxation (Fig. 5).

Calcium is another critical regulator in intracellular signal transduction. Fluxes in intracellular calcium regulate cell contraction, migration, and growth. Through its G protein–coupled receptor-like activity and/or integrin interactions, CD47 has been associated with changes in calcium in neurons, T cells, mast cells, and both melanoma and prostate tumor cells (Frazier et al. 2010). In the cardiovascular system, endogenous NO production by eNOS requires calcium, and fibronectin-stimulated increases in endothelial calcium can



CD47, Fig. 5 Thrombospondin-1 interaction with CD47 regulates crosstalk between cGMP and cAMP in vascular smooth muscle



CD47, Fig. 6 Thrombospondin-1, via CD47, inhibits agonist driven calcium flux and eNOS activation

be blocked by a CD47 antibody. Both ionomycin and the physiologic activator acetylcholine increase eNOS-stimulated production of NO by increasing cytoplasmic calcium levels. TSP1 and a CD47-specific recombinant domain of TSP1 inhibit activator-based calcium fluxes and eNOS activation in endothelial cells (Fig. 6) (Bauer et al. 2010).

Summary

CD47 is a ubiquitously expressed transmembrane receptor for two members of the SIRP/SHPS family and TSP1. Signaling between CD47 and SIRPα is bidirectional, but signaling through CD47 in response to SIRPα ligation remains poorly characterized. TSP1 binding to CD47 alters its lateral interactions with several integrins, VEGFR2, Fas, and possibly SIRPα. This results in altered signaling through each of these receptors to modulate cell adhesion, survival, contractility, proliferation, and motility. Downstream signaling through CD47 controls levels of the second messengers calcium, cAMP, and cGMP in a cell-specific manner. In vascular cells, NO is a major physiological target of CD47 signaling. CD47 signaling redundantly controls both synthesis and effector pathways downstream of NO, enabling it to control both intracellular and intercellular signaling between vascular cells. This signaling has physiological roles in angiogenesis, cardiovascular dynamics, and hemostasis. Antagonism of NO signaling by CD47 also limits tissue responses to ischemic and radiation stress.

CD53 antigen; Cell surface glycoprotein CD53; Leukocyte surface antigen CD53; MOX44; OX44; Ox-44; Tetraspanin-25; Tspan25l; Tspan-25

Historical Background

CD53 is a member of the tetraspanin family of hydrophobic membrane-spanning proteins. Tetraspanins form microdomains on the cell surface that can interact with many different proteins implicated in signaling. CD53 has no known extracellular ligand. The specific function of CD53 has not yet been defined, but CD53 has been shown to modulate cell adhesion, migration, cell proliferation, and survival. Ligation of CD53 with antibodies protects cells from apoptosis; this effect is mediated by phosphorylation and activation of Akt, increased levels of Bcl-Xl, decreasing the amount of Bax, and reducing caspase activation. In mesangial cells, CD53 ligation stimulates the induction of DNA synthesis via the MEK-Erk pathway. CD53 ligation induces calcium mobilization, activation of PKCα, and expression of the inducible nitric oxide synthase genes resulting in increased nitric oxide production. But all these effects may be a consequence of the tetraspanin complex on which CD53 is integrated in specific cell types (Yunta and Lazo 2003b).

Protein Structure

The CD53 protein belongs to the tetraspanin family (Horejsi and Vlcek 1991). Tetraspanins are highly hydrophobic and have four transmembrane domains, but a specific function for these proteins has not yet been identified (Hemler 2003, 2005; Maecker et al. 1997). Tetraspanins can organize into membrane microdomains, known as the tetraspanin web, that interact with many different proteins on the cell surface (Boucheix and Rubinstein 2001; Yunta and Lazo 2003b). Thus, tetraspanin proteins may function as facilitators of other cellular functions (Hemler 2005). CD53 has two extracellular loops, a short (EC1) and a long one (EC2), that are maintained by disulfide bonds (Fig. 1). The structure of the EC2 determines the type of tetraspanin protein (Seigneuret et al. 2001).

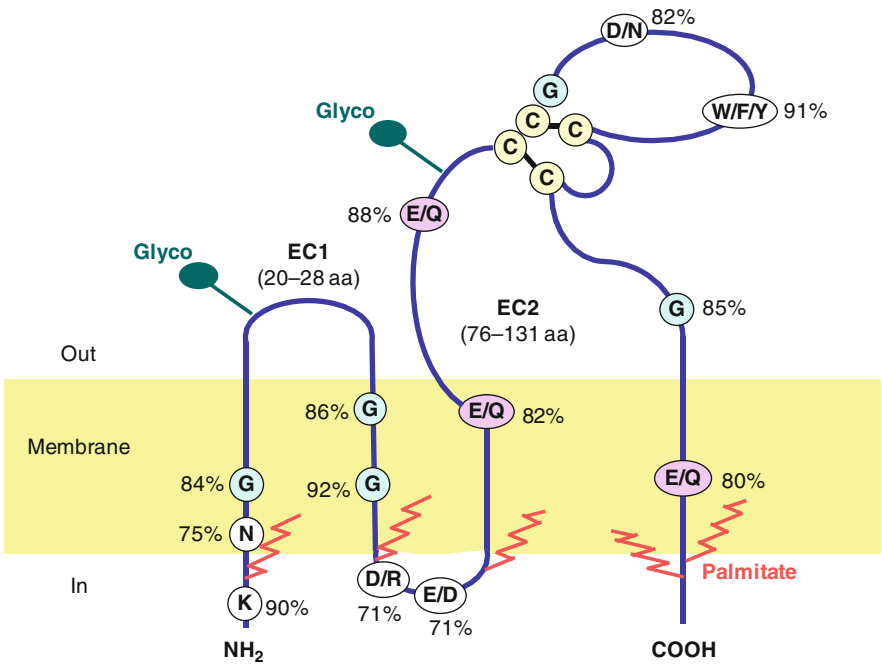
Protein Function

Most of the functional data associated with CD53 was obtained by CD53 ligation with antibodies. Ligation induces homotypic adhesion in lymphoma cell lines (Cao et al. 1997; Lazo et al. 1997; Yunta and Lazo 2003a). CD53 ligation induces phosphorylation of Akt, increased Bcl-Xl level, reduction of Bax, and activation of caspases, thus protecting cells against apoptosis induced by serum deprivation (Yunta and Lazo 2003a).

CD53 ligation induces a burst of DNA synthesis and initiation of the cell cycle through activation of the MEK-Erk pathway in mesangial cells. However, additional stimuli are required for completion of the cell cycle (Yunta et al. 2003); in the U937 monocytic cell line, CD53 ligation blocked proliferation (Stonehouse et al. 1999). In macrophages ligation of CD53 induces nitric oxide production through calcium mobilization, activation of PKCα, and expression of the inducible nitric oxide (iNOS) synthase gene (Bosca and Lazo 1994). Calcium mobilization has also been detected in human monocytes and B cells (Olweus et al. 1993). CD53 appears to play an adaptor or scaffold protein that influences adhesion, proliferation, and survival. Additional studies are required to elucidate the precise role for CD53 in these and other cellular processes.

Tetraspanin Web and CD53 Protein Interactions in Plasma Membranes

CD53 interacts with other tetraspanins forming the tetraspanin web (Hemler 2005; Yunta and Lazo 2003b). The web composition may vary depending on the pattern of tetraspanin expression in particular cell types. No ligand of any tetraspanin is known, and the web is likely to function as a facilitator of other signals. Tetraspanins interact with several types of proteins, although it is not clear which component of the web is modulating cell signaling. The same types of molecules are found in these complexes, independently of the specific tetraspanin studied, complicating efforts to understand the precise identity and stoichiometry of components within the tetraspanin web. As many of the interactions described below were identified by co-immunoprecipitation, it is not necessarily clear with which components CD53 interacts directly. Thus, unless otherwise noted, these interactions probably take place within the tetraspanin web, but not necessarily with CD53. In the tetraspanin web in human cells, CD53 interacts with other tetraspanins CD9, CD37, ▶ CD81, CD82, and CD151 determined by use of different detergents



CD53, Fig. 1 Structure of human CD53 antigen. Extracellular loops (EC1 and EC2). Cysteine disulfide bonds in EC2, conserved residues among tetraspanins (*circles*), and glycosylation and palmitoylation sites are indicated (Lazo 2007)

(Angelisova et al. 1990; Hemler 2003). Palmitoylation contributes to the interaction with CD81 and CD53 (Charrin et al. 2002). CD53 interacts with class II antigens of the major histocompatibility complex (MHC) or human leukocyte antigen (HLA) systems in murine and human cells (Angelisova et al. 1994; Damjanovich et al. 1998; Szollosi et al. 1996); these molecules are within 2–10 nm range since fluorescence could be transmitted between HLA (MHC class I molecules and at least one DR, DQ), CD20 and CD53, and CD81 and CD82. The simultaneous energy transfer from CD20, CD53, CD81, and CD82 to DR suggests that all these molecules are in a single complex (Szollosi et al. 1996). Several associated molecules were identified by atomic force microscopy. Nonrandom co-localization of MHC class I and II; intercellular adhesion molecule-1 (ICAM-1); the T-cell receptor (TCR)–► CD3–CD4 complex; the CD81, CD82, and CD53 tetraspanins; and the α, β and γ subunits of the IL-2 receptor was detected in a lymphoma cell line (Damjanovich et al. 1998).

CD53 directly interacts in these microdomains with several integrins (ITG) containing the β_1 chain. The presence or absence of particular integrin α chains varies depending on cell type, but integrin $\alpha_4\beta_1$ coprecipitated with CD53 in cell lines (Mannion et al. 1996).

Tetraspanin Web and CD53 Interactions with Intracellular Signaling

Several intracellular signaling molecules interact with tetraspanins. PKC can be associated with CD9, CD53, CD81, CD82, and CD151. Although formation and maintenance of tetraspanin-PKC complexes is not dependent on integrins, tetraspanins can act as linker molecules that bring PKC into proximity with specific integrins. The specificity for PKC association probably resides in the cytoplasmic tails or the first two transmembrane domains of tetraspanins, and CD53 has been found to interact with PKCα (Zhang et al. 2001). CD53 crosslinking induces effects mediated by PKCα, such as nitric oxide production by the inducible nitric oxide synthase (iNOS) (Bosca and Lazo 1994), and homotypic cell adhesion in a B cell lymphoma (Lazo et al. 1997). Also CD53, CD21, CD19, CD81, and CD82 interact with γ-glutamyl transpeptidase (GGT), a membrane protein involved in recycling extracellular glutathione and regulation of intracellular redox potential (Nichols et al. 1998). This might be relevant for cell sensitivity to radiation mediated, which is affected by the redox state. CD53 is overexpressed 20–50 fold in murine B cells that are resistant to radiotherapy and apoptosis (Voehringer et al. 2000). CD53 coprecipitates with GGT in lymphocytes from patients with rheumatoid arthritis that are

also resistant to apoptosis (Pedersen-Lane et al. 2007). CD53 can protect cells from apoptosis by inducing AKT survival signals (Yunta and Lazo 2003a). CD53, CD9, and CD81 have been detected in budding HIV-1 particles in infected macrophages (Deneka et al. 2007).

CD53 Gene Expression and Regulation

Human CD53 is restricted to normal B cells during B-cell development (Barrena et al. 2005b). The promoter of the human *CD53* gene contains two sites that are recognized by Sp1 and PU.1 transcription factors. These sites are essential for its expression in different cell types, but play different roles, in some are activators and in other repressors (Hernandez-Torres et al. 2001). Other transcription factors regulating CD53 expression are the B-cell factor (EBF-1), which is required for B-cell differentiation (Mansson et al. 2007); and 1,25-Dihydroxyvitamin D3 (1,25-(OH)2 D3), which by its receptor, modulates the expression of CD53 and induces monocytic differentiation of HL-60 leukemic cell (Brackman et al. 1995).

CD53 Protein Level Regulation and Pathology

Neutrophil activation with ▶ TNF-α, PDGF, N-formyl-methionyl-leucyl-phenylalanine, or phorbol esters downregulated surface expression of CD53; which involves a proteolytic mechanism triggered by PKC and leads to a complete loss of surface antigen, but the effect is transitory lasting a few hours (Mollinedo et al. 1998). CD53 surface expression was also downregulated in leukocytes from patients with myelodysplastic syndromes (MDSs), and correlates with the activation status of these cells (Kyriakou et al. 2001).

In humans, the only phenotype reported associated to CD53 loss corresponds to a family with three affected members in which CD53 is not detected in B cells, T cells, or neutrophils, and present a syndrome characterized by recurrent bacterial and viral infections of heterogeneous origin, which resembles a leukocyte adhesion defect (Mollinedo et al. 1997).

CD53, along with CD81, CD63, SAS, and CD82, were expressed at high levels in over 90% of tested Burkitt lymphoma (BL) cell lines. There are no major differences in tetraspanin expression pattern among sporadic or endemic tumors, type of translocation, or Epstein-Barr virus status, suggesting that the cell of origin for these tumors is the same (Ferrer et al. 1998). Neutrophils aging in vitro resulted in a significant increase of CD53 and CD63 expression (Beinert et al. 2000).

In human B-cell malignancies CD53 is expressed at very high levels in malignancies that are well differentiated, like multiple myeloma, while its expression is much lower in less differentiated malignancies, such as diffuse large B-cell lymphomas or follicular lymphomas (Barrena et al. 2005b). The expression of CD53 in combination with CD81 can be used to discriminate two different tumors in a single patient. Combined expression of CD53 and CD81 distinguishes B-chronic lymphocytic leukemia (B-CLL) from splenic marginal zone B-cell lymphoma (SMZL) in the same patient (Barrena et al. 2005a).

Summary

CD53 is one of the least characterized members of the tetraspanin family. CD53 is integrated in the tetraspanin web, and sends intracellular signals, directly or indirectly via PKC, AKT, and γ-glutamyl transpeptidase (GGT). Its expression can affect cell survival, resistance to apoptosis, and radiation sensitivity. In B-cell development CD53 is a marker of mature B cells. In human B-cell malignancies, the pattern of tetraspanin expression identifies the developmental stage of the corresponding tumors. The pattern of tetraspanins can be used to differentiate B-cell malignancies in an individual patient with several lymphoid tumors.

CD72, a Historical Background

B lymphocytes express several surface molecules other than the B cell receptors (BCR) that function as markers of differentiation as well as molecules that can fine-tune BCR signaling. Current research has identified a function for most antigens that were previously classified as markers of lymphocyte differentiation. ▶ CD72 is one such molecule that was originally discovered as a marker of B cell differentiation using conventional serological and classical genetic techniques. Subsequently generation of monoclonal antibodies helped its definition as a molecule that can affect B cell growth and differentiation on its own or in the context of BCR signaling. Initially Sato and Boyse described an activity in sera from C3H.I mice immunized with 1.29 ascites tumor cells that reacted only with a subset of spleen cells after it was absorbed to remove an unknown reactivity and subsequently the cell type in the spleen was identified as the B cell (Sato and Boyse 1976). Early studies identified ▶ CD72 as an antigen expressed on early pre-B and mature B cells but not on plasma cells. This serum was designated as anti-Lyb2 and the antigen identified by the antiserum was given the name Lyb 2.1. Genetic studies demonstrated that Lyb2 was specified by a gene on chromosome 4 that was closely linked to the *Ly-19* and *Ly-32* loci. Later biochemical studies established that antibodies to Lyb2, Ly19, and Ly32 were all recognizing the same molecule (Wu and Bondada 2002). The Lyb 2.1 allele was expressed in a subset of mouse strains such as C57Br, C58J, C58L, CBA/J, and DBA/2 mice as defined by reactivity with this antiserum and the allele in BL/6 mice as Lyb 2.2 (Sato and Boyse 1976). Two monoclonal antibodies, 9-6-1 and 10.1.D2 were generated by Yakura et al. and Subbarao et al., respectively, which allowed an analysis of functional properties of Lyb 2 and recognition that it was not simply a differentiation marker but affected B cell function (Wu and Bondada 2002). These and other monoclonal antibodies demonstrated that there are four alleles for the *Lyb2* locus in the mouse (Wu and Bondada 2002). After molecular cloning of the gene for Lyb2 and the characterization of the human analogue, the name Lyb2 was changed to ▶ CD72 to be consistent with the nomenclature for other cluster differentiation antigens (Nakayama et al. 1989). The human analogue was subsequently identified both by molecular cloning and by isolation of monoclonal antibodies. Two recent reviews have summarized the function of murine and human ▶ CD72 molecules and their ligands (Mizui et al. 2009; Wu and Bondada 2009). Despite its original discovery as a B cell-specific molecule, new functions for this molecule are being discovered such as in NK cells and mast cells (Kataoka et al. 2010; Alcón et al. 2009). This entry will review the molecular nature and function of the ▶ CD72 molecule in the context of B lymphocyte activation and differentiation.

► CD72 is a 45 kDa type II glycoprotein of 359 amino acids in human (354 in mouse) that exists as a dimer on the cell surface (trimers have also been identified) (Wu and Bondada 2009; Robinson et al. 1993). The oligomerization may involve the alpha-helical coiled-coil stalk region in the extracellular domain which is known to facilitate receptor oligomerization. The presence of 11 cysteines in the extracellular domain and two each in the transmembrane and cytoplasmic domain may also have a role in the formation of ► CD72 oligomers. Remarkably all the cysteines except the residue at position 178 are highly conserved among all the mammalian ► CD72 proteins (human, chimpanzee, mouse rat, dog, porcine, and bovine). The cysteines thought to form the intramolecular disulfide bridge are also conserved between the mammalian and the avian forms of ► CD72. There is a single N-linked glycosylation site at position 136 in the mouse sequence, which is also conserved in the mammalian isoforms. The C-terminal domain has a c-type lectin-like structure similar to CD23 and the asialoglycoprotein found on natural killer cells, but the nature of the carbohydrate moiety recognized by ► CD72 has not been defined (Nakayama et al. 1989). Similar lectin-like domain is found in ► CD72 molecules from human, mouse, rat, chimpanzee, dog, and chicken. Surprisingly, sequence homology analysis predicts that the c-type lectin domain in the bovine isoform of ► CD72 shows less homology to other species and may be truncated (http://www.ncbi.nlm.nih.gov/sites/homologene/1350). The alleles of ► CD72 found in mouse strains are considered complex alleles as they exhibit multiple differences in amino acid sequence which are more often found in the extracellular domain (Wu and Bondada 2002). Alternate splicing may be involved in the ► CD72 polymorphisms in the mouse. The intracellular domain of ► CD72 exhibits greater conservation among different mouse strains and across the species. The cytoplasmic domain has three tyrosines that are potential phosphorylation sites and their role in ► CD72 signaling will be discussed further in the later sections.

Early studies showed that antibodies to ► CD72 inhibited T-dependent antibody responses to the particulate antigen, sheep erythrocytes (SRBC) suggesting that ► CD72 may be involved in cell-cell interactions or as a receptor for cytokines (Yakura et al. 1982). Accordingly it was demonstrated that biotinylated membrane CD5 isolated from T cells bound to ► CD72 expressing cell lines leading to the proposal that CD5 and ► CD72 might form a ligand receptor pair (Wu and Bondada 2002). However, subsequent studies with fusion proteins of CD5 and the Fc region of human Ig failed to detect binding of such proteins to ► CD72 expressing cells suggesting that ► CD72 ligand may be distinct from CD5 (Bikah et al. 1998). In 2000 Kumanogoh et al. provided unequivocal evidence that ► CD72 binds to CD100, a member of semaphorin family of molecules (Sema 4D) that is expressed frequently in the nervous system but also in the immune system (Kumanogoh and Kikutani 2004). This finding and the generation of ► CD72 knockout mice (Pan et al. 1999) have helped advance the understanding of the physiological role of ► CD72.

Functional Role of CD72

► CD72 ligation induces blast transformation and proliferation of purified murine B cells which was initially interpreted to suggest that ► CD72 provides a positive signal to B cells (Subbarao and Mosier 1983). Anti-► CD72 antibodies inhibited T-dependent antibody response to SRBC, which required the antibodies to be present at early stages of B cell activation with the SRBC (Yakura et al. 1982). One interpretation of these studies was that anti-► CD72 enhances polyclonal B cell expansion at the expense of antigen-specific B cells reducing the antibody response to SRBC. Accordingly anti-► CD72 was shown to enhance polyclonal B cell activation induced by T-helper cell lines. Subsequently, several studies have shown that ► CD72 ligation synergizes with B cell receptor (BCR) signaling, which would have predicted an expansion of antigen-specific B cells (Wu et al. 2001; Wu and Bondada 2002). In the light of the discovery that ► CD72 can be present on dendritic cells (DC) also and that T cell CD100 binds ► CD72, the effects of anti-► CD72 on SRBC response may be more complex, since the early studies did not test for the presence of DCs in the purified cell populations (Yakura et al. 1982; Kumanogoh and Kikutani 2004; Kikutani and Kumanogoh 2003). Hence the ability of anti-► CD72 antibodies to modulate antibody responses to T-independent antigens, in particular TNP-Ficoll (which is a well-established activator of B cells without T cell help) was tested. Consistent with the findings

on synergy between anti-▶ CD72 and anti-BCR antibodies, ▶ CD72 ligation enhanced antigen-specific responses to TNP-Ficoll (Wu 2002). These later studies showed for the first time that ▶ CD72 may also affect B cell differentiation into antibody secreting cells.

Despite the extensive data showing positive effects of ▶ CD72 ligation in B cells, three observations suggested that ▶ CD72 may actually be a negative regulator of B cells. Thus Wu et al. showed that in a cell line model ▶ CD72 may have a role in B cell apoptosis (Wu et al. 1998). The B cells from ▶ CD72-deficient mice exhibited a small increase in B cell proliferation in response to BCR ligation (Pan et al. 1999). The crucial finding that ▶ CD72 associated with an SH2 domain containing protein tyrosine phosphatase, SHP-1 lent strong support to the concept that ▶ CD72 may be a negative regulator of B cells, which will be discussed further in the section on ▶ CD72-mediated signaling (Wu and Bondada 2002, 2009). Despite this ▶ CD72-deficient mice remain relatively healthy although a few aged ▶ CD72-deficient mice develop autoantibodies (Li et al. 2008). Analysis of mice transgenic for hen egg white lysozyme bred to ▶ CD72 knockout mice suggested that ▶ CD72 may have a role in the antigen-induced B cell anergy. Interestingly CD100 (Semaphorin 4D)-deficient mice exhibited an expansion of marginal zone B cells and development of a variety of autoantibodies such as anti-ssDNA, anti-dsDNA, rheumatoid factors, and anti-ribonucleoprotein (Kumanogoh et al. 2005). Somewhat unexpectedly, mice doubly deficient for CD100 and ▶ CD72 did not develop autoimmune disease suggesting that CD100 may be having effects on non-B cells.

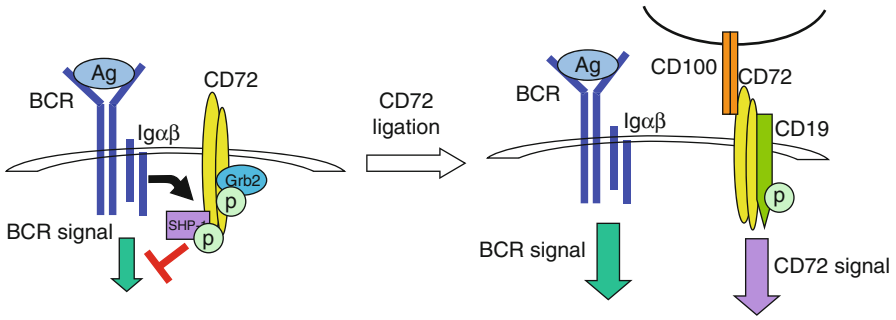
CD72, Table 1 Summary of observations supporting the concept that CD72 ligation can trigger BCR-independent positive signals as well as positively regulate BCR-mediated signals

▶ *CD72 ligation*
–Induced ERK activation in BCR-deficient A20 cell line
–Activated JNK in SHP-1-deficient splenic B cells
–Rescued BCR ligation-induced apoptosis in immature and Xid B cells
–Induced differential signals when compared to BCR ligation
–▶ CD72 induced while BCR reduced Blimp-1 expression
–▶ CD72 activated ERK, JNK, Lyn, Blk, Btk but not Syk while BCR can activate all these kinases
B cell development in ▶ CD72-deficient mice
–Reduced numbers of mature B cells in the bone marrow, spleen, lymph nodes, and Peyer's patches
–Reduced numbers of follicular B cells in the spleen
BCR ligation in CD72-deficient BAL-17 cell line
–Less BCR-induced $Ca2^+$ influx
–Impaired BCR-mediated phosphorylation of CD19, Btk, Vav, and PLCγ2 and association of CD19 with PI-3 kinase
–Reduced ERK, JNK, and p38 MAPK activation

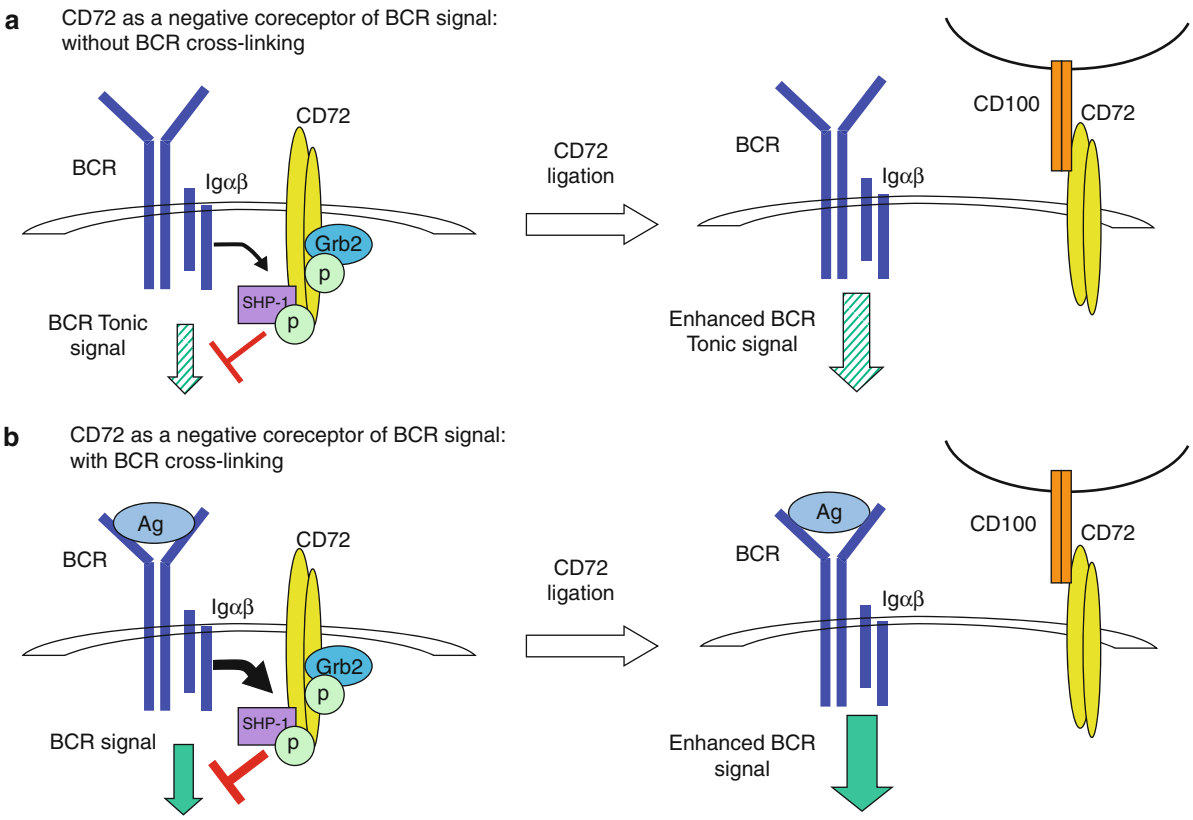
Reproduced from Wu and Bondada (2009)

Signaling Mechanisms Important for the Functional Effects of ▶ CD72 in B Cells

Earlier studies indicated that ▶ CD72 ligation mediated positive signaling events in B cells (Wu and Bondada 2009) (Table 1). However, many later studies focused on ▶ CD72 as a negative regulator of B cell receptor (BCR) signaling pathway (Kumanogoh and Kikutani 2004; Pan et al. 1999; Wu et al. 1998; Adachi et al. 2000) (Table 1). A dual signaling model was proposed to explain both positive and negative roles of ▶ CD72 in B cells based on the published data as summarized below (Fig. 1). The cytoplasmic domain of ▶ CD72 contains two immunoreceptor tyrosine-based inhibitory motifs (ITIM). When antigen encounters BCR, the signals triggered through BCR induce recruitment of ▶ CD72 to the kinase-rich BCR complex which leads to the phosphorylation of ▶ CD72 and recruitment of SHP-1 and Grb2 to ▶ CD72 (Wu et al. 1998; Kumanogoh et al. 2005). The ▶ CD72-associated SHP-1, a tyrosine phosphatase, can dephosphorylate protein tyrosine kinases and negatively regulate BCR signal. Hence, ▶ CD72 is a negative regulator of B cells. In this regard, the positive signals observed after ▶ CD72 ligation are due to ligation-triggered ▶ CD72 dephosphorylation that causes the dissociation of ▶ CD72 and SHP-1 which in turn leads to enhanced tonic BCR signaling (Fig. 2a) (Wu and Bondada 2009; Wu et al. 1998; Adachi et al. 2000). However, BCR-induced CD72 phosphorylation is mostly observed in immature but not mature B cells suggesting that ▶ CD72 may have stronger negative effects on BCR signals in immature cell types but not so much in mature B cells or B cell lines (Fig. 2a). Indeed, in contrast to immature B cells, ▶ CD72 was shown to regulate positive signals in mature B cells. Thus, a reduced BCR ligation induced Ca^{2+}, ERK, and JNK activation was observed in



CD72, Fig. 1 *Dual signaling model of CD72*. Overview of BCR and B-cell coreceptor signaling. CD19 complex enhances while CD22 decreases BCR signals. CD19 associates with BCR transiently upon BCR ligation. ▶ CD72 may increase or decrease BCR signals depending on its association with the CD19 complex. The figure shows only the CD19 molecule to be associated with ▶ CD72 but currently there is no data about its association with CD21 and CD81 partners of the CD19 complex (Reproduced from Wu and Bondada 2009)



CD72, Fig. 2 *Two models for CD72-mediated signals*. ▶ CD72 as a negative coreceptor of BCR signaling. (**a**) Without antigen stimulation, tonic BCR signals can trigger a low level of ▶ CD72 phosphorylation which can recruit SHP-1 and Grb2 that in turn negatively regulate tonic signals derived from BCR. Ligation of ▶ CD72 removes ▶ CD72 away from the kinase-rich BCR signaling complex resulting in dephosphorylation of ▶ CD72. This relieves the negative effect of ▶ CD72 from BCR tonic signals. Therefore, the positive signal seen in ▶ CD72 ligation is simply an enhanced BCR tonic signal. (**b**) Same as A, except that BCR ligation triggers a stronger ▶ CD72 phosphorylation, and presumably, creates a stronger negative effect of ▶ CD72 on BCR signals. ▶ CD72 ligation generates an enhanced BCR signal. (c) Dual signaling model of ▶ CD72. In addition to being a negative coreceptor of BCR-mediated signals (same as panels **a** and **b**), ligation of ▶ CD72 can also trigger positive signals through its association with CD19 (Reproduced from Wu and Bondada 2009)

a ▶ CD72$^{-/-}$ mature B cell line, BAL cells. Importantly, these effects can be mostly reversed by reexpression of ▶ CD72 (Ogimoto et al. 2004). This result suggested that ▶ CD72 can function as a positive regulator of B cells. In addition, just as in the normal B cells, ▶ CD72 ligation induced similar levels of ERK activation in a mature B cell line, A20, and in BCR-deficient A20 cells (Wu 2002). Moreover, the JNK activation of B cells from SHP-1 deficient, viable moth-eaten mice was strongly enhanced by ▶ CD72 ligation. These results suggest that ▶ CD72 can signal on its own in the absence of BCR or SHP-1. Thus, ▶ CD72 ligation can also transmit BCR-independent positive signals. ▶ CD72 might transmit positive signals through its association with CD19, a B cell coreceptor, or Grb2, an adaptor protein required for activation of the Ras/▶ MEK/ERK pathway (Fusaki et al. 2000). Thus, ▶ CD72 ligation not only can trigger BCR-independent positive signals but also can positively regulate BCR-mediated signals. Therefore, it was hypothesized that ▶ CD72 can positively or negatively regulate BCR signaling. The dual role of ▶ CD72 explains why both positive effect of ▶ CD72/CD100 interaction, such as its roles in mature B cell signaling events and B cell development, and negative effect of ▶ CD72/CD100 interaction such as its roles in autoimmune diseases have been both observed in the past studies (Mizui et al. 2009; Pan et al. 1999; Li et al. 2008; Rojas et al. 2003; Besliu et al. 2011). Therefore, the contribution of ▶ CD72 signaling to the outcome of B cell fate is likely to depend on a combination of multiple factors such as the developmental stage of B cells, the strength of BCR signals, and the accessibility and concentration of CD100, the ▶ CD72 ligand, during the interaction of B cells and their milieu.

CD72 Signaling in Other Immune Cell Types

In addition to B cells, ▶ CD72 was also found to be expressed on mast cells and NK cells in recent reports (Kataoka et al. 2010; Alcón et al. 2009). In contrast to the resting B cells, there appears to be a constitutive phosphorylation of ▶ CD72 and association of ▶ CD72 with SHP-1 in resting human mast cells (Kataoka et al. 2010; Wu et al. 1998). Therefore, ▶ CD72 may help maintain the steady state of the mast cells. Simultaneous activation of ▶ CD72 and KIT further enhanced the phosphorylation of ▶ CD72 and the recruitment of SHP-1 to ▶ CD72. Subsequently, the ▶ CD72-SHP-1 complex can reduce the KIT-dependent mast cell activity: growth of mast cells, stem cell factor-induced mast cell chemotaxis, chemokine ligand 2 production, and the IgE-dependent degranulation.

Unlike B cells, not all NK cell express ▶ CD72 on their surface. Activation of NK cells by IL-2 can further increase the ▶ CD72 expression on NK cells. Upon stimulation with IL-12 and IL-18, NK cells that expressed ▶ CD72 produced significantly less IFN-γ than those expressing none or low levels of ▶ CD72 (Alcón et al. 2009). Ectopic expression of ▶ CD72 in the ▶ CD72-deficient murine NK-cell line, KY2 cells, inhibits cytokine-induced ▶ IFN-γ production in NK cells. Both ITIM motifs are required for inhibition of IFN-γ secretion by ▶ CD72. Interestingly, although the extracellular domain of ▶ CD72 was also shown to be required for inhibitory effect of ▶ CD72, ligation of ▶ CD72 on NK cells with anti-▶ CD72 had no effect on ▶ IFN-γ production by NK cells. Thus, it still remains to be determined whether binding of ▶ CD72 to its natural ligand could have any impact on the function of NK cells.

Functional Effects and Disease Associations of Human ▶ CD72

The positive and negative regulatory effects of ▶ CD72 signaling in BCR-dependent and independent activation suggest a potential role for ▶ CD72 in autoimmunity and cancer. The developmental stage of B cells where ▶ CD72 exhibits differential effects upon CD100 interaction in the context of BCR signaling could influence the outcome of B cell responses in health and disease. Differential regulation of ▶ CD72 and BCR-induced response to protein kinase A and ▶ IFN-γ-mediated signaling events suggest potential alternative ▶ CD72-mediated regulatory pathways to overcome signals that downregulate BCR-induced proliferation and differentiation signals (Wu and Bondada 2002, 2009; Wu 2002). Defective ▶ CD72 signaling events are likely to influence the B cell selection, expansion, and immune response thus contributing to autoreactive B cells in the bone marrow and/or abnormal expansion in response to antigenic and microenvironmental stimuli in the periphery.

Polymorphisms in the negative regulatory receptor FcRγIIb (Ile232thr) are associated with systemic lupus erythematosus (SLE) in humans. Because both FcRγIIb and ▶ CD72 contain ITIM motifs, Hitomi and colleagues investigated the human ▶ CD72 polymorphisms for a possible association with SLE (Hitomi et al. 2004). Although no association with susceptibility to SLE was identified, the ▶ CD72 *1 allele, which contains a single 13-bp repeat in intron 8, was significantly associated with nephritis in Japanese patients. An alternatively spliced ▶ CD72 transcript that replaced 42 amino acids of the extracellular domain with 49 amino acids caused by skipping of exon 8 and inclusion of exon 9 was noticed in these patients. The ratio of alternatively spliced/common isoforms was found to be increased in individuals with *2/*2 genotype, which contains two 13-bp repeats in intron 8, when compared with *1/*1 or *1/*2 genotypes. Interestingly, significant association of the inhibitory FcRγIIb receptor 232thr/thr genotype with SLE was observed only within the ▶ CD72 *1/*1 genotype. Thus ▶ CD72 *2 allele may decrease risk for human SLE conferred by FCGR2B 232thr/thr, possibly by increasing the alternative isoform of ▶ CD72 (Hitomi et al. 2004).

Abnormalities in CD100 or ▶ CD72 counter receptors involved in T and B cell interaction were associated with autoimmunity. This was exemplified by the report from Besliu et al. (2011) who showed increases in $CD100^{+}$ T cells in the PBMCs from patients with systemic sclerosis (SSc), a connective tissue disease characterized by immune abnormalities, chronic inflammation, and fibrosis of skin and internal organs with microvascular damage and thrombosis. Both in human and mice CD100 has been shown to influence T cell activation, ▶ CD40 ligand-induced B cell aggregation, and survival (Kumanogoh and Kikutani 2004; Kikutani and Kumanogoh 2003). Triggering CD100 with mAb has shown to result in costimulation of T cells in response to CD3 or CD2. Association of CD100 with CD45 results in increased T cell homotypic adhesion induced by a CD45 mAb and interaction of CD100 cytoplasmic domain with a serine-threonine kinase activity in T and NK cells suggest a potential role of ▶ CD72/CD100 signaling in activation of T cells and NK cells (Kumanogoh and Kikutani 2004; Kikutani and Kumanogoh 2003). Association of CD100 with tyrosine phosphatase activities in B lymphocytes, its promotion of homotypic adhesion as well as increase in survival of B cells provide evidence for the functional role for CD100/▶ CD72 in B cell function (Kumanogoh and Kikutani 2004; Kikutani and Kumanogoh 2003). Aberrations in the expression and/or function of either of these molecules are likely to result in deregulation of the B and T cell homeostasis leading to autoimmune functions (Kumanogoh et al. 2005). A role for ▶ CD72 in CD100-mediated T cell costimulation remains to be explored further.

Aberrant ▶ CD72/CD100 interaction in mature B cell signaling events could potentially contribute to hitherto unidentified lympho-proliferative disorders. Deaglio et al. have described a potential role for CD100/▶ CD72 network in chronic lymphocytic leukemia (CLL) (Deaglio et al. 2005). ▶ CD38/CD31 interaction triggers relocalization of BCR/CD19 to the ▶ CD38/CD31 contact areas, increased cell survival and proliferation of CLL B cells. This is associated with upregulation of CD100, mainly in proliferating cells, and a concomitant decrease in ▶ CD72, low-affinity CD100 ligand (Deaglio et al. 2005). Nurse-like cells from B-CLL patients express CD31 and plexin-B1, a high-affinity ligand for CD100, which deliver growth and survival signals to ▶ CD38+/CD100+ B-CLL as well as downregulation of ▶ CD72 (Deaglio et al. 2005). Simultaneous cross-linking of ▶ CD72 has been shown to inhibit BCR-mediated apoptosis in Burkitt's lymphoma cells, but enhanced CD20-mediated apoptosis suggesting receptor-dependent positive and negative regulatory roles for ▶ CD72 in leukemia and lymphoma (Mimori et al. 2003). Consistent with a role for ▶ CD72 in B cell malignancies, CLL and mantle cell lymphoma (MCL) cells have been shown to proliferate in response to ▶ CD72 activation exhibiting ▶ CD40-like costimulatory effects. CD5 and/or ▶ CD72 engagement also has been shown to deliver critical costimulatory signals in B-1a, B-2, and B cells from patients with chronic lymphocytic leukemia, but with different requirements and patterns (Planken et al. 1998). Interestingly ▶ CD72 is reported to be present at high levels in B-lineage acute lymphoblastic leukemias (ALL) and has also been shown to serve as an effective target for therapy with anti-▶ CD72 immunotoxin for refractory ALL in vitro and in vivo animal models (Myers and Uckun 1995). High levels of expression of ▶ CD72 in a wide range of B cell malignancies including precursor B-cell

lymphomas, Burkitt's lymphomas, germinal center lymphomas, chronic lymphocytic leukemias, and hairy cell leukemia (Schwarting et al. 1992) warrants further exploration and development of ▶ CD72 and CD100 targeted therapeutic agents.

Summary

▶ CD72 is a B cell surface molecule with ability to modulate B cell receptor-derived signals. CD100, a member of semaphorin family, is the physiological ligand for ▶ CD72. ▶ CD72 is type II transmembrane protein with two immunoreceptor inhibitory motifs in the cytoplasmic domain. ▶ CD72 has been shown to associate with SHP-1 and Grb2 which play a role in its positive and negative regulatory effects. In lupus patients certain polymorphisms in the FcγRIIb are associated with polymorphisms in ▶ CD72. ▶ CD72 is also expressed in a variety of B cell malignancies and could be a therapeutic target. Recent studies suggest that mast cells and natural killer cells also express ▶ CD72 where it may negatively regulate their ability to degranulate and secrete γ-interferon respectively.

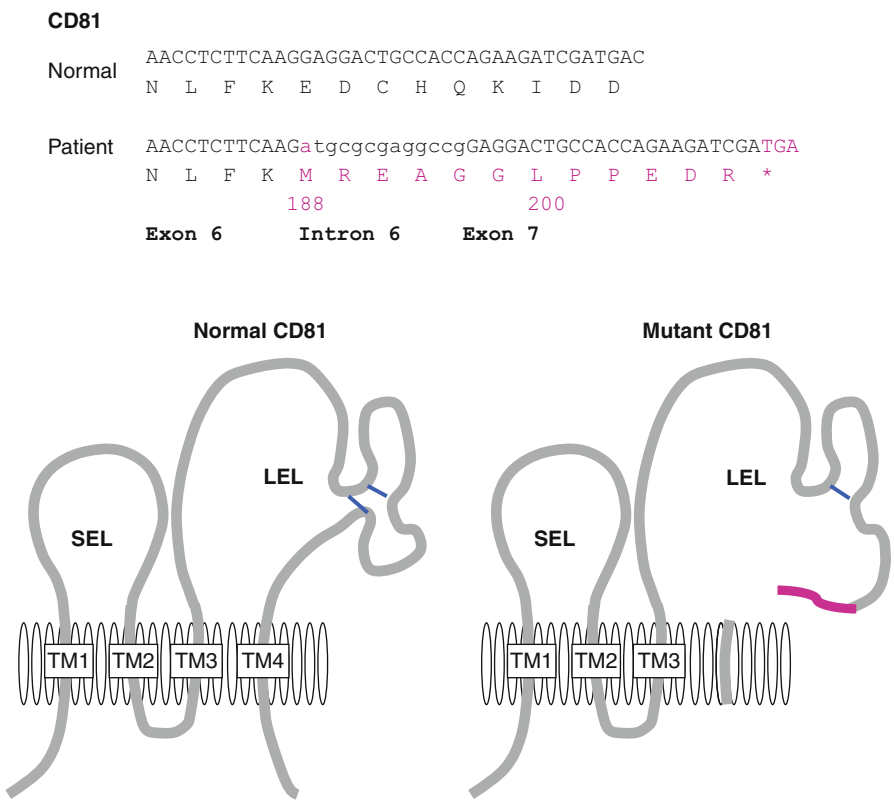
Historical Background

CD81 was originally identified as a Target of an Anti-Proliferative Antibody (TAPA-1) in a study that also defined a new family of transmembrane proteins, later named tetraspanins (Oren et al. 1990). CD81 is expressed on most human cell types; however, Oren et al. have shown that the sensitivity of diverse cell lineages to the anti-proliferative effect of the anti-CD81 antibody differed (Oren et al. 1990). Therefore, subsequent immune-co-precipitation studies were performed to reveal that CD81 associates with different partner proteins in the various cells types. For example, in B cells CD81 associates with CD19, a B cell specific signaling molecule. Similar studies on additional family members confirmed that tetraspanins tend to associate in the membrane with each other and with additional partner proteins. These tetraspanin-enriched microdomains (TEMs) are dynamic membrane entities, which act as signaling platforms (reviewed in (Levy and Shoham 2005)). Indeed, CD81 functions as an organizer and a facilitator of signaling for its associated partners, it is also required for cell fusion and cell–cell interactions, functions that have been subverted by human pathogens.

The discovery that CD81 is a receptor for the hepatitis C virus (HCV) was made more than a decade ago (Pileri et al. 1998), it demonstrated that the viral envelope protein E2 binds CD81. Multiple subsequent studies confirmed the key role of CD81 in the life cycle of HCV (reviewed in (Dubuisson et al. 2008)). Remarkably, HCV is the only known natural ligand for human CD81.

Subsequent studies have shown that CD81 is also required for the life cycle of another major human pathogen, *Plasmodium,* the malaria-causing pathogen. A study by Silvie et al. has shown that $Cd81^{-/-}$ mice cannot be infected by *P. yoelii* sporozoites, the first stage of the parasite's life cycle (Silvie et al. 2003). Follow-up studies demonstrated that anti-human CD81 mAbs blocked the infection of hepatocytes by *P. falciparum* sporozoites, the human malarial pathogen (Silvie et al. 2003). The mechanism by which CD81 enables the productive invasion of sporozoites into liver cells and their subsequent development into merozoites is not known; however, CD81 is not a receptor for this pathogen, as it does not bind the sporozoites directly.

Additional studies have suggested that CD81 has a role in the life cycle of HIV, especially it has been found to co-localize with this viral proteins in TEMs. For example, CD81 and additional tetraspanins have been shown to associate with the viral Gag and Env proteins and to modulate the release of HIV particles from a chronically infected T cell line. Interestingly, anti-CD81 mAb reduced HIV release and infectivity, whereas silencing of CD81 reduced viral release but increased infectivity (Grigorov et al. 2009).



CD81, Fig. 1 A common variable immunodeficiency disorder (CVID) diagnosed in a human patient with a homozygous splice site mutation in CD81. *Upper panel*: location of a homozygous splice site CD81 mutation in the recently diagnosed CVID patient. The G → A mutation, frameshift, and stop codon are shown (*magenta*). *Lower panel*: Normal CD81 contains two disulfide bonds in the large extracellular loop (LEL) (*blue lines*), whereas the mutant CD81 protein does not form the second disulfide bond in LEL. It contains a frameshift peptide (*magenta*) and is not anchored in the membrane by TM4

CD81 also plays a role in fusion of egg with sperm – *Cd81*$^{-/-}$ female mice are infertile (Rubinstein et al. 2006). Interestingly, this defect became evident only after several backcrosses of the original outbred knockout mice onto inbred mice strains, because of this impairment *Cd81*$^{-/-}$ mice need to be bred as heterozygotes.

CD81 also plays a role in cell surface expression of its associated partner proteins. The best-studied example is in B cells, where CD81 is required for normal expression levels of CD19, an important B cell signaling molecule. In human, an immunodeficient girl was recently diagnosed. Further characterization has shown that her B cells lacked CD19 surface expression; however, no mutations were detected in her CD19 locus. Because CD19 was shown to associate with CD81 subsequent studies focused on CD81, which was also absent in the patient. The deficiency was due to a homozygous splice site mutation downstream of exon 6 in the CD81 gene (van Zelm et al. 2010), as illustrated in Fig. 1. By contrast, surface expression of CD19 is not completely abolished (just reduced) in three independently derived lines of *Cd81*$^{-/-}$ mice.

Structure

CD81 is embedded in the plasma membrane by four transmembrane domains that flank short amino and carboxyl cytoplasmic termini and a small and large extracellular loop, SEL and LEL, respectively (Seigneuret 2006). This overall structure is shared by tetraspanins, a large evolutionarily conserved family of proteins (Garcia-Espana et al. 2008). In addition to a similar overall topology, tetraspanins share certain conserved amino acid motifs that distinguish them from other four transmembrane domain molecules. To date, human CD81 is the only tetraspanin molecule whose three-dimensional (3D) structure of the LEL domain has been determined (Kitadokoro et al. 2001). CD81-LEL is composed of a stalk of two longer α-helices and a novel mushroom-like head structure folded with the help of two disulfide bridges. Seigneuret (2006) proposed a structural model, based on the LEL 3D structure and on additional molecular modeling, as shown in Fig. 2.

Unlike most other tetraspanins, CD81 is not glycosylated. The molecule contains six juxtamembrane cysteines, which have been shown to be palmitoylated,

a modification that is common to tetraspanins. No other modifications have been reported for CD81.

The short cytoplasmic domains of CD81 do not contain known signaling motifs.

CD81-Associated Membrane Partner Proteins

CD81 associates with partner proteins, the latter differ in various cell types. A large number of studies have documented these interactions; few examples highlighting the functional consequences of such interactions are detailed below.

CD19

Early biochemical studies aimed at understanding the preferential sensitivity of B cell lines to engagement by an anti-CD81 mAb revealed an association with CD19, a signaling molecule belonging to the immunoglobulin (Ig) superfamily. Subsequently, B cells derived from three independently derived lines of $Cd81^{-/-}$ mice showed reduced CD19 expression. Interestingly, complete lack of CD81 in mice results in a milder effect on CD19 expression than that seen in a human patient diagnosed with a homozygous exon splice mutation in CD81 (Fig. 1), which resulted in complete lack of surface CD19. It is noteworthy that although redundancy in tetraspanins' function has been suggested frequently, CD19 expression is dependent exclusively on CD81 and not on other tetraspanins. Indeed, re-introduction of CD81 into human or mouse B cells that lack CD81 restores CD19 expression (van Zelm et al. 2010). The absence of normal CD81 expression, both in human and in mouse, results in aberrant glycosylation of CD19. Thus, the absence of CD81 results in impaired trafficking of CD19, as evident by high mannose glycans that are sensitive to digestion by endoglycosidase-H, indicating residence in the endoplasmic reticulum (ER) without further exit through the Golgi to the cell surface.

CD4

In T cells CD81 was shown to be associated with CD4, a T cell specific molecule expressed on T helper cells. The cytoplasmic region of CD4 was sufficient for the association with CD81. Interestingly, these molecules associated with each other after removal of the Lck-binding site from the cytoplasmic domain of CD4, and the binding of Lck to CD4 inhibited the association with CD81. These findings led the authors' suggestion that CD4 exist in two states, one associated with Lck, the other with tetraspanins (Imai et al. 1995).

EWI-2

Another Ig family member that associates with CD81 is EWI-2, an association that is maintained in harsh lysis conditions. This cellular partner of CD81 has been shown to modulate susceptibility to HCV infection. Hepatocytes express the complete EWI-2 and are susceptible to viral infection. However, EWI-2 exists in a form that lacks an Ig domain "without its N-terminus (EWI-2wint)" in some cell types. Cells that express EWI-2wint are not susceptible to HCV infection. For example, EWI-2wint, which is expressed in lymphocytes, blocks HCV entry by inhibiting the interaction of the viral envelope proteins with CD81 (Rocha-Perugini et al. 2008).

Integrins

Biochemical studies have repeatedly shown that tetraspanins tend to associate with specific integrins in various cell types. This specificity of interaction was

demonstrated in cells where only one specific integrin associated with an individual tetraspanin molecule, although the cell contained several integrin molecules. A study that analyzed the functional consequence of the association of CD81 with α4β1 integrin in B cells has shown that CD81 facilitated integrin-dependent adhesion strengthening (Feigelson et al. 2003).

G-Protein-Coupled Receptors (GPCR)

A search for CD81-associated proteins in a teratocarcinoma cell line identified GPR56, an orphan G-protein-coupled receptor. The association with CD81 was also seen in transfected cells where an additional tetraspanin molecule, CD9, was associated with GPR56 (Little et al. 2004). Further studies demonstrated that CD81 was required for the association of GPR56 with $G\alpha_{q/11}$ and that engagement of CD81 by an antibody led to the dissociation of the G-protein from the GPCR (Little et al. 2004).

Role of CD81 in Cell Signaling

The presence or absence of CD81 can greatly affect downstream signaling events in a cell-of-origin-dependent manner. For example, while B cell signaling is impaired in the CVID patient shown in Fig. 1, her T cells responded normally to mitogens as measured by proliferation and interferon γ (IFNγ) production. Correspondingly, responses to CD81 engagement are highly dependent on the cell type. The examples below summarize studies that have delineated signaling pathways triggered in response to CD81 engagement either by antibodies or by the HCV envelope proteins. It is noteworthy that although these signaling cascades differ in the various cell types, they all ultimately provide a connection to the actin cytoskeleton.

B Cells

The engagement of CD81 on human B cells induces tyrosine phosphorylation of a large number of proteins. Analysis of these phosphorylated proteins by mass spectrometry identified ezrin, an actin-binding protein, as the major tyrosine-phosphorylated band (Coffey et al. 2009). Coffey et al. also demonstrated that engagement of CD81 induced the phosphorylation of spleen tyrosine kinase (Syk) and that phosphorylation of Syk was required for the tyrosine phosphorylation of ezrin. Finally, the study demonstrated that the cytoplasmic C-terminal domain of CD81 was required for the induction of activated ezrin. The model emerging from this study is that CD81 interfaces between the cell membrane and the cytoskeleton where its engagement leads to activation of Syk, which in turn activates ezrin, which then recruits filamentous actin (F-actin) to facilitate cytoskeletal organization and cell signaling.

T Cells

CD81 was demonstrated to be a costimulatory molecule both in human and in mouse T cells, namely, the coengagement of CD81 potentiated the stimulation induced in response to engagement of ▶ CD3 on these cells. Interestingly, these studies have also shown that the costimulatory effect induced by engaging CD81 is similar in magnitude to that induced in response to coengagement of CD3 and CD28, the latter being a classical T cell costimulatory molecule. However, while the cytoplasmic domain of CD28 contains tyrosine activation motifs, CD81 lacks such motifs. The detailed mechanism of T cell costimulation by CD81 is yet to be delineated. However, a recent study demonstrated that costimulation of CD3 and CD81 induced phosphorylation of Erk1/2 and activated the actin cytoskeleton (Crotta et al. 2006). An earlier study by the same group has shown that costimulation of T cells by CD81 was mediated by Lck. These and additional studies, which were aimed at understanding the interaction of HCV with human T cells have shown that the costimulatory potential of the envelope protein E2 of HCV (HCV-E2) was comparable to that of the anti-CD81 mAbs.

Hepatocytes

The hepatocyte cell line, Huh-7, which is susceptible to infection by HCV in cell culture (HCVcc) was used in the following study. Engagement of CD81 in this cell line by a mAb or by HCV-E2 induced the phosphorylation of Erk; moreover, an inhibitor of the Raf/Mek/Erk signaling pathway inhibited viral infection (Brazzoli et al. 2008). The same study also demonstrated that CD81 provided a linkage to the actin cytoskeleton. Briefly, engagement of CD81 induced its movement to the zone of cell–cell contact; in addition, treatment by drugs that inhibit F-actin formation blocked the relocation of CD81 to the cell-to-cell contact areas. Further analysis revealed that CD81 mediated the activation of the actin cytoskeleton by increasing the level of the active GTP-bound Rho

family GTPases (Rho-A, Rac1, and Cdc42). Moreover, use of knockdown and of inhibitors of these GTPases reduced viral infectivity (Brazzoli et al. 2008). Thus, HCV subverts key cellular functions of CD81.

Summary

The tetraspanin molecule CD81 is a membrane-embedded protein. It functions as an organizer and a facilitator of signaling for its associated protein partners. CD81 associates with different partners in the various cell types. CD81, its partner proteins, and additional tetraspanins form TEMs, which act as signaling platforms connecting the cell membrane to the actin cytoskeleton. The role of CD81 has been subverted by major human pathogens.

Historical Background

CD91, also known as the low density lipoprotein receptor-related protein 1 (LRP1), is a receptor on the plasma membrane involved in receptor-mediated endocytosis and in various signaling events. CD91 is a member of a gene family found in diverse species, including *C. elegans*, *Drosophila*, *Xenopus*, and mammals (Gaultier et al. 2008). Seven structurally closely related cell surface receptors constitute the core of the low density lipoprotein (LDL) receptor gene family. They include the LDL receptor, the LDL receptor-related protein (CD91), LRP1b, megalin, very low density lipoprotein (VLDL) receptor, apolipoprotein E receptor 2 (apo-ER2), and MEGF7 (multiple epidermal growth factor-like domains containing protein 7) (Herz and Strickland 2001). This review focuses on CD91 and its role as a signaling receptor for several ligands and in various physiological processes.

CD91 was originally identified by virtue of its structural similarity and sequence homology to the LDL receptor (Herz et al. 1988). As expected of a lipoprotein receptor, CD91 was found to play an important role in lipoprotein metabolism and cholesterol homeostasis by the discovery of apolipoprotein E as its ligand. The function of CD91 in vivo as a chylomicron remnant receptor is now well established. The sequencing of the receptor soon revealed that it was identical to the receptor proposed for removal of α_2M-proteinase complexes (Lillis et al. 2008).

Protein Structure

CD91 is synthesized as a 600-kDa type I transmembrane protein which during transit to the cell surface is processed by furin within a β-propeller domain into a large 515-kDa α- and a smaller 85-kDa β-subunit in the *trans*-Golgi network. An ER-resident chaperone, termed the receptor associated protein (RAP), binds tightly to CD91 on multiple sites and prevents premature association of ligands to the newly synthesized CD91 in the ER enabling it to be successfully delivered to the plasma membrane (Lillis et al. 2008).

CD91 is composed of modular structures that include cysteine-rich complement-type repeats, EGF repeats, and β-propeller domains, all on the α-chain, and a transmembrane and cytoplasmic domain on the β-chain. The cysteine-rich complement-type repeats, also commonly referred to as ligand-binding repeats, are localized into regions as clusters and are termed clusters I–IV, each containing variable numbers of complement-type repeats. Most CD91 ligands have been shown to bind to clusters II and IV (Lillis et al. 2008).

The β-chain contains a small extracellular domain, a single-pass transmembrane domain, and an intracellular domain of 100 amino acid residues. After furin cleavage in the ER, the β-chain stays non-covalently connected to the larger α-subunit through its small extracellular domain. The intracellular domain of CD91 contains many potential motifs which are postulated to have a role in basolateral sorting, internalization, recycling of the receptor, and binding of several different adaptor proteins for signal transduction. These motifs on the β-chain include two NPXY motifs, the distal one overlapping with an YXXL internalization motif; two di-leucine internalization motifs; and several serine, threonine, and tyrosine phosphorylation sites. Unlike the other LDL receptors, the YXXL motif rather than the NPXY and di-leucine motifs was shown to be the dominant endocytosis signal in CD91 mini-receptor constructs (Li et al. 2000).

The receptor is expressed in a variety of cell types, including macrophages (Misra et al. 1995), dendritic cells (Basu et al. 2001), T helper cells (Banerjee et al. 2002), adrenal cortical cells, hepatocytes, neurons and neuroblastoma, follicular cells of the ovary, fibroblasts, measengial cells (Zheng et al. 1994), and adipocytes (Corvera et al. 1989).

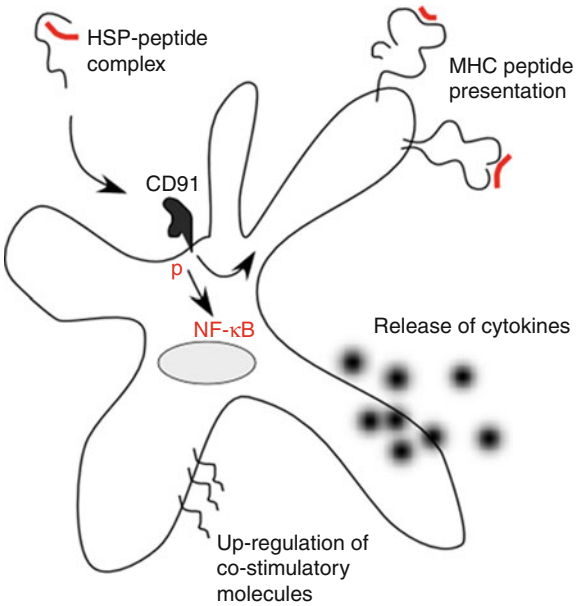
The Role of CD91 in Cell Signaling

A significant number of biological functions have been attributed to CD91 due to its ability to bind to a large number of ligands. Mice deficient in CD91 expression die early during embryonic development demonstrating a critical function for CD91 in prenatal development (Herz and Strickland 2001). Mice engineered to lack expression of CD91 in vascular smooth muscle cells display overexpression of, and abnormal signaling through, the platelet-derived growth factor (PDGF) receptor which causes proliferation of smooth muscle cells, aneurysm formation, and marked susceptibility to cholesterol-induced atherosclerosis (Boucher et al. 2003). Generally the functions of CD91 are mediated

through two major physiological processes; endocytosis and regulation of signaling pathways. During endocytosis, CD91 is capable of binding approximately 30 ligands with high affinity and delivering them to endo-lysosomal compartments. The receptor itself is usually recycled. The details of CD91-mediated endocytosis are outside the scope of this review.

In addition to the numerous ligands that are recognized and bound by the CD91 α-chain in the extracellular space, it is becoming apparent that several cytoplasmic proteins also associate with the CD91 β-chain. CD91 promotes intracellular signaling, which downstream mediates proliferation, migration, maturation and differentiation of different types of cells, including macrophages, dendritic cells, vascular smooth muscle cells, and neurons (Herz and Strickland 2001; Lillis et al. 2008; Pawaria and Binder 2011). Phosphorylation of the CD91 intracellular domain regulates association with adaptor molecules. While phosphotyrosine binding PTB domains were originally thought to recognize phosphorylated tyrosine residues within the NPXY sequence, in an increasing number of cases it has become apparent that phosphorylation of the tyrosine residue in these motifs is not required for binding to PTB domains. Both the proximal NPXY and distal NPXYXXL motifs are capable of interacting with cytoplasmic adaptors and scaffold proteins, like Disabled-1 (DAB-1), FE65, JNK-interacting protein 1 (JIP1), Postsynaptic density protein 95 (PSD-95), Src homology 2 domain containing protein (SHC), Sorting nexin 17 (Snx17), and CED-6/GULP (May et al. 2007). Although most of these proteins have been shown to bind only the distal NPXYXXL motif in the CD91 intracellular domain, FE65 can bind both motifs, and Snx17 is the only interacting protein so far identified to bind exclusively to the proximal NPXY motif. Phosphorylation at the Tyr can be inhibitory also as in case of Snx17 where binding is inhibited after Tyr 4473 phosphorylation (Betts et al. 2008). Recently Guttmen et al. used each NPXY motif microdomain separately in both phosphorylated and unphosphorylated forms and reported a large number of proteins that selectively interact with either the phosphorylated or the unphosphorylated form (Guttman et al. 2009). Very few binding partners were detected for the membrane proximal Tyr 4473 including Shc3 and Grb2. The proximal NPXY 4473 motif has been shown to be involved in receptor recycling and demonstrated a strong phenotype in knock-in mice (Roebroek et al. 2006). The proteins that bound to the Tyr 4507 included signaling molecules like PLC-γ, ▶ PI3K, Shp-2, ▶ Src, CSK, Shc-3, and Grb-2, which get phosphorylated on the tyrosine in response to extracellular signals (Guttman et al. 2009). Other studies have implicated the NPXY4507 motif in CD91 in binding intracellular signaling proteins such as ShcA, Fe65, and Disabled (Dab1) which have a phosphotyrosine binding (PTB) domain (Barnes et al. 2001). The association of CD91 with specific (set of) adaptor molecules is dictated by the binding of different ligands and is essential for the differentiation of CD91 function in cargo transport or in signaling pathways. The diversity of extracellular and intracellular CD91 binding partners highlights its multiple signaling functions in physiological and pathophysiological processes.

1. *The role of CD91 signaling in apoptosis:* CD91 is one of the numerous cell surface receptors that have been shown to engage apoptotic cells and promote phagocytosis (Kinchen and Ravichandran 2007). CD91 was first shown to be a receptor for calreticulin, a Ca^{2+}-binding protein normally found in the endoplasmic reticulum, in 2001 (Basu et al. 2001). Those experiments were performed with soluble calreticulin in the extracellular space. In an extension of those studies, CD91 has been shown to bind calreticulin on the surface of apoptotic cells which in turn directly interacts with phosphatidylserine on the apoptotic cell surface. These interactions are important for clearance of apoptotic cells by signaling an "eat me" signal within phagoctytic cells such as macrophages (Gardai et al. 2006). The nature of the signaling pathway with respect to CD91 and apoptosis is currently unknown.
2. *The role of CD91 signaling in immune cells:* The HSPs, gp96 (▶ Grp94), hsp70, hsp90, and calreticulin are immunogenic. Upon immunization with HSPs, frogs, mice, rats, and humans elicit immune responses to peptides that are chaperoned by the HSP (Binder 2008). Upon examination of the mechanism of action, CD91 was first identified by Binder et al. as the receptor for gp96 (Binder et al. 2000), and then by Basu et al. as a common receptor for other immunogenic HSPs such as hsp70, hsp90, and calreticulin (Basu et al. 2001). Utilizing antigen-presenting cells in the form of dendritic cells or macrophages, CD91 has been demonstrated in



CD91, Fig. 1 Dual effects of HSPs are mediated through CD91. Peptides chaperoned by HSPs are cross-presented on MHC I and II after CD91-dependent endocytosis. HSPs signal through CD91 by phosphorylating CD91 leading to activation of NF-kB. As a result of this signaling pathway, antigen-presenting cells release cytokines and upregulate expression of co-stimulatory molecules

numerous laboratories to be essential for endocytosis of HSP-peptide complexes and cross-presentation of the chaperoned peptide. While the role of CD91-dependent endocytosis in HSP-mediated immunity is well established, its potential role in signaling is just beginning to be evaluated. Recent data shows that in response to binding any one of the immunogenic HSPs, gp96, hsp70, or calreticulin, (a) CD91 is phosphorylated; (b) CD91 associates with the Shc adaptor protein, a process that involves the Src family kinases; and (c) ▶ NF-κB is activated in a CD91-dependent manner (Pawaria and Binder 2011). This signaling pathway which includes various kinases is important for the maturation of antigen-presenting cells and the resulting elaboration of co-stimulation. CD91 thus appears to play a dual role in HSP-mediated immunity; provision of signal 1 by way of cross-presentation of antigens and signal 2 via co-stimulation (Fig. 1). These events play key roles in initiation of antitumor immune responses in tumor-bearing mice and for therapeutic purposes in the clinic.

3. *The intracellular domain of CD91 as a transcriptional regulator:* It has been recognized for some time that a soluble form of CD91 circulates in the plasma, indicating that the receptor is subject to proteolysis, thereby releasing portions of receptor as a soluble polypeptide (Quinn et al. 1999). Similar to other type I integral membrane proteins, the CD91 cytoplasmic domain can also be cleaved by an enzyme with γ-secretase-like activity (May et al. 2002) releasing CD91 polypeptides of about 12kDa into the cytosol. This polypeptide has been shown to efficiently translocate to the nucleus where it limits the transcription of the inflammatory genes ▶ TNF-α and IL-6 in response to LPS activation of cells (Zurhove et al. 2008). Briefly, the nuclear CD91 polypeptide co-localizes with histone acetyltransferase Tip60, a transcriptional modulator with a role in linking proteolytic cleavage of β-amyloid precursor protein (APP) to transcriptional activation (Cao and Sudhof 2001; Baek et al. 2002). These studies suggest that a portion of the β-chain of CD91 can function directly as a transcriptional regulator. The identification of other genes regulated in a similar mechanism by this polypeptide is expected.
4. *The role of CD91 signaling in the nervous system:* Bu et al. found that the cytoplasmic tail of CD91 is phosphorylated in neuronal-derived cell lines and that nerve growth factor rapidly increases the amount of phosphorylation (Bu et al. 1998). A result of this is the rapid increase of cell surface CD91. CD91 serves as a receptor for α_2M with or without the amyloid peptide apolipoprotein E, tissue factor pathway inhibitor, and APP among others. These proteins are associated with the onset or pathology of Alzheimer's disease. An increase in CD91 expression on neurons suggests a mechanism for increased clearance of these proteins in the brain. In addition, signaling through phosphorylation of CD91 has been suggested to be crucial for the redistribution of CD91 from a silent pool (in the endosomes) to an active endocytic pool (on the cell surface). Redistribution of CD91 in neurons by this mechanism serves as a rapid way to regulate concentration of its ligands in the local environment of the brain.
5. *Other signaling events that have not been associated with a physiological outcome*: These studies

have largely been performed on cells in an in vitro setting and thus their role in physiological events is not yet readily apparent. Barnes et al. identified the CD91 β-chain bound to Shc PTB domain and showed that CD91 is tyrosine-phosphorylated in v-Src transformed cells. The tyrosine-phosphorylated CD91 binds to Shc which might provide a link to the RAS-ERK/MAP kinase pathway and alternative pathways downstream of Shc (Barnes et al. 2001). Those results are consistent with our own observations on the role of CD91 in immune cells described above. Tyrosine phosphorylation of CD91 suggested that a member of the receptor tyrosine kinase family might be responsible for this effect. Loukinova et al. found that PDGF BB induces a transient tyrosine phosphorylation of the CD91 cytoplasmic domain in a process dependent on PDGFβ receptor activation and ▶ c-Src family kinase activity (Loukinova et al. 2002). Lastly, CD91 is phosphorylated on cytoplasmic tyrosines in response to platelet-derived growth factor (Boucher et al. 2002) and Tyr 4507 was identified as the principle v-Src phosphorylation site (Barnes et al. 2001).

Summary

The endocytic functions of CD91 have been avidly examined and described. With respect to over 30 ligands described to bind to the α-chain of CD91, most have been demonstrated to be endocytosed into endo-lysosomes. There are an increasing number of examples of important roles for signaling via CD91 in various physiological events as described here. While an association of CD91 and its ligands in Alzheimer's disease has been studied for a number of years, the role of CD91 in immune responses is only beginning to emerge. In other physiological events, the crucial role of CD91 in clearing apoptotic cells signifies the far reaching consequences a deficiency of CD91 function would have. Indeed no such deficiencies have been found. In our own laboratory signaling of CD91 in response to immunogenic HSPs is a critical pathway for initiation of immune responses by dendritic cells and also for directing the type of immune response that is primed. This ancient receptor that has a major role in endocytosis appears to have been hijacked for evolutionarily newer functions of higher organisms. A major challenge for the study of CD91 is its sheer size of 600kDa and the intricate conformation of its domains which makes expression of recombinant protein with the right protein conformation challenging. In addition mice that are created to be deficient in CD91 expression die early during embryonic development due to its role in prenatal development (Herz and Strickland 2001). Recent advances in artificial chromosomes and conditional knock-out mice technology using the Cre-lox system will provide invaluable reagents for further investigation into the role in pathology and pathogenesis of disease and the role of CD91 signaling in physiological pathways.

Cdc7

Hisao Masai
Genome Dynamics Project, Department of Genome Medicine, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan

Synonyms

Cdc7 (*S. cerevisiae*); Cdc7L1; Hsk1 (homologue of Cdc7 [seven] kinase, *S. pombe*); Spo4 (second Cdc7 homologue in *S. pombe*)

Historical Background

Cdc7 was originally discovered as a temperature-sensitive mutant of budding yeast defective in progression of cell cycle (Hartwell 1973). The growth of *cdc7* (ts) is arrested immediately before the onset of the S phase at a nonpermissive temperature. Upon return to a permissive temperature, cells resume growth and can complete S phase in the absence of ongoing protein synthesis. This led to the notion that Cdc7 is required for DNA replication at the stage where all other proteins required for DNA synthesis are prepared. Cdc7 was later cloned and was identified as encoding a serine/threonine kinase (Hollingsworth and Sclafani 1990). Dbf4, another cell cycle regulator required at the onset of the S phase, was then shown to encode an activation subunit for Cdc7. An ortholog of Cdc7 was first identified in fission yeast (Hsk1; (Masai et al. 1995)) and was later shown to be conserved in higher eukaryotes as well (Sato et al. 1997).

Structure of Cdc7 Kinase and Activation by Dbf4 Subunit

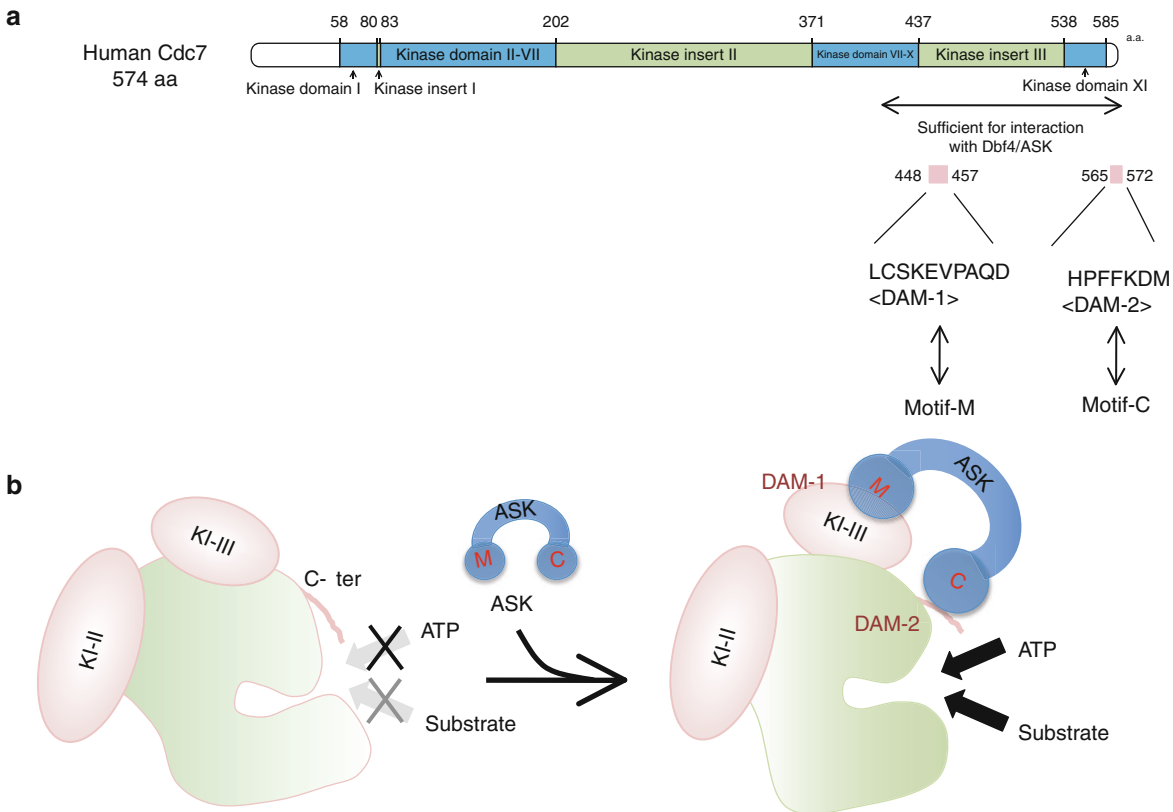
Cdc7 belongs to a rather unique branch of the kinase phylogeny tree and the closest member may be the casein kinase. Cdc7 kinase is unique in that it carries two or three so-called kinase insert sequences at the conserved locations within the kinase-conserved domains (Kim et al. 1998). The sequences and lengths of the kinase insert are not generally conserved. Analyses in human Cdc7 kinase indicated that the kinase insert II between the kinase domains VII and VIII is required for efficient nuclear localization as well as for chromatin association of Cdc7 (Kim et al. 1998; Masai and Arai 2002), whereas a small segment (DAM-1, Dbf4/ASK Association Motif-1) in the kinase insert III between the domains X and XI is required for interaction with Dbf4/ASK activation subunit. A conserved sequence present at the C-terminus of Cdc7 (DAM-2) also plays an essential role in interaction with Dbf4/ASK. Furthermore, DAM-1 and DAM-2 were shown to interact with motif-M and motif-C of Dbf4/ASK (Kim et al. 2007), respectively. Dbf4/ASK stimulates binding of ATP to the Cdc7 catalytic subunit as well as recognition of specific substrates ((Ogino et al. 2001); Fig. 1).

Identification of Orthologs of Cdc7 in Other Species

An ortholog of budding yeast Cdc7 was first identified in fission yeast (*hsk1*$^+$; (Masai et al. 1995)). Hsk1 and Cdc7 shares about 40% identity in the kinase-conserved domains (Kim et al. 1998). Hsk1 contains characteristic insert sequences at the conserved locations among the kinase-conserved domains. Cdc7 homologues were then identified in humans, mice, and *Xenopus* (Jiang and Hunter 1997; Sato et al. 1997; Kim et al. 1998). It is now known to be conserved over a wide range of species (Masai and Arai 2002). In fission yeast, another kinase, *spo4*$^+$, related to Cdc7 was identified (Nakamura et al. 2002). Spo4 is expressed specifically during late meiosis and forms a complex with Spo6, a meiosis-specific Dbf4-like molecule. Spo4-Spo6 is required for second meiotic cell division and sporulation.

Regulation of Expression

In normal proliferating yeast cells, Cdc7 is expressed constitutively during cell cycle. In fission yeast, the transcription of *hsk1*$^+$ slightly oscillates during cell



Cdc7, Fig. 1 Structure of Cdc7 kinase and interaction with Dbf4/ASK subunit. (**a**) Schematic drawing of amino acid sequences of human Cdc7. Two small segments of Cdc7 (*pink boxes*) termed DAM-1 and DAM-2 interact with motif-M and motif-C, respectively, of Dbf4/ASK protein (Ogino et al. 2001; Kitamura et al. 2011). (**b**) Schematic drawing showing interaction between Cdc7 and Dbf4/ASK. The interaction induces conformational change in Cdc7, thus permitting access to ATP and facilitating the recognition of substrates

cycle, peaking at the G1/S boundary. However, the protein level of Hsk1 is more or less constant during cell cycle (Takeda et al. 1999). In mammalian cells, the transcription of Cdc7 is under regulation of E2F transcription factor (Kim et al. 1998). Its transcription is repressed in quiescent cells, and induced after addition of mitogenic stimuli. The human Cdc7 transcription is regulated also during the cell cycle, increasing at late G1 through early S phase. The Cdc7 protein level also increases after growth stimulation of quiescent cells. In cycling cells, human Cdc7 protein level decreases during G1 phase, probably due to proteolytic degradation, since the Cdc7 protein expressed from a constitutive promoter similarly oscillates during cell cycle (Masai et al. 2006).

Cdc7 protein associates with chromatin during S phase and dissociates from it during G2/M phase (Masai et al. 2006). It is expressed also during M phase, and is present in cytoplasm. It is phosphorylated by Cdk (cyclin-dependent kinase) during M phase, and the phosphorylated Cdc7 is dissociated from chromatin, although the significance of this phosphorylation is not clear at the moment.

Substrate Specificity of Cdc7 Kinase

Cdc7 is a serine-threnine kinase, the primary structure of which shares some similarity with casein kinase. Like casein kinase, Cdc7 is an acidophylic kinase, favoring the acidic environment surrounding the target site. It has been reported that prior phosphorylation by another kinase such as Cdk or a checkpoint kinase can stimulate Cdc7-mediated phosphorylation by creating acidic environment surrounding the target sites (Masai et al. 2000; Montagnoli et al. 2006; Wan et al. 2008; Randell et al. 2010). SSP or STP may be one of the typical Cdc7 target sequences in which second serine

or threonine is first phosphoryalated by Cdk and the first serine is subsequently phosphorylated by Cdc7 (Cho et al. 2006; Masai et al. 2000; Montagnoli et al. 2006; Wan et al. 2008).

Functions in Initiation of DNA Replication

Cdc7 is essential for cell viability in yeasts under normal growth condition. Conditional knockout of Cdc7 gene in ES cells resulted in inhibition of DNA synthesis and eventual cell death due to accumulation of DNA damages (Kim et al. 2002), indicating that Cdc7 is also essential for mammalian cell growth. Early characterization of *cdc7*(ts) in budding yeast suggested its essential role in initiation of S phase. Later, it was shown that Cdc7 is required for initiation of DNA replication at each replication origin throughout S phase (Donaldson et al. 1998; Bousset and Diffley 1998). One-hybrid assays showed association of Dbf4 with replication origins in budding yeast (Dowell et al. 1994). These findings led to the notion that the pre-RC generated at each origin may be the target of Cdc7. Indeed, human Cdc7 was shown to phosphorylate MCM (minichromosome maintenance) in vitro (Sato et al. 1997). In budding yeast, MCM2 was shown to be phosphorylated in a manner dependent on Cdc7 (Lei et al. 1997). Accumulating evidence pointed to MCM complex as a major conserved substrate of Cdc7 kinase. Phosphorylation of MCM2 and MCM4 at the N-terminal segments promotes association of Cdc45 ((Masai et al. 2006; Sheu and Stillman 2006); Fig. 2), facilitating generation of the replication fork complex containing an active DNA helicase. In fission yeast, Hsk1 was shown to be essential for loading of Sld3 which is needed for assembly of an active replication fork. Hsk1 was also shown to regulate the efficiency of origin firing in fission yeast.

A bypass mutation (*bob1*) of *cdc7* or *dbf4* function was reported (Hardy et al. 1997). *bob1* was mapped in mcm5 (P83L), supporting the importance of phosphorylation of MCM in Cdc7-mediated regulation of initiation. The mutation may cause conformational changes in the MCM complex which may be permissive for origin activation in the absence of Cdc7 (Hoang et al. 2007). More recently, deletion of an N-terminal segment of MCM4 was shown to bypass Cdc7 function. It was proposed that the sole essential function of Cdc7 in budding yeast is to relieve an inhibitory activity residing within this N-terminal domain of MCM4 (Sheu and Stillman 2010). It remains to be seen whether this is conserved in other species.

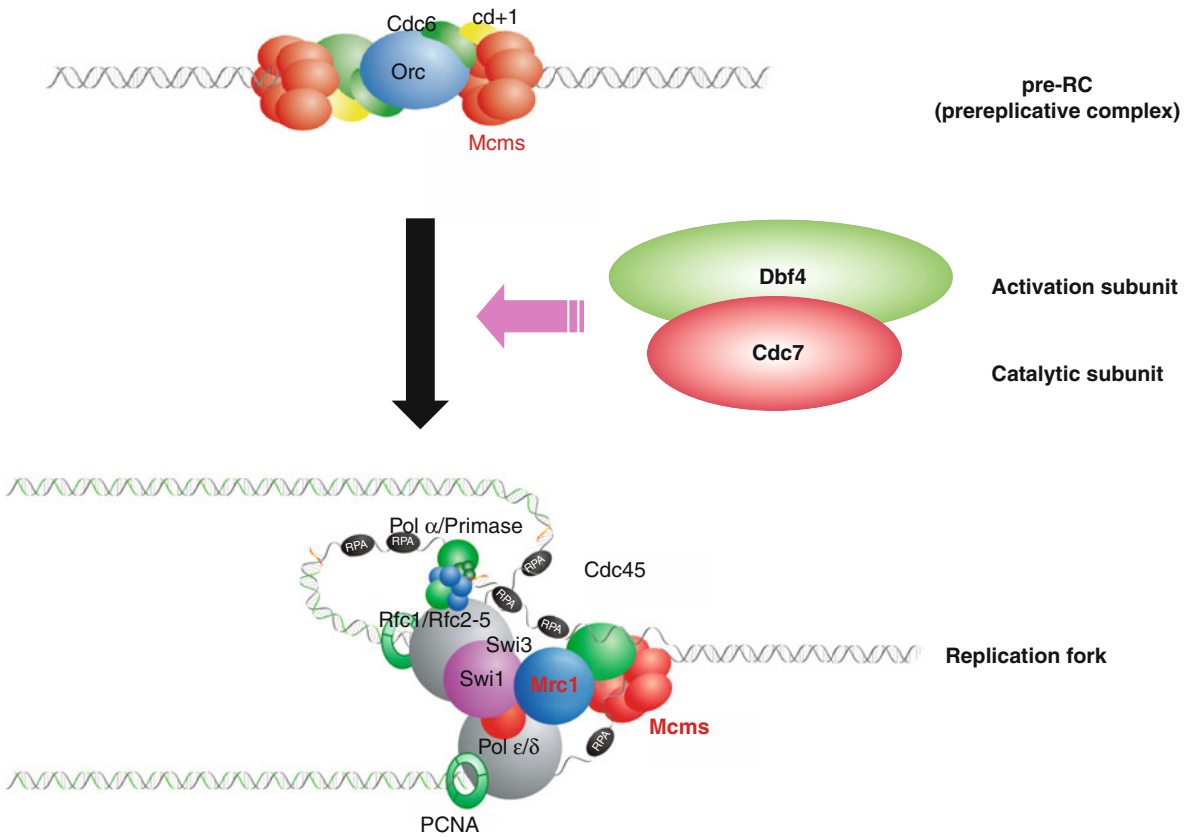
Functions During Mitotic Cell Cycle

Although the major and conserved role of Cdc7 kinase is in regulation of initiation of DNA replication, recent investigation has pointed to important roles of Cdc7 kinase in regulation of other mitotic events (see Fig. 3 and Table 1). Centrometric sister chromatid cohesion is partially impaired in *hsk1*(ts) (Takeda et al. 2001; Bailis et al. 2003). Consistent with this, the mutants are synthetic lethal with Rad21, a cohesin component, and is sensitive to the anti-microtubule drug thiabendazole (TBZ, (Takeda et al. 2001)). These results suggest a role of Hsk1 kinase in regulation of sister chromatid cohesion. In *Xenopus* egg extracts, Cdc7 was shown to form a complex with Scc2-Scc4 which is required for loading of cohesin onto chromatin (Takahashi et al. 2008). The kinase activity of Cdc7 is required for this process, although the exact target of Cdc7 is not known. It is also not known whether Cdc7 behaves similarly in other species including mammals.

In budding yeast, Cdc7-Dbf4 interacts with Polo kinase (*cdc5*) through N-terminal nonessential segment of Dbf4, and appears to regulate mitotic exit. In fission yeast as well, *hsk1*(ts) is synthetic lethal with a *plo1* (fission yeast homologue of Polo kinase) mutant (Matsumoto et al.). In human cancer cells, depletion of Cdc7 inhibited the cell-cycle progression from G2 phase arrest induced by nocodazole. These results suggest conserved roles of Cdc7 kinase during mitosis.

Functions During Meiotic Cell Cycle

Important roles of Cdc7 in meiotic cell cycle were originally reported in *cdc7*(ts) mutants of budding yeast (see Fig. 3 and Table 1). Defect in meiotic recombination and in synaptonemal complex formation were initially observed, while premeiotic DNA replication was reported not to be significantly affected. More recently, using fission yeast *hsk1*(ts) mutant, it was demonstrated that Hsk1 is required for formation of DSBs (double-stranded DNA breaks) which is prerequisite for meiotic recombination



Cdc7, Fig. 2 Roles of Cdc7 kinase in initiation of DNA replication. Cdc7-Dbf4 kinase recognizes pre-replicative complex (pre-RC) on the chromosome and phosphorylates MCM complex. This will facilitate the recruitment of replisome factors including Cdc45 required for generation of an active replication fork

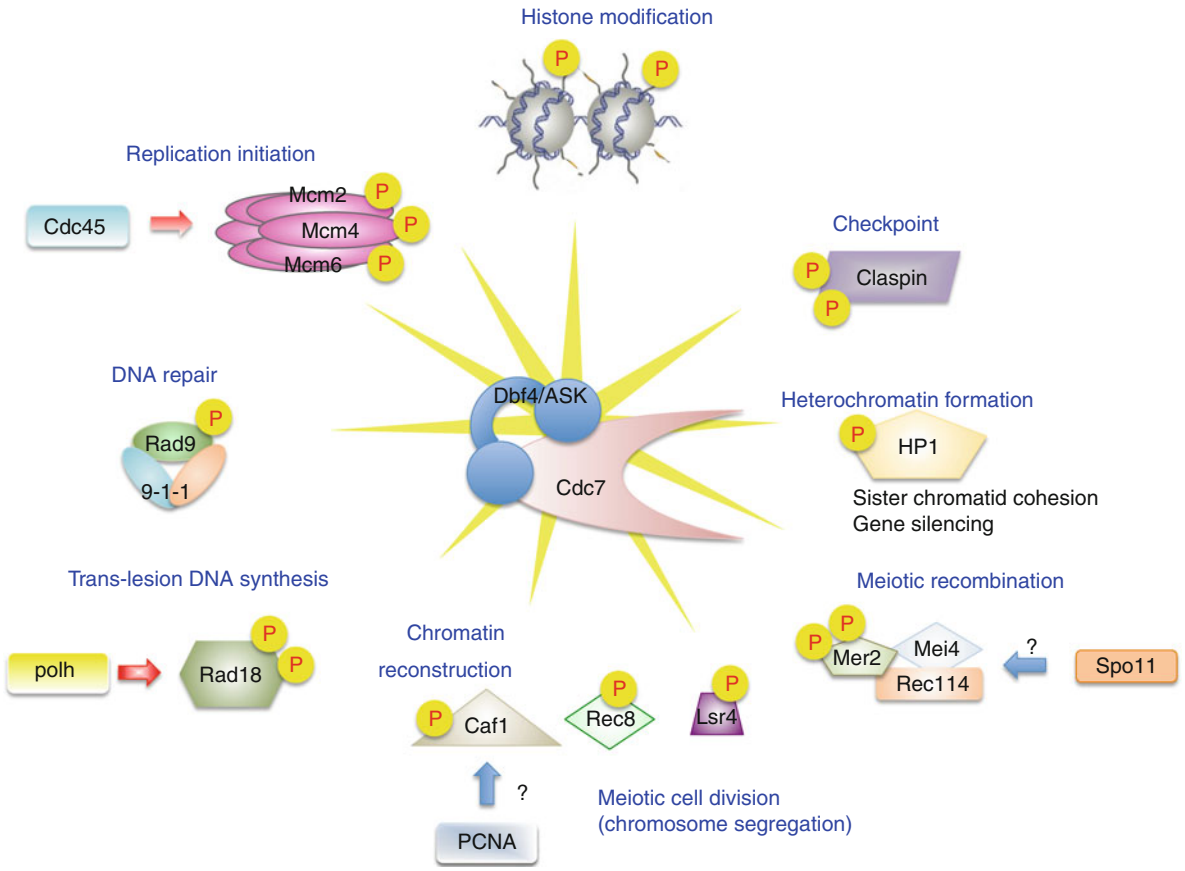
(Ogino et al. 2006). Premeiotic DNA replication could continue in *hsk1*(ts) mutant, albeit at a slightly slower rate. Similar conclusion was reached in budding yeast. However, using a tet-repressible transcription system, premeiotic DNA replication was shown to require Dbf4 function in budding yeast. Thus, it appears that Cdc7 may facilitate the initiation of premeiotic DNA replication but its requirement may be less stringent than for mitotic DNA replication. Phosphorylation of Mer2 protein, a component of the Mer2-Mei4-Rec114 complex required for initiation of meiotic recombination, by combined actions of Cdk and Cdc7 was shown to play essential roles in generation of meiotic DSB (Sasanuma et al. 2008; Wan et al. 2008).

Cells arrest with one nucleus state in a *hsk1*(ts) mutant in meiosis, suggesting that Hsk1 is required also for meiotic cell division. Consistent with this prediction, Cdc7 in budding yeast, in conjunction with casein kinase 1, was shown to phosphorylate Rec8 and to regulate cohesion cleavage by separase. Cdc7 was also shown to play essential roles in separation of the homologous chromosomes during meiosis I by phosphorylating Lsr2 protein and also by stimulating NDT80 transcription (Lo et al. 2008; Matos et al. 2008).

Cdc7 during meiosis is likely to be conserved in mammalian cells. Cdc7 hypomorphic mutant mice were sterile and germ cell development was severely disrupted (Kim et al. 2003). Sperm development was arrested at an early prophase, consistent with completion of premeiotic S phase but arrest before meiotic cell division.

Roles of Cdc7 in Other Chromosome Transactions

Cdc7 regulates chromosome processes other than DNA replication (see Fig. 3 and Table 1). It regulates



Cdc7, Fig. 3 Chromosome dynamics regulated by Cdc7 kinase. Various chromosome transactions, as indicated in the figure, are regulated by Cdc7 kinase. The potential target proteins in these events are shown. The red arrows indicate the recruitment by the phosphorylation which has been proven, and blue arrows indicate that which has been speculated but not been proven

DNA replication checkpoint, since *hsk1*(ts) is sensitive to HU and checkpoint kinase Cds1 is not fully activated in this mutant (Takeda et al. 2001) as well as in *cdc7* deletion and hsk1deletion cells made viable by a suppressor. Activation of Chk1 in response to replication stress in human cells also requires Cdc7 function and claspin may be a target of Cdc7 kinase during this process as well as during the normal course of DNA replication (Kim et al. 2008).

Roles of Cdc7 in UV-induced mutagenesis were suggested in the initial characterization of budding yeast *cdc7*(ts) mutants. More recently, budding yeast cdc7 was shown to be required for trans-lesion synthesis branch of Rad6 epistasis group (Pessoa-Brandão et al. 2004). In humans, Cdc7 phosphorylates a C-terminal segment of Rad18 and this phosphorylation facilitates the recruitment of a lesion-bypass polymerase, Polη (Rad30 counterpart), at the site of damage though its interaction with the phoshophorylated Rad18 (Day et al. 2010).

In fission yeast, Hsk1 phoshporylates Rad9 clamp loader and induces its dissociation from the damaged sites, facilitating the repair process (Furuya et al. 2010). Replication-associated phosphorylation of threonine 45 of Histone H3 is mediated by Cdc7-Dbf4 in budding yeast and may play a role in maintenance of genomic integrity during DNA replication and repair (Baker et al. 2010). Human Cdc7 interacts with chromatin assembly factor 1 (CAF1), and phosphorylates p150 subunit. This phosphorylation facilitates interaction of Caf1 with PCNA (proliferating cell nuclear antigen, known as a clamp protein) (Gérard et al. 2006). Thus, Cdc7 may play a role in the coordination between DNA replication and chromatin assembly by Caf1.

Cdc7, Table 1 List of chromosome events regulated by Cdc7 kinase, potential target proteins, and known phosphorylation sites mediated by Cdc7

Chromosome transactions	Target	Phosphorylation sites	Collaboration with Cdk?	Protein recruited	References
DNA replication	MCM2 MCM4	S26, S40, and other SSP	Yes (S27, S41/T7)	Cdc45 (Sld3)	(Masai et al. 2000, 2006; Montagnoli et al. 2006; Sheu and Stillman 2006)
Meiotic recombination	Mer2/Rec7	S29 and S11,15,19,22 (Mer2)	Yes (S30)	Spo11/ Rec12	(Ballabeni et al. 2009; Landis and Tower 1999; Takahashi and Walter 2005)

Proteins Interacting with Cdc7

Cdc7 is an enzyme which may interact with the substrates only transiently. Thus, interaction with Cdc7-Dbf4 kinase is generally weak. Physical interaction with MCM subunits have been reported, as expected from the fact that MCM is one of the most robust substrates of Cdc7. Yeast two-hybrid assays with mouse Cdc7 showed its interaction with Orc1 and 6 and with MCM2, 4, 5, and 7 (Kneissl et al. 2003).

Interaction of Cdc7 with other replication factors has been reported. In human cells and fission yeast, Cdc7 (Hsk1) interacted with Claspin (Mrc1) protein (Kim et al. 2008; Uno and Masai 2011). In human cells, Cdc7 interacts with Cdt1 and this interaction may facilitate the loading of Cdc45 onto chromatin (Ballabeni et al. 2009).

Developmental Role of Cdc7

The *Drosophila* chiffon mutant exhibits thin, fragile chorions and female sterility, and is deficient in chorion gene amplification (Landis and Tower 1999). The mutant also shows rough eyes and thin thoracic bristles. Chiffon encodes a Dbf4-like molecule which is required for normal development of Drosophila.

In *Xenopus* egg extracts, Cdc7-Drf1/ASKL1 is a major Cdc7 complex, but the level of Drf1/ASKL1 decreases and that of Dbf4 increases after gastrulation, when the cell cycle acquires somatic characteristics (Takahashi and Walter 2005). It is not known whether similar developmental regulation operates in human cells.

Xenopus Dbf4 (XDbf4) is required for heart and eye development. XDbf4 inhibits Wnt signaling through interaction with Frodo. This role of XDbf4 is independent of its function as an activator of Cdc7 kinase, since XDbf4 that cannot activate Cdc7 can still rescue the cardiac marker expression induced by XDbf4 depletion (Brott and Sokol 2005).

Cdc7 as a Target for Novel Cancer Therapy

Inhibition of Cdc7 expression in normal somatic cells generally causes stable G1 arrest (Tudzarova et al. 2010; Montagnoli et al. 2004). On the other hand, inhibition of Cdc7 in cancer cell lines causes robust cell death regardless of the p53 status. Generally in p53-negative background, cells tend to get arrested at G2 and then proceed into aberrant mitosis, whereas p53-positive cancer cells have tendency to proceed into aberrant S phase, before they die. These incidents

happen because of deficiency in various checkpoint systems found in cancer cells. Efforts are being made to develop specific chemical inhibitors of Cdc7 kinase and use them as potent agents that may induce cancer cell-specific cell death. Indeed, panels of low molecular weight chemical compounds have been identified that inhibit Cdc7 kinase in vitro and can suppress tumor growth in xenograft cancer model mice (Montagnoli et al. 2008). Those who are interested in learning more about eukaryotic DNA replication are recommended to read the reference (Masai et al. 2010).

Summary

Cdc7 is a serine-threonine kinase conserved from yeasts to human and regulates initiation of DNA replication by phosphorylating MCM, essential components of pre-replicative complexes generated at prospective replication origins. This phosphorylation triggers recruitment of Cdc45 and other replisome proteins to generate active replication forks. Cdc7 forms a complex with an activation subunit Dbf4/ASK to generate an active kinase. In addition to DNA replication, Cdc7 regulates varieties of chromosome dynamics including meiotic DNA recombination, meiotic cell division, DNA damage repair through trans-lesion DNA synthesis, DNA replication checkpoint and chromatin structures. Cdc7 emerges as a novel cancer therapy target since inhibition of Cdc7 in cancer cells causes efficient cell death by inducing abortive DNA synthesis or aberrant mitosis while that in normal cells generally arrests the cell growth in G1.

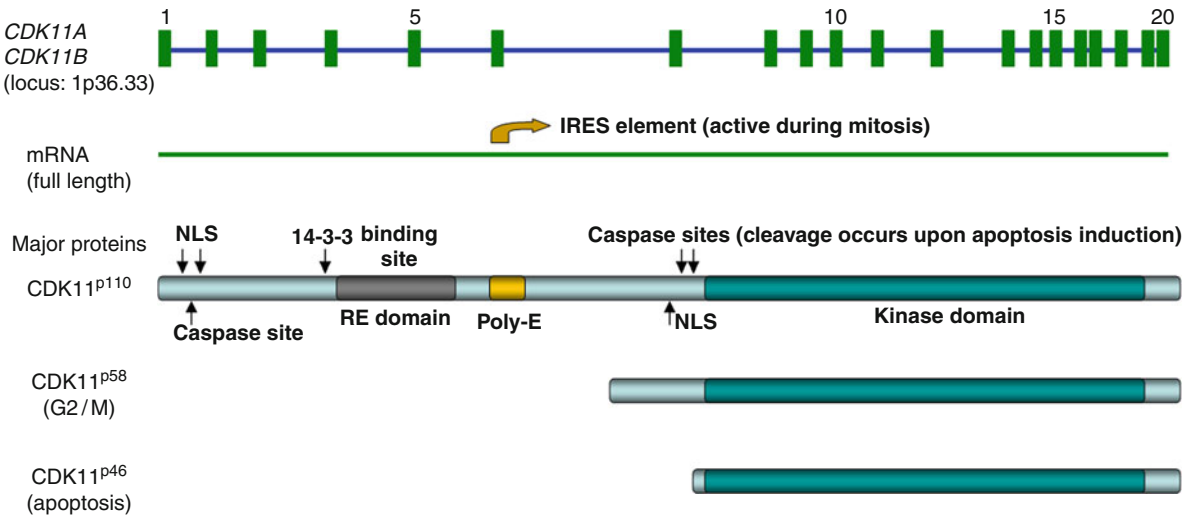
Historical Background

The CDK11A and CDK11B kinases (cyclin-dependent kinase 11A and B), formerly known as PITSLRE protein kinases, are serine/threonine protein kinases that belong to p34CDC2-related protein kinase superfamily. p34CDC2-related kinases play essential roles in many aspects of the cellular processes, especially cell cycle control and the regulation of transcription. There are two *CDK11* genes in humans (*CDK11A* and *CDK11B* formerly known as *CDC2L2* and *CDC2L1*), and one *CDK11* gene in mouse (*Cdk11*, previously known as *cdc2*l) (Malumbres et al. 2009). *CDK11* genes are evolutionarily conserved. *CDK11* homologs are found in human, mouse, rat, frog, cattle, fruit fly, yeast, and even in protozoa amoeba (Trembley et al. 2004; Goldberg et al. 2006). The almost identical human *CDK11A* and *CDK11B* genes are tandemly located within ~140 kb on chromosome 1p36.33. Each gene contains 20 exons and 19 introns and the full-length CDK11A^{p110} and CDK11B^{p110} proteins differ by only 16 amino acids (Gururajan et al. 1998; Lahti et al. 1994; Trembley et al. 2004). All data to date suggest that these two genes are functional equivalent; therefore, to simplify the nomenclature we will use the term "CDK11" to represent the human genes and proteins as well as the single mouse gene and protein in the following text.

CDK11 mRNA and protein are expressed in all cell types examined to date, although the mRNA and proteins are most abundant in testes, bone marrow, spleen, brain, lymph nodes, thymus, and hematopoietic cell lines (Xiang et al.1994). The three major CDK11 isoforms are CDK11^{p110}, CDK11^{p58}, and CDK11^{p46} (Fig. 1). There are many human transcript variants encoding the most abundant CDK11 isoform, CDK11^{p110}. These transcripts are generated by alternate promoter usage and alternative splicing of exons 1–11 which are located upstream of the Ser/Thr protein kinase domain of the CDK11 genes. CDK11^{p110} is expressed throughout the cell cycle. In contrast, CDK11^{p58} is specifically expressed during G2/M (Gap 2 and mitosis) phase of the cell cycle. This protein is generated via an IRES (internal ribosome entry site) located within the coding region of the CDK11 full-length transcript (Cornelis et al. 2000; Wilker et al. 2007). Finally, CDK11^{p46} is produced by caspase-mediated cleavage of both CDK11^{p110} and CDK11^{p58} during apoptosis (Lahti et al. 1995; Beyaert et al. 1997; Tang et al. 1998). Like other CDKs, CDK11 protein kinases are associated with and regulated by the cyclin partners, cyclin L1 and L2 (Dickinson et al. 2002; Loyer et al. 2008).

CDK11 is an essential gene. Genetic deletion of the *Cdk11* gene in mouse leads to early embryonic lethality at E3.5 (embryonic day 3.5), while the heterozygous mice (CDK11$^{+/-}$mice) appear to develop



CDK11, Fig. 1 The schematic diagram of the human CDK11 gene, transcript, and the major protein isoforms. The human *CDK11A* and *CDK11B* genes are located on chromosome 1p36.33. The exons are represented by the *green bars*. Several known functioning motifs are indicated on the full-length CDK11^{p110} diagram, and the relative location of the internal ribosomal entry site (IRES) element facilitating the mitotic expression of CDK11^{p58} is indicated on the transcript. The caspase cleavage sites used for generating apoptotic CDK11^{p46} are also indicated by *arrows* on the full-length protein. Additional CDK11 isoforms are generated by alternative splicing of exons 1–11 of the pre-mRNA

normally (Li et al. 2004). Likewise, decreasing CDK11 expression using siRNA leads to mitosis abnormalities, apoptosis, and cell death (Hu et al. 2007; Petretti et al. 2006). Interestingly, heterozygous deletion or translocations of the human *CDK11* genes are frequently observed implying its role in tumorigenesis (Trembley et al. 2004). In addition to potential roles in tumorigenesis and mitosis, data published to date have shown that CDK11 is involved in transcription, RNA processing, neuronal signaling, apoptosis, and cell cycle regulation.

CDK11 and Transcription

The first clue that CDK11 might be involved in transcriptional regulation came from yeast two hybrid studies using CDK11^{p110} as a bait protein. The RNA polymerase II transcription elongation factor ELL2 was identified as a CDK11^{p110} interacting protein in these studies (Trembley et al. 2002). Characterization of purified CDK11 complexes from Hela nuclear extracts revealed that the largest subunit of RNA polymerase II (RNAP II), the SSRP1 (structure-specific recognition protein 1), and SPT16 (chromatin-specific transcription elongation factor 140 kDa subunit) subunits of the transcription elongation factor FACT (facilitates chromatin transcription, a histone chaperone) and ▶ Casein kinase II (CKII) and ELL2, all proteins involved in transcription, are present in CDK11^{p110} complexes. Furthermore, co-immunoprecipitation analyses indicated that CDK11^{p110} associates with the TFIIF (transcription initiation factor IIF), TFIIS (transcription elongation factor IIS), and both hypo- and hyperphosphorylated forms of the largest subunit of RNAP II. Importantly, addition of CDK11 antibody, which bind to the carboxyl terminal domain of CDK11, and presumably disrupts interactions between CDK11 and transcriptional complex proteins, substantially reduced the production of RNA transcript in an in vitro transcription assay (Trembley et al. 2002, 2003).

CDK1, CDK7, CDK8, and CDK9 are also involved transcription regulators and phosphorylate the carboxyl-terminal domain (CTD) of RNAP II complexes to positively or negatively regulate transcription (reviewed in Hirose and Ohkuma 2007). In contrast, CDK11^{p110} does not directly phosphorylate the RNAPII CTD; however, CDK11^{p110} interacts with casein kinase II (CKII) which phosphorylates both CDK11 and the RNAP II CTD (Trembley et al. 2002, 2003, 2004). Despite data clearly indicating that CDK11^{p110} interacts with transcriptional proteins and is required for high level in vitro transcription, the

exact role of CDK11^{p110} in transcription in vivo and the biological substrates of the kinase remain undetermined.

CDK11 and RNA Processing

The role of CDK11^{p110} is consistent with the fact that CDK11^{p110} has several putative nuclear localization signal sequences. Indirect immunofluorescence analysis of CDK11 localization revealed that a portion of the cellular CDK11^{p110} is diffusely localized in the nucleoplasm, while the majority of the protein is found in nuclear speckles. These nuclear speckles also contain general splicing factors suggesting that CDK11^{p110} may also play a role in splicing. Consistent with this hypothesis, the splicing factors RNPS1 and 9G8 were identified as CDK11^{p110} interacting proteins by yeast two-hybrid analyses and 9G8 is phosphorylated by CDK11^{p110} (Loyer et al. 1998; Hu et al. 2003). Additionally, the CDK11 regulatory proteins, cyclin L1 and L2, have roles in RNA splicing (Loyer et al. 1998, 2008; Dickinson et al. 2002; Hu et al. 2003).

Further evidence for the role of CDK11^{p110} in splicing was demonstrated both in vitro and in vivo. Immunodepletion of CDK11^{p110} from nuclear extract severely reduced splicing activity in an in vitro splicing assay using a β-globin minigene as a substrate, while re-addition of the CDK11^{p110} complexes restored splicing activity. Additionally, disrupting the interaction between CDK11^{p110} and other splicing component using a recombinant N-terminal 50 amino acids fragment of the CDK11^{p110} protein kinase greatly reduced splicing activity (Hu et al. 2003). Ectopic expression of cyclins L1α, L1β, L2α, L2β, or catalytically active CDK11^{p110} proteins individually enhances intron splicing activity, while expression of catalytically inactive form of CDK11, CDK11^{p110DN}, CDK11^{p58}, or CDK11^{p46} represses splicing activity when using the pTN24 transcription/splicing dual in vivo reporting system. More importantly, co-expression of cyclin Lα and Lβ and CDK11^{p110} alters constitutive splicing of the TN24 plasmid and alternative slicing of the E1A minigene reporter in vivo (Loyer et al. 2008). CDK11^{p110} and 9G8 also appear to be involved in mRNA 3′ end processing based on a recent study which showed that CDK11 and 9G8 are involved in regulating HIV-1 mRNA 3′ end processing. These investigators also found that the eukaryotic initiation factor 3 subunit f (eIF3F) can block the 3′ mRNA processing by altering the 3′ end pre-mRNA sequence recognition by 9G8 coupled with CDK11 (Valente et al. 2009). Taken together, these data indicates CDK11^{p110} protein kinase activity plays crucial role in pre-mRNA splicing processing possibly by coupling mRNA processing with transcription.

CDK11 and Mitosis

CDK11^{p58} is specifically expressed during the G2/M phase of the cell cycle from the same mRNA that produces CDK11^{p110} via an internal ribosome entry site (IRES) sequence in the coding region of the transcript (Cornelis et al. 2000). This uniquely regulated expression strongly suggested that CDK11^{p58}, most likely in association with cyclin L proteins, functions during mitosis. Defects in IRES directed cap-independent translation during mitosis (e.g., lack of translation of the IRES regulated protein 14-3-3σ) leads to reduced CDK11^{p58} expression and mitotic defects, such as the absence of polo-like kinase 1 (Plk1) at the midbody, the impairment of cytokinesis, and the accumulation of binucleated cells (Wilker et al. 2007). Further evidence that CDK11^{p58} expression is tightly regulated during G2/M comes from studies showing that minimal overexpression of CDK11^{p58} in CHO (Chinese hamster ovary) cells resulted in aneuploidy, a delay in cytokinesis exemplified by the present of a large number of cells with tubulin midbodies, telophase defects, and apoptosis (Lahti et al. 1995; Bunnell et al. 1990). More recent studies using siRNAs targeting CDK11 have shown that CDK11^{p58} is required for proper mitosis (Petretti et al. 2006; Hu et al. 2007). Moderate depletion of CDK11 expression in Hela cells using siRNAs targeting CDK11 causes misaligned chromosomes but does not prevent mitotic progression. Further diminution of CDK11 expression leads to centrosome morphological defects, centrosome number abnormalities, abnormal mitotic spindle, defective chromosome congression as well as premature sister chromatid separation, permanent mitotic arrest, and cell death. Importantly, the mitotic defects caused by CDK11 depletion can be rescued, at least in part, by ectopic expression of GFP-CDK11^{p58} (Hu et al. 2007; Petretti et al. 2006).

These studies and immunofluorescence experiments also revealed that CDK11 associates with

centrosomes throughout the cell cycle but that the association intensity is increased as the mitotic spindles form and the chromosomes congress. Staining is then reduced as the cells enter anaphase (Petretti et al. 2006). Studies in *Xenopus* system have also shown that CDK11 localizes on spindle poles and microtubules, stabilizes microtubules in RanGTP-dependent manner, and that CDK11 kinase activity is important for spindle assembly and function (Yokoyama et al. 2008).

CDK11 depletion also causes spindle checkpoint activation and mitotic arrest. The spindle checkpoint machinery does not function properly when CDK11 is depleted since sister chromatids are able to partially separate and BubR1 (a mitotic checkpoint regulatory serine/threonine-protein kinase) is retained on the separated kinetochores. Moreover, immunofluorescence studies on CDK11 RNAi-treated cells showed that the cohesion subunit Scc1 prematurely dissociates from the kinetochores and the localization of the cohesion guardian Sgo1 at the kinetochore region is altered (Hu et al. 2007). These data support the conclusion that CDK11 plays a crucial role in the regulation of sister chromatid cohesion.

Finally, *CDK11* gene knockout studies demonstrate a role for CDK11 in mitosis during development. Deletion of the mouse *Cdk11* gene resulted in embryonic lethality at E3.5. The CDK11-deficient blastocyst cells exhibited cell proliferation defects (as judged by the low level of BrdU incorporation) and mitotic arrest (illustrated by staining with Histone 3 phosphor-Ser10 antibody) (Li et al. 2004), indicating at least one isoform of the CDK11 protein kinase is involved in mitotic regulation.

CDK11 and Apoptosis

The early hypothesis that CDK11 might function in apoptosis was based on the discovery of the $CDK11^{p46}$ isoform. This 46kD isoform is generated by caspase-dependent cleavage of the preexisting pools of $CDK11^{p110}$ and $CDK11^{p58}$ upon the induction of apoptosis. $CDK11^{p46}$ contains the intact kinase catalytic domain but lacks the N-terminal region of p110 and the N-terminal 52 amino acids that are present in the $CDK11^{p58}$ isoform (Lahti et al. 1995; Beyaert et al. 1997). The production of this isoforms may be regulated by phosphorylation since phosphorylation of $CDK11^{p110}$ is coupled with caspase cleavage during Fas-mediated cell death (Tang et al. 1998). Ectopic expression of the kinase active form of $CDK11^{p46}$, not the inactive form, in CHO cells induces apoptosis (Lahti et al. 1995). It has also been reported that $CDK11^{p46}$ induces anoikis, a special form of apoptosis caused by disruption of cell–matrix interactions, and associates with PAK1 (p21-activated kinase 1) leading to the inhibition of PAK1 kinase activity (Chen et al. 2003). Other studies demonstrated that $CDK11^{p46}$ interacts with and phosphorylates elF3f, a subunit of eukaryotic elongation factor 3. The phosphorylation of elF3f enhances its association with the core elF3 complex during apoptosis, suggesting that phosphorylation of this protein by $CDK11^{p46}$ may inhibit protein translation by enhancing the binding of elF3f to the elF3 core during apoptosis (Shi et al. 2009). Like the other larger CDK11 isoforms, $CDK11^{p46}$ associates with cyclin L1α, L2α, and L2β, although it is not clear whether this association regulates $CDK11^{p46}$ function. Taken together the data mentioned above suggest $CDK11^{p46}$ is involved in apoptotic signaling pathway, like p34cdc2 (Shi et al. 1994).

CDK11 and Tumorigenesis

Given the many important biological functions observed thus far for CDK11, it is very logical to speculate that any genetic abnormalities for *CDK11* gene and its regulation defects could lead to severe human disease. Indeed, deletion of one allele of 1p36.3 chromosome region, which contains the two human *CDK11* genes, is often observed in human tumors, including neuroblastoma, melanoma, colon cancer, ovarian cancer, breast cancer, and pheochromocytoma (reviewed in Trembley et al. 2004). Although the $Cdk11^{+/-}$ heterozygous mice have normal development (Li et al. 2004) indicating that loss of *Cdk11* alone is not sufficient for tumorigenesis, when *Cdk11* heterozygous and control mice were challenged with skin cancer inducing carcinogens there was an threefold increase in the number of tumors per mouse and an increased frequency of larger papillomas in *Cdk11* heterozygous mice as compared to wild-type mice (Chandramouli et al. 2007). Furthermore, a 2.5-fold downregulation of *Cdk11* gene expression was found in the invasive mouse skin carcinomas in association with mutant ▶ *p53* and mutant H-*ras* status (Zhang et al. 2005). Another line of evidence implicating

CDK11 in tumorigenesis comes from the discovery that CDK11 regulates the Hh (hedgehog) signaling pathway. Disruption or improper activation of this pathway is associated with developmental abnormalities and tumorigenesis (Evangelista et al. 2008). CDK11 was also identified as a kinase regulator for Wnt/β-catenin signaling pathway in a high-throughput siRNA screening (Naik et al. 2009). These studies showed that decreasing CDK11 expression resulted in reduced β-catenin-dependent transcription suggesting that CDK11 could be a potential therapeutic target in tumors with dysregulation of Wnt/β-catenin signaling, for example, colorectal cancer, breast cancer, and hepatocellular carcinoma (Clevers 2006).

Loss of CDK11 also causes defects in cell cycle, especially during mitosis. Cell cycle misregulation is one of the hallmarks of cancer cells. As mentioned above, the G2/M-specific CDK11^{p58} isoform regulates mitotic progression (Petretti et al. 2006; Hu et al. 2007). Defects in IRES directed cap-independent translation machinery, which is responsible for generating most of the proteins that are produced during late G2 and mitosis, causes reduced CDK11^{p58} expression and which results in mitotic abnormalities and in turn contributes to aneuploidy and tumorigenesis (Wilker et al. 2007). Expression of the ▶ Myc oncogene in Eμ-Myc/+ mice disrupts IRES-mediated translation of proteins during mitosis and leads to tumor formation (Barna et al. 2008). Further analysis of these tumors revealed decreased CDK11^{p58} expression and increased aneuploidy (Barna et al. 2008). Importantly, this defect can be suppressed by restoring CDK11^{p58} expression to normal levels (Barna et al. 2008). These observations strongly suggest that *CDK11* may be a tumor suppressor gene.

CDK11, Table 1 The major functions of different CDK11 protein isoforms

CDK11 proteins	Major functions
CDK11^{p110}	Transcription
	RNA processing/splicing
	Hh signaling
	Wnt/β-catenin signaling
	Other functions?
CDK11^{p58}	Mitosis progression
	Centrosome function
	Spindle formation and functioning
	Sister chromatid cohesion
	Spindle checkpoint control
	Chromosome congression
	Other functions?
CDK11^{p46}	Apoptosis
	Other functions?

Summary

Since the discovery of *CDK11* gene roughly two decades ago, studies from many labs have advanced our understanding of *CDK11* gene function and regulation. Based on these studies it is now clear that CDK11 is essential for cell growth, and that the different CDK11 isoforms function in distinct cellular processes such as transcription, mRNA processing/splicing (CDK11^{p110}), mitotic progression (CDK11^{p58}), apoptosis (CDK11^{p46}), and tumorigenesis (Table 1). More detailed analysis is needed to establish the roles of the various CDK11 isoform in vivo and the roles in tumorigenesis. Likewise, although CDK11 protein kinases associate with cyclin L1 and L2, and co-expression of L cyclins and CDK11^{p110} strongly affect alternative splicing and results in differences in the number and type of transcripts that are produced by alternate splicing in comparison with expressing those proteins individually (Loyer et al. 2008), the detailed regulatory mechanisms on their cooperative and synergistic activities remain to be clarified. Current studies are also highly focused on identifying CDK11 kinase substrates. Since CDK11 protein kinases have multiple functions in different cellular processes, the identification of more bona fide substrates is a key step in improving our understanding of the function and regulation of the various CDK11 isoforms. To date, 9G8 and eIF3f are the only substrates that have been studied extensively. However, the exact CDK11^{p110} phosphorylation site (s) on 9G8 and the functional relevance of this phosphorylation are yet to be elucidated. The other challenge in understanding CDK11 function is generating appropriate molecular tools to define or discriminate between the many different CDK11 protein isoforms and splice variants and to determine their functions in various signaling pathways. Additionally, determining how CDK11 influences tumorigenesis remains an important question for further investigation. Generating CDK11 mouse models that allow modulation of CDK11 expression in specific tissues is necessary to

understand the role of CDK11 in tumorigenesis and to address the possibility of developing CDK11-specific protein kinase inhibitors for the therapeutic purposes.

CEACAMs

Bernhard B. Singer
Department of Anatomy, University Hospital Essen, University Duisburg-Essen, Essen, NRW, Germany

Synonyms

Bgp; C-CAM; CD66

Alternative Names

CEACAM1: Bb-1; Bgp; Bgp1; Bgpa (human); Bgpd (mouse); BGPI; Biliary glycoprotein 1; C-CAM; C-CAM105; NCA-160; nonspecific cross-reacting antigen 160; CD66; CD66a; Cea-1; Cea-7; CEA-related cell adhesion molecule 1; Cea1; Cea7; Carcinoembryonic antigen-related cell adhesion molecule 1; CEACAM1; Ceacam1; mCEA1; MHVR; mmCGM1; mmCGM1a; mmCGM2.

CEACAM3: CD66d; CGM1; MGC119875; W264; W282.

CEACAM4: CGM7.

CEACAM5: CEA; CD66e.

CEACAM6: CD66c; NCA; NCA-90; NCA-50/90; CEAL.

CEACAM7: CGM2.

CEACAM8: CD66b; CD67; CGM6; NCA-95.

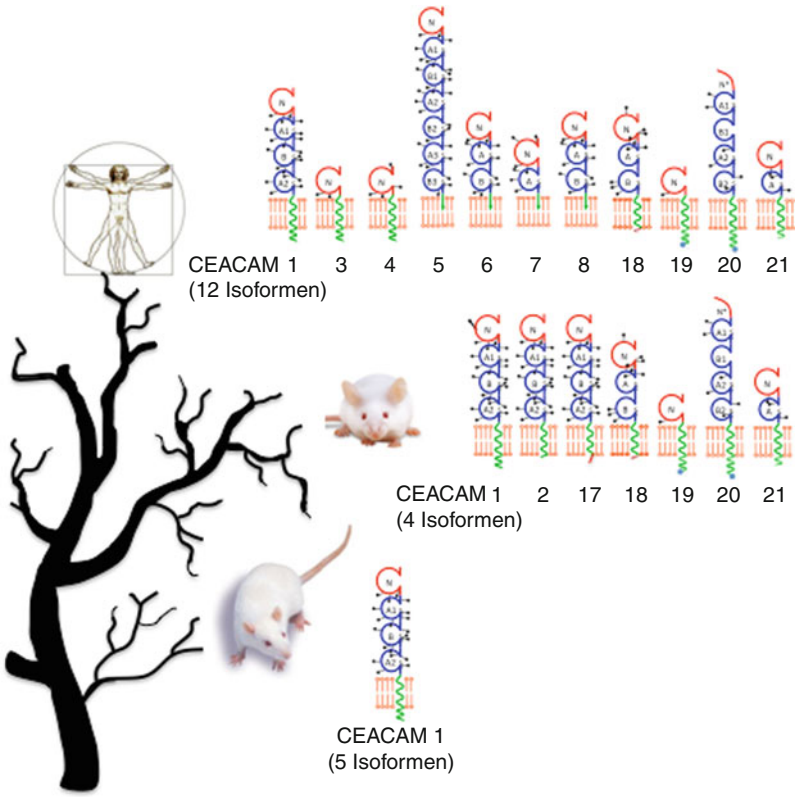
CEACAM9, CEACAM10, CEACAM11, CEACAM12, CEACAM13, CEACAM14, CEACAM15, CEACAM16, CEACAM17, CEACAM18, CEACAM19, CEACAM20, and CEACAM21: no synonyms.

Historical Background

CEA-related cell adhesion molecules (CEACAMs) are members of the carcinoembryonic antigen (*CEA*) gene family, which belongs to the immunoglobulin superfamily. Two subgroups of the *CEA* gene family, the CEA-related cell adhesion molecules and the pregnancy-specific glycoproteins (PSGs), are located within a 1.2 Mb cluster on the long arm of human chromosome 19 (19q13.2), the mouse chromosome 7, or the rat chromosome 1 (Kammerer and Zimmermann 2010). All CEACAMs are heavily glycosylated. The CEACAM subgroup in humans consists of 12 members composed of a single immunoglobulin variable (IgV)-like N-terminal (N) domain followed by zero to six Ig constant (IgC)-like domains of A and B subtypes and one member which consists of two IgC-like domains and two IgV-like domains, one at each end of the molecule. Due to its orthologs found in numerous species, CEACAM1 was identified as the ancestral founder molecule of the CEACAM-family (Beauchemin et al. 1999). However, as a result of its early recognition to be a potent tumor marker CEA/CEACAM5 represents the best-known CEACAM family member (Hammarström 1999; Horst and Wagener 2004). In mice, rats, and cattle, but not in humans, at least two CEACAM1 alleles each have been determined (Kammerer and Zimmermann 2010). Species-specific alternative splicing of several family members further enhances the diversity of the CEACAM family (Singer and Lucka 2005). For example, CEACAM1 mostly appears in at least two co-expressed isoforms one with a long (CEACAM1-L; 73 amino acid), one with a short (CEACAM1-S; 10 amino acid) cytoplasmic tail. The cytoplasmic domain of CEACAM1-L contains tyrosine residues within an immunoreceptor tyrosine inhibition motif (ITIM) that interacts with protein tyrosine kinases of the Src family. CEACAM1, CEACAM3, CEACAM4, CEACAM18, CEACAM19, CEACAM20, and CEACAM21 are transmembrane-anchored molecules while CEA/CEACAM5, CEACAM6, CEACAM7, and CEACAM8 are linked to the cell membrane via glycosylphosphatidylinositol (GPI) anchors, a type of semipenetrating membrane anchorage that exists only in human *CEA* gene family members. Thus, the variety of CEACAMs expressed in rat and mouse is less (Fig. 1). CEACAM16 represents most likely a secreted molecule. Interestingly, also CEACAM1, CEA/CEACAM5, CEACAM6, and CEACAM8 can appear as secreted variants. The transmembrane-anchored CEACAM17 and the secreted CEACAM9, CEACAM10, CEACAM11, CEACAM12, CEACAM13, CEACAM14, and CEACAM15 exist in rat and mouse but not in human. The transmembrane-bound CEACAM2 is solely found in mice (Beauchemin et al. 1999). Because very little is known about the relatively new discovered CEACAM9-CEACAM21 proteins, this entry will concentrate on CEACAM1-CEACAM8.

Expression Patterns of CEACAMs

CEACAMs show a very heterogeneous expression pattern. Thus, CEACAM1 is expressed in several leukocyte-subtypes, most epithelia and endothelia of newly formed small blood vessels (Singer and Lucka 2005). Notably, angiogenically activated microvascular endothelial cells express significant less CEACAM1 than angiogenically activated lymphendothelial cells. The CEACAM1 expression is up-regulated in activated granulocytes, B- and T-lymphocytes as well as in confluent, contact-inhibited epithelial cells (Singer and Lucka 2005; Gray-Owen and Blumberg 2006; Singer et al. 2010). Beside the altered CEACAM expression in contact inhibited versus proliferating epithelia cells, the CEACAM1-L to CEACAM1-S ratio can also differ (Singer et al. 2010). The CEACAM3- and CEACAM8-expression is restricted to human granulocytes whereas CEACAM5 and CEACAM7 can solely be found on epithelia. CEACAM6 is expressed in granulocytes and some epithelia. Until now, the expression pattern of CEACAM4 is not finally understood but it is believed to be present in granulocytes, in T- and B-cell lymphoblastic leukemia.



CEACAMs, Fig. 1 Domain structure of membrane-anchored members of the *CEA* gene family expressed in rat, mouse, and human. Each receptor has an amino-terminal IgV-like domain (N domain) followed by a variable number of A or B subsets of IgC2-like domains, a transmembrane and a cytoplasmic domain. Additionally, GPI-anchored CEACAMs appear in human. Alternative spliced variants can be found in of some of the CEACAMs and further enhance the complexity of the *CEA* gene family. CEACAM1 is believed to be the ancestral founder gene of the *CEA* gene family. The most common isoforms of CEACAM1 carry either a long (CEACAM1-4L) or a short (CEACAM1-4S) cytoplasmic tail. The number of CEACAM1 isoforms varies significantly between the different species. Further information about the *CEA* gene family can be found at http://www.carcinoembryonic-antigen.de

The overexpression of CEA/CEACAM5 in tumors of epithelial origin is the basis of its widespread use as a tumor marker. As a result, the CEA serum levels from individuals with colorectal carcinoma, gastric carcinoma, pancreatic carcinoma, lung carcinoma, breast carcinoma, as well as medullary thyroid carcinoma, and under some non-neoplastic conditions like in ulcerative colitis, pancreatitis, cirrhosis, COPD, Crohn's disease, and in smokers are usually increased (Hammarström 1999; Horst and Wagener 2004). Also the CEACAM6 expression is significantly up-regulated in colon, lung, gastrointestinal, and pancreatic carcinomas. On the contrary, the CEACAM7 expression appears to be decreased in rectal cancer (Horst and Wagener 2004). CEACAM1 can be up-regulated or down-regulated both in the cancerous tumors. For example, in epithelial tumors of colorectal, liver, breast, prostate, bladder, and renal cancer the CEACAM1 expression level is decreased, whereas in thyroid, gastric, lung cancer as well as in malignant melanoma the CEACAM1 expression is significantly higher (Öbrink 2008). Thus, it is believed that the deregulated expression of CEA/CEACAM5, CEACAM6, CEACAM7, and CEACAM1 is able to provide important tumorigenic contributions to carcinogenesis. However, malignant tumors seem to produce so far unidentified factors that induce microvascular endothelial and lymphendothelial cells to express significant amounts of CEACAM1 (Öbrink 2008).

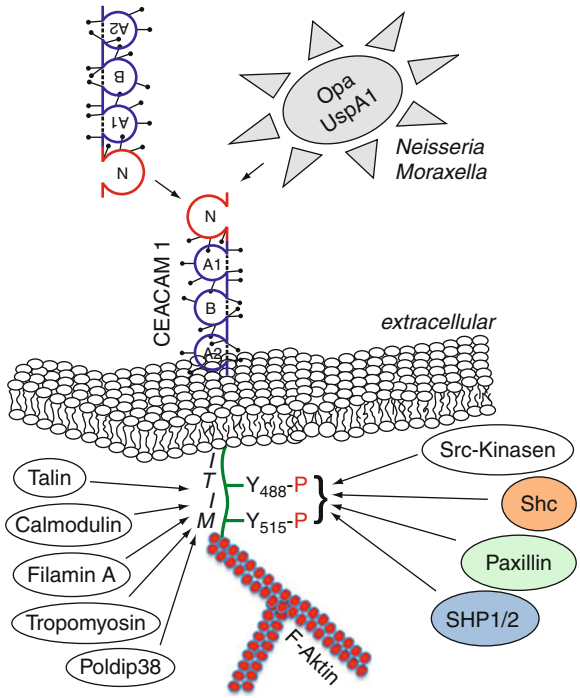
The fact that at least two distinct isoforms of CEACAM1, namely, CEACAM1-L and CEACAM1-S, are co-expressed in most if not all cell types enhances the complexity of the CEACAM1 expression

pattern. In addition, human CEACAM1 appears with cell type specific glycosylation levels altering its molecular weight from approximately 120 to 160 kDa in epithelial cells and granulocytes, respectively (Singer and Lucka 2005).

Functions Mediated by CEACAMs

Members of the CEA family trigger a broad range of diverse functions. It is well established that CEACAM1, CEA/CEACAM5, and CEACAM6 act as cell-cell adhesion molecules (Fig. 2). They mediate either homophilic adhesion (e.g., CEACAM1 to CEACAM1) or they interact heterophilically by binding to other CEACAMs (e.g., CEACAM1 binds to CEA/CEACAM5 and CEACAM6) (Öbrink 2008). CEACAM1 can bind to membrane-anchored as well as soluble CEACAMs (Öbrink. 1997). However, these intercellular adhesive bonds are rather weak and thus CEACAMs most likely represent sensor molecules at the cell surface that regulate cellular signaling. Importantly, the N-domains of CEACAMs are crucial for the homophilic and heterophilic interaction. Furthermore, the N-domains of CEACAM1, CEACAM3, CEACAM5, and CEACAM6 emerged to be pathogen receptors (Fig. 2). It was found that opacity-associated (Opa) proteins of various *Neisseria* strains, UspA1 molecules of *Moraxella catarrhalis*, and OmpP5 proteins of *Haemophilus influenzae* specifically ligate to human CEACAMs whereas the Mouse Hepatatis Virus (MHV) solely binds to murine CEACAM1 (Gray-Owen and Blumberg 2006; Slevogt et al. 2008). Furthermore, in human, CEACAM1 is a receptor for *Salmonella* and *Escherichia coli*, binds to galectin-3 and to E-selectin via its LewisX and sialyl-LewisX-epitopes latter specifically expressed in CEACAM1 of human granulocytes (Singer and Lucka 2005). It is worth noting that CEACAM ligands like microorganisms, CEACAMs, and CEACAM specific antibodies of one species are not cross-reactive with CEACAMs of any other species.

In answer to ligand binding, membrane-anchored CEACAM1 controls apoptosis, cell migration, cell invasion, morphogenesis, insulin metabolism, endocytosis, angiogenesis, lymphangiogenesis, and cell proliferation (Öbrink 2008; Singer and Lucka 2005). Hereby, CEACAM1-L, but not CEACAM1-S, appears to be decisive in mediating these cellular functions.

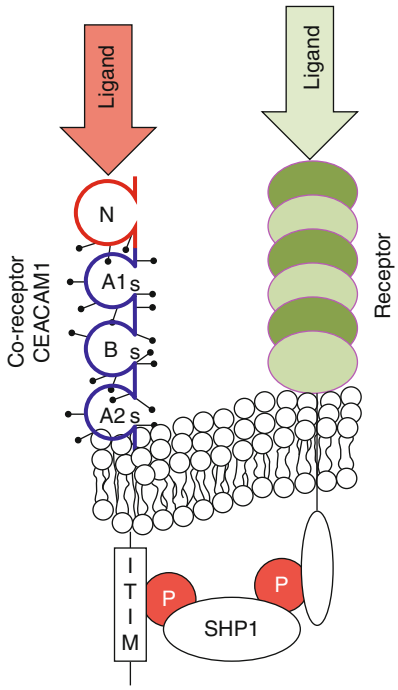


CEACAMs, Fig. 2 Overview of the extracellular ligands and intracellular interaction partners of CEACAM1-L. Precious few extracellular binding partners exist for CEACAM1. Intracellularly, many different molecules can interact with CEACAM1. Thus the evolutionary pressure toward the extracellular CEACAM1 domains should be less than toward its cytoplasmic tail. That notion could explain why CEACAMs expressed in different species share common intracellular binding partners but never extracellular ones

Thus, in epithelia, CEACAM1-L negatively triggers proliferation via its ITIM domain and maintains the post-confluent contact inhibition, whereas the disturbances of the CEACAM1-L signaling by CEACAM1-4S, CEACAM6 or CEA/CEACAM5 leads to undifferentiated cell growth and malignant transformation (Singer et al. 2010). In agreement with this finding, CEACAM6-overexpressing pancreatic adenocarcinoma cells were more proliferative, more invasive and more chemoresistant to gemcitabine compared to cells with normal CEACAM6 level (Duxbury et al. 2004). CEACAM6 and CEA/CEACAM5 also were shown to inhibit apoptosis/anoikis further emphasizing their role in promoting aberrant growth (Kuespert et al. 2006).

In immunity, CEACAM1 regulates natural killer cell inhibition, dendritic cell maturation, granulocyte survival, and T and B lymphocyte proliferation and

activation (Gray-Owen and Blumberg 2006). Also CEACAM3, CEACAM6, and CEACAM8 are crucial for the regulation of granulocyte activation. Notably, CEACAM8 (CD66b) is a widely utilized differentiation and activation marker for human granulocytes. Recently, it has been shown that several pathogens can diminish the immune response by binding to CEACAM1 on CD4+ T cells as well as in pulmonary epithelial cells via CEACAM1-L(ITIM) mediated signaling (Sadarangani et al. 2010; Slevogt et al. 2008). However, antibodies to CEACAM1 have been reported to increase or decrease T-cell activation in response to T-cell receptor cross-linkage in vitro (Singer and Lucka 2005; Gray-Owen and Blumberg 2006). This apparent discrepancy seems to reflect the different signaling capabilities of CEACAM1 to generate both stimulatory and inhibitory signals via the complex cooperation between the ratio of CEACAM1-L to -S, the equilibrium between monomers, *cis*- and *trans*-dimers, levels of phosphorylation and the interactions with intracellular and cytoskeletal molecules. In contrast, CEACAM3 harbors an immunoreceptor tyrosine-based activation motif (ITAM) within its cytoplasmic tail and is believed to function as a phagocytic receptor involved in the clearance of CEACAM-binding bacteria by human granulocytes (Sadarangani et al. 2010).



CEACAMs, Fig. 3 Initial steps of the CEACAM1-L mediated signaling. Ligation of CEACAM1-L triggers the tyrosine phosphorylation within its cytoplasmic ITIM and the recruitment of SHP-1. Subsequently, CEACAM1 can interact via SHP-1 with other receptors and modulate their signaling capacity and thus influence the functional outcome

Regulation of the Activity of CEACAMs

CEACAMs represent multifunctional adhesion receptor proteins influencing pleiotropic effects in epithelia, endothelia, and hematopoietic cells. The long isoform of CEACAM1 and some other transmembrane-anchored CEA family members can transduce signals directly via their cytoplasmic domains into the cytoplasma. Hereby, CEACAM1-L forms homodimers in a cis-configuration (Öbrink 1997). However, the GPI-linked CEACAMs have a higher lateral mobility in the plasma membrane but need to utilize transmembrane partner molecules like CEACAM1 for signaling. As an example, GPI-linked CEACAMs are able to alter the CEACAM1-L maintained post-confluent contact inhibition (Singer et al. 2010). In addition, CEACAM1-S can interfere with the CEACAM1-L mediated functions most likely via *cis*-dimerization (Öbrink 1997). Thus, the ratio of CEACAM1-L to CEACAM1-S possibly together with additionally co-expressed CEA family members seems to be decisive for the functional outcome mediated by CEACAM1 (Singer et al. 2010).

The homophilic and heterophilic adhesion of CEACAM1 and other CEACAMs as well as pathogen binding is mediated by N-terminal domain interactions (Öbrink 1997). The ligand binding induces signal cascades starting with the phosphorylation of distinct tyrosine residues within the cytoplasmic tail of the transmembrane-anchored CEACAMs (Fig. 3). Human CEACAM1 contains two ITIM in its cytoplasmic domain, whereas in rodents one CEACAM1 ITIM is replaced by an immunoreceptor tyrosine-based switch motif (ITSM) (Kammerer and Zimmermann 2010). Human CEACAM3 and probably CEACAM4, CEACAM19, and CEACAM20 carry ITAM in their cytoplasmic tails. In contrast, except for CEACAM19 and CEACAM20 no such ITAM-containing CEA family members exist in rodents. It is general accepted that the phosphorylation of the tyrosine residues within the ITIM represents the initial step of CEACAM1 mediated

signaling. CEACAM1-L can be phosphorylated by protein tyrosine kinases of the ▶ Src family, by the insulin receptor kinase (IR) and by the epithelial growth factor receptor (EGFR) (Öbrink 1997; Singer and Lucka 2005). Upon phosphorylation, CEACAM1-L can bind and activate both protein tyrosine kinases (such as c-src, lyn, and hck) and protein tyrosine phosphatases such as SHP-1 and SHP-2 (Singer and Lucka 2005).

Besides CEACAM1-L, CEACAM1-S has the potential to directly induce signal transduction. Thus, protein kinase C (PKC) can phosphorylate the serine and threonine residues of CEACAM1-S and -L (Singer and Lucka 2005). Additionally, both splice variants interact with the DNA polymerase delta-interacting protein 38 (Poldip 38) (Klaile et al. 2007) as well as with actin, talin, paxillin, and filamin A (Fig. 2) (Singer and Lucka 2005). The PKC mediated phosphorylation of CEACAM1 induces calmodulin binding to the cytoplasmic domain of CEACAM1 and as a result regulates its cis-dimerization. CEACAM1 associates also in cis with integrin αvβ3 probably to promote cellular invasion (Singer and Lucka 2005). Moreover, CEACAM3 is phosphorylated within its ITAM by Src-kinases, in particular Hck and Fgr (Kuespert et al. 2006). This phosphorylation is triggered by bacterial binding stimulating in the following the small GTPases Rac. Consequently, the pathogen becomes phagocytozed and killed. In addition, there are reports showing that GPI-anchored members of the CEA family are able to induce signal transduction. Thus, ligation of CEACAM8 leads to an activation of the extracellular signal-regulated kinase 1/2 (Erk1/2) and the overexpression of CEACAM6 leads to an increased activity of the tyrosine kinase c-Src and the serine/threonine kinase akt-1 (Singer et al. 2002; Duxbury et al. 2004). Furthermore, CEACAM6 and CEACAM8 (as well as CEACAM1 and CEACAM3) can initiate adhesion of neutrophilic granulocyte to endothelial cells most likely by activating integrins (Singer and Lucka 2005). Although it is not finally understood how GPI-anchored CEACAMs manage to kick off their signaling cascades, it is likely that they employ CEACAM1 or other transmembrane molecules for signaling.

In recent times, several groups have demonstrated that CEACAM1 acts as a co-receptor of numerous cell receptors (Fig. 3). In lymphendothelial cells membrane-bound CEACAM1 mediates pro-angiogenic functions by interfering with the vascular endothelial growth factor receptor-3 (VEGFR-3) (Kilic et al. 2007). Hereby, CEACAM1-L(ITIM) is tyrosine-phosphorylated upon VEGF treatment in a SHP-1- and Src-dependent manner. Lately, CEACAM1 was shown to be co-receptor of the VEGFR-2 regulating the VEGFR2/Akt/eNOS-mediated vascular permeability pathway and angiogenesis (Nouvion et al. 2010). Furthermore, under certain circumstances IR and EGFR are able to phosphorylate Tyr-488 of the CEACAM1-L (ITIM). Subsequently, the SH2 domain of the Src homology 2 domain-containing transforming protein 1 (Shc) can associate leading to decreased Ras/MAPK Erk1/2 pathway induction (Kuespert et al. 2006). As a result, CEACAM1 negatively regulates cell proliferation in response to insulin and EGF, respectively. Moreover, various antibodies to CEACAM1 have been reported to enhance or diminish T-cell activation in response to ligation of the T-cell receptor (TCR) (Singer and Lucka 2005). However, in activated $CD4^+$ T-lymphocytes, CEACAM1 appeared to be an inhibitory co-receptor of the TCR/▶ CD3 complex. CEACAM1-L (ITIM) phosphorylation and subsequent association with SHP-1 were identified as the initiating signaling steps. Afterward, CEACAM1 interacts via SHP1 with the TCR/CD3 complex which leads to decreased CD3-zeta, ▶ ZAP-70, and IL2-R signaling (Gray-Owen and Blumberg 2006; Sadarangani et al. 2010). Similar to its function as co-receptor for the TCR, CEACAM1 was described to function as an inhibitory co-modulator of the human B cell receptor (BCR), likely through the recruitment of SHP-1 and inhibition of the phosphatidylinositol 3-OH kinase–Akt kinase (PI3K)-promoted pathway (Lobo et al. 2009). In contrast, other studies showed that certain CEACAM1-specific monoclonal antibodies or the homophilic CEACAM1-CEACAM1 interaction strongly triggered proliferation of mouse B cells when combined with the ligation of the BCR (Greicius et al. 2003). CEACAM1 acts also as co-inhibiting receptor of the Toll-like receptor 2 (TLR2). The inhibitory effects were mediated by tyrosine phosphorylation of CEACAM1-L(ITIM) and recruitment of SHP-1, which negatively regulates the TLR2-dependent activation of the PI3K activation pathway and the initiation of the NF-kappa B–dependent inflammatory responses (Slevogt et al. 2008). Consequently, the generation and release of pro-inflammatory cytokines such as GM-CSF and IL8 were reduced. Last but not least, CEACAM1 was described to be a co-inhibitory receptor molecule for the granulocyte

colony-stimulating factor receptor (G-CSFR) regulating granulopoiesis through CEACAM1-L(ITIM) phosphorylation and SHP-1 interaction leading to decreased Stat3 activation (Pan and Shively 2010).

Summary

CEACAMs are members of the *CEA*-gene family. Nowadays, the CEACAM1 to CEACAM8 are well analyzed whereas very little is known about CEACAM9 to CEACAM21. The CEACAM1 to CEACAM8 expression pattern varies considerably in accordance with the species, the cell type, the cell growth, and activation state. Notably, the CEACAM expression is frequently deregulated in many types of cancer indicating their putative role in tumor-growth regulation. However, most membrane-bound CEACAMs function as cell-adhesion receptor molecules mediating a broad range of functions including apoptosis, cell migration, cell invasion, contact-inhibition, morphogenesis, insulin metabolism, endocytosis, angiogenesis, lymphangiogenesis, and cell proliferation. In addition, CEACAM1 was found to be a crucial co-receptor for TCR, BCR, TLR-2, IR, EGFR, G-CSFR, VEGFR-2, and VEGFR-3. CEACAM1 interacts with diverse signal transducing proteins depending on its phosphorylation stage. Some CEACAMs were also identified to bind species specific certain pathogens like *Moraxella catarrhalis* or *Neisseria gonorrhoeae*. Thus, CEACAMs seem to play a central role in controlling pathogens by the innate immune system. Furthermore, a putatively pathogen driven evolution of the *CEA* gene family could be responsible for the high variability of the number of diverse CEACAMs expressed in the different species. However, more knowledge is needed about the abundance of CEACAM1, the relative proportion of CEACAM1-L to CEACAM1-S isoforms and the appearance of further co-expressed CEACAMs to fully understand the signaling and functional potential of members of the CEA family.

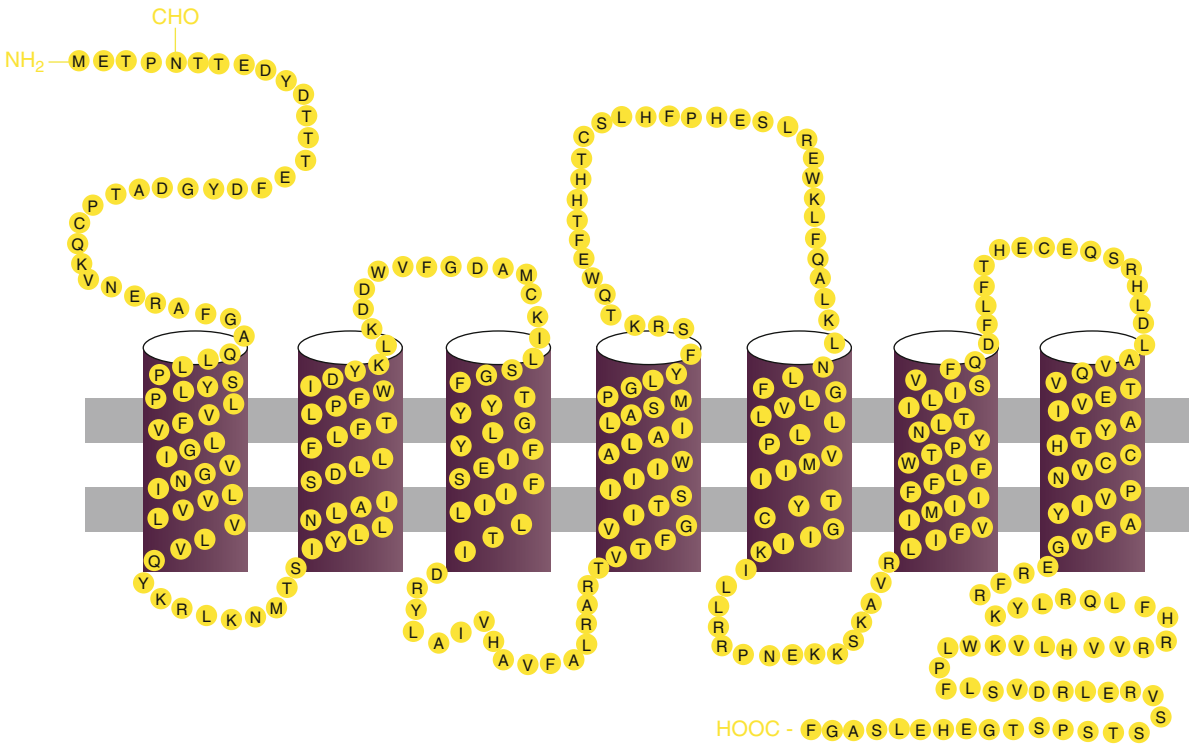
Historical Background

Although numerous reports had described specific effects of the chemokines RANTES (CCL5) and MIP-1α (CCL3) on T lymphocytes and monocytes

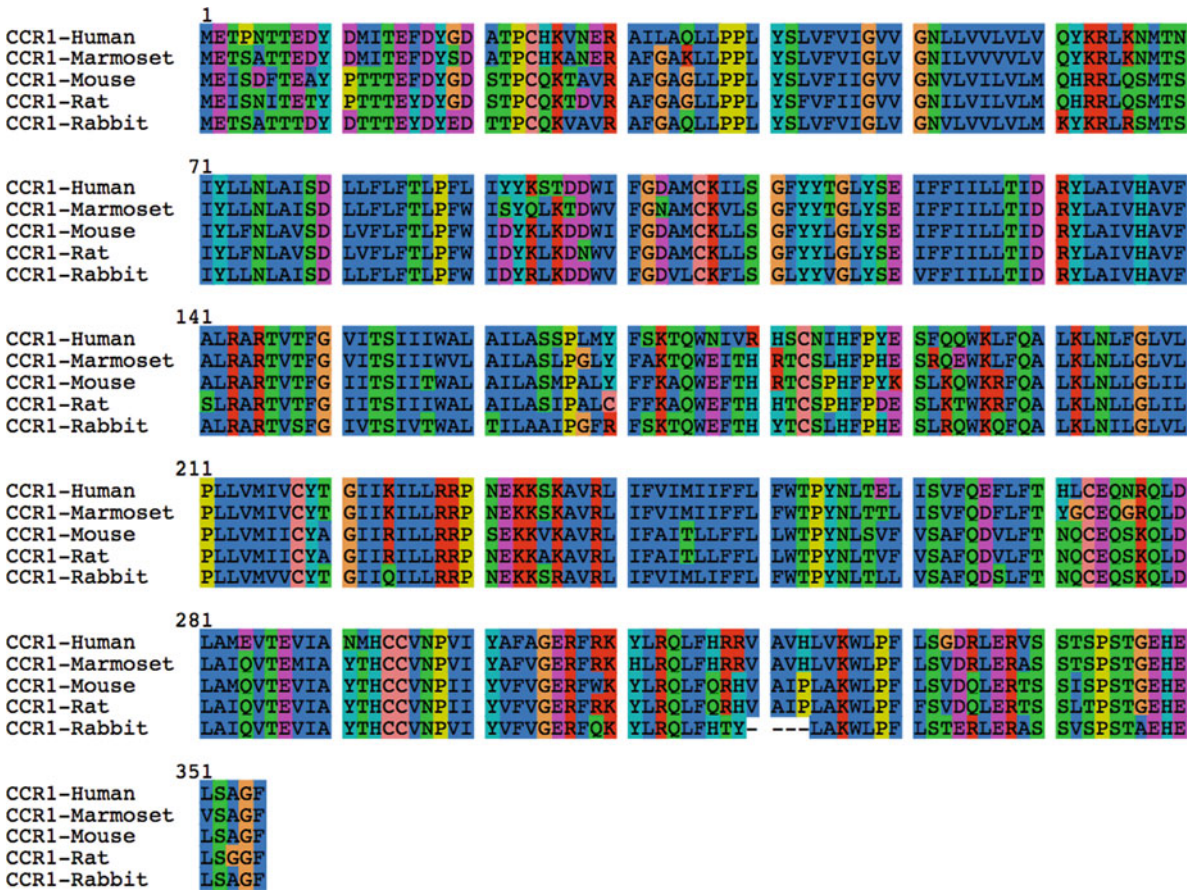


Chemokine Receptor CCR1, Fig. 1 Proposed membrane topography of CCR1. Membrane spanning alpha helices are defined based on hydropathy analysis. CHO, potential N-Linked glycosylation sites

the identity of the putative receptor for these ligands was unknown. However, cloning of this receptor was aided by the fact that the primary sequences of the C5a, fMLP, and IL-8 receptors revealed domains which were conserved in receptors associated with cell motility, but not in other seven-transmembrane-spanning receptors (Holmes et al. 1991). These similarities were exploited using polymerase chain reaction (PCR) technology to obtain several orphan receptor cDNA clones which were then expressed and screened by receptor binding and functional assays. Using this homology hybridization cloning approach, the molecular cloning and functional expression of CCR1 was reported by two separate groups (Gao et al. 1993; Neote et al. 1993). The open reading frame for human CCR1 is on a single exon and predicts a protein of 355 amino acids (Fig. 1). The gene, CCR1, is located on human chromosome 3p21. The expressed human CCR1 was able to bind CCL3 and CCL5 with high affinity and physiological concentrations of both ligands induced an increase in intracellular Ca^{2+}. CCR1 was specific for these ligands and showed a poor response to MIP-1ß (CCL4) and MCP-1 (CCL2). In addition, to these ligands CCR1 has been shown to respond with high affinity and to signal in response to a variety of other C-C chemokines including MCP-3 (CCL7), MPIF-1 (CCL23), leukotactin-1(CCL15), and HCC-1 (CCL14).

CCR1 was the first human CC chemokine receptor to be identified at the cDNA level. It has a functional viral homolog, US28, which is a human cytomegalovirus (Gao et al. 1993; Neote et al. 1993). Chemokine receptors like CCR1 are all members of the rhodopsin-like subfamily of G-protein-coupled receptors (GPCRs) (Gao et al. 1993; Neote et al. 1993). Although CCR1 was initially described as a receptor for the chemokines CCL3 and CCL5, a number of other chemokine ligands have since been identified, including CCL6, CCL7, CCL9 (MIP-1 gamma), CCL14, CCL15, CCL16 (LEC), and CCL23. Interestingly CCL6, CCL9, CCL15, and CCL23 (CKbeta-8) are initially weak CCR1 agonists but appear to be made more potent by proteolytic modification at the N-terminus during inflammatory responses in vivo.

Amino-terminal processing of chemokines can change the specificity of the ligand for its receptor.



Chemokine Receptor CCR1, Fig. 2 Alignment of the primary structures of the cloned human, marmoset, rat, mouse, and rabbitt CCR1

For example, activated human peripheral lymphocytes secrete an amino-terminal truncated form of CCL4 (3–69) with novel functional specificity for CCR1, 2, and 5 (Guan et al. 2004). This chemokine is generated by proteolytic cleavage of the full length CCL4, which has poor affinity for CCR1, by CD26 a membrane-bound ectopeptidase with dipeptidyl peptidase IV activity. The kinetics of conversion of CCL4 from intact to CCL4(3–69) in activated peripheral lymphocytes correlates with cell surface expression of CD26.

The protein sequences of CCR1 receptors from 14 different species including human, rat mouse, marmoset and rabbit have been cloned (Fig. 2). The sequences of CCR1 are highly homologous and the human receptor is 81% and 80% identical to the mouse and rat sequences, respectively. Interestingly, human CCR1 has also been proposed to have a consensus site for tyrosine sulfation, which affects the affinity and binding of some chemokine receptors to their ligand (s) and has been hypothesized to play an important role in regulating their activity (Liu et al. 2008).

CCRI plays an important role in host defense and is involved in regulating the chemotaxis of immune cells, a feature it shares in common with all chemokine receptors. Dysregulation of this response leads to autoimmunity and CCR1 has been associated with the pathophysiology of a number of diseases including rheumatoid arthritis, multiple sclerosis, transplant rejection, and allergic inflammation (Murphy et al. 2000). CCR1 activates the Gi/o class of guanine nucleotide binding regulatory proteins (Murphy et al. 2000). This activation, can in turn, regulate several effectors, including adenylyl cyclase (inhibition), phospholipase C (activation), protein kinase C (activation), calcium flux (stimulation), and phospholipase A2 (PLA2) (activation).

Not all CCR1 ligands appear to mediate the same functions. For example, although CCL3, CCL5, and CCL16 are all able to transduce signals through CCR1 in a human osteosarcoma line via Gi/Go, phospholipase C, and protein kinase Cdelta mediated pathways, CCL16 can also signal via p38 MAP kinase and in contrast to the other two ligands does not induce calcium transients. The CCR1 ligands CCL3, CCL7, CCL5, and CCL15 can all inhibit adenylyl cyclase activity in cells transiently transfected with CCR1. Of these CCR1 ligands, however, only CCL15 was unable to signal via Ga14 or Ga16 coupled pathways. In addition, most of the CCR1 ligands are promiscuous and can activate other chemokine receptors (Murphy et al. 2000).

The cytomegalovirus, which causes acute, latent, and chronic infections in humans, has been shown to encode a CCR1 homolog, US28, which strongly activates classical G-protein signal transduction networks within the cell (Gao et al. 1993; Neote et al. 1993). It can bind a number of chemokines including CCL3 and CCL5 with high affinity (Gao et al. 1993; Neote et al. 1993). In addition, US28 can signal in a ligand-independent, constitutive manner both through the Gq/phospholipase C pathway and through activation of the transcription factor NF-kappaB as well as through the cyclic AMP response element binding protein.

Regulation of Activity

In common with most GPCRs CCR1 undergoes receptor desensitization upon ligand binding (Neote et al. 1993). The mechanism involves phosphorylation of specific serines in the serine-rich carboxy-terminal tail which is mediated by G-protein receptor kinases and results in the uncoupling of the receptor from its G-protein and the recruitment of arrestin. These processes induce receptor internalization and terminate CCR1 signaling.

A series of CCR1 cytoplasmic tail mutants indicate that the phosphorylation sites for CCR1 are located in a cluster of serine and threonine residues between amino acids 340–346 (Richardson et al. 2000). Phosphorylation of these residues leads to receptor desensitization and inhibits CCL3 and CCL5-induced calcium transients and GTPase activity. Interestingly the activity of CCR1 can be independently regulated by unrelated chemokine receptors. For example in a cell line coexpressing CCR1 and CXCR2 the CXCR2 ligand CXCL8 was able to cross-phosphorylate CCR1 and desensitize its ability to stimulate GTPase activity and Ca^{2+} mobilization. Conversely CCR1 ligands were able to induce the phosphorylation and desensitization of CXCR2.

Retinoic acid has been shown to increase the expression of CCR1 in human monocytes (Ko et al. 2007). It increased calcium influx and chemotactic activity in response to the CCR1 ligands CCL15, CCL3, and CCL5 and appears to be mediated through a p38 MAPK and ERK pathway since pretreatment with inhibitors of these kinases blocked the retinoic acid-induced effects.

In an animal model of myocarditis a CCR1 antagonist, BX 471 was able to inhibit disease and improve cardiac function (Futamatsu et al. 2006). The beneficial effects of the antagonist were likely associated with its ability to block T-cell proliferation and suppress ERK1/2 and JNK activities in T cells stimulated with myosin.

Interactions with Ligands and Other Proteins

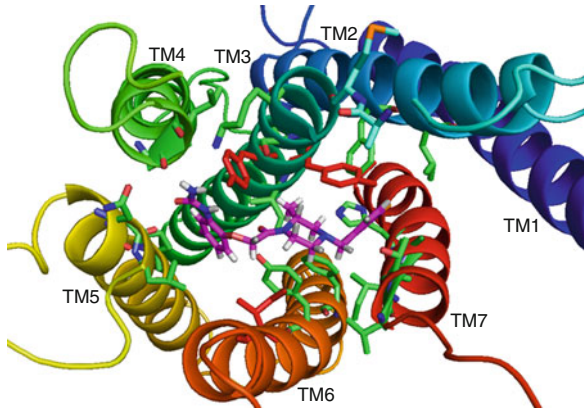
CCR1 responds to a number of protein ligands and to small molecule antagonists. The interaction of the receptor with these distinct ligands has been described in a number of studies and is very different. Structure-function studies have revealed that chemokines such as CCL3 bind to CCR1 via residues in the N-terminus and in the extracellular loops (Pease et al. 1998; Zoffmann et al. 2002). For example, a photoactivatable derivative of CCL3 labeled with a benzophenone group at the N-terminal end was used to probe contact points on CCR1 (Zoffmann et al. 2002). These studies revealed that the N terminus of CCL3 interacts in a specific manner with the second extracellular loop of CCR1, within a segment comprising amino acids 178 – 194. The chemokine receptors CCR1 and CCR3 are 54% identical in amino acid sequence and chimeras of these receptors have been used to map the CCL3 binding determinants for CCR1 (Pease et al. 1998). Using this approach, chimeras in which the N-terminal extracellular segments of the two receptors were switched were constructed. CCL3 was able to bind with high affinity to both chimeras; however, it was not able to function as an agonist with the chimeric receptors in either calcium flux or chemotaxis assays. These data are consistent with the idea that chemokines bind to their receptors via multiple extracellular binding sites which determine their selectivity and their ability to activate their receptors.

CCR1 Antagonists

In contrast, potent CCR1 antagonists like BX 471, in common with other chemokine receptor antagonists binds to CCR1 in the transmembrane domain (Vaidehi et al. 2006), similar to the transmembrane binding domain of 11-cis-retinal in rhodopsin. Through its interaction with residues in the transmembrane domain, Tyr113 and Tyr114 on transmembrane domain 3 and Ile259 on transmembrane domain 6, BX 471 induces a conformational change in the receptor that leads to displacement of bound chemokine from its extracellular binding site (Fig. 3). In contrast, when radiolabeled BX 471 is bound, CCR1 agonists are unable to competitively displace the antagonist (Vaidehi et al. 2006).

Several companies have disclosed small molecule CCR1 antagonists and a standard feature of many of these compounds is their lack of crossreactivity with non-human CCR1. This is a common problem in drug discovery for GPCRs and numerous examples abound in the literature. Drug substances that are limited in specificity to human target proteins can be problematic during drug development because they are difficult to test in surrogate animal efficacy models. Without efficacy data, it can become very difficult to justify further development of the drug given the considerable risks and costs involved.

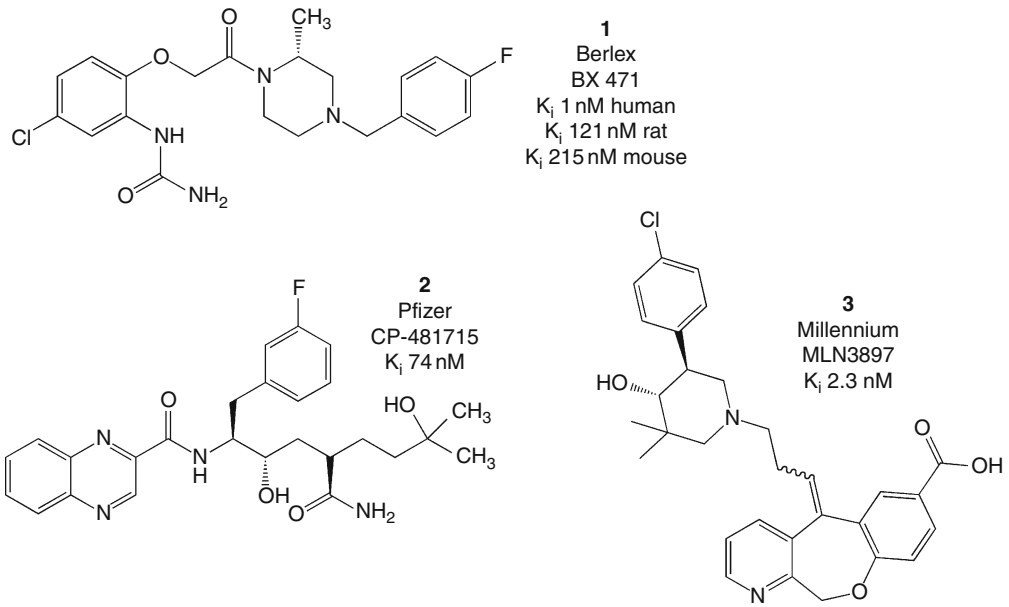
Berlex has disclosed a number of CCR1 compounds and the most advanced BX 471 is a potent diacyl piperazine more than 1000-fold selective for CCR1 (Liang et al. 2000). The antagonist has a reported K_D of 1.0 nM for human CCR1 calculated from radiolabeled binding studies. The compounds from this series also had issues with crossreactivity with rodent CCR1 (Fig. 4 compound 1) but they had sufficient affinity that they could be tested in animal models. BX 471 was efficacious in a number of mouse and rat models of disease including an acute rat experimental allergic encephalomyelitis (EAE) model of multiple sclerosis (Liang et al. 2000) a rat heart transplant model in the rat (Horuk et al. 2001) and mouse models of renal fibrosis (Anders et al. 2002) and multiple myeloma (Menu et al. 2006). Based on these data and positive phase I safety studies the CCR1 antagonist entered phase II clinical trials for multiple sclerosis in early 2004. Although the drug was well tolerated and showed no safety concerns its development was stopped after the clinical Phase II study failed to show a reduction in the number of new inflammatory central nervous system (CNS) lesions (detected by Magnetic Resonance Imaging, MRI) .



Chemokine Receptor CCR1, Fig. 3 The structure of human CCR1 predicted using MembStruk showing the BX 471 antagonist binding site predicted using HierDock. A top view of the predicted structure of BX 471 in the CCR1 binding pocket. The residues shown in red (Tyr113, Tyr114 and Ileu259) are responsible for anchoring the ligand in this cavity

Pfizer has been very active in the CCR1 field and has disclosed a number of CCR1 compounds including CP-481,715, a quinoxaline-2-carboxylic acid derivative (Gladue et al. 2003) (Fig. 4 compound 2). The antagonist has a reported K_i of 74 nM for human CCR1 calculated from displacement of radiolabeled CCL3 binding studies, and 71 nM from inhibition of Ca^{2+} transients (Gladue et al. 2003). The CCR1 antagonist is a competitive and reversible antagonist and is more than 100-fold selective for CCR1 as compared to a panel of G protein-coupled receptors including related chemokine receptors (Gladue et al. 2003). The compound successfully completed phase I safety studies and was successful in a 16 patient phase Ib clinical trial (Haringman et al. 2003). In this trial patients with active rheumatoid arthritis responded to the antagonist as demonstrated by a significant reduction in the number of macrophages and CCR1 positive cells in the synovium compared with a placebo group. A trend but no significant clinical improvements were seen in treated patients (Haringman et al. 2003). Based on these data CP-481715 entered phase II studies for rheumatoid arthritis in February 2004, however the trial was stopped after 6 weeks since although the compound was well tolerated it did not demonstrate any efficacy.

Millennium has disclosed a number of CCR1 antagonists the most advanced of which is MLN3897 (Fig. 4



Chemokine Receptor CCR1, Fig. 4 Structures of Berlex, Pfizer, and Millenium CCR1 receptor antagonists

compound 3) a substituted pyridylbenzoxepine. It demonstrated high affinity binding for CCR1 (K_i 1.2 nM) and had an IC_{50} of 3.4 nM for the inhibition of chemotaxis induced by CCL3. The compound was effective *in vivo* and demonstrated an EC_{50} of 0.03 mg/kg in inhibiting CCL3 induced immune cell recruitment in a guinea pig skin sensitization model (Pharmacokinetic studies revealed that it had a half-life of 3 h in rat and oral bioavailability of 35% in rat and 100% in dog. In 2004, Millennium announced that they were in phase I clinical trials with MLN3897 and the major indications appeared to be rheumatoid arthritis, multiple sclerosis and psoriasis. In November 2007, Millennium announced that they were terminating the development of MLN3897 for rheumatoid arthritis because it failed to reach its clinical endpoint in a phase II trial. Millennium, along with partner Sanofi-Aventis is assessing the next steps for the program.

Regulation of Concentration

CCR1 has been reported to be regulated by a number of factors including cytokines, lipopolysaccharide, statins, substance P, and estrogen amongst others.

CCR1 activity is coordinately regulated by cytokines like GM-CSF and IL-2. For example, although CCR1 is constitutively expressed on murine neutrophils, almost no expression is seen on human cells. However the mRNA for CCR1 is rapidly upregulated in cells that have been treated with the cytokine GM-CSF, and these cells, but not untreated neutrophils, respond to the CCR1 ligands CCL3 and CCL5 in chemotaxis and intracellular calcium mobilization assays . Freshly isolated CD45RO + lymphocytes cultured for 10 days with IL-2 migrated in response to the CCR1 ligand CCL5 while control cells cultured in the absence of the cytokine did not. This functional response of these cells correlated to an induction of mRNA for CCR1 in the cytokine-treated cells.

Interestingly recent work shows that proinflammatory signals can also deactivate normally functional chemokine receptors and turn them into decoy receptors. Treatment of dendritic cells with LPS + IL-10 showed high expression of CCR1 and other CC chemokine receptors. However, these receptors were unable to elicit migration in response to their ligands. Similar results were obtained for monocytes exposed to activating signals and IL-10. Thus, in an inflammatory environment, IL-10 generates functional decoy receptors on DC and monocytes, which act as molecular sinks and scavengers for inflammatory chemokines.

In addition to their lipid-lowering effects statins have potent anti-inflammatory properties and part of this can be ascribed to their ability to modulate

chemokine and chemokine receptor activity. *In vitro* experiments on human vascular endothelial cells and human primary macrophages. revealed that simvastatin significantly reduced CCL2 in endothelial cells and macrophages stimulated with TNF-alpha or IFN-gamma, respectively. Messenger RNA analysis revealed that expression of the chemokines CCL2, CCL3, and CCL4, as well as the chemokine receptors CCR1, CCR2, CCR4, and CCR5, was decreased by simvastatin, both in endothelial cells and macrophages. The statin effects were reversed by mevalonate and mimicked by the geranylgeranyl transferase inhibitor, whereas the farnesyl transeferase inhibitor had no effect. These results suggest that statins act via inhibition of the geranylgeranylation of proteins.

Neuropeptides like substance P play an important role in the active communication between the nervous and immune systems. A recent study revealed the modulatory effect of substance P on chemokine production and chemokine receptor expression in primary mouse neutrophils. Substance P induced both the mRNA and protein expression of the chemokines CCL3 and CXCL2 in neutrophils and upregulated their receptors CCR1 and CXCR2. This stimulatory effect on chemokine and chemokine receptor expression in neutrophils was further found to be neurokinin-1 receptor specific.

It is well established that estrogens appear to be beneficial in reducing relapses in patients with multiple sclerosis. This protective effect of the hormone may be partly due to its effects on the expression of chemokines and chemokine receptors as revealed by a recent study{Matejuk, 2001 #7003}. In EAE protected mice, 17 beta-estradiol strongly inhibited the mRNA expression of a number of chemokines including CCL3 and CCL5, and of the chemokine receptors CCR1, CCR2, and CCR5. Conversely, ovariectomy, which abrogated basal 17 beta-estradiol levels and increased the severity of EAE, enhanced the expression of CCR3 that were over-expressed by inflammatory mononuclear cells. Elevated expression of CCR1 and CCR5 by lymph node cells was also inhibited in 17 beta-estradiol treated mice with EAE. These results suggest that the beneficial effects of 17 beta-estradiol are mediated in part by strong inhibition of recruited inflammatory cells, resulting in reduced production of inflammatory chemokines and cytokines in CNS.

Major Sites of Expression

CCR1 is widely expressed in both immune and nonimmune cells (Murphy et al. 2000). Expression of this receptor has been observed in airway smooth muscle cells in the lung suggesting a possible role in asthma, in both normal neurons (Hesselgesser and Horuk 1999) and in dystrophic neurons from patients with Alzheimer's dementia (Halks-Miller et al. 2003), in astrocytes (Tanabe et al. 1997), which suggests a role in inflammation in the CNS, in endothelial cells which can be induced to chemotax in response to CCL23 and may play a role in angiogenesis, and in multiple myeloma cells and osteoclasts (Moller et al. 2003; Oba et al. 2005) hinting at a role for CCR1 in bone cancer. CCR1 is also abundantly expressed on immune cells, including monocytes, memory T cells, basophils, dendritic cells (Gao et al. 1993; Murphy et al. 2000; Neote et al. 1993) and is induced by GM-CSF in neutrophils.

Phenotypes

CCR1-deficient mice generated by targeted gene disruption have revealed that CCR1 has a number of non-redundant functions in host defense and inflammation. The role of CCR1 in host defense has been examined in a number of studies. In the first study when CCR1 knockout mice were challenged with Aspergillus fumigatus, a fungus controlled mainly by neutrophils, they showed an increase in mortality. Interestingly, knockout animals in the same study showed a 40% reduction, compared to their wild-type littermates, in the size of lung granulomas induced by intravenous injection of Schistosoma mansoni eggs. In another study CCR1 knockout mice were challenged with the obligate intracellular protozoan parasite Toxoplasma gondii. In comparison with parental wild-type mice, knockout mice showed an increased mortality to T. gondii in association with an increased tissue parasite load. The increased mortality appeared to be correlated to a reduction in the trafficking of neutrophils to inflamed areas in the knockout mice during early infection.

The role of CCR1 in host defense was further examined in a model of viral-induced neurologic disease. Intracerebral infection of mice with mouse hepatitis virus results in an acute encephalitis followed by a chronic demyelinating disease similar in pathology to that observed in multiple sclerosis. Although no increase in mortality was observed during the acute phase of disease following infection by 21 days

post-infection, 74% of CCR1 knockout mice had died compared to only 32% mortality of wild-type mice. The CCR1 knockout mice appeared to have a reduction in T-cell accumulation within the CNS during acute, but not chronic, disease. However, despite this other components of the immune response appeared to be unaltered in the knockout mice Despite the reduction in T-cell trafficking into the CNS of CCR1 knockout mice during acute disease, components of host defense such as T-cell effector functions including cytolytic activity and proliferation and the expression of IFN-gamma remained unaltered. These findings suggest that T-cell and macrophage trafficking are not dependent on CCR1 and suggest a non-redundant role for CCR1 in promoting survival during chronic mouse hepatitis virus infection.

Both CCR1 and one of its ligands, CCL3, appear to be important for protection against infection with paramyxovirus pneumonia virus in mice. Infection of wild-type mice with the virus results in pulmonary neutrophilia and eosinophilia accompanied by local production of CCL3. Mice deficient in CCL3 or its receptor, CCR1 showed an attenuated inflammatory response to the virus with limited neutrophil trafficking and no eosinophils detected in bronchoalveolar lavage fluid. This was accompanied by a higher rate of mortalitry compared to wild-type mice. These results suggest that the CCL3/CCR1-mediated acute inflammatory response protects mice by delaying the lethal events of infection.

CCR1 also appears to play an important role in the pathopysiology of disease. In an animal model of inflammation CCR1 knockout mice were protected from pulmonary inflammation secondary to acute pancreatitis. The protection from lung injury was associated with decreased levels of cytokines such as TNF-alpha suggesting that the activation of the CCR1 receptor is an early event in the systemic inflammatory response syndrome. CCR1 also appears to be involved in remodeling after myocardial infarction. Studies with CCR1 deficient mice revealed that when myocardial infarction was induced, although initial infarct areas and areas at risk did not differ between groups, the infarct size increased in wild-type mice compared to CCR1 deficient animals. This attenuation in infarct expansion was associated with preserved left ventricular function and was accompanied by an altered post-infarct inflammatory pattern characterized by diminished neutrophil infiltration, accelerated monocyte/lymphocyte infiltration, decreased apoptosis, increased cell proliferation and earlier myofibroblast population in the infarcted tissue. This reduction in functional impairment and structural remodeling after myocardial infarction in CCR1 knockout animals suggests a role for this receptor in cardiac disease.

Since CCR1 appears to be expressed in demyelinating lesions in patients with multiple sclerosis and neutralization of one of its ligands, CCL3, is protective in a relapsing remitting model of multiple sclerosis in mice the role of the receptor was examined in a myelin oligodendrocyte glycoprotein (MOG) induced model of disease in mice. After immunization with MOG nearly all of the wild-type animals developed disease with a clinical score of 2.5. In contrast CCR1 deficient mice showed a decreased incidence to disease, less than 55%, and the severity of those with disease was reduced by around 50% with a clinical score of 1.2. In addition there were elevated levels of mRNA for the chemokines CCL2 and CCL5 in the CNS of wild-type animals compared to CCR1 deficient animals.

While there is no question that CCR1 gene deletion studies in mice have been extremely useful in illuminating the role of this receptor both in normal and in pathophysiology we need to exercise some caution in extrapolating these studies for human CCR1. It is known that the immune system in rodents can be very different from that in humans. For example CCR1 is expressed constitutively in mouse neutrophils whereas it is inducible in human neutrophils (Murphy et al. 2000). Thus it is likely that the role of this receptor will be somewhat different in rodents than in humans when responding to an attack by pathogenic organisms. In addition, although CCR1 knockouts hint at a role for CCR1 in diseases like multiple sclerosis the fact that there is not a total abrogation of the disease in CCR1 deficient animals suggests that there is some redundancy in the system and this might partly account for the failure of a number of CCR1 antagonists in clinical trials.

Summary

CCR1 was the first human CC chemokine receptor to be identified at the cDNA level. It has a functional viral homolog, US28, which is a human cytomegalovirus (Gao et al. 1993; Neote et al. 1993). Although CCR1 was initially described as a receptor for the

chemokines CCL3 and CCL5 a number of other chemokine ligands have been described, some of which are generated from weak agonists by proteases during inflammatory responses in vivo. The ligands of many of the chemokine receptors, including those of CCR1, can also act as agonists on other chemokine receptors and this ligand redundancy has made it difficult to successfully therapeutically target these proteins. In humans, CCR1 is expressed in a variety of cell types including monocytes, memory T cells, basophils, dendritic cells, platelets, neurons, and astrocytes (Gao et al. 1993; Neote et al. 1993; Weber et al. 2001) and is induced by GM-CSF in neutrophils. Since CCR1 appears to play role in host defense and inflammation it represents a potential target for therapeutic intervention in a variety of clinically important diseases including rheumatoid arthritis, multiple sclerosis, transplant rejection, and allergic inflammation. Several companies have disclosed small molecule CCR1 antagonists and a number of these have been tested in clinical trials, for multiple sclerosis, rheumatoid arthritis, psoriasis, and endometriosis. Disappointingly, however, none of these approaches reached their clinical endpoints and the programs were all halted.

CCK(A) receptor; CCK1; CCK-A receptor; CCKA; CCKAR; CCK-AR; Cholecystokinin receptor 1; Cholecystokinin type A receptor; Cholecystokinin-1 receptor: CCK-1 receptor; Peripheral type CCK receptor

Historical Background

The hormone cholecystokinin (CCK) was discovered in 1928 by Ivy and Oldberg, based on its ability to stimulate gallbladder contraction. Fifteen years later, Harper and Raper described a factor capable of stimulating pancreatic exocrine secretion (pancreozymin). When Jorpes and Mutt finally isolated the CCK peptide from porcine duodenum in 1966, it became clear that this single hormone was responsible for both of these classical physiological gastrointestinal regulatory activities. Many years later, in 1992, the receptor mediating these effects was finally identified and characterized as a family A guanine nucleotide-binding protein (G protein)-coupled receptor, the CCK-1 receptor (Liddle 1994). Of interest, the cDNA encoding this receptor was initially cloned and described in the same issue of the *Proceedings of the National Academy of Sciences, USA,* as the structurally closely related CCK-2 receptor (see the following chapter on this receptor). The CCK-1 receptor has subsequently been recognized as having multiple effects on tissues including gallbladder, pancreas, gut, and neurons in the periphery and central nervous system, with most of these effects related to maintenance of nutritional homeostasis. This includes optimization of the digestive milieu, regulation of the rate of transit of intestinal chyme for optimal nutrient absorption, and the control of appetite. Indeed, this receptor has become the target of substantial efforts by pharmaceutical companies to develop an agonist drug that might be useful in the treatment of obesity as a noncaloric satiety agent.

Tissue Distribution and Physiological Actions of CCK-1 Receptors

The distribution and functions of CCK receptors differ among species, with much of the fundamental physiologic studies having been performed in rats, mice, guinea pigs, and dogs in the period of time before the CCK receptor genes had been cloned. Now that the molecular nature of the two types of CCK receptors have been established, and highly specific and sensitive assays for their presence and activity are now in place, the role of the CCK-1 receptor in human physiology can be better established. Human tissues with established physiological functions for the CCK-1 receptor include gallbladder smooth muscle,

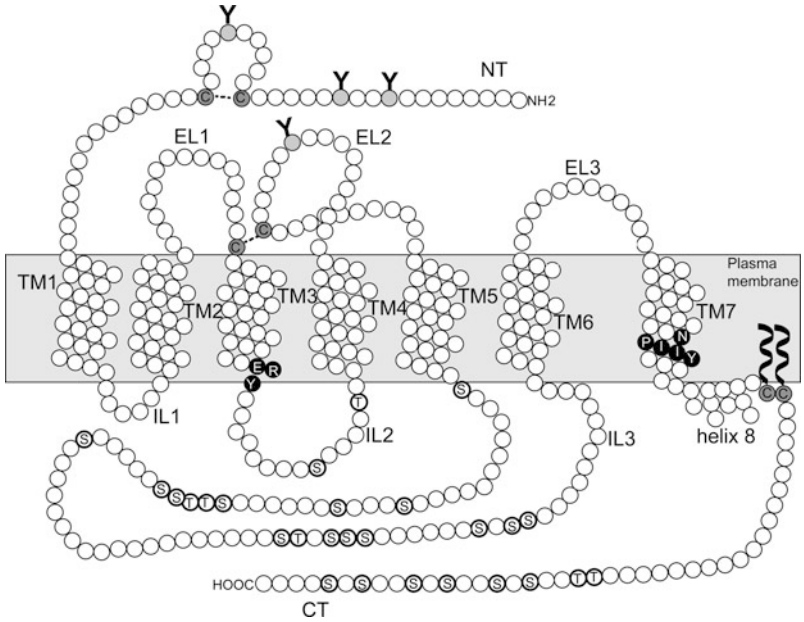
pancreatic neurons (and low levels of expression on acinar cells), gastric and intestinal smooth muscle, vagal afferent neurons, and distinct central nervous system nuclei (Noble et al. 1999). These targets are involved in the normal physiologic stimulation of gallbladder emptying, stimulation of pancreatic exocrine secretion, regulation of gastric emptying and bowel transit, and induction of postcibal satiety. These functions naturally follow from the distribution and secretory pattern of the hormone that activates them. CCK is produced in I cells scattered within the mucosa of the proximal small intestine, and is secreted into the bloodstream in response to luminal nutrients, such as protein and fat. These complex nutrients require micelle formation (fat), digestion (protein and fat), and regulated enteric transit of chyme for optimal absorption. CCK is also produced in some neurons where it can have neurocrine effects. Other possible effects of this hormone on CCK-1 receptors expressed on healthy cells, with less clearly established physiological roles, include stimulation of the secretion of somatostatin from gastric D cells and secretion of pepsinogen and leptin from chief cells, trophic effects on the exocrine pancreas, and the regulation of secretion of insulin, pancreatic polypeptide, and somatostatin from the pancreatic islets.

Structure of CCK-1 Receptors and Molecular Basis of Ligand Binding

The CCK-1 receptor is a typical peptide-binding receptor in the rhodopsin-β adrenergic family (family A) of G protein-coupled receptors (Miller and Gao 2008). It contains seven transmembrane helical segments that form a helical bundle within the plasma membrane, glycosylated extracellular loop and amino-terminal tail domains, a conserved disulfide bond linking cysteine residues at the top of transmembrane segment 3 with a cysteine in the second extracellular loop, an intradomain disulfide bond linking two cysteine residues within the amino-terminal tail region, phosphorylated intracellular loop and carboxyl-terminal tail domains, and palmitoylated cysteine residues beyond the seventh transmembrane segment that help to form a membrane-associated intracellular eighth helical segment region (Fig. 1). This receptor includes the signature sequences typical of this receptor family, including the D/ERY motif at the cytosolic face of transmembrane segment 3 and the NPxxY motif in transmembrane segment 7. The glycosylation of this receptor appears to help with its normal folding during biosynthesis and to protect the receptor against proteolytic cleavage. The cytosolic sites of phosphorylation are on serine and threonine residues within the second and third intracellular loop and carboxyl-terminal tail domains, representing targets of protein kinase C, a signaling kinase activated by CCK action, as well as by action of a G protein-coupled receptor kinase (Klueppelberg et al. 1991).

The natural peptide agonist ligand for the CCK-1 receptor binds at the extracellular surface of this receptor, with key determinants within loop and amino-terminal tail epitopes (Miller and Gao 2008). This has been well established in receptor truncation and mutagenesis studies, chimeric receptor studies, ligand structure-activity studies, and photoaffinity labeling studies. The latter represent the most direct evidence for mode of docking, and have been performed to establish spatial approximation constraints involving six of the seven residues within the focused pharmacophoric domain of this hormone, as well as the amino-terminal region of the hormone just outside this domain. Of note, analogous studies with the CCK-2 receptor have suggested a distinct mechanism for the binding of the same peptide to that receptor, with the possibility that the carboxyl terminus of CCK dips down within the helical bundle of the CCK-2 receptor. It is noteworthy that the structure-activity characteristics for peptide binding and activation of the two types of CCK receptors are quite distinct, with the CCK-1 receptor requiring the carboxyl-terminal heptapeptide-amide of CCK for high-affinity binding and activation, while only the carboxyl-terminal tetrapeptide-amide is required for the CCK-2 receptor. With gastrin sharing the carboxyl-terminal pentapeptide-amide with all CCK peptide species, it is clear that both gastrin and CCK bind and activate the CCK-2 receptor with high affinity and potency, while only CCK peptides have these actions at the CCK-1 receptor.

For the CCK-1 receptor, in addition to the orthosteric natural peptide hormone-binding site, there is an allosteric ligand-binding pocket within the intramembranous helical bundle that is the site of docking a series of small molecule benzodiazepine ligands. This pocket has been shown to be totally distinct from the CCK-binding site using classical



Cholecystokinin-1 Receptor, Fig. 1 Shown is a schematic diagram of the primary structure of the human CCK-1 receptor, with the seven transmembrane helices (TM) shown within the gray area representing the plasma membrane and the extracellular amino-terminal tail (NT) and loop (EL) regions above the membrane and the intracellular loop (IL) regions, helix 8 and carboxyl-terminal tail (CT) regions below the membrane. Also identified are sites of glycosylation ("Y" structures), disulfide bonds (S-S), and sites of palmitoylation (*curved lines*). Sites of phosphorylation (S and T) are present in the intracellular loop and tail regions. Conserved D/ERY and NPxxY motifs are also shown in their positions in the cytosolic face of TM3 and the end of TM7

manipulations, such as the ability of natural ligand to accelerate the dissociation of receptor-bound benzodiazepine (Gao et al. 2008). Molecular models also support the separate and distinct nature of the peptide and non-peptidyl small molecule binding sites within the CCK-1 receptor.

Signaling at the CCK-1 Receptor

The classical pathway of signaling stimulated by natural agonist action at the CCK-1 receptor is mediated via coupling with heterotrimeric G proteins in the G_q family (G_q, G_{11}, and G_{14}), involving the rapid hydrolysis of phosphatidylinositol bisphosphate by phospholipase C enzymes (principally β isoforms) to generate inositol trisphosphate and diacylglycerol. This results in calcium mobilization from intracellular stores and the subsequent activation of various isoforms of protein kinase C (Williams 2001). High concentrations of CCK can also stimulate coupling of this receptor with G_s, with subsequent activation of adenylate cyclase, increase in cAMP, and activation of protein kinase A, although the physiologic nature of this signaling pathway is not clear. There have also been reports of CCK acting through this receptor to stimulate mitogen-activated protein kinases (MAPKs). These include extracellular signal-regulated kinases 1 and 2 (ERK 1 and ERK 2), c-jun kinases (JNKs), and ERK 5 and p38 MAPK. These signaling events are downstream of the G protein coupling events. Phosphatidylinositol 3-kinases (PI 3-kinases), p125-focal adhesion kinase (FAK), and Janus kinases (JAKs) are also activated by CCK action on this receptor. Current understanding of the linkage and interrelationship of these signaling molecules has been reviewed elsewhere (Williams 2001; Cawston and Miller 2010).

In addition to association with the classical proximal mediator of signaling, representing coupling of the heterotrimeric G proteins with the CCK-1 receptor, this receptor is also known to associate with arrestin molecules. Arrestin binding to a G protein-coupled receptor can occur as a result of agonist binding with signaling kinase action leading to phosphorylation of the receptor, as well as direct interaction of arrestin

with non-phosphorylated portions of the receptor. Arrestin is a known multifunctional adapter protein that can contribute to receptor endocytosis and to signaling events in the cell, including some of those described above (Whalen et al. 2011).

Biochemical and Cellular Regulation of the CCK-1 Receptor

Like most G protein-coupled receptors, the CCK-1 receptor is regulated by both biochemical and cellular mechanisms to protect the cell from overstimulation (Miller and Gao 2008). Indeed, hyperstimulation through this receptor is the basis for one of the most frequently used animal models of pancreatitis, in which very high doses of the CCK analogue caerulein is administered and results in fusion of the zymogen granules with the lateral (rather than the apical) plasmalemma and release of these enzymes into the pancreatic parenchyma where they become activated and initiate autodigestion of this organ and surrounding tissues. The most common biochemical mechanism of regulation of this receptor involves phosphorylation. This occurs exclusively on serine and threonine residues within the intracellular loops and carboxyl-terminal tail domains. The earliest and most sensitive phosphorylation events result from activation of protein kinase C. Of interest the phosphorylation of key protein kinase C substrates within the third intracellular loop has been shown to produce a conformational change that makes the second loop accessible for its phosphorylation and for its interaction with cellular regulatory molecules. Higher concentrations of CCK also stimulate the slower action of a G protein-coupled receptor kinase that adds to the phosphorylation of this receptor. These phosphorylation events have been shown to interfere with the normal coupling of this receptor with its G proteins. Presumably, this also contributes to arrestin association, known to effect such disruption of coupling.

Because the natural agonists for the CCK-1 receptor are hydrophilic peptides that are unable to cross the lipid bilayer, internalization of the receptor is another very effective mechanism for desensitization in which the hormone is unable to bind to and stimulate the receptor. Indeed, the agonist occupation of this receptor has been shown to result in the internalization of this receptor, with clathrin-dependent endocytosis representing the major pathway (Roettger et al. 1993). In CHO cell lines, potocytosis into caveolae has also been described. Another interesting cellular mechanism for desensitization that has been described was identified as insulation in which the receptor is moved into a highly specialized plasmalemmal domain that is devoid of G proteins for coupling with the receptor. These cellular regulatory mechanisms are typically slower of onset and slower to reverse than the biochemical mechanisms described above.

Clinical Relevance of the CCK-1 Receptor

The CCK-1 receptor has been implicated in mediating some of the intestinal dysmotility responsible for abdominal crampy pain and abnormal bowel habits in irritable bowel syndrome, as well as the gallbladder inertia and incomplete gallbladder emptying found in cholesterol gallstone disease. It has also been proposed as playing a role in the reduced satiety and increased food consumption present in some patients with obesity and obesity-related medical disorders. Indeed, it is the latter that has stimulated most of the work by pharmaceutical companies to develop noncaloric agonists of this receptor as a means for inducing satiety and reducing food intake.

There has also been substantial work focused on CCK receptors in neoplastic diseases (Reubi et al. 1997). This follows the established trophic effects of this hormone on target tissues that are mediated by these receptors. Indeed, many epithelial cancer cell lines have been described to express CCK-1 and/or CCK-2 receptors, or misspliced variants of these receptors (Korner and Miller 2009). The major cancers that can express the CCK-1 receptor include pancreatic ductal adenocarcinoma, colorectal carcinoma, meningiomas, and some neuroblastomas. Antagonists of this receptor are being studied to examine their potential therapeutic role in pancreatic cancer. Additionally, reagents directed to this receptor may have an imaging, staging, or stratification role for these tumors.

Summary

The CCK-1 receptor is physiologically quite important for normal digestion, bowel transit, and appetite

control, all roles key for normal nutritional homeostasis. Additionally, this receptor plays various roles in common gastrointestinal disorders, including irritable bowel syndrome and gallstone disease, as well as likely contributing to the development of obesity and potentially playing a therapeutic role in this disorder and in obesity-related medical diseases. It also can be expressed on various cancers, where agents targeting this receptor can be used in diagnosis, staging, stratification, and possibly also treatment.

Synonyms

The cholecystokinin-B receptor

Historical Background

With the availability of modern biochemical and molecular techniques developed in the 1980s and 1990s, it was possible to characterize and clone the two cholecystokinin receptors known today. They are now identified as the cholecystokinin-1 (CCK-1) and the cholecystokinin-2 (CCK-2) receptor subtypes.

In this review entry, we will summarize what we now know about the CCK-2 receptor. More specifically, we will discuss its biochemical characterization, its organ localization, its functions in normal organs, its role in cancer along with the intracellular signaling routes used to relay its messages. References to the other cholecystokinin receptor are given in the preceding chapter.

Biochemical Characterization

Initially, the CCK-1 receptor was known as the CCK_A receptor (A for alimentary) and the CCK-2 receptor as the CCK_B receptor (B for brain). This reclassification of the CCK receptor subtypes occurred recently based on recommendations from the International Union of Pharmacology Committee regarding receptor nomenclature and drug classification.

These two receptors can be differentiated by their respective affinity for CCK and gastrin, their respective natural agonist. Indeed, the CCK-1R binds and responds to sulfated CCK with a 500–1,000-fold higher affinity or potency than sulfated gastrin or nonsulfated CCK. On the contrary, the CCK-2R binds and responds to gastrin and CCK with almost the same affinity or potency, and discriminates poorly between sulfated and nonsulfated agonists (Dufresne et al. 2006). The CCK-2R gene has been cloned in five

different species (human, rat, mouse, dog, and rabbit). According to published data, the human CCK-2R has 90% identity to the rat and canine receptor. The predicted mouse CCK-2R shares 87% and 92% amino acid identity with the human and rat receptor, respectively. The rabbit CCK-2R protein exhibits 93–97% amino acid similarly with corresponding cDNA identified in human, canine and rat brain or stomach. In general, the CCK-2R cloned from different species exhibits a comparable high affinity for the agonists CCK-8 and gastrin-17-1 with IC50 in the nM range. On the contrary, it has a higher affinity for its specific antagonist, L-365,260 (IC_{50} around 10 nM) than for the CCK-1R antagonist L-364,718 (IC_{50} around 1 μM). Finally, as opposed to the CCK-1R, the CCK-2R binds to a single class of high affinity sites with a K_D in the range of 0.2–2.0 nM (Morisset 2005).

Localization

The presence and cellular localization of a receptor in a specific organ can be detected and determined by at least five different techniques: agonist- or antagonist-binding studies, RT-PCR, Western blot, immunological staining, and autoradiography. Of these five, the Western blot and the immunological staining techniques are the most reliable and informative on the presence of the receptor and its specific localization if the specificity of the antibodies used has been carefully evaluated. However, so far, the nonquantitative RT-PCR technique has been the major method of analysis. This technique is indeed very sensitive but there is always this possibility that the message levels detected could be extremely low and therefore, may not translate into the expression of functional levels of receptors. The autoradiography technique with a radioactive ligand seems the least sensitive while the binding technique mostly used cell membrane preparations. All five techniques can be used for receptor detection but cellular localization can be most efficiently and accurately revealed by immunological staining and confirmation with Western blot using preferably the same antibody. Therefore, to relate a physiological response to a specific receptor's occupation, we need to know that the receptor is there and that it is really localized on the cell where the physiological response originates from in the target organ.

The CCK-2R was mainly found throughout the central nervous system in areas that parallel the distribution of CCK and gastrin immunoreactivity and mRNAs. Samples from rat brain tissue allowed the detection of CCK-2R mRNA. Mature forms of the receptor mRNA were identified in cerebral cortex, hypothalamus, and hippocampus. Moreover, a truncated form of the receptor was identified in all regions of the brain studied (Jagerschmidt et al. 1994). Using the PCR amplification technique, the CCK-2R was also identified in the brain, but also in the stomach, pancreas, small intestine, liver, colon, spleen, lung, thymus, ovary, breast, prostate, testes, adrenals, and kidneys, as opposed to what was observed previously (Morisset 2005).

CCK binding sites were also identified on rat adipocyte membranes and their occupation lead to the control of leptin release (Attoub et al. 1999). In the adrenal glands, CCK-stimulated aldosterone release was related to occupation of both CCK subtypes in rats, but exclusively through CCK-2R occupation in humans (Mazzocchi et al. 2004). In normal esophagus, the CCK-2R has been revealed by RT-PCR and localized to columnar epithelia within the glandular and lower crypt regions of the mucosa by microautoradiography (Haigh et al. 2003).

Even though the CCK-2R was first identified in the brain, historically it was originally cloned by Kopin through the expression of a canine parietal cell cDNA library and isolation of a cDNA clone encoding a 453-amino-acid protein.

Although there is no doubt that the CCK-2R is present in the stomach, its precise location at the cellular level still presents some controversies depending on the technique used for detection. By RT-PCR, the receptor was identified in rat and mice antrum mucosae, and in the fundus by Northern blot analysis. By in situ hybridization, the CCK-2R was present only on parietal cells during the perinatal period in rats and mainly in ECL cells in adult rodents (Waki et al. 1998). This absence of CCK-2Rs on rat adult parietal cells was confirmed by Fluo-CCK-8 binding studies which located the receptor only on ECL cells co-localized with histidine decarboxylase (Bakke et al. 2001). These data contradict the cloning data of Kopin performed on a 95% pure isolated canine parietal cell preparation, but contamination with only a few ECL cells could be enough to give one CCK-2R clone.

Adding to the confusion about CCK-2R localization in the stomach, immunohistochemistry and electron

microscopy studies performed with polyclonal antibodies to human gastrin indicate, on one hand, that gastrin binding sites were found in the guinea pig stomach on parietal and chief cells but much less on ECL and somatostatin cells (Tarasova et al. 1996). On the other hand, using an antibody raised against the C-terminal decapeptide of the CCK-2R, it was found that undifferentiated rat gastric epithelial cells express CCK-2R. Furthermore, other epithelial cells in the progenitor zone of the adult gastric gland also expressed the receptor and among them were the parietal, chief, and ECL cells (Tommeras et al. 2002).

In the pancreas, we encountered the same location problems as in the other organs with the usual techniques used. Indeed, from whole human pancreas and isolated acini, RT-PCR amplified both receptor subtypes mRNA but the receptor protein could not be identified. On the contrary, this CCK-2R has been detected in the pig pancreas by Northern blot analysis as well as in the whole human and rat fetal and adult pancreas and isolated islets; this finding was confirmed by Western blot analysis and by immunohistochemistry with a precise location on islet somatostatin cells (Julien et al. 2004). Binding studies with labeled G-17 confirmed the presence of high affinity sites on dog pancreatic acini (Fourmy et al. 1984). A similar situation was found in guinea pig pancreas with the same technique (Yu et al. 1987) and on rat acini by immunofluorescence (Morisset 2005). Such a location on pancreatic delta cells was also confirmed in six different species, the calf, pig, horse, rat, human, and dog. However, with a different antibody, the receptor was also localized on human islet glucagon cells. The only other location observed for the CCK-2R in the pancreas by immunofluorescence besides the somatostatin cells was on the ductal cells in the young calf and adult cow (Morisset 2005).

By comparing and analyzing all these data using different techniques, we can easily ascertain that technology has not yet been successful in helping us localize this CCK-2R in any tissues at the cellular level. We therefore need to produce more specific receptor antibodies which will have to be certified for their specificity by different laboratories using the same technique of immunohistochemistry for cellular localization and Western blot for protein detection. When this is elucidated, it will be much easier to definitively associate this receptor occupation with a cellular physiological response.

Physiological Response to the CCK-2 Receptor Occupation

The stomach remains one of the main targets of gastrin, and the CCK-2R expressed in this organ is an important part of the system that regulates functions of the gastric epithelium. Two main pathways of activation of stomach secretion by gastrin have been proposed: direct and indirect. Direct implies the gastrin action on parietal and chief cells while indirect means that the gastrin effect is mediated by histamine stored and released by the enterochromaffin-like (ECL) cells of the mucosa. According to Bakke (2001), the indirect effect of gastrin via the ECL cells would prevail for the control of acid secretion since they could not locate the CCK-2R on parietal cells. Since these data were obtained by fluorescence CCK-8 binding, they will have to be confirmed by immunofluorescence or immunocytochemistry. Studies performed in gastrin-CCK double KO mice to study control of acid secretion via the CCK-2R are of limited use since acid secretion in such a case becomes only controlled by cholinergic vagal stimulation (Tarasova et al. 1996).

Besides being involved in the control of acid secretion, the occupation of the CCK-2R was also associated with proliferation of the gastric mucosa, especially during lactation in rats (Takeuchi and Johnson 1987). Gastrin was also described as a growth factor for the small intestine and colon. However, an elaborate study performed in fed rats using relatively high doses of pentagastrin for 5 days did not have any major effect on DNA synthesis in the stomach, duodenum, and colon, nor on the total organ weight of these three organs and their total DNA contents (Solomon et al. 1987). Furthermore, more recently, it was shown that gastrin elicited increased DNA synthesis in ECL cells but failed to do so in parietal cells. This increased DNA synthesis was preceded by phosphorylation and activation of MAP kinase as well as *c-fos* and *c-jun* gene expression only in the ECL cells (Kinoshita et al. 1998). These data clearly indicate that occupation of the CCK-2R can induce growth in this specific subpopulation of gastric cells and suggest that gastrin could act to promote commitment or differentiation of stomach precursor cells. The presence of the CCK-2R on the proliferating progenitor cell population remains to be confirmed.

As indicated earlier in this review, the location of the CCK-2R in the pancreas of mammals as well as humans remains an unsolved situation which should be

addressed soon. Indeed, in recent literature, we can observe that the human pancreatic acinar cells lack functional responses to CCK and gastrin (Ji et al. 2001), while a more recent study (Murphy et al. 2008) clearly claimed a secretory response of purified human pancreatic acinar cells to CCK. However, when the human CCK-2R receptor is either transfected in purified human acinar cells or present in the murine pancreas via transfection using the elastase promoter, both models exhibited amylase release from their respective acini in response to CCK and gastrin (Ji et al. 2001; Saillan-Barreau et al. 1998). This indicates that the acini of these preparations can respond to CCK-2R activation when the receptor is present and that it can use the cell's intracellular machinery leading to enzyme release.

The implication of the CCK-2R in the control of pancreas growth and regeneration via its agonist gastrin is far from being established. However, pentagastrin, given to pregnant rats, was found to be the most potent factor, with hydrocortisone, responsible for fetal pancreas growth as its effect was blocked by the specific CCK-2R antagonist L-365,260. The fetal rat pancreas also expressed gastrin whose expression disappeared early after birth (Morisset et al. 2004). Furthermore, after pancreatitis induction in rats, significant overexpression of the CCK-2R mRNA was observed quite early during the destruction period as well as during early regeneration; the presence of caerulein was however constantly needed for prolonged expression of the receptor (Morisset and Calvo 1998). Recent data obtained in transgenic CCK-2R mice with CCK-2R overexpression in pancreatic acinar cells supported the possibility of this receptor being involved in pancreas growth as significant increases were observed in pancreas weight and areas occupied by the exocrine cells. Further increases in pancreatic weight were observed when these rats were bred with insulin-gastrin transgenic mice to achieve continuous stimulation of the acinar cells overexpressing the CCK-2R (Morisset et al. 2004). With regard to the human pancreas, even though Tang claimed that the CCK-2R are distributed all over the exocrine pancreas as established by phosphorimaging detection, it remains that no one has yet established first, that the CCK-2Rs are present at any other location than on the endocrine delta cells and second, that the human pancreas did not show any sign of regeneration after partial pancreatectomy. Since we and others have shown that the pig pancreas can regenerate after partial pancreatectomy, perhaps we should use this species as a model to study pancreas regeneration (Morisset et al. 2004). However, prior to initiating such studies, it is mandatory that we clearly establish the location of this CCK-2R in human and pig pancreas to secure the pig model.

Role of CCK-2R in Cancer

The expression of both CCK receptor subtypes in human gastrointestinal cancers remains poorly documented and is still of controversial nature. From a potential therapeutic point of view, it is very important to ascertain which CCK receptors are present on gastrointestinal tumors. Indeed, these receptors might act in concert with oncogenes to promote neoplastic transformation or contribute to tumor invasiveness. The presence of a known receptor may offer the opportunity to use receptor antagonists or a cytotoxic toxin linked to a stable ligand of this receptor as an adjunct in the treatment of a target cancer.

As an example of the confusion existing on the presence of CCK-2R on specific tumors, one study indicated that this receptor, evaluated by RT-PCR, was not detected in esophageal cancers (Clerc et al. 1997), while its presence was confirmed with gastrin in 100% of patients with Barrett's metaplasia and in 70% of patients with esophageal adenocarcinomas. This suggests that an autocrine signal could be involved in the pathogenesis of Barrett's metaplasia before development of dysplasia and cancer. Does this mean that this receptor disappears during cancer development?

Controversy also exists on the presence of the CCK-2R on gastric cancer cells. The receptor and gastrin were detected in some human gastric adenocarcinoma by immunohistochemistry while detected in only 7% of gastric cancer samples by RT-PCR or by receptor autoradiography. To amplify the doubt, another study, using the RT-PCR technique, claimed that seven out of eight specimens of gastric adenocarcinomas express the receptor (Clerc et al. 1997).

Data on the presence of the CCK-2R in colon cancer are less controversial. Indeed, by autoradiography the CCK-2R was either rarely or not at all expressed in colorectal cancer in one study, while found in only two out of 12 colon adenocarcinoma samples by RT-PCR in another study. In this organ, however, isoforms of the CCK-2R were detected, the short and longer forms. The short form, also called CCK-C, was detected in

100% of the tumors tested along with gastrin mRNA. This truncated form does not discriminate between amidated and glycine-extended forms of gastrin, and since the colonic adenocarcinomas synthesize progastrin but fail to process the prohormone, this prohormone could be the specific agonist of this receptor and thus be the intracrine growth factor in human colorectal cancer (Biagini et al. 1997). It thus becomes important to search for this receptor type in any other type of gastrointestinal cancers, and the presence of this new subtype may be the reason why so few CCK-2Rs were detected in colon cancer, we were not looking for the appropriate one.

The pancreatic tumors are no different than the others as some authors have failed to find transcripts of the CCK-2R at the mRNA level whereas others reported expression. A CCK-C receptor was also characterized in human pancreatic cancer (Smith et al. 2002). However, it is not yet clear if this newly reported pancreatic CCK-CR is comparable to the one reported in the colon. Although some authors claimed that the CCK-2Rs were present in all pancreatic carcinomas, others reported their occasional presence in gastroenteropancreatic tumors with rare expression in ductal pancreatic carcinoma (Morisset et al. 2004). However, when the CCK-2R is transfected in pancreatic acinar cells of the murine pancreas along with the already present CCK1R, its new presence seems to play a key role in the development of pre- and neoplastic lesions in the pancreas of these mice (Clerc et al. 2002). The new feature of this experimental approach is the simultaneous expression of CCK-1 and CCK-2Rs in the same cell. Could this result in novel signaling secondary to receptor cross talk and/or heterodimerization of these receptors? We could expect potentiation of signal transduction, and heterodimerization may represent a new mechanism for modulation of these receptors which may lead to cancer development.

The presence of both CCK receptor subtypes in cancer cell lines is not a negligible phenomenon, as we will see. Furthermore, the expression of CCK receptors in cancer cell lines has mostly given rise to controversial reports with regard to their type and density.

In SEG-1 cells, a human esophageal adenocarcinoma cell line, RT-PCR has established the presence of the CCK-2R receptors responsive to gastrin for their growth with growth inhibition by L-365,260, the specific CCK-2R antagonist. However, one study on esophageal cancers reported expression of low levels of CCK-2R mRNA with the CCK-1Rs being overexpressed (Morisset 2005).

In AGS-B cells, a human gastric carcinoma cell line expressing the CCK-2R, amidated gastrin G-17 was associated with increased DNA synthesis which was inhibited by the L-365,260 antagonist. This cell line could be derived from the 7% of the gastric cancer samples expressing the CCK-2R (Morisset 2005).

Contrary to the rare incidence of CCK receptors in colon cancer as seen above, it seems that some colorectal carcinoma cell lines Colo 320, HCT 116, LoVo, and the immortalized mouse colon cell line YAMC express the CCK-2R as they respond to gastrin for their growth and tumorigenicity. However, such cell lines are believed to be the exception because, as for tumors, most colorectal carcinoma cell lines do not express gastrin/CCK-2 receptors or the CCK-1Rs (Baldwin and Shulkes 1998). In general, however, expression of the CCK-2R isoform is always coupled with co-expression of the gastrin gene in GI tumor cell lines, implying the presence of a gastrin/CCK-2R autocrine loop. If there is any involvement of peptides of the CCK and gastrin family in the development of colon cancer, it could be through glycine-extended gastrin and progastrin as high concentrations of these two peptides have been observed in colon tumors and in blood of patients with colorectal cancer. The receptor for these peptides was described but never cloned (Dufresne et al. 2006).

In non-GI tract tumor cell lines, co-expression of gastrin and CCK-2R was not found, except in the lymphoblastic leukemia cell line Molt 4 which also expresses the receptor's isoform. High CCK-2R density and incidence was reported in medullary thyroid carcinomas, small cell lung cancers, and stromal ovarian cancers; leiomyo-carcomas express both CCK-R subtypes (Dufresne et al. 2006).

In some pancreatic cell lines of ductal origin, a gastrin autocrine loop involving the CCK-2R exists as in the MIA PaCa-2 cells but such is not the case in the PANC-1 cells possessing also the CCK-2R (Morisset et al. 2004). In these same two cell lines, transfection of both CCK-R subtypes led to inhibition of their growth by CCK-8, a result which contradicts what was previously observed in these same cells. Would it be possible that overexpression of these CCK-Rs leads to inhibition of their growth? In the

rat AR4-2J cells, an acinar cell line which expresses both CCK-R subtypes, a trophic response to gastrin has been shown which is coupled to CCK-2R occupation (Scemama et al. 1989). In BxPC-3 human cancer cells, the expression of the recently characterized CCK-CR was confirmed as its specific antibody resulted in growth inhibition (Smith et al. 2002). In the RIN-14B cells, a pancreatic somatostatin endocrine cell line, the presence of both CCK-Rs was revealed by Western blot and immunofluorescence; in these cells, occupation of both receptors by caerulein and gastrin led to somatostatin secretion, while cell growth was inhibited during stimulation of the CCK-1R (El-Kouhen and Morisset 2010). The message which can be drawn from these studies on cancer cell lines driven from any type of cancer is that it is very important to establish what kind of CCK-Rs are present and if there is any type of autocrine loop existing involving both specific agonists, CCK and gastrin. The other major observation remains that cancers in situ or cancer cell lines are unique in their growth control and that each typical cancer cell could respond to a specific chimiotherapeutic treatment depending on the intracellular signaling systems activated by the agonist.

Intracellular Signaling Pathways

Besides mutations of specific genes often causing cancer development, activation of intracellular signaling pathways by occupation of hormones and growth factor receptors in an unregulated way can be part of the tumor growth and invasiveness processes.

Occupation of the CCK-2R by gastrin is no exception and results in activation of a variety of cell-type–specific transduction pathways involved in proliferation. Among them are phospholipase C, c-src-like tyrosine kinases, p125 FAK, phosphatidylinositol 3-kinase and the MAPK, ERK and p38 kinases (Rozengurt and Walsh 2001).

Besides proliferation, malignant transformation also results in loss of epithelial differentiation, acquirement of mesenchymal characteristics, and increasing invasive and metastatic potential. Gastrin and the CCK-2R seem to be involved in epithelial-mesenchymal transition, and this process could involve p60-src. PI-3-kinase and ERK1/2 activation for periods of up to 4 h, leading to reduced association between E-cadherin, $p120^{CTN}$, and β-catenin resulting in loss of cell adhesion and scattering (Bierkamp et al. 2002).

How can we now reconcile the growth-promoting effect of gastrin via occupation of its CCK-2R on different cancer cells with recent observations indicating that gastrin through this same CCK-2R can prevent rather than promote colorectal carcinogenesis via activation of the MAPK/ERK/AP-1 pathway and inhibition of NF-κB (Muerkoster et al. 2005)? Furthermore, how to explain this other finding that occupation of the CCK-2R in CHO and Swiss 3T3 cells activated similar intracellular signals with opposite growth effects. The reason given was that it depends on the cell model (Detjen et al. 1997).

With so many conflicting data on the effects of gastrin through occupation of its CCK-2R regarding growth and intracellular signaling pathways activated, it seems that all of these controversies come from the choice of the cell line selected to perform these studies and whether they possess the CCK-2 receptor or that it has been transiently or stably transfected. Indeed, we can list these cell lines: the MDCK cells, the CHO cells, the Swiss 3T3 cells, the COS-7 cells, the AR42J cells, the Colo 320 cells, the Lovo cells, the SW707 cells, and the HCT-115 cells, among others. It is believed that in order to have a clear image of the effects of gastrin on cancer cell growth and transformation through CCK-2R occupation, all the different signaling pathways involved in these processes should be studied in one selected cell line preferably expressing the CCK-2R. In doing so, it will then be possible to assign pathways to different responses happening in the cell leading to cancer development, growth control, and invasiveness.

Summary

The message to be stretched out of this review is that a lot of uncertainty still exists on the location and roles played by this CCK-2R on normal and tumoral cells. In order to clarify the existing dilemmas, we need, as scientists, to set up standard protocols to be followed using well-accepted techniques and tools which everybody agrees on. In this way, it will then be possible to clearly establish which organ or tumor expresses the receptor and on which specific cell it is operating. With all this new knowledge, we shall be able to clearly establish the physiological roles of this receptor on normal cells and possibly target or use the receptor for chemotherapy on tumor cells, if applicable.

Synonyms

CKIP-1 (CK2 interacting protein-1); JBP (c-Jun-binding protein); OC120 (osteoclast maturation-associated gene 120 protein); PLEKHO1 (pleckstrin-homology domain containing, family O member 1)

Historical Background

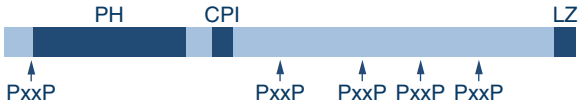
CKIP-1 (CK2-interacting protein-1) was initially described on the basis of its interactions with protein kinase ▶ CK2 (Bosc et al. 2000). In this respect, the first publication on CKIP-1 described isolation of a cDNA encoding this novel protein from a human B-cell cDNA library using a yeast two-hybrid screen to identify interaction partners of protein kinase CK2. Interactions between CK2 and CKIP-1 were confirmed by co-immunoprecipitation experiments and in vitro interaction assays using recombinant and in vitro translated proteins. Prior to that report, a partial cDNA encoding its C-terminal 72 amino acids had been isolated from a mouse embryo cDNA library, using a yeast two-hybrid screen to identify interaction partners for the leucine-zipper region of the c-Jun transcription factor (Chevray and Nathans 1992). Collectively, these reports suggested that the primary functions of CKIP-1 were mediated by interactions with other proteins within cells. Since these initial reports, subsequent studies have reinforced that suggestion by demonstrating that CKIP-1 interacts with a number of other cellular proteins.

Domain Structure and Architecture

The human CKIP-1 cDNA encodes a protein of 409 amino acids with an N-terminal pleckstrin-homology (PH) domain and a C-terminal domain containing a putative leucine zipper (Fig. 1). The central region that separates the PH domain and leucine zipper contains a significant number of proline residues including P-X-X-P motifs that may be involved in protein interactions and S-P or T-P motifs that could be sites of phosphorylation for proline-directed protein kinases such as ▶ MAP kinases or cyclin-dependent kinases (CDKs). Homologs of CKIP-1 in other species, including mouse, rats, chickens, and zebrafish contain the same general domain structure and a reasonably high level of conservation. For example, the deduced protein sequences of mouse, chicken, or zebrafish CKIP-1 display approximately 90%, 80%, and 60% identity to human CKIP-1, respectively. Independent reports have demonstrated that CKIP-1 has the capacity to form leucine-zipper-mediated dimers, an event that may regulate interactions with other cellular partners (Zhang et al. 2007; Tokuda et al. 2007)

Regulation of CKIP-1

While a detailed understanding of its regulation remains incomplete, a number of potential mechanisms for



CKIP-1, Fig. 1 Schematic illustration of the domain structure of CKIP-1. The pleckstrin homology (*PH*) domain, capping protein interaction (*CPI*) motif, and putative leucine zipper (*LZ*) are indicated. *P-X-X-P* motifs that may also be involved in protein: protein interactions are also marked

controlling the activity of CKIP-1 have been reported. These mechanisms include both changes in its level of expression and posttranslational mechanisms. In terms of changes in its level of expression, CKIP-1 has been shown to be up-regulated during muscle differentiation (Safi et al. 2004) and to be induced by cytokines (Zhang et al. 2007). Posttranslational mechanisms include ▶ PI 3-kinase-dependent interactions between its PH domain and phosphatidylinositol 3-phosphate in the plasma membrane (Safi et al. 2004). By comparison, independent studies have demonstrated that CKIP-1 is constitutively localized to the plasma membrane and exhibits relatively nonspecific interactions with membrane phospholipids raising questions about its precise interactions with phosphatidylinositols (Olsten et al. 2004). It does not appear that the PH domain of CKIP-1 is exclusively involved in interactions with membrane phospholipids. In this respect, the PH domain of CKIP-1 has also been shown to be important for interactions with some of its protein partners, including ▶ CK2 and Akt (Olsten et al. 2004; Tokuda et al. 2007). In addition to its localization to the plasma membrane, it has also been reported that CKIP-1 can be localized within the cytoplasm and the nucleus of cultured cells (Bosc et al. 2000; Litchfield et al. 2001; Xi et al. 2010). In one instance, CKIP-1 has been identified as a substrate for caspase 3 following the induction of apoptosis (Zhang et al. 2005). In this situation, a C-terminal fragment of CKIP-1 is translocated to the nucleus where it represses AP-1 activity, presumably through interactions with c-Jun. An additional mechanism that may contribute to its regulation in cells is phosphorylation (Zhang et al. 2005; Zhang et al. 2006).

Biological Functions of CKIP-1

Based on its domain structure and absence of obvious sequence similarities to known catalytic domains, it has been proposed that CKIP-1 could be an adaptor protein or targeting protein that participates in cellular events through interactions with other cellular proteins (Litchfield et al. 2001; Canton et al. 2005; Canton and Litchfield 2006). Following its identification as a ▶ CK2-interacting protein (Bosc et al. 2000) and putative partner for the leucine zipper of the c-Jun transcription factor (Chevray and Nathans 1992), additional partners for CKIP-1 were identified (Fig. 2). CKIP-1 interacting proteins included other protein kinases such as ATM (Zhang et al. 2006) and Akt (Tokuda et al. 2007). As was the case with CK2, CKIP-1 was shown to recruit a proportion of ATM to the plasma membrane. Other interaction partners for CKIP-1 include the heterodimeric actin capping protein comprised of CPα and CPβ (Canton et al. 2005; Canton et al. 2006; Hernandez-Valladares et al. 2010; Takeda et al. 2010), interferon-induced proteins IFP35 and Nmi (Zhang et al. 2007), and Smurf1 that is a HECT-type ubiquitin ligase involved in SMAD protein regulation in the bone morphogenetic protein (BMP) pathway (Barrios-Rodiles et al. 2005; Lu et al. 2008).

In view of its relatively diverse collection of binding partners, it is perhaps not surprising that CKIP-1 appears to participate in a variety of biological events (Fig. 2). In this respect, when it is expressed in cells under the control of an inducible promoter, increased expression of CKIP-1 promotes changes in cell morphology and the actin cytoskeleton, presumably through its interactions with the actin capping protein (Canton et al. 2005). Through its induction by cytokines and interactions with IFP35 and Nmi, CKIP-1 has also been implicated in cytokine signaling (Zhang et al. 2007). Since interfering with activation of the ▶ PI 3-kinase pathway or the expression of CKIP-1 in C2C12 cells blocks differentiation, it appears that CKIP-1 is a component of ▶ PI 3-kinase-regulated muscle differentiation (Safi et al. 2004). Additional involvement with the ▶ PI 3-kinase pathway comes from the demonstration that increased CKIP-1 expression results in impaired growth of tumor cells in vitro and in mouse Xenografts that is accompanied by inactivation of Akt (Tokuda et al. 2007). In addition to its involvement in these events, there is mounting evidence demonstrating that CKIP-1 has an important role in bone homeostasis (Lu et al. 2008), a function that may relate to its designation as an Osteoclast Maturation-Associated Gene (i.e., OC120). Through its interactions with Smurf1, CKIP-1 promotes an activation of the ubiquitin ligase

CKIP-1, Fig. 2 Interaction partners for CKIP-1 and consequences of interaction. Additional detail is presented in the text

CKIP-1 PARTNER	FUNCTION	CONSEQUENCES OF INTERACTION
Akt	protein kinase	inhibition of Akt/PI3 kinase pathway
ATM	protein kinase	membrane recruitment
CK2	protein kinase	membrane recruitment
CPα/CPβ	F-actin capping	regulation of actin cytoskeleton/morphology
IFP35/Nmi	interferon-inducible	modulation of Akt/PI3 kinase pathway
Smurf1	ubiquitin ligase	increased activity & Smad 1/5 degradation

activity of Smurf1. Furthermore, in CKIP-1 deficient mice, a decrease in Smurf1 activity is accompanied by an age-dependent increase in bone mass. Additional confirmation of its role in bone formation comes from studies where bone mass was enhanced in rats in response to targeted delivery of CKIP-1-specific siRNA to osteogenic cells in rats (Zhang et al. 2012).

Summary

Since its original characterization as a CK2-interacting protein and as a putative partner for the leucine zipper of the c-Jun transcription factor, additional partners for CKIP-1 have been characterized. In conjunction with the identification of its partners, CKIP-1 has been implicated in a number of distinct biological events. Although it would appear that a comprehensive understanding of CKIP-1 and its regulation and functions is far from complete, its involvement in processes such as muscle differentiation, tumor growth, and bone homeostasis suggests that a detailed understanding of CKIP-1 could ultimately yield novel approaches for preventing or treating disease. It can also be envisaged that the involvement of CKIP-1 in processes that underlie human health and disease will spur more attention on its regulation and functional properties. Challenges for the future include efforts to elucidate its high-resolution structure, comprehensive identification of its cellular partners, and thorough evaluation of its expression levels at both gene and protein levels during development and in response to different stimuli. Collectively, this information will yield a more precise understanding of CKIP-1 and its role in biological processes that could ultimately instruct efforts to target its activity for the prevention or treatment of diseases such as cancer or musculoskeletal disorders.

Historical Background

CLEC-1 is a C-type lectin-like molecule. Based on its protein sequence, it is predicted to be a type 2 transmembrane protein with an N-terminal cytoplasmic tail, a single transmembrane domain and a C-terminal extracellular C-type lectin-like domain, that is separated from the transmembrane domain by a short stalk region. The cytoplasmic domain contains a tyrosine residue within the sequence YSST, which may represent a novel signaling motif (Fig. 1). CLEC-1 is encoded within the natural killer gene complex on human chromosome 12 and mouse chromosome 6 in a cluster of genes termed the Dectin-1 cluster, which also includes MICL, CLEC-2, CLEC12B, CLEC9A,

CLEC-1, Fig. 1 Alignment of the cytoplasmic domains of mouse, rat, and human CLEC-1. The human CLEC-1 cytoplasmic domain contains a single tyrosine residue in the sequence YxxT. The mouse and rat CLEC-1 cytoplasmic domains each contain two tyrosine residues in the sequence YxxT x_{13} YxxT. Several serine and threonine residues are also present and could be phosphorylation sites

Dectin-1, and LOX-1. Like other Dectin-1 family members, CLEC-1 is predominantly expressed by dendritic cells, endothelial cells, monocytes, and macrophages. Expression of CLEC-1 is downregulated by inflammatory stimuli and increased by immunoregulatory mediators. Recently, a role for CLEC-1 in immune tolerance has been proposed. CLEC-1 lacks the conserved residues that mediate calcium coordination and sugar binding in classical carbohydrate-binding C-type lectins, suggesting that CLEC-1 may not have a carbohydrate ligand. Currently, there are no known ligands for CLEC-1.

CLEC-1 Expression

Human *CLEC-1* is transcribed in placenta, lung, and bone marrow (Colonna et al. 2000). Lower expression levels are found in thymus and heart, and very low levels are also detected in pancreas, kidney, bladder, prostate, testis, ovary, small intestine, and colon (Colonna et al. 2000). The wide tissue distribution of human *CLEC-1* transcription is also found in the rat, with high levels of expression in spleen, kidney, lung, lymph node and aorta, moderate expression in liver, heart, muscle and brain, and low expression levels in bone marrow, thymus, and testis (Thebault et al. 2009; Flornes et al. 2010). At the protein level, rat CLEC-1 is strongly expressed in lung, moderately expressed in spleen and heart, and weakly expressed in thymus, consistent with the transcript expression distribution (Thebault et al. 2009).

At the cellular level, human *CLEC-1* is transcribed in unstimulated dendritic cells (DC) and in DC stimulated with lipopolysaccharides (LPS), tumor necrosis factor alpha (TNF-α), or by CD40-CD40 ligand interaction (Colonna et al. 2000; Sobanov et al. 2001). High levels of human *CLEC-1* transcripts are also detected in endothelial cells (unstimulated and LPS-stimulated human umbilical vein endothelial cells (HUVEC)) (Sobanov et al. 2001). *CLEC-1* is weakly expressed in primary human monocytes (Colonna et al. 2000) and in the U937 human monocytic lymphoma cell line following LPS stimulation (Sobanov et al. 2001). No expression was detected in peripheral blood mononuclear cells, granulocytes, B, T, or NK cells (Colonna et al. 2000).

In the rat, *CLEC-1* is expressed in concavalin-A stimulated blasts, DC, peritoneal macrophages, B cells, granulocytes, and LAK (IL2-stimulated NK cells or lymphokine-activated killers) (Thebault et al. 2009; Flornes et al. 2010). Low-level rat-*CLEC-1* transcription is detected in $CD4^+$ and $CD8^+$ T cells, RNK16 (NK cell line), and an endothelial cell line (Thebault et al. 2009; Flornes et al. 2010). Rat CLEC-1 is observed at the cell surface of bone marrow-derived DC, macrophages, and endothelial cells (Thebault et al. 2009). However, in transfected COS cells (Colonna et al. 2000) and transfected HUVEC (Sobanov et al. 2001), CLEC-1 is located intracellularly. Immunofluorescence studies demonstrate that CLEC-1 accumulates in perinuclear regions of the transfected cells (Sobanov et al. 2001). These observations raise the possibility that CLEC-1 may need to associate with a second molecule to be expressed as a transmembrane protein at the cell surface. Certain C-type lectin molecules such as CLEC4E interact with adaptor proteins in the plasma membrane, and this interaction is required for efficient cell-surface expression (Yamasaki et al. 2008). It is unclear whether CLEC-1 has a similar requirement, but it does not have a charged residue in its predicted transmembrane region, and such associations are typically mediated by charge-charge interactions within the plasma membrane.

Regulation of CLEC-1 Expression

As discussed above, *CLEC-1* expression is induced in human monocytic U937 cells following LPS stimulation (Sobanov et al. 2001). However, in rat bone marrow–derived DC, *CLEC-1* expression is reduced by LPS, interferon (IFN) gamma, or poly (I:C) treatment after 48 h (Thebault et al. 2009). IFN-γ and LPS treatment also significantly reduce *CLEC-1* expression in human aortic endothelial cells and human monocyte–derived DC, respectively. In contrast, treatment with IL10 or TGF-beta increases *CLEC-1* expression

in rat bone marrow–derived DC and human monocyte-derived DC. Furthermore, IL10 and TGF-beta are able to inhibit the LPS-induced downregulation of *CLEC-1* expression in human monocyte–derived DC (Thebault et al. 2009).

In a model of rat allograft tolerance, CLEC-1 has been shown to be overexpressed on PECAM-1^+ endothelial cells of tolerated allografts compared with allografts that are chronically rejected or syngeneic grafts (Thebault et al. 2009). In vitro and in vivo induction of CLEC-1 expression in the endothelial cells of tolerated allografts is dependent upon alloantigen-specific regulatory $CD4^+CD25^+$ T cells from tolerant recipients, involving a cell contact-dependent mechanism. $CD4^+CD25^+$ T cells from naive rats are not able to upregulate *CLEC-1* in allograft endothelial cells in vitro, and neither regulatory $CD4^+CD25^+$ T cells from tolerated recipients nor T cells from naive rats can induce CLEC-1 expression on syngeneic grafts in vivo (Thebault et al. 2009). Therefore, regulatory $CD4^+CD25^+$ T cells from tolerant recipients that accumulate in allografts may be able to regulate the expression of CLEC-1 in donor-specific endothelial cells.

CLEC-1 is an Orphan Receptor

There are no known endogenous or exogenous ligands for CLEC-1. Unlike classical C-type lectins which contain conserved residues that mediate the coordination of calcium, which is involved in sugar binding, CLEC-1 is a C-type lectin-like receptor that lacks these conserved residues and so is unlikely to have a carbohydrate ligand. CLEC-1 may bind to protein ligands, as has been shown for other C-type lectin-like molecules, including CLEC-2 (Watson and O'Callaghan 2005; Suzuki-Inoue et al. 2006; Suzuki-Inoue et al. 2007; Christou et al. 2008), NKG2D (Bauer et al. 1999; Cerwenka et al. 2000; Diefenbach et al. 2000) and CD94/NKG2A/B (Braud et al. 1998). CLEC-1 belongs to the Dectin-1 family of C-type lectin-like receptors, which are encoded in the natural killer gene complex on human chromosome 12 and mouse chromosome 6 ((Sobanov et al. 2001); reviewed in (Kanazawa 2007; Huysamen and Brown 2009)), and Dectin-1 is able to bind to fungal β-glucans (Brown and Gordon 2001) in a calcium-independent manner and so has a different mode of sugar binding to the classical C-type lectins (Adachi et al. 2004, Brown et al. 2007). A carbohydrate ligand for CLEC-1 cannot be ruled out.

CLEC-1 is highly conserved; rat and mouse CLEC-1 have 95.5% identity, human and rat CLEC-1 have 71.3% identity, and human and mouse CLEC-1 have 69.4% identity (Flornes et al. 2010).

CLEC-1 Function and Regulation of its Activity

CLEC-1 contains a tyrosine residue within the sequence YSST in its cytoplasmic domain, which may represent a novel signaling motif. Mouse and rat CLEC-1 contain an additional tyrosine residue in the intracellular domain (YxxT x_{13} YxxT) (Flornes et al. 2010) (Fig. 1). The cytoplasmic domain of CLEC-1 also contains several serine and threonine residues that are putative phosphorylation sites. Putative CLEC-1 signaling and downstream effector functions have not been deciphered, but it is possible that ligand binding to CLEC-1 may lead to phosphorylation of the intracellular tyrosine(s), triggering effector functions. A knockout mouse model of CLEC-1 has not yet been generated.

Inhibition of CLEC-1 expression in rat LPS-stimulated bone marrow–derived DC using RNAi does not affect DC generation or maturation as assessed by cytokine production and expression of MHC class II, CD86, and CD80 cell-surface markers (Thebault et al. 2009). However, in a mixed leukocyte reaction, inhibition of CLEC-1 in DC increases the differentiation of allogeneic Th17 T cells and decreases the number of regulatory $Foxp3^+$ T cells, but has no overall effect on T cell proliferation (Thebault et al. 2009). These effects could not be accounted for by levels of the cytokines IL6 and TGF-β, which were unaffected by CLEC-1 inhibition. The increase in $CD4^+$ Th17 differentiation is not due to a direct effect on Th17 differentiation of naïve T cells or to the plasticity of regulatory $CD4^+CD25^+$ T cells. It is suggested that the Th17 differentiation may be due to an effect on the suppression mediated by regulatory $CD4^+CD25^+$ T cells (Thebault et al. 2009). Therefore, CLEC-1 expressed on DC can inhibit Th17 differentiation and increase the numbers of regulatory $Foxp3^+$ $CD4^+CD25^+$ T cells. Inhibition of CLEC-1 expression also downregulates IL13 secretion by $CD4^+CD25^-$ T cells (Thebault et al. 2009). This suggests a role for CLEC-1 in Th2 differentiation.

In a rat model of long-term tolerated allografts, in which CLEC-1 expression on graft endothelial cells is upregulated, the level of IL17 transcript is reduced, and the level of Foxp3 transcript is increased compared to the levels in chronically rejected allografts, which do not significantly express CLEC-1 (Thebault et al. 2009). This is consistent with the idea that CLEC-1 regulates the balance between effector and regulatory T cells and, hence, modulates T-cell activation. CLEC-1 may therefore play a role in allograft tolerance.

Summary

CLEC-1 is a C-type lectin-like receptor belonging to the Dectin-1 family of immune receptors. It is predominantly expressed by DC, endothelial cells, monocytes, and macrophages. Expression of CLEC-1 is downregulated by inflammatory stimuli and increased by the immunoregulatory mediators IL10 or transforming growth factor beta (TGF-β). CLEC-1 is overexpressed on endothelial cells of tolerated allografts compared with allografts that are chronically rejected or syngeneic grafts in a rat model, and CLEC-1 is believed to play a role in allograft tolerance by regulating the balance between Th17 effector and $Foxp3^+$ regulatory T cells. A ligand for CLEC-1 has not yet been identified. Ligand binding to CLEC-1 might lead to phosphorylation of the intracellular tyrosine(s) present in the cytoplasmic domain, and this may trigger effector functions. Future studies to identify endogenous and exogenous ligands for CLEC-1 are required to better understand CLEC-1 signaling and function.

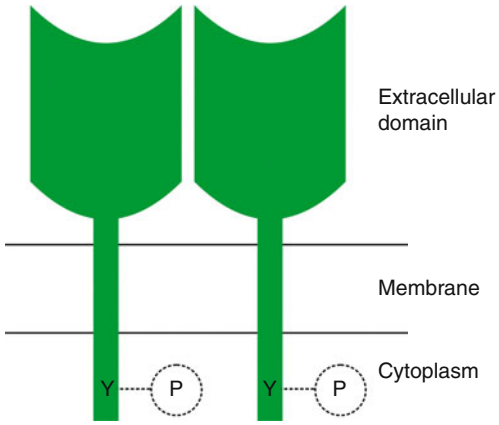
Historical Background

CLEC-2 is a 32 kDa C-type lectin-like immune receptor (Colonna et al. 2000; O'Callaghan 2009). CLEC-2 (gene name CLEC1B) is part of the NK (natural killer) gene cluster found on human chromosome 12 and mouse chromosome 6. Within this cluster, CLEC-2 is part of the Dectin-1 subfamily which consists of all type 2 transmembrane proteins with extracellular C-type lectin-like domains (CTLDs) and immune or homeostatic roles. Other members of this cluster include: ▶ CLEC-1, ▶ Dectin-1, CLEC8A (Lox-1), CLEC9A, CLEC12A, and CLEC12B.



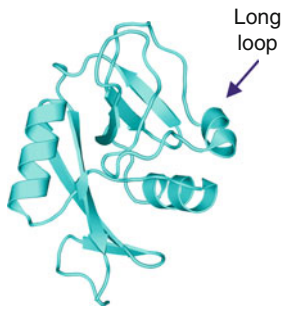
CLEC-2, Fig. 1 Schematic representation of CLEC-2. Upon ligand engagement, the cytoplasmic tyrosine residue in the YxxL motif is phosphorylated, initiating a signalling cascade

CLEC-2 is a type 2 transmembrane signalling protein with its N-terminal region within the cell and its C-terminal region outside the cell. CLEC-2 has a short cytoplasmic region containing a single YxxL motif followed by a single pass transmembrane domain and then an extracellular C-type lectin-like domain (Colonna et al. 2000) (Fig. 1).

CLEC-2 is expressed on the surface of platelets and ligand binding results in platelet activation and aggregation (Suzuki-Inoue et al. 2006). CLEC-2 is also expressed on megakaryocytes and liver sinusoidal endothelial cells (Chaipan et al. 2006), and transcripts have been reported in peripheral blood cells, including NK cells, monocytes, granulocytes, and dendritic cells (Colonna et al. 2000; Suzuki-Inoue et al. 2006; Fuller et al. 2007; Christou et al. 2008). CLEC-2 has also been shown to be a phagocytic receptor on mouse neutrophils. There are two currently identified ligands for CLEC-2: the snake venom protein rhodocytin and the endogenous protein podoplanin (Suzuki-Inoue et al. 2006; Suzuki-Inoue et al. 2007; Christou et al. 2008).

Structure

The protein sequence of CLEC-2 shares similarity with other C-type lectin-like proteins, such as ▶ NKG2D. The structure of the extracellular portion of CLEC-2 has been solved by crystallization and X-ray diffraction analysis and reveals a C-type lectin-like structure consisting of two antiparallel β-sheets flanked by two α-helices with a short 3–10 helix in the long loop



CLEC-2, Fig. 2 The structure of CLEC-2. This view is based upon the crystal structure of the extracellular domain of CLEC-2 (Watson et al. 2007). The molecule is oriented as if the membrane were at the bottom of the figure. The long loop region which contributes to ligand binding is indicated

region (Watson and O'Callaghan 2005; Watson et al. 2007) (Fig. 2). Site-directed mutagenesis studies demonstrate that this flexible long loop region is important for ligand binding (Watson et al. 2007).

Sugar-binding C-type lectins typically coordinate calcium ions as part of their interaction with a sugar. However, CLEC-2 does not contain the residues required for calcium coordination, and no Ca^{2+} ions were seen in the CLEC-2 crystal structure, (Watson et al. 2007) indicating that CLEC-2 is unlikely to bind a carbohydrate ligand. Furthermore, the CLEC-2 ligand rhodocytin is unglycosylated, indicating that this interaction is not mediated by sugars. CLEC-2 has been shown to be found at the cell surface as a non-disulphide-linked homodimer (Watson et al. 2009).

Signalling

CLEC-2 has a single conserved YxxL motif in its cytoplasmic domain (Colonna et al. 2000). This YxxL motif is preceded by three acidic residues and has been termed a *hemiTAM*. As CLEC-2 is dimeric at the cell surface, two such motifs will be in close proximity (Watson et al. 2009) (Fig. 1).

Binding of ligand or antibody to CLEC-2 triggers phosphorylation of the tyrosine residue in the YxxL motif (Suzuki-Inoue et al. 2006) and mutation of this tyrosine prevents signalling (Fuller et al. 2007). Upon ligand engagement, CLEC-2 translocates to lipid rafts, and this translocation appears essential for phosphorylation and, therefore, signalling (Pollitt et al. 2010). Tyrosine phosphorylation is mediated by ▶ Src kinases, and Src kinase inhibition prevent signalling (Fuller et al. 2007). CLEC-2 phosphorylation results in binding to, and phosphorylation of, Syk (spleen tyrosine kinase) (Suzuki-Inoue et al. 2006; Fuller et al. 2007). This initiates a signalling cascade culminating in phosphorylation of PLCγ2 (phospholipase-Cγ2) (Suzuki-Inoue et al. 2006; Fuller et al. 2007). Both of the SH2 (Src-homology domain 2) domains of Syk are required for productive binding to phosphorylated CLEC-2 (Fuller et al. 2007). Since CLEC-2 only has a single YxxL motif, these two SH2 domains must therefore bind to two chains of CLEC-2 (Hughes et al. 2010b), although whether this is achieved through binding to two YxxLs within a single CLEC-2 dimer or to one from each of two dimers is not currently understood. Downstream phosphorylation has additionally been shown of Vav3, LAT, Btk, and ▶ SLP-76 (Src-homology 2 domain-containing leukocyte protein of 76 kDa), although activation through CLEC-2 is only partially dependent upon the SLP-76/Blnk family of adapter molecules (Suzuki-Inoue et al. 2006; Fuller et al. 2007).

Ligands

Two ligands, rhodocytin and podoplanin, have been identified for CLEC-2 (Suzuki-Inoue et al. 2006; Suzuki-Inoue et al. 2007; Christou et al. 2008). Rhodocytin (also known as aggretin) is a venom protein from the Malayan pit viper *Calloselasma rhodostoma* that was known to activate platelets; CLEC-2 was identified as its ligand by affinity purification and mass spectrometry (Suzuki-Inoue et al. 2006). The crystal structure of rhodocytin shows it to be a tetramer, consisting of two heterodimers each composed of an α and a β chain (Watson et al. 2007; Hooley et al. 2008). These α and β chains each contain C-type lectin-like domains. Rhodocytin binds directly to CLEC-2 and is not glycosylated (Watson et al. 2007).

Podoplanin (also known as aggrus) is an endogenous ligand for CLEC-2 and binds directly to CLEC-2 (Suzuki-Inoue et al. 2007; Christou et al. 2008). Podoplanin was identified as a ligand for CLEC-2 when similarities were noted between the signalling profiles of platelets stimulated with rhodocytin and podoplanin (Watanabe et al. 1990; Suzuki-Inoue et al. 2006). Podoplanin is a heavily O-glycosylated type 1 membrane protein with a short cytoplasmic region. However, it seems unlikely that CLEC-2 could recognize a carbohydrate ligand in addition to the non-glycosylated protein rhodocytin. A recent

study indicates that the state of glycosylation of podoplanin does not have a significant effect on the interaction with CLEC-2 (Cueni et al. 2010).

Podoplanin is expressed on podocytes in the kidney (from where it takes its name) and on lymphatic endothelial cells, but not upon vascular endothelial cells. Podoplanin expression has also been reported in skeletal tissue, muscle, type I alveolar cells in the lung, heart, myofibroblasts in breast and salivary glands, osteoblasts, certain mesothelial cells, and follicular dendritic cells. Podoplanin is expressed by several tumor types, and expression at the leading edge of some tumors has been observed. CLEC-2 has been identified as an attachment factor for HIV-1, facilitating capture of the virus by platelets (Chaipan et al. 2006). CLEC-2 appears to bind to podoplanin incorporated into the virion from the virus-producing cells (Chaipan et al. 2010).

Knockout Studies

A number of groups have generated murine CLEC-2 knockout models which are embryonic/neonatal lethal (Bertozzi et al. 2010; Hughes et al. 2010a; Suzuki-Inoue et al. 2010; Tang et al. 2010). Knockout results in severe defects in lymphatic development with blood-filled lymphatics indicating a failure of blood/lymphatic separation. Similarly, mice deficient in podoplanin die at birth from respiratory failure and also have a failure of blood/lymphatic separation (Schacht et al. 2003). Indeed, the phenotypes of CLEC-2, podoplanin, Syk, SLP76, PLCγ2, and platelet-defective mice all share similar characteristics of a failure in blood/lymphatic separation (Abtahian et al. 2003; Schacht et al. 2003; Ichise et al. 2009; Bertozzi et al. 2010; Hughes et al. 2010a; Suzuki-Inoue et al. 2010; Tang et al. 2010). This suggests that the developmental interaction between CLEC-2 on platelets and podoplanin on the future lymphatic endothelial cells may induce separation of the vascular and lymphatic systems by triggering platelet aggregation, so sealing the future lymphatic vessels.

Antibody-mediated depletion of CLEC-2 from circulating platelets results in normal adhesion, but reduced aggregation, of platelets under flow conditions and is associated with increased bleeding times and inhibition of occlusive arterial thrombus formation (May et al. 2009). One of the knockout studies in which irradiated wild type mice were reconstituted with CLEC-2 deficient fetal liver cells and so have CLEC-2 deficient platelets also showed a decrease in aggregation under flow and observed defects in thrombosis formation following injury, supporting a role for CLEC-2 in stabilizing thrombus formation (Suzuki-Inoue et al. 2010). However, a second, independent, knockout study observed no decrease in platelet aggregation under shear conditions (Hughes et al. 2010a). Neither of these mouse knockout studies reported statistically significant decreases in tail bleeding times (Hughes et al. 2010a; Suzuki-Inoue et al. 2010), in contrast to the study in which CLEC-2 expression was reduced by antibody administration (May et al. 2009), and the role of CLEC-2 in hemostasis and thrombosis remains unclear.

Summary

CLEC-2 is an important platelet receptor, which may also have an immune role. Ligand engagement of CLEC-2 results in tyrosine phosphorylation in its cytoplasmic YXXL motif and triggers platelet activation and aggregation. Knockout models reveal a key role for CLEC-2 in blood/lymphatic separation during development. For the function of CLEC-2 beyond platelets to be understood, its cellular expression pattern and the regulation of this expression need further study, especially in immune cells.

The involvement of CLEC-2 in platelet aggregation makes it a key medical target in a variety of contexts, including myocardial infarction and ischaemic stroke (O'Callaghan 2009). The structure of podoplanin should accelerate the development of reagents to inhibit the CLEC-2 axis.

Synonyms

CLECSF9; C-type (calcium-dependent, carbohydrate recognition domain) lectin superfamily member 9; C-type lectin domain family 4 member E; Immunoreceptor; Macrophage-inducible C-type lectin; MINCLE

Historical Background

CLEC4E is a member of the C-type lectin family of immune receptors. It is expressed on the cell surface of activated macrophages, and its expression is

strongly upregulated by inflammatory stimuli. CLEC4E is encoded in the natural killer gene complex on human chromosome 12 and mouse chromosome 6 within a cluster of genes, which also includes BDCA-2, DCAR, DCIR, Dectin-2, and Clecsf8. *CLEC4E* encodes a type 2 transmembrane protein with a short N-terminal cytoplasmic domain, a single transmembrane domain and a C-terminal extracellular C-type lectin carbohydrate recognition domain. The transmembrane domain contains a positively charged arginine residue, which mediates association with the Fc receptor gamma chain (FcεRIγ) signaling adaptor which carries an immunoreceptor tyrosine-based activation motif (ITAM) in its cytoplasmic domain. CLEC4E is a classical C-type lectin that contains conserved residues for calcium coordination and sugar binding within its extracellular domain. This includes a predicted mannose-binding motif, suggesting that CLEC4E might have mannose-containing sugar ligands. CLEC4E is a fungal receptor on macrophages and has a role in the innate immune response to *Candida albicans* and *Malassezia* species. However, the ligand on fungi has not yet been identified. Recently, CLEC4E has been identified as a mycobacterial receptor, and it recognizes the mycobacterial glycolipid trehalose-6,6′-dimycolate. Recognition of *Malassezia*, and mycobacteria has been shown to be dependent upon the predicted mannose-binding motif of CLEC4E. However, CLEC4E also binds an endogenous nuclear protein ligand released from necrotic cells, spliceosome-associated protein 130 (SAP130), in a carbohydrate-independent manner. Ligand binding to CLEC4E leads to cytokine and chemokine production through a pathway involving FcεRIγ, spleen tyrosine kinase (Syk) and caspase recruitment domain family, member 9 (CARD9). CLEC4E is also essential for granuloma formation, which is an important characteristic of *Mycobacterium tuberculosis* infection.

CLEC4E Expression Pattern and Regulation of Expression

At the transcript level, mouse *CLEC4E* is expressed in bone marrow, lymph node, spleen, and lung (Comelli et al. 2006), and has recently been found to be expressed in healing corneas (Saravanan et al. 2010). *CLEC4E* is transcribed in a wide range of leukocytes, including macrophages, neutrophils, dendritic cells, B cells, $CD4^+$ T cells, $CD8^+$T cells, concanavalin A blasts, and M1 myeloblastic leukemia cells (Matsumoto et al. 1999; Flornes et al. 2004; Nakamura et al. 2006), as well as in microglia in the brain (McKimmie et al. 2006). At the protein level, mouse CLEC4E is predominantly expressed on activated macrophages (Matsumoto et al. 1999; Wells et al. 2008; Yamasaki et al. 2008; Yamasaki et al. 2009; Schoenen et al. 2010) and also on the cell surface of $CD11b^+Gr1^+$ neutrophils, present in the thymus of irradiated mice (Yamasaki et al. 2008). Human *CLEC4E* is transcribed in LPS-stimulated THP1 monocytic leukemia cells (Matsumoto et al. 1999) and in bone marrow–derived mononuclear cells of rheumatoid arthritis patients (Nakamura et al. 2006). Human CLEC4E protein was detected in in vitro $CD34^+$ progenitor-derived mast cells upon IgE receptor cross-linking (Ribbing et al. 2010).

CLEC4E expression is induced on macrophages by a variety of inflammatory stimuli, including lipopolysaccharide (LPS), ▶ TNF-α, interleukin (IL)-6, ▶ interferon-gamma (IFNγ), zymosan, mannan, β-glucan, *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP) (a bacterial peptidoglycan-derived small peptide), CpG oligodeoxyribonucleotides, curdlan, and mycobacterial glycolipids (Matsumoto et al. 1999; Guo et al. 2009; Schoenen et al. 2010). Expression of *CLEC4E* is also induced by various infections, including *Streptococcus pneumoniae*, influenza A virus (Rosseau et al. 2007); *Mycobacterium tuberculosis* bacillus Calmette-Guérin (Khajoee et al. 2006), Semliki forest virus (McKimmie et al. 2006), and *C. albicans* (Wells et al. 2008). At the protein level, CLEC4E is upregulated by *Malassezia* fungal stimulation of thioglycollate-elicited peritoneal mouse macrophages (Yamasaki et al. 2009). Human *CLEC4E* is upregulated in bone marrow-derived mononuclear cells from rheumatoid arthritis patients compared with those from osteoarthritis patients (Nakamura et al. 2006).

CLEC4E is a transcriptional target of the CCAAT/enhancer binding protein, beta (C/EBP-β) and interferon regulatory factor-8 (IRF-8) transcription factors (Matsumoto et al. 1999; Tamura et al. 2005). C/EBP-β activity is induced by inflammatory stimuli, and it plays a role in the regulation of genes involved in immune and inflammatory responses in activated macrophages. IRF-8 is a transcription factor that controls myeloid differentiation.

Interaction with Endogenous Ligands and Pathogens

CLEC4E is a classical C-type lectin with a carbohydrate recognition domain that has conserved residues forming what has been termed "Ca^{2+}-binding site 2," which plays a role in calcium-dependent carbohydrate binding (Matsumoto et al. 1999; Flornes et al. 2004). CLEC4E is, therefore, predicted to bind carbohydrate ligands, and in particular mannose-containing carbohydrates, since it contains an EPN (glutamic acid-proline-asparagine) motif, which is a well-characterized mannose-binding motif present in a number of other C-type lectins, including DC-SIGN (CD209), Dectin-2, and Langerin. Indeed, recombinant CLEC4E protein binds to a highly multivalent form of α-mannose in a Ca^{2+}-dependent manner, but notably not to mannan (Yamasaki et al. 2009).

CLEC4E is a receptor for *Candida albicans* and *Malassezia* fungal species, although the precise ligand on fungi has yet to be identified. Mouse CLEC4E binds to a soluble component of heat-killed *Candida albicans* and *Saccharomyces cerevisiae* (Bugarcic et al. 2008; Wells et al. 2008). Recognition of *Malassezia* is dependent upon the EPN motif of CLEC4E (Yamasaki et al. 2009). CLEC4E is also a receptor for mycobacteria, and the mycobacterial glycolipid, trehalose-6,6′-dimycolate (TDM) has been identified as the CLEC4E ligand on mycobacteria (Ishikawa et al. 2009; Schoenen et al. 2010). TDM is a potent immunostimulant causing IL1 and TNF release and granuloma formation in vivo. TDM is also an effective adjuvant. TDM is composed of a trehalose moiety (a disaccharide made up of two glucose units) and two long-chain α-branched, β-hydoxyl fatty acids, known as mycolic acids. Proteins with EPN mannose motifs are also able to bind structurally related sugars such as glucose, and indeed CLEC4E recognition of *M.bovis* and *M.tuberculosis* is dependent upon the EPN motif of CLEC4E. However, neither trehalose nor purified mycolate alone stimulates CLEC4E-expressing cells. In addition, the long, branched structure of mycolic acids is also not essential for stimulatory activity since a synthetic analogue of TDM, trehalose dibehenate (TDB), which contains shorter fatty acid chains, is also a potent stimulator of CLEC4E-expressing cells. CLEC4E may, therefore, be specific for the ester linkage between the fatty acid and trehalose.

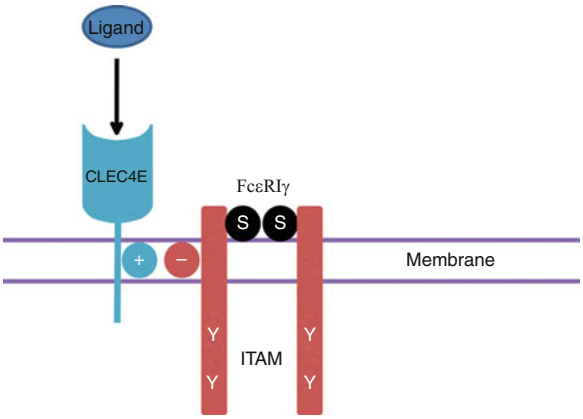
An endogenous ligand for CLEC4E has also been identified (Yamasaki et al. 2008). CLEC4E binds to spliceosome-associated protein 130 (SAP130) in a carbohydrate-independent manner. SAP130 is normally located in the nucleus as a component of the SF3b complex, which forms part of the U2 snRNP. U2 snRNP is involved in the assembly of spliceosomes. It is proposed that during cell death, SAP130 is released into the extracellular environment.

CLEC4E Signaling and Regulation of Activity

The transmembrane domain of CLEC4E contains a positively charged arginine residue, which mediates association with the ITAM-bearing FcεRIγ signaling adaptor (Yamasaki et al. 2008) (Fig. 1). The negatively charged aspartic acid residue in the transmembrane domain of FcεRIγ associates with the positively charged amino acid in the transmembrane domains of other immune receptor molecules (reviewed in (Humphrey et al. 2005)). Ligand binding to FcεRIγ-associated receptors results in phosphorylation of FcεRIγ on the two tyrosine residues at positions 65 and 76 that form the ITAM motif. A number of related C-type lectin and C-type lectin-like proteins also interact with signaling molecules in the plasma membrane, including ▶ CLEC5A which interacts with Dap12, ▶ NKG2D which associates with Dap10 and Dap12 and DCAR (CLEC4B) which associates with FcεRIγ.

Efficient cell-surface expression of CLEC4E on bone marrow–derived macrophages in response to LPS stimulation requires the expression of FcεRIγ (Yamasaki et al. 2008). FcεRIγ is essential for CLEC4E-mediated signaling. Stimulation of thioglycollate-elicited peritoneal macrophages or bone marrow–derived macrophages with monoclonal antibodies to CLEC4E (Yamasaki et al. 2008), or with fungal species (Wells et al. 2008; Yamasaki et al. 2009), induces the production of proinflammatory cytokines and chemokines in an FcεRIγ-dependent manner (Yamasaki et al. 2008). Furthermore, inflammatory cytokine production, lung swelling, and the formation of granulomas in response to TDM stimulation in vivo are dependent upon FcεRIγ (Ishikawa et al. 2009). FcεRIγ is also essential for the adjuvant properties of TDB (Schoenen et al. 2010).

Cross-linking of CLEC4E induces phosphorylation of the kinases Syk and extracellular signal-regulated kinase (Erk) in peritoneal macrophages (Yamasaki et al. 2008). The adaptor molecule CARD9 has an important role in the downstream signaling, resulting in chemokine production (Yamasaki et al. 2008).



CLEC4E, Fig. 1 MINCLE interactions. MINCLE interacts with the FcεRIγ signaling adaptor within the membrane. The interaction employs a charge–charge interaction between polar residues within the membrane

The CLEC4E cytoplasmic domain contains two putative phosphorylation sites, Ser 3 and Thr 12 (Matsumoto et al. 1999).

Functional Significance of CLEC4E Signaling

CLEC4E is a macrophage receptor for a number of pathogens, including *Candida albicans*, several species of *Malassezia*, and mycobacteria (Bugarcic et al. 2008; Wells et al. 2008; Ishikawa et al. 2009; Yamasaki et al. 2009; Schoenen et al. 2010). An endogenous ligand, SAP130, has also been identified (Yamasaki et al. 2008). Ligand binding and triggering of CLEC4E on macrophages stimulates a signaling cascade through FcεRIγ, Syk, and CARD9, which induces the production of cytokines and chemokines, including TNF-α, ▶ IL6, IL10, CXCL1 (KC), and CXCL2 (MIP-2) (Wells et al. 2008; Yamasaki et al. 2008; Ishikawa et al. 2009). Absence or inhibition of CLEC4E reduces cytokine and chemokine production in response to challenge with *Candida albicans* (Wells et al. 2008) and *Malassezia* species (Yamasaki et al. 2009). Partial inhibition of the transcription of G-CSF and IL6 and MIP-2 production in CLEC4E-deficient bone marrow macrophages were observed following stimulation with *M.tuberculosis and M.bovis* BCG (Bacille Calmette-Guerin) (Ishikawa et al. 2009; Schoenen et al. 2010). However, no inhibition of TNF production was observed in these cells. Since whole mycobacteria contain many immunostimulatory components, it is suggested that the lack of significant impairment in cytokine and chemokine production is due to signaling through other receptors, including toll-like receptors (TLR) and the NOD-like receptor family. Indeed, cytokine production is substantially inhibited in MyD88$^{-/-}$CLEC4E$^{-/-}$ double deficient macrophages compared with macrophages deficient in CLEC4E or MyD88 alone following stimulation with *M.tuberculosis* (Ishikawa et al. 2009).

In response to TDM or TDB, mouse bone marrow–derived macrophages produce nitric oxide, IL6, and G-CSF in a CLEC4E-dependent manner (Ishikawa et al. 2009; Schoenen et al. 2010). Production of nitric oxide is important for the direct killing of mycobacteria. In vivo administration of TDM induces the production of IL6 and TNF in sera, inflammatory lung swelling, and importantly granuloma formation in a CLEC4E- and FcεRIγ-dependent manner (Ishikawa et al. 2009). Transcription of TNF, IL1β, and MIP-1α in the lungs is induced by TDM in a CLEC4E-dependent manner, and TDM induces thymic atrophy through CLEC4E stimulation. Both TDM and TDB are effective adjuvants controlling Th1 and Th17 responses. CLEC4E plays a key role in the adjuvant effect of TDB in subunit vaccination with *M.tuberculosis* fusion protein Ag85B-ESAT6 (H1); the absence of CLEC4E reduces cellularity in the draining lymph node, and significantly impairs IFN gamma and IL17 production by lymph node cells (Schoenen et al. 2010).

The production of inflammatory cytokines and chemokines plays an important role in the recruitment of neutrophils to sites of inflammation (Yamasaki et al. 2008). In vivo, mouse CLEC4E has a role in neutrophil recruitment to sites of thymocyte necrosis in the thymus caused by whole-body irradiation, or to the peritoneal cavity after injection of dead cells or *Malassezia* fungal species (Yamasaki et al. 2008; Yamasaki et al. 2009). Blockade of CLEC4E-mediated MIP-2 and TNF-α production from macrophages by injection of a monoclonal antibody to CLEC4E significantly inhibits the migration of neutrophils to sites of substantial cell death in vivo (Yamasaki et al. 2008).

CLEC4E localizes to the phagocytic cup that forms around yeast particles after exposure to *C. albicans* (Wells et al. 2008). However, it is not involved in the phagocytosis of *C. albicans* (Wells et al. 2008) or dead cells (Yamasaki et al. 2008). CLEC4E may have a role in autoimmune disease as its expression is considerably upregulated in patients with rheumatoid arthritis (Nakamura et al. 2006).

Phenotype of CLEC4E Knockout Models

To date, two knockout mouse models of *CLEC4E* have been generated (Wells et al. 2008, Yamasaki et al. 2009). In terms of total white blood cell counts and subpopulations of the thymus, spleen, lymph node, and peritoneal cells, no significant phenotype is observed in either of these models. Bone marrow macrophages show normal differentiation, morphology, and number. CLEC4E is therefore not required for the development of the hematopoietic lineage, including the differentiation of macrophages. Immune functions, as measured by delayed-type hypersensitivity responses and immunoglobulin production, are also unaffected by CLEC4E deficiency (Wells et al. 2008).

However, in response to challenge with *C. albicans* (Wells et al. 2008), *Malassezia* species (Yamasaki et al. 2009), and the mycobacterial glycolipid TDM (Ishikawa et al. 2009; Schoenen et al. 2010), macrophages from CLEC4E-deficient mice have significantly impaired production of cytokines (TNF-α, IL10, IL6, and G-CSF), chemokines (MIP-2 and KC), and nitric oxide. In vivo, CLEC4E-deficient mice show increased susceptibility to systemic candidiasis (Wells et al. 2008) and a reduced inflammatory response to intraperitoneal injection of *Malassezia* (Yamasaki et al. 2009) compared with control mice. CLEC4E-mediated production of inflammatory cytokines and chemokines by macrophages is implicated in neutrophil migration into damaged tissue (Yamasaki et al. 2008). In response to challenge with the TDM, CLEC4E-deficient mice display impaired IL6 and TNF-α production in sera and show reduced lung inflammation compared to wild-type mice. Furthermore, TDM-induced granuloma formation is absent in CLEC4E-deficient mice (Ishikawa et al. 2009).

Although *CLEC4E*-knockout mice do not show any gross anatomical phenotype, they seem to show evidence of abnormal heart valves, with accumulation of higher levels of extracellular matrix compared to heart valves from wild-type mice. This suggests a role for CLEC4E in heart valve development (Wells et al. 2008).

Summary

CLEC4E is an important pathogen recognition receptor of the C-type lectin family. It is involved in the recognition of fungal species and mycobacteria in a carbohydrate-dependent manner. There is also evidence indicating that CLEC4E recognizes an endogenous protein ligand, SAP130, in a carbohydrate-independent manner. CLEC4E is predominantly expressed on activated macrophages and associates with the FcεRIγ signaling adaptor. Ligand binding to CLEC4E triggers a signaling cascade through FcεRIγ, Syk, and CARD9, which results in the production of inflammatory cytokines and chemokines. CLEC4E mediates the adjuvant properties of the trehalose glycolipid, TDB. This is an important finding as it provides a target for the design of synthetic adjuvants for effective vaccination strategies against infectious diseases and cancer.

CLEC5A

Michael Reschen and Christopher A. O'Callaghan
Centre for Cellular and Molecular Physiology, Nuffield Department of Clinical Medicine, University of Oxford, Headington, Oxford, UK

Synonyms

CLECSF5; C-type (calcium-dependent, carbohydrate-recognition domain) lectin, superfamily member 5; C-type lectin-domain family 5, member A; Ly100; MDL1; MDL-1; Myeloid DAP-12-associating lectin-1

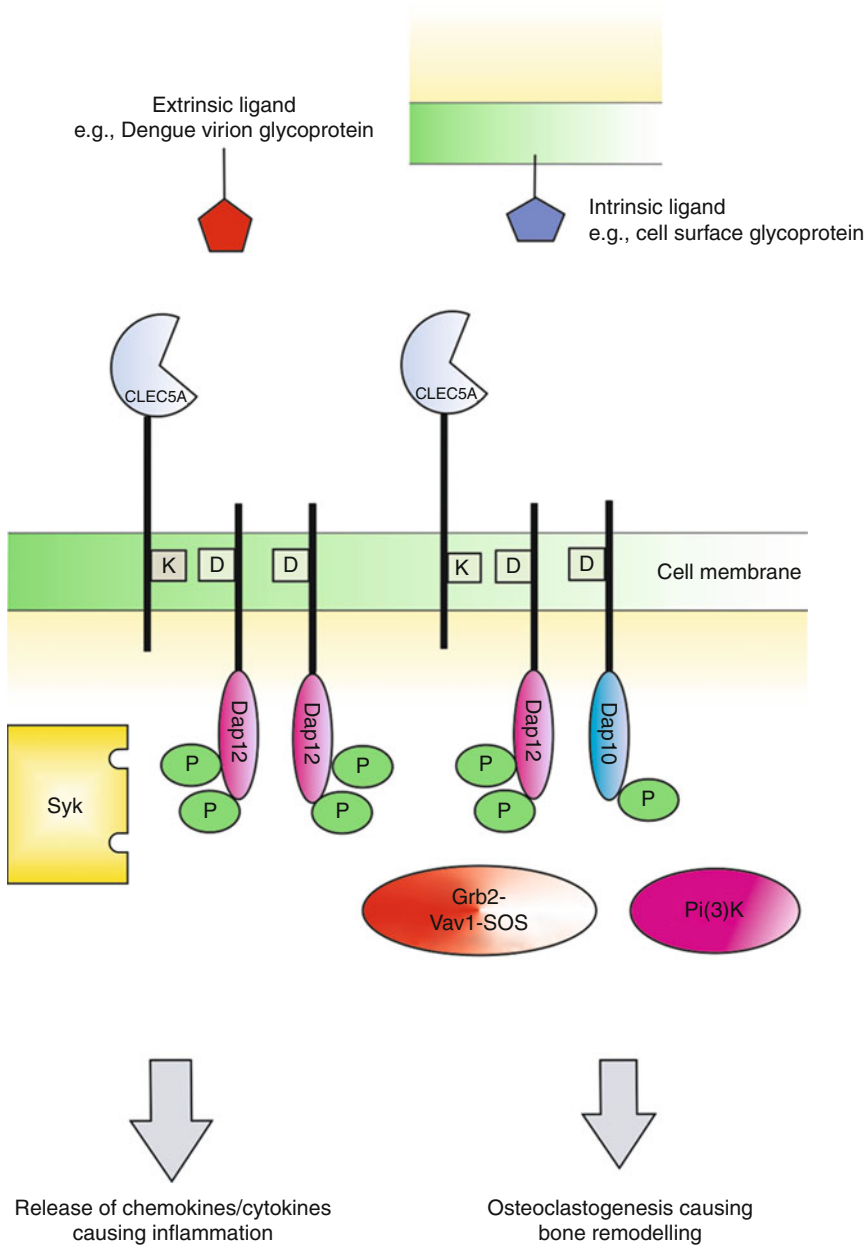
Historical Background

CLEC5A is a type 2 transmembrane receptor originally identified by its ability to stabilize DAP (DNAX associating protein)-12 at the cell surface in myeloid cells (Bakker et al. 1999). It is emerging as a key component of the innate immune system; it activates macrophages, regulates osteoclastogenesis, and plays a role in inflammatory diseases such as dengue virus–induced lethality and autoimmune arthritis (Bakker et al. 1999; Chen et al. 2008; Aoki et al. 2009; Joyce-Shaikh et al. 2010).

Structure

CLEC5A contains a C-type lectin-like domain in its extracellular carboxy-terminal region. However, the N-terminal cytoplasmic tail is predicted to be only four amino acids in length and, thus, lacks a signaling motif. The putative 23 amino acid single pass transmembrane domain contains a conserved lysine residue. CLEC5A associates with DAP-12 by an interaction between this positively charged lysine and a negatively charged aspartate residue which is present in the transmembrane region of DAP-12 (Bakker et al. 1999). DAP-12 transduces activating signals in myeloid and natural killer cells and contains an immunoreceptor tyrosine activation motif (ITAM) in its cytosolic domain. Ligand binding by DAP-12-associated receptors in myeloid cells results in phosphorylation of the two key tyrosine residues within the ITAM motif by ▶ Src kinases; the two SH2 domains of Syk (Spleen tyrosine kinase) can then bind to the phosphorylated ITAM, resulting in Syk activation (Aoki et al. 2003; Lanier 2009). DAP-12 has only a very short extracellular domain and exists as a disulphide linked homodimer in association with CLEC5A or another member of the set of receptors with which it interacts (Lanier et al. 1998; Bakker et al. 1999).

In mouse osteoclasts and bone marrow–derived macrophages, CLEC5A has been shown to associate with both DAP-10 and DAP-12 to form a trimolecular complex (Inui et al. 2009). DAP-10 is a 10 kDa transmembrane protein encoded by a gene which is located very close to the DAP-12 gene. DAP-10 has a cytosolic signaling motif defined by the sequence YINM, that when phosphorylated recruits phosphatidylinositol-3



CLEC5A, Fig. 1 Signaling mechanism of CLEC5A. The positively charged lysine residue (K) in CLEC5A's transmembrane domain interacts with a negatively charged aspartate residue (D) in the DAP-12 or DAP-10 transmembrane domain. Activation of CLEC5A results in phosphorylation of DAP-12 and/or DAP-10 which allows signaling through distinct pathways. Dap12 forms a disulphide-bonded homodimer which contains an ITAM in its intracellular domain. Upon phosphorylation Syk kinases are activated which trigger a signaling cascade that leads to intracellular calcium release and production of chemokines and cytokines. In osteoclasts, DAP-10 can form a heterodimer with DAP-12 and signal through a distinct pathway, ultimately causing osteoclastogenesis and bone remodeling. The intracellular domain of DAP-10 contains a YINM motif which when phosphorylated recruits the p85 subunit of Pi(3)K and a complex of Grb2-Vav1-SOS. CLEC5A interacts directly with the Dengue virion, but other extrinsic or intrinsic ligands have not yet been identified

kinase (► PI3K) and Grb2; Grb2 then interacts with ► Vav1 (Upshaw et al. 2006; Lanier 2008). Thus CLEC5A can access two distinct pathways (see Fig. 1 for a schematic representation of these signaling pathways).

Orthologues of the CLEC5A gene have been identified in several species, including rat, mouse, dog, pig, cow, and chimpanzee (Bakker et al. 1999; Yim et al. 2001). In vitro studies have shown murine and porcine CLEC5A to be glycosylated (Yim et al. 2001; Aoki et al. 2009). Glycosylation is greater in murine neutrophils than macrophages (Aoki et al. 2009), and these differences may influence ligand binding.

Function

Macrophages are phagocytic cells which are derived from monocytes and play a key role in immunity.

CLEC5A can play a role in macrophage activation (Bakker et al. 1999). When the murine macrophage cell line J774 is transfected with CLEC5A, then cross-linking of CLEC5A/DAP-12 complexes results in calcium mobilization (Bakker et al. 1999). Signaling through CLEC5A in murine myeloid 32Dcl3 cells upregulates expression of the leukocyte adhesion molecule CD11b and of cytokines, including RANTES (Regulated upon activation normal T-cell expressed and presumably secreted), IP-10 (Interferon-gamma-induced protein 10), and MDC (macrophage-derived chemokine) (Aoki et al. 2009). Stimulation of ▶ Toll-like receptor 4 by lipopolysaccharide had a synergistic effect with CLEC5A on the expression of RANTES and MDC (Aoki et al. 2009).

CLEC5A interacts with dengue virus causing DAP-12 phosphorylation, which is temporally associated with tumor necrosis factor (TNF)-α production (Chen et al. 2008). Conversely, knockdown of CLEC5A suppresses the release of TNF-α, IL-6, IL-8, macrophage inflammatory protein (MIP), and IP-10. Overall, signaling through CLEC5A increases expression of cell adhesion and chemotactic molecules, contributing to inflammation.

CLEC5A also has a role in bone metabolism. Bone homeostasis depends on the opposing action of osteoblasts of mesencyhmal origin which promote bone-matrix formation and osteoclasts derived from myeloid precursor cells which enhance bone resorption. Stimulation of CLEC5A enhances osteoclastogenesis from murine bone marrow–derived monocytes by signaling through DAP-10 and DAP-12 (Inui et al. 2009; Joyce-Shaikh et al. 2010).

In murine inflammatory arthritis models, CLEC5A stimulation increased mRNA expression of pro-inflammatory cytokines (IL-β, IL-6, IL-17, TNF), bone remodeling genes (receptor activator of NF-κB ligand, Tartrate-resistant acid phosphatase, matrix metallopeptidase 9, ATPV0D2), and myeloid associated genes (CXCL1, CD11b, DAP-12, RANK)(Joyce-Shaikh et al. 2010). These changes are associated with loss of bone and increased inflammation in the murine arthritis model used (see below).

Expression

In humans, CLEC5A is expressed in peripheral blood monocytes and in the monocyte/macrophage cell lines U937 and MonoMac6 but not in cells of nonmyeloid origin (Bakker et al. 1999). Surface expression of CLEC5A was detected on human peripheral blood cells expressing either CD66 or CD14 (Chen et al. 2008). CLEC5A is expressed on porcine monocytes and pulmonary alveolar macrophages but not lymphocytes or polymorphonuclear granulocytes (Yim et al. 2001). In mice, CLEC5A expression has been detected on granulocytes ($CD11b^+$ $Ly6G^{high}$) and monocytes ($CD11b^+$ $Ly6G^{low}$) from bone marrow and peripheral blood, on peritoneal macrophages, thioglycollate-ellicited neutrophils, and osteoclasts (Aoki et al. 2009; Inui et al. 2009; Joyce-Shaikh et al. 2010). In humans and mice, the main tissue sites of expression are in bone marrow, synovium/joint, and lung (Joyce-Shaikh et al. 2010). In inflamed pannus from patients with rheumatoid arthritis CLEC5A was expressed in $CD68^+$ macrophages. (Joyce-Shaikh et al. 2010).

CLEC5A expression is affected by cell ontogeny. CLEC5A expression is higher in peripheral blood derived $CD14^+$ mature monocytes than in undifferentiated $CD34^+$ bone marrow cells. Expression is lower in fetal tissue compared to adult tissue and in malignant cells compared to normal cells (Gingras et al. 2002). Differentiation of myeloid precursor 32Dcl3 cells into neutrophils induces CLEC5A expression (Aoki et al. 2009). Expression is downregulated when monocytes differentiate into dendritic cells (Bakker et al. 1999). Surface expression of murine CLEC5A is upregulated during pulmonary mycobacterial infection (Aoki et al. 2004) and correlates with upregulation of the type 1 cytokines TNF-α and IFN-γ. However, whereas TNF-α is critical for induction of CLEC5A during murine pulmonary mycobacterial infection, IFN-γ suppresses CLEC5A expression (Aoki et al. 2004).

Genetics and Splice Variants

The human CLEC5A gene is on chromosome 7 and encodes a 3,524 basepair mRNA ((Maglott et al. 2007) NM_013252.2). Two isoforms have been identified at the transcript level in humans with isoform 1 (encoding 188 amino acids – Uniprot identifier: Q9NY25-1) being referred to as the canonical sequence. Isoform 2 (Uniprot identifier: Q9NY25-2) differs in that it lacks a lysine residue at position 116. At position 141, there is a single-nucleotide polymorphism (C → T)

encoding a missense mutation altering the amino acid from arginine to histine ((Sherry et al. 2001) rs35942193). Estimates of the frequency of the minor allele (T) range from 0 to 0.027, but this polymorphism is not known to be associated with any diseases. CLEC5A exists as alternatively spliced variants in mice and pigs, with the noncanonical isoforms lacking 25 and 19 amino acids in their extracellular domains, respectively (Bakker et al. 1999; Yim et al. 2001). The significance of these alternatively spliced transcripts is unknown.

CLEC5A −/− mice display a dysregulated bone phenotype with irregular trabecular bone connectivity (Joyce-Shaikh et al. 2010). DAP-10 −/− mice display mild osteopetrosis and a reduction in the number of osteoclasts (Inui et al. 2009). DAP-12 deficient mice also display altered T-cell activity due to impaired antigen priming (Bakker et al. 2000) and have impaired osteoclast development and function (Lanier 2009) and macrophages which are hyperresponsive to in vitro exposure to TLR ligands (Lanier 2008). In humans, lack of DAP-12 results in Nasu-Hakola disease, characterized by presenile dementia and bone cysts (Aoki et al. 2003). However, it is important to note that DAP-12 interacts with a multitude of cell membrane receptors, so this effect is not necessarily mediated by CLEC5A.

Function in Disease

A role for CLEC5A is evident in the immune response and pathogenesis of several infections and in inflammatory arthritis. Human and murine CLEC5A react directly with dengue virus strain 2 in a calcium-independent manner, although the precise ligand on the virus is unknown. This interaction can be inhibited in vitro by the monosaccharide fucose, suggesting that dengue envelope protein glycans are important in mediating this interaction. Infection of macrophages with dengue virus caused phosphorylation of DAP-12, but knockdown of CLEC5A did not reduce viral replication, suggesting that the interaction is important in the inflammatory changes associated with the disease rather than the mechanisms of cellular infection. In vivo blockade of the dengue virus-CLEC5A interaction with an antagonistic anti-CLEC5A antibody reduced lethality of dengue virus infection in STAT−/−mice with decreased plasma leakage and hemorrhage, but no suppression of viral replication. (Chen et al. 2008). CLEC5A may also be involved in the immune response to another flavivirus, Japanese encephalitis virus. Murine infection was associated with increased expression of CLEC5A in brain and splenic tissue and was temporally associated with increased interferon-gamma, TNF-alpha, and IL1-alpha production (Gupta et al. 2010). Murine pulmonary mycobacterial infection induces CLEC5A expression, suggesting a role in mycobacterial immunity (Aoki et al. 2004).

CLEC5A has recently been shown to have an important role in autoimmune-mediated synovial injury and bone erosion in murine models of inflammatory arthritis. Activation of the CLEC5A pathway was associated with a significant increase in the clinical severity, including bone destruction (Joyce-Shaikh et al. 2010). The therapeutic potential of this pathway was demonstrated by improvement in the clinical course brought about by intravenous administration of a CLEC5A-Fc fusion protein. The Fc binding site was mutated to attenuate antibody binding, and the fusion protein presumably bound to and blocked an unknown ligand for CLEC5A. Similar results were achieved by deleting the CLEC5A gene in mice (Joyce-Shaikh et al. 2010).

Summary

CLEC5A is a C-type lectin-like molecule which can activate macrophages and osteoclast production by signaling through DAP-12 and DAP-10. CLEC5A is likely to bind to an endogenous ligand and to viral ligands. It has a role in the pathogenesis of inflammatory arthritis in a mouse model and binds directly to dengue virus contributing to lethality. Future research objectives include: characterization of endogenous and pathogen ligands, understanding the cell surface events that lead to signaling through DAP-12, assessing its role in other TNF-mediated diseases such as inflammatory bowel disease, and exploring the therapeutic potential of CLEC5A blockade.

Synonyms

Dectin-1; β-glucan receptor

Historical Background

The existence of a macrophage β-glucan-binding receptor had been recognized for about three decades before the identification of Dectin-1 in 2001 as the receptor for these carbohydrates (Brown and Gordon 2001). Many of the immunomodulatory properties attributed to β-glucans were previously ascribed to the Complement Receptor (CR-3, Mac-1, CD11b/CD18), which was thought to directly recognize β-glucan, among many other ligands. Although additional receptors recognizing β-glucan have been identified, such as lactosylceramide, Langerin, and the scavenger receptors CD5, CL-P1, SCARF1, and CD36, the generation of Dectin-1 knockout (KO) mice has demonstrated that β-glucan recognition by this receptor is central to the immune response to many fungal pathogens. From data generated over the past decade, it is now known that Dectin-1 has a pivotal role in the innate immune protective response to fungi, and that this receptor can induce the adaptive immune system driving the development of T helper (Th-1) and Th-17 responses. Dectin-1 has also been implicated in the recognition of *Mycobacterium tuberculosis* (Mtb), and recognizes an unidentified endogenous ligand. Indeed, Dectin-1 was originally identified in 2000 by Ariizumi et al. as a dendritic cell (DC)-specific molecule which was able to recognize and co-stimulate T cells, via this endogenous ligand. (See Brown 2006; Goodridge et al. 2009; Marakalala et al. 2011b for reviews.)

Structure: Dectin-1 is a type II receptor which contains an extracellular carbohydrate recognition

domain (CRD), a stalk region, a transmembrane domain, and an intracellular tail containing a nonclassical immunoreceptor tyrosine activatory motif (ITAM), known as either an ITAM-like or a hemITAM. Based on CRD sequence similarity, Dectin-1 is part of the Group V C-type lectin-like family with high homology to the natural killer (NK) C-type lectin-like receptors (CLRs), and although it contains the conserved structural characteristics of these proteins, it lacks the residues normally thought to be responsible for carbohydrate binding. In fact, unlike these NK CLRs which have proteinaceous ligands, Dectin-1 binds soluble and insoluble β-(1,3)-linked glucans in a calcium-independent manner. Furthermore, Dectin-1 does not form homo- or heterodimers, and it lacks the cysteine residues within its stalk region; features often found in other NK CLRs (Brown and Gordon 2001; Ariizumi et al. 2000). Dectin-1 does, however, form higher molecular mass structures in the presence of its ligands, such as laminarin (Brown et al. 2007), and two Dectin-1 molecules are thought to be necessary for signaling via spleen tyrosine kinase (Syk) (discussed more in detail below).

Similar to the other closely related C-type lectin-like receptors in the NK gene complex, Dectin-1 is encoded by six exons. Two functional β-glucan-binding isoforms are expressed: one full-length version translated from all six exons (Dectin-1a) and one stalkless version (Dectin-1b) lacking exon 3. The human Dectin-1 has a further six alternatively spliced variants, some lacking intact exons and others with small insertions resulting in premature stop codons. Within the CRD is a shallow surface ligand-binding groove thought to be the ligand-binding site, and Trp221 and His223, which flank this groove, have been shown to be essential for binding to β-glucans. Although the endogenous ligand is still unidentified, binding of Dectin-1 to T cells was not inhibitable by β-glucans suggesting a second ligand-binding site (See Brown 2006, Marakalala et al. 2011b; and Brown 2010 for reviews).

Function and Ligands

The binding efficiency of Dectin-1 depends on both the backbone chain length and degree of branching of the β-glucan polysaccharide. A variety of β-glucan and β-glucan–rich polymers are used in vitro as Dectin-1 ligands, the most frequent being the antagonists, laminarin and glucan-phosphate, the agonist curdlan, and zymosan, a complex *Saccharomyces cerevisiae* – derived β-glucan-rich particle that also contains multiple ligands for receptors other than Dectin-1. The purity, degree of polymerization, branching, structure, and solubility can vary extensively between these ligands and all of these factors influence the cellular responses triggered through Dectin-1. β-glucans are present in the cell wall of most fungal species, but are often only exposed during specific morphological states. Through recognition of these carbohydrates, Dectin-1 binds to a variety of fungal species including *Candida, Aspergillus*, *Coccidioides*, *Pneumocystis*, *Saccharomyces*, *Trichophyton*, *Microsporum*, and *Penicillium*. In addition to fungi, β-glucans are found in plants, and in some bacteria (but not *Mycobacteria*). As β-glucans are not produced by mammals, they act as pathogen-associated molecular patterns (PAMPs) (Brown and Gordon 2001; Adams et al. 2008; Rosas et al. 2008; Brown 2010; Kerrigan and Brown 2010).

Binding of these carbohydrates to Dectin-1 induces the production of various cytokines and chemokines, such as interleukin (IL)-1beta, IL-1alpha, IL-2, IL-6, IL-10, IL-23, macrophage inflammatory protein (MIP)-1alpha and MIP-2, tumor necrosis factor (► TNFalpha), and the production of arachidonate metabolites. Dectin-1 can also induce phagocytosis and the respiratory burst, in both neutrophils and macrophages. Stimulation of Dectin-1 is able to drive maturation of DCs and promote CD4+ and CD8+ T-cell responses to exogenous antigens, leading to the development of Th1 and Th17 adaptive immunity (see Willment and Brown 2010; Kerrigan and Brown 2010 for reviews).

Engagement of Dectin-1 with its unidentified, but non-carbohydrate, endogenous ligand induces the expression of activation markers on T cells, production of ► IFN-γ, and cellular proliferation. Evidence suggests that Dectin-1 may also have a role in phagocytosis of apoptotic cells and cross presentation of cellular antigens. A further endogenous ligand, the intracellular Ran-binding protein RanBPM, has been identified for the cytosolic human Dectin-1E isoform, which lacks both the transmembrane and stalk regions. RanBPM interacts with the GTPase Ran and may act as a scaffolding protein to coordinate signaling from cell surface receptors (Willment and Brown 2010).

Signaling

Upon engagement of Dectin-1, the cytoplasmic ITAM-like motif becomes phosphorylated on the membrane-proximal tyrosine (Tyr 15) by Src family kinases, leading to recruitment of Syk. The exact mechanism of Syk binding is unclear, as binding normally requires two phosphorylated tyrosine residues in traditional ITAMs, although it has been suggested that Syk links two Dectin-1 molecules. Dectin-1 is able to signal through various pathways, the most well characterized to date involves Syk, caspase recruitment domain (CARD)-9, Bcl-10, and ▶ Malt1,which results in the activation of the transcription factor NFkB canonical c-Rel and p65 subunits and the non-canonical RelB subunit. The more recently identified pathway involves the kinase ▶ Raf1 which integrates with the Syk pathway by sequestering the RelB and p65 into inactive dimers and ultimately biases the cytokine production toward a Th1 and Th17 profile. Both Syk and ▶ Raf1 pathways are required for directing Dectin-1-mediated adaptive responses. The following signaling molecules are also involved in Dectin-1-mediated signaling: the Src family kinases (Lck and ▶ Src), ▶ phosphoinositide 3-kinase, mitogen-activated protein kinases (ERK and p38), and protein kinases (Akt and Jnk). The SLP76-BLNK adapter proteins are partially required, and the Tec kinase Btk is differentially used depending on the cell type examined. Dectin-1 signaling also leads to the activation of the transcription factor ▶ NFAT through PLC-γ2, acting downstream of Syk, resulting in the induction of transcription factor early growth response (Egr)2 and Egr3. ▶ NFAT activation by Dectin-1 induces cyclooxygenase (cox)-2 and regulates the production of IL-2, IL-10, and IL-12 (See Goodridge et al. 2009; Kerrigan and Brown 2010; Willment and Brown 2010; Mocsai et al. 2010; den Dunnen et al. 2010; and Kerrigan and Brown 2011 for recent reviews).

Pathogens present a diverse set of ligands or PAMPS to the immune system and therefore it is not surprising that a number of pattern recognition receptors (PPRs) are engaged simultaneously. Depending on the combination of receptors activated, the resultant response can vary significantly from a synergistic enhancement to repression of downstream responses. Triggering via Dectin-1 and MyD88-coupled Toll-like receptors (TLRs), for example, gives rise to a synergistic upregulation of MIP-2, MIP-1α, IL-10, IL-23, IL-6, and ▶ TNFalpha, but simultaneously downregulates the production of IL-12. Both Syk and ▶ Raf1 are required for the collaboration between Dectin-1 and the TLRs, and cross talk between the pathways functions to regulate the balance of Th17 and Th1 responses (Gringhuis et al. 2009).

In addition to collaborating with the TLRs, interactions with other non-TLR PPRs, have been shown to modulate responses to pathogens. For example, triggering the mannose receptor or DC-SIGN, modulates the DC responses to Mtb, and SIGN-R1 and Dectin-1 are both required for the production of reactive oxygen species (ROS) in response to *Candida* in macrophages (Zenaro et al. 2009; Takahara et al. 2011). It was also recently demonstrated that expression of IL-1beta in response to β-glucans in human macrophages occurs via Dectin-1/Syk and required the activation of the intracellular NRLP-3 inflammasome, the production of ROS, and a potassium efflux (Gross et al. 2009; Hise et al. 2009; Kankkunen et al. 2010).

It should be noted that the downstream responses and signaling pathways utilized by Dectin-1 are controlled by the environment within which the receptor is expressed, both in terms of the type of cell and its state of activation, and the nature of the ligand being recognized by the receptor. For example, Dectin-1 does not induce cytokine production in some macrophage populations, but it can induce cytokine production in DCs. This has been linked to differential utilization of CARD9 and effects of various cytokines, such as granulocyte macrophage-colony-stimulating factor (GM-CSF), used to generate the DCs. In the generation of Fms-related tyrosine kinase 3 ligand (Flt3L), matured DCs or bone marrow derived macrophages, both cell types, despite expressing Dectin-1, display Dectin-1–nonresponsive phenotypes. Conversely, use of GM-CSF or IFNgamma in vitro induces a Dectin-1 responsive cell type. Levels of Dectin-1 surface expression are also dependent on posttranslational modifications such as glycosylation, the formation of complexes with other PPRs, such as the TLRs and integral membrane proteins such as CD37 and CD63, and its ability to translocate to lipid rafts where it can co-localize with Syk and PLC-gamma2. The co-localization of Dectin-1 with TLR-2 requires osteopontin, an intracellular protein, which also acts as an adapter molecule facilitating interactions with Syk, increasing Dectin-1-mediated responses, such as cytokine production and facilitating the respiratory burst (Marakalala et al. 2011b; Willment and Brown 2010; Inoue et al. 2011).

Expression and Regulation

Murine Dectin-1 is present in immune cell-rich tissues such as the spleen, lung, thymus, kidney, and liver as well as other organs such as the stomach and small intestine. It is a predominantly myeloid expressed molecule with macrophages, neutrophils, $CD11c^{low}$ and $CR\text{-}3^{+}$ splenocyte, and macrophage subpopulation of splenic red and white pulp all expressing high levels of Dectin-1. Peripheral blood monocytes, inflammatory and alveolar macrophages, Kupffer cells, microglia, lamina propria macrophages, and inflammatory-recruited neutrophils also express this receptor. Dectin-1 positive DC subsets in the peripheral blood, lymph nodes, spleen, dermis, medullary and corticomedullary regions of the thymus, and lamina propria have been identified. Low levels of Dectin-1 expression have been observed on resident peritoneal macrophages, while eosinophils, B cells, and DCs and macrophages of the kidney, heart, eye, and brain are all Dectin-1 negative. The levels of murine Dectin-1 expression can be upregulated by the presence of cytokines that bias the immune response toward a Th-2 profile, such as IL-4 and IL-13, and which gives rise to alternatively activated macrophages. While exogenous GM-CSF will increase Dectin-1 levels, the addition of IL-10, lipopolysaccharide (LPS), dexamethasone, and β-glucans will downregulate surface expression. On T-cell populations, Dectin-1 has been detected on a subset of splenic T cells and on an IL-17–producing subset of γδ T-cell receptor and chemokine receptor 6–positive T cells (See Brown 2006; Willment and Brown 2010; Reid et al. 2009 for reviews).

Human Dectin-1 is expressed on monocytes, immature and mature human monocyte-derived DCs, B cells, eosinophils, neutrophils, $CD1a^{+}$ Langerhans cells, and peripheral blood DCs ($CD1c^{+}CD19^{-}$), but not on plasmacytoid DCs (although there is mRNA present in these cells) or NK cells. However, some unidentified $CD4^{+}$ T-cell subsets do express this receptor. Cell-specific expression of human Dectin-1 mRNA has been reported in monocytes, macrophages, neutrophils, mast cells, eosinophils, and monocytic, B- and T-cell lines. Regulation of the transcription has been observed in vitro with the addition of various cytokines, TLR ligands, and pathogens influencing levels (Willment and Brown 2010).

Dectin-1 is a type II transmembrane receptor, however, when overexpressed in cell lines Dectin-1 localizes to both the perinuclear compartments and the cell surface. There is relatively less Dectin-1b expressed on the cell surface compared with Dectin-1a, possibly due to the lack of glycosylation signals within the former. In human neutrophils, Dectin-1 is located on the plasma membrane (γ-fraction) and within the azurophilic granules (α-fraction) inside the cytoplasm, and in murine macrophages the amounts of intracellular Dectin-1 versus the surface expressed Dectin-1 is affected by the levels of the tetraspanin CD37. The intracellular route of Dectin-1 after binding to soluble ligands, such as laminarin, allows it to be recycled to the surface, whereas larger ligands retain Dectin-1 within the phagosomal compartment leading to de novo–synthesized Dectin-1 expressed on the cell surface. After uptake of ligand, Dectin-1 co-localizes with the lysosomal membrane glycoprotein-1 (LAMP-1) and the tetraspanin CD63. Depending on the nature of the ligand, Dectin-1 can be observed in phagolysosomal compartments, during zymosan uptake, or only in early phagosomes during *Candida* uptake (Brown 2006; Willment and Brown 2010).

Role in Immunity and Homeostatis

The role of Dectin-1 has been extensively examined using murine models but there are now human studies, discussed more in detail below, which highlight the importance of Dectin-1 in antifungal immunity. The Dectin-1 KO mice are phenotypically normal in the absence of infection, however, they show increased susceptibility to infections with *Candida* (with some mouse and *Candida* strain variation), *Aspergillus*, and *Pneumocystis* (Drummond et al. 2011). Macrophages derived from KO animals were still able to recognize *Pneumocystis* and *Candida albicans* (strain 18804, but not strain SC5314), despite the demonstrated in vitro role of Dectin-1 in the recognition of zymosan and live fungi. *Pneumocystis* and *Candida albicans* 18804 elicited similar cytokine profiles in KO and wild-type (WT) macrophages; however, *Candida albicans* SC5314 recognition was impaired by the absence of Dectin-1 and the observed cytokine profile was altered. Both *Pneumocystis* and *Aspergillus* do not induce a ROS response in the KO mice, highlighting Dectin-1's role in killing of fungi (Drummond et al. 2011). In addition to these earlier KO studies, more recent reports have reinforced Dectin-1's role in cell-specific antifungal immunity. Mice with a macrophage-specific

Dectin-1 KO, examined in the context of gastrointestinal models of candidiasis, show a more severe phenotype, and mice with a neutrophil-specific calcineurin deficiency are more susceptible to disseminated candidiasis. Dectin-1, and not the TLRs, was shown to be the activator of calcineurin in neutrophil responses to *Candida* (Greenblatt et al. 2010; Gales et al. 2010).

Classically the induction of a Th-1 immune response was thought to be required for antifungal immunity, but the role of Th-17 and T-regulatory cells has recently become prominent with mice lacking a Th-17 response being more susceptible to *Candida* infection (see Vautier et al. 2010 for review). The induction of the adaptive response, in particular the Th-17 response, is completely dependent on the presence of CARD9, but was not altered in the Dectin-1 KO mice during *Candida* infection (Kerrigan and Brown 2011). This induction was recently demonstrated to be mediated by Dectin-2, signaling via Fc-gamma receptor, Syk, and CARD9, which interacts with the alpha-mannans present in *Candida* (Saijo et al. 2010). In contrast to *Candida* infections, murine Dectin-1 is essential during *Aspergillus* infections for both the innate immune response and the induction of a Th-17 response, modulating the balance between Th-1 and Th-17 responses by inhibiting Th-1 CD4 T-cell differentiation (Werner et al. 2009; Rivera et al. 2011).

There are a few examples where a role for Dectin-1 has been demonstrated in vitro but analysis of the KO response to infectious challenge has not shown any significant role for Dectin-1 in vivo. In vitro experiments had demonstrated roles for Dectin-1 in binding and developing a Th1/Th17 profile for Mtb, whereas the in vivo experiments using the Dectin-1 KO mouse provided evidence that alternative receptors are able to compensate for the lack of Dectin-1 (Kerrigan and Brown 2011; Zenaro et al. 2009; Marakalala et al. 2011a). In the case of *Cryptococcus*, spores were demonstrated to bind Dectin-1 in vitro, but the KO mice are not more susceptible than WT to infection (Giles et al. 2009; Nakamura et al. 2007). Although not yet examined using Dectin-1 KO mice, susceptibility to *Coccidioides* infection was found to be dependent on the strain of mice, with C57BL/6 mice more susceptible than DBA/2. The differences in susceptibility may be due to the relative levels of Dectin-1a and Dectin-1b mRNA transcripts, with some mouse strains either expressing both transcripts equally or predominantly the Dectin-1b transcript. In vitro, these two isoforms have been shown to have slightly different activities, for example, cells expressing Dectin-1b produce more ▶ TNFalpha than Dectin-1a under the same conditions. There are also three murine Dectin-1 single nucleotide polymorphisms (SNPs) (R37Q, S73P, and V165A) differing between C57BL/6 and BALB/c mice that have been identified, but these SNPs have not been linked to any functional effects (Willment and Brown 2010).

A role for Dectin-1 in human antifungal immunity was recently demonstrated with the characterization of two different SNPs, which affect the levels of human Dectin-1 surface expression, and their ability to induce cytokine responses to *Candida*. These data demonstrate that patients with a homozygous Dectin-1 Y238X SNP, resulting in a prematurely truncated protein, are more susceptible to mucocutaneous fungal infections, but not systemic infections. Cells from these patients display defective cytokine production, in particular IL-17, ▶ TNFalpha and IL-6, but are still able to bind and phagocytose live *Candida*. This same SNP also has been implicated in increased susceptibility to both invasive *Aspergillosis* and *Candida* colonization during transplantation, and has clinical relevance if either the donor and/or transplant recipient of hematopoietic stem cells carries the Y238X SNP. The second characterized SNP I223S, which renders cells transduced with I223S Dectin-1 unable to bind fungal particles due to lack of surface expression, may play a role in the immunity to fungi (Marakalala et al. 2011b; Cunha et al. 2010; Plantinga et al. 2010).

The Y238X SNP patient studies have demonstrated a role for human Dectin-1 in mucosal immunity and not in systemic *Candida* fungal infections, due to an impaired Th-17 response, which is now thought to be pivotal during mucosal infections. This is contrary to the role in the mouse where the induction of IL-17 in response to *Candida* is not Dectin-1 dependent (see above). A further difference in host response is observed during *Aspergillus* infections; human Dectin-1 induces a strong Th-1 and a weak Th-17 response, while murine Dectin-1 inhibits the Th-1 response and induces a protective Th-17 response. These differences in immune responses may be due to site-specific immune reactions, such as mucosal versus systemic, and species diversity in the role of Th17 cells. The disparity between the human and

murine immune responses to fungal infections needs further investigation, before significant progress can be made using β-glucan adjuvants targeting Dectin-1 for clinical applications (Vautier et al. 2010; Rivera et al. 2011; Kerrigan and Brown 2011; Chai et al. 2010).

Using a mouse model of zymosan-induced arthritis, a role for Dectin-1 in autoimmune disease has been suggested. The clinical relevance of Dectin-1 in human autoimmune disease is less clear as in studies of chronic inflammation, the Y238X polymorphism did not appear to be a susceptibility factor in irritable bowel diseases or rheumatoid arthritis (RA). This is despite an observed influx of Dectin-1 expressing macrophages in bowel sections obtained from both Crohn's disease and diverticulitis patients, and synovial tissue sections from RA patients, but not those from osteoarthritis patients. It has been suggested, although not proven, that human Dectin-1 may play a role in psoriasis, firstly because Dectin-1 mRNA and those of a number of other PPRs, is upregulated in skin epidermis biopsies obtained from psoriasis patients relative to healthy controls, and secondly, the larger number of infiltrating Langerhans cells in the psoriasis samples are Dectin-1 positive (Willment and Brown 2010; Marakalala et al. 2011b).

Summary

Dectin-1 has a pivotal role in the immune response to fungal pathogens, as evidenced both from human and mouse studies. It is a predominantly myeloid restricted receptor, and its expression on these cell types is crucial for the recognition and killing of fungal pathogens and induction of the subsequent antifungal immune responses. Depending on the cell type and the nature of the ligand, it triggers intracellular signaling via its ITAM-like motif through various pathways, including Syk/CARD9 and Raf1, resulting in the activation of nuclear transcription factors. Collaborating together with multiple other PPRs, a variety of other cellular responses, such as phagocytosis, the respiratory burst, and arachidonate metabolism are initiated and the innate and adaptive immune responses are modulated through the regulation of cytokine and chemokine production. Although Dectin-1 recognizes β-glucans, it also has an uncharacterized ligand on *Mycobacteria* and an endogenous, non-carbohydrate ligand, on T cells and apoptotic cells. In addition to a clearly demonstrated role in antifungal immunity, Dectin-1 has been implicated in autoimmunity and may play a role in other inflammatory diseases. The study of Dectin-1, and its collaboration with other receptors, has given significant new insights into the underlying mechanisms involved in the development of the innate and adaptive immunity to fungi.

Synonyms

CLK kinases; LAMMER kinases; STY (CLK1)

Historical Background

CLK1 (cdc2-like) kinase was initially described in mammalian systems (mouse and human cells), and

was so-named because of amino-acid sequences similar to cdc2 kinase (now cdk1) in specific kinase catalytic subdomains (Stodjl and Bell 1999 and references therein). CLK1 was also referred to as STY, since it was the first kinase which autophosphorylated with dual-specificity, i.e., on Ser/Thr and Tyr (S/T and Y in the single-letter amino-acid code). Subsequent studies identified four CLK kinases in vertebrate genomes, CLK1-4. The cloning and characterization of the *Drosophila* orthologue, DOA, enabled the recognition of family members in many additional species, including *Arabidopsis thaliana* (AFC1-3), *Nicotiana tabacum* (PK12), *Schizosaccharomyces pombe* (Lkh1), and *Saccharomyces cerevisiae* (KNS1) (Yun et al. 1994; Savaldi-Goldstein et al. 2003; Kang et al. 2010 and references therein). These were collectively referred to as "LAMMER" protein kinases, due to a conserved amino-acid motif including this sequence in kinase catalytic domain X, specific to this sub-family. CLK/LAMMER kinases are found throughout eukaryotes and are considered to be among the 347 eukaryotic "signature" proteins (Hartman and Federov 2002). The amino-acid identities leading to the CLK nomenclature ("cdc2-like" kinase) have since been identified in numerous other related kinases, including the cdk and MAP kinases, placing them in the CMGC kinase family. No cyclin-dependence has been described for CLK/LAMMER kinases, and the name CLK has unfortunately been the cause of confusion, since the circadian rhythm genes of the nematode *C. elegant* are CLOCK genes, (clk), and and their human orthologues were named HCLK.

Structure of the LAMMER/CLK Kinases

The catalytic domains of LAMMER/CLK kinases define the C-terminal domain of the protein and comprise roughly two-third of the overall structure in most cases (Yun et al. 1994). The catalytic domains of these kinases are remarkably similar to each other in overall structure and amino-acid sequence, with near 100% amino-acid identity in key residues and motifs throughout catalytic subdomains. Examples are found in kinase catalytic subdomains VIb and VIII where the motifs HTDLKPENIL and STRHYRAPEVIL are respectively either 100% identical or are nearly so in all family members. Both motifs are intimately involved in catalysis or substrate interaction. In particular, the former motif is exclusive to the LAMMER kinases, although the Thr residue, more frequently Arg or Cys in other kinases, is also found in the SRPK kinases. The SRPKs phosphorylate many of the same substrates as the LAMMER kinases, i.e., the SR proteins, albeit not on the same sites. Although the LAMMER motif (EHLAMMERIL) is itself conserved and easily recognizable in all family members, some amino-acid substitutions occurred during evolution, as for example, in *S. cerevisiae* KNS1p (EHMAMMQRIL) and mammalian CLK3 (EHLVMMEKIL, Table 1). Indeed, in *S. cerevisiae* KNS1p an insert of 20 residues relative to other LAMMER kinases occured at the C-terminus of the motif between the terminal I and L residues. The LAMMER motif was hypothesized to lie on the surface of the lower lobe of the kinase domain based upon alignments with other CMGC kinases and thought to perhaps play a role in protein–protein interactions with interacting molecules. However, this idea was not upheld by in vitro studies introducing amino-acid substitutions in the tobacco orthologue PK12 (Savaldi-Goldstein et al. 2003), nor was it validated by recent crystallographic studies performed on the catalytic domains of mammalian CLK1 and CLK3 (Bullock et al. 2009). These latter studies revealed the existence of insertions relative to other kinases placing the LAMMER motif in the interior of the molecule.

Several studies have demonstrated that LAMMER kinases, unlike their cousins in the SRPK family of kinases, do not possess specific docking sites for their substrates, perhaps explaining their broader substrate specificity. Interestingly, the crystal structures for the CLK1 and CLK3 catalytic domains show that they are constitutively active in their non-autophosphorylated state (Bullock et al. 2009). This data is supported by unpublished results showing that autophosphorylation of the DOA catalytic domain represses kinase activity (C. Du and L. Rabinow).

The non-catalytic N-termini of LAMMER kinases are highly diverged from each other and thus were not subjected to stringent constraints during evolution. However, the N-termini are all positively charged, possessing high pI values if considered independently of their catalytic domains (Rabinow unpublished). Most also contain short motifs of Ser-Arg residues in unique or double (but not triple) repeats, somewhat reminiscent of one class of their substrates, the SR proteins. It would nevertheless be erroneous to

designate these as "RS" domains such as those found in the SR and SR-like proteins, which contain multiple and extensive Arg-Ser repeats.

LAMMER Kinase Autophosphorylation, Consensus Phosphorylation Sites, and Substrates

All LAMMER kinases tested autophosphorylate on Ser/Thr and Tyr residues, but none has been demonstrated to possess tyrosine kinase activity toward an exogenous substrate. Autophosphorylation of CLK2 affects its intranuclear distribution in cultured cells. The autophosphorylation site is conserved among all mammalian CLKs (Nayler et al. 1998) but not among non-vertebrate LAMMER kinases, although the *A. thaliana* LAMMER kinases AFC1-3 all possess potential autophosphorylation sites at similar locations (Rabinow unpublished). Interestingly, autophosphorylation on different sites of CLK1 differentially alters its substrate specificity (Prasad and Manley 2003).

A consensus phosphorylation sequence for three LAMMER kinases from humans (CLK2), *Drosophila* (DOA), and *N. tabacum* (PK12) revealed substantial substrate similarities among the three kinases (Nikolakaki et al. 2002, Table 2).

The consensus phosphorylation site was defined by in vitro phosphorylation of peptide libraries and contains an Arg residue fixed at −3 to the phosphorylation site. Curiously, both positively and negatively charged

residues on both sides of the phosphorylation site are favored. To date only Ser residues on exogenous substrates have been found to be phosphorylated with the exception of Thr735 on c-Abl tyrosine kinase, which is phosphorylated by CLK1 and CLK4, creating a potential 14-3-3 protein binding site. The consensus site as defined in the above study did not reveal a preference for a Pro residue at the +1 position, although the familial relationship of LAMMER kinases with "proline-directed" kinases such as cdk's and MAPKs, all in the CMGC group, suggested that Pro should be a favored amino-acid at this position. This hypothesis was borne out by the examination of protein as opposed to peptide substrates, both in vitro and in vivo, as well as by a more recent peptide-based approach using different technology to examine substrate specificity of CLK1 and CLK3 (Bullock et al. 2009). This later study otherwise supports the features of the LAMMER kinase consensus phosphorylation sites for CLK2, DOA, and PK12.

All LAMMER kinase family members tested phosphorylate SR and SR-like proteins in vitro and in vivo (Nayler et al. 1997; Stodjl and Bell 1999; Nikolakaki et al. 2002). The SR proteins regulate multiple steps in mRNA maturation, and their phosphorylation is tightly regulated. Thus LAMMER kinases play important regulatory roles in the alternative and constitutive splicing of pre-mRNAs through phosphorylation of their substrates. However, the presence of the LAMMER orthologue KNS1 in the yeast *S. cerevisiae* suggests that the ancestral function of these kinases must involve a function other than the regulation of splicing, since the genome of this yeast does not encode any SR or SR-like proteins, nor is there alternative splicing per se; and even constitutive splicing is dispensable for vegetative growth of this yeast.

Several publications comparing the substrate specificities of LAMMER and the related SRPK kinases, which also phosphorylate SR proteins, showed that the former possess wider substrate specificity and can conceivably phosphorylate different substrates in addition to the SR proteins (Stodjl and Bell 1999 and references therein). This is in part due to the lack of a substrate-docking site in the LAMMER kinases, as opposed to SRPK kinases (Velazquez-Dones et al. 2005). In vitro substrates used to assay LAMMER kinase activity have included myelin basic protein and histone H1, although the latter is not phosphorylated by all family members, specifically CLK2 and DOA. Aside from SR and SR-like proteins, LAMMER kinase substrates in mammalian cells include the chromatin and RNA-binding protein SAF-B, the protein tyrosine phosphatase PTP1B, prp4 kinase, c-Abl tyrosine kinase, and cyclophilin-RS (Table 3). CK-I was also phosphorylated by CLK2 in vitro. In *Drosophila* several substrates in addition to SR and SR-like proteins have been identified, among which is eEF1βγ (formerly known as EF1γ), a putative translational elongation factor, but which was recently found to participate in the nuclear 3′ end pre-mRNA cleavage complex.

In the yeast *S. pombe*, Lkh kinase phosphorylates RNA-binding protein Csx1 and the TUP11 and TUP12 transcriptional repressors. Global analysis of phosphorylation networks in *S. cerevisiae* has revealed a large number of potential substrates, including the kinases CDC15 and ATG1, although these have not been tested for biological effects.

In short, the substrate specificity of the LAMMER kinases demonstrates that SR and related proteins as well as other regulators of RNA maturation are targeted, although additional processes and substrates including signaling molecules are also clearly phosphorylated.

Genetic, Functional, and Expression Studies on LAMMER Kinases

Mammalian CLKs

CLK1–4 all phosphorylate SR proteins and alter splicing of reporter constructs when over-expressed in cultured cells (Nayler et al. 1997). Alternative splicing of adenovirus is also affected by CLK1. CLK1, 2, and 4 are widely, perhaps ubiquitously, expressed in mammalian tissues, while in contrast CLK3 expression is enriched in testes and spermatozoa (Menegay et al. 1999). It is released from sperm with the acrosome, resulting in the suggestion that it may play a role in fertilization. Mammalian CLK kinases are generally nuclearly localized, but cytoplasmic kinase has also been detected via immunocytochemistry and western blotting when fixation conditions were appropriate (see references Table 3), or on immunoblots when cell fractionations were performed (Prasad and Manley 2003). An antibody directed against the LAMMER motif reveals a large component of nuclear staining in fixed HeLa cells, but cytoplasmic staining as well (K. Lee and L. Rabinow unpublished). Moreover, cell fractionations of HeLa cells followed by immunoblot analysis using the same antibody also detect LAMMER kinases in the cytoplasmic, as well as nuclear fractions (ibid).

Consistent with a role in the phosphorylation of SR proteins, over-expression of CLK1 in cultured cells results in the dispersion of nuclear "speckles," which are thought to be storage sites of SR and other splicing-related proteins (Stodjl and Bell 1999 and references therein). Dispersion of the speckles necessitates transfection with an active form of CLK kinase, since transfections with a catalytically inactive construct of the kinase using a single amino-acid replacement have no effect on speckle number or distribution. All four mammalian CLKs are regulated at the level of splicing, where exclusion of exon 4 (in both mouse and human CLK1) results in use of an in-frame stop codon just upstream of the kinase catalytic domain, resulting in possible production of a truncated peptide. It has been suggested that the mRNA including the premature termination codon is subjected to nonsense-mediated decay (NMD) and thus accumulation of significant levels of truncated CLK peptides might not occur (Hillman et al. 2004). Regulation of CLK1 exon 4 inclusion occurs through autoregulation, but also at least in part through interaction of CLK4 with an SR-like protein, CLASP, the mammalian orthologue of *Drosophila suppressor of white-apricot, su(w^a)* (see reference Table 3). CLASP phosphorylation by CLK4 induces exon 4 exclusion in CLK1 transcripts, thus down-regulating CLK1 levels.

Inclusion or exclusion of exon 4 in CLK1 is regulated in response to stress and also during erythroleukemic cell differentiation. In the first case it was found that cage-restraint and water-immersion of mice reduced accumulation of CLK1 transcripts in the brain, while the balance of the two alternatively spliced transcripts was altered toward the exclusion of exon 4, and hence the production of the non-coding RNA (Murata et al. 2005). Transcripts encoding both the full-length and truncated proteins of all four CLK kinases were up-regulated during HMBA-induced differentiation of MEL erythroleukemia cells (Garcia-Sacristan et al. 2005). In undifferentiated cells, CLK1 transcripts encoding the full-length protein predominated, whereas at later stages of differentiation the transcript including exon 4 became the major form, presumably down-regulating kinase levels and suggesting a role for the kinase in the differentiative process. CLK1 kinase also affects alternative splicing of additional target transcripts which include the choice between pro- and anti-angiogenic forms of VEGF and the splicing of tissue-factor (TF) required for thrombus formation in anucleate human platelets. In addition to its role in the phosphorylation of SR proteins, CLK1 kinase was also reported to negatively regulate expression of Super-Oxide Dismutase (SOD1), since reduction of CLK1 via RNA interference increased SOD1 activity, protein and mRNA in both HeLa and MCF-7 cell lines.

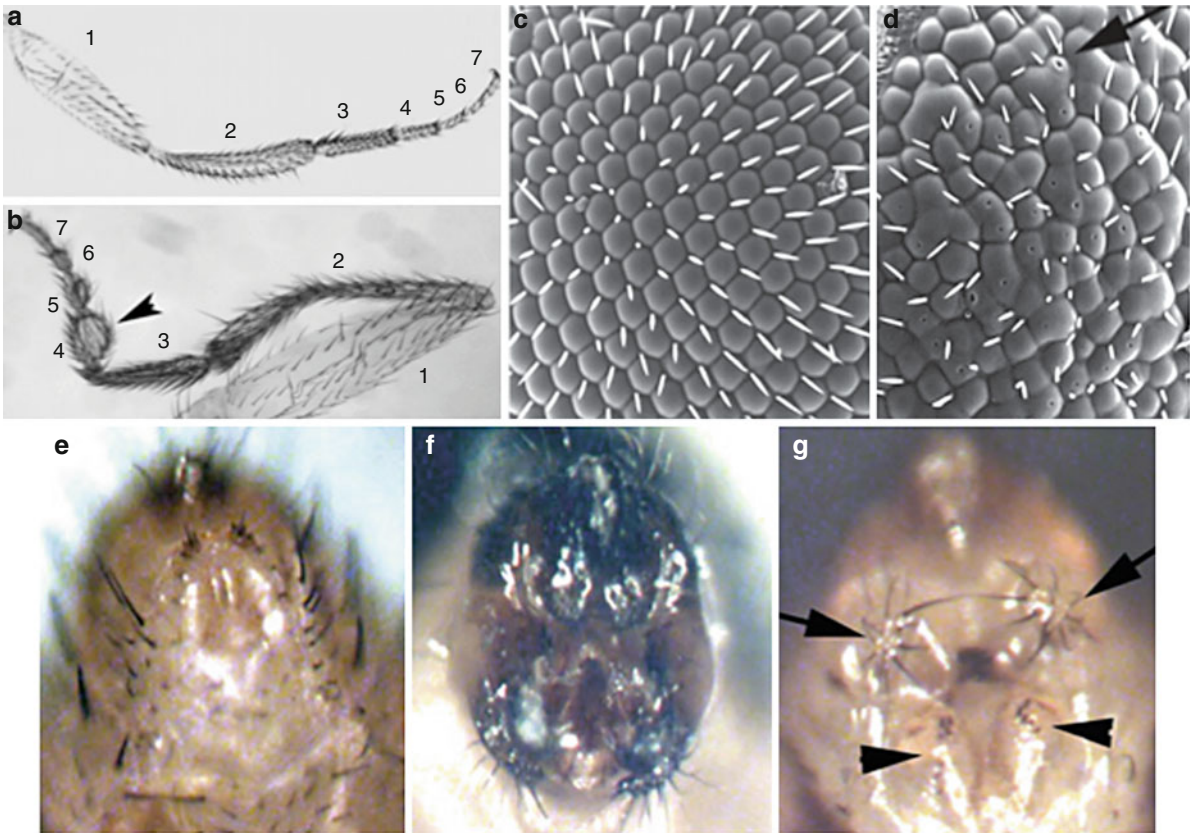
CLK2 was recently described as an insulin-regulated suppressor of gluconeogenesis in primary hepatocytes, repressing activity of the transcriptional co-activator PCG1a through direct phosphorylation of its RS-domain (Rodgers et al. 2010). Repression of PCG1a target genes was also observed in cell cultures when transfected with active CLK2, as well as in the livers of mice infected with an adenovirus-CLK2 transformation construct. Moreover, CLK2 protein levels were induced by feeding, under control of insulin and AKT signaling, while its mRNA levels were largely unaffected. Induction of CLK2 protein was due at least in part to stabilization of the protein and required CLK2 kinase activity and autophosphorylation. Furthermore, diabetic and obese *db*/*db* mice downregulated hepatic CLK2 levels, apparently due to lower protein levels. Reintroduction of active CLK2 restored normal glucose levels to near that of control animals. CLK1 kinase was also directly phosphorylated and activated by AKT kinase (Jiang et al. 2009, see below), leading to effects on alternative splicing of a transcript encoding a PKC isoform.

Interestingly, an earlier report demonstrated the interaction of CLK1, 2, and 4 with an ubiquitin-like molecule (UBL-5, or beacon), whose administration leads to obesity and weight-gain in *Psammomys obesus* (Israeli sand-rats). The beacon molecule was not phosphorylated by the CLKs and so the molecular basis or function of the interaction is not clear. However, these results taken together with those described above suggest that CLK2 is a crucial and newly characterized component of the insulin-signaling pathway. Moreover, these results reveal a specific role for the LAMMER kinases in the regulation of nuclear processes in addition to that of alternative splicing, and their regulation by a crucial evolutionarily conserved signaling pathway.

DOA Kinase of *Drosophila*

The single LAMMER kinase orthologue of *Drosophila* is encoded at the *Darkener of apricot* (*Doa*) locus, so-named because mutants partially suppress the $white^{apricot}$ allele. The locus is the best genetically characterized of all LAMMER kinase-encoding genes due to the facility of genetics in the fly. Mutations are almost invariably recessive lethal at early developmental stages. Homozygous mutant embryos hatch and die as early larvae; this late lethality is allowed by maternal contribution of both RNA and protein to the oocyte (Yun et al. 1994). In contrast, somatic mosaic experiments revealed that null alleles are cell lethal. Clonal analyses also showed that the kinase is essential for early oocyte development. Although homozygous animals are generally inviable, specific allelic combinations (heteroallelic animals) permit recovery of adults, which reveal extensive pleiotropic phenotypes, including roughened eyes, ectopic wing-veins, duplicated bristles (external touch organs of the fly), sterility, transformation of somatic female tissues into male structures, and aberrant development of distal segments of the legs (Fig. 1). Over-expression of specific kinase isoforms can also induce pleiotropic aberrations. Two alleles due to chromosomal rearrangements permit occasional survival of homozygotes which display striking degeneration of retinal photoreceptor cells in the rare surviving adults. Homozygous embryos obtained from heteroallelic mothers (to eliminate maternal contribution) show disrupted development of the central nervous system and cuticular structures. Finally, complete phenotypic suppression of $white^{apricot}$ in several classes of *Doa* heteroallelic mutants is accompanied by reduction in levels of transcripts prematurely truncating within the copia retrotransposon, whose insertion caused this allele. The amount of copia transcript levels in the fly is also doubled. Specific alleles of *Hw* and *Bx* also induced by insertion of copia elements are also phenotypically suppressed by *Doa* mutations. Interestingly, suppression is independent of the orientation of insertion of the element with respect to the affected gene, arguing against a strand-specific (i.e., RNA processing) effect.

DOA is the only LAMMER kinase for which a role in alternative splicing has been documented in whole animals. Female-to-male sex transformations of varying degrees are observed in different classes of *Doa* mutants (Fig. 1), due to aberrant splicing of *doublesex (dsx)* transcripts (Du et al. 1998; Rabinow and Samson 2010). *dsx* encodes a transcription factor whose transcripts are alternatively spliced under the control of several SR and SR-like proteins to yield male or female-specific isoforms. As for other LAMMER kinases, DOA phosphorylates SR and SR-like proteins in vitro. Moreover, the SR and SR-like proteins TRA2 and RBP1 are hypophosphorylated and delocalized from chromatin in *Doa* mutant flies. Finally, genetic epistasis experiments showed that *Doa's* effects on sex-determination were at or parallel to the level of phenotypes induced by mutation of the gene encoding the SR-like protein TRA, which assembles directly



CLK, Fig. 1 Pleiotropic phenotypes of *Doa* mutations Heteroallelism for various combinations of *Doa* alleles or over-expression of specific kinase isoforms yields pleiotropic phenotypes: (**a**) Wild-type leg structure; (**b**) Aberrant leg structure due to failure of the distal segments of the tarsi (tarsi 4–6, *arrow*) to elongate in $Doa^{DEM}/Doa^{l(3)01705}$; (**c**) Wild-type eye at high magnification: (**d**) An eye derived from an animal over-expressing the ubiquitously expressed 55 kD nuclear kinase, showing fused ommatidia and pinpoint holes in the lens covering the photoreceptor cells (*arrow*); (**e**) Normal female genitalia; (**f**) Normal male genitalia; (**g**) Somatic transformation of XX-females (female genitalia, *arrowheads*) to males (male genitalia, *arrows*)

onto the Exonic Splicing Enhancer complex responsible for activation of the female-specific *dsx* splice. It was therefore concluded that DOA directly phosphorylates SR and SR-like proteins responsible for splicing of the *dsx* transcript in vivo.

In contrast to the mammalian LAMMER kinases, no alternative splicing leading to insertion of an exon encoding a premature stop codon has been observed in *Doa* of *Drosophila*. However, the locus encodes six polypeptides of 55, 69, 91, 105, 138, and 227 kD generated by transcripts originating from alternative promoters. These proteins possess virtually identical catalytic domains, but aside from some partial overlaps, differing non-catalytic N-termini. These proteins perform at least three different functions as shown through genetic dissection using isoform-specific mutations, over-expressing alleles, and RNAi constructs. This idea is supported by the observation that the 55 kD protein is primarily nuclearly localized, while another of 105 kD is exclusively cytoplasmic, at least during pupal development. Additionally, the 105 kD protein is not predicted to alter splicing of the transcripts affecting the somatic sex-determination cascade, since over-expression, in vivo RNAi and isoform-specific mutations affecting this isoform do not induce sex transformations. Finally, the 227 kD isoform has recently been implicated in the control of cell trafficking (V. Gelfand, personal communication).

Doa has also been identified in mutageneses, various genomic screens, and systematic RNAi in S2 cells (Table 4). For example, analysis of genes differentially expressed during autophagy and death of the salivary

CLK, Table 4 Identification of DOA kinase in various mutagenic and other screens

Screen/effect	Cells/whole animals	Reference
Suppression of mutagenic effects of copia transposable-element insertions	Whole animal	Rabinow and Birchler 1989
Copia transcript levels elevated in mutants		Rabinow et al. 1993
Oocyte development blocked	Whole animal	Morris et al. 2003
RNAi blocks cell cycle progression, increased% G1	S2 cells	Bettencourt-Dias et al. 2004 and Bjorklund et al. 2006
RNAi blocks protein secretion, DOA localized to ER	S2 cells	Bard et al. 2006
RNAi to DOA inhibits specific splicing events	S2 cells	Park et al. 2004
Doa mRNA induced to high levels during autophagy	Salivary glands (tissue)	Lee et al. 2003 and Gorski et al. 2003
Reduced *Doa* mRNA associated with higher aggression	Whole animal	Edwards et al. 2006
Reduced *Doa* mRNA correlates with reduced "startle" response	Whole animal	Yamamoto et al. 2008
Female-to-male somatic sex transformations; aberrant splicing of *dsx* and *exu* transcripts; hypophosphorylation and aberrant localization of SR and SR-like proteins	Whole animal	Du et al. 1998

glands during pupation demonstrates that *Doa* transcripts are one of the four most induced. *Doa* transcripts were significantly reduced in screens for hyperaggressive flies and in animals showing an altered "startle" response, while screens in S2 cells showed that *Doa* is required for cell cycle progression as well as for protein secretion.

These observations, coupled with the molecular analysis of *Doa* expression and genetic dissection of isoform functions provide further support that LAMMER kinases target multiple processes in addition to alternative splicing through the phosphorylation of SR proteins.

The LAMMER Kinases of Yeast: Lkh1 of *S. pombe* and KNS1p of *S. cerevisiae*

The LAMMER kinase of *Schizosaccharomyces pombe* Lkh1/Kic1 has been well characterized (see references Table 3; Kang et al. 2010). It negatively regulates filamentous growth, and its mutation causes asexual flocculation of the yeast. *lkh* mutants of *S. pombe* are sensitized to oxidative stress due to decreased levels of catalase and super-oxide dismutase. Decreased oxidative stress response is mediated by lower expression of the Atf1 transcription factor in *lkh1* mutants. It was additionally found that the RNA-binding protein Csx1 was directly phosphorylated by Lkh1 in response to oxidative stress and that Csx1 protein binds and stabilizes *atf1* mRNA. This last observation suggests a mechanism by which Lkh1 phosphorylation may reduce accumulation of Atf1 protein. Over-expression of Lkh1/Kic1 produced elongated cells, while others failed to undergo cytokinesis. Finally, it was recently reported that Lkh1 phosphorylates the Tup11 and 12 transcriptional repressors and that this phosphorylation is required for their activity (Table 3 and references therein).

In contrast to the detailed information available concerning the *S. pombe* LAMMER kinase, little is known about the orthologue of budding yeast, KNS1. Mutants undergo normal cell division, vegetative growth, and glucose utilization. Moreover, no authentic SR or SR-like proteins are encoded in the *S. cervevisiae* genome, and no alternative splicing is known for this yeast, strongly suggesting a role for the kinase other than that of splicing regulation. A synthetic lethal screen failed to recover any interacting loci rendering the locus vital (M. Horn, L. Neigeborn and L. Rabinow unpublished). Data from high-throughput proteomic screens revealed interactions between KNS1 and the ATG1 and CDC15 kinases. The former interaction supports the hypothesis of a role for LAMMER kinases in autophagy, as suggested by the observation of strong induction of *Doa* transcripts upon autophagy in the *Drosophila* salivary glands.

Plant LAMMER Kinases

The genome of *Arabidopsis thaliana* encodes three LAMMER kinase paralogues (Table 1 and references therein). AFC1 was identified in transgenic screens

for loci capable of complementing mutations in *S. cerevisiae* FUS3 (a MAP kinase). The AFC2 and AFC3 paralogues were subsequently identified by PCR analysis, but no further work has been performed on them.

The best characterized of the plant LAMMER protein kinases is PK12 of tobacco, whose transcript and protein levels are both induced by the hormone ethylene (Savaldi-Goldstein et al. and references therein). As all other LAMMER kinases tested, PK12 phosphorylates SR proteins and affects alternative splicing in vivo. Analysis of amino-acid replacements in the LAMMER motif showed that this sequence affects subnuclear localization of the kinase, but did not affect substrate selection. Replacement of the motif with random amino-acids instead resulted in loss of catalytic activity. Analysis of transgenic *Arabidopsis* expressing a constitutively active PK12 revealed a subset of developmental effects typical of overexpression of ethylene-pathway response loci.

Regulation of LAMMER Kinases

Aside from the alternative splicing of exon 4 in mammalian CLK1-4 kinases described above, relatively little is published concerning the regulation of the LAMMER protein kinases. In *tobacco*, the PK12 kinase is activated both transcriptionally and catalytically by the hormone ethylene (Table 5). In *Drosophila* two *Doa* isoforms are transcriptionally induced by the steroid hormone ecdysone during pupariation.

Phosphorylation and activation of CLK1 by AKT occurs in response to insulin signaling, consistent with CLK2 activation and stabilization described above in conjunction with its role as a suppressor of gluconeogenesis. One recent study demonstrated increased cell survival following phosphorylation of CLK2 by AKT in response to ionizing radiation.

LAMMER Kinases on Drugs

Several inhibitors of LAMMER/CLK kinases have been developed which have altering degrees of specificity for the individual family members (Table 6 and references therein). The first of these, TG003, is a benzothiazole that inhibits CLK1 kinase in tests of its ability to alter splicing in vitro and in mammalian cells, as well as in phosphorylation of ASF/SF2. TG003 also blocked CLK1-induced dissociation of nuclear speckles, as well as defects induced due to presumed excess CLK activity in *Xenopus* embryos that had been injected with mRNA for one of the *Xenopus CLK* kinases. No toxic effects on growth or cell-cycles of COS-7 cells were observed. TG003 has high specificity for both murine CLK1 (IC_{50}: 20 ηM) and CLK4 (IC_{50}: 15 ηM), whereas CLK2 and CLK3 were less affected (IC_{50} 200 ηM and >10 μM, respectively).

Chlorhexidine was identified as a second CLK inhibitor in a high-throughput screen for modulators of alternative splicing in mammalian cells using a luciferase splicing-reporter construct. Chlorhexidine inhibited splicing of the reporter and also a specific subset of a panel of alternatively spliced exons on DNA chips. CLK4 and CLK3 were most sensitive (IC_{50}: 10 and 50 μM, respectively), while CLK2 and CLK1 were less inhibited (IC_{50}: 25 and 50 μM). Inhibition of CLKs by chlorhexidine in mammalian cells resulted in specific reduction in phosphorylation of SRp75, SRp55, and SRp30, while the phosphorylation of SRp20, SF2/ASF, and SRm160 was not noticeably affected. Other SR protein kinases, such as SRPK, were not inhibited by chlorhexidine.

Finally, substituted 6-arylquinazolin-4-amines were identified as potent inhibitors of CLK4, with varying degrees of effects on the other family members, apparently via competitive inhibition of ATP binding. These compounds bind the kinases at the "hinge" region separating the two lobes of the catalytic domain. Interestingly, one of these compound specifically poisoned *Doa* mutant flies in comparison with wild type in preliminary tests, although no mutant phenotypes were observed (L. Rabinow and D. Auld unpublished).

Summary

Additional analysis of the mammalian LAMMER kinases, CLK1-4, may reveal multiple isoforms, as suggested by their occurrence in *Drosophila*. These alternative isoforms represent differentiable functions in flies, as evidenced by their genetic dissection. While it is clear that one of the major functions of the LAMMER protein kinases is the regulation of alternative splicing through the phosphorylation of SR and SR-like proteins, it also is equally apparent that additional classes of substrates exist, including other protein kinases and phosphatases, chromatin, and other proteins. Given the recently demonstrated involvement of the insulin pathway in the regulation of CLK1 and CLK2 activity, the LAMMER kinases would appear to lie at the intersection of one or more signaling cascades. Finally, despite their well-documented roles in the regulation of splicing, the ancestral function of the LAMMER kinases remains to be determined given the existence of a family member in the yeast *S. cerevisiae*.

Acknowledgments I apologize to the colleagues working on the LAMMER protein kinases whose excellent work could not be completely described or cited due to severe limitations on space and the number of references allowed. Wherever possible I have cited the most recent reference from each group to allow readers to identify prior citations of interest. Work in the laboratory of LR is supported by the University of Paris Sud and the CNRS.

c-Myb

Scott A. Ness
Department of Molecular Genetics & Microbiology, University of New Mexico Health Sciences Center, Albuquerque, NM, USA

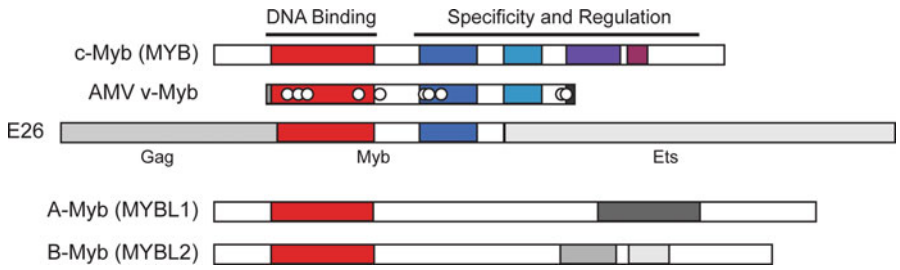
Synonyms

MYB; v-myb myeloblastosis viral oncogene homolog

Historical Background

The c-Myb protein is a DNA-binding transcription factor that regulates the expression of other genes, controls the proliferation and differentiation of hematopoietic, epithelial, and neural cells, and can be mutated into an oncogenic form that induces leukemias and other tumors in animals and humans (Zhou and Ness 2011) (Note: I use c-Myb and c-*myb* to distinguish between the protein and gene, respectively. Readers are encouraged to consult the cited review articles for links to the primary literature, which cannot be listed here due to limitations on space and the number of citations). The c-*myb* gene (MYB) is the normal counterpart to two v-*myb* oncogenes encoded by avian leukemia viruses that induce leukemias in animals and transform immature hematopoietic cells in tissue culture (Lipsick and Wang 1999; Ness 1996; Zhou and Ness 2011). Avian myeloblastosis virus (AMV) encodes a v-Myb protein that when compared to c-Myb (Fig. 1) is truncated at both the N-terminal and C-terminal ends and has several point mutations leading to changes in amino acid residues, which turn out to be critical for controlling the activity of the v-Myb protein and for altering the spectrum of target genes that it regulates (Lipsick and Wang 1999; Ness 2003; Zhou and Ness 2011). The E26 virus has a more complex structure, with an N-terminal domain comprised of 272 amino acids of the retroviral Gag protein fused to 285 amino acids of Myb, fused in turn to a C-terminal domain derived from 491 amino acids of another transcription factor, Ets-1 (Ness 1996; Zhou and Ness 2011). Both v-Myb proteins contain the DNA binding domain of c-Myb, which recognizes specific, but degenerate sites in DNA (Biedenkapp et al. 1988) and is required for the transforming and transcriptional activation functions of the Myb proteins (Lipsick and Wang 1999; Ness 2003; Zhou and Ness 2011).

The c-Myb DNA binding domain is highly conserved and defines a family of related transcription factors. In addition to c-Myb, vertebrates also express A-Myb (MYBL1) and B-Myb (MYBL2) proteins, which have highly related structures including nearly identical DNA binding domains near their N-termini and large, unique C-terminal domains (Fig. 1). The three Myb proteins are often co-expressed, can bind the same sets of DNA sequences and can activate the same reporter genes in transfection assays, but they activate different sets of target genes and have non-overlapping functions in differentiation and development (Gonda et al. 2008; Greig et al. 2008; Lipsick et al. 2001; Ness 2003; Ramsay 2005; Ramsay and Gonda 2008; Sala 2005; Zhou and Ness 2011), suggesting that the conserved DNA binding domains are not sufficient to determine the target gene specificities or activities of the Myb proteins (Ness 2003; Zhou and Ness 2011). All three Myb proteins are probably derived from a primordial precursor similar to the one D-Myb protein found in Drosophila, which appears to be most closely related in function to the vertebrate B-Myb protein (Lipsick 1996; Lipsick et al. 2001). Interestingly, plants have a much larger family of Myb-related transcription factors, involved in controlling the expression of differentiation-specific genes (Allan et al. 2008; Du et al. 2009).



c-Myb, Fig. 1 *Conserved domains in Myb proteins*. The structures of the c-Myb protein and the v-Myb proteins encoded by AMV and E26 viruses are diagrammed, with the most highly conserved domains shaded. The highly conserved DNA binding domain is shaded *red*, and the *dots* indicate the locations of point mutations in the AMV v-Myb protein. The structures of the A-Myb and B-Myb proteins, which have highly related DNA binding domains but different biological activities, are diagrammed below

The c-Myb DNA binding domain is composed of three "Myb Repeats," only two of which are retained in the v-Myb proteins, which have structures that resemble Homeo domains. The structures of the Myb repeats have been solved using both solution and crystallographic methods, providing important information about the locations of the v-Myb mutations that affect transcriptional activity (Ness 1996). One of the most interesting features of the Myb proteins is that the Myb DNA binding domain has been so highly conserved – even the surface-exposed residues that do not contact DNA are conserved. This conservation suggests that the surface-exposed residues of c-Myb are important for protein-protein interactions. Indeed, the DNA binding domain of c-Myb has been found to interact with a large number of protein partners (discussed below), suggesting that the so-called DNA binding domain is actually an important DNA- and protein-binding domain (Ness 1996, 1999; Zhou and Ness 2011). DNA-binding proteins with Myb repeats are found in microorganisms, insects, plants, and vertebrates (Lipsick 1996). Recently, some laboratories have begun referring to the Myb repeats as "SANT" domains, to reflect their relatedness to several other regulatory proteins that also contain complete or partial Myb domains (Boyer et al. 2002).

c-Myb in Stem Cells and Non-hematopoietic Tissues

The v-Myb oncoproteins transform hematopoietic cells, and the c-Myb protein has been linked to the regulation of hematopoietic cell differentiation and proliferation, both through anti-sense knockdown experiments demonstrating that c-Myb is required for hematopoietic progenitor cell differentiation in vitro and through mouse knockout experiments showing that c-Myb deficient mice die in utero due to a defect in definitive erythropoiesis. More recent experiments using conditional knockout strategies demonstrated that c-Myb function is required for the development of most, if not all myeloid and lymphoid cells and that c-Myb plays an important role in many other tissues, including breast and colon epithelia and some neural tissues (Ramsay 2005; Ramsay and Gonda 2008; Zhou and Ness 2011). Thus, although it is often thought to be a hematopoietic cell–specific transcription factor, c-Myb is actually expressed in a wide variety of tissues, especially in cells that are proliferating and/or differentiating, and likely plays an important regulatory role in many cell types.

With the understanding that c-Myb is expressed in and plays an important role in many other cell types has come the realization that mutated, rearranged, and/or overexpressed versions of c-*myb* play an important role in the development of many types of human tumors. Once thought of as an oncogene that was specific for leukemias and lymphomas, c-Myb is now recognized as an important oncogene in a variety of human malignancies, including colon and breast tumors and some neural and head and neck tumors (Gonda et al. 2008; Ramsay and Gonda 2008; Zhou and Ness 2011). Although the perceived importance of c-Myb in human tumorigenesis has grown, the role that c-Myb plays in cell transformation and tumor formation has yet to be delineated. For example, it is not known what genes c-Myb regulates in different types of tumors, or even if c-Myb regulates the same genes in hematopoietic, epithelial or other tumor types.

The activities of c-Myb appear to be complex and context-specific, and it is not yet clear how those activities play a role in human malignancies (Gonda et al. 2008; Ramsay and Gonda 2008; Zhou and Ness 2011).

Multiple Pathways Regulate c-Myb Expression

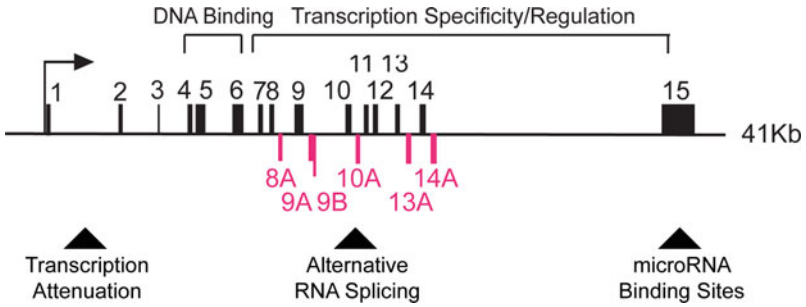
Expression of the c-*myb* gene is complex and controlled at the transcriptional and posttranscriptional levels. The promoter of the c-*myb* gene is a CpG island and resembles a "housekeeping gene" promoter, suggesting that it is relatively steadily expressed in cells that have the gene activated. However, a major regulator of c-*myb* transcription lies in the highly conserved first intron (Fig. 2), where multiple proteins bind and control the efficiency of RNA elongation. Several laboratories have studied c-*myb* transcriptional attenuation, which appears to be a major mechanism for controlling c-*myb* mRNA synthesis, and which is tightly regulated by a number of transcriptional regulators including estrogen receptors (Gonda et al. 2008; Ramsay et al. 2003).

The c-*myb* gene is also subject to dramatic and highly regulated alternative RNA splicing, which primarily involves the region of the gene (Fig. 2) that encodes the large C-terminal regulatory domain of c-Myb protein (Fig. 1). Recent studies have shown that the c-*myb* gene can generate as many as 60 distinct splice variants in some cell types. The variants are formed through the use of alternative exons (e.g., 8A, 9A, 9B), by skipping exons, by using alternative splice donor sites that effectively create "short" versions of some exons (e.g., 9 S), and through the combinatorial mixing of these mechanisms in single mRNA molecules. The levels of alternative splicing can be quite variable, but in some leukemia samples the alternatively spliced variants represent the majority of the c-*myb* transcripts. Interestingly, the alternative splicing does not affect the part of the c-*myb* gene that encodes the highly conserved DNA binding domain, but leads to changes in the large C-terminal domains of c-Myb protein that affect regulation and activity. Thus, the alternative splicing results in the synthesis of a family of c-Myb proteins with the same DNA binding domains, but different C-terminal domains and distinct activities. Alternative RNA splicing allows the c-*myb* gene to generate numerous, slightly different c-Myb transcription factors with altered specificities. Context-specific regulation of alternative splicing could lead to the production of specialized versions of c-Myb proteins capable of regulating different target genes, for example during T-cell or B-cell differentiation (Ness 2003; Zhou and Ness 2011).

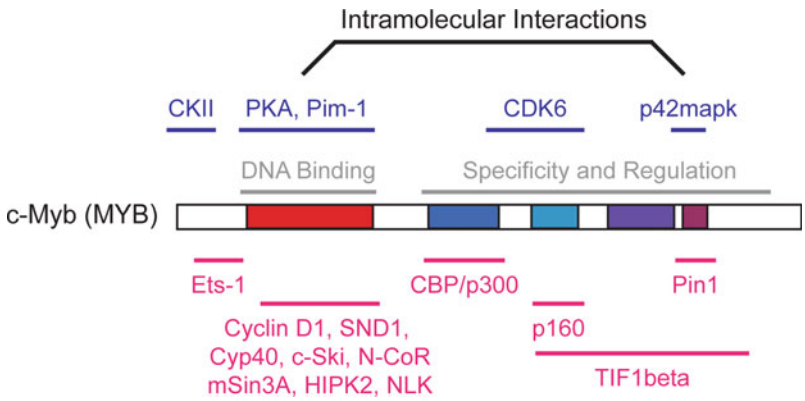
Mechanisms Controlling the Specificity and Activities of c-Myb

Much of the research into c-Myb has focused on the regulation of its activities and the differences that distinguish c-Myb from the oncogenic v-Myb. Early studies showed that c-Myb lacked the transforming or leukemia-inducing activities of the v-Myb proteins, and that truncations of the C-terminal domains were required to unleash the oncogenic potential (Lipsick and Wang 1999; Ness 1996). The C-terminus of c-Myb is the site of phosphorylation, ubiquitinylation, and sumoylation and is the location of peptide sequences that make the protein unstable and lead to its degradation. Thus, truncation of the C-terminus stabilizes the protein, which is one mechanism that leads to higher transforming activity by v-Myb. Other studies have shown that c-Myb undergoes intramolecular interactions that regulate its activity (Fig. 3). These interactions are likely regulated by one or more kinases, including ▶ Casein Kinase II (CKII), Protein Kinase A (PKA), and mitogen-activated protein kinases (▶ MAP Kinases) that phosphorylate c-Myb at several sites along the protein (Fig. 3). Phosphorylation at the N-terminus and in the DNA binding domain can affect DNA binding and some of the phosphorylation sites are altered by the truncations and mutations in AMV v-Myb, suggesting that phosphorylation, at least at some sites, could be involved in a negative regulatory loop that is disabled in the oncogenic variant (Ness 1999; Ness 2003; Zhou and Ness 2011).

The c-Myb protein has also been shown to interact with numerous proteins that are likely to modify or regulate its activity or help control which target genes are regulated and in which situations (Fig. 3). Some of these interacting proteins include ▶ Pim-1, an oncogenic protein kinase that binds and phosphorylates the c-Myb DNA binding domain and that is regulated in turn by upstream JAK-STAT signaling pathways, cyclin D1 and the cyclin-dependent kinases CDK4



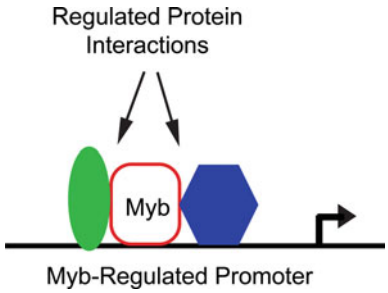
c-Myb, Fig. 2 *Regulation of c-myb gene expression*. The c-*myb* gene structure is summarized, with the start site of transcription shown at *left*, the normal exons shown above the line in *black*, and the alternative exons shown below the line in *pink*. Transcription attenuation occurs between exons 1 and 2, alternative RNA splicing occurs primarily between exons 7–14 and the large exon 15 contains numerous binding sites for regulatory microRNAs (miRs) and RNA binding proteins that affect mRNA stability and efficiency of translation



c-Myb, Fig. 3 *Multiple regulatory pathways affect c-Myb protein*. The diagram summarizes the structure of the c-Myb protein, with the most highly conserved domains shaded (see Fig. 1). The N- and C-terminal ends of c-Myb form intramolecular interactions, which is likely involved in the regulation of c-Myb DNA binding and/or transcriptional activation activity. Several protein kinases that have been reported to phosphorylate c-Myb are shown in *blue* and above the c-Myb diagram, and a subset of the proteins shown to interact with c-Myb are shown in *pink* and below the diagram, organized according to the domains of c-Myb that they interact with

and CDK6, which could regulate c-Myb during the cell cycle (Quintana et al. 2011), and the proline isomerases Cyp40 and ▶ Pin1, which could induce changes in conformation of the c-Myb protein (Ness 1999; Ness 2003). Several recent studies have identified regulatory complexes or mechanisms that involve Homeodomain-interacting protein kinase 2 (HIPK2) and simultaneous interactions with both the DNA binding and the C-terminal domains, suggesting that c-Myb is likely folded into one or more different conformational states that influence which partner proteins it is able to interact with and consequently which genes it can regulate (Zhou and Ness 2011).

Many of the best-characterized Myb-regulated promoters require cooperation or combinatorial interactions between c-Myb and other transcription factors, such as C/EBPbeta (Ness 1996, 1999; Ness 2003). The DNA sequences recognized by the Myb DNA binding domains are degenerate and are present at least three million times in the human genome, so combinatorial or cooperative interactions at promoters are likely required to increase the specificity of c-Myb for specific binding sites and specific target genes (Fig. 4). However, protein-protein interactions are subject to rapid and dramatic changes through regulatory mechanisms such as posttranslational modifications, which can be affected by upstream signaling pathways. This offers an attractive mechanism for how c-Myb target gene specificity can be regulated by upstream pathways. For example, activation of upstream protein



c-Myb, Fig. 4 *Combinatorial and cooperative binding at target promoters.* The c-Myb protein requires interactions with other proteins to determine its specificity, but protein-protein interactions are subject to regulation by posttranslational modifications and other mechanisms

kinases such as FMS-like tyrosine kinase receptor-3 (FLT3), c-KIT, AKT (also known as Protein Kinase B), or Epidermal Growth Factor (EGF) receptor could lead to the activation of downstream protein kinases that phosphorylate c-Myb or one or more of the interacting co-regulators, leading to changes in protein-protein interactions and a redirection of c-Myb and its co-regulators to different promoters. This mechanism also provides an explanation for how c-Myb could participate in oncogenesis, if upstream oncogenic kinases result in the retargeting of c-Myb to different promoters, such as genes that stimulate proliferation instead of differentiation. There is evidence that c-Myb moves to different sets of target genes during the cell cycle (Quintana et al. 2011), consistent with the proposal that c-Myb specificity is regulatable and changes as a result of upstream signals. Finding drugs or interventions that retarget c-Myb to differentiation-inducing genes in cancer cells would be a novel treatment strategy that could take advantage of the flexibility in c-Myb activity.

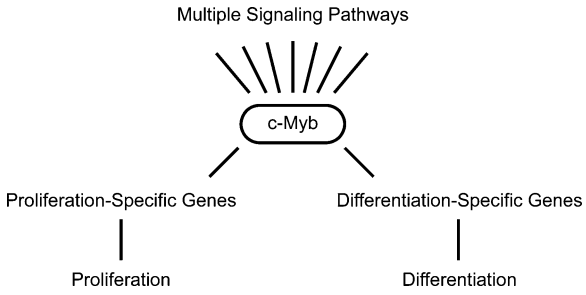
Myb Functions at the Decision Point Between Proliferation and Differentiation

A number of studies have linked the activity of c-Myb to the proliferation and differentiation of hematopoietic, epithelial, and neural stem cells (Ramsay 2005; Ramsay and Gonda 2008; Zhou and Ness 2011). The results suggest that c-Myb plays a critical role in the initial differentiation of stem cells to the most immature committed progenitor cells, where c-Myb probably plays an important role in regulating proliferation and the cell cycle. This highlights one of the most important and most difficult to understand properties of c-Myb: It is involved in the regulation of both proliferation and differentiation, two processes that are often thought of as opposite and contradictory. The oncogenic v-Myb proteins have been described as transforming cells by "blocking" differentiation. But experiments using temperature-sensitive variants of v-Myb showed that reactivating or reintroducing the v-*myb* oncogene into differentiated cells induced the cells to "de-differentiate," showing that the v-Myb proteins actually induced a transformed phenotype, probably by inducing the expression of target genes that are specific for immature, proliferating cells, which resulted in increased proliferation.

The oncogenic activity of c-Myb appears to be linked to the role it plays regulating the balance between differentiation and proliferation. Since c-Myb has the ability, in the right conditions, to induce either proliferation or differentiation, relatively modest changes in its activity can lead to dramatic changes in cell fate. For example, activating the appropriate upstream signaling pathway that leads indirectly to posttranslational modifications in c-Myb could push the cells out of proliferation and into terminal differentiation, or vice versa. The oncogenic v-Myb proteins appear to be variants of c-Myb that are locked, through mutations, into a proliferation-inducing activity, which is why they are able to transform cells and to induce leukemias. Judging from the large number of proteins and kinases that can interact with or phosphorylate c-Myb (Fig. 3), it seems likely that c-Myb lies downstream of multiple signaling pathways, perhaps acting as an integrator of upstream signals (Fig. 5), converting them into changes in gene expression based upon a complex protein-interaction code (Ness 2003) and resulting in cell fate decisions (e.g., proliferation vs. differentiation).

The Importance of c-Myb as a Human Oncogene

As an oncogene, c-*myb* was first identified in the context of avian leukemia virus-induced leukemias, but mapping the integration sites in retrovirus-induced leukemias in mice showed early on that the c-*myb* gene was a preferred target for activation and that it was an important mammalian oncogene



c-Myb, Fig. 5 *Myb as an integrator of upstream signals.* The c-Myb protein lies downstream of multiple signaling pathways, and likely acts as an integrator of signals, converting a protein-protein interaction code, which is affected by posttranslational modifications, into choices about which target genes get regulated and whether the cell proliferates or enters a differentiation pathway

(Ness 1996). Nevertheless, despite high levels of expression in most leukemias and lymphomas and many other tumors, convincing evidence that c-*myb* plays a causal role in human tumorigenesis was only discovered relatively recently. The c-*myb* gene was found to be involved in recurrent chromosomal translocations in some types of human T-cell acute leukemia (T-ALL) and in carcinomas of the breast and head and neck (Ramsay and Gonda 2008; Zhou and Ness 2011). These results showed conclusively that activation of the c-*myb* gene by amplification and/or rearrangement is associated with specific types of human cancers, demonstrating definitively that c-*myb* is an important oncogene in human hematopoietic and solid tumors.

Although there are no longer any arguments about whether c-*myb* is a human oncogene, there is still relatively little information about how c-*myb* transforms cells, either in human or animal systems. The transforming activities of v-Myb require both the DNA binding and transcriptional activation domains, suggesting that v-Myb transforms cells by activating specific target genes that lead to transformation and oncogenesis (Lipsick and Wang 1999; Ness 2003). However, the identities of those genes have not been elucidated. One of the most intriguing results came from the use of microarrays to compare the patterns of gene expression induced by the normal c-Myb and oncogenic v-Myb proteins. Surprisingly, expression of the c-Myb and v-Myb proteins in human cells led to the activation of totally different sets of target genes. Thus, v-Myb is not merely a more active or deregulated version of c-Myb, but instead activates an entirely different set of target genes (Ness 2003; Zhou and Ness 2011). Furthermore, the two proteins activated almost totally different sets of genes when expressed in different cell types, showing that their activities were extremely context-specific. Thus, it seems likely that mutated or alternatively spliced variants of c-Myb expressed in tumor cells probably activate totally different sets of target genes than the normal "wild-type" c-Myb protein. In addition, "normal" c-Myb expressed in cells that have constitutively activated upstream signaling pathways, as often happens in tumors, is likely to regulate different target genes than it would in normal cells.

Summary and Future Directions

The c-Myb protein is a transcription factor with many activities that change in response to numerous upstream signals. It is subject to complex regulation at the level of expression, alternative splicing, stability, and through posttranslational modifications. The oncogenic activity of c-Myb may be due to its role as an integrator of many different upstream signals. This flexibility, even "plasticity" also makes it vulnerable to activation through mutations or when the upstream signaling pathways that regulate it become corrupted. However, understanding how the activities of c-Myb change and respond to various signals may also offer a potential means of regulating it. Small molecules targeted to c-Myb might be able to shift its activity to induce tumor cells to stop proliferating and instead to differentiate. Clearly, the most important things to do are to identify and characterize the target genes that c-Myb regulates in different situations, in different cell types, in response to different upstream signals and in normal vs. transformed cells. This information will unleash new types of assays for determining how c-Myb is regulated and how its activity might be influenced as a novel therapeutic strategy.

Historical Background

The entry of the calcium ion into the cytoplasm of cells from the extracellular medium or from intracellular stores plays an important signaling role. Cytoplasmic calcium acts as a signal by binding to high-affinity calcium-binding proteins. These proteins in turn act as transducers of the signal by activating other proteins, or may be activated directly to carry out enzymatic or structural changes. In this way, many extracellular signals are converted into intracellular activities.

An important subset of these intracellular calcium-binding proteins are proteins that also interact with membranes in a calcium-regulated fashion. In the resting cell, many of these proteins are freely soluble in the cytoplasm (or nucleoplasm). However, when calcium enters the cell, these proteins move onto membrane surfaces. In this way, they make fundamental changes in the character of the membrane surface. Some, such as the annexins (Gerke et al. 2005), are so abundant that up to one half of the intracellular surface of all membrane systems may be covered by annexins in stimulated cells. This influences the organization of the lipids in the membrane, may promote membrane–membrane contacts, and may regulate ion channel activities or the properties of other peripheral or integral membrane proteins.

One of the most interesting members of this class of calcium-dependent, membrane-binding proteins was not characterized until the membrane-binding proteins of the important model secretory cell, *Paramecium tetraurelia* were studied (Creutz et al. 1998; Tomsig and Creutz 2002). In contrast to either mammals or green plants, in which the majority of membrane-binding proteins are annexins, Paramecium extracts contain only a single major membrane-binding protein. Sequencing of this protein revealed that it was not an annexin, but a protein that bound to membranes through a pair of C2 domains, homologous to the domain of protein kinase C that binds calcium and phospholipids. Further sequence analyses revealed that EST and genomic sequencing databases included many copies of homologous sequences from plants, animals, and slime molds, although the encoded proteins had not been previously studied or described, possibly because they are of much lower abundance than annexins in mammalian or plant cells. This new class of proteins was named "copines," derived from the French word *copine* (pronounced ko-peen'), which means a *friend*, because of the association (poetically, the friendship) of these proteins with membranes. Interestingly, not only are copines almost ubiquitously present in eukaryotes (although absent from yeast and *Drosophila*), they are generally present in a given organism as a family of multiple homologs – for example, humans have 9 copines, nematodes 6, *Dictyostelium* 6, and plants at least 3. This high degree of conservation and multiplicity of this protein family strongly suggests that the copines play a fundamentally important role in cell biology.

Nomenclature of Copine Family Members in Diverse Organisms

The broad distribution of copines in various organisms has led to the use of a variety of names for these proteins. Important examples are listed below.

In Humans: copine I, copine II, copine III, copine IV, copine V, copine VI, copine VII, copine VIII, copine IX

In Paramecium: *CPN1, CPN2*

In Arabidopsis: copine 1, copine 2, copine 3; bon1, bon2, bon3

In Dictyostelium: copine A, copine B, copine C, copine D, copine E, copine F; cpnA, cpnB, cpnC, cpnD, cpnE, cpnF

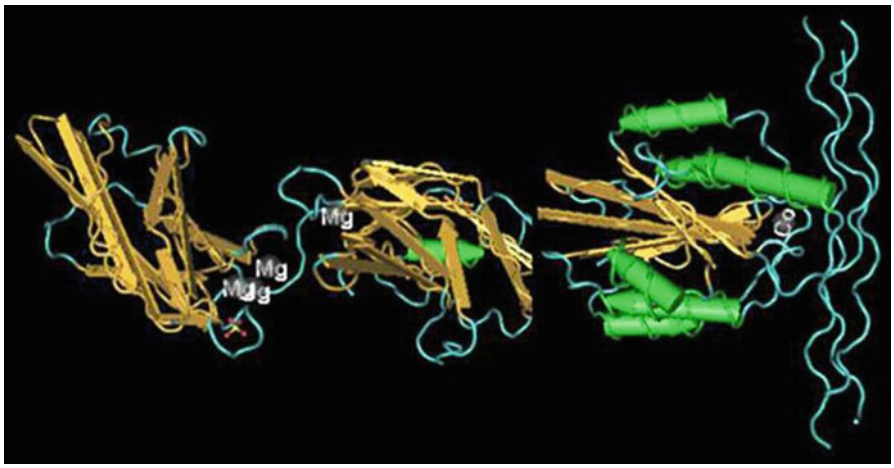
In Caenorhabditis: gem-4 copine, NRA-1 copine

Domain Structure of Copines

Analysis of the full sequences of the copines revealed an interesting domain structure (see Fig. 1). The N-terminal half of a copine protein contains the two C2 domains that are responsible for binding calcium and membranes. The C-terminal half shows a distant relationship to the "A domain" in the extracellular portion of integrins (or von Willebrand domain) (Lee et al. 1995). In the integrin protein family, this domain is responsible for the binding of extracellular matrix proteins. Although the sequence identity is only 23%, there is additional evidence that the copine domain is similar to the integrin domain. First of all, the integrin domain is known to bind magnesium and manganese, and the residues that coordinate magnesium are known from the X-ray structure of the integrin domain (Lee et al. 1995). These same residues are conserved in the copine domain (Creutz et al. 1998). In addition, it was demonstrated that copine binds magnesium or manganese (Tomsig and Creutz 2000). The secondary structure predictions for the copine A domain parallel closely the known secondary structure of the integrin domain – a pattern of alternating alpha helices and beta sheets (Creutz et al. 1998).

Functions of Copines

A key to understanding the biological functions of the copines may be to understand the role of their unique A domain. The similarity to the integrin A domain suggests two rather distinct possibilities. First, the integrin A domain has the classic form, called a Rossman fold, that is present in many nucleotide-binding proteins (Lee et al. 1995). This suggests the copines might require a nucleotide cofactor in order to function. There is one report in the literature that copine III has an associated protein kinase activity (Caudell et al. 2000), although the specific enzymatic activity was extraordinarily low and has not been reported for other members of the protein family.



Copine, Fig. 1 Schematic illustration of the domain structure of copine. The pair of N-terminal C2 domains are on the left. The A domain is on the right and is bound to a "target" protein (wavy vertical lines). This figure was assembled using the known structure of the C2 domains of synaptotagmin on the left, and the known structure of the integrin A domain bound to a triple helical collagen peptide on the right (Emsley et al. 2000). The actual structures of the copine domains, or their relative orientations in space, are not known

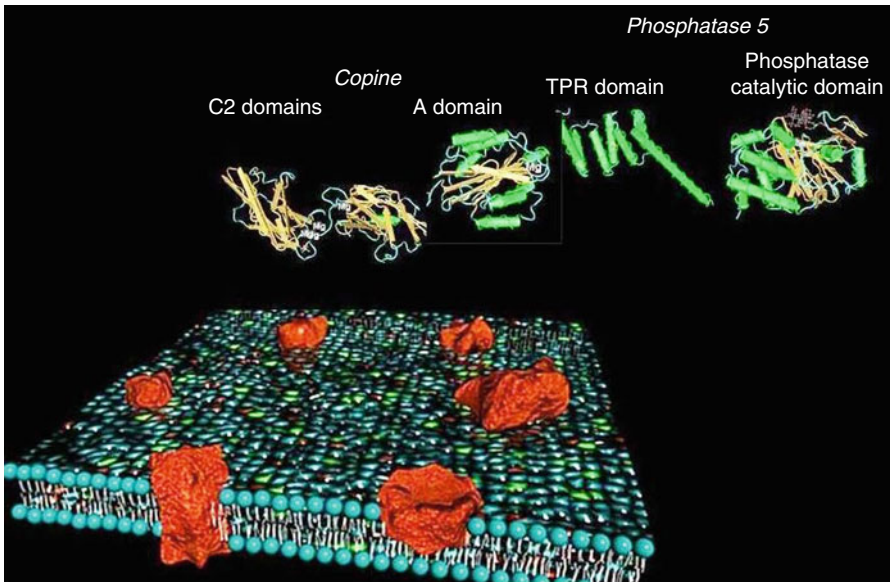
The other hypothesis suggested by the similarity of the copine A domain to the integrin A domain is that the copine A domain is a site for protein–protein interactions. This hypothesis was tested by screening for proteins that interact with the copine A domain. Using a yeast two-hybrid system with the A domains of three human copines as baits, a number of proteins were identified that interact with the copine A domain (Tomsig et al. 2003). The ability of these proteins to interact directly with copine was tested in in vitro assays using recombinant proteins in which the interactions were found to be of very high affinity, stable to extensive washing. Furthermore, the copines were found to be able to recruit the target proteins to phospholipid surfaces in vitro. In contrast to the integrin A domain, the proteins that were found to interact with the copine A domain are almost exclusively intracellular proteins (Tomsig et al. 2003).

Interaction of Copines with Signaling Proteins

The most interesting characteristic of the potential targets identified for copines is that the majority are proteins that are involved in intracellular signal transduction pathways. These targets could be grouped into several categories (Tomsig et al. 2003):

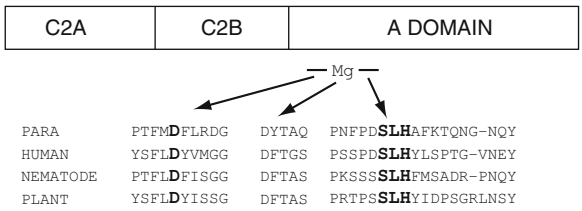
1. Regulators of phosphorylation: MEK1, protein phosphatase 5, CDC42 binding kinase (homolog of the myotonic dystrophy kinase), TAB2 (TAK1 kinase-binding protein).
2. Regulators of transcription: Generally these potential targets are not DNA-binding transcription factors but act as regulators of known transcription factors - Myc-binding protein (PAM), Sno proto-oncogene product, Wilm's tumor associated protein, BcoR (BCL-6 corepressor).
3. Calcium-binding proteins: Copine I (target of copine IV), ALG2.
4. Regulators of ubiquitination/NEDDylation: UBC12, E2-230.
5. Cytoskeletal regulation: Radixin, BICD2 (dynamitin-binding protein).

Although there is obviously considerable variety in the structures and functions of these targets, it was found that in the majority of cases the binding site for the copine could be mapped to a coiled-coil region of the target protein. Significant specificity for the particular coiled-coil domains in these targets was evident since the copines did not bind coiled-coils of abundant structural or fibrous proteins such as keratins or myosins. A consensus sequence for the coiled-coil copine target motif was determined and found to have predictive value for identifying new copine targets, in particular, the kinase MEK1 (Tomsig et al. 2003).



Copine, Fig. 2 Schematic illustration of the hypothetical role of copine in recruiting a signaling protein to a membrane surface. The A domain of copine binds the TPR domain of protein phosphatase 5. The C2 domains of copine migrate to the membrane surface in a calcium-dependent manner, therefore recruiting the phosphatase to the membrane

This array of potential targets suggests the copines may be involved generally in providing calcium regulation of intracellular signaling pathways. In this respect, the copines may be compared to the universal calcium transducer calmodulin. Calmodulin activates a number of enzymes, ion channels, or other "targets" when calcium activates calmodulin and causes it to bind other proteins. The "targets" for copine might be similarly regulated. Indeed, the binding of copine to the N-terminal domain of protein phosphatase 5 enhances the activity of the phosphatase (Tomsig et al. 2003). In addition, by virtue of binding to membranes as well as target proteins, the copines may be able to specifically localize signaling pathway components to certain membranes in the cell (see Fig. 2). This could enhance the assembly of signaling complexes involved in signaling across the plasma membrane. Alternatively, factors involved in regulating gene transcription could be sequestered and downregulated by binding to membranes through copine action.



Copine, Fig. 3 Novel, conserved sequence features of the copine A domain. The domain structure of copine is illustrated at the top. Underneath, the sequences near a magnesium-binding site of the A domains from Paramecium, human, nematode, and Arabidopsis copines are aligned. The SLH motif downstream from the magnesium-chelating residues is conserved in all species, as is a unique aspartate (D) upstream from the magnesium-chelating residues

A Dual-Function Hypothesis

It is possible that the copines may perform both of the hypothetical roles outlined above: They may bind certain target proteins as well as possess an enzymatic activity. This dual-function hypothesis is suggested by the presence of a very highly conserved sequence motif in the A domain whose presence is not explained either by the protein-binding activity or the calcium and phospholipid-binding activity of copine. Just C-terminal of certain critical residues involved in chelation of magnesium by the A domain is a sequence motif conserved from plants to humans (Creutz et al. 1998; see Fig. 3). Theoretically, this portion of the protein would be part of the A domain since it is flanked on either side by features conserved in integrin-like A domains in other proteins. However, this particular motif cannot be aligned with other A domain features and appears to represent an extended loop or fold of the protein between beta strands. Since this highly conserved motif contains an absolutely conserved serine and histidine, and there is

an absolutely conserved aspartate nearby, it is possible that these residues could be involved in forming a catalytic triad of serine, histidine, and aspartate. Such triads are frequently found in hydrolytic enzyme families of diverse substrate specificities and overall structures. If this speculation is correct and the copines possess enzymatic activity, it is possible that copines might regulate other signaling proteins by altering posttranslational modifications, either through the addition of a modifying group or the removal of such a group by hydrolysis.

Additional Diverse Studies of the Biology of Copines

Recent studies in animal and plant systems have implicated copines in a variety of functional contexts. Although the mechanistic roles of the copines in these systems are not well defined, they presumably rely on the ability of calcium to regulate the C2 domains and on the functions of target proteins interacting with the copines.

In the brain, copine VI (or N-copine for neural copine) is one of a number of proteins that is upregulated in the hippocampus after nerve stimulation with kainic acid (Nakayama et al. 1998). It has therefore been speculated that copine may be involved in synaptic potentiation. In addition, it was determined by two-hybrid analysis that the second C2 domain of copine VI interacts with OS-9, a protein of unknown function that is upregulated in certain cancers (Nakayama et al. 1999).

A copine has been identified in *C. elegans* that interacts genetically with a plasma membrane cation channel (Church and Lambie 2003). The copine may be involved in the trafficking or insertion of the ion channel into the cell membrane since mutation of the copine gene suppresses certain phenotypes of mutations in the ion channel gene.

A *C. elegans* copine is also associated in a multiprotein complex with the nicotinic acetylcholine receptor (Gottschalk et al. 2005). Furthermore, mutation of the copine, or downregulation of its expression by siRNA, reduces the number of receptors in the cell membrane therefore implicating the copine in the process of receptor trafficking or membrane insertion.

Genetic experiments in the green plant *Arabidopsis* have demonstrated that copine plays important roles in controlling cell growth and the hypersensitivity response. In a random screen for mutations causing dwarfism, it was found that plants with a copine mutation grow to a small size (hence the proposed name BON1 (Bonsai) for the copine gene) (Hua et al. 2001). In independent studies, a mutant *Arabidopsis* plant was isolated that was hypersensitive to low humidity and had enhanced apoptotic responses to stress (Jambunathan et al. 2001). The mutation was mapped to the same copine gene responsible for dwarfism. Green plants have multiple copine genes, similar to the situation in mammals. Therefore, the observation that modification of a single plant copine gene has significant phenotypic effects suggests that copines are not redundant in function.

Dictyostelium discoidem has six copine genes that are differentially regulated during development, indicating the corresponding gene products may each have unique functions (Damer et al. 2005). A knockout of the gene for copine A results in defects in cytokinesis and contractile vacuole function, suggesting roles in membrane biogenesis or function (Damer et al. 2007). In addition, the knockout model has a partial arrest in a late developmental stage.

Copine I appears to regulate signaling from the TNF-α receptor (Tomsig et al. 2004). ▶ TNF-α is a potent cytokine that elicits critical biological responses such as inflammation and apoptosis. One specific role of copine in this context is apparently to confer calcium sensitivity on the TNF-α//NF- κB signaling pathway. This leads to cross talk with signaling pathways that introduce calcium into the cytoplasm of cells such as activation of muscarinic receptors coupled to phospholipase C.

Copine III has recently been found in association with ErB2, the human epidermal growth factor receptor 2 in breast cancer cells, where it may play a role in regulation of cancer cell motility (Heinrich et al. 2010).

Summary

The copines are a family of calcium-dependent, membrane-binding proteins that consists of nine different gene products in humans. Homologous proteins are expressed in most plants, animals, and protists. The copines are soluble proteins that associate with

negatively charged phospholipids in a calcium-dependent fashion through the action of two C2 domains in the N-terminal half of the molecule. The C-terminal half of the copine molecule has an "A domain," or Von Willebrand domain, that may bind to and recruit target proteins to membrane surfaces. A hypothetical function for the copines is to provide a mechanism for the regulation of various signaling pathways by recruiting components of these pathways to membranes in a calcium-dependent fashion. Additional studies are needed to define the full set of copine-interacting proteins and to determine the effects on these proteins of relocalization or modification by copines.

Historical Background

Cyclic AMP-responsive element binding protein (CREB) is a transcription factor that was originally discovered and characterized from studies of hormone-induced cAMP-dependent regulation of cellular functions. In particular, CREB was found to be critical for stimulus-induced somatostatin upregulation downstream of glucagon and epinephrine. The mechanism of hormone-induced cAMP-dependent increase in somatostatin gene transcription was narrowed down to a 8-bp element in the somatostatin promoter region, which was named cAMP-responsive element (CRE). CREB was identified as a protein factor that bound to CRE sequence, and was purified to homogeneity from nuclear extracts using a CRE affinity chromatography. CREB binds to a specific palindromic CRE sequence, 5′-TGACGTCA-3′ as well as a half-site CRE motif (5′-TGACG-3′) (Montminy and Bilezikjian 1987; Mayr and Montminy 2001). Early experiments identified that CRE-bound CREB was in a dimerized state through binding of the C-terminal basic and leucine zipper domain (bZIP), and when the intracellular level of the second-messenger cAMP increased upon various hormonal stimuli, this in turn triggered cAMP-dependent gene transcription in the nucleus via cAMP/PKA-dependent phosphorylation of CREB (Gonzales and Montminy 1989; Mayr and Montminy 2001). Several other intracellular signaling pathways, such as CaMKs and several MAPK-dependent cascades, have also been shown to determine CREB phosphorylation status (Shaywitz and Greenberg 1999; Bito and Takemoto-Kimura 2003). Through regulation of CRE-dependent gene expression, CREB mediates cell growth, survival, death, proliferation, and differentiation, in response to a variety of stimuli in many different cell types. CREB function has especially been studied in the nervous system, among other organs. In the central nervous system, CREB is considered to have a major role in long-term memory formation.

More than 5% of mammalian genes appear to be potentially regulated by CREB-dependent transcription, as determined by genome-wide analyses of CREB-bound promoters (Impey et al. 2004; Zhang et al. 2005). The presence of CRE sequences have been reported within putative promoter elements that drives transcription of numerous functional proteins such as transcription factors (e.g., c-Fos, Egr-1, Per1, and CCAAT-enhancer-binding protein β), cellular metabolic enzymes (e.g., cytochrome c, phosphoenolpyruvate carboxykinase, cyclooxygenase-2, superoxide dismutase 2, and Bcl-2), growth factors and neuropeptides (e.g., somatostatin, enkephalin, brain-derived neurotrophic factor, insulin-like growth factor, fibroblast growth factor 6, and vasopressin), as well as many neuronal proteins (e.g., synapsin I, TrkB).

Gene and Protein Structure

Creb1 gene consists of at least 12 exons, several of which are alternatively spliced, resulting in a variety of isoforms. CREB expression is rather ubiquitous. The major isoforms of CREB are α- and Δ-CREB in most tissues. The β isoform is also expressed but at much lower levels, and can be upregulated when other isoforms are downregulated. α-CREB is longer than Δ-CREB, by the presence of 14-residue-long insert, termed α-peptide. Alternative splicing of several 5′-exons generates β-CREB, which lacks the first 40 amino acid residues of CREB protein. α-CREB, Δ-CREB, and β-CREB are all able of activating CRE-dependent transcription in response to cAMP increase, while several other splice variants, lacking the C-terminal bZIP domain, have been shown to generate inhibitory forms of CREB.

The characteristic functional domains of CREB are: an N-terminal glutamine-rich domain (Q1), a kinase-inducible domain (KID) with a phosphorylation site at Ser-133, another glutamine-rich domain (Q2), and a C-terminal bZIP domain (Mayr and Montminy 2001).

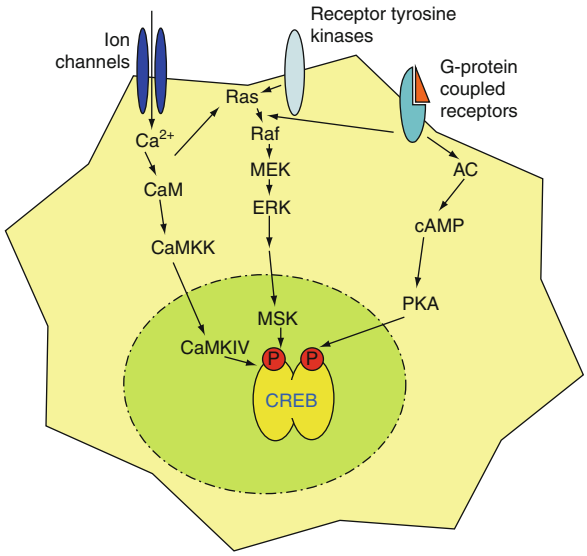
Activating transcription factor 1 (ATF1) and cAMP-responsive element modulator (CREM) share structural and functional similarities with CREB as regulators of CRE-dependent gene transcription, and form a CREB/ATF family.

CREM has an extensive sequence identity with CREB and has a notably interesting function. This gene generates both activator and repressor forms of CREM from the same gene by alternative splicing. The CREM isoforms α, β, and γ function as inhibitors of CREB- and cAMP-mediated transcription. However, another variant which is most similar to CREB with regards to its amino acid sequence, CREMτ, functions as an activator of CRE-mediated transcription.

Mechanistic Basis of CREB-Mediated Transcriptional Activation

CREB activity, as a transcription factor, is predominantly upregulated by phosphorylation of Ser-133 (amino acid residue number based on the full-length α-CREB) (Gonzalez and Montminy 1989). In the nucleus, a sizable amount of CREB is constitutively bound to CRE sites in the chromatin, regardless of cellular activity. The Ser-133 residue is located in the KID domain, and phosphorylation of this residue favors a structural conformation that allows high-affinity interaction with a KID-interacting (KIX) domain of the transcriptional coactivator CREB-binding protein (CBP), thus enabling an efficient docking of the transcriptional preinitiation complex (Chrivia et al. 1993). The signaling events that lead to phosphorylation of Ser-133 have been intensively investigated in many cell types and tissues which were exposed to many physiological and pathological stimuli (Mayr and Montminy 2001). The identity of a CREB kinase in a given context heavily depends on the stimulus conditions and cell types. Demonstrated functional CREB kinase pathways include: cAMP-dependent protein kinase (PKA), protein kinase C (PKC), RSK, MSK, MAP kinase-activated protein-kinases (MAPKAPK1/2), AKT, and CaMKI, CaMKII, and CaMKIV (Gonzales and Montminy 1989; Bito et al. 1996; Shaywitz and Greenberg 1999) (Fig. 1).

Compared with the variety of kinase-signaling pathways activating CREB, much less information is available about phosphatases that dephosphorylate pSer133. Either Ser/Thr protein phosphatase 1 (PP-1)

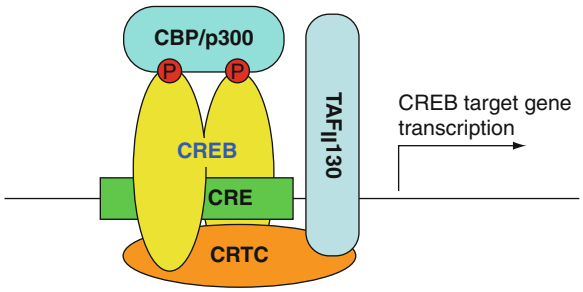


CREB, Fig. 1 *Signaling from the cell surface to nuclear CREB.* Cell growth, hormonal or neurotransmitter signals trigger CREB phosphorylation at residue Ser-133 through activation of either Ras-Raf-MEK-ERK-MSK, adenylate cyclase (AC)-cAMP-PKA or Ca^{2+}/CaM-CaMKK-CaMKIV cascades, respectively. This phosphorylation allows recruitment and stable anchoring of a CBP-containing transcription initiation complex near CRE sites

or PP-2A are shown to dephosphorylate CREB directly at Ser133 after pCREB dissociates from CBP, depending on the cell types. Several studies indicate that other phosphatases such as calcineurin (PP2B), PTEN, and protein tyrosine phosphatase 1B (PTP1B) may indirectly regulate dephosphorylation of phospho-Ser133, either by suppressing upstream CREB kinases or activating CREB phosphatases.

CREB Coactivators and CREB-Interacting Proteins

It has been shown that CREB constitutively binds functional CRE sites of many genes, even prior to cAMP elevation or Ser-133 phosphorylation events. Thus, the dominant effect of CREB phosphorylation at Ser-133 is to potentiate its transcriptional activity via enhanced interaction of CREB with CBP and its paralog p300. The binding of CBP/p300 to CREB leads to the recruitment of the RNA polymerase II complex to initiate transcription from transcriptional start sites that are adjacent to the CRE sites. Hence, the regulated CREB-CBP interaction via the KID and KIX domains plays a major



CREB, Fig. 2 *A CREB complex binds CRE to initiate transcription.* CREB homodimerizes and binds to a well-conserved DNA element named CRE. CREB Ser-133 is phosphorylated by several kinases in an activity-dependent manner, and this accelerates binding of CBP/p300 to CREB. The CREB coactivator CRTC binds to the bZIP domain of CREB. Recruitment of an RNA polymerase II complex may be facilitated by a higher affinity of CBP/p300 to phospho-CREB or by CRTC via $TAF_{II}130$

role in determining the level of CRE-dependent transcription activity. Additionally, the CREB Q2 domain recruits $TAF_{II}130$ present in the TFIID complex and may contribute to regulating CRE transcription in a rather stimulus-independent manner (Ferreri et al. 1994). An N-terminal glutamine-rich domain (Q1) may also contribute to transcription activity, but the extent of this has not been extensively demonstrated. While CREMτ, a transcription activator among the CREM isoforms, and which is highly similar to CREB protein, includes both Q1 and Q2 domains, CREM repressor isoforms possess no domains sharing sequence identities with either Q1 or Q2 regions. These contrasting facts also support the notion that both Q1 and Q2 may play additional roles in CREB transcription activation.

Both CREB homodimerization and CREB binding to the double-stranded DNA of CRE loci are mediated by the C-terminal bZIP domain. However, this bZIP domain also binds to CREB-regulated transcription coactivators (CRTCs, also known as transducers of regulated CREB activity, or TORCs) (Conkright et al. 2003; Iourgenko et al. 2003). Structurally, the Arg-314 residue in the bZIP domain of CREB is absolutely required to associate with the N-terminal coiled-coil region of CRTC, and this N-terminal end of CRTC may also be important for its tetramerization. CRTC also appears to recruit $TAF_{II}130$ and this may be another potential mechanism for enhancing CREB-regulated gene expression, though a detailed picture of how CRTC activates CREB is yet missing (Fig. 2).

The CREB coactivator role of CRTC is stimulated by CRTC dephosphorylation, which enables its nuclear entry. On the other hand, phosphorylated CRTC, which is excluded from the nucleus, localizes to the cytoplasm and remains in an inactive state. The nucleocytoplasmic shuttling of CRTC is strongly regulated by a balance between calcineurin-dependent dephosphorylation that occurs as a result of cellular calcium mobilization, and various regulated kinases (such as SIK and AMPK) that inhibit CRTC function (Screaton et al. 2004; Bittinger et al. 2004). Thus, CRTC appears to be a valuable sensor of intracellular milieu that can influence CREB function in a manner that is independent of phospho-CREB formation.

Physiological Functions of CREB

Physiological functions of CREB have been investigated in various organs using genetically modified model animals. In particular, in vivo CREB actions have been intensively studied in the developing and mature nervous and immune systems, as well as in the control of hepatic gluconeogenesis, insulin resistance in obesity, and oncogenesis (Silva et al. 1998; Kandel 2001; Bito and Takemoto-Kimura 2003; Conkright and Montminy 2005; Nonaka 2009).

A full CREB-null phenotype was obtained in knockout mice in which the bZIP domain of CREB gene was deleted. These CREB-null mutants were smaller than wild-type littermates and died immediately after birth due to respiratory distress. The commissural fibers in the brain were markedly reduced. There were also severe impairments in the development of T cells of the α/β lineage but not those of the γ/δ lineage (Lonze et al. 2002). A double mutant mouse line harboring mutations in both CREB and CREM genes showed a more severe neurodegeneration phenotype during brain development, suggesting that CREM gene products may compensate for the loss of CREB gene, especially in the developing central nervous system (Mantamadiotis et al. 2002). A dominant negative CREB inhibitory peptide (A-CREB) that interferes with the bZIP domain function of CREB (Ahn et al. 1998) has also been successfully used to probe CREB function in various organs such as liver, adipocyte, bone, skin, and brain, using tissue-specific promoters. In particular, liver-targeted A-CREB

expression has demonstrated the critical involvement of CREB in regulating hepatic gluconeogenesis (Dentin et al. 2007).

Interestingly, a CREB mutant mouse line, in which the exon 1 of CREB1 gene was deleted, showed a loss of both α- and Δ-isoforms of CREB, but a compensatory expression of both β-CREB (transcribed in this case from a cryptic alternate promoter) and CREMτ was found in a wide range of organs, except for the brain. These CREB mutant mice showed no obvious developmental abnormality in the body and also no obvious anatomical disorders in the brain. However, when hippocampus-dependent memory tasks were carried out, these adult mice exhibited a profound specific impairment in long-term memory while the short-term memory remained unaltered (Silva et al. 1998).

In order to investigate the roles of CREB activity in hippocampus, brain-targeted VP16-CREB transgenic mice have been generated (Barco et al. 2002). The hippocampal CA1 neurons of these transgenic mice exhibited a strong facilitation of a persistent late phase of long-term potentiation (L-LTP), which could be elicited even with weak stimuli that would otherwise only induce an early phase of LTP (E-LTP) in the wild-type mice. The results indicate that elevation of CRE-driven gene products in the brain might be sufficient to accelerate consolidation of LTP, and are consistent with a "synaptic tagging and capture" hypothesis.

Finally, from recent studies, it appears that aberrant CREB activity may be linked to oncogenesis and the etiology of certain leukemia (Conkright and Montminy 2005). Enhanced CREB expression or dominant active mutation in CRTC1 was found in primary human cancer or leukemic cells. Consistently, a transgenic mouse line, which overexpressed CREB specifically in the macrophage/monocyte lineage, exhibited increased proliferation of bone marrow cell in a growth factor–independent manner.

Summary

CREB is a well-studied transcription factor that is ubiquitously expressed, and is activated by a variety of cellular signaling pathways, downstream of cell growth, hormonal or neurotransmitter stimuli. Mobilization of various second-messenger pathways leads to CREB activation via phosphorylation of Ser-133, and this event is regulated by many kinases such as PKA, CaMKIV, or MSK, as a function of the activation context. CREB has many coactivators that potentiate its transcriptional activity. The phosphorylation of Ser-133 in the KID domain of CREB facilitates the binding of the KIX domain of CBP/p300 to KID, thereby stabilizing the recruitment of RNA polymerase II complex and allowing transcriptional initiation. CRTC is another important coactivator and interacting protein of CREB. CREB plays a key role in determining cellular proliferation in the developing nervous and immune systems, while also controlling protein-synthesis-dependent forms of long-term memory in the mature brain. Furthermore, CREB is essential in the control of hepatic gluconeogenesis, insulin resistance in obesity, and also in oncogenesis.

C-Src kinase; C-terminal Src kinase

Historical Background

The activity of the ► Src family tyrosine kinases (SFKs), known as representative proto-oncogene products, is negatively regulated by the phosphorylation at

their C-terminal regulatory tyrosine (Brown and Cooper 1996; Cooper et al. 1986). The protein tyrosine kinase Csk was identified as a specific kinase that directs the negative regulatory sites of SFKs (Nada et al. 1991; Okada and Nakagawa 1988). Analysis of Csk-deficient mice and cells provided evidence that Csk functions as an indispensable negative regulator of SFKs (Nada et al. 1991, 1993). The molecular basis of Csk-SFK interaction is recently verified by the crystal structure of Csk/c-Src complex (Levinson et al. 2008). Csk is expressed ubiquitously, but is highly concentrated in developing nervous system and the immune system (Okada et al. 1991). Csk is highly conserved in animal kingdom from the unicellular choanoflagellate to human in parallel with SFKs (Segawa et al. 2006). Csk is a cytosolic protein, consisting of the kinase domain and the conserved domains responsible for the protein-protein interaction (Ogawa et al. 2002) (Fig. 1). Several Csk-binding proteins, for example, Cbp/PAG1 and paxillin, were identified as specific scaffolds that recruit Csk to the sites where SFK is activated (Kawabuchi et al. 2000; Oneyama et al. 2008a; Sabe et al. 1994). The Csk-mediated inhibition of SFKs is crucial for suppressing oncogenic ability of SFKs (Oneyama et al. 2008b).

Structure of Csk

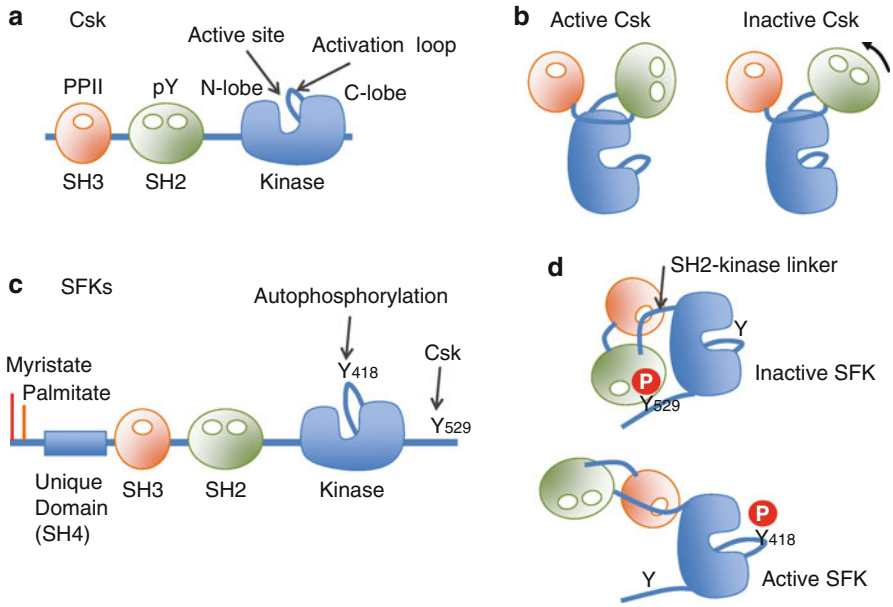
Csk is a non-receptor type of protein tyrosine kinase with a molecular mass of 50 kDa. It contains a Src homology 3 (SH3) and a ▶ Src homology 2 (SH2) domains in its N-terminal half and a kinase domain in its C-terminus. This primary structural arrangement of functional domains is similar to that of SFKs, but Csk lacks the N-terminal fatty acylation sites, the autophosphorylation site in the activation loop, and the C-terminal negative regulatory sites, all of which are crucial for regulating SFK activity (Fig. 1). The lack of autophosphorylation is a unique feature as a protein tyrosine kinase. The crystal structures of inactive and active forms of Src reveal the regulatory mechanism of SFKs (Cowan-Jacob et al. 2005; Xu et al. 1997). Upon phosphorylation at the C-terminal tyrosine, SFKs adopt the inactive conformation stabilized by two intramolecular inhibitory interactions: (1) binding of the C-terminal phosphotyrosine to the SH2 domain and (2) binding of the SH2-kinase linker to the SH3 domain. The dephosphorylation of the C-terminal tyrosine results in an open structure where the kinase domain adopts an active conformation (Fig. 1).

The crystal structure of Csk reveals significantly different dispositions of the functional domains from those of SFKs (Ogawa et al. 2002), indicating that Csk is regulated differently to SFKs (Fig. 1). The most intriguing difference in the domain organization between Csk and SFKs is that the binding pockets of SH3 and SH2 domains of Csk are oriented outward, enabling the intermolecular interactions. The crystal structure of Csk further predicts that Csk can adopt active and inactive conformations. It is suggested that the kinase domain of Csk is intrinsically inactive, but the direct interaction with the SH2 domain induces conformational change, resulting in an upregulation of the kinase activity (Wong et al. 2005).

Function of Csk

Accumulated evidence shows that SFKs are the major physiological substrates of Csk. Csk-deficient mice exhibit early embryonic lethality, accompanied by a constitutive activation of c-Src, Fyn, and Lyn (Nada et al. 1993). Conditional mutagenesis of the *csk gene* in specific tissues causes severe defects that are associated with constitutive activation of SFKs. Loss of Csk induces dysfunction in acute inflammatory responses (Thomas et al. 2004) and T-cell development (Schmedt et al. 1998), hyperplasia of the epidermis (Yagi et al. 2007), and defects in cell adhesion and migration (Nada et al. 1994). Even in invertebrates, such as *Drosophila* and *C. elegans*, the loss of Csk leads to constitutive activation of SFKs, causing hyperproliferation and defective cytoskeletal function, respectively (Read et al. 2004; Takata et al. 2009). These findings indicate that Csk is an indispensable regulator of SFKs.

As a protein tyrosine kinase, Csk has an exceptionally high specificity for the C-terminal regulatory tyrosine (Y527) of SFKs. The surrounding sequence of the regulatory site of SFKs (QYQ) is unique and well conserved among SFKs, but biochemical and structural studies reveal that a region (aa 504–525) located distantly from Y527 is rather crucial for specific recognition by Csk (Lee et al. 2003, 2006; Levinson et al. 2008). In addition to SFKs, several signaling proteins have been reported to serves as substrates of Csk.

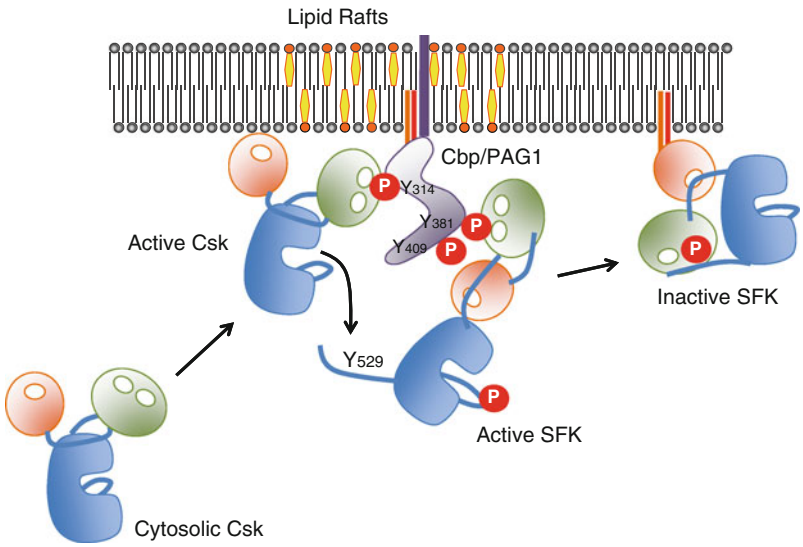


Csk, Fig. 1 Structural features of SFKs and Csk. (**a**) Domain organization of Csk. SH3; Src homology 3 domain, SH2; Src homology 2 domain. The ligands of SH3 and SH2 domains, PPII and pY, respectively are indicated. PPII; the polyproline type II helical structures, pY; the phosphotyrosine-containing protein ligands. The kinase domain consists of N-lobe and C-lobe. Active site and activation loop are indicated. (**b**) Schematic representation of the crystal structure of Csk. The binding pockets of SH3 and SH2 domains of Csk are oriented outward enabling the intermolecular interactions. Csk adopts active and inactive conformations. The 60° rotation of the SH2 domain, associated with the active-inactive form transition, is indicated by an *arrow*. (**c**) Domain organization of SFKs. SFKs has fatty acyl moieties (myristate and/or palmitate) and the non-conserved unique domains (SH4) in the N-terminal region. The autophosphorylation site (Y418) in the activation loop and the C-terminal negative regulatory site (Y529) are indicated. (**d**) Schematic representation of the inactive and active structures of SFKs based on the crystal structures of c-Src and Hck. The intramolecular interactions between pY529 and SH2 domain and between SH2-kinase linker and SH3 domain stabilize the inactive conformation. Dephosphorylation of pY529 unlocks the inactive conformation and the trans-autophosphorylation at Y418 makes the enzyme fully active

Those include paxillin (Sabe et al. 1994), $P2X_3$ receptor (D'Arco et al. 2009), c-Jun (Zhu et al. 2006), and Lats (Stewart et al. 2003). However, the physiological relevance of the phosphorylation of these proteins still remains unclear.

Regulation of Csk

Csk is predominantly present in cytosol due to the lack of fatty acyl modification, while its substrate SFKs are anchored to the membrane via the N-terminal myristate and palmitate moieties. Thus, the translocation of Csk to the membrane, where SFKs are activated, is one of the critical steps of Csk regulation (Howell and Cooper 1994). So far several scaffolding proteins have been shown to serve as anchors of Csk to the membrane. A well-characterized example is Cbp/PAG1 (Csk-binding protein/phosphoprotein associated with glycosphingolipid-enriched membrane) that is a transmembrane protein having both myristoyl and palmitoyl modifications like SFKs. Cbp/PAG1 is highly concentrated in the cholesterol-enriched membrane microdomain "lipid rafts" and serves an excellent substrate of SFKs. Upon phosphorylation of Y314 of Cbp/PAG1 by the activated SFKs, pY314 binds to the SH2 domain of Csk, and this in turn recruits Csk to the plasma membrane. Csk on the plasma membrane then efficiently inactivates SFKs that are also recruited to Cbp/PAG1. This negative feedback loop is crucial in preventing tumorigenesis and in controlling the cell signaling evoked by the activation of growth factor receptors (Fig. 2). Other Csk-binding proteins, such as paxillin (Sabe et al. 1994) and caveorin-1 (Cao et al. 2002), are also phosphorylated by SFKs and are involved in the negative regulation of SFKs by recruiting Csk to the sites where SFKs are activated in a manner similar to Cbp/PAG1.



Csk, Fig. 2 Negative regulatory loop of SFK via Cbp/PAG1 on lipid rafts. When SFKs are activated in response to cell stimulation, they phosphorylate Cbp/PAG1 residing in lipid rafts to create a binding site of Csk (pY314) and their own binding sites (pY381/409). Inactive Csk in cytosol is then recruited to the phosphorylated Cbp/PAG1, and the activated Csk efficiently phosphorylates Y529 of SFKs that are also recruited to Cbp/PAG1. The phosphorylated SFKs are released from Cbp/PAG1 by restoring the intramolecular interaction between SH2 domain and pY529

The binding of scaffolds to the SH2 domain of Csk can also activate the enzyme activity of Csk. The occupation of the SH2 domain of Csk by phosphorylated Cbp affects conformation of the catalytic domain, thereby increasing the activity toward SFKs (Takeuchi et al. 1993; Wong et al. 2004, 2005). Thus, it is likely that the scaffold proteins positively regulate Csk functions not only by recruiting Csk to the membrane but also by directly activating Csk.

It is also reported that the activity of Csk can be regulated by the oxidation state of the disulfide bond in the SH2 domain, suggesting the regulation mechanism by the redox state (Mills et al. 2007). Furthermore, there is a report indicating that Csk is phosphorylated by PKA at S364, resulting in an increase in kinase activity (Yaqub et al. 2003). However, their physiological relevance has not yet been addressed. Although the expression of Csk is substantially high in the developing nervous system and lymphoid cells, the mechanisms underlying the regulation of Csk at the expression levels are thoroughly unknown.

Csk in Diseases

Since Csk has a tumor-suppressive function by inhibiting oncogenic activity of SFKs, it is reasonable that Csk is involved in human cancer. Although there are some reports suggesting that Csk is downregulated in some cancers (Masaki et al. 1999), it seems that Csk downregulation is rather rare and it is more likely that Csk is expressed in various cancer cells at a comparable level as a housekeeping protein. In contrast, it is clear that the expression of Cbp/PAG1 is appreciably downregulated in a variety of cancer cells (Oneyama et al. 2008a), potentially via the epigenetic mechanism (Suzuki et al. 2011). The downregulation of Cbp/PAG1 may interfere with the translocation of Csk to the membrane, thereby upregulating SFK functions. This mechanism may account for the upregulation of SFKs in some cancer cells. Thus, the further analysis of Cbp-/PAG1-mediated regulatory system would provide new opportunities for therapeutic intervention in cancer.

Summary

The non-receptor tyrosine kinase Csk serves as an indispensable negative regulator of SFKs, by specifically phosphorylating the negative regulatory site of SFKs to suppress their oncogenic potential. Csk is mainly regulated through its SH2 domain, which is required for membrane translocation of Csk via

binding to scaffold proteins such as Cbp/PAG. The binding of scaffolds to the SH2 domain can also upregulate the kinase activity. These regulatory features are mostly clarified by the analysis of Csk structure at atomic levels. Although Csk itself is not directly relevant to human cancer, the perturbation of the regulation system of SFKs, which consists of Csk, Cbp/PAG1, or other scaffolds, and some tyrosine phosphatases, would be attributed to the upregulation of SFKs which is frequently observed in human cancers.

CSK-Homologous Kinase, Fig. 1 A model of activation of Src-family kinases (SFKs). Upon phosphorylation of the C-terminal regulatory tyrosine by CSK and CTK, the SFK molecule adopts the inactive conformation. In this conformation, the kinase domain is stabilized in the inactive configuration by two inhibitory intramolecular interactions: (**a**) binding of the SH2 domain to the phosphorylated C-terminal regulatory tyrosine and (**b**) binding of the SH2-kinase linker (linker) to the SH3 domain. Ligands of SH2 and SH3 domains disrupt these interactions and activate SFKs. The activated SFKs then undergo autophosphorylation which further stabilizes the kinase domain in the active configuration

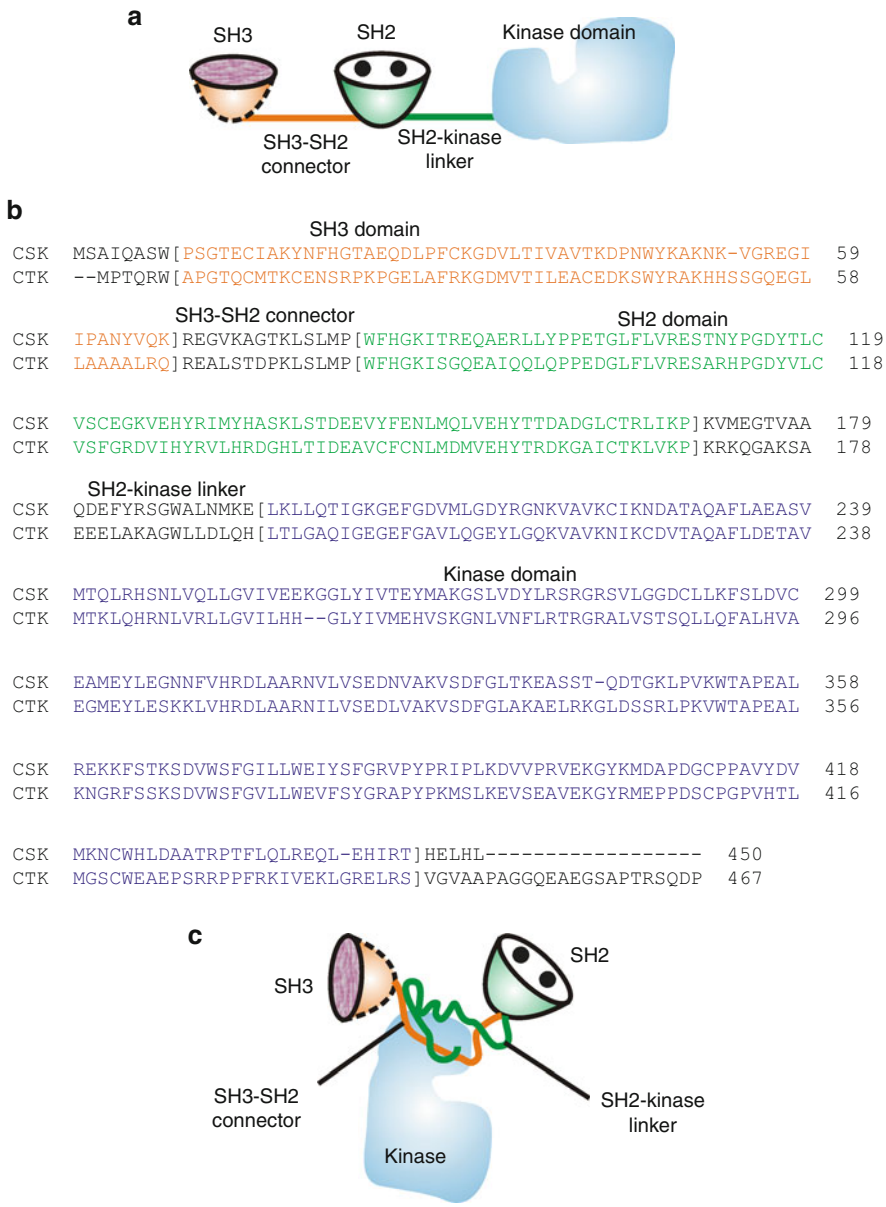
Historical Background

C-terminal Src kinase (► CSK) and CSK-homologous kinase (also referred to as CSK-type kinase, CTK) are the endogenous inhibitors of ► Src family of protein tyrosine kinases (SFKs) including ► c-Src, Fyn, Yes, Lyn, Hck, Blk, Fgr, and Lck. Both inhibitors inactivate SFKs by phosphorylating their consensus C-terminal inhibitory tyrosine (corresponds to Tyr-527 in c-Src) that stabilizes the inactive SFK conformation (Fig. 1). The discovery of CSK can be traced back to an important study performed two decades ago (Okada and Nakagawa 1989). The study showed that Tyr-527 of c-Src did not undergo autophosphorylation. Rather, it was phosphorylated by a putative upstream tyrosine kinase that was originally termed neonatal brain type of protein tyrosine kinase (N-PTK) isolated from the membrane fraction of neonatal rat brain. Okada and Nakagawa then conducted experiments to characterize the specificity of phosphorylation of c-Src by Ntk. First, c-Src phosphorylated by Ntk was subjected to sequential proteolytic digestion by trypsin and α-chymotrypsin. Phosphopeptide mapping revealed two major phosphopeptide fragments. Among them, one was recognized by an antibody raised against the C-terminal (residues 524–533) in c-Src. Further biochemical analysis of this fragment identified Tyr-527 as the phosphorylation site. Hence, Ntk was later referred to as the Carboxyl terminal Src Kinase (CSK).



CSK-Homologous Kinase, Fig. 2 Comparison of amino acid sequences of CSK and CTK. (**a**) Domain organization of CTK. From the N-terminal end, CTK contains a SH3 domain. It is linked to the SH2 domain by the SH3–SH2 connector. The SH2 domain is linked to the kinase domain by the SH2-kinase linker. (**b**) Alignment of sequences of CSK and CTK. (**c**) A model of the disposition of the functional domains of CSK. The three-dimensional structure of CSK shows that the SH2 and SH3 domains are located near the top of the N-lobe of the kinase domain. The SH3–SH2 connector and SH2-kinase linker interact with structures in the N-lobe of the kinase domain. Given the high degree of sequence homology of CSK and CTK, it is logical to predict that CTK also adopts a similar structure in solution

The cDNA sequence of *CSK* was later isolated (Nada et al. 1991). The sequence revealed that it encodes a protein with an SH3 domain, an SH2 domain and a kinase domain (Fig. 2). The homologue of CSK termed CSK-homologous kinase (also referred to as *C*SK-*T*ype *K*inase, CTK) was discovered a few years after identification of CSK. Depending on its structural features and the origins of the cDNA libraries, CTK was also named Hyl, BatK, Matk, CHK, and Ntk ((Cheng et al. 2006) and references quoted therein). CTK shares 54% identity with its closely related kinase CSK and retains similar structural organization and functional domains with CSK. Similar to CSK, CTK resides predominantly in cytosol. Unlike CSK, CTK expression is less ubiquitous. Its expression is mainly confined to neuronal and hemopoietic cells. In addition, Zhu et al. reported expression of CTK in normal colon epithelial cells (Zhu et al. 2008).

Alternative splicing of the *CTK* transcript gives rise to two CTK isoforms of 56 kDa and 52 kDa. The 56 kDa isoform contains an additional 41-residue segment at the N-terminus (reviewed in (Cheng et al. 2006) and references quoted therein). Northern blot analyses demonstrated that the 56 kDa CTK isoform is expressed in normal colon cells and hematopoietic cells of megakaryocyte lineage while the 52 kDa CTK isoform is expressed in brain cells ((Cheng et al. 2006; Zhu et al. 2008) and references quoted therein). Whether and how the two isoforms differ in their regulatory properties and functions remain unknown.

Structure and Domain Organization of CTK

CTK has similar domain organization like its CSK counterpart. Namely, it has a Src-homology 3 (SH3), an SH2 and a kinase domain (Okada and Nakagawa 1989). In addition, SH3 and SH2 domains are connected by the SH3–SH2 connector while SH2 and kinase domain through the SH2-kinase linker (Fig. 2). But unlike c-Src it lacks an N-terminal fatty acid acylation site as well as autophosphorylation site and C-terminal regulatory tyrosine phosphorylation site (reviewed in (Chong et al. 2005a)). Because of the absence of the N-terminal fatty acid acylation motif which targets cellular proteins to plasma membrane, CTK mostly localizes in the cytoplasm (reviewed in (Chong et al. 2005a)). It is well established that intramolecular interactions of the CSK kinase domain with the SH2 and SH3 domains play a significant role in regulating CSK kinase activity ((Lin et al. 2005) and references quoted therein). Given the similarity in the domain organizations of CSK and CTK, it is logical to predict that both the SH2 and SH3 domains are involved in regulating the kinase activity of CTK.

Comparison of the sequences of the SH2 and SH3 domains of CTK and CSK reveal significant differences in the residues dictating the binding of ligands. For example, Glu-127 which dictates the binding specificity of the CSK SH2 domain is substituted by Ile-126 at the homologous position in the CTK SH2 domain. These structural differences account for the striking difference in binding specificity of the CTK and CSK SH2 domains (Ayrapetov et al. 2005). In this entry, how these structural differences govern the differences in functions and regulation of CSK and CTK is discussed.

Much is known about the three-dimensional structure of CSK – the structures of CSK kinase domain, full-length CSK protein, and CSK kinase domain complexed with the c-Src kinase domains have been solved (Fig. 4) (reviewed in (Ia et al. 2010)). In contrast, only the structure of SH2 domain of CTK has been solved. Exactly how the various functional domains arrange in the three-dimensional structure of CTK remains unclear. Owing to the similarity of organizations of SH3, SH2, and kinase domains in the CSK and CTK sequence, it is logical to predict that their three-dimensional structures are very similar. Unlike SFKs, the SH2 and SH3 domains of CSK are located above the minor lobe of the kinase domain with both the SH3–SH2 connector (referred to as connector) and the SH2-kinase linker (linker) sitting atop the α-helix C (Fig. 1 and 2c). Such an arrangement allows both the SH3 and SH2 domains to control the conformation of kinase domain via the connector and linker which make intimate contacts with the kinase domain (Fig. 2c) (reviewed in (Ia et al. 2010; Chong et al. 2005b)). It is likely that a similar arrangement of the connector, linker, and the three functional domains can be found in the three-dimensional structure of CTK. With this arrangement, binding of the cognate ligands to SH2 and SH3 domains is expected to modulate kinase domain conformation and hence the kinase activity of CTK.

Phenotypes of *CTK*-Deficient Mice

Three groups of researchers reported the generation of *CTK* knockout mice (reviewed in (Cheng et al. 2006)). They all reported that the $CTK^{-/-}$ mice displayed no defect in hematopoiesis. However, upon stimulation with interleukin-7, bone marrow cells from $CTK^{-/-}$ mice display enhanced proliferation in culture, resulting in a higher number of pre-B cells. Lee *et al.* suggested that the phenotype is attributed to the ability of CTK to act as a negative regulator of pre-B cell proliferation (Lee et al. 2006). In addition, T-cells from $CTK^{-/-}$ mice exhibited impaired interferon γ production in culture. Taken together, the phenotypes revealed the unique role played by CTK in immune function. Furthermore, the milder-than-expected phenotypes of $CTK^{-/-}$ mice indicate significant functional overlap between CTK and CSK in cells expressing both enzymes.

SFK-Dependent and SFK-Independent Functions of CTK

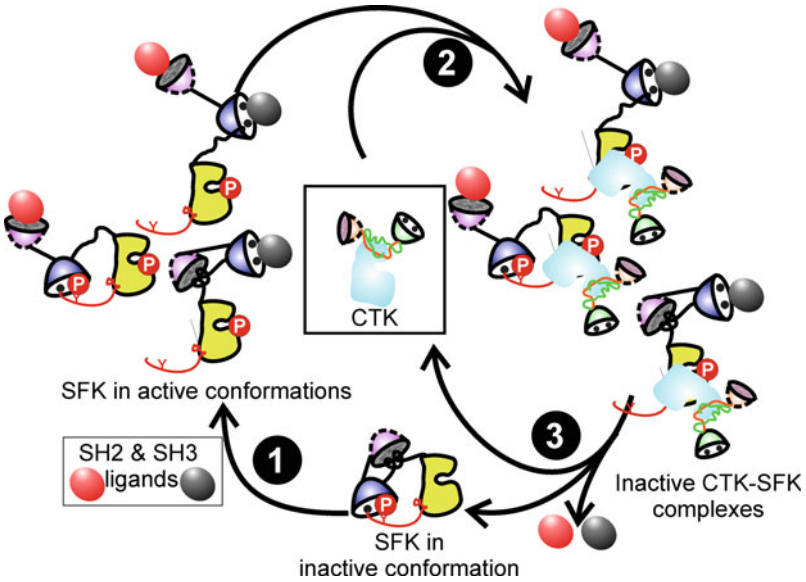
Since aberrant activation of SFKs contributes to formation of cancer ((Cheng et al. 2006; O'Hare et al. 2008) and reference therein), in normal cells, they are kept at the inactive conformation mainly by CSK and CTK. As shown in Fig. 1, SFKs in the inactive conformation are phosphorylated at the C-terminal tail tyrosine by CSK or CTK. Two intramolecular inhibitory interactions are required to keep the kinases in the inactive state: (1) binding of the phosphorylated C-terminal tail tyrosine to SH2 domain and (2) binding of the SH2-kinase linker to the SH3 domain. These interactions stabilize the kinase domain in the catalytically inactive state. Disruption of one or both inhibitory interactions activates SFKs. The active SFKs then undergo autophosphorylation at a conserved tyrosine (e.g., Tyr-416 of c-Src) in the kinase domain and/or dephosphorylation of the phosphorylated C-terminal tail tyrosine by a phosphatase. Upon autophosphorylation, SFKs prefer to adopt the active conformation (reviewed in (Chong et al. 2005b)).

Previous studies by Chong *et al*. demonstrated that CTK suppresses the activity of SFKs by two mechanisms (Fig. 3). The first mechanism, referred to as the catalytic mechanism, involves specific phosphorylation of the C-terminal regulatory tyrosine of SFKs (reviewed in (Cheng et al. 2006; Chong et al. 2005b, 2006) and references quoted therein). Upon phosphorylation, SFKs adopt the inactive conformation. The second mechanism, referred to the non-catalytic inhibitory mechanism, involves direct binding of CTK to the kinase domain of SFKs adopting different active conformations; and the binding alone is sufficient to suppress SFK activity (Chong et al. 2004; 2006). Furthermore, this unique non-catalytic inhibitory mechanism is reliant upon the ability of CTK to bind tightly to SFKs to form stable CTK/SFK complexes (Fig. 3) (Chong et al. 2006). In contrast, CSK fails to exhibit this non-catalytic inhibitory mechanism to suppress SFK activity.

How might CTK recognize SFKs as its physiological substrates? Although the three-dimensional structures of CTK/SFK complexes have not been solved, the structure of CSK/c-Src complex solved by Levinson *et al*. provides the conceptual framework that predicts how CTK selects SFKs as the substrates (Levinson et al. 2008) (Fig. 5a). In the CSK/c-Src structure, the two proteins are engaged in extensive contacts at an interface formed by the αD-helix and αF–αG loop of CSK (Fig. 4) and the segment consisting of residues 504–525 in the αI helix near the C-terminal regulatory motif of c-Src (Fig. 5b and c). Among the interactions between CSK and c-Src at the interface, the most notable are (1) the electrostatic interactions between the five basic residues (R279, R281, R283 of the αD helix and R384 and R389 of the αF–αG loop) of CSK and several acidic residues (E504, R510, E517, D518) of c-Src; and (2) the hydrophobic interaction between R279 of CSK with Y511 of c-Src (Fig. 5b). It is noteworthy that the sequences of the αD helices and αF–αG loops of CSK and CTK are highly conserved. Thus, it is logical to predict that CTK interaction with SFKs also involves the basic residues in the αD helices and αF–αG loops of CTK and acidic and hydrophobic residues near or in the αI helix of the SFK kinase domains. These predicted contacts may direct the active site of CTK to exclusively phosphorylate the C-terminal regulatory tyrosine of SFKs.

How might CTK bind SFKs and suppress their activity? Relevant to this question, CTK was found to bind active forms of SFKs while CSK exhibited binding with much lower affinity or no binding at all (Chong et al. 2006; Levinson et al. 2008). This suggests that in addition to the interactions of basic residues in the αD helices and αF–αG loops of CTK with acidic and hydrophobic residues in the αI helix of SFKs, additional motifs exist in both CTK and SFKs to mediate the tight binding to form the stable CTK/SFK complexes. Furthermore, it is logical to predict that the interactions of CTK with SFKs via these additional motifs underpin the ability of CTK to suppress SFK activity by the non-catalytic inhibitory mechanism. Elucidation of the structural basis of the CTK non-catalytic inhibitory mechanism awaits definition of these unknown additional interaction motifs in CTK and SFKs. The best approach to define these motifs is to determine the crystal structures of the CTK/SFK complexes.

Being a major endogenous inhibitor of SFKs, CTK is a potential tumor suppressor preventing aberrant activation of the oncogenic SFKs. Of relevance, CTK expression is suppressed in colon carcinoma cell lines and biopsies from patients suffering from colon cancer. Furthermore, expression of recombinant CTK in colon cancer cells suppresses SFK activity, anchorage-independent growth, and cell invasion (Zhu et al.



CSK-Homologous Kinase, Fig. 3 A model of inhibition of SFKs by CTK. Step 1: Activation of the inactive SFK by disruption of the two inhibitory intramolecular interactions by SH2 and SH3 domain ligands. Depending on binding of ligands to the SH2 and/or SH3 domains, SFK adopts different active conformations. The active SFK then undergoes autophosphorylation at the conserved tyrosine in the activation loop of the kinase domain. Step 2: CTK employs the non-catalytic inhibitory mechanism to suppress the activity of SFKs. This mechanism involves binding of CTK to the active forms of SFKs to form stable CTK/SFK complexes. Step 3: CTK phosphorylates the C-terminal regulatory tyrosine. The autophosphorylation site of SFKs is dephosphorylated by phosphatases. Upon dissociation of CTK, the SFK molecules with the phosphorylated C-terminal tyrosine adopt the inactive conformation

2008). In addition, overexpression of CTK was found to suppress growth and proliferation of human breast carcinoma MCF-7 cells (reviewed in (Cheng et al. 2006; Chong et al. 2005a)).

SFKs are not the only physiological substrates of CTK. There is a growing body of evidence suggesting that CTK is capable of phosphorylating other cellular proteins to perform SFK-independent functions. For example, CTK expression causes activation of MAP kinase signaling pathway in $SFY^{-/-}$ cells which lack SFKs (Zagozdzon et al. 2006), suggesting that the activation was governed by an SFK-independent mechanism. Relevant to these findings, CTK overexpression could induce phosphorylation of an immunoglobulin superfamily protein called the tyrosine-protein phosphatase non-receptor substrate 1 (SHPS-1) in PC12 cells (reviewed in (Ia et al. 2010)). The authors provided data suggesting that CTK binds to SHPS-1 and directly phosphorylate it at Tyr-428, Tyr-452, Tyr-469, and Tyr-495. In addition to SFKs and SHPS1, CTK may also phosphorylate other cellular proteins. The KESTREL method (Cohen and Knebel 2006), which has been used for searching and identifying potential physiological substrates of a number of protein kinases, will be useful for identifying potential physiological substrates of CTK.

The Roles of SH3 and SH2 Domains in Regulation of Kinase Activity and Subcellular Localization of CTK

Unlike SFKs, CTK lacks the N-terminal fatty acid acylation domain. For this reason, CTK resides predominantly in the cytosol in a number of cell types. Apart from directly binding to SFKs to form stable protein complexes (Chong et al. 2006), CTK interacts with three transmembrane receptor tyrosine kinases including ErbB2, c-kit, and TrkA, the focal adhesion kinase-related kinase Pyk2/RAFTK and the scaffolding protein paxillin (reviewed in Chong et al. 2005a, b). Since SFKs are localized to plasma membrane, endosomes, and perinuclear regions (Seong et al. 2009), CTK needs to be recruited from cytosol to these organelles to inhibit SFKs. Both the SH2 and

(**c**) The Src-binding motifs of CSK and the homologous regions in CTK. R279, R281, and R283 of αD-helix and R384 and R389 of αF–αG loop of CSK and their homologues in CTK are underlined

SH3 domains are involved in targeting CTK to specific subcellular compartments to perform its physiological functions.

CTK SH2 domain crystal structure has been solved by Murthy and Webster in 2001 (PDB: 1JWO; deposited in 2001, modified in 2009). This structure was superimposed to the structure of Lck SH2 domain with the bound pYEEI peptide ligand to generate a hypothetical structure consisting of the CTK SH2 domain with the pYEEI peptide docked to its ligand-binding sites (Fig. 6a and b). The hypothetical structure reveals the amino acid residues of CHK SH2 domain essential for interacting with the phosphotyrosine (pY) and residues at the first, second, and third positions (pY + 1, pY + 2, and pY + 3 positions) from the C-terminal end of pY in the peptide ligand. As illustrated in Fig. 6c, the main structural features on SH2 domain is the presence of two groups of hydrophobic residues in EF loop and BG loop (thr-138 and Ile-139 of the EF loop and Ile-162 of the BG loop). Together with Tyr-128 of the βD strand, these two groups of EF loop and BG loop hydrophobic residues form the binding pocket for the pY + 3 residue in peptide ligand. Indeed, Huang et al. found that CTK SH2 domain prefers phosphopeptide ligands with hydrophobic residues at the pY + 3 position (Huang et al. 2008). For binding to pY in the peptide ligand, the interacting residues include the basic residues Arg-106, His-127, and Arg-129, as well as Tyr-128. Screening with oriented peptide library (OPL) revealed that the CHK SH2 domain preferred a hydrophobic pY + 3 residue in the ligand (Fig. 6d) (Huang et al. 2008). For the pY + 1, Y + 2, and Y + 4 positions, the preferred residues in the peptide ligand are also hydrophobic residues (Fig. 6b, c). This finding is in agreement with the previous prediction by Ayrapetov et al. that Ile-126 in the βD strand governs the preference of the CHK SH2 domain for hydrophobic pY + 1 residue in the peptide ligand (Ayrapetov et al. 2005). Using the SMALI algorithm developed by Huang et al. (2008), a number of tyrosine-phosphorylated cellular proteins were predicted to be recognized by CTK SH2 domain. Among them are the growth factor receptor kinases ErbB2 and c-Kit, which were previously identified to be ligands of the CTK SH2 domain (reviewed in (Chong et al. 2005a)).

Although the ligands of CTK SH3 domain have yet to be identified, evidence provided by Hirao et al. suggests that the CTK SH3 domain can interact with an unknown adaptor protein located on the plasma membrane in megakaryocytic Dami cells. The binding recruits CTK to the plasma membrane. The recruitment is associated with inhibition of the SFK member Lyn and may contribute to suppression of fibronectin-stimulated cell spreading (reviewed in (Chong et al. 2005a)). Little is known about CTK SH3 domain binding specificity. Similar to CSK SH3 domain, binding of

CTK SH3 domain to its ligand is expected to govern the subcellular localization of CTK. Identification of the ligands targeting the CTK SH3 domain will provide further insight into regulation of subcellular localization of CTK. Most SH3 domains bind peptide ligands with the PxxP motif, the two prolines in the motif interact with four conserved hydrophobic aromatic residues in the SH3 domain. In CSK, they are Tyr-18, Phe-20, Trp-47, and Tyr-64 (Fig. 2b). Intriguingly, three out of four of these residues are substituted by the less hydrophobic residues (Cys-17, Asn-19, and Ala-63) in CTK (Fig. 2b). It is unclear whether the lack of hydrophobic aromatic residues at the PxxP motif-binding pocket affects the specificity of CTK SH3 domain binding to cellular protein ligands. In addition to binding ligand, the SH3 domain was demonstrated to mediate dimerization of CSK (Levinson et al. 2009). In contrast to CSK, CTK exists as a monomer in solution (Chan et al. 2010), indicating that the CTK SH3 domain does not govern dimerization of the enzyme. How might the SH3 and SH2 domains of CTK govern its kinase activity? Chan et al. (2010) compared the specific enzymatic activities of recombinant CTK and CSK and found that they exhibit similar efficiency in phosphorylating the SFK member Lyn, indicating that the basal activity of both kinases are similar. Other than this, little is known about the regulation of CTK activity. In contrast, it is well documented that the SH2 and SH3 domains play significant roles in governing the kinase activity of CSK (reviewed in (Ia et al. 2010)). Owing to the high degree of sequence homology between CTK and CSK (Fig. 2 and 4), structural comparison of both kinases allows one to make predictions of CTK regulation. The presence of SH2 and SH3 domains suggests that CTK kinase activity is likely to be regulated by protein ligands that bind to these two domains (Fig. 3). The activity of many protein kinases is governed by the orientation of a conserved structural motif in the kinase domain called the α-helix C (Fig. 3) (see (Ia et al. 2010) for review). Results by biochemical analysis by Mikkola and Bergman (reviewed in (Chong et al. 2005b)) suggest that the SH2-kinase linker interacts with the α-helix C and controls CTK kinase activity. Their results imply that protein ligands that specifically bind to the SH2 domain of CTK can regulate CTK activity by modulating this interaction. Of relevance, the SH2 domain of CTK was reported to bind to a motif containing the phosphorylated Tyr-1248 of ErbB2 (Fig. 6). It will be worthwhile to examine if and how binding of CTK to the phosphorylated ErbB2 affects CTK kinase activity and its efficiency in inhibiting SFKs. Unlike many other protein kinases, CTK lacks the conserved autophosphorylation tyrosine in the activation loop of the kinase domain, suggesting that it is not regulated by tyrosine phosphorylation of the activation loop.

Summary

Studies of the phenotypes of $CTK^{-/-}$ mice and biochemical studies of CTK functions in cancer cell lines demonstrated that CTK plays unique roles in modulating immune cell signaling and functions as a tumor suppressor. Presumably, these functions of CHK are attributed to its ability to suppress the activity of SFKs. In addition to hematopoietic cells, neurons also express high level of CTK. Little is known about the function of CTK in neurons. Future investigation should focus on elucidating the mechanism of regulation and functions of CTK in neurons. Even though CTK is a major endogenous inhibitor of SFKs, little is known about the structure, regulation, and the structural basis of its inhibition of SFKs. There are two outstanding questions concerning the structure and function of CTK: What is the structural basis of the non-catalytic inhibitory mechanism employed by CTK to inhibit SFK activity? What are the other physiological substrates of CTK?

Deciphering the structural basis of CTK inhibition of SFKs by the non-catalytic inhibitory mechanism requires mapping of the SFK-binding determinants in CTK and the CTK-binding determinants in SFK. A previous study demonstrated that these determinants reside in the kinase domain of both CTK and SFKs (Chong et al. 2006). As shown in Fig. 5, similar to CSK, the conserved basic residues in the αD-helix and αF–αG loop of CTK are likely SFK-binding determinants. However, the binding of CTK to SFKs is much tighter than that of CSK to SFKs (Chong et al. 2006). It is logical to predict that in addition to these determinants in the αD-helix and αF–αG loop, determinants residing in other regions of CTK kinase domain are required for its tight binding to SFKs. Further, biochemical analyses are needed to map these determinants. Finally, determination of the three-dimensional structures of CTK and CTK/c-Src

complex will provide valuable insights into the structural basis of this non-catalytic inhibitory mechanism of CTK.

There is no doubt that small-molecule inhibitors specifically inhibiting SFKs are needed for development as therapeutics for cancer treatment. A number of inhibitors targeting the ATP-binding pocket of the active SFKs have been developed for clinical use or for preclinical studies. Among them, Dasatinib, AZD0530, and SKI-606 are currently in clinical trials for the treatment of different forms of cancer. The use of Dasatinib for the treatment of drug-resistant chronic myelogenous leukemia has been approved. Owing to the ability of these small molecule compounds to inhibit other protein kinases and possibly some non-protein kinase enzymes, use of these compounds for the treatment of cancer may cause significant side effects in patients receiving the treatment. Thus, the second-generation chemical inhibitors which target SFKs with exquisite selectivity are urgently needed. Since CTK can employ the non-catalytic inhibitory mechanism to specifically suppress the activity of SFKs adopting the active conformations. Future investigation to define the structural basis of the non-catalytic inhibitory mechanism of CTK will benefit the development of this new generation of inhibitors.

Historical Background

In 1911, pathologist Francis Peyton Rous isolated a virus from a Plymouth Rock chicken that has continued to bear his name, the Rous sarcoma virus (RSV) (Rous 1911). Rous sarcoma virus is the archetypal retrovirus, capable of causing tumors in chickens and rapidly transforming cells in culture with high efficiency through production of the protein viral sarcoma (v-Src), the first identified transforming protein. In 1976, Bishop and Varmus demonstrated that the *v-Src* gene has a normal cellular homolog gene (protooncogene), *c-Src*, and that the *v-Src* gene product, pp60v-Src or v-Src, is a phosphoprotein with an apparent molecular mass of 60 kDa with intrinsic protein kinase activity (Stehelin et al. 1976). Sequencing of the chicken *c-Src* gene and the RSV *v-Src* gene demonstrated that the two genes are closely related except at the *C*-terminal end, and it is this structural difference that leads to constitutive activation of *v-Src*, which underlies its transforming capacity (Takeya and Hanafusa 1983).

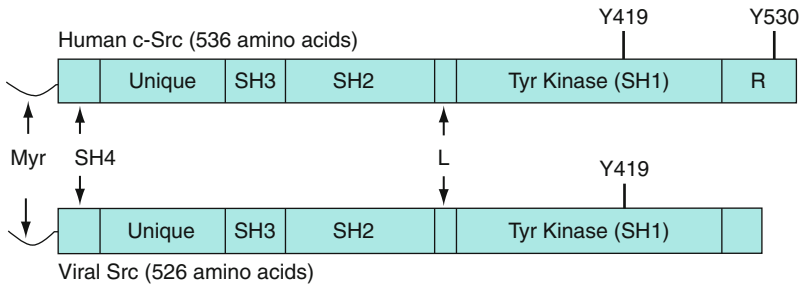
c-Src is the prototypic member of a family of non-receptor, membrane-associated tyrosine kinases comprising 11 c-Src family kinases (SFKs); the other ten are Fyn, Yes, Blk, Yrk, Frk (also known as Rak), Fgr, Hck, Lck, Srm, and Lyn (Sen and Johnson 2011). The human genome contains a Yes pseudogene known as *YESps*. c-Src, Yes, and Fyn are ubiquitously expressed in a variety of tissues. Srm is found in keratinocytes, whereas Blk, Fgr, Hck, Lck, and Lyn are found primarily in hematopoietic cells. Frk occurs chiefly in bladder, breast, brain, colon, and lymphoid cells. In fact, Frk has been shown to be a nuclear protein with growth-inhibitory effects when ectopically expressed in breast cancer cells. Blk occurs chiefly in colon, prostate, and small intestine cells, but it was initially isolated from a breast cancer cell line.

SFKs are activated by cytokine receptors, receptor protein tyrosine kinase, G-protein coupled receptors, and integrins. They promote cancer cell proliferation, survival, motility, and invasiveness (Summy and Gallick 2003).

Structure

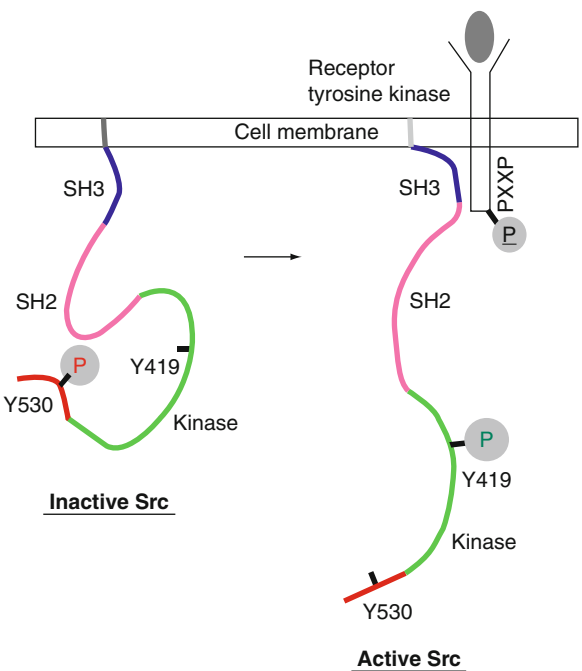
SFKs are proteins of approximately 60 kDa composed of several functional domains: (a) a myristic acid moiety at the *N*-terminal region responsible for localization at the inner surface of the cell membrane; (b) a unique domain that provides unique functions and specificity to each member of the SFK family; (c) an SH3 domain that is able to bind proline-rich sequences to mediate both intracellular and intercellular interactions; (d) an SH2 domain that binds phosphorylated tyrosine residues on the SFK molecule itself or its substrates; (e) a linker domain that binds to the SH3 domain; and (f) a catalytic domain that is composed of two lobes separated by a catalytic cleft in which the ATP and substrate-binding sites reside and phosphate transfer occurs. The cleft forms an activation loop that contains tyrosine (Y419, c-Src, human) which is a positive regulatory site responsible for maximum kinase activity. The SFKs also include (g) the *C*-terminal tail, which contains a negative regulatory tyrosine (Y530, c-Src, human) residue (Fig. 1 and reviewed in Johnson and Gallick 2010).

Upon phosphorylation of Y530, the SFK attains a "closed" or inactive conformation by binding its



c-Src Family of Tyrosine Kinases, Fig. 1 Cartoon representation of the structural domain of human-Src and viral-Src. Src is composed of an N′-terminal myristic acid chain attached to SH4 domain, a unique region followed by SH3 and SH2 domain. A short linker domain (L) followed by tyrosine kinase domain (SH1) harboring Tyr 419 and a C′-terminal regulatory domain (R) harboring Tyr 530. Viral Src differ from human Src in a number of ways with one major difference being the lack of a regulatory domain (R) at its C′-terminal end

C-terminal region to its SH2 domain. In this closed conformation, the activation loop adopts a compact structure, which fills the catalytic cleft and precludes access of ATP and substrate. The closed conformation masks the Y419 residue, furthermore, preventing activation by autophosphorylation (Fig. 2). Although c-Src and v-Src exhibit several single amino acid differences, the most striking difference is the substitution of the most *C*-terminal 19 amino acids of chicken c-Src (533 amino acids) by 12 completely different amino acids in RSV v-Src (526 amino acids) (Takeya and Hanafusa 1983). Following loss of the *C*-terminal negative regulatory Tyr residue, v-Src and v-Yes are no longer regulated by intramolecular interaction and become constitutively active.



c-Src Family of Tyrosine Kinases, Fig. 2 Schematic representation of Src kinase regulation by differential phosphorylation at kinase domain (Tyr 419) and C′-terminal regulatory domain (Tyr 530)

Regulation of c-Src Kinase Activity

v-Src is a constitutively activated form of c-Src capable of eliciting many dramatic biological responses, including adhesion, migration, invasion, proliferation, differentiation, and survival. Because of the extensive involvement of c-Src in multiple cellular processes (described below), investigators have searched for the mechanisms behind c-Src activation and discovered that many different processes can alter c-Src kinase activity.

Structure of the C-terminal Regulatory Domain

Phosphorylation of the *C*-terminal regulatory residue (Y530, c-Src) may be mediated by any of several kinases and phosphatases. As already described, phosphorylation of Y530, deletion or mutation of the *C*-terminal regulatory region, and displacement of the SH3 or SH2 domain mediated by intramolecular interactions regulate c-Src activity in cells. Because of the loss of the *C*-terminal negative regulatory Tyr residue, v-Src and v-Yes are no longer regulated by intermolecular interactions. Rare activating mutations in c-Src have been reported in some cases of advanced colon and endometrial cancers

(Irby et al. 1999). These mutations result in a stop codon at 531, one residue beyond the Y530, resulting in a truncated c-Src that is unable to form the closed conformation.

Cytoplasmic Kinases

Two important protein tyrosine kinases in the phosphorylation of SFKs are c-Src kinase (▶ CSK) and its homolog CSK-homologous kinase (▶ CHK), which are both able to phosphorylate Y530. Substantial evidence suggests that CSK and CHK are negative regulators of SFKs that play distinct roles during development of the nervous system. Their distinct biological effects may be due to distinct signaling effects. Specifically, CHK was shown to enhance MAPK signaling, while the role of CSK was mediated predominantly by c-Src regulation. In cancer cells, CHK was able to downregulate ErbB-2/neu-activated Src kinases. CSK is structurally similar to c-Src, comprising an SH2 domain, an SH3 domain, and a tyrosine kinase domain, but it lacks the regulatory tyrosine residue at its *C*-terminal end. A number of proteins that specifically bind CSK and regulate its activity toward c-Src have been identified, including tyrosine-protein phosphatase non-receptor type 12 with a *C*-terminal PEST motif (PTP-PEST), which could potentially counteract the activity of CSK by dephosphorylating c-Src at Y530. Another mechanism of CSK regulation is through the transmembrane adapter protein Cbp (CSK-binding protein OR protein associated with glycosphingolipid-enriched microdomains (PAG)), which is a c-Src substrate. Following phosphorylation by c-Src, Cbp can bind to the SH2 domain of CSK, thus allowing its recruitment to the plasma membrane where active c-Src resides, creating a negative regulatory loop (Sen and Johnson 2011).

Protein Tyrosine Phosphatases

Several protein tyrosine phosphatases (PTPs) have been implicated in regulation of c-Src kinase activity, including PTP-alpha, PTP-gamma, SHP-1, SHP-2, and PTP-1B. PTP-alpha is ubiquitously expressed and enriched in brain tissue and is able to dephosphorylate both Y419 and Y530 in vitro in cancer cells (Zheng et al. 1992). However, it is unclear whether PTP-alpha acts as an activator or repressor molecule. Both c-Yes and c-Fyn are dephosphorylated and activated by PTP-alpha. In contrast, PTP-gamma is capable of dephosphorylating Y530 and is responsible for elevated c-Src kinase activity (Bjorge et al. 2000).

SHP-1 (also known as PTP-1 C) and SHP-2 are cytosolic, SH2 domain-containing PTPs expressed in epithelial and hematopoetic cells. They can dephosphorylate Y530 and subsequently increase c-Src kinase activity. The SH2 domain of SHP-2 binds to the SH3 domain of c-Src, which results in allosteric regulation of c-Src.

PTP-1B (also known as PTP-N1) was purified from breast cancer cells as a phosphatase that can dephosphorylate a Y530-containing peptide (Bjorge et al. 2000). Biochemical analysis showed that cancer cells have elevated levels of PTP activity, which correlates with reduced phosphorylation of the *C*-terminal residue of c-Src and may have an important role in controlling c-Src kinase activity.

Membrane-Associated Receptors and Cytoplasmic Kinases

c-Src can act as an upstream or downstream modulator of receptor molecules, including receptor tyrosine kinases (RTKs), steroid hormone receptors, and G-protein coupled receptors (GPCR). c-Src can also be activated by non-receptor tyrosine kinases.

SFKs physically interact with activated RTKs, creating a positive regulatory loop that contributes to robustness of RTK signaling. Upon stimulation by its ligands, RTKs cause receptor dimerization and autophosphorylation of tyrosine residues of the cytoplasmic domain. The resulting phosphorylation acts as a docking site to recruit and activate c-Src, which in turn phosphorylates other RTKs and creates other SH2 binding recruitment sites, allowing binding of the Grb2-SOS complex leading to activation of downstream signaling of the Ras-MAPK and PI3K signaling pathways. c-Src can associate with overexpressed epidermal growth factor receptor (EGFR) to cause synergistic mitogenicity. c-Src activity can be stimulated by EGFR autophosphorylation of Tyr 845. EGF has been shown to stimulate invasion and metastasis of carcinoma cells through Src-mediated activation of ▶ p^{130}Cas. RTKs and integrins also act synergistically in promoting cell survival, proliferation, cytoskeletal reorganization, and invasion through signaling mediated by c-Src.

The binding of SFKs to various proteins plays important roles in SFK regulation. Several structural features of SFKs facilitate their interactions with

proteins that regulate them. X-ray crystal structure analysis revealed that the inactive Src conformation can be achieved by interaction between the SH2 domain and the *C*-terminal Tyr residue or between the SH3 domain and the SH2 kinase linker. A variety of Src-binding proteins can compete for binding in this cleft, disrupting the intramolecular interaction and activating c-Src. Platelet-derived growth factor receptor (PDGFR) and focal adhesion kinase (FAK) can bind to the c-Src SH2 domain and activate c-Src and Hck (another member of SFK). p^{130}Cas can bind to the c-Src SH2 and SH3 domains, activating c-Src.

Increased Expression and Altered Protein Stability

Recent evidence suggests that c-Src is subject to ubiquitin-dependent degradation. Specifically, activated forms of c-Src are turned over more rapidly than inactive c-Src. One possible explanation is that c-Src and Fyn bind to and phosphorylate c-Cbl. Upon binding with c-Src, c-Cbl acts as an E3-ubiquitin ligase, leading to c-Src degradation (Frame 2002).

SFK Regulation of Cancer Cell Function

SFKs are important in various aspects of tumor development, including proliferation, migration, invasiveness, apoptosis, and angiogenesis. It is well documented that c-Src is responsible for dynamic regulation of the actin cytoskeleton, resulting in cell motility, cell membrane adhesion, and cell-cell adhesion. c-Src acts as one of the central components of the focal adhesion complex. The c-Src SH3 domain associates with actin filaments upon activation, which then drive translocation of c-Src to cell-cell and cell-matrix adhesion sites where c-Src can interact with plasma membrane-bound molecular partners to take part in two major transduction events: signaling from RTKs, which mainly affects cell growth, proliferation, and migration; and signaling from adhesion receptors such as integrins and E-cadherin, which mainly regulates cytoskeletal functions (Fig. 3 and reviewed in (Johnson and Gallick 2010)).

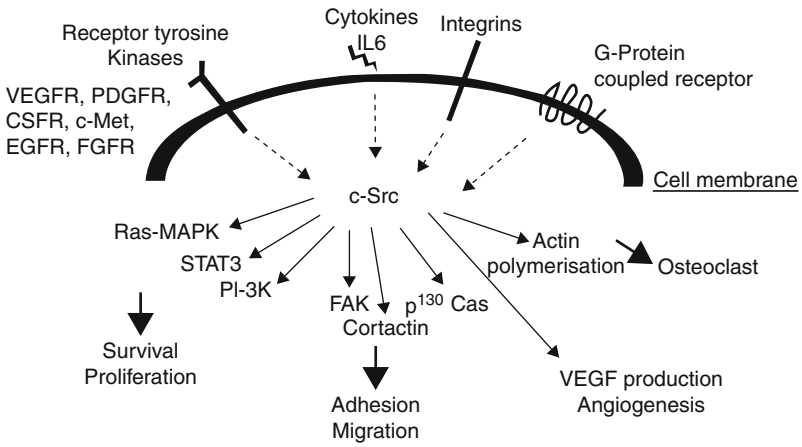
SFKs are frequently overexpressed and/or aberrantly activated in a variety of cancers. The contributions of c-Src to cell regulation and cancer development were discussed by Summy and Gallick (2003). Activation is very common in colorectal and breast cancers and less frequent in melanomas and ovarian, gastric, head and neck, pancreatic, lung, brain, and hematologic cancers. The extent of increased SFK activity often correlates with malignant features and patient survival.

Colon Cancer

Involvement of c-Src in cancer development and progression has been studied more extensively in colon cancer than in any other human cancer. c-Src kinase activity is elevated in premalignant ulcerative colitis lesions, and lesions with the highest extent of dysplasia have the greatest potential for progression to carcinoma. Surprisingly, adenomas displayed stronger immunohistochemical staining for active c-Src than advanced adenocarcinomas (Summy and Gallick 2003).

c-Src-specific kinase activity via phosphorylation is elevated in colon cancer cell lines. Although c-Src is frequently activated in human colon cancers, it is not the only SFK whose activation corresponds with malignant progression. c-Yes is also frequently activated in colon cancers. c-Yes kinase activity was elevated in three of five colon cancer cell lines and 10 of 21 primary colon carcinomas relative to normal colonic mucosa (Summy and Gallick 2003). Because of the high homology between c-Src and c-Yes, it has been assumed that both kinases perform similar functions in cancer development, but c-Yes is evidently unable to compensate fully for the lack of c-Src in these processes because of its substrate specificity among different SFKs. Regulation of actin cytoskeleton dynamics is crucial to the motility, invasiveness, and metastatic spread of tumor cells, and thus the contribution of c-Yes to tumor development may differ from that of c-Src. Interestingly, Lck is also expressed in colon cancer as a result of abnormal activation of the *Lck* promoter due to loss of its transcriptional repressor.

Treatment of a human colon tumor cell line with tyrosine kinase inhibitor herbimycin-A caused a reduction in c-Src kinase activity followed by subsequent reduction in colon cancer cell growth. c-Src kinase activity as measured by phosphorylated Y419 is important for proliferation and growth of primary tumors derived from human colon cancer cells. SFKs may contribute to the invasiveness of colon carcinoma cells through dynamic regulation of the actin cytoskeleton and activation of matrix proteases. c-Src expression also regulates the cadherin-catenin association, thereby regulating cell-cell contact. Another report suggested that the level of vascular endothelial



c-Src Family of Tyrosine Kinases, Fig. 3 Cartoon representation of Src signaling in tumor development and progression

growth factor (VEGF) varied directly with c-Src level in a colon cancer cell line (Johnson and Gallick 2010; Summy and Gallick 2003).

Breast Carcinoma

Considerable data support a role for SFKs in the progression of breast cancer. Several independent reports have demonstrated elevated levels of c-Src kinase activity in breast carcinoma tissue in comparison to normal breast epithelium. Lehrer et al. showed that tumors expressing the progesterone receptor generally displayed higher kinase activity than those that did not express progesterone receptor and that 70% of tyrosine kinase activity in breast cancer could be attributed to c-Src (Lehrer et al. 1989). Female mice with forced expression of active c-Src frequently developed epithelial hyperplasia, which occasionally progressed to full neoplasia. As with colon cancer, c-Src is important in the induction of VEGF transcription in breast cancer, suggesting the importance of c-Src in cancer angiogenesis.

Zhang et al. provided both clinical and experimental evidence that c-Src plays a critical role in establishment of latent bone metastasis in breast cancer. Using a bioinformatic approach, they identified a c-Src activity gene expression signature that was highly associated with the late onset of bone metastasis in breast cancer (Zhang et al. 2009).

Melanoma

Human melanoma is one of the few cancers in which c-Yes plays a more crucial role in the cancer development than c-Src. c-Yes kinase activity is increased in melanoma cells compared to normal melanocytes, but c-Src kinase activity is not upregulated. Likewise, c-Yes is activated in the presence of nerve growth factor, whereas c-Src is not (Johnson and Gallick 2007).

Head and Neck Cancer
