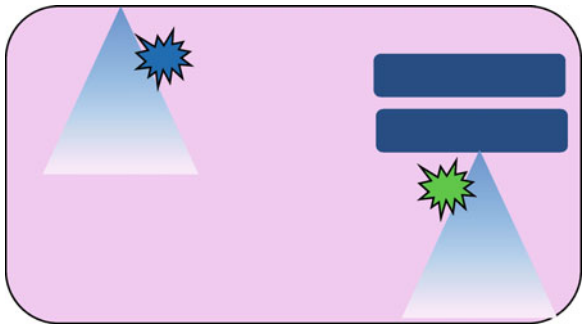
Many Ca^{2+}-permeable channels in the plasma membrane include within their oligomeric structures everything that is required to respond to an extracellular stimulus, a chemical messenger or a change in membrane potential, for example. These channels, and there is an enormous diversity of them, are the simplest and, presumably, the most ancient means of linking extracellular stimuli to changes in $[Ca^{2+}]_c$. Why then should cells also have evolved pathways that allow release of Ca^{2+} form intracellular stores? There are several, inevitably speculative, possibilities. First, it is less expensive to pump Ca^{2+} across the ER membrane (2 Ca^{2+} per ATP hydrolyzed), where there is a concentration gradient but no electrical gradient, than it is to pump Ca^{2+} across the plasma membrane against an electrical and concentration gradient (1 Ca^{2+} per ATP). A Ca^{2+} signal evoked by releasing Ca^{2+} from the ER is, therefore, cheaper than that evoked by Ca^{2+} entry across the plasma membrane. Second, the ER invades most of the cell and provides more abundant opportunities to deliver Ca^{2+} locally to specific intracellular targets. Third, because luminal Ca^{2+} within the ER is itself an important regulator of protein synthesis and folding, it seems likely that selective pressures had provided the machinery to maintain a stable source of Ca^{2+} within the ER before it was exploited as a reliable source of an intracellular messenger. Whatever the evolutionary history, it is clear that the ER is now the major intracellular source

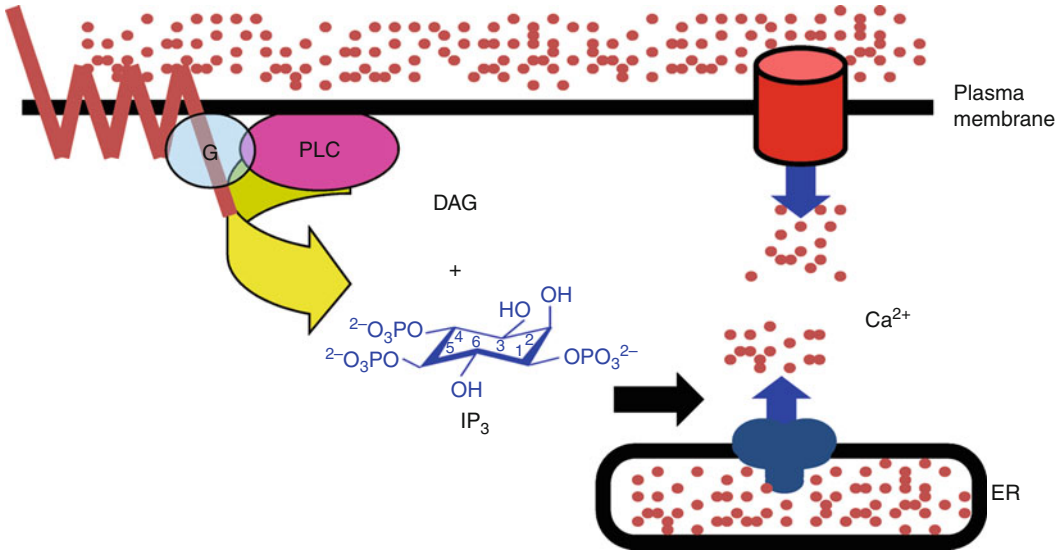


IP_3 Receptors, Fig. 1 Local decoding of Ca^{2+} signals. Because Ca^{2+} diffuses slowly in the cytosol, Ca^{2+} gradients persist around the mouths of open Ca^{2+} channels. Ca^{2+}-binding proteins positioned within these gradients can then respond selectively to opening of specific Ca^{2+} channels in, for example, the plasma membrane (*blue*) or ER (*green*)

of Ca^{2+} signals, although accumulating evidence suggests that the Golgi apparatus, secretory vesicles, the nuclear envelope, and lysosomes may also play more specialized roles. The inositol 1,4,5-trisphosphate receptors (IP_3R) that are the focus of this section are expressed primarily in the ER but occur also in some other intracellular organelles (e.g., Golgi apparatus, secretory vesicles, nuclear envelope) and even in the plasma membrane of some cells (Dellis et al. 2006). Although the diversity of intracellular Ca^{2+} channels does not approach that of Ca^{2+}-permeable channels in the plasma membrane, IP_3R are not the only intracellular Ca^{2+} channels. After IP_3R, their relatives, the ▶ ryanodine receptors, are probably the most abundant intracellular Ca^{2+} channels. Other intracellular Ca^{2+} channels that can mediate release of Ca^{2+} into the cytosol include those that respond to ▶ sphingosine-1-phosphate; the Ca^{2+}-activated channel, ▶ polycystin-2, and other transient receptor potential (▶ TRP) channels; and the two-pore channels (TPC) in acidic organelles that respond to NAADP (Patel et al. 2010). The interactions between IP_3R and some of these channels are considered later, but first it is instructive to recount briefly the discovery of IP_3 and its receptors.

Discovery of IP_3 and Its Receptors

Bob Michell, in a prescient review (Michell 1975), was the first person to propose a causal link between the ability of some receptors to stimulate hydrolysis of a minor class of membrane lipids, the phosphoinositides, and their ability to cause an increase in



IP_3 Receptors, Fig. 2 IP_3 links cell-surface receptors to release of Ca^{2+} from the ER. Receptors, like the G-protein-coupled receptor shown in the figure, stimulate PLC and, thereby, hydrolysis of phosphatidylinositol 4,5-bisphosphate into DAG and IP_3; both are important intracellular messengers. IP_3, via its receptor in the ER, stimulates release of intracellular Ca^{2+} stores, but it may also (directly or indirectly) stimulate Ca^{2+} entry across the plasma membrane (see text for details)

$[Ca^{2+}]_c$. At this stage, the thinking was that hydrolysis of phosphoinositides by phospholipase C (PLC) was linked directly to stimulation of Ca^{2+} entry across the plasma membrane, but as the story unfolded, it became clear that the link was with release of Ca^{2+} from intracellular stores mediated by IP_3 acting at its receptor. We know now that many extracellular stimuli acting via either G protein-coupled receptors or those with intrinsic ▶ protein tyrosine kinase activity stimulate PLCs, and these then catalyze hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) to produce IP_3 and diacylglycerol (DAG) (Fig. 2). The signaling pathway is intriguing because the substrate (PIP_2) and both products of its hydrolysis (DAG and IP_3) are each important regulators of cellular activity. IP_3 is the soluble messenger that links the initial events at the plasma membrane to release of Ca^{2+} from intracellular stores. The salivary gland of the blowfly, in the hands of Mike Berridge, played a prominent role in the development of our present understanding. The blowfly spits digestive enzymes onto its food, and to do so quickly (and avoid being swatted!), its salivary glands must sustain impressive rates of fluid secretion. ▶ 5-hydroxytryptamine (5-HT) evokes this secretion via its ability to stimulate both formation of cyclic AMP (another important intracellular messenger) and an increase in $[Ca^{2+}]_c$. Berridge showed in the early 1980s that the *first* water-soluble product of 5-HT-stimulated PLC activity was IP_3, that IP_3 formation *preceded* the increase in $[Ca^{2+}]_c$, and that the formation of IP_3 was *required* for the Ca^{2+} signaling. Only later, and informed by these results from the uniquely favorable experimental attributes of the insect glands, were the findings extended to mammalian cells. That the seemingly arcane studies of a tiny gland from the common blowfly should have paved the way for unraveling a ubiquitous signaling pathway in eukaryotic cells illustrates how the most profound discoveries can come from the most unexpected places. The decisive experiment came in 1983, when IP_3, the first water-soluble product of PLC, was shown to release Ca^{2+} from non-mitochondrial intracellular Ca^{2+} stores of mammalian cells (Streb et al. 1983). Within months, the work had been repeated in countless cell types and, before long, it was in all the standard textbooks: IP_3 is the intracellular messenger that links many cell-surface receptors to release of Ca^{2+} from intracellular stores (Fig. 2).

Ca^{2+} Signals Evoked by IP_3 Receptors

IP_3R are the channels via which IP_3 regulates Ca^{2+} signals in animal cells, and they do so by controlling

both Ca^{2+} release and Ca^{2+} entry across the plasma membrane. Most IP_3R are expressed in the membranes of the ER, where they directly mediate Ca^{2+} release. In most cells, loss of Ca^{2+} from the ER then stimulates store-operated Ca^{2+} entry. Here, loss of Ca^{2+} from the luminal EF-hand of the STIM protein allows it to activate a Ca^{2+}-permeable channel, formed by Orai proteins, in the plasma membrane (Lewis 2007). In some cells, IP_3R can also more directly regulate Ca^{2+} entry either because the IP_3R is itself expressed in the plasma membrane (Dellis et al. 2006) or through interactions of intracellular IP_3R with other plasma membrane Ca^{2+} channels. A key point is that only rarely are release of Ca^{2+} from intracellular stores and Ca^{2+} entry entirely independent processes, more often complex interactions between Ca^{2+} channels in both membranes allow both sources of Ca^{2+} to contribute to the increase in $[Ca^{2+}]_c$. In this context, an important feature of many Ca^{2+} channels, including IP_3R, is that they are both Ca^{2+}-permeable and Ca^{2+}-regulated. IP_3R, for example, are rapidly stimulated by modest increases in $[Ca^{2+}]_c$ and more slowly inhibited by larger increases. The feedback interactions that this Ca^{2+} regulation provides allow regenerative propagation of Ca^{2+} signals by IP_3R, and it allows Ca^{2+} signals evoked by other Ca^{2+} channels to stimulate IP_3R. The interplay between different Ca^{2+} channels is an important and recurrent theme in Ca^{2+} signaling.

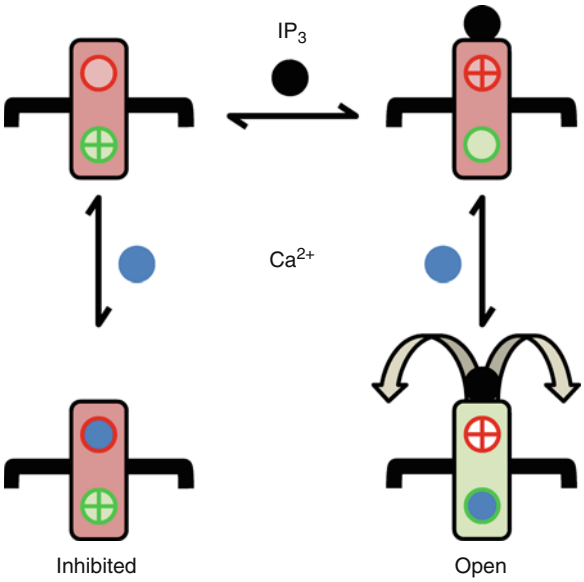
Optical imaging, using confocal or total internal reflection fluorescence (TIRF) microscopy, of cells loaded with fluorescent Ca^{2+} indicators has been used to resolve the openings of individual IP_3R in intact cells and the growth of these tiny Ca^{2+} signals into larger ones involving larger numbers of IP_3R (Smith et al. 2009). As the intracellular IP_3 concentration increases, it triggers a hierarchy of elementary Ca^{2+} release events, beginning with the openings of single IP_3R ("Ca^{2+} blips"), progressing to the coordinated openings of a cluster of several IP_3R ("Ca^{2+} puffs") and, finally, with sufficient IP_3, culminating in a regenerative Ca^{2+} wave invading the entire cell (Bootman et al. 1997) (Fig. 3). Current thinking, derived from both experimental and theoretical analyses, is that recruitment of these Ca^{2+} release events is mediated by the positive feedback provided by Ca^{2+} released by IP_3R. This conclusion focuses our attention on understanding how IP_3R are regulated by Ca^{2+} and IP_3, and on the processes that appropriately position IP_3R in ER membranes to allow interactions between them.

Regulation of IP_3 Receptors by IP_3 and Ca^{2+}

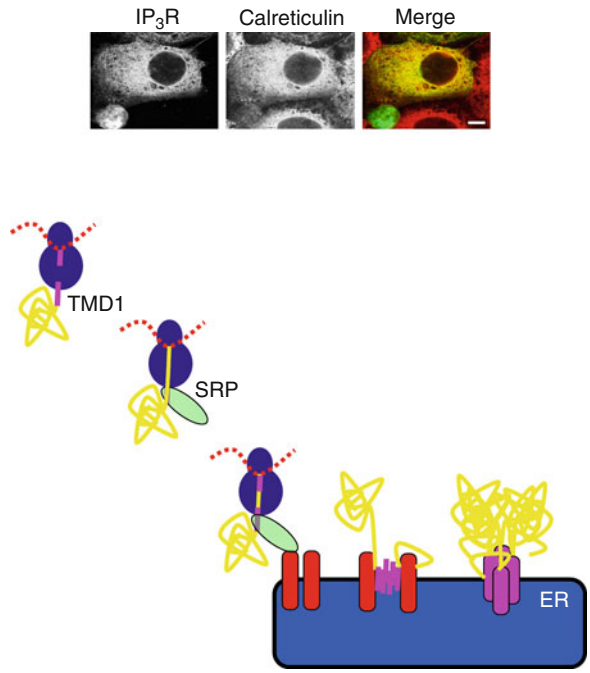
All IP_3R require both IP_3 and Ca^{2+} for their activation (Foskett et al. 2007). The consensus is that binding of IP_3 to the IP_3R is essential to initiate its activation. It is not, however, entirely clear whether all four subunits of the tetrameric IP_3R must bind IP_3. The effects of Ca^{2+} on IP_3R activity are probably mediated by two distinct Ca^{2+}-binding sites: one site promotes opening of the channel, and the other is inhibitory. Although details of the interactions between IP_3 binding and these Ca^{2+}-binding sites are not resolved, our use of methods that allow rates of Ca^{2+} release to be measured with very rapid temporal resolution (Adkins and Taylor 1999) provided a simple scheme that is consistent with most experimental observations. The essence of the scheme is that IP_3 controls IP_3R activation by regulating whether the stimulatory or inhibitory Ca^{2+}-binding site is accessible. IP_3 binding causes the inhibitory Ca^{2+}-binding site to become inaccessible, while simultaneously exposing the stimulatory Ca^{2+}-binding site. Binding of Ca^{2+} to the latter directly promotes channel opening. Others have presented more elaborate schemes (Foskett et al. 2007), but whatever the details, the key point is that Ca^{2+} ultimately controls gating of IP_3R; IP_3 works by priming IP_3R to respond to Ca^{2+} (Fig. 3).

Tuning of the Ca^{2+} regulation of IP_3R by IP_3 has important physiological consequences. It allows, IP_3 to set the gain on the regenerative propagation of Ca^{2+} signals by IP_3R. There is an apt analogy with a spreading bushfire: IP_3 can be envisaged as drying the tinder, while Ca^{2+} provides the spark. Dual regulation of IP_3R by IP_3 and Ca^{2+} may also allow IP_3R to behave as molecular coincidence detectors, opening only when IP_3 is provided by one signaling pathway (any of the receptors that stimulate PLC) and Ca^{2+} by another (Berridge 1998). The latter from either intracellular Ca^{2+} channels, like polycystin 2 or TPC2, or by Ca^{2+} channels in the plasma membrane.

Ca^{2+} and IP_3 are the essential regulators of IP_3R gating, but there are two additional important physiological influences. First, other organelles, most notably mitochondria closely abutting the ER, my rapidly sequester Ca^{2+} released by IP_3R and thereby modulate the relationship between released Ca^{2+} and its feedback effects on nearby IP_3R (Rizzuto et al. 2004). Second, many additional intracellular signals (like ATP, cyclic AMP, and calmodulin) or proteins,



IP_3 Receptors, Fig. 3 IP_3 activates IP_3 receptors by controlling Ca^{2+} binding. Binding of IP_3 (*black circle*) to the IP_3R determines whether a stimulatory (*green*) or inhibitory (*red*) Ca^{2+}-binding site is accessible. IP_3 binding causes the stimulatory site to become accessible and the inhibitory site to become hidden. Binding of Ca^{2+} (*blue circle*) to the former then triggers opening of the pore



IP_3 Receptors, Fig. 4 Co-translational targeting of IP_3 receptors to the ER. The upper panel shows confocal images of cells expressing EGFP-IP_3R1 and immunostained for calreticulin (a luminal ER protein). The colored overlay shows that IP_3R1 is expressed in the ER. Recognition of a signal sequence in TMD1 of IP_3R1 by SRP targets it to the ER membrane, where translation continues (see text for details)

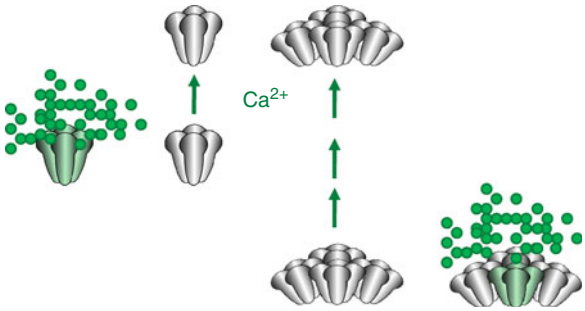
including protein kinases, also associate with IP_3R and modulate their sensitivity to IP_3, Ca^{2+}, or the links between their binding and opening of the pore. These interactions further endow IP_3R with an ability to process information arising from diverse signaling pathways and transduce it into an intracellular Ca^{2+} signal.

Putting IP_3 Receptors in the Right Place

IP_3R, like most integral ER membrane proteins, are co-translationally targeted to the ER (Fig. 4). This begins when the signal recognition particle (SRP) binds hydrophobic residues within a signal sequence on the nascent peptide chain. For IP_3R, the signal sequence lies within the first of the six transmembrane domains (TMD) of each subunit (Pantazaka and Taylor 2010). The SRP-ribosome-nascent chain complex is recognized by the SRP receptor in the ER membrane, allowing the growing protein to be threaded into a channel in the ER membrane, the translocon. The hydrophobic TMD initially remain within the translocon, while intervening hydrophilic loops are pushed into the cytosol or ER lumen. By this stage, the entire cytosolic N-terminal region of the IP_3R has folded. This is important in determining the final topology of the IP_3R because the massive N-terminal is too large to enter the translocon and so remains cytosolic and, thereby, dictates the orientation of successive TMD across the ER membrane. As remaining TMD are synthesized, they co-assemble and then pass through the wall of the translocon into the ER membrane (Fig. 4). A minority of IP_3R moves onward from the ER to the Golgi apparatus, secretory vesicles, or plasma membrane, but most remain within the ER. Pairs of TMD (TMD1-2, TMD3-4, or TMD5-6) provide ER retention or retrieval signals. There are, therefore, many effective signals working to keep IP_3R within the ER. This provides a satisfying explanation for the observation that most IP_3R are expressed in the ER but begs the question of how those IP_3R that do progress to later membrane compartments succeed in overcoming these powerful signals. Although the details lie beyond the scope of this review, IP_3R can

also be selectively directed to specific parts of the ER network: to one end of a polarized cell, for example, or become associated specifically with cell-surface receptors (via interaction with ▶ Homer, for example) or caveolae.

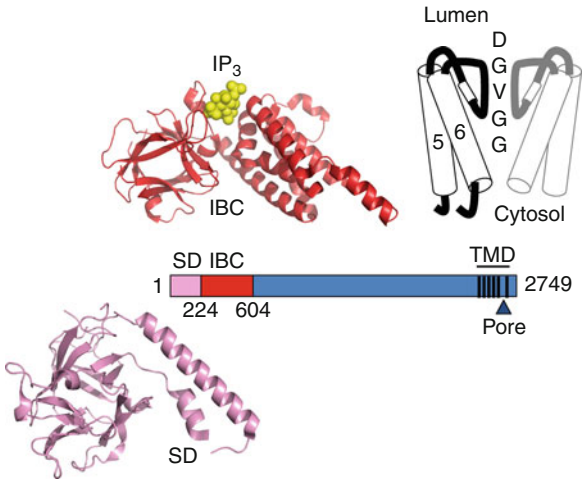
Fluorescence recovery after photobleaching (FRAP) studies have shown that most IP_3R within the ER are mobile. Our studies of IP_3R in the nuclear envelope, where they are accessible to electrophysiological analyses, has shown that IP_3 causes these mobile IP_3R rapidly and reversibly to assemble into small clusters of a few IP_3R (Rahman et al. 2009). Within these clusters, regulation of IP_3R by IP_3 and Ca^{2+} is retuned: lone and clustered IP_3 respond differently to IP_3 and Ca^{2+}. The functional significance of this clustering is twofold. First, it brings IP_3R together so that instead of being insulated from each others' activities by high concentrations of cytosolic Ca^{2+} buffers, they can immediately sense the Ca^{2+} released by a neighbor. Second, clustering at resting $[Ca^{2+}]_c$ reduces the sensitivity of IP_3R to IP_3, but this then reverses when $[Ca^{2+}]_c$ increases. Both effects serve to coordinate the openings of small groups of IP_3R by exaggerating the stimulatory effect of locally released Ca^{2+} (Rahman et al. 2009) (Fig. 5). We suggest, although others argue otherwise (Smith and Parker 2009), that IP_3, in addition to regulating opening of IP_3R, plays an essential role in assembling the small clusters of IP_3R responsible for the "Ca^{2+} puffs" observed in intact cells.



IP_3 Receptors, Fig. 5 IP_3-evoked clustering of IP_3R exaggerates the coordinating effect of Ca^{2+}. IP_3 causes IP_3R to form small clusters of about 4–5 IP_3R within which they become less sensitive to IP_3, but more susceptible to regulation by the Ca^{2+} released by a neighbor. Increased $[Ca^{2+}]_c$ reverses the inhibition caused by clustering and so increases the dynamic range for Ca^{2+} regulation (see text for details)

Structural Determinants of IP_3 Receptor Behavior

In vertebrates, three genes encode closely related IP_3R subunits, while invertebrates express only a single subtype. These subunits are amongst the largest of all ion-channel subunits, each comprising about 2,700 amino acid residues. All IP_3R are tetrameric assemblies of either the same or different subunits, each predicted to form a similar structure. Each subunit comprises three major regions: an N-terminal region to which IP_3 binds, the C-terminal portion with its six transmembrane regions (TMD), and a very large intervening sequence (Fig. 6). The outstanding problem is to explain how IP_3 binding leads to opening of the pore. We have some way to go before that explanation is fully in place.



IP_3 Receptors, Fig. 6 Major structural domains of the IP_3 receptor. The three key regions defined by the primary sequence of a single IP_3R subunit are highlighted: the N-terminal with its SD and IBC, the C-terminal region with its 6 TMD and the pore, and the large central region. Atomic structures of the SD and IBC with IP_3 bound are also shown. A possible structure of the IP_3R pore is shown with its luminal selectivity filter and a constriction formed by the tepee-like structure of TMD6. Only two of the four IP_3R subunits are shown

Several groups have published 3D structures of the entire IP_3R, all derived from rebuilding the structure from electron microscopy images of single IP_3R, but the resolution of these images is presently too low to provide much insight into the workings of IP_3R (Taylor et al. 2004). Instead, much of what we know

has come from analysis of mutant IP_3R, from single-channel analyses using patch-clamp methods and from high-resolution structures of fragments of IP_3R.

The pore of the IP_3R allows the selective passage of cations, although it discriminates only weakly between Ca^{2+} and K^+. Despite the lack of selectivity, IP_3R within the ER are likely to conduct mainly Ca^{2+} because only Ca^{2+} has an appreciable gradient across the ER membrane. The pore of the IP_3R is formed by the final pair of TMD (TMD5-6) and the luminal loop that links them from each of the four subunits (Fig. 6). The loop includes a sequence (GGVGD in IP_3R) similar to that of the selectivity filter of K^+ channels, consistent with the idea that the overall architecture of the pore region may be broadly similar to that of K^+ channels. This idea is consistent with mutagenesis of residues within this region affecting ion permeation, and with biophysical and structural analyses of the equivalent region of ryanodine receptors.

We know more about the IP_3-binding site. IP_3 binds to the so-called "IP_3-binding core" (IBC, residues 224–604) and a high-resolution structure shows IP_3 cradled within a clam-like structure in which the negatively charged phosphate groups of IP_3 are coordinated by basic residues (Bosanac et al. 2002) (Fig. 6). The two sides of the clam, the α- and β-domains, interact with the two essential 4- and 5-phosphate groups of IP_3, suggesting perhaps that IP_3 might pull the α- and β-domains together, causing the clam to close. We can envisage, therefore, that the first step in IP_3R activation requires IP_3 binding to the IBC to effectively cross-link its two domains and thereby initiate the processes that lead to opening of the pore. As discussed above, there are essential interactions between IP_3 and Ca^{2+} binding, with IP_3 proposed to reciprocally regulate the accessibility of stimulatory and inhibitory Ca^{2+}-binding sites, but the structural basis of these interactions is entirely unresolved. We do, however, have a high-resolution structure of the N-terminal of the IP_3R, the so-called "suppressor domain" (SD, residues 1–223) (Bosanac et al. 2005) (Fig. 6), and it is known to be essential for coupling IP_3 binding to opening of the pore (Rossi et al. 2009). We have shown that the conformational changes initiated by IP_3 binding to the IBC must pass entirely via the SD on their way to the pore (Rossi et al. 2009), but we can only speculate on how the SD might then communicate with either Ca^{2+}-binding sites or the pore. In the simplest of plausible, but speculative, schemes, we have suggested that the essential steps in IP_3R activation begin with IP_3 binding to the IBC, closure of the clam then initiates conformational changes that pass entirely via the SD. The SD may then directly contact a cytosolic helix linking TMD4 to TMD5 and so prise the pore open. Further work is urgently needed both to test and elaborate this, almost certainly over-simple, scheme.

Summary

IP_3 receptors are intracellular Ca^{2+} channels expressed in the membranes of the endoplasmic reticulum of all animal cells, where they mediate Ca^{2+} release in response to the many extracellular stimuli that evoke IP_3 formation. IP_3 receptors both release Ca^{2+} and respond to it, and this allows them to both initiate and regeneratively propagate intracellular Ca^{2+} signals. The resulting spatiotemporal complexity of the cytosolic Ca^{2+} signals underlies the versatility of Ca^{2+} as an intracellular messenger. Future challenges include resolving the means, whereby Ca^{2+} regulates IP_3 receptors and the processes that target IP_3 receptors to specific subcellular locations.

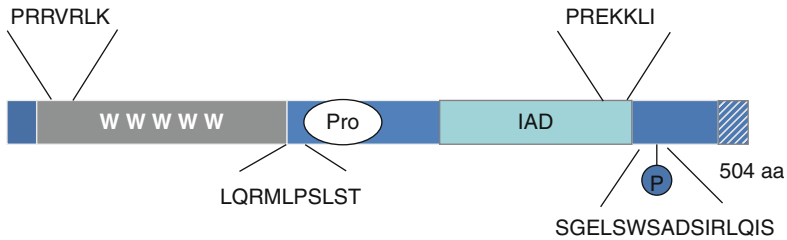
Interferon regulatory factor 5, IRF5

Historical Background

The transcription factor interferon regulatory factor 5 (IRF5) is one of the newer members of the IRF family to be characterized. All cellular family members share a region of homology in the amino-terminus, encompassing a highly conserved DNA binding domain consisting of five tryptophan repeats. By crystallography, this region has been shown to bind to conserved elements, termed "interferon (IFN)-stimulated response elements" (ISREs), in the promoters of target genes (Chen et al. 2008) thereby exerting the biological effects of IRF5. Given the nomenclature of this family, it is not surprising that the first function of IRF5 to be recognized was its ability to regulate type I *IFN* gene expression (Barnes et al. 2001). However, unlike other IRF family members, such as IRF3 and IRF7, the activity of IRF5 is regulated in a virus-specific manner leading to the induction of distinct *IFNA* genes (Barnes et al. 2001).

Regulation of IRF5 Biological Function

IRF5 is expressed primarily in human lymphoid tissues including the spleen, lymph nodes, peripheral blood lymphocytes, and bone marrow; low levels have been detected in the thymus and skeletal muscle (Barnes et al. 2001). High levels of IRF5 are constitutively expressed in purified immune cell subpopulations of activated B cells, natural killer cells, monocytes, plasmacytoid dendritic cells (PDC), and monocyte-derived dendritic cells (MDDC), suggesting an important role for IRF5 in the innate immune response



IRF5, Fig. 1 Domain structure of IRF5. Structural and functional domains involved in DNA binding, subcellular localization, posttranslational modification, and interaction with other proteins are shown. DNA binding domain is shown by the *gray box* containing the tryptophan repeat, the *white circle* represents a proline-rich region, the IAD (IRF activation domain) illustrates the protein-interacting domain, the circled P represents the carboxyl-terminal region, where phosphorylation occurs with residues shown below. *Top* two sequences are nuclear localization signals (NLS), *bottom* first sequence (behind the DNA binding domain) represents the nuclear export signal (NES)

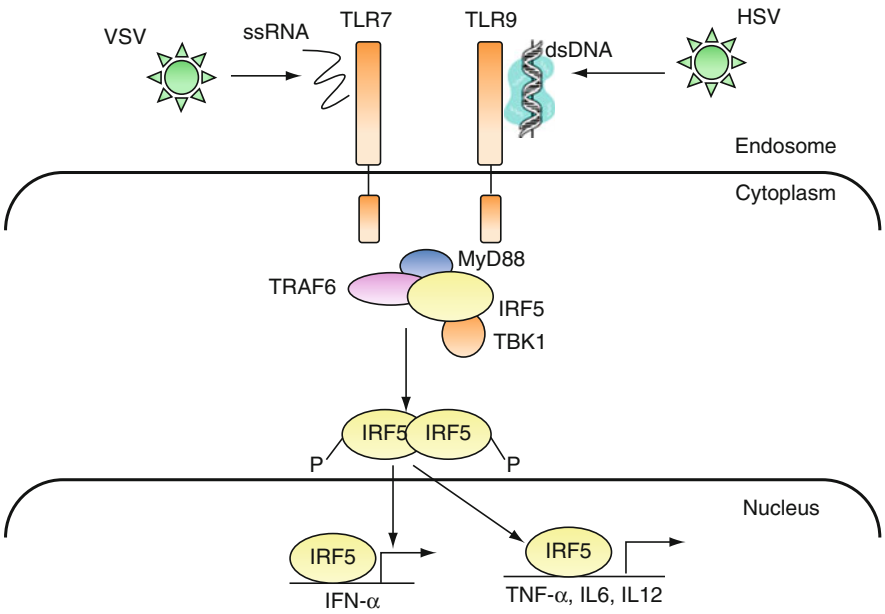
(Mancl et al. 2005). Expression of IRF5 can also be detected in other cell types after stimulation with type I IFN or other inducers.

IRF5 is generally localized to the cytoplasm of a cell in an inactivate state, and undergoes nuclear translocation upon "activation." The exact mechanism of IRF5 nuclear translocation in response to a given stimuli has not been fully elucidated but generally requires post-translational modification and homodimerization or heterodimerization with other IRF family members and proteins (Barnes et al. 2002; Cheng et al. 2006). IRF5 contains two functional nuclear localization signals (NLS), one in the amino-terminus and the other in the carboxyl-terminus of the protein (Barnes et al. 2002). IRF5 also contains a nuclear export signal (NES) that has been shown to regulate the dynamic shuttling of cellular IRF5 between the cytoplasm and the nucleus (Cheng et al. 2006). The molecular pathways leading to IRF5 activation include virus infection (Barnes et al. 2001, 2002), Toll-like receptor (TLR) signaling (Schoenemeyer et al. 2005; Takaoka et al. 2005), DNA damage (Hu et al. 2005), and death receptor signaling (Hu and Barnes 2009). Current data support the phosphorylation of IRF5 within the carboxyl-terminal autoinhibitory domain (Barnes et al. 2002; Chen et al. 2008) resulting in activation. The structural and functional domains of the IRF5 polypeptide are shown in Fig. 1.

Human *IRF5* exists as multiple alternatively spliced variants whose regulation is controlled at least in part by the presence of two functional promoters (Mancl et al. 2005). A number of these splice variants encode for functional polypeptides that have distinct cell type–specific expression, cellular localization, and biological function (Mancl et al. 2005). IRF5 expression may also be subject to regulation by hypermethylation as it contains a large CpG-rich island upstream of these promoters and has been shown to be regulated by hypermethylation in hepatocellular carcinoma tissues (Shin et al. 2010).

Role of IRF5 in the Innate Immune Response

In addition to coordinating the expression of type I IFNs in response to virus infection, IRF5 regulates the expression of a number of other cytokines and chemokines. Virus-infected B cells generated to overexpress human IRF5 were found to express a number of chemokines important for the recruitment of T lymphocytes to sites of inflammation such as RANTES, macrophage inflammatory protein (MIP1α) and monocyte chemoattractant protein 1 (MCP1) (Barnes et al. 2002). Data from microarray analyses further supported these findings and demonstrated a distinct role for IRF5 in the regulation of antiviral and early inflammatory genes (Barnes et al. 2004). Subsequently, IRF5 was shown to be a central mediator of TLR signaling (Schoenemeyer et al. 2005; Takaoka et al. 2005). Members of the TLR family are essential recognition and signaling components of mammalian antiviral host defense. Studies in both humans and mice reveal the critical role that IRF5 plays in the gene induction program activated by TLR4, TLR7, and TLR9 (Schoenemeyer et al. 2005; Takaoka et al. 2005) (Fig. 2). In hematopoietic cells from mice deficient in the *irf5* gene ($irf5^{-/-}$ mice), the induction of cytokines interleukin 6 (IL6), IL12, TNFα, and IFNα by various TLR ligands was severely impaired, along with type I IFNs in response to virus



IRF5, Fig. 2 Role of IRF5 in TLR signaling. IRF5 interacts with MyD88, TRAF6, and TBK1 in response to TLR7 and 9 activation. IRF5 becomes phosphorylated, homodimerizes, and translocates to the nucleus where it induces proinflammatory cytokine expression

infection (Takaoka et al. 2005; Paun et al. 2008). In human dendritic cells, IRF5 was shown to be required for late-phase TNF secretion through its direct and indirect binding to the TNF promoter (Krausgruber et al. 2010). While the mechanism of IRF5-mediated gene induction via virus is not well understood, induction by TLR ligands includes interaction and activation by MyD88, TRAF6 and TBK1 (Takaoka et al. 2005).

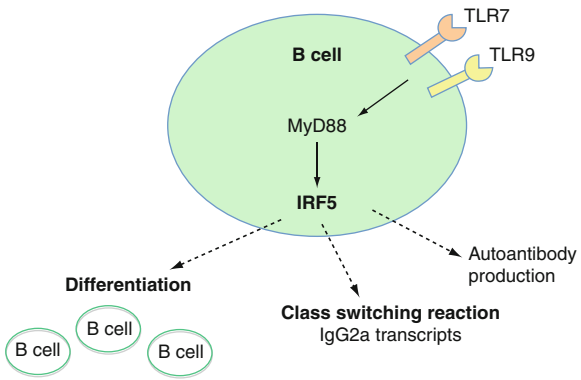
IRF5 as an SLE Susceptibility Gene

Using the genome-wide association approach, multiple laboratories have identified and confirmed *IRF5* gene variants with strong statistical association to SLE susceptibility (Kozyrev and Alarcon-Riquelme 2007). SLE is a complex systemic autoimmune disorder characterized by enhanced IFN production, loss of immune tolerance to self-antigens, persistent production of pathogenic autoantibodies, complement activation, immune complex (IC) deposition, inflammation, and end-organ damage. Identification of the *IRF5* gene in the susceptibility to develop SLE has marked an important breakthrough in the understanding of SLE pathogenesis since it has provided the first evidence that both the type I IFN and TLR signaling pathways are involved in disease pathogenesis. Association has now been convincingly replicated in SLE patients from multiple populations and distinct *IRF5* haplotypes that confer either susceptibility to (risk), or protection from, SLE in persons of varying ethnic ancestry have been identified (Kozyrev and Alarcon-Riquelme 2007). Genetic polymorphisms in the *IRF5* gene are thought to alter *IRF5* expression and/or lead to the expression of several unique isoforms (Kozyrev and Alarcon-Riquelme 2007).

Role of IRF5 in SLE Pathogenesis

IRF5 expression and alternative splicing are significantly upregulated in primary blood cells of SLE patients compared to healthy donors; enhanced transcript and protein levels are associated with an SLE risk haplotype suggesting a functional role for IRF5 in disease pathogenesis (Feng et al. 2010). Important insight on the potential function of IRF5 in SLE was gained by demonstrating an association between serum IFNα activity and *IRF5* risk haplotype in SLE patients (Niewold et al. 2008); however, no direct evidence in humans has shown that the observed upregulation of IRF5 expression in SLE patients causes enhanced IFN production. Recent studies in mice have begun to elucidate how the dysregulation of IRF5 expression, and therefore function, may alter disease pathogenesis. Mice that produce IFNα, IFNβ, and IL6 in response to sera or IgG-RNA IC from lupus patients were shown to be *tlr7*, *irf5*, and *irf7* dependent (Yasuda et al. 2007).

Additional data revealed that *irf5* is required for lupus development and autoantibody production in the $FcγRIIB^{-/-}Yaa$ and $FcγRIIB^{-/-}$ murine lupus models; however, no mechanism was provided (Richez et al. 2010). Subsequently, wild-type ($irf5^{+/+}$) and $irf5^{-/-}$ mice injected with pristane oil, which typically induces development of features characteristic of human SLE, was found to markedly reduce IgG glomerular deposits and antinuclear antibodies, and lack of IgG2a autoantibody secretion in $irf5^{-/-}$mice (Savitsky et al. 2010). Data support that IRF5 is responsible for the secretion of pathogenic IgG2a antibodies through class-switch recombination of the γ2a locus and intimates a critical role for IRF5 in B cell activation and/or responses to pathogens (Savitsky et al. 2010) (Fig. 3).



IRF5, Fig. 3 Role of IRF5 in B cell function associated with lupus pathogenesis. TLR7 and 9 are thought to signal in response to SLE immune complexes resulting in pathogenic autoantibody production. The dysregulation of IRF5 expression in SLE affects autoantibody production by altering B cell differentiation and/or class-switch recombination

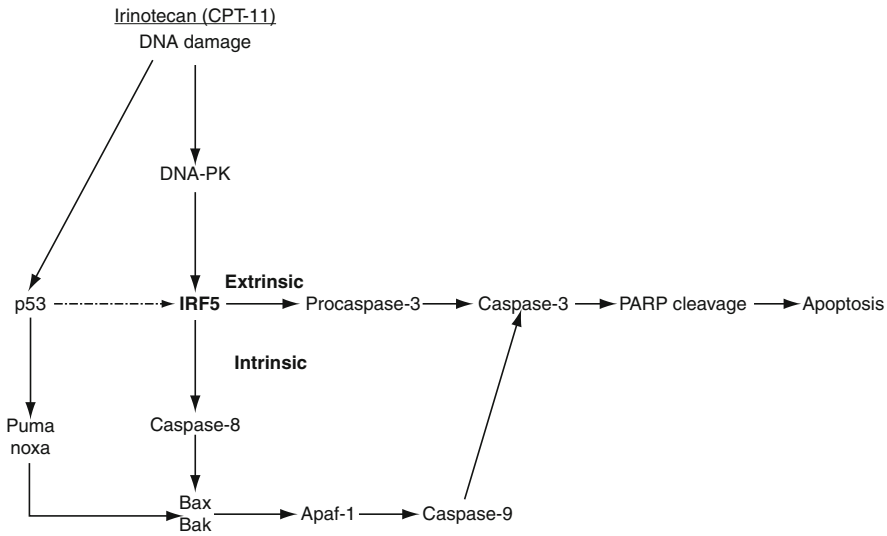
IRF5 in Cancer and as a Mediator of Apoptosis

Several lines of evidence support the notion that *IRF5* is a candidate tumor suppressor gene. IRF5 expression is absent in a variety of immortalized tumor cell lines of hematologic malignancies (Barnes et al. 2001) and was shown to be a direct target of the tumor suppressor p53 (Mori et al. 2002). Analyses of IRF5 expression in primary mononuclear cells from healthy donors and patients with acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL), and acute monocytic leukemia (AML) confirmed a loss of IRF5 expression in cancers of hematologic origin (Barnes et al. 2003). Overexpression of IRF5 in a B cell lymphoma lacking functional p53 demonstrated for the first time the ability of IRF5 to recapitulate p53 tumor suppressor function (Barnes et al. 2003). Ectopic overexpression of IRF5 inhibited colony formation on soft agar and in vivo tumor cell growth in athymic nude mice (Mori et al. 2002; Barnes et al. 2003). In addition, IRF5 overexpression induced a G2/M cell cycle arrest and apoptosis by targeting genes with these functions (Barnes et al. 2003). Later studies in p53-deficient tumor cell lines demonstrated that IRF5 could sensitize them to DNA damage–induced apoptosis (Hu et al. 2005). Examination of the molecular mechanism(s) for sensitization revealed that DNA damage activated IRF5 by posttranslational modification resulting in nuclear translocation and induction of specific target genes (Hu et al. 2005). Data in $irf5^{-/-}$ mice have corroborated these findings in human cells demonstrating that loss of *irf5* makes cells resistant to DNA damage–induced apoptosis (Yanai et al. 2007). Furthermore, evidence is provided for its tumor suppressor function since $irf5^{-/-}$ mice are predisposed to tumorigenic transformation (Yanai et al. 2007). While the exact DNA damage–induced signaling pathway that IRF5 mediates is not known, studies in mice and humans support that it is acting on a pathway distinct from p53 (Fig. 4) (Hu et al. 2005; Yanai et al. 2007).

IRF5 has also been shown to regulate apoptosis in response to death receptor ligands Fas and TRAIL (tumor necrosis factor–related apoptosis-inducing ligand) thus supporting its critical role in the apoptotic response (Couzinet et al. 2008; Hu and Barnes 2009). While the mechanism of IRF5-mediated Fas-induced cell death is unknown, but appears to be cell type–specific (Couzinet et al. 2008), the mechanism of IRF5-mediated TRAIL-induced apoptosis has been worked out and supports the mechanism requiring IRF5 activation by post-translational modification and nuclear translocation (Hu and Barnes 2009).

Summary

IRF5 is a critical mediator of the cellular response to extracellular stressors including virus, DNA damage, pathogenic stimuli (i.e., TLR ligands), and death ligands. IRF5 functions downstream of these signaling pathways thereby providing a mechanism of cellular



IRF5, Fig. 4 IRF5 signals independent of p53 in response to DNA damage. DNA-PK is the candidate kinase for IRF5 activation in response to DNA damage induced by the chemotherapeutic agent Irinotecan (CPT-11). IRF5 target genes are shown, in addition to some known p53 target genes

protection in multiple cell types (i.e., immune cells, fibroblasts, epithelial cells). Once activated by post-translational modification, IRF5 translocates to the nucleus where it acts as a transcription factor regulating the expression of genes involved in innate immunity, cell growth regulation, and apoptosis. Given that IRF5 expression has been found to be dysregulated in a variety of cancers (most prominently in hematologic malignancies), combined with the fact that mice lacking *irf5* are susceptible to oncogene-induced tumor transformation and resistant to DNA damage–induced apoptosis, provides convincing support for its role as a new tumor suppressor gene. The fact that IRF5 mediates a DNA damage–induced signaling pathway that is distinct from p53 (Fig. 4) suggests that therapeutic strategies targeting this pathway will be useful for the treatment of p53-deficient cancers. Identifying the kinase(s) responsible for IRF5 activation in response to DNA damage, along with determining the p53-independent and IRF5-dependent signaling pathway induced by DNA damage, will be of critical importance for the design of agents that can upregulate and/or activate this pathway. Additionally, data support the inhibition of IRF5 activation and/or signaling in autoimmune disease. IRF5 expression is significantly upregulated in SLE patients; therefore, the design of therapeutic agents targeting the inhibition of IRF5 signaling in autoimmune diseases should prove beneficial. The ultimate challenge will be finding a balance in turning on and off IRF5 signaling that will not compromise a patients risk for cancer and autoimmune disease.

ITPK1 (Inositol 1,3,4-Triphosphate 5/6 Kinase)

Yixing Zhou, Tobias M. H. Schenk and Stephen B. Shears
Laboratory of Signal Transduction, Inositol Signaling Section, National Institute of Environmental Health Sciences (NIEHS/NIH), NC, USA

Synonyms

Inositol 3,4,5,6-tetrakisphosphate 1-kinase; Inositol trisphosphate 5/6-kinase

Historical Background

The 6-kinase that stimulates the phosphorylation of inositol (1,3,4)P3 (Ins(1,3,4)P3) to Ins(1,3,4,6)P4 was first discovered in 1987 (Shears et al. 1987; Balla et al. 1987). It was this discovery of a pathway to InsP5 and InsP6 synthesis which prompted researchers (see York et al. 1999) to consider there might be other aspects to cell signaling by inositol phosphates in addition to calcium mobilization. Shortly after, a catalytic activity that phosphorylated Ins(3,4,5,6)P4 to Ins(1,3,4,5,6)P5 was discovered (Stephens et al. 1988). Interestingly, Ins(3,4,5,6)P4 and Ins(1,3,4)P3 were found to inhibit each other's phosphorylation. This observation led to the hypothesis that both activities were performed by two similar enzymes. Almost 10 years later, the gene encoding the 6-kinase reaction was cloned (Wilson and Majerus 1996). Subsequently, this single 46 kDa protein was found to phosphorylate both substrates, Ins(1,3,4)P3 and Ins(3,4,5,6)P4 (Yang and Shears 2000).

This enzyme was termed inositol trisphosphate kinase 1 (ITPK1) by HUGO. However, this HUGO-approved nomenclature does not reflect the versatile nature of ITPK1 to catalyze multiple phosphorylation reactions, whether as an Ins(1,3,4)P3 6-kinase, or an Ins(3,4,5,6)P4 1-kinase.

ITPK1 genes are well conserved from *Caenorhabditis elegans* to humans. To date, only yeast and drosophila genomes are known not to encode an ITPK1 gene (Seeds et al. 2004). Mammalian genomes only encode one ITPK1 gene, deletion of which is embryonic lethal; however, in plants there are often four to six genes encoding different isoforms of ITPK1 (Shears 2009). The reason for this diversity in plants is not well understood, but likely it reflects metabolic specialization of ITPK1.

Human *ITPK1* is comprised of 12 exons on chromosome 14. The mRNA transcripts of *ITPK1* were found to be ubiquitously expressed in tissues with highest expression levels in the brain and the heart (Wilson and Majerus 1996). Alternative splicing at the 5′ untranslated region is possible, although the significance is unknown (Yang and Shears 2000). ITPK1 is not only a key enzyme in inositol phosphate metabolism but also plays an important role in cell signaling to specifically regulate a CaMKII-activated cell surface chloride channel (ClC-3) to control neuronal plasticity, salt and fluid secretion, and endosomal ClC-3 to modulate inflammation, vesicular trafficking, and insulin secretion from the pancreatic β-cells.

It was thought for a while that ITPK1 was also a protein kinase (Wilson et al. 2001). Subsequent studies (Qian et al. 2005) have shown that the protein kinase activity associated with the recombinant ITPK1 expressed in insect cells is a persistent contaminant. When free of the contaminant, ITPK1 showed no protein kinase activity (Qian et al. 2005), yet the inositol kinase activity was similar to that observed by Wilson et al. (2001). A similar conclusion that ITPK1 is not a protein kinase can also be drawn from the crystal structure of the human ITPK1 (Chamberlain et al. 2007).

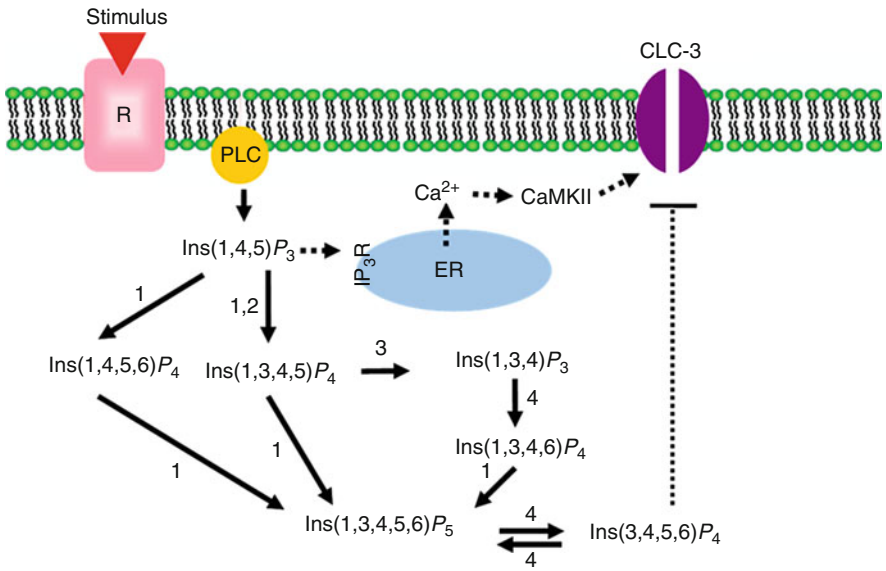
ITPK1 as an Important Metabolic Enzyme in the De Novo Synthesis of Inositol Phosphates

Inositol phosphates are freely diffusible intracellular signaling molecules which play many important roles in cell biology. ITPK1 is a multifunctional enzyme which is involved in both signaling and metabolic pathways. One important function of the Ins(1,3,4)P3 6-kinase activity of ITPK1, particularly in mammals, is to supply the precursor molecule, Ins(1,3,4,6)P4, for the synthesis of Ins(1,3,4,5,6)P5, as well as InsP6, and diphosphorylated inositol phosphates. Verbsky et al. (2005) have shown that overexpression of ITPK1 leads to increased levels of Ins(1,3,4,6)P4, Ins(3,4,5,6)P4, InsP5, and InsP6, whereas depletion of ITPK1 by RNAi results in decreased levels of these products. However, in some other species, such as slime molds, alternative synthetic routes are used as the major route for Ins(1,3,4,5,6)P5 synthesis. Yeast and *Drosophila* exclusively use an alternative synthetic route involving inositol polyphosphate multikinase (IPMK), since they lack the ITPK1 gene.

ITPK1 Regulates the Metabolism of the Ins(3,4,5,6)P4 Signaling Molecule

Another important function of ITPK1 is to control the signaling strength of the messenger molecule Ins (3,4,5,6)P4 which inhibits ClC-3 specific chloride current (Fig. 1). The key to this aspect of ITPK1 function is its phosphotransferase activity. ITPK1 not only phosphorylates Ins(3,4,5,6)P4 at the 1 position to produce InsP5, it can also remove the same phosphate so as to resynthesize Ins(3,4,5,6)P4 (Ho et al. 2002). In this manner, ITPK1 controls both the synthesis and the metabolism of Ins(3,4,5,6)P4 (Fig. 1).

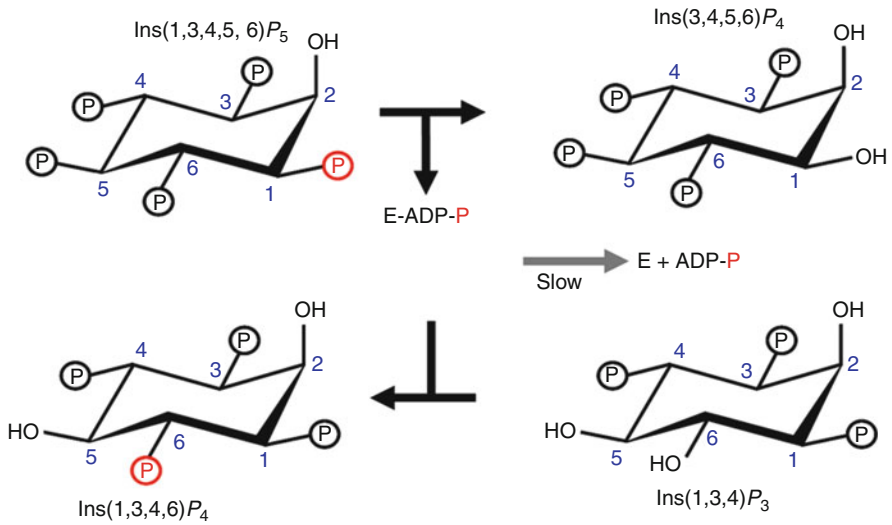
The phosphate group that is removed from Ins (1,3,4,5,6)P5 is not released into the bulk phase, instead it is retained by the enzyme and offered to Ins (1,3,4)P3, the alternative substrate of ITPK1 (Shears 2009). Therefore, elevations in the levels of Ins(1,3,4) P3 act in a phosphotransferase reaction to augment Ins (1,3,4,5,6)P5 dephosphorylation and competitively inhibit Ins(3,4,5,6)P4 phosphorylation (Fig. 2). Other experiments have shown that the addition of a cell-permeant analogue of Ins(1,3,4)P3 to cells leads to a specific increase in the cellular levels of Ins(3,4,5,6) P4 (Yang et al. 1999). This phosphotransferase activity of mammalian ITPK1 is a phenomenon that is unique in the inositol phosphate field (Michell 2002; Saiardi and Cockcroft 2008). This phosphotransferase activity provides the molecular mechanism by which Ins (3,4,5,6)P4 levels are coupled to receptor-regulated



ITPK1 (Inositol 1,3,4-Triphosphate 5/6 Kinase), Fig. 1 The metabolic pathway of receptor-dependent PLC activity and Ins(3,4,5,6)P4 synthesis in mammalian cells. The figure shows the most important metabolic reactions (*solid arrows*) in mammalian cells that link Ins(1,4,5)P3 to Ins(1,3,4,5,6)P5 through several possible pathways. Cell surface receptor activation of PLC generates the second messenger Ins(1,4,5)P3 which in turn is metabolized to Ins(1,3,4,5,6)P5. Ins(1,4,5)P3 binds to IP3 receptor (IP3R) at the ER to elicit intracellular calcium release (shown in *broken arrows*). Calcium together with calmodulin stimulates CaMKII which then activates the cell surface chloride channel ClC-3 (shown in *broken arrows*). On the other hand, ITPK1 converts Ins(1,3,4,5,6)P5 to Ins(3,4,5,6)P4 which specifically inhibits the very chloride channel that CaMKII activates (shown in *broken lines*). Numbers in the figure refer to various enzymes as follows: 1, Inositol phosphate multikinase (EC 2.7.1.151); 2, Ins(1,4,5)P3 3-kinase (EC 2.7.1.127); 3, Ins(1,4,5)P3/Ins(1,3,4,5)P4 5-phosphatase (EC 3.1.3.56); 4, ITPK1 (EC 2.7.1.134). Abbreviations used in the figure are listed as follows: R, receptor; PLC, phospholipase C; IP3R, Ins(1,4,5)P3 receptor; ER, endoplasmic reticulum; CaMKII, Calcium/calmodulin-dependent protein kinase II; ClC-3, type 3 member of the ClC gene family

phospholipase C (PLC) activity (Fig. 1) (Shears 2009). Upon cell surface receptor activation of PLC, cellular levels of Ins(1,3,4)P3 dramatically increase due to mass action effects of Ins(1,4,5)P3 metabolism. Receptor-dependent increases in Ins(1,3,4)P3 levels in turn stimulate the phosphotransferase activity of ITPK1 to increase the rate of Ins(1,3,4,5,6)P5 dephosphorylation, thereby generating increases in Ins(3,4,5,6)P4 levels (Fig. 1). Studies have confirmed that control over the levels of expression of the ITPK1 can regulate Ins(3,4,5,6)P4 signaling (Yang et al. 2006). More importantly, these studies also show that the strength and duration of the Ins(3,4,5,6)P4 signal is inevitably linked to the degree and duration of the receptor-dependent phospholipase C activity. This obligatory connection between Ins(3,4,5,6)P4 levels and PLC-dependent production of Ins(1,4,5)P3 is a vital component of this entire signaling system (Fig. 1).

Although the reaction mechanism of the phosphotransferase activity of ITPK1 has not been established, crystallographic structures have been obtained for the human and amoeboid forms of ITPK1 (Chamberlain et al. 2007; Miller et al. 2005). The determinants of ligand binding in human ITPK1 ensure that the enzyme's specificity depends upon the three-dimensional arrangement of phosphates and hydroxyls around the inositol ring, and also the three-dimensional stereochemistry at each position of the ring (Chamberlain et al. 2007). The amoeboid ITPK1 structure, however, reveals an unusually versatile catalytic cleft that was proposed not to impose any stereospecific constraints upon substrate binding (Miller et al. 2005). Interestingly, the phosphotransferase activity is found only in the mammalian ITPK1, but not in the amoeboid or soybean homologues (Chamberlain et al. 2007). That is, increases in Ins(1,3,4)P3 do not stimulate the



ITPK1 (Inositol 1,3,4-Triphosphate 5/6 Kinase), Fig. 2 The phosphotransferase activity of ITPK1. The graphic illustrates the proposed enzymatic reactions by which the 1-phosphate on Ins (1,3,4,5,6)P5 (*red*) is transferred to Ins(1,3,4)P3. The evidence for this reaction pathway came from HPLC analysis of the reaction products following the metabolism of [1-32P]-Ins (1,3,4,5,6)P5 by ITPK1 (Chamberlain et al. 2007). It has not yet been established whether or not a phosphoryl-enzyme (E-P) intermediate is involved, but this is a likely possibility (Adapted from Shears 2009)

dephosphorylation of Ins(1,3,4,5,6)P5 by amoeboid or soybean ITPK1. It is likely that mammalian ITPK1 has specifically evolved this signaling function. A substrate-bound human ITPK1 crystal has not yet been obtained, which contributes to the ambiguities concerning the phosphotransferase reaction mechanism. Nevertheless, a model has been put forth to suggest the structural determinants of ligand specificity for mammalian ITPK1 (Fig. 3). It is proposed that there are three modes of binding of inositol phosphates to mammalian ITPK1. Mode 1 binding is designated for Ins(3,4,5,6)P4 to allow 1-kinase activity; Mode 2 binding is designated for Ins(1,3,4)P3 to permit 6-kinase activity, and Mode 3 for Ins(1,3,4)P3 to permit 5-kinase activity (Shears 2004, 2009).

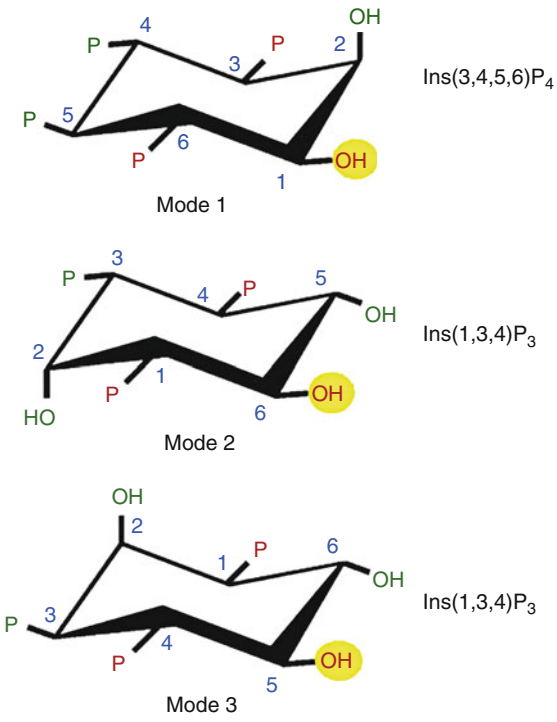
Simultaneous binding of both Ins(1,3,4)P3 and Ins (1,3,4,5,6)P5 to the same active site seems implausible from analysis of the enzyme's structure, but a sequential reaction model (Fig. 4) has been proposed in order to explain the transfer of a phosphate group between different substrates (Chamberlain et al. 2007). The key to this intersubstrate phosphate transfer is that the enzyme tightly binds nucleotide, either ATP or ADP, instead of releasing them into the bulk phase during this series of reactions.

Biological Significance of ITPK1

The biological significance of ITPK1 originates from the intracellular signaling molecule Ins(3,4,5,6)P4 and its ability to regulate chloride conductance in mammalian cells through inhibition of ClC-3 chloride channels (Mitchell et al. 2008). No other inositol phosphates are able to inhibit ClC-3, and ClC-3 is the only chloride channel known to be inhibited by Ins(3,4,5,6)P4 (Mitchell et al. 2008).

In hippocampal neurons, ClC-3 is responsible for the Ins(3,4,5,6)P4 regulated chloride conductance, which contributes to the overall regulation of the synaptic efficacy in generating action potentials. Therefore, Ins (3,4,5,6)P4 has the potential to affect electrical excitability in neurons via regulating chloride fluxes and hence has a direct influence on neuronal development (Ho et al. 2002; Mitchell et al. 2008; Shears 2009).

Because the regulation of ClC-3 by Ins(3,4,5,6)P4 also has an impact on salt and fluid secretion by epithelial cells, ITPK1 plays an important role in several environmentally influenced diseases of secretory epithelia, such as cystic fibrosis (CF), asthma, and bronchitis (Shears 2005, 2009). The nature of CF, for example, is primarily due to the mutation of cystic



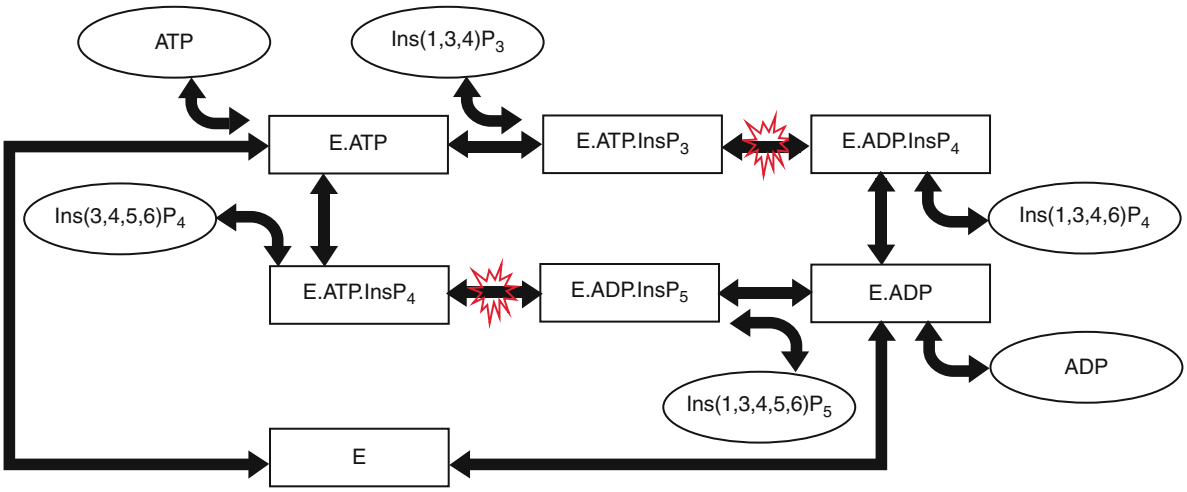
ITPK1 (Inositol 1,3,4-Triphosphate 5/6 Kinase), Fig. 3 A model for the structural determinants of ligand specificity for mammalian ITPK1. The figure depicts the proposal that there are three modes of binding of inositol phosphates to mammalian ITPK1. It can be illuminating to consider these different binding modes (i.e., "1", "2", and "3") as permitting 1-kinase, 6-kinase, and 5-kinase activities, respectively. The phosphorylation sites are marked with a *yellow circle*. Groups conserved in all three of these proposed binding modes are colored in *red*. Additional groups that contribute to structural specificity are colored in *green* (Adapted from Shears 2009)

fibrosis transmembrane regulator (CFTR) leading to reduction of Cl^- ion secretion from CF airway epithelia. This in turn perturbs the airway surface liquid volume and the height and composition of the mucus layer. This perturbation leads to impaired ciliary beating to expel pathogens. Thus, there is bacterial colonization of the airways, culminating in inflammatory responses and lung tissue death (Shears 2005). Cell surface receptor stimulated PLC activity mobilizes Ca^{2+}, thereby activating CaMKII, to stimulate ClC-3 (Fig. 1) to drive secretion of Cl^-. This mechanism aids CFTR in maintaining adequate airway liquid volume. Therefore, purinergic receptor agonists are potential drug candidate for CF patients. However, it needs to be taken into consideration that purinergic activation also leads to ITPK1-dependent formation of Ins (3,4,5,6)P4 that inhibits the very chloride channel that Ca^{2+}/CaMKII activates. Therefore, it could be useful to consider that the therapeutic efficacy of purinergic agonists might depend upon the expression levels of ITPK1 in individual patients. In other words, ITPK1 might be a modifier gene for the CF condition (Yang et al. 2006). In those with low ITPK1 expression, purinergic agonists would be beneficial to treat CF; on the other hand, for patients with high protein level of ITPK1 it might be of value to consider developing Ins(3,4,5,6)P4 antagonists (Shears 2005).

Ins(3,4,5,6)P4 not only regulates ClC-3 at the plasma membrane, it also inhibits ClC-3 channels at membranes of intracellular vesicles such as insulin granules and endosomal compartments. In these vesicles, chloride conductance through the ClC-3 serves as a charge neutralization shunt that supports acidification of these vesicles (Shears 2004). Intra-vesicular pH helps determine the fate of vesicular trafficking whether for recycling of plasma membrane proteins or exocytosis. The inhibition of chloride influx into vesicles by Ins(3,4,5,6)P4 leads to a more alkaline compartment (Mitchell et al. 2008). In the case of insulin granules in pancreatic β-cells, their alkalinization by Ins(3,4,5,6)P4 reduces insulin secretion (Renstrom et al. 2002). Abnormally elevated cellular Ins(3,4,5,6)P4 levels might contribute to hyperglycemia-dependent refractoriness of β-cells which typifies type2 diabetes.

Although ITPK1 has no obvious consensus sequences for membrane localization, it has been reported that ITPK1 is concentrated near the apical membrane of polarized mouse tracheal epithelial cells (Yang et al. 2006). It is not known yet how the compartmentalization of ITPK1 is achieved, whether by interaction with other membrane associated proteins, for example. This further leads to a question as to whether Ins(3,4,5,6)P4 could be compartmentalized in cells to locally affect a specific pool of ClC-3 channels. This idea contrasts with from the more general perception that Ins(3,4,5,6)P4 is uniformly distributed throughout the cell.

Note that ITPK1 knockout is embryonic lethal (Wilson et al. 2009), whereas the ClC-3 knockout is not (Dickerson et al. 2002; Yoshikawa et al. 2002). This suggests that there is more to the function of ITPK1 than just regulating ClC-3. Therefore, there may be other functions of ITPK1 that are independent from ClC-3. This idea awaits further exploration.



ITPK1 (Inositol 1,3,4-Triphosphate 5/6 Kinase), Fig. 4 Sequential intersubstrate phosphate transfer hypothesis for human ITPK1. The graphic suggests at the molecular level how a single active site of ITPK1 can accommodate two substrates. It is hypothesized that the phosphate from one substrate is not released into the bulk media (from dephosphorylation of Ins(1,3,4,5,6)P5); instead, it is retained by the enzyme or enzyme-nucleotide intermediate. This phosphate is then transferred to the other substrate of ITPK1, Ins(1,3,4)P3. The two enzymatic reactions occur in a sequential manner. Additionally, the presence of Ins(1,3,4)P3 stimulates the dephosphorylation of Ins(1,3,4,5,6)P5. The enzyme-bound nucleotide acts as the phosphate carrier. Unliganded ITPK1 is represented by E; phosphotransferase reactions are indicated by *red graphics*. The position of the [32P] group that is transferred between inositol phosphates is shown in *red* (Adapted from Chamberlain et al. 2007)

Summary

The synthesis and metabolism of Ins(3,4,5,6)P4 are solely regulated by a single multifunctional kinase and phosphotransferase, ITPK1. This enzyme dynamically couples the cell surface receptor activated PLC hydrolysis of phosphatidyl inositol lipids to the cellular levels of Ins(3,4,5,6)P4. This is a biologically significant event because Ins(3,4,5,6)P4 regulates a specific pathway for transmembrane chloride conductance that is involved in numerous cellular functions including synaptic efficacy, epithelial salt and fluid secretion, insulin release from pancreatic β-cells, and inflammatory responses.

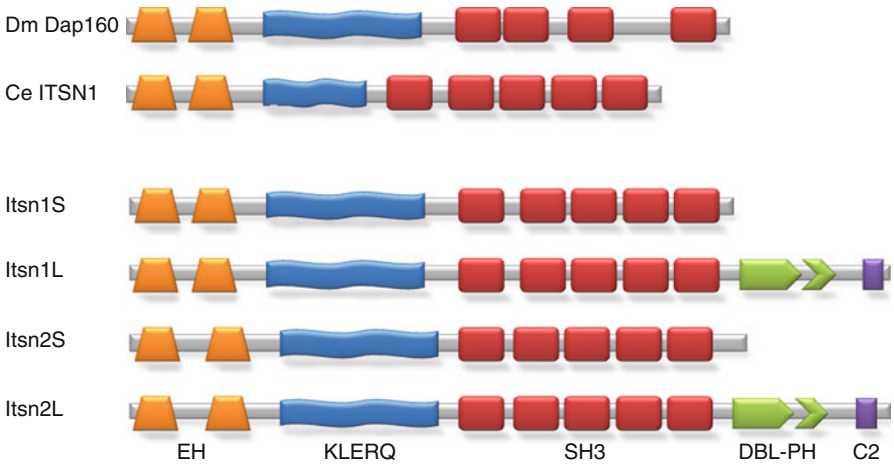
The Intersectin Family

The Intersectin family refers to a group of proteins that share N-terminal EH domains, a central coiled-coil domain, and multiple SH3 domains. In mammals, there are Intersectin1 and 2 genes (Itsn1 and Itsn2, respectively), whereas in invertebrates, only one gene appears to be present.

Historical Background

Intersectins are conserved modular scaffold proteins with two Eps15-homology (EH) domains, an extended KLERQ coiled-coil domain, four or five Src-homology 3 (SH3) domains, and, in some vertebrate splice variants, DBL/PH and C2 domains (Fig. 1). The Itsn proteins were discovered independently in a number of organisms and in a number of labs. For example, the single Itsn in *Drosophila melanogaster*, Dap160, or Dynamin-associated protein 160 kDa, copurified with the proline-rich C-terminus of Dynamin (Roos and Kelly 1998). Human *ITSN1* was cloned following identification of a trapped exon that coded for a novel EH domain (Guipponi et al. 1998). *Xenopus*, mouse and rat *Itsn1* genes were isolated in screens for proteins that bound to specific proline-rich sequences or to the coiled-coil protein Snap-25, respectively (Yamabhai et al. 1998; Okamoto et al. 1999; Sengar et al. 1999).

Drosophila Dap160 and vertebrate Itsn1 are very highly expressed in the nervous system (Roos and Kelly 1998; Hussain et al. 1999; Sengar et al. 1999). A second, widely expressed Itsn gene has also been identified. This gene, originally designated *Ese2*, is now known as *Itsn2* (Sengar et al. 1999; Pucharcos et al. 2000). There are many speculated functions for Itsn proteins in the literature. Based on protein domain structure and binding partners, as well as a series of overexpression experiments in cultured cells, it was accepted early on that Itsn proteins play a role in clathrin-mediated endocytic trafficking and in regulation of the actin cytoskeleton (Hussain et al. 1999; Sengar et al. 1999; Hussain et al. 2001). Tissue culture experiments have been used to assign biological context to the endocytic and signaling functions. Indeed, the number of processes where Itsn proteins are reported to function has continued to grow over the past decade, mostly based on in vitro or ex vivo experiments. The first genetic studies on Itsn were



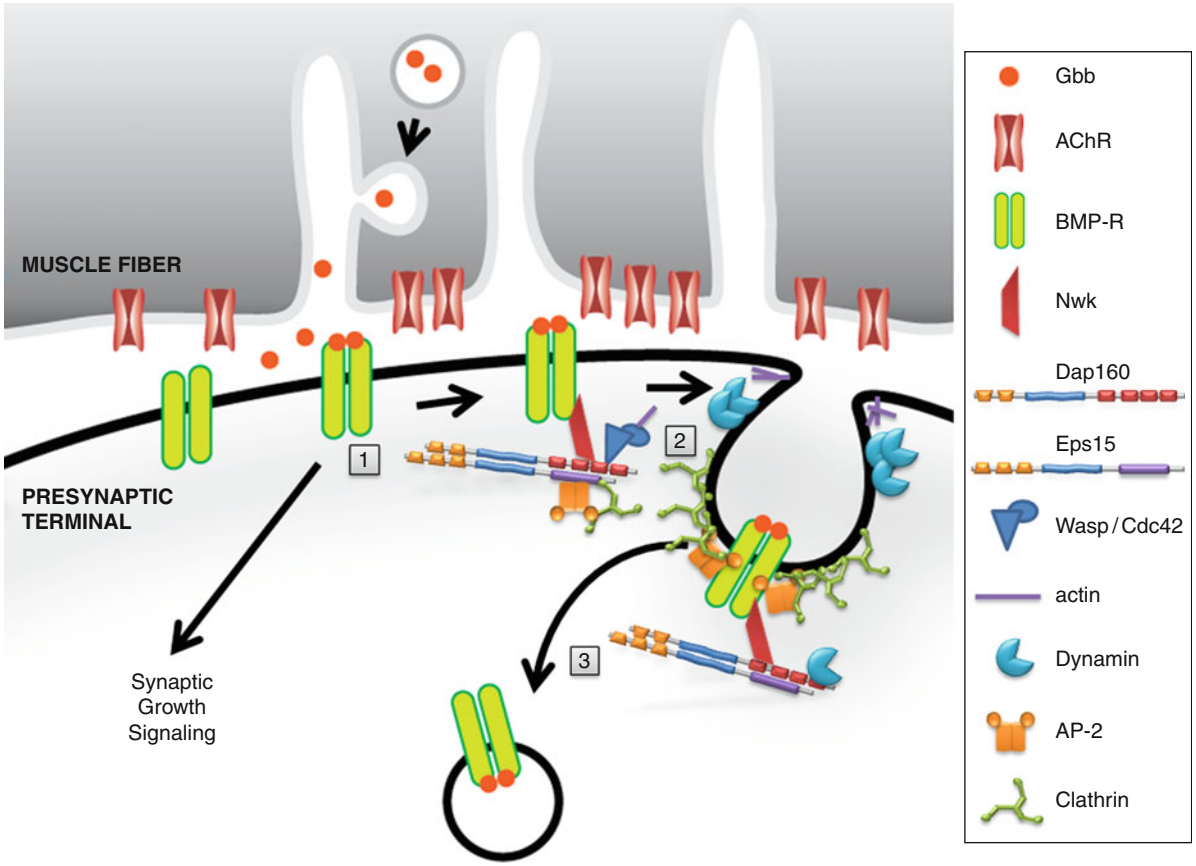
ITSN, Fig. 1 Schematic representation of *Drosophila* Dap160 and *C. elegans* Itsn1 proteins as well as major isoforms of Intersectin1 and 2 in mammals

performed in the fruit fly, where Dap160 was found to control synaptic structure and vesicle recycling at the neuromuscular synapse (see below) (Koh et al. 2004; Marie et al. 2004). Subsequent studies in nematodes have confirmed a role in synaptic vesicle recycling (Rose et al. 2007; Wang et al. 2008). Itsn1 mutant mice have also been reported (Yu et al. 2008). While these mice were born at the expected Mendelian frequency, some failed to thrive and died at a young age with evidence of enlarged endosomes in brain sections. These abnormalities were not seen in the majority of mutant animals, although exocytic and endocytic defects were observed in ex vivo cultures from the mice.

Synaptic Structure

Dap160 mutant flies show neuromuscular junction (NMJ) overgrowth, with an increased number of small sized satellite boutons (Koh et al. 2004; Marie et al. 2004). This phenotype is associated with disruption of Dap160 in the neuron, as opposed to the muscle target cell, and is therefore presynaptic. A similar mutant phenotype is also observed in other endocytic mutants, including mutants of Dynamin, Eps15, Endophilin, Synaptojanin, Rab11, and Spinster (Rikhy et al. 2002; Sweeney and Davis 2002; Verstreken et al. 2003; Khodosh et al. 2006; Majumdar et al. 2006). Interestingly, mutations in the Bone Morphogenic Protein (BMP) ligand, Glass Bottom Boat (Gbb), in its type I or II BMP receptors, or in the downstream Smad signaling proteins, cause the opposite effect, with undergrowth at the NMJ (McCabe et al. 2003). Indeed, BMP is a retrograde signal that stimulates growth and branching of presynaptic boutons. Dap160 and its partners inhibit this signal, likely through inhibition of BMP receptor signaling and/or recycling within the periactive zone (Fig. 2). The F-BAR/SH3 domain protein, nervous wreck (Nwk), facilitates this by binding to the cytoplamic domain of type I BMP receptors and also to Dap160 (O'Connor-Giles et al. 2008). This is mediated through interaction between a region of Nwk that maps near or within its second SH3 domain, and a region of Dap160 that maps to its third and fourth SH3 domains.

A number of studies in yeast have shown that endocytic proteins can regulate actin, and conversely, that actin regulatory proteins frequently control endocytosis. More recently, this phenomena has been demonstrated in higher organisms. Indeed, Wasp proteins, which regulate actin, also control internalization and trafficking of cell surface receptors. Consistent with this, mutants in *Drosophila* Wasp or its activator small GTPase, Cdc42, also enhance synaptic growth in a BMPR-dependent manner (Rodal et al. 2008; Nahm et al. 2010). Interestingly, Wasp and Dynamin are thought to compete for overlapping site(s) on Dap160, suggesting that Dap160-Wasp and Dap160-Dynamin complexes may perform distinct functions, perhaps during different steps of internalization and/or endocytic trafficking of BMPR (Rodal et al. 2008). Thus, at the periactive zone that surrounds each neuronal synapse, a region thought to perform functions in common with recycling endosomes of non-neuronal



ITSN, Fig. 2 Model of Dap160-dependent BMP receptor antagonism at the *Drosophila* neuromuscular junction. (1) Gbb ligand bound BMP receptors activate signaling pathways for synaptic growth. (2) Wasp/Cdc42 are recruited by Dap160 to promote actin polymerization, a necessary step for vesicle internalization. (3) Nwk links the Dap160/Eps15/Dynamin complex to BMP receptors to initiate vesicle scission

cells, Dap160/Itsn forms a complex with Wasp and Nwk to downregulate BMPR signaling (Fig. 2) (Rodal et al. 2008). In addition, Dap160/Itsn also forms complexes with Dynamin and Nwk, perhaps following dissolution of the Wasp complex (O'Connor-Giles et al. 2008). One or both of these complexes is likely associated with suppression of BMPR signaling, or recycling through the Rab11 compartment for return to the plasma membrane (Rodal et al. 2008). The Itsn partner Eps15 is also involved in these processes as Eps15 mutant neuromuscular junctions show the same overgrowth phenotype (Koh et al. 2007). In mammals, Itsn-1 also binds to TUC-4b, an orthologue of *C. elegans* UNC-33, which is thought to control neurite extension and branching (Quinn et al. 2003). Finally, in the differentiated synapse, Intersectins function within the periactive zone to coordinate events involved in efficient synaptic vesicle recycling. This function is independent of Nwk, and therefore involves distinct Itsn-protein complexes (see next section below).

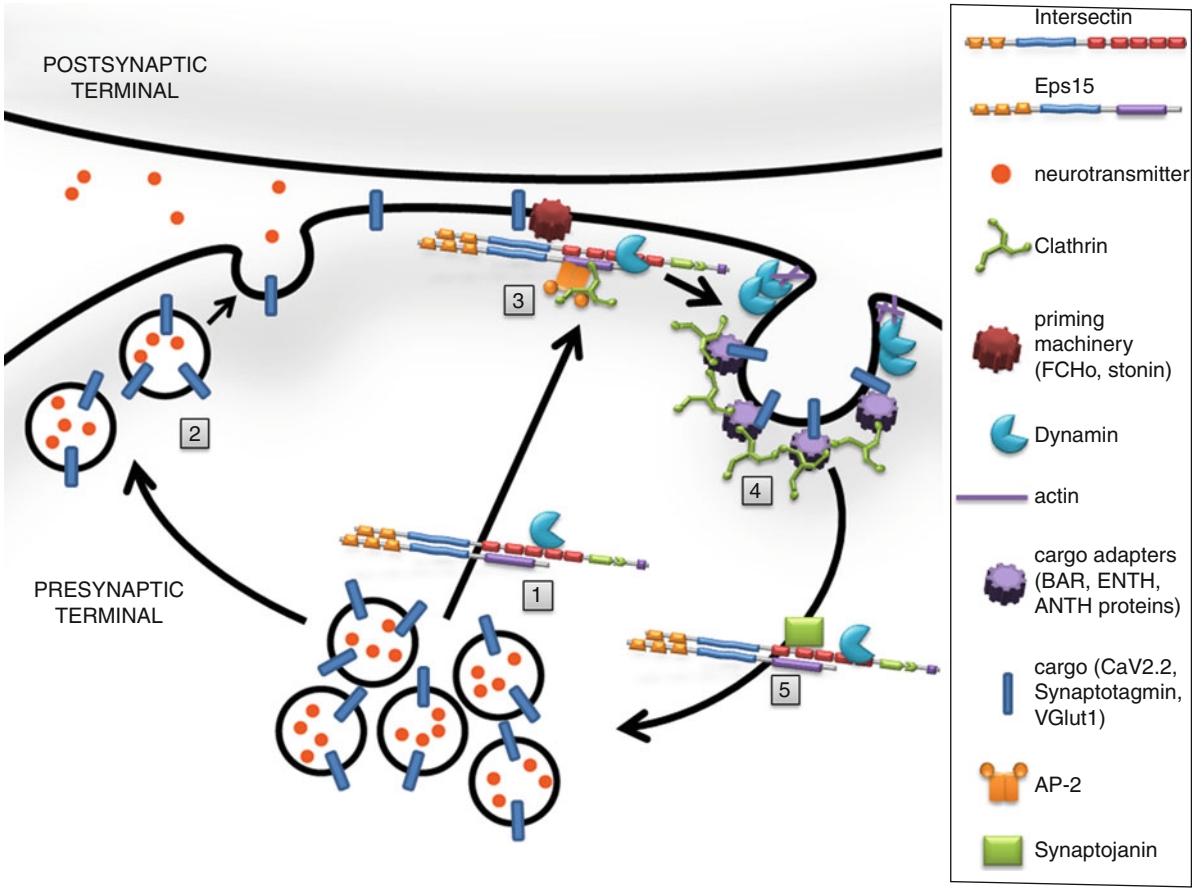
While genetic studies in flies have shown a very important role for Dap160 and its orthologues in control of pre-synaptic growth, other work has revealed post-synaptic functions for Itsn. For example, the N-terminal EH domain region of Itsn1L binds to the kinase domain of EphB2 receptors in cultured hippocampal neurons (Irie and Yamaguchi 2002). Activation of EphB2 receptor signaling thus leads to activation of the DBL/PH domain Cdc42 GEF activity coded within the C-terminus of Itsn1L. N-Wasp and the endocytic protein Numb are bound to distinct SH3 domains of Itsn1L in this complex (Nishimura et al. 2006). This helps alleviate intrinsic SH3-mediated repression of the Itsn GEF domain and thereby enhances GTP-loading of Cdc42. In cultured neurons,

Itsn1L colocalizes with F-actin at dendritic spines (Thomas et al. 2009). In turn, Cdc42-GTP and Itsn1L SH3 domains stimulate N-Wasp-mediated actin polymerization and dendritic spine formation, whereas Itsn1 siRNA knockdown disrupts spine maturation (Hussain et al. 2001; Thomas et al. 2009).

Synaptic Vesicle Recycling

A complex and specialized form of endocytosis is required in neurons to recover synaptic vesicle proteins and membranes in order to facilitate sustained synaptic transmission. This process appears to include fast and slow endocytic retrieval pathways that differ in their dependence on specific proteins, and that may also differ depending on whether they occur at small or large synapses, or in different synapses within the CNS. Based primarily on work in flies, a role for Itsn proteins in synaptic vesicle recycling has been definitively established (Pechstein et al. 2010b). Indeed, loss of Dap160 impaired membrane retrieval and caused altered localization and expression of key endocytic proteins Dynamin, Synaptojanin, Endophilin, LAP (Like-AP180) as well as the reserve pool marker Synapsin (Koh et al. 2004; Marie et al. 2004). Likewise, mutants of LAP in *Drosophila* show mislocalization of the presynaptic Ca^{++}-sensor and cargo protein Synaptotagmin as well as Dap160. Proteomic analysis of Synaptotagmin complexes from rat brain synaptosomes has identified a complex comprised of Synaptotagmin, Stonin2, AP180, Itsn1, Epsin, Clathrin, Dynamin, and AP-2 (Khanna et al. 2006). These findings in conjunction with in vitro identification of binding partners strongly support the notion that Itsn proteins act as scaffolds to regulate activity and localization of the endocytic machinery. For example, in giant reticulospinal synapses, Itsn1 is localized to synaptic vesicle clusters where it sequesters Dynamin prior to membrane depolarization. Following K^+ stimulation, however, Itsn1 redistributes to Clathrin-coated pits in the periactive zone where it recruits AP-2 to the budding vesicle and targets Dynamin to sites of vesicle fission (Evergren et al. 2007; Pechstein et al. 2010a). In the chicken calyx presynaptic terminal, an endocytic complex that includes Itsn1S and AP180 is tightly bound to CaV2.2 N-type calcium channels that cluster at transmitter release-sites. This complex also associates with a Dynamin, Clathrin, and Itsn1L containing subcomplex to facilitate rapid vesicle recovery (Khanna et al. 2007). Consistent with this conserved function, hippocampal neurons cultured from Itsn1 knockout mice show impaired synaptic vesicle recycling (Yu et al. 2008).

The diversity of synapses as well as the multiple distinct forms of synaptic vesicle recycling that occur in the nervous system have made it difficult, and perhaps inappropriate, to even try to establish one coherent model for the role of Itsn in synaptic vesicle recycling (Smith et al. 2008). Despite this, some general features have emerged from studies in different systems (Fig. 3). During very early steps of Clathrin-mediated endocytosis, including the specialized form involved in synaptic vesicle recycling, membrane bending FCHo1 and FCHo2 (F-BAR-domain-containing Fer/Cip4 homology domain-only) proteins, bind to $PI(4,5)P_2$ in the plasma membrane to establish endocytic hotspots (Henne et al. 2010). FCHo1/2 bind directly to Itsn1 and Eps15, thus forming a membrane-bound complex for recruitment of the AP-2 Clathrin adaptor complex and cargo (Henne et al. 2010). There are multiple forms of cargo that must be internalized together, in order to recreate synaptic vesicles of defined and consistent structure. Perhaps most important in this regard are the transmembrane Synaptotagmin proteins which link Ca^{++}-induced exocytosis to membrane retrieval. Synaptotagmin 1, following exocytosis and deposition into the plasma membrane, is bound by specialized adaptor proteins of the Stonin family (Maritzen et al. 2010). Interestingly, Stonins also bind Intersectins, Eps15 and AP-2. Thus, following establishment of endocytic hotpots in the periactive zone (with FCHo1/2, Intersectin and Eps15), these proteins are linked to Synaptotagmin cargo and even Clathrin, through Stonin and AP-2. Other cargo, including vesicular transporters or cotransporters like VGlut1, must also be recruited into Clathrin-coated pits to initiate synaptic vesicle recovery (Maritzen et al. 2010). Some cargo is recruited through alternative adaptor molecules including the N-BAR-domain protein, Endophilin. Indeed, a number of cargo adaptors and membrane-bending or curvature-sensing proteins with BAR-, ENTH-, or ANTH-domains are involved in linking cargo to Clathrin at endocytic hotspots. These proteins induce membrane bending and tubulation through an actin-dependent process (Ferguson et al. 2009).



ITSN, Fig. 3 Model of Itsn-dependent vesicle recovery at a central nervous system synapse. (1) Itsn-containing protein complex rest within the reserve pool during synaptic inactivity. (2) Neurotransmitters are released into the synaptic cleft following vesicle fusion. (3) Itsn complexes translocate to predetermined sites of internalization marked by FCHo proteins, where Itsn associates with cargo proteins (CaV2.2, Synaptotagmin, and VGlut1), Stonins, AP-2, and Clathrin. (4) Membrane-bending adapters (BAR-, ENTH-, and ANTH-domain proteins) force the membrane to invaginate while fission is induced after Dynamin recruitment to the neck of Clathrin-coated pits. (5) Itsn bound to Synaptojanin uncoats vesicles, thereby replenishing neurotransmitter reserve pools

Interestingly, the ANTH-domain and Itsn-binding protein AP180 is involved in defining the size of recovered synaptic vesicles. Finally, tubulation is terminated through vesicle scission by Dynamin, which is recruited to the neck of budding vesicles by Itsn1 (Evergren et al. 2007; Ferguson et al. 2009). As the vesicle buds from the plasma membrane, Itsn1L binds inositol-5-phosphatase, Synaptojanin 170, a protein involved in PI(4,5)P_2 turnover and vesicle uncoating (Pechstein et al. 2010a). Many of the steps involved in synaptic vesicle recycling are regulated by phosphatidylinositols. In non-neuronal cells, Itsn1S binds the Ship2 inositol 5′-phosphatase, likely to coordinate Clathrin-coated pit formation in a more general context (Xie et al. 2008). Indeed, the speed of membrane invagination is controlled by recruitment of inositol-5-phosphatases to the SH3 domains of Itsn1 (Xie et al. 2008; Nakatsu et al. 2010). Modulating the rate of vesicle formation may be important for ensuring efficient and complete loading of cargo. Thus, Itsn serves as a key scaffolding protein for early endocytic events, from assembly of the budding vesicle to fission to uncoating (Pechstein et al. 2010b).

While most efforts have focused on dissecting the role of Itsn in endocytosis, there is some evidence to suggest that Itsn may function in exocytosis as well. Indeed, Itsn1 can bind directly to the SNARE protein, Snap25 (Okamoto et al. 1999), while cultured

chromaffin cells from Itsn1 knockout mice and siRNA knockdown in the same cell type showed reduced secretion and lower Cdc42-dependent exocytic activity (Malacombe et al. 2006; Yu et al. 2008). Once again, details of how Itsn1 coordinates exo-endocytic trafficking remain to be determined.

Additional Functions for Itsn

Intersectins are also expressed in non-neuronal tissues and are therefore expected to have non-neuronal functions (Sengar et al. 1999). In support of this, Itsn1S has been implicated in endocytosis of the renal K^+ channel ROMK1 and Itsn2L in T-cell antigen receptor endocytosis (McGavin et al. 2001; He et al. 2007). Itsn1 and 2 have also been reported to regulate caveolar-based endocytosis. In endothelial cells, Itsn1S associates with Dynamin and Snap23 patches to help facilitate caveolae-mediated internalization (Predescu et al. 2003, Klein et al. 2009). In contrast, knockdown of Itsn2L by siRNA increased endocytosis through caveolae, whereas overexpression of the Cdc42-activating GEF domain of Itsn2L blocked it, suggesting that Itsn2L-dependent actin polymerization may inhibit caveolae-mediated endocytosis (Klein et al. 2009).

Itsn1 is also thought to control cell survival, polarity and mitosis. For example, the Itsn1 mouse knockout has decreased levels of NGF in the septal region of the brain, suggesting a role for Itsn1 in NGFR endocytosis or trafficking (Yu et al. 2008). Indeed, Itsn1 regulates survival signaling (Loeb et al. 2006; Das et al. 2007; Predescu et al. 2007). siRNA knockdown of Itsn1 in differentiated neurons causes cell death, which may be associated with loss of an Itsn1/PI3K-C2β/Akt survival signal (Das et al. 2007). siRNA knockdown of Itsn1 in endothelial cells also causes cell death (Predescu et al. 2007). Itsn1 can activate Epidermal Growth Factor Receptor (EGFR) internalization and signaling to the mitogenic transcription factor, Elk-1. Regulation of this pathway may involve Sos, Ras, and Jnk signaling but not Erk1/2 (Mohney et al. 2003). Expression of a dominant active form of Itsn1L in NIH3T3 cells was strongly transforming as a result of Cdc42 and Ras activation (Wang et al. 2005). In *Drosophila*, Dap160 directly binds and activates aPKC in an endocytosis-independent pathway to modulate neuroblast polarity and cell cycle progression (Chabu and Doe 2008). In mammalian cells, Itsn2 is thought to control activation of Cdc42 near centrosomes in order to control spindle orientation and lumen formation. In this context, Itsn2L SH3 domains bound to p150Glued, a subunit of the Dynactin complex (Rodriguez-Fraticelli et al. 2010). Interestingly, a Dynactin complex protein was also identified in association with *C. elegans* ITSN1 (Wang et al. 2008).

Summary

Thus, a series of elegant studies in organisms ranging from flies to worms to mice have revealed a conserved role for Itsn proteins in coordinating endocytosis and signaling in neurons. For example, Itsn functions in the periactive zone of neuromuscular junctions to regulate BMP-mediated synaptic growth (O'Connor-Giles et al. 2008). It also functions in distinct complexes to coordinate synaptic vesicle recycling at this location. Many non-neuronal Itsn functions have been identified on the basis of in vitro or ex vivo experiments. Genetic studies in *Drosophila*, *C. elegans* and mice have yet to support such roles (Koh et al. 2004; Marie et al. 2004; Rose et al. 2007; Wang et al. 2008; Yu et al. 2008). This may be due to redundancy between Itsn and other scaffolding or signaling proteins, and also to an early focus of genetic studies on synaptic transmission. Since an Itsn2 knockout mouse has yet to be described, it is difficult to interpret the rather limited effect of deleting Itsn1 in mice (Yu et al. 2008). Indeed, Itsn2 deletion may cause major problems in endocytosis and/or trafficking of channel proteins, antigen receptors, caveolae-based internalization, or lumen formation. Of course, Itsn1 and Itsn2 may function redundantly in a number of processes. Double mutant mice will be required to test this possibility. Beyond expected redundancies based on the homology of Itsn1 and 2 with each other, or homologies between Itsn proteins and other proteins with EH domains, SH3 domains, or DBL/PH domains that hint at shared functions, a small screen for synthetic lethal or synthetic sick interactions in *C. elegans* has revealed that Itsn proteins can function redundantly with unrelated proteins like Disabled, Dab-1 (Wang et al. 2008). This redundancy may be based on parallel Itsn- and Dab-mediated pathways for endocytosis and/or signal transduction downstream of common cargo proteins.

Future genetic studies are likely to yield insights into novel functions for Itsn proteins in neurons and many other cell types.

EPM2A; LAF-PTPase; MELF

Historical Background

Two groups searching for genes mutated in Lafora disease patients simultaneously discovered the *EPM2A* gene (*epilepsy, progressive myoclonic type 2A*) that encodes the protein laforin (Minassian et al. 1998; Serratosa et al. 1995). Laforin is a bimodular protein containing a dual specificity phosphatase (DSP) domain and a carbohydrate-binding module (CBM) (Fig. 1). Dual specificity phosphatases (DSPs) are a diverse group of phosphatases whose members dephosphorylate phosphoserine/phosphothreonine, phosphotyrosine, phosphoinositols, ribo/deoxyribonucleotide 5′-triphosphates, pyrophosphate/triphosphate, or phospho-glucans. DSPs are members of the larger protein tyrosine phosphatase (PTP) superfamily that all utilize a cysteine-dependent mechanism to hydrolyze phosphoester bonds. This mechanism is dependent on the conserved CX_5R active site motif common to all protein tyrosine phosphatases. Laforin is the founding member of a small group within the DSPs called the glucan phosphatases, that is, laforin liberates phosphate from glucans such as glycogen. CBMs are divided into 63 families based on primary, secondary, and, when available, tertiary structure. In addition to binding and dephosphorylating glucans, laforin also appears to act as a scaffolding protein. The gene encoding laforin is conserved in all vertebrates and in a subset of protists and invertebrates (Gentry et al. 2007). Loss of function recessive mutations in the gene encoding laforin results in a fatal disease called Lafora disease (LD).

Lafora Disease

Lafora disease (LD) is a fatal neurodegenerative epilepsy that is autosomal recessive and is characterized by declining neurological functions over time. LD is one of four diseases that represent the inherited progressive myoclonus epilepsy (PME) family; the PMEs collectively constitute ≈ 1% of all epilepsies. Due to the progressive nature of neurodegeneration, the frequency of myoclonic seizures, and the variety of seizure types that can present, PMEs are often difficult to diagnose at onset (reviewed in Minassian 2001).

Lafora disease is characterized by myoclonic, tonic-clonic, and focal-occipital seizures among other

Laforin: Function and Action of a Glucan Phosphatase,
Fig. 1 A schematic of laforin. Laforin contains an amino-terminal carbohydrate-binding module (CBM) followed by a dual specificity phosphatase (DSP) domain. Lafora disease missense mutations are shown

seizure types that increase in frequency and severity with age, with the first tonic-clonic epileptic presentation occurring in late childhood or early adolescence. Other symptoms include dementia, visual hallucinations, ataxia, absence and grand mal seizures along with epilepsy triggered by stimulus (reviewed in Minassian 2001). Death occurs within 10 years following progressive neurodegeneration due to complications such as status epilepticus, aspiration pneumonia, or respiratory failure. There is significant neuronal loss across the CNS upon death with no signs of inflammation (reviewed in Ganesh et al. 2006; Minassian 2001).

Approximately 50% of LD cases result from recessive inactivating mutations in the *EPM2A* gene that encodes laforin. Mutations in laforin disrupt activity, substrate binding, interaction partner binding, or localization, and are evenly distributed across the protein (Fig. 1) (reviewed in Dukhande et al. 2010). LD also results from recessive mutations in the *EPM2B* (*epilepsy, progressive myoclonic type 2B*) gene encoding the laforin-binding partner and E3 ubiquitin ligase malin (Chan et al. 2003).

A hallmark of LD is the presence of insoluble polyglucosan bodies termed Lafora bodies (LBs) in the cytoplasm of cells from most tissues. These tissues, including neurons, cardiac muscle, and liver, also display increased laforin expression in normal individuals (reviewed in Ganesh et al. 2006). The spherical LB inclusions are 3–40 μm in size and can grow large enough to occupy the entire cytoplasm. The inclusions found in LD contain only a small amount of ubiquitinated protein and are instead composed of improperly branched and hyperphosphorylated glucose moieties. Despite the presence of LBs in a variety of tissues throughout the body, non-neurological symptoms are uncommon (reviewed in Minassian 2001).

Laforin Expression, Isoforms, and Localization

Laforin mRNA is widely expressed in the human body. All tissues examined contain laforin mRNA, including brain, heart, skeletal muscle, liver, lung, placenta, kidney, testis, spleen, thymus, prostate, ovary, small intestine, and pancreas (Minassian et al. 1998). Various brain regions such as cerebellum, cortex, medulla, putamen, and spinal cord also express laforin transcript at similar levels, demonstrating the ubiquitous expression of laforin in brain.

There are at least two laforin isoforms. One isoform is a 331 amino acid protein (laforin-331) and the other is a 317 amino acid product (laforin-317) (Ganesh et al. 2002b). Laforin-317 lacks 22 residues from the carboxy-terminus of laforin-331 and has a unique 8 amino acid extension. Laforin-331 is the dominant species and unless otherwise noted is the one discussed throughout this review.

Overexpressed laforin is largely found in the cytosol with some signs of endoplasmic reticulum (ER) localization, and lower levels are found in the nucleus (reviewed in Minassian 2001). Overexpressed laforin also localizes at polyribosomes on rough ER and at the inner surface of cell membranes. The ER-localized laforin forms aggregates at centrosomes following treatment with proteasomal inhibitor. Conversely, laforin-317 localizes to both the ER and nucleus when overexpressed (Ganesh et al. 2002a).

Due to its CBM, laforin has the inherent ability to bind glucans and this domain leads to co-localization of laforin with glycogen synthase and glycogen granules. Mutations in the CBM disrupt this co-localization. A study employing mice overexpressing catalytically inactive phosphatase domain (C266S) of laforin showed that laforin preferentially binds LBs

over glycogen. While multiple studies have investigated laforin localization when overexpressed in mammalian cell culture, no study has described the localization of endogenous laforin in a vertebrate. Endogenous laforin localization was reported for the red algae *Cyanidioschyzon merolae*. In *C. merolae*, laforin co-localized with the outer surface of starch granules as demonstrated by immunogold electron microscopy (Gentry et al. 2007).

There is no study describing transcriptional or translational regulation of laforin concentration. However, laforin protein levels are regulated by the ubiquitin-proteasome system and a direct correlation has been described between laforin protein levels and muscle glycogen content. Both of these mechanisms are discussed in detail below in "Regulation of Laforin Activity and Concentration".

Laforin Activity

Consistent with its designation as a dual specificity phosphatase, laforin exhibits in vitro phosphatase activity against phospho-serine, threonine, and tyrosine residues of various exogenous substrates (reviewed in Ganesh et al. 2006). In addition to this activity, laforin can utilize the artificial substrates 3-O-methylfluorescein phosphate (OMFP) and *para*-nitrophenyl phosphate (*p*-NPP) (reviewed in Dukhande et al. 2010; Gentry et al. 2007). While none of these substrates are physiologically relevant, they do establish that laforin is an active phosphatase and allow one to compare the activity of laforin to other phosphatases.

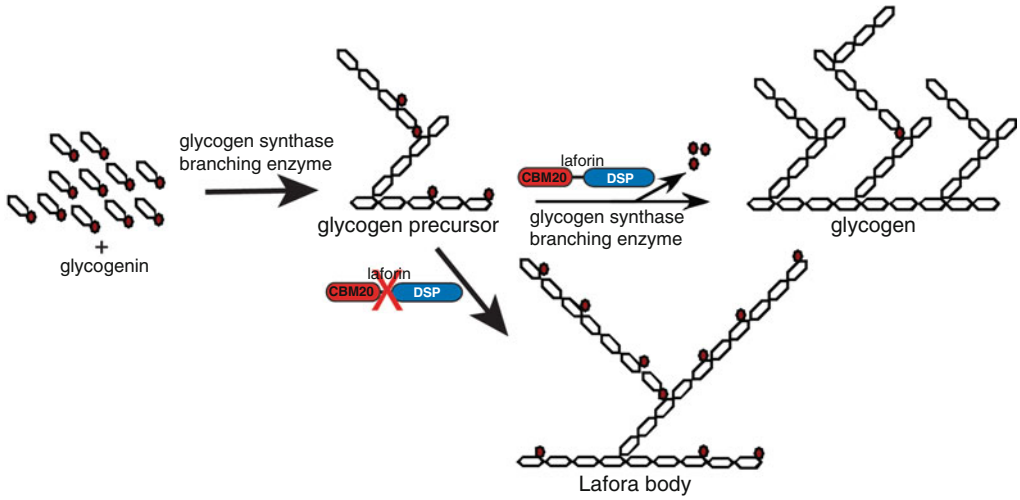
Dixon and colleagues first identified that laforin contains a CBM and demonstrated that this domain allows laforin to bind glucans (Wang et al. 2002). LD patient mutations in the CBM of laforin disrupt glucan binding both in vitro and in vivo. Out of 68 dual specificity phosphatases, laforin is the only DSP with a CBM. This fact coupled with a finding from the 1960s that Lafora bodies have increased phosphate prompted Gentry and colleagues to test whether laforin could liberate phosphate from glucans. Laforin does indeed dephosphorylate glucans, while other DSPs and phosphatases from other families lack this activity (Worby et al. 2006). Subsequently, multiple labs have demonstrated that laforin utilizes its two domains to bind and dephosphorylate glycogen. In addition, loss of function mutations in laforin leads to increased phosphate content in glycogen (Sakai et al. 1970; Tagliabracci et al. 2007). Furthermore, LD patient mutations in the CBM or DSP of laforin abolish its glucan phosphatase activity (Gentry et al. 2007). Recent work from the Roach lab demonstrated that as phosphate levels increase in glycogen the glycogen becomes insoluble (Tagliabracci et al. 2007, 2008). These inclusions eventually form LBs and more closely resemble plant starch than glycogen.

Cumulatively, these results strongly suggest that laforin regulates glycogen phosphate levels to inhibit LB formation. The targeting of laforin to sites of glycogen synthesis by the CBM in order to regulate phosphate is critical for normal glycogen formation, with covalent phosphate occurring as an error of glycogen synthesis (reviewed in Gentry et al. 2007, 2009; Tagliabracci et al. 2011) (Fig. 2).

Regulation of Laforin Activity and Concentration

One mechanism that appears to modulate laforin protein levels is fluctuations in glycogen stores. Investigation into mouse models that accumulate higher or lower levels of glycogen revealed that laforin protein expression is upregulated as glycogen stores increase (Wang et al. 2006a). This result suggests that glycogen and laforin levels are closely linked. In addition, laforin levels in the brains of adult mice have also been seen to increase with age, indicating that laforin may have a vital role in the maturation of the CNS. While these links have been described, exact mechanisms regulating these fluctuations in laforin protein levels are unknown.

The ubiquitin-proteasome degradation pathway carries out a second mechanism regulating laforin protein levels. The single-subunit RING-type E3 ubiquitin ligase malin binds, polyubiquitinates, and promotes the proteasomal degradation of laforin in cell culture (Gentry et al. 2005). The interaction between laforin and malin is mediated by the NHL (NCL-1, HT2A, and LIN-41 proteins) domains of malin (Gentry et al. 2005). Inhibition of proteasome activity by MG-132 results in increased laforin levels, indicating that laforin levels are regulated by the proteasome. In addition, malin ubiquitination of laforin was recapitulated using purified components in vitro (Gentry et al. 2005). In support of this finding, inactivating mutations in malin leads to increased levels of laforin in both humans and mice



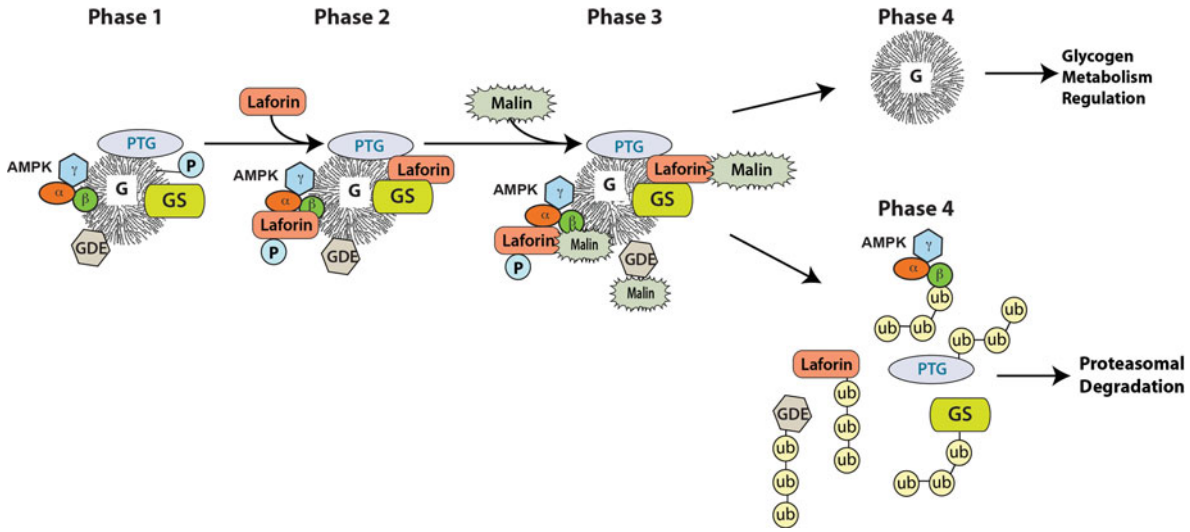
Laforin: Function and Action of a Glucan Phosphatase, Fig. 2 Model of Lafora body formation caused by loss of laforin activity. Glycogen synthesis involves the concerted efforts of glycogen synthase and branching enzyme covalently attaching glucose moieties, initially in the form of UDP-glucose, to glycogenin. UDP-glucose are depicted on the far *left* as hexagons with phosphate (*red circles*). Glycogen is composed of α-1,4-linked glucose moieties with branches occurring via α-1,6-glycosidic linkages. Glycogen contains a small amount of covalently linked phosphate that is present as both a phosphomonoester and phosphodiester. *Red circles* represent phosphate with monoester linkage depicted adjacent to hexagons, and diester linkage depicted between two glucose hexagons. Glycogen synthase incorporates ≈ 1 phosphate per 10,000 glucose residues as a phosphomonoester during glycogen synthesis. Laforin dephosphorylates glycogen phosphomonoesters so that glycogen remains water-soluble. In the absence of laforin, glycogen phosphomonoesters accumulate and glycogen becomes less branched; phosphomonoesters inhibit glycogen solubility and eventually result in Lafora body formation

(Chan et al. 2003; DePaoli-Roach et al. 2010). Currently, it is unknown what triggers malin ubiquitination of laforin, but in vitro biochemical and in vivo LD patient data both support this finding.

Inactivating recessive mutations in *EPM2B*, the gene encoding malin, also results in Lafora disease. The downregulation of laforin by malin is puzzling with regard to LD pathogenesis, as LD occurs due to loss of function of either malin or laforin. Why then would one protein that inhibits LD (i.e., malin) trigger degradation of the second protein (i.e., laforin)? The answer to this question is still unresolved, but malin-directed ubiquitination of laforin is supported by in vitro biochemical data, in vivo mouse models, and LD patient data (Chan et al. 2003; DePaoli-Roach et al. 2010; Gentry et al. 2005).

A third means of regulating laforin activity is homodimerization and heterodimerization of different laforin splice variants. Ganesh and colleagues characterized the interaction of two laforin isoforms that possess different carboxy termini (Dubey and Ganesh 2008). The major isoform consists of 331 amino acids and the minor isoform consists of 317 amino acids. They found that monomeric laforin-317 and homodimers of laforin-317 lack phosphatase activity and both are unable to bind glucans. In addition, these two isoforms form heterodimers that lack phosphatase activity and are unable to bind glucans. Thus, heterodimer formation is a mechanism to modulate laforin glucan binding and its phosphatase activity.

Recently, insights into the regulation of the laforin-malin interaction were provided by a study reporting that AMP-activated protein kinase (AMPK) phosphorylates laforin (Solaz-Fuster et al. 2008). A subsequent study identified serine 25 within the CBM of laforin as the residue that is phosphorylated by AMPK. Ser25 phosphorylation results in increased interaction between laforin and malin. Thus, the laforin-malin interaction is enhanced in conditions that activate AMPK. These studies identify a direct signaling link responsible for modulating the laforin-malin complex and a means to regulate laforin-directed malin ubiquitination of glycogen metabolism enzymes.



Laforin: Function and Action of a Glucan Phosphatase, Fig. 3 Schematic depicting proposed role of laforin and its interactions in glycogen metabolism. In phase 1, the heterotrimeric AMP-activated protein kinase (AMPK), protein targeting to glycogen (PTG), glycogen synthase (GS), and glycogen debranching enzyme (GDE) bind to glycogen. Laforin binds glycogen via its CBM in phase 2 and dephosphorylates glycogen. In addition, AMPK phosphorylates laforin. In phase 3, malin is targeted to laforin and laforin acts as a targeting subunit to direct malin ubiquitination of PTG, GS, and AMPK. Laforin is also ubiquitinated by malin. In addition, malin ubiquitinates GDE, but the role of laforin in this event is unknown. These ubiquitination events lead to the degradation of laforin, AMPK, GS, GDE, and PTG in phase 4. Despite data from multiple labs utilizing multiple models and techniques, malin-deficient mice do not show increased levels of PTG, GS, or GDE. Therefore, the validity of these findings is currently in question. For simplicity purposes, the spatial-temporal nature of these interactions is not depicted and many of them are unknown

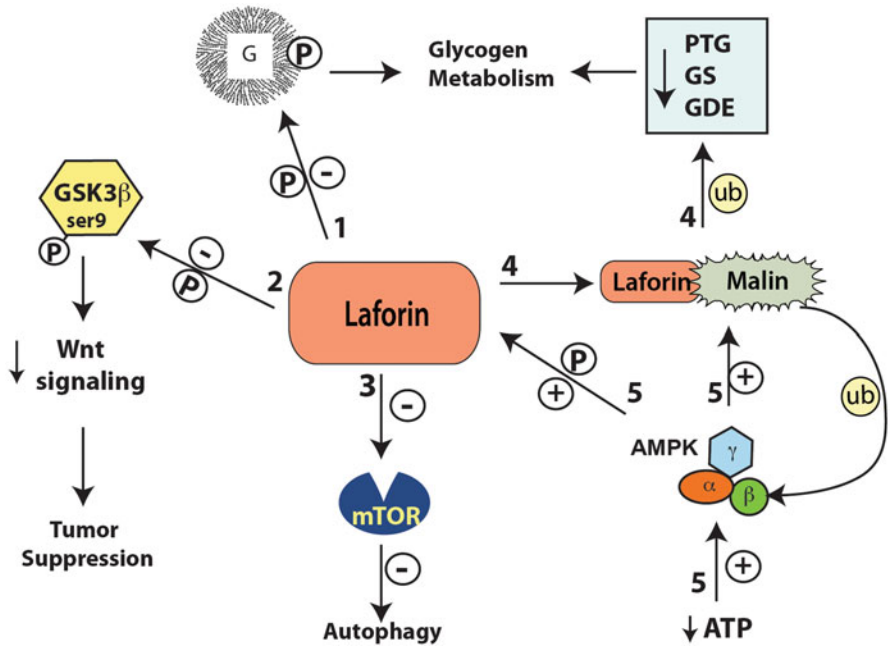
Interactions and Signaling

Laforin interacts with multiple cellular components via its DSP and CBM domains. Laforin interactions can be classified based on the following: (1) binding to glucans, (2) dephosphorylation of substrates, (3) role as a scaffolding protein, and (4) other protein-protein interactions. Many of these interactions are directly involved in glycogen metabolism (Fig. 3).

Laforin is the only phosphatase in vertebrate genomes to have a CBM and the presence of the CBM enables laforin to bind cellular glycogen (Wang et al. 2002). Similarly, the functional homolog of laforin in plant and green algal genomes called as Starch EXcess4 (SEX4) binds and dephosphorylates the glucan starch (Gentry et al. 2007). Mutations in the CBM of SEX4 or laforin disrupt this interaction and abolish their glucan phosphatase activity (Gentry et al. 2007; Tagliabracci et al. 2007). Laforin not only interacts with glucans in vitro, but it also co-localizes with Lafora bodies in mice overexpressing inactivated laforin. Thus, the glucan binding of laforin is supported by data from both in vivo and in vitro systems.

There is now overwhelming evidence that laforin is a glucan phosphatase. First, laforin dephosphorylates glucans such as glycogen and amylopectin in vitro (Tagliabracci et al. 2007; Worby et al. 2006). Conversely, other phosphatases tested are not able to liberate phosphate from glucans (Worby et al. 2006). In addition, laforin homologs in protists and plants also dephosphorylate glucans (Gentry et al. 2007). The glucan phosphatase activity of laforin is also supported by the finding of increased phosphate content of LBs isolated from LD patients compared to phosphate levels in glycogen (reviewed in Gentry et al. 2009; Sakai et al. 1970). Similarly, the phosphate content of LBs isolated from muscle and hepatic tissue of *EPM2A* knockout mice is higher than the phosphate content of glycogen from wildtype mice (Tagliabracci et al. 2007, 2008) (Fig. 4).

In addition to dephosphorylating glycogen, some have reported that laforin also dephosphorylates glycogen synthase kinase3β (GSK3β) at serine-9 and modifies the function of GSK3β in Wnt signaling (Lohi et al. 2005; Wang et al. 2006b). However, this point is currently under debate since other groups have



Laforin: Function and Action of a Glucan Phosphatase, Fig. 4 Model of the proposed roles of laforin in signaling events. (1) Laforin dephosphorylates glycogen to allow normal glycogen metabolism and inhibit Lafora body formation. (2) Laforin is proposed to dephosphorylate pSer9 of GSK3β and decreasing Wnt signaling. Loss of laforin is proposed to result in increased tumor formation. As discussed in the text, data from other labs do not support these findings. (3) Recently, laforin was shown to positively affect autophagosome formation by decreasing mTOR activity via an unknown mechanism. (4) Laforin forms a complex with malin that ubiquitinates protein targeting to glycogen (PTG), glycogen synthase (GS), and AMP-activated protein kinase (AMPK). In addition, malin has been shown to ubiquitinate glycogen debranching enzyme (GDE). As discussed in the text and in Fig. 3, data from the malin knockout mouse do not support these findings. (5) Decreases in ATP activate AMPK to phosphorylate laforin and this increases the interaction between laforin and malin

not observed GSK3β dephosphorylation by laforin (Wang et al. 2007; Worby et al. 2006a). Additionally, laforin has been shown to dephosphorylate the microtubule-stabilizing protein tau (Puri et al. 2009). It is interesting to note that pathological accumulations of misfolded tau, denoted as tangles, are observed in brains of Alzheimer's disease patients, thus uncovering a potential similar mechanism of neurodegeneration between Alzheimer's disease progression and that of LD. Lastly, loss of laforin was recently shown to decrease the activity of the mTOR pathway and inhibit autophagosome formation (Aguado et al. 2010). Thus, it appears that laforin positively influences autophagy (Fig. 4).

In addition to binding and dephosphorylating glucans and perhaps proteins, laforin is also postulated to act as a scaffolding protein for the E3 ubiquitin ligase malin. As discussed above, malin is a single-subunit RING-type E3 ubiquitin ligase that ubiquitinates laforin, and autosomal recessive mutations in the gene encoding malin also cause LD (Chan et al. 2003; Gentry et al. 2005). In addition to ubiquitinating laforin, malin also appears to form a functional complex with laforin (Moreno et al. 2010; Solaz-Fuster et al. 2008; Worby et al. 2008). In this complex, laforin acts as a targeting protein to direct the laforin-malin complex to ubiquitinate and degrade protein targeting to glycogen (PTG), glycogen synthase, and AMP-activated protein kinase (AMPK) (Moreno et al. 2010; Solaz-Fuster et al. 2008; Worby et al. 2008) (Fig. 4). Despite complementary work from multiple labs, the levels of PTG and glycogen synthase did not change in tissues from malin knockout mice compared to wild-type (DePaoli-Roach et al. 2010). Thus, the functional significance of laforin-malin-mediated degradation of these proteins is not completely elucidated.

Lastly, laforin interacts with two other proteins whose relevance to LD is not currently understood

(Fig. 4). Both proteins were identified by yeast two-hybrid screens and verified by immunoprecipitation of overexpressed proteins. The first protein is EPM2A-interacting protein1 (EPM2AIP1). EPM2AIP1 has no reported domains and no known function. In addition to EPM2AIP1, the CBM of laforin interacts with the NifU domain of HIRIP5. NifU is an iron-sulfur cluster assembly domain and HIRIP5 has been implicated in iron-sulfur cluster biosynthesis in yeast. Currently, the functional significance of these interactions is not known.

The Role of Laforin in Lafora Disease

Laforin prevents the accumulation of polyglucosan inclusions by decreasing the amount of phosphate present in glycogen. Failure to remove phosphate covalently attached to glucose moieties disrupts packing within glycogen or glycogen branching (Fig. 2), leading to the accumulation of insoluble LBs. Previously, it was not understood whether LB formation was a result of an overactive polyglucosan biosynthetic pathway or a disrupted degradative metabolic pathway. Recent work determined that phosphate is incorporated into glycogen at a rate of ≈ 1 phosphate per 10,000 glucose residues by glycogen synthase during glycogen metabolism (Tagliabracci et al. 2011). Based on these results, the role of laforin is to negate the errors of glycogen synthase and remove phosphate from glycogen that is incorporated by glycogen synthase (Tagliabracci et al. 2011). The lack of this function in patients with mutations in the *EPM2A* gene leads to hyperphosphorylated, insoluble glycogen accumulations that eventually form LBs.

The accumulation of LBs appear to be particularly detrimental in neurons, possibly disrupting cellular trafficking, disturbing neuronal membrane excitability, or perturbing energy homeostasis that results in neuronal cell death. However, cell death has been observed in the absence of LBs, indicating that other factors may be influencing neuron death (Ganesh et al. 2002b).

In addition to LBs, cells overexpressing mutant laforin also exhibit impaired clearance of misfolded proteins with the appearance of ubiquitin-positive perinuclear aggresomes (Ganesh et al. 2002b). These aggregates of proteins marked for proteasomal degradation are also present in neurons of both LD patients as well as laforin-deficient mice. Impaired protein clearance may also be involved in neuronal cell death in LD patients. Upregulation of the unfolded protein response due to endoplasmic reticulum stress is seen when laforin is mutated or missing. The fact that malin, an E3-ubiquitin ligase, is mutated in LD also provides support that LD is a disease of impaired protein clearance as the ubiquitination pathway is involved in protein turnover by the proteasome. Furthermore, disruption of exon 4 of the *EPM2A* gene in mice leads to cell death often prior to the formation of LBs, and neurons containing LBs often did not deteriorate in these mice (Ganesh et al. 2002b). Therefore, neuronal cell death might be driven by a combination of impaired protein clearance and LBs.

Summary

Laforin is a bimodular protein that contains an amino-terminal CBM followed by a DSP domain and is encoded by the *EPM2A* gene. Recessive, loss of function mutations in *EPM2A* results in Lafora disease (LD). Laforin participates in a number of interactions, and these interactions can be classified based on the following: (1) binding to glucans, (2) dephosphorylation of substrates, (3) role as a scaffolding protein, and (4) other protein-protein interactions. While there is currently debate regarding the role of laforin in many of its proposed functions, it is clear that laforin activity impacts glycogen metabolism. The central theme of Lafora disease revolves around glycogen metabolism: LBs are a "foreign" type of "glycogen," laforin binds glucans, and malin regulates the level of proteins involved in glycogen metabolism. Multiple labs have now demonstrated that laforin binds and dephosphorylates glycogen, making it a glucan phosphatase. Designation of laforin as a glucan phosphatase is supported by in vitro biochemical data, data from mouse models, and LD patient data. While the other proposed functions of laforin are intriguing and supported by some lines of evidence, they require more research to determine which are biologically correct and relevant to Lafora disease.

Historical Background

Engagement of the T cell receptor (TCR) with MHC-peptide complexes leads to the activation of protein tyrosine kinases (PTK), ultimately leading to the activation of downstream signaling events, such as calcium flux and mitogen-activated protein kinase (MAPK) activation (Chan et al. 1994). For many years, it was observed that a 36–38 kDa protein, localized to the plasma membrane, was highly tyrosine phosphorylated upon ligation of the TCR and associated with Grb2, PLC-γ1, and the p85 subunit of PI3K. It was hypothesized that this protein served as a critical link connecting TCR engagement at the membrane to activation of signaling events in the cytosol. In 1998, the gene encoding this protein was identified after microsequencing phosphorylated proteins purified from the membrane fractions of activated Jurkat T cells and was named LAT, *l*inker for *a*ctivation of *T* cells. Sequencing of cDNA clones revealed that LAT is a type III transmembrane protein that contains a short extracellular domain, a transmembrane domain, and a long cytoplasmic tail. While LAT has no apparent structural domains, it has multiple tyrosine motifs for binding Grb2. Further biochemical analysis confirmed that it does interact with Grb2, PLC-γ1, and p85 (Zhang 1998a). The indispensible role of LAT in TCR-mediated signaling and thymocyte development was subsequently demonstrated by studies using LAT-deficient Jurkat T cell lines and knockout mice. In 2003, the other member of the LAT protein family, linker for activation of B cells (LAB)/non-T cell activation linker (NTAL), was discovered (Janssen et al. 2003; Brdicka et al. 2002).

LAT Palmitoylation

Biochemical analyses indicate that LAT is constitutively localized to lipid rafts, similar to Lck and Fyn. In the juxtamembrane region of LAT, there are two conserved cysteine residues, which are covalently modified by palmitate, a 16-carbon fatty acid. Studies using LAT cysteine mutants clearly demonstrate that palmitoylation is required for LAT phosphorylation and function in TCR-mediated signaling (Zhang 1998b). Moreover, LAT palmitoylation is impaired in anergic T cells (Hundt et al. 2006). As of yet, the role of LAT palmitoylation remains unclear. While palmitoylation targets LAT to lipid rafts, raft localization is not essential for LAT function (Zhu et al. 2005). It is possible that palmitoylation is required for trafficking of LAT from the Golgi to the plasma membrane (Hundt et al. 2009) or simply for stably tethering LAT to the plasma membrane.

The Positive Role of LAT in TCR-Mediated Signaling

Upon T cell receptor ligation with an MHC-peptide complex, Src family kinases, specifically Lck and Fyn, are activated and phosphorylate the immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic domains of the TCRζ and ▶ CD3 chains. Phosphorylation of ITAMs creates binding sites for ▶ ZAP-70, which is subsequently activated by Lck and Fyn. ZAP-70 phosphorylates LAT and other signaling proteins (Samelson 2002). There are nine conserved tyrosine residues between murine and human LAT. Among these tyrosine residues, the four distal tyrosines of LAT mediate the binding of Grb2, Gads, and PLC-γ1 and are vital for T cell activation. Grb2 recruits the Ras guanine nucleotide exchange factor, Son of sevenless (Sos), which activates the Ras-Raf-MAP kinase pathway and results in the activation of the transcription factor AP-1. In addition, Grb2 also stabilizes the interactions between LAT and its other binding partners, Gads and PLCγ1 (Zhu et al. 2003). By binding to LAT, Gads mediates the interaction between LAT and ▶ SLP-76, another important adaptor protein. SLP-76 regulates actin polymerization and cytoskeleton rearrangement via recruitment of ▶ Vav, the guanine nucleotide exchange factor for Rac/Rho. Additionally, SLP-76 stabilizes PLC-γ1 binding to LAT and recruits the Tec kinase, Itk, which phosphorylates and activates PLC-γ1 (Jordan et al. 2003). PLC-γ1 is responsible for the hydrolysis of phosphatidylinositol bisphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 is important for

TCR-mediated calcium mobilization and subsequent activation of the transcription factor ▶ NFAT. DAG has dual functions in that it activates protein kinase C (PKC), triggering downstream ▶ NF-κB nuclear translocation, as well as serving to activate the Ras-Erk pathway through the Ras guanine nucleotide exchange factor, ▶ RasGRP1. Since all of these pathways depend on LAT for their activation, the absence of LAT has severe ramifications on TCR signaling. In LAT-deficient Jurkat cell lines, TCR-mediated calcium flux, Erk activation, and IL-2 production are greatly impaired compared to normal Jurkat cells. Phosphorylation of PLC-γ1 and SLP-76 in these cells is also reduced. These signaling defects can be corrected by the reconstitution of LAT expression in these cells (Finco et al. 1998).

In addition to its vital role in the TCR-mediated signaling pathway, LAT is also essential for T cell development in the thymus. LAT-deficient mice show an early block at the DN3 ($CD44^-CD25^+$) stage, indicating its importance in pre-TCR signaling. Consequently, LAT-deficient mice lack mature αβ T cells. Moreover, γδ T cells also need LAT signaling during development to enter the periphery (Zhang et al. 1999). Recent data indicate that LAT is necessary to transmit signals through a functional rearranged TCRαβ receptor during the transition from DP ($CD4^+CD8^+$) to SP ($CD4^+$ or $CD8^+$) (Shen et al. 2009).

In addition to its well-defined role as a positive regulator of TCR-mediated signaling, LAT is also critical for FcεRI-mediated signaling in mast cells. LAT-deficient mast cells have impaired MAPK activation, cytokine production, and degranulation. $LAT^{-/-}$ mice are resistant to IgE-mediated passive systemic anaphylaxis, indicating the essential role of LAT in FcεRI-mediated signaling in mast cells (Saitoh et al. 2000).

The Negative Role of LAT in TCR-Mediated Signaling

While LAT mainly serves to positively regulate TCR-mediated calcium mobilization and MAPK activation through binding Grb2, Gads, and PLC-γ1, it also negatively impacts TCR signaling by recruiting other proteins, such as ▶ Gab2 and SHIP-1. After TCR activation, Grb2 associated binding protein 2 (Gab2), which is constitutively associated with Gads and Grb2, is recruited to LAT and is then phosphorylated by Zap-70. Gab2, in turn, recruits SH2 domain-containing tyrosine phosphatase-2 (SHP2) to dephosphorylate key signaling molecules, such as CD3ζ (Yamasaki et al. 2003).

LAT can also recruit Src homology 2 domain–containing inositol polyphosphate 5-phosphatase-1 (SHIP-1) to the TCR complex through its interaction with Grb2. SHIP-1 is required to anchor downstream of kinase-2 (Dok-2) to the LAT complex as well as for Dok-2 tyrosine phosphorylation. Together with Dok-1, Dok-2 then negatively regulates Zap-70 and Akt kinase activation (Dong et al. 2006). Through its association with negative regulators, LAT plays a critical role in dampening the signals which emanate from the TCR.

LAT in Autoimmunity

Further evidence indicating that LAT plays a negative role in T cell activation comes from studies examining the interaction between LAT with PLC-γ1. LAT-deficient Jurkat T cells reconstituted with the LATY136F mutant, which fails to bind PLC-γ1, have impaired calcium flux and Erk activation (Zhang et al. 2000). To test the role of this interaction in vivo, two groups independently generated LATY136F knock-in mice. Analyses of these mice show that there is a partial block in thymocyte development at the DN3 stage, demonstrating the positive role of the LAT and PLC-γ1 interaction in thymocyte development. However, a small population of thymocytes is able to progress to the DP and SP stages. Mutant T cells that enter the periphery then undergo uncontrolled expansion, revealing the importance of the LAT and PLC-γ1 interaction in the control of T cell homeostasis. LATY136F mice display lymphadenopathy, splenomegaly, as well as lymphocyte infiltration in the lungs, liver, and kidneys. These mice have very few $CD8^+$ T cells in the periphery and the $CD4^+$ T cells are Th2-skewed, producing high levels of IL-4. They have low levels of surface TCR expression and have an activated/effector memory phenotype, characterized by high surface expression of CD44 and low surface expression of CD62L. As a result of the large population of Th2 T cells, B cells are hyperactivated, producing autoantibodies, mainly IgE and IgG_1 (Sommers et al. 2002; Aguado et al. 2002).

Further analysis of LATY136F mice demonstrates that they do not contain natural T regulatory cells, which are $CD4^+CD25^+Foxp3^+$. Adoptive transfer of normal T regulatory cells into neonatal LATY136F mice can prevent development of the autoimmune syndrome (Koonpaew et al. 2006). In addition, transfer experiments show that LATY136F $CD4^+$ T cells can also expand in MHC Class II-deficient mice, indicating that the uncontrolled expansion of these mutant T cells is independent of the TCR-MHC-peptide interaction (Wang et al. 2008). Interestingly, while mice expressing the LATY136F mutant develop a severe lymphoproliferative syndrome, mice with LAT inducibly deleted in mature T cells also develop a similar, albeit less severe, autoimmune syndrome. LAT-deficient $CD4^+$ T cells expand and secrete large amounts of cytokines despite a severe defect in TCR-mediated signaling (Shen et al. 2010).

Additionally, LAT3YF mice, in which LAT fails to bind Gads and Grb2 due to mutations at Y175, Y195, and Y235, exhibit uncontrolled T cell expansion in the periphery. These mice show a block in thymic development at the DN stage, with a complete block in αβ T cell development. Interestingly, γδ T cell development does not seem to be affected, and these cells exit the thymus and populate the periphery. In aged mice, these γδ T cells have undergone significant expansion and, unexpectedly, produce Th2 cytokines. Thus, B cell populations also expand, causing high serum levels of IgG1 and IgE (Nunez-Cruz, Aguado et al. 2003). These data suggest a role for LAT in the negative regulation of γδ T cell expansion and indicate that αβ and γδ T cells have different requirements for LAT during thymic development. Together, these data clearly indicate the critical role of LAT in T cell homeostasis, but the mechanism by which LAT controls T cell homeostasis remains to be further investigated.

Summary

LAT, a transmembrane adaptor protein that is exclusively expressed in hematopoietic cells, is required for thymocyte development and LAT deficiency leads to a complete lack of mature T cells. LAT is also vital for T cell activation downstream of the TCR. LAT is constitutively localized in lipid rafts and contains two cysteine residues that can be palmitoylated. LAT palmitoylation is essential for its function in T cells. Upon T cell activation, LAT is phosphorylated on multiple tyrosine residues by ZAP-70 tyrosine kinase and interacts with Grb2, Gads, and PLC-γ1 directly, as well as Cbl, SLP-76, Vav, and other proteins indirectly. The ability of LAT to interact with these signaling proteins is required for TCR-mediated MAPK activation, calcium mobilization, and cytokine production. Recent studies indicate that LAT also controls T cell homeostasis. The deletion or mutation of LAT causes the development of a lymphoproliferative autoimmune syndrome due to uncontrolled T cell expansion and cytokine production. In summary, LAT is a key signaling molecule that functions in T cell development, activation, and homeostasis. LAT or LAT-mediated signaling pathways could serve as effective targets for the design of improved therapies to enhance or inhibit T cell function during immune responses.

FLJ38026; KIAA1795; Ligand-dependent nuclear receptor corepressor (LCoR); Mblk1-related protein 2 (MLR2); RP11-175O19.1

Historical Background

Gene expression is a fundamental part of cell biology as it initially produces an mRNA transcript that ultimately results in a functional protein. Within this process, gene transcription is a tightly controlled mechanism in cell nuclei through the action of specific DNA-binding transcription factors and an array of ancillary proteins known as co-activators or corepressors, depending on whether they act to stimulate or repress transcription. In general, most co-activators have histone acetyltransferase (HAT) activity, which acts in part to loosen the association of positively charged histones with DNA, facilitating chromatin remodeling and recruitment of the transcriptional machinery. On the other hand, corepressors often recruit histone deacetylases (HDACs) or methyltransferases, which reinforce the structural integrity of the histone–DNA association, effectively denying DNA access to the transcriptional machinery. However, evidence has accumulated showing that the precise transcriptional roles of cofactors can be promoter-specific, as many examples exist in the literature of proteins that can function as a co-activator or corepressor in different contexts. As such, it is perhaps better to globally refer to these proteins as transcriptional co-regulators.

Ligand-dependent nuclear receptor corepressor (LCoR) was originally identified by two independent laboratories through the use of cDNA library screens. Both laboratories identified LCoR as a transcriptional co-regulator. However, Fernandes et al. (2003) extensively characterized it as a ligand-dependent transcriptional corepressor of nuclear receptor–mediated transactivation, whereas Kunieda et al. (2003) showed

preliminary evidence that suggested that it is a transcriptional activator through sequence similarity to mushroom body large-type Kenyon cell-specific protein 1 (Mblk-1). Future studies should provide more definitive evidence confirming that LCoR also regulates gene expression in a context-specific manner.

Domain Structure and Function

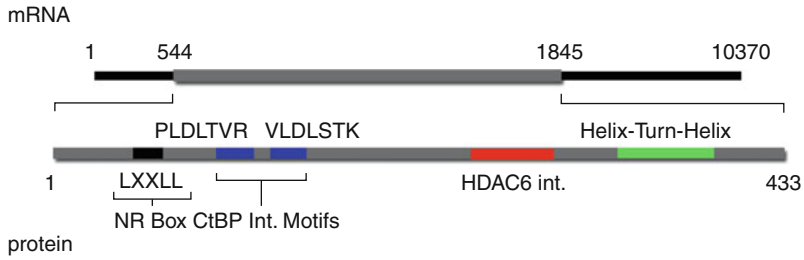
Currently, there exists no direct experimental evidence for different LCoR splice variants, or if these variants display any differences in terms of tissue/cellular localization or function. However, the National Center for Biotechnology Information (NCBI)-curated genomic Reference Sequences lists two potential isoforms of LCoR. Isoform 2 differs from isoform 1 in its 5′ UTR, 3′ UTR, and coding region, while maintaining the open reading frame. This results in similar proteins, with isoform 2 lacking 27 C-terminal amino acids. The region truncated in isoform 2 does not appear to contain any functional domain, yet there is a putative sumoylation motif. Accumulating evidence suggests that sumoylation is important for general repressor function (Geiss-Friedlander and Melchior 2007), but no experimental data exists that suggests differential LCoR isoform function. For the remainder of this entry, when referencing LCoR, it is the longer 433 (isoform 1) amino acid variant that is referenced.

Domain characterization of LCoR (Fig. 1) revealed that it contains a nuclear receptor (NR) box or LXXLL motif in its N-terminal region through which it interacts with class I and II agonist-bound nuclear receptors (Fernandes et al. 2003). The human nuclear receptor superfamily comprises 48 transcription factors that function in a ligand-dependent manner. Each nuclear receptor responds to a particular ligand that can range from steroids and related compounds, retinoic acids, and thyroid hormones to fatty acids, thereby creating classes depending on which ligand they respond to: steroidal (I), nonsteroidal (II), and orphan (III). They regulate many biologically important processes from development to homeostasis (Perissi and Rosenfeld 2005). Specifically, LCoR was shown to associate directly in a ligand-dependent manner through its NR box with estrogen receptor α (ERα, NR3A1), estrogen receptor β (ERβ, NR3A2), progesterone receptor (PR, NR3C3), Vitamin D receptor (VDR, NR1I1), retinoic acid receptor (RAR)-α (NR1B1), RARβ (NR1B2), and RARγ (NR1B3), and retinoid X receptor α (RXRα; NR2B1) (Fernandes et al. 2003). LCoR suppressed transactivation by ERα, PR, glucocorticoid receptor (GR, NR3C1), VDR, and thyroid receptor α (TRα, NR1A1) (Fernandes et al. 2003; Wang et al. 2007). This suggests that LCoR plays an important physiological role through regulation of nuclear-receptor-mediated transcription.

LCoR also contains tandem extended N-terminal PXDLS motifs that recruit C-terminal Binding Proteins 1 (CtBP1) and 2 (Fig. 1) (Fernandes et al. 2003; Palijan et al. 2009b). CtBP1 and CtBP2 function predominanlty as transcriptional corepressors whose activity is modulated by the nuclear ratio of NADH/NAD+ (Chinnadurai 2003). Mutation of both CtBP-binding motifs is required in order to abolish CtBP binding, and attenuation of LCoR corepressor function occurs upon individual mutations at the binding sites in transcription regulated by PR and TRα, with the greatest effect observed when both sites are mutated (Palijan et al. 2009b; Wang et al. 2007). A negligible effect occurred in the transcription regulated by ERα or GR, when individual or combined mutations of the binding sites was carried out, which suggests a minimal role for CtBPs in LCoR-mediated repression of these receptors (Fernandes et al. 2003).

The helix-turn-helix motif located near the C-terminal tail (Fig. 1) also appears to be critical for LCoR function, as deletion of this motif attenuates corepression of estrogen-regulated gene expression and abolishes corepression of progesterone-regulated transcription in T47D human breast cancer cells (Palijan et al. 2009b). How this motif functions in repression, however, remains a topic for future research.

LCoR also recruits HDAC3 and 6 through central domains. HDAC6 recruitment occurs through a region that is delineated by amino acid 203–319 in LCoR (Fernandes et al. 2003; Palijan et al. 2009a). The interaction between HDAC6 and LCoR is somewhat surprising, given that LCoR is nuclear, but HDAC6, unlike HDAC3, is cytoplasmic in many malignant cells (Yang and Seto 2003). However, studies in normal breast epithelial cells show that HDAC6 is nuclear, and that responsiveness to endocrine therapy correlates with HDAC6 localization in breast cancer (Saji et al. 2005). Palijan et al. (2009a) also found that HDAC6 was partially nuclear in ERα-positive MCF-7 breast cancer cells. This suggests that the LCoR–HDAC6 interaction



LCoR, Fig.1 Domain structure of LCoR

is lost in malignant cells in which HDAC6 is cytoplasmic resulting in unknown effects in tumorigenesis.

Cyclical recruitment of LCoR to the promoters of several ERα and PR target genes was demonstrated with a peak occurring 30–45 min after hormone treatment (Palijan et al. 2009a; Palijan et al. 2009b). Although no direct interaction was found between LCoR and CtBP-interacting protein (CtIP), they were found to interact indirectly, and colocalize on the promoters of several ERα and PR target genes (Palijan et al. 2009b). Hence, it is possible that they function as a complex on specific nuclear receptor target genes. Additionally, LCoR was shown to bind specific target gene promoters together with the PR, ERα, CtBP1, or HDAC6, substantiating previous experiments that indicate that these proteins are cofactors (Palijan et al. 2009a; Palijan et al. 2009b).

Furthermore, LCoR was found in a multi-subunit CtBP corepressor complex, which represses the tumor invasion suppressor E-cadherin through specific transcription factor promoter targeting and coordinated histone modifications (Shi et al. 2003). LCoR was also found to interact with lysine (K)-specific demethylase 1 (LSD1), a pivotal member of the Krüppel-like zinc finger E-box binding homeobox 1 (ZEB1)-LSD1-repressor element 1 silencing transcription factor corepressor (CoREST)–CtBP repressive complex (Wang et al. 2007). This large complex binds to the promoters of several genes such as growth hormone 1 (*GH1*) in developing pituitary lactotropes, and is thought to direct a precise transcriptional program that includes both activation and repression (Wang et al. 2007).

Small interfering RNA (siRNA)-mediated knockdown of LCoR revealed an increase in endogenous expression of progesterone-regulated target genes, which is consistent with reporter gene assays that show a role as a corepressor in T47D breast cancer cells (Palijan et al. 2009b). Surprisingly, results from the same type of experiment on estrogen-regulated transcription were conflicting. An increase in estrogen induced expression of an ectopic reporter gene after LCoR knockdown confirmed its role as a repressor of estrogen-mediated transcription (Palijan et al. 2009a). However, analysis of endogenous estrogen target gene expression revealed that abrogation of LCoR expression had either no effect or was required for optimal expression of specific target genes such as insulin-like growth factor binding protein 4 (IGFBP4) and cytochrome P450, family 26, subfamily B, polypeptide 1 (CYP26B1) (Kaipparettu et al. 2008; Palijan et al. 2009b). Future studies might reveal the mechanism through which LCoR functions as a co-activator/-repressor with precise tissue and gene specificity such as another member of the ligand-dependent corepressor family, RIP140 (Cavailles et al. 1995; Lee et al. 1998). The specificity of the effect on transcriptional regulation might depend on the constituents of the transcriptional regulating complex, developmental stage, and tissue. The most compelling evidence for this was presented in a study which found opposing, activator or repressor, functions for a multi-protein complex containing LCoR during mouse development (Wang et al. 2007). Which signals direct the assembly of this function-specific multifactor complex, and how this regulates transcription remain topics of future research.

Regulation of LCoR

Currently, there is very little experimental data that explains how LCoR mRNA or protein expression is regulated. It is not known if different signals direct differential isoform expression, or if this translates into altered functionality. Nevertheless, Wang and colleagues demonstrated that LCoR mRNA expression is increased by estrogen-treatment of human osteosarcoma U2OS cells (Wang et al. 2007). However, widespread and early LCoR expression suggests that there

must be other signals that direct its expression, and clarifying these mechanisms might shed new light on its role in development and potentially disease.

Expression

Tissue Localization

LCoR mRNA is expressed as early as the two-cell stage during development, and is ubiquitously expressed in a variety of fetal and adult human tissues. Highest expression is observed in the placenta, the cerebellum and corpus callosum of the brain, the adult kidney, and a number of fetal tissues (Fernandes et al. 2003). Analysis of placental tissue revealed that LCoR predominantly localizes to the syncytiotrophoblast layer of terminally differentiated cells, which is critical for controlling maternal hormonal signals that regulate fetal metabolism and development (Pepe and Albrecht 1995).

Curiously, generation of a mouse LCoR knockout (*Lcor* $^{-}/^{-}$) model revealed that even though LCoR is expressed early during development it is not essential for it as most *Lcor* $^{-}/^{-}$ animals survived to birth, but failed to suckle and died within hours. Additionally, a growth difference was noticeable starting at the 18th day of gestation (E18.5) as *Lcor* $^{-}/^{-}$ mouse embryos were slightly (~15%), but significantly, smaller than wild-type littermates (Dr. Yaacov Barak, unpublished results). Furthermore, immunohistochemical analysis of neonatal mouse pituitary tissue showed that LCoR expression increased postpartum potentially through signaling by estrogen, which is consistent with the mouse knockout model, which suggests a critical role for LCoR postpartum (Wang et al. 2007). Similarly, CtBP1 knockout mice were viable, but were small and died early (Chinnadurai 2003). This suggests that LCoR and CtBP1 might be co-regulating the same genes during development. These results coupled with the observation that LCoR localizes to and represses the *GH1* promoter in a mouse pituitary cell line (Wang et al. 2007) indicate that although its role in early development is not critical, signal-dependent postpartum induction of LCoR and its subsequent regulation of genes is essential in later development.

Subcellular Localization

Immunohistochemical analysis has shown that LCoR localizes to discrete nuclear bodies in the cell. The same type of analysis has also shown that these bodies contain CtBP1, CtBP2, CtIP, and polycomb ring finger oncogene (BMI1) (Fernandes et al. 2003; Palijan et al. 2009a; Palijan et al. 2009b). CtIP and BMI1, integral components of polycomb group repressor (PcG) complexes (Chinnadurai 2006; Fasano et al. 2007; Sewalt et al. 1999), associate indirectly with LCoR (Palijan et al. 2009b), and as such these observations suggest a possible role for LCoR in PcG complexes, which play an important role in cellular identity during development (Schuettengruber and Cavalli 2009).

Disease

Little is known concerning LCoR and its expression in disease states. In bladder cancer, a study found that LCoR mRNA expression was significantly (more than 0.5 fold) lower in more aggressive human cell lines compared with a less aggressive cell line (Abedin et al. 2009). A similar analysis of LCoR expression in a panel of breast cancer cell lines did not establish a correlation between LCoR and expression of ERα, or of cofactors CtBP1 or histone deacetylase 6 (HDAC6), nor did there appear to be a correlation with cancer aggresiveness (Dr. Sylvie Mader, unpublished results). Nevertheless, caution must be exercised when drawing conclusions from mRNA data as it may not correlate well with protein expression. Indeed, early and ubiquitous expression of LCoR, its critical role postpartum, and the possibility of various pleiotropic effects through interactions with different nuclear receptors, suggest that LCoR might be an important player in disease, particularly cancer development. However, determination of whether it acts in a tumor suppressor or oncogene fashion requires more experimental data.

Summary

A survey of the literature on LCoR reveals that it has been characterized extensively as a ligand-dependent nuclear receptor corepressor, which is expressed early in development and ubiquitously. Additionally, its developmental role becomes crucial postpartum. However, no information exists on the specific mechanisms controlling LCoR expression and turnover neither in the embryo nor the adult.

LCoR functions by recruiting the NAD(H)-dependent repressors, CtBPs, and histone deacetylases. The fact

that CtBP activity is dependent on the NADH/NAD+ ratio suggests that LCoR repression could be affected by metabolic activity. Furthermore, it is not known how LCoR recruits cofactors, and if it is dependent on other signals. Accumulating evidence shows that LCoR may also have co-activator roles. Differential co-activator/corepressor roles enacted by transcriptional regulating complexes must depend at least in part in endogenous signals. These signals could result in posttranslational modifications that direct the assembly of complexes with transcriptional roles specific to different tissues. How LCoR is modified by these signals and participates in these multiprotein complexes remains poorly understood and highlights the fact that much remains to be accomplished in order to elucidate the mechanisms surrounding LCoR function.

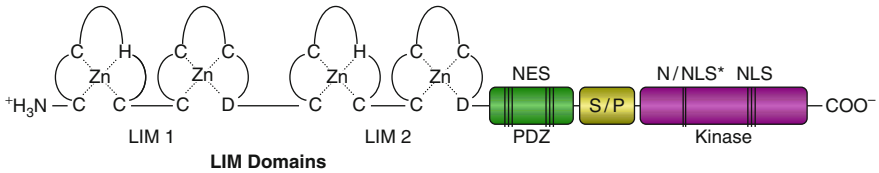
Historical Background

The two members of the LIM kinase (LIMK) family of proteins include LIMK1 and LIMK2. LIMK1, the first of these unique serine kinases to be characterized, was also identified as the murine Kiz-1 protein (Bernard et al. 1994). The second highly related family member, LIMK2, was cloned using a LIMK1 cDNA probe (Okano et al. 1995). These two LIMK family members have identical genomic structures with 16 exons and identical intron/exon boundaries (Bernard et al. 1996; Ikebe et al. 1997). They share a total of ~50% amino acid sequence identity with ~70% identity in their kinase domain (Okano et al. 1995). The structure of the LIMK proteins is unique as they contain two different protein–protein interaction domains, namely, LIM (Lin 11, Isl 1, Mec 3) and PDZ (PSD-95, Dlg, ZO-1) domains. Two tandem LIM domains lie at the N-terminal followed by a central PDZ domain. These two domains are separated from the kinase domain by a serine- and proline-rich region (S/P) with an unknown function (Stanyon and Bernard 1999). The LIMK kinase domain contains putative tyrosine kinase sequences as well as serine/threonine kinase motifs. However, to date no cellular tyrosine kinase activity has been identified as well as cellular substrate phosphorylation on threonine residues, therefore implicating the LIMK proteins as serine kinases. The kinase domain also contains a putative nuclear localization signal and only LIMK2 has a specific nuclear and nucleolar localization signal (Fig. 1).

The LIMK Isoforms

Several isoforms resulting from alternative splicing were identified for LIMK1 and LIMK2. There are three LIMK1 isoforms: full length LIMK1, LIMK1 short (LIMK1-s) lacking 20 amino acids in the kinase domain rendering it inactive because of modifications to the ATP binding site (Stanyon and Bernard 1999), and a truncated protein dLIMK1, which is devoid of the kinase domain (Edwards and Gill 1999). LIMK2 has two major isoforms that are transcribed from two independent sites, resulting in the full-length LIMK2a and the N-terminal truncated LIMK2b that lacks the first zinc finger of the LIM domain but contains 22 new amino acids acquired from the adjacent 5′ intron (Ikebe et al. 1997). Functional differences between the two LIMK2 isoforms have recently been determined and will be discussed below. Another less studied LIMK2 isoform is tLIMK2, a testis-specific isoform that lacks LIM domains and part of the PDZ domain, suggesting a role of this protein in spermatogenesis (Takahashi et al. 2002).



LIMK, Fig. 1 *LIMK protein domain organization*. The LIMK proteins consist of an N-terminal double LIM domain region, a central PDZ domain followed by a serine and proline rich region (S/P), and a C-terminal protein kinase domain. NLS is the site of a putative nuclear localization signal, and NES represents the two nuclear export signals. N/NLS* is the LIMK2 specific nuclear and nucleolar localization signal

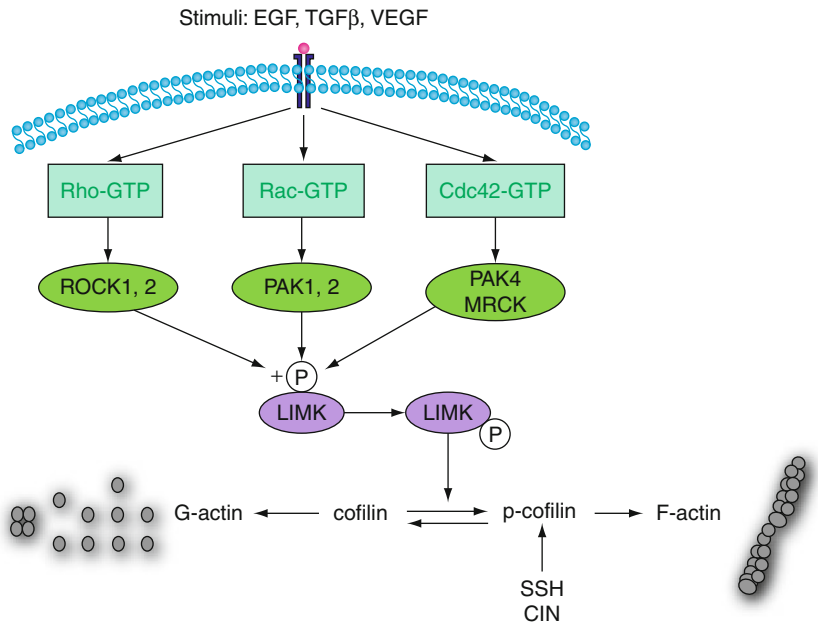
LIMK Substrates: Function and Regulation

LIMK substrates and general function: The most extensively characterized substrates of LIMK are cofilin 1 (non-muscle cofilin), cofilin 2 (muscle cofilin), and destrin (actin depolymerizing factor or ADF). The ADF/cofilin family of actin depolymerizing factors are central players in the regulation of actin-driven cellular processes such as cytokinesis, membrane ruffling, phagocytosis, cell motility, fluid phase endocytosis, and neurite outgrowth (Bamburg 1999). These small molecular weight (15–20 kDa) proteins (referred to herein as cofilin) are essential for the high turnover rates of actin filaments seen in cells. Cofilin binds to both filamentous actin (F-actin) and globular actin (G-actin). Upon binding to F-actin, it induces a conformational change that leads to a twist in the filament and increases the off rate of actin subunits at the pointed end. These conformational changes increase the thermodynamic instability of the actin polymer which is also responsible for cofilin's severing activity (Bamburg 1999). Cofilin is also able to form a complex with G-actin; however, it has a greater binding affinity to actin-ADP than actin-ATP. Binding of cofilin to actin-ADP inhibits nucleotide exchange and thus acts as a sequestering protein by reducing the pool of actin-ATP available for polymerization. The combined functions of cofilin (depolymerizing, severing, and sequestering) increase actin turnover by increasing the number of free-barbed ends as well as actin monomers necessary for the assembly of a new filament (Bamburg 1999). Cofilin's activity is primarily regulated by phosphorylation at the highly conserved serine 3 residue. Phosphorylation at this site inhibits cofilin's ability to bind to F-actin and to induce its depolymerization, resulting in the accumulation of actin filaments (Moriyama et al. 1996; Nebl et al. 1996). The important discovery that LIMK phosphorylates cofilin and inhibits its activity, resulting in the accumulation of F-actin, identified the members of the LIMK family as important regulators of actin dynamics (Arber et al. 1998; Yang et al. 1998).

Other less studied LIMK substrates are the transcription factors ▶ CREB and Nurr1, suggesting a link through LIMK to transcriptional regulation. LIMK activation by FGF leads to increased CREB phosphorylation and CREB-responsive promoter activity (Yang et al. 2004). Nurr1 is an orphan receptor belonging to the nuclear receptor family that regulates gene transcription via hormone response elements in promoter sequences. LIMK1 phosphorylated Nurr1, leading to diminished transcriptional activity from a promoter/reporter construct (Sacchetti et al. 2006).

Another LIMK1 substrate is p25, also known as tubulin polymerization promoting protein (TPPP). When phosphorylated by LIMK1, p25/TPPP loses its ability to promote microtubule (MT) assembly resulting in MT disassembly in vitro and in cells (Acevedo et al. 2007).

LIMK regulation: In the initial studies leading to the discovery that LIMK1 regulates actin dynamics via phosphorylation of cofilin, it was demonstrated that LIMK1 was activated through the Rho-GTPases (Arber et al. 1998; Yang et al. 1998). This identified a novel pathway by which the Rho-GTPases regulate the actin cytoskeletal changes in response to the cellular environment via LIMK1. Furthermore, it was shown that the activity of the LIMK proteins is regulated by the phosphorylation of a threonine residue in the activation loop by the kinases activated by the Rho-GTPases. Both LIMK1 and LIMK2 are phosphorylated by the Rho effectors ▶ Rho-associated kinase 1 and 2 (ROCK1 and ROCK2) on the conserved threonine residues, Thr-508 (LIMK1) (Ohashi et al. 2000) and Thr-505 (LIMK2) (Amano et al. 2001; Sumi et al. 2001a). p21-activated kinase (PAK) 1, 2, and 4 were



LIMK, Fig. 2 *Regulation of LIMK activity*. LIMK activity is regulated by the Rho family of small GTPases via their downstream serine/threonine kinases. ROCK 1 and 2 and PAK 1, 2, and 4. These kinases phosphorylate LIMK on a threonine residue in the activation loop of their kinase domains (LIMK1 Thr508 and LIMK2 Thr505). Activated phospho-LIMK phosphorylates cofilin at Ser3. Phospho-cofilin (p-cofilin) loses its ability to bind to actin filaments (F-actin) and sequester actin monomers (G-actin) resulting in accumulation of F-actin. The cofilin phosphatases SSH and CIN reactivate cofilin and increase its activity

also shown to activate LIMK1 (Edwards et al. 1999; Misra et al. 2005; Dan et al. 2001). PAK 4 activates LIMK1 not only through phosphorylation of Thr-508 but also through phosphorylation and inactivation of the LIMK phosphatase slingshot (see below) (Soosairajah et al. 2005). The myotonic dystrophy kinase-related Cdc42-binding kinase (MRCKα) has been reported to phosphorylate and activate both LIMK1 and LIMK2 (Sumi et al. 2001b). The most studied LIMK activators are ROCK1 and 2. Only limited information on the role of the other kinases mentioned above in LIMK activation is available.

LIMK activity is also regulated by auto- and trans-phosphorylation. Unphosphorylated LIMK1 has a short half-life of ~4 h, in comparison the phosphorylated protein has a half-life of ~24 h. LIMK transphosphorylation is mediated by its association with Hsp90 which promotes homodimerization and transphosphorylation, leading to the formation of stable LIMK dimers with increased specific activity (Li et al. 2006).

Other less studied LIMK1 activators are summarized below:

- MAPK/MK2 phosphorylates both Hsp27 and Ser323 of LIMK1, via VEGF-A regulation.
- Semaphorin upregulates LIMK2 activity in the presence of plexin C1, a receptor for semaphorin 7A.
- Neuregulin interacts with and activates LIMK1.
- The interaction between 14-3-3 and LIMK1 increases cofilin phosphorylation by an unknown mechanism.
- PKA activates LIMK1 by phosphorylation at serine 323 and 596.
- PKC activates LIMK1 by direct interaction.
- SDF-1a activates LIMK1.
- Nogo-66 activates LIMK1 by a ROCK-dependent phosphorylation.
- Ionomycin/CaMKIV activate LIMK1 by direct phosphorylation at Thr508.

Phosphorylation and activation of proteins can be reversed by dephosphorylation. The slingshot 1 (SSH1) phosphatase, previously identified as a cofilin phosphatase (Niwa et al. 2002), was also found to dephosphorylate and inactivate LIMK1 (Soosairajah et al. 2005). Another less studied cofilin phosphatase is chronophin (CIN) (Gohla et al. 2005) (Fig. 2).

The association of the LIM and PDZ domains with the kinase domain inhibits LIMK activity, while deletion of both the LIM and the PDZ domains as well as mutations in the second LIM and PDZ domains lead to a significant increase in LIMK activity, suggesting that the N-terminal region controls the activity of LIMK. LIMK activity can be negatively regulated by unknown, mechanism

through its interaction with several proteins as summarizes below:

- The ubiquitin ligases Rnf6 and parkin induce the proteasomal degradation of LIMK.
- Nischarin inhibits the Rac/PAK activation of both LIMK1 and LIMK2 by direct association with LIMK.
- LATS1 interacts with and reduces LIMK1 activity.
- Par-3 interacts with and inhibits LIMK2 activity in vitro and its overexpression suppresses cofilin phosphorylation that is induced by lysophosphatidic acid.
- The cytoplasmic tail of BMPR-II interacts with and inhibits the activity of LIMK.

In addition, miR-134 inhibits LIMK1 mRNA translation in neurons.

Specific regulation of the LIMK2 isoforms: Recently, it was reported that ▶ p53 induces the expression of LIMK2b, but not that of LIMK2a, after DNA damage by binding to a p53-binding consensus motif in intron 1 of the LIMK2b gene (intron 2 of LIMK2a) (Hsu et al. 2010). The transcription factor p53 is an important cell cycle regulator. After DNA damage, p53 activation induces cell cycle arrest and the activation of pro-survival pathways allowing DNA damage repair. However, with excessive DNA damage, p53 activation may lead to apoptotic cell death. Ectopic p53 expression increases LIMK2b expression and cofilin phosphorylation (Hsu et al. 2010), suggesting that the LIMK2b-mediated actin regulatory function is required for cell cycle arrest. While these results demonstrate that LIMK2b has a role in G2/M cell cycle arrest, the reason for specific p53-mediated LIMK2b induction remains elusive. It is possible that LIMK2b has a distinct role in the cell.

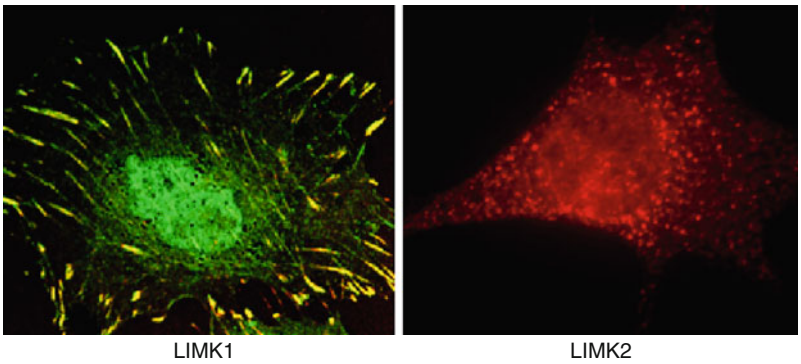
Apart from specific LIMK2b induction following increased p53 levels after DNA damage caused by radiation or drugs such as doxorubicin, no other functional difference between the LIMK2 isoforms have been established to date. Overexpression of LIMK2a or LIMK2b reduced both cell proliferation and viability, and resulted in multi-nucleated cells. These cellular changes were more pronounced with enforced LIMK2b expression, suggesting that the additional 22 amino acids replacing the first zinc-finger may increase LIMK2 activity. Finally, analysis of a large cohort of cell lines by RT-PCR demonstrated that LIMK2a and LIMK2b were differentially expressed in a number of cell lines. Interestingly, the levels of LIMK2a and LIMK2b are downregulated in thyroid cancers while in esophageal cancers LIMK2b is downregulated but LIMK2a levels are increased in comparison to normal tissues (Hsu et al. 2010).

Expression and Cellular Localization of LIMK

LIMK1: Early studies on the expression of LIMK1 mRNA identified it mainly as a brain specific protein (Bernard et al. 1994; Mizuno et al. 1994). However, with the development of good anti-LIMK1 antibodies it was demonstrated that LIMK1 is expressed in all the cells of mouse tissues but at different levels (Foletta et al. 2004). LIMK1 gained special attention due to its high level of expression in cell lines generated from metastatic human breast and prostate tumors, with the notion that LIMK1 may be involved in cancer metastasis (see below).

LIMK1 has a distinct cellular localization. It resides mainly in the cytoplasm with lower levels in the nuclei. In the cytoplasm it localizes with F-actin in stress fibers and at focal adhesions. At focal adhesions it colocalizes with paxillin (Fig. 3) (Foletta et al. 2004). In Human umbilical vein endothelial cells (HUVEC) LIMK1 is localized to microtubules (MT) (Gorovoy et al. 2005). Similarly, LIMK1 colocalizes with MTs during mitosis, in particular during prophase, metaphase, and anaphase, while it accumulates at the contractile ring during telophase. However, Sumi et al. demonstrated that during cell division LIMK1 dynamically localizes to the mitotic apparatus. At metaphase it localizes to the spindle poles, while at late anaphase it is distributed exclusively along the lateral cytoplasmic membrane before transitioning to the contractile ring during telophase (Sumi et al. 2006). The activation and dynamic localization of LIMK1 during mitosis suggests the involvement of LIMK1 in cell division (Kaji et al. 2008).

LIMK2: As for LIMK1, early data on LIMK2 expression in mouse tissues relied on mRNA expression due to the lack of suitable anti-LIMK2 Abs. LIMK2, like LIMK1, is expressed in all mouse tissues (Acevedo et al. 2006). Although both proteins are expressed in both the nuclei and the cytoplasm the subcellular localization of LIMK2 is distinct from that of LIMK1. LIMK2 clearly localizes to punctae resembling endosomes in several cell lines and mouse embryonic fibroblasts (Fig. 3) (Acevedo et al. 2006). In NIH3T3 cells LIMK2 protein is also associated with GM130, a protein associated with the *cis*-compartment of the Golgi apparatus (Acevedo et al. 2006).



LIMK, Fig. 3 *Cellular localization of LIMK1 and LIMK2*. In the cytoplasm, LIMK1 localizes with F-actin in stress fibers (*green*) and at focal adhesions. At focal adhesions it colocalizes with paxillin (*yellow*). LIMK2 clearly localizes to punctae resembling endosome. Both proteins are also found in the nucleus

Immunofluorescence staining showed that during mitosis the localization of LIMK2 is similar to that of LIMK1 (Gamell-Fulla and Bernard). LIMK2 is associated with the mitotic spindle-like structure during mitosis and accumulates at the centrosomes in prometaphase. During the metaphase to anaphase transition, LIMK2 redistributes to the mitotic spindle and finally to the spindle midzone in telophase (Sumi et al. 2006). The distinct subcellular localization of LIMK2 suggests that it may have different substrates and cellular functions to that of LIMK1.

LIMK1 and Cancer Metastasis

Consistent with the role of LIMK1 in the regulation of the actin cytoskeleton there is growing evidence to indicate that LIMK1 plays an important role in tumor cell invasion and metastasis. High LIMK1 expression was found in metastatic melanoma cells (Wang et al. 2004), breast and prostate tumors (Wang et al. 2004; Davila et al. 2003), and tumor cell lines (Davila et al. 2003; Yoshioka et al. 2003). Several studies have implicated the involvement of LIMK1 in cell invasion and cancer metastasis. Downregulation of LIMK1 activity by expression of dominant-negative LIMK1 in the invasive human breast cancer cell line MDA-MB-231 reduced their invasion in vitro and in mice while overexpression of LIMK1 in the non-invasive MCF7 human breast cancer cells increased their invasion (Yoshioka et al. 2003). Similarly, expression of LIMK1 in MDA-MB-435 human breast cancer cells enhanced their proliferation, invasiveness, and promoted angiogenesis in vitro. When injected to immunocompromised nude mice these cells grew faster, promoted tumor angiogenesis, and induced liver and lung metastasis. (Bagheri-Yarmand et al. 2006). Benign prostate epithelial cells overexpressing LIMK1 exhibit increased expression of Membrane type matrix metalloproteinase 1 (MT1-MMP), a critical modulator of extracellular matrix (ECM) turnover through pericellular proteolysis that plays crucial roles in neoplastic cell invasion and metastasis. MT1-MMP and LIMK1 are both highly expressed in prostate tumor tissues (Tapia et al. 2011).

A recent study demonstrated that not only LIMK1 but also LIMK2 promote the metastasis of pancreatic cancer cells using a cell-based in vitro migration assay, as well as two zebra fish xenograft assays. The double knock down of LIMK1 and LIMK2 completely blocked invasion and formation of micrometastasis in vivo suggesting that both LIMK proteins have an important role in tumor progression and metastasis formation (Vlecken and Bagowski 2009). Scott et al. demonstrated that inhibition of LIMK activity by the pharmacological agent BMS3 (LIMKi) or by siRNA mediated knockdown blocks the collective invasion of MDA-MB-231 breast carcinoma cells growing in three-dimensional (3D) matrices (Scott et al. 2010). LIMK activity was also required for the collective invasion of squamous carcinoma cells (SCCs) in a 3D organotypic skin model, but it was not required for cell motility in two dimensions (2D). However, as described previously (Bagheri-Yarmand et al. 2006), LIMK was responsible for extracellular matrix (ECM) degradation in 3D cultures but not for path finding in MDA-MB-231 or SCCs (Scott et al. 2010).

Summary

The members of the LIM kinase family, LIMK1 and LIMK2 are ubiquitously expressed serine kinases that share identical genomic structure and ~50% overall identity. The most studied substrates of LIMK1 and

LIMK2 are the actin depolymerizing factor ADF/cofilin family of proteins. These actin binding proteins bind to and severe actin filaments (F-actin) and sequester actin monomers resulting in actin depolymerization. Phosphorylation of cofilin by LIMK inhibits its actin binding activity resulting in the accumulation of F-actin. The activity of the LIMK proteins is regulated by the Rho-GTPases: Rho, Rac, and Cdc42 via their downstream effector kinases ROCK 1 and 2, PAK 1, 2, and 4, which phosphorylate LIMK on a threonine residue. Although the LIMK proteins show significant structural similarity, their expression pattern, subcellular localization, regulation, and functions are different. They are involved in many cellular functions, such as cell migration, cell cycle, and neuronal differentiation and also have a role in cancer cell invasion and metastasis. The actin cytoskeleton plays a pivotal role in the motility of normal cells and in the invasive capacity of tumor cells. Both polymerization and depolymerization of actin are required for cell motility and invasion. LIMK1 levels are high in metastatic breast, prostate, and melanoma tumors and in a variety of invasive cell lines. Overexpression of LIMK1 in breast and prostate cancers increased their invasion in vitro and in mice while downregulation of its activity reduced their invasiveness, suggesting that inhibition of LIMK activity with pharmacological agents may be used to inhibit the metastatic spread of cancer cells.

Lysyl oxidase

Background

The extracellular matrix (ECM) is a dynamic milieu that provides a structural and signaling environment necessary for cell proliferation, differentiation, and migration in normal and pathological processes including embryonic development, tissue homeostasis and repair, inflammation, tumor invasion, and metastasis. While the composition of the ECM is unique in each organ, its main components consistently include various types of collagens, noncollagenous glycoproteins, and a range of enzymes essential for ECM assembly and maintenance. Lysyl oxidase (LOX) is one of these enzymes in the ECM. LOX is a copper-dependent amine oxidase that oxidatively deaminates specific peptidyl lysine and hydroxylysine residues within its substrates of which best known are fibrillar collagens and elastin. The resulting reactive aldehyde residues then spontaneously condense to form covalent intra- and intermolecular cross-linkages leading to the development of insoluble ECM matrices. Besides the cross-linking activity of LOX in the ECM of skin, lung, cardiovascular, and other systems, novel roles have also been recognized for LOX including significant ECM and cellular signaling. In mammals, the LOX family has five members, including LOX and four LOX-like proteins (LOXL1-4). The C-terminal region is highly conserved among all five members and includes a copper-binding site, a cytokine receptor-like (CRL) domain, and residues that form the lysine tyrosylquinone (LTQ) cofactor (Csiszar 2001). The N-terminal regions of the LOX-like proteins are more variable and different from LOX and include a proline-rich region in LOXL1 and four scavenger receptor cysteine-rich (SRCR) domains within LOXL2, LOXL3, and LOXL4. Emerging evidence indicates that the LOX-like proteins are also catalytically active but have different temporal and tissue specific expression, different substrates, and different functions.

Regulation of LOX Expression

The mRNA transcribed from the human LOX gene (chromosome 5q23.3–31.2) that encodes a 417 amino acid polypeptide, varies in size from 2.0 to 2.4, 4.3, and 5.5 Kb due to the use of alternate polyadenylation and multiple transcription initiation sites for which the regulating mechanisms and functions are poorly defined. During development and tissue remodeling, LOX expression is prominently associated with the assembly of collagen and elastic fibers in tissues including skin, aorta, placenta, and lung. A large number of cell types have been shown to express LOX and these include fibroblasts, smooth muscle cells from the aorta and lung, osteoblasts, osteosarcoma cells, myofibroblasts, chondrocytes, epithelial and endothelial cells, basal cells, liver parenchymal cells, spleen reticulum cells, kidney glomeruli, medulla, and other renal cell lines. LOX mRNA expression is highly responsive to a variety of cytokines and growth factors. Basic fibroblast growth factor (b-FGF) downregulates LOX in fibroblastic, epithelial, and osteoblastic cell lineages. Similarly, interferon-γ (IF-γ) downregulates LOX in aortic smooth muscle cells and prostaglandin E2 (PGE2) in embryonic smooth muscle cells and neonatal lung fibroblasts. Among the positive LOX regulators, transforming growth factor-β1 (TGF-β1) upregulates LOX mRNA, protein levels and activity in fibroblasts, osteoblasts, and aortic smooth muscle cells. Platelet-derived growth factor (PDGF) upregulates LOX mRNA in retinal pigment epithelial cells and vascular smooth muscle cells. Insulin-like growth factor-I (IGF-I) increases LOX protein level in oral tissue. Among hormonal regulators, follicle stimulating hormone (FSH) decreases LOX mRNA expression and activity in granulosa cells, while testosterone increases both LOX mRNA level and activity. Stem cell factor (SCF), brain-derived neurotropic factor (BDNF), and C-type natriuretic peptide (CNP) stimuli induce LOX transcription as noted during chondrocyte differentiation. Bone Morphogenetic Protein-2 and Bone Morphogenetic Protein-4 (BMP-2, -4) also upregulate LOX protein expression during adipocyte stem cell differentiation, while blocking the BMP-2

pathway by knockdown of Sma and Mad Related Protein 4 (SMAD4) results in reduced LOX expression and abolished acquisition of the adipocyte phenotype that is critically dependent on LOX expression.

Regulation of LOX Activity

The human LOX protein is synthesized as a 48 kDa preproenzyme with a 21 amino acid signal sequence at the N-terminus. Following N-terminal glycosylation, the signal peptide is removed and the copper cofactor is incorporated into the protein within the Golgi apparatus resulting in an intermediary, catalytically inactive 50 kDa proenzyme that is subsequently secreted to the extracellular space. In the ECM, the pro-LOX is activated by proteolytic cleavage by procollagen C-proteinase/BMP-1. The proteolytic activation of the intermediary proenzyme yields a mature ECM enzyme of 30 kDa and an 18 kDa N-terminal propeptide fragment. Fibronectin and the microfibrillar network play a role in regulating LOX activation and localization in the ECM.

LOX in Fibrotic Disorders and TGF-β Signaling

In fibrotic diseases, increased collagen expression and enhanced LOX expression and activity result in increased cross-linking and accumulation of insoluble collagen fibers. Strong association has been reported between organ fibrosis and increased LOX activity in experimental fibrosis, lung, arterial, dermal, kidney fibrosis, and pathological conditions leading to fibrosis.

During the fibrotic process, changes in the expression level of type III collagen were noted to parallel changes both in the level and activity of LOX (Kim et al. 1999). Subsequently, the active LOX was reported to translocate into the nuclei and enhance collagen-3A1 (*COL3A1*) gene promoter activity in monkey renal (COS-7) and human primary skin fibroblasts. In addition to the association between LOX and type III collagen expression, increases in LOX expression were also linked to type I collagen expression (Hong and Trackman 2002) and it was proposed that the LOX and the *COL1A1* and *COL1A2* genes may be co-regulated by their similar TGF-β response elements within their promoters. Consistent with this mechanism, upregulated TGF-β/p38 mitogen-activated protein kinase (p38MAPK) signaling increased both LOX levels and collagen synthesis in maternal obesity-associated fetal muscle fibrogenesis.

Notably, a direct interaction between the LOX protein and TGF-β1 has also been reported by which interaction LOX was able to suppress TGF-β1 induced SMAD3 phosphorylation. Significantly, this effect proved to be due to the BAPN-sensitive amine oxidase activity of LOX, and not to its peroxide production that is a dominant LOX-associated signaling mechanism in multiple tumor types. In interactions with TGF-β1, LOX may be involved in oxidative deamination of lysine residues within the lysine-rich terminus in TGF-β1, a process that could change charges or covalently stabilize the conformation of TGF-β1. Such change may interfere with binding of TGF-β1 to its receptor leading to diminished signaling via SMAD3 in a cross-talk with Phosphoinositide 3-kinase (PI3K) and Akt serine-threonine protein kinase (Atsawasuwan et al. 2008).

Interestingly, in a novel microfibrillar network-associated fibrotic skin disorder, LOX overexpression was not accompanied by either increased TGF-β1 expression or signaling (Szauter et al. 2010). However, genes of the microfibrillar network including fibrillin-2 (FBN2), microfibril-associated glycoprotein 2, microfibril-associated protein 4, latent TGFβ-binding protein 1 (LTBP1), fibulins 1 and 3 (FBLN1, 3), and decorin were found downregulated leading to compromised synthesis and assembly of the microfibrillar scaffold reflected in the disorderly assembly of elastic fibers. Interactions between LOX and microfibrillar proteins FBLN-1, FBLN-4, and fibrillin 1 (FBN1) have been established and in this case of dermal fibrosis the disorderly microfibrillar network clearly contributed to deregulated LOX expression and activity. The microfibrillar network is also known to regulate TGF-β1 activity; however, in this case, there was no increase in SMAD2 phosphorylation further supporting the conclusion that TGF-β1 did not play a major role in LOX regulation in the pathomechanism of this particular fibrotic disease.

LOX in Tumor Development and Invasion

LOX, in addition to its function in the ECM, has also been noted for significant intracellular and intranuclear

activities, a tumor suppressor role (Csiszar 2001), and contrasting essential roles during tumor invasion and metastasis (Payne et al. 2005; Baker et al. 2011). Studies of LOX signal transduction suggested that LOX is able to affect signaling pathways downstream of extracellular signal-regulated kinase (ERK2) and influence oncogenic RAS-dependent meiotic maturation. A RAS-related tumor suppressor activity for LOX (RAS-recision gene or *RRG*) was reported in RAS-transformed mouse NIH3T3 (Kenyon et al. 1991) and other Ha-ras transformed fibroblasts. Some of the complex signaling pathways associated with the tumor suppressor activity of LOX have been since localized to the LOX propeptide (LOX-PP) and are summarized in the subsequent section.

In the hypertrophic stroma surrounding the in situ tumors in human breast and bronchopulmonary carcinomas increased LOX expression likely participates in the formation of a peritumor barrier, however, the significance of LOX functions in the tumor stroma remained largely unexplored. Importantly, a recent study identified a role for tissue stiffness linked to increased LOX cross-linking of collagen I in the tumor ECM resulting in increased focal adhesion and integrin β1 signaling, and elevated phosphorylation of focal adhesion kinase (FAK)^{Y397}and CRISPR-associated protein ^{p130}CAS. Modified ECM-induced integrin β1 signaling additionally activates PI3K and EGF-mediated phosporylation of Akt^{S473} resulting in increased tumor cell adhesion and invasion (Levental et al. 2009).

In breast tumor epithelial cells, increased LOX expression and enzyme activity proved to be strongly associated with invasive properties. As noted earlier in monocytes and smooth muscle cells, in tumor epithelial cells, cell migration depended on H_2O_2 generated during the catalytic reaction of the active LOX with its substrates. LOX-generated H_2O_2 mediated breast tumor cell migration and invasion by activating FAK/SRC signaling (Payne et al. 2005) that was also confirmed in colorectal cancer cells (Baker et al. 2011). Furthermore, LOX expression was associated with increased metastasis of breast tumors (Erler et al. 2006; Payne et al. 2006). Astrocytoma and glioma cell lines and tissues also demonstrated high levels of LOX expression that correlated with increased tumor grade and increased activation of FAK/paxillin signaling (Laczko et al. 2007). In tumor cells, the LOX-associated invasive mechanism further involved increased lamellipodia formation by affecting signaling downstream of FAK, involving the CAS/CRK/DOCK signaling complex, activation of RAC GTPase, and a direct activation of the PI3K/Akt pathway as demonstrated in human colorectal carcinoma cell lines (Pez et al. 2011).

Within tumors, hypoxic conditions are known to upregulate LOX involving the hypoxia inducible factor (HIF) demonstrated in breast (Erler et al. 2006) and colorectal carcinoma cells where the HIF-1α subunit induced LOX expression (Pez et al. 2011). In turn, LOX is able to reciprocally enhance HIF-1α expression through its catalytic activity and the subsequent production of H_2O_2 through PI3K/Akt signaling, thus the mutually regulated HIF and LOX synergistically promote tumor cell growth and proliferation.

The LOX Propeptide in RAS, NF-κB, and FAK Signaling

The 18 kDa LOX propeptide (LOX-PP) is required for optimal LOX secretion and is proteolytically removed in the ECM as part of the activation process by BMP-1. LOX-PP due to its high isoelectric point can reenter the cell and interact with intracellular binding partners in addition to ECM molecules. Moreover, LOX-PP has a putative nuclear localization signal, and has been detected in the nucleus where it was proposed to function as a signaling molecule (Li et al. 2010).

LOX-PP inhibits several distinct signal transduction pathways that oncogenic RAS activates, including the PI3K/Akt and RAF/MAPK/ERK and the Nuclear Factor-κB (NF-κB) pathways. In lung cancer and pancreatic cancer cells ectopic expression of LOX-PP reduces activation of the ERK cascade inhibiting growth and invasive colony formation (Wu et al. 2007). LOX-PP also inhibits Akt-dependent induction of RAS in c-Ha-RAS-transformed NIH3T3 cells resulting in decreased cell proliferation and migration. Signaling of FGF-2 that induces ERK/MAPK phosphorylation was also inhibited by LOX-PP in MC3T3 and osteoblast cultures by reducing FGF-2 binding to its receptors. In androgen-independent prostate cancer cell lines with high levels of RAS, LOX-PP inhibited serum-stimulated DNA synthesis in a dose-dependent manner: in DU145 cells through the MEK/ERK and PI3K/Akt pathways, and in PC-3 cells through a different mechanism, demonstrating that

LOX-PP has more than one molecular target (Palamakumbura et al. 2009). In smooth muscle cells (SMC), LOX-PP effectively reduced TNF-α stimulated ERK/MAP kinases, cell proliferation, and matrix metalloproteinase-9 (MMP-9), mechanisms that are relevant to the development of atherosclerosis (Hurtado et al. 2008).

NF-κB directly induces expression of genes that promote tumor cell survival and proliferation, resistance to chemotherapy, neoplastic transformation, and maintenance of an invasive phenotype. In pancreatic and lung cancer cell lines LOX-PP substantially reduced levels of NF-κB and its tissue specific target BCL-2 and decreased the ability of these cells to migrate (Wu et al. 2007). LOX-PP also inhibited transformation of murine breast cancer cells driven by Her-2/neu, an upstream activator of RAS via NF-κB activation. In these cells LOX-PP reversed Her-2/neu-induced migration and epithelial to mesenchymal transition (EMT) as measured by reduced levels of Snail and vimentin, upregulation of E-cadherin, and inhibited tumor formation (Min et al. 2007). In mice a mutation within neuronal nuclear protein induced by axotomy (Nna1) was noted to increase expression and intranuclear localization of LOX-PP in Purkinje cell nuclei. This excess LOX-PP inhibited NF-κB/RelA signaling and decreased microtubule-associated proteins MAP1B and MAP2, regulators of microtubule stability leading to underdevelopment of Purkinje cell dendrites (Li et al. 2010).

The FAK/SRC/CAS signaling pathway that is crucial for cell migration and invasion is also affected by LOX-PP that was found to inhibit fibronectin-mediated signaling via FAK and CAS^{p130} and fibronectin-stimulated migration of breast cancer cells (Zhao et al. 2009). In murine breast cancer cells, LOX-PP decreased the phosphorylation of FAK Y397 and Y576 that resulted in diminished recruitment of its substrate CAS to focal adhesion sites. Recombinant LOX-PP protein also inhibited the migration of the invasive human MDA-MB-231 and Hs578T breast cancer cells. Recently, a G473A polymorphism resulting in an Arg-to-Gln substitution has been found to impair the ability of LOX-PP to inhibit the invasive phenotype and tumor formation of breast cancer cells (Min et al. 2009). This polymorphism was associated with an increased risk of estrogen receptor (ER)-negative breast cancer, further supporting a role for impaired LOX-PP signaling in breast cancer.

Summary

LOX is a copper-dependent amine oxidase essential for the development and maintenance of the ECM that provides a structural and signaling environment necessary for cellular and tissue functions during normal and pathological processes. LOX is one of five members of the LOX family that have variable N-terminal domains and highly conserved C-terminal regions that include the Cu-binding site and residues that form the LTQ cofactor both critical for catalytic activity, and a CRL domain. Following multiple processing steps, the 48 kDa LOX preproprotein is secreted and activated in the ECM by BMP-1 cleavage that produces an 18 kDa LOX-PP and a 30 kDa active LOX, both with distinct ECM, cellular and intranuclear functions. LOX expression is regulated by various cytokines and growth factors including b-FGF, IF-γ, PGE2, PDGF, TGF-β1, IGF-I, and hormones including FSH and testosterone. While TGF-β1 is a prominent LOX regulator in fibrotic disorders, the active LOX also directly interacts with and likely modifies lysine residues within TGF-β1 leading to reduced binding of TGF-β1 to its receptors and reduced TGF-β1/SMAD signaling. Furthermore, analysis of the pathomechanism of a novel fibrotic disorder also revealed a prominent LOX regulatory function for the microfibrillar network that appears independent of TGF-β1. The active LOX proved essential in promoting tumor development and invasion both through ECM-cell signaling and peroxide-mediated cellular signaling. The LOX-modulated ECM increases integrin β1 signaling through FAK, CAS, and PI3K/Akt signaling resulting in increased tumor cell adhesion and invasion. While peroxide generated by the catalytic reaction of LOX activates FAK/SRC/paxillin and CAS/CRK/DOC signaling and directly upregulates the PI3K/Akt pathway further promoting tumor cell migration, invasion, and metastasis. In contrast, the LOX-PP appears to function as an active inhibitor of the transformed cell phenotype through inhibiting RAS signaling and RAS-activated PI3K/Akt, RAF/MAPK pathways, signaling of FGF-2 and subsequent induction of ERK/MAPK phosphorylation, and NF-κB. Through these mechanisms LOX-PP reduces cell proliferation, migration, EMT, and tumor formation. LOX-PP can also inhibit fibronectin-mediated FAK signaling and recruitment of CAS to focal adhesion sites. Thus, the active LOX and the LOX-PP provide a dynamic balance in contrasting

functions that depend on the expression, ECM processing, and activation of LOX and turnover of the different LOX forms.

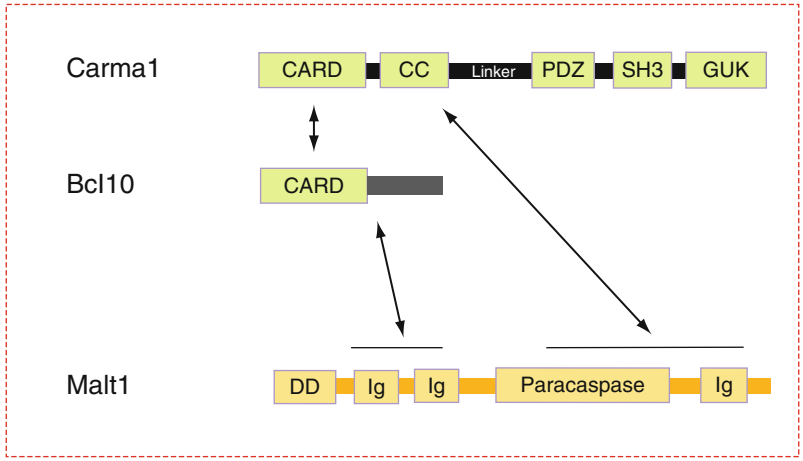
Historical Background

Around the beginnings of the 1990s several cytogenetic studies reported the occurrence of t(11;18)(q21;q21)

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

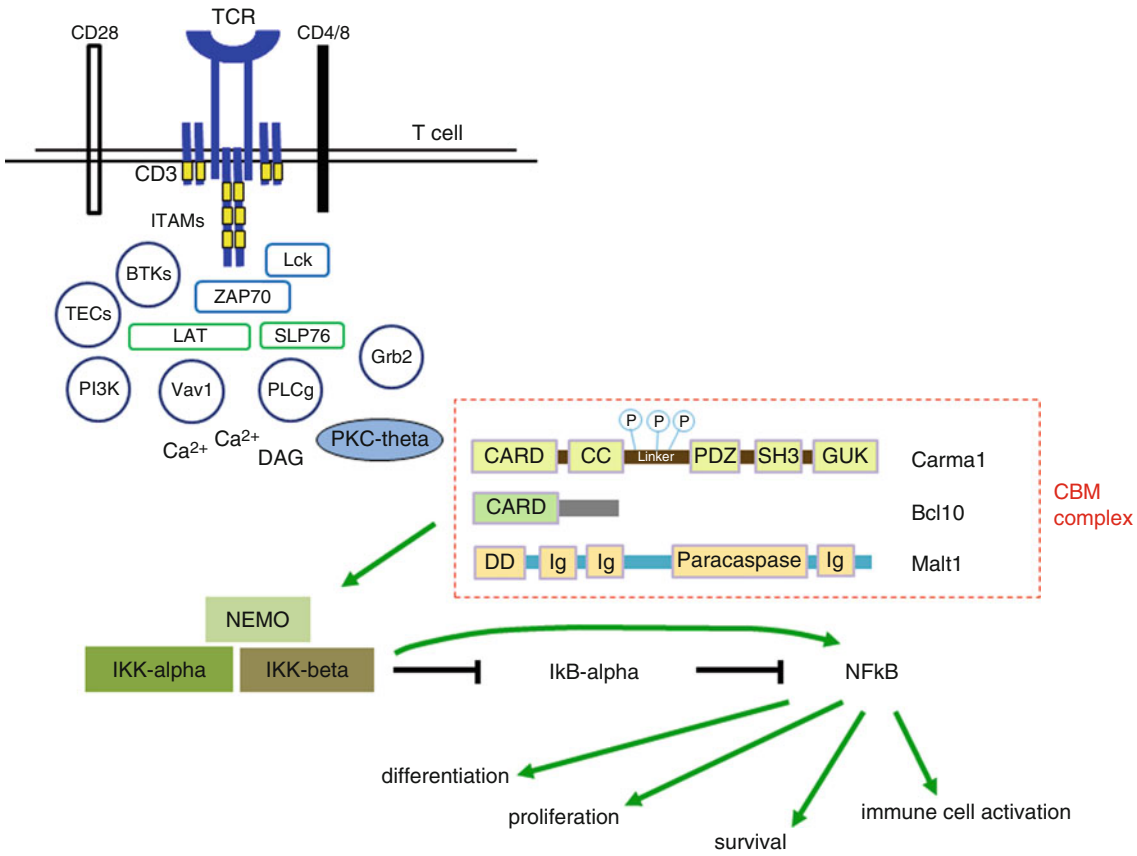


MALT1(Mucosa-Associated Lymphoid Tissue Translocation Gene 1), Fig. 1 *The CBM complex*. The CBM complex consists of the three proteins Carma1 (Card11), Bcl10, and Malt1. Bcl10 and Malt1 interact via a sequence immediately downstream of the Bcl10 CARD domain and the Ig-like domains of Malt1. While the Bcl10-Malt1 interaction is assumed to be constitutive, Bcl10-Malt1 is recruited to Carma1 in response to antigen-receptor signaling. Bcl10 and Carma1 associate via CARD-CARD interaction, and the Carma1 coiled-coil domain can bind to the C-terminal part of Malt1 that contains the paracaspase domain. The CBM complex is believed to form the core of a molecular scaffold that upon activation recruits various further signaling components to activate NF-κB and other signaling pathways

chromosomal translocations in several cases of low-grade Mucosa-Associated Lymphoid Tissue (MALT) lymphoma. Later, Akagi and colleagues identified a novel gene on chromosome 18 to be involved in the t (11;18)(q21;q21) translocation which they named *MALT1* as a candidate gene involved in the pathogenesis of MALT lymphoma (Akagi et al. 1999). Already a few months earlier, Dierlamm and colleagues also reported *MALT1* (which they named *MLT*) as part of the t(11;18)(q21;q21) translocation as well its translocation partner on chromosome 11, the *API2* gene, resulting in the expression of a *5′-API2-MALT1-3′* fusion transcript (Dierlamm et al. 1999). While the function of the *MALT1* gene product was completely unclear at that time, the *API2* gene had already been known to encode for a member of the family of inhibitor of apoptosis (IAP) proteins. Breakpoint analyses showed that the *API2* gene contributed its three baculovirus IAP repeat (BIR) motifs to the 5′ part of the *API2-MALT1* fusion transcript. Since the BIR region was known to be sufficient for the inhibition of caspases and, therefore, for the suppression of apoptosis, it was suggested that the API2-MALT1 fusion might be involved in an inappropriate inhibition of apoptosis and thereby might confer a survival advantage to MALT lymphomas. However, subsequent biochemical and genetic characterization did not support a direct role for API2-MALT1 or MALT1 in apoptosis inhibition but revealed that MALT1 (and the API2-MALT1 fusion) promotes the activation of the ▶ NF-κB signaling pathway.

MALT1 as Part of the CBM Complex

In silico analyses revealed that a C-terminal part of the MALT1 amino acid sequence has similarity to the proteolytic domain of caspases, a family of cysteine proteases centrally involved in the induction of apoptosis. Importantly, the essential catalytic histidine and cysteine diad is conserved in the MALT1 sequence. Uren and colleagues therefore proposed that human MALT1 and its orthologs in, for example, mouse, zebrafish, and *Caenorhabditis elegans* should be classified as a novel family of caspase-related proteins, the paracaspases (Uren et al. 2000). The caspase-like catalytic domain of MALT1 was called the paracaspase domain which is preceded by an N-terminal death domain (DD) and two immunoglobulin (Ig)-like domains (Fig. 1). MALT1 is known to be constitutively associated with the BCL10 protein: the interaction occurs between the MALT1 Ig-like domains and a sequence stretch (aa 107–119) immediately downstream of the Bcl10 CARD domain. BCL10 is encoded



MALT1(Mucosa-Associated Lymphoid Tissue Translocation Gene 1), Fig. 2 *TCR signaling via the CBM complex to NFkB*. The signaling events emanating from the activated T-cell receptor (TCR) complex have been studied in detail. Receptor proximal signaling leads to the activation of various kinases such as Scr and Syk family kinases and to the recruitment of adaptor molecules such as LAT and SLP76. The adaptors assemble and activate a plethora of signaling molecules, among others phospholipase C-gamma (PLCg) and protein kinase C theta (PKC-theta). PKC-theta and other kinases are thought to activate Carma1 by phosphorylation leading to the assembly of the CBM complex for activation of the IKK complex and the NF-κB transcriptional program which affects various biological processes

by a gene that had been previously shown to be involved in t(1;14)(p22;q32) chromosomal translocations associated with cases of MALT lymphomas and which upon overexpression induces NF-κB. BCL10 also interacts with the CARD-containing protein ▶ CARMA1 which also is able to activate NF-κB upon overexpression. The NF-κB-activating potential of CARMA1 and BCL10 is dependent on homotypic interaction between the CARD domains of BCL10 and CARMA1 for the formation of oligomeric protein complexes (Fig. 1). The ectopic overexpression of *Bcl10* or *CARMA1* by itself induces NF-κB, whereas overexpression of *MALT1* alone is not sufficient for NF-κB activation. However, MALT1 was shown to enhance Bcl10-mediated activation of NF-κB and it was proposed that BCL10 mediates the oligomerization of MALT1 molecules for the enhanced activation of NF-κB. This hypothesis was supported by the observation that the oligomerization of the MALT1 paracaspase domain or oligomerization of API2-MALT1 via the N-terminal BIR domains resulted in NF-κB activation. Mutation of the active-site cysteine residue of the proteolytic paracaspase domain reduced the capacity of API2-MALT1 for induction of NF-κB, however, not completely. Taken together, MALT1 was identified to be part of a complex with BCL10 and CARMA1 – the so-called CBM (CARMA1-BCL10-MALT1) complex (Thome et al. 2010) – which is involved in NF-κB activation (Fig. 2). How MALT1 is thought to be activated within the CBM complex and

how MALT1 participates in the regulation of NF-κB under physiological settings will be described within the subsequent paragraphs.

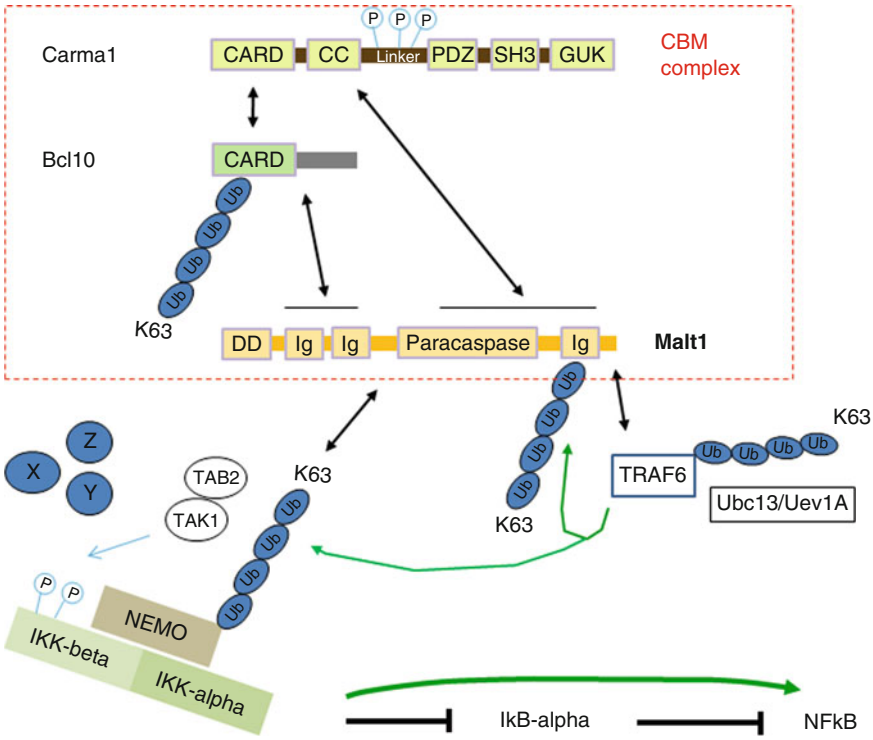
MALT1 in Antigen-Receptor

Phenotype of MALT1 Knockout Mice

A role for the CBM complex in cells of the immune system could be expected from the expression patterns of its components: in the mouse, *Malt1* and *Carma1* are predominantly expressed in lymphoid organs whereas *Bcl10* is quite ubiquitously expressed in various tissues including the lymphoid compartments. Analysis of *Bcl10*-deficient mice revealed severe immunodeficiency with strong defects in antigen receptor (AgR)-mediated activation, proliferation, and NF-κB signaling of B and T cells (Ruland et al. 2001), which is comparable to the phenotype of mice deficient in Carma1. The importance of the CBM complex in the immune system is further supported by the phenotype of *Malt1*-deficient mice (Ruefli-Brasse et al. 2003; Ruland et al. 2003). *Malt1*-deficient mice proved to be viable and fertile, and are born at the expected Mendelian ratio. Of note, while a fraction of *Bcl10*-deficient mice die during embryonic development due to a neural tube closure defect, *Malt1*-deficient mice as well as *Carma1*-deficient mice are not affected by a developmental defect, indicating that Bcl10 can exert functions independent of Malt1 and Carma1. *Malt1*-deficient mice are severely immunodeficient with markedly reduced basal immunoglobulin serum levels and a defective antibody response after immunizations. While Bcl10 is essential for the development of all main subtypes of B cells, follicular B2 cells, marginal zone B (MZB) cells and B1 cells (Xue et al. 2003), Malt1-deficiency revealed impairment of MZB and B1 cell development but showed normal follicular B2 cell development. *Malt1*-deficient mice display normal numbers of peripheral T lymphocytes despite some irregularity during thymocyte development due to a premature maturation of double-negative thymocytes. However, it was demonstrated that Bcl10/Malt1 signaling is dispensable for negative and positive selection of thymocytes (Jost et al. 2007). T cells isolated from *Malt1*-deficient mice reveal severe impairment of proliferation, IL-2 production, and NF-κB activation in response to stimulation with phorbol-12-myristate-13-acetate (PMA) plus ionomycin or with anti-► CD3 plus anti-CD28 antibodies. While ERK1/2 activation, calcium release, and JNK1 activation proves to be normal, the activation of JNK2 is impaired. Ruefli-Brasse and colleagues reported that B lymphocytes isolated from their *Malt1* knockout mouse strain also showed severe defects in the proliferative response and in NF-κB activation (Ruefli-Brasse et al. 2003). However, the *Malt1*-deficient mouse strain of Ruland and colleagues revealed only a moderate effect of Malt1 on B-cell receptor (BCR) signaling, since conventional B2 cells from those mice were still able to activate NF-κB and showed only a partial reduction of proliferation after stimulation (Ruland et al. 2003). More detailed analysis of this *Malt1* knockout mouse strain revealed that Malt1-deficiency in B cells does not affect the activation of the NF-κB subunit RelA but selectively impairs the formation of cRel-containing complexes (Ferch et al. 2007). The same study demonstrated that Malt1, therefore, seems to control only certain aspects of BCR-mediated NF-κB signaling such as activation of survival signals but does not control cell proliferation. This is in contrast to the role of Bcl10 which is essential for all aspects of BCR-mediated NF-κB activation (Ruland et al. 2001). Taken together, analysis of *Malt1*-deficient mice clearly demonstrated its central importance for a regular adaptive immune response and its essential involvement in AgR-mediated NF-κB signaling downstream of Bcl10.

MALT1 as an Adaptor Protein in AgR-Mediated CBM Signaling

During recent years, the mechanisms by which MALT1, as part of the CBM complex, contributes to AgR-mediated NF-κB activation were intensely studied on the molecular level. The early T-cell receptor (TCR)-proximal events had already been studied quite in detail: ligation of the TCR and its costimulatory CD28 receptor at the immunological synapse first results in the recruitment and activation of the Src protein tyrosine kinase Lck. Lck phosphorylates the immunoreceptor tyrosine based activation motives (ITAMs) of ► CD3 subunits to which the Syk family protein tyrosine kinase ► ZAP-70, and subsequently the adaptors ► LAT and ► SLP-76 are recruited. Then several additional molecules, such as Grb2, Vav1, and Tec kinases, associate with the activated receptor complex by which multiple signaling events are initiated, including the activation of the MAP kinases, phospholipase C (PLC)-gamma, and phosphatidylinositole-3-kinase (PI3-K). Those events again trigger a cascade



MALT1(Mucosa-Associated Lymphoid Tissue Translocation Gene 1), Fig. 3 *Malt1 as a scaffold protein in IKK activation*.As part of the activated CBM complex, Malt1 serves as a scaffold protein that recruits further signaling components such as the ubiquitin ligase complex consisting of TRAF6 and Ubc13/Uev1A. This results in the K63-type ubiquitination of several molecules, among others Malt1 and TRAF6 themselves but also of Bcl10 and the regulatory IKK subunit NEMO. Those ubiquitination events contribute to the association of NEMO and the IKK complex to the CBM complex with subsequent activation of the IKK complex and NF-κB

of downstream events such as the formation of diacylglycerol(DAG), the release of intracellular calcium, and activation of the serine/threonine protein kinases Akt/PKB and PKC-theta (Fig. 2). Upon activation, PKC-theta translocates into specialized membrane microdomains, the so-called lipid rafts, where it is essential for TCR-mediated NF-κB and AP-1 activation. Importantly, in unstimulated T cells CARMA1 was identified to be constitutively present in lipid rafts, whereas BCL10 was not. However, upon TCR stimulation, BCL10 was shown to be recruited from the cytoplasm to the membrane lipid raft fraction in a CARMA1-dependent manner. Upon activation of the AgR signaling pathways, PKC-theta in T cells or PKC-beta in B cells as well as other kinases such as IKK-beta and CK1-alpha were described to phosphorylate CARMA1 within its linker region. This might result in a conformational change of CARMA1, enabling its CARD-dependent interaction with BCL10 which on the other hand is constitutively associated with MALT1 (Thome et al. 2010). Once recruited to the immunological synapse by CARMA1 and BCL10, MALT1 contributes to the activation of the inhibitor of NF-κB kinase (IKK) complex for NF-κB activation. Up to now, the mechanisms by which MALT1 (in synergy and/or in parallel with BCL10) activates and regulates IKK activity are not completely understood. It seems to be clear, however, that MALT1 acts as an adaptor protein that recruits several binding partners for the induction of downstream signaling events. For example, the association of MALT1 with ▶ TRAF6-containing ubiquitin ligase complexes results in the addition of K63-linked ubiquitin chains to a multitude of proteins, among others TRAF6, Bcl10, and MALT1 but also to the regulatory domain of the IKK complex, NEMO (Fig. 3). The modification with K63-linked ubiquitin chains is essential for the recruitment of the IKK complex and other signaling molecules to the CBM complex at the immunological synapse and subsequent NF-κB activation (Duwel et al. 2010). First evidence for the participation of a TRAF6-dependent ubiquitin ligase complex in CBM-mediated NF-κB activation was obtained from studying a cell-free system (Sun et al. 2004). Sun and colleagues were able to reconstitute BCL10- and MALT1-dependent IKK activation in vitro in the presence of recombinant TRAF6, Ubc13/Uev1A, and TAK1/TAB1/TAB2. This study also suggests that MALT1 oligomers must be formed via its interaction with BCL10. Those MALT1 oligomers supposedly bind to the RING domain-containing ubiquitin ligase TRAF6 which in concert with the

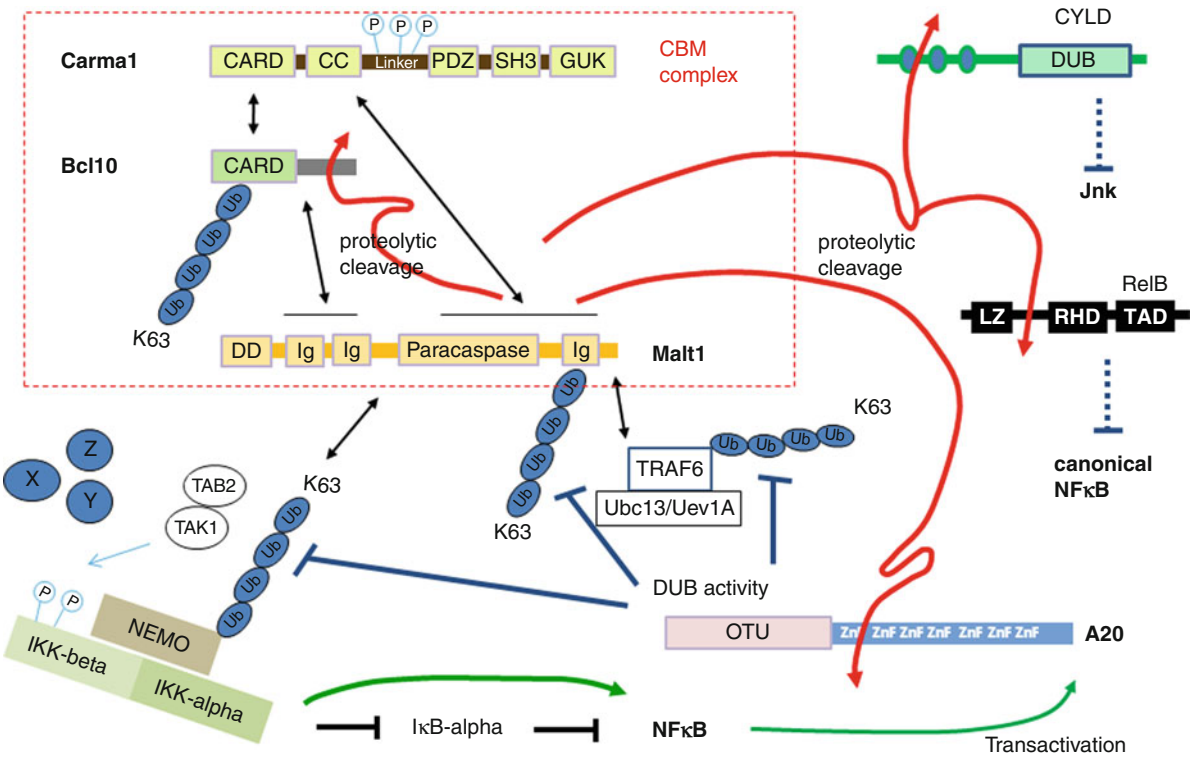
ubiquitin-conjugating enzyme complex Ubc13/Uev1A is activated as a ubiquitin ligase. TRAF6 was shown to directly bind and K63-ubiquitylate MALT1. Subsequently, the IKK complex can be recruited to the CBM complex since NEMO binds to K63-polyubiquitylated MALT1 via its ubiquitin-binding domain (UBD). Besides NEMO, also the TAK1/TAB2 kinase complex was shown to be associated with ubiquitylated MALT1 (Oeckinghaus et al. 2007) and might contribute to the activation of the IKK complex by phosphorylating two serine residues within the activation loop of IKK-β. However, the exact role and mode of function of TAK1 in IKK activation is not yet resolved.

Evidence accumulated for a surprising contribution of caspase-8 to TCR signaling including NF-κB activation. In this setting, caspase-8 does not signal for apoptosis but associates with various NF-κB signaling molecules in lipid rafts. Kawadler and colleagues demonstrated that MALT1 associates with procaspase-8 and promotes a partial proteolytical processing and activation of procaspase-8, which was shown to contribute to the activation of NF-κB via cleavage of $cFlip_L$ (Kawadler et al. 2008). The interaction between MALT1 and procaspase-8 proved to be dependent on the MALT1 paracaspase domain but independent of paracaspase activity since inactivation of the paracaspase active site did not interfere with procaspase-8 binding and processing.

In conclusion, the role of MALT1 as an adapter protein that recruits several signaling molecules to the CBM complex for the activation of NF-κB is well established.

MALT1 as a Protease in the Regulation of AgR-Mediated NF-κB Signaling

Uren and colleagues recognized that MALT1 belongs to a family of proteins that contain a common domain with sequence homology to the large protease subunit of caspases. Members of this protein family were identified in mammals, fish, nematodes, and amoeba and were collectively named paracaspases (Uren et al. 2000). Like caspases, the paracaspases possess an active-site cysteine together with a catalytic histidine and belong to the CD clan of cysteine-dependent proteases. In contrast to caspases, which specifically cleave behind aspartatic acid residues in the substrates P1 position, paracaspases were predicted to have different substrate specificities. Indeed, upon stimulation of human lymphocytes, MALT1 was shown to cleave BCL10 behind an arginine residue at its very C-terminal end (Rebeaud et al. 2008). The tetrapeptide inhibitor z-VRPR-fmk was able to block MALT1-mediated cleavage of BCL10 and thereby was validated as an inhibitor of MALT1 paracaspase proteolytic activity. Z-VRPR-fmk treatment of stimulated human T cells also reduced NF-κB signaling. However, BCL10 cleavage was not required for NF-κB signaling but instead might be important for integrin-mediated adhesion of activated lymphocytes to the extracellular matrix. Those findings suggest that other MALT1 paracaspase substrates should exist. In fact, Coornaert and colleagues recognized that the zinc-finger protein A20 is also cleaved by MALT1 paracaspase activity in stimulated human T and B cells (Coornaert et al. 2008). The cleavage site was identified behind an arginine residue between the first and second zinc finger of human A20. The MALT1 cleavage site in human A20 is different from that in BCL10 and is not conserved in the murine A20 protein which instead is presumably cleaved by MALT1 at another more C-terminal site. MALT1-dependent cleavage of A20 might indeed represent a mechanism that contributes to the regulation of CBM-mediated NF-κB signaling. A20 is a transcriptional target of NF-κB and, implementing a negative feedback loop, downregulates NF-κB signaling by removing K63-linked ubiquitin chains from various signaling molecules such as TRAF6, NEMO, and MALT1. MALT1-mediated A20 cleavage inactivates A20 as a negative regulator of NF-κB and, therefore, might contribute to a more sustained or amplified NF-κB signal (Fig. 4). This view is supported by the findings of Düwel and colleagues upon reconstitution of *Malt1*-deficient murine T cells with either wild-type *MALT1* or the active-site mutant *MALT1* C464A. *MALT1* C464A was able to restore early events in NF-κB activation such as IκBα degradation but displayed a reduced long-term response in terms of IL2 production compared to reconstituted wild-type MALT1 (Duwel et al. 2009). Very recently, MALT1 paracaspase was reported to cleave the deubiquitinating enzyme CYLD and thereby positively regulate JNK signaling (Staal et al. 2012) and to cleave RelB leading to RelB degradation with concomitant increase in canonical NF-κB signaling (Hailfinger et al. 2012). It appears likely that there are even more MALT1 paracaspase substrates which contribute to the regulation of CBM complex-mediated NF-κB signaling and beyond.



MALT1(Mucosa-Associated Lymphoid Tissue Translocation Gene 1), Fig. 4 *MALT1 as a paracaspase for the regulation of CBM signaling*. As a paracaspase Malt1 possesses proteolytic activity which is induced upon CBM activation. It has been reported that Malt1 as a paracaspase cleaves Bcl10, A20, CYLD, and RelB. A20 as a deubiquitinatin enzyme removes polyubiquitin chains from several proteins such as TRAF6, Malt1, and NEMO and, therefore, acts as a negative regulator of NF-κB signaling which transcriptionally upregulates A20 in a negative autoregulatory manner. A20 cleavage by Malt1 paracaspase therefore is believed to enhance CBM-mediated NF-κB signaling. CYLD is also a deubiquitinating enzyme and has been shown to be a negative regulator of Jnk activation. Inactivating cleavage of CYLD by Malt1 paracaspase therefore has been proposed to enhance Jnk signaling. Malt1-mediated cleavage of RelB leads to the degradation of RelB resulting in enhanced canonical NF-κB signaling

MALT1 Functions Beyond AgR Signaling

After AgR ligation, the most immediate sequence of events is the phosphorylation of ITAM motifs within coreceptor transmembrane proteins leading to the recruitment and activation of Syk kinase family members. Activation of ITAMs and Syk kinases is absolutely essential for the activation of most signaling pathways downstream of the AgRs including the formation of the CBM complex for NF-κB activation. Many other immunoreceptors also signal via ITAM or ITAM-like motifs and via activation of Syk kinases (Mocsai et al. 2010). And indeed, Malt1 as part of the CBM complex was found to be centrally involved in the activation of NF-κB upon stimulation of a variety of ITAM-coupled immunoreceptors other than AgRs. As a first example, Klemm and colleagues reported the essential contribution of Bcl10 and Malt1 to FcεRI-mediated NF-κB activation in mast cells, suggesting an important role for the CBM complex in the regulation of allergic inflammatory responses (Klemm et al. 2006; Klemm and Ruland 2006). Of special interest was the finding that Malt1 together with Bcl10 and the Carma1 homolog Card9 mediates NF-κB signaling triggered by innate C-type lectin receptors such as Dectin-1 for the immune response to fungal infections (Gross et al. 2006). This demonstrated for the first time that Bcl10 and Malt1 not only are central for adaptive immunity provided by AgR signaling on T and B lymphocytes but also for innate immunity provided by so-called pattern recognition receptors (PRRs) on dendritic cells (DCs) and macrophages (Hara and

Saito 2009). Another example for the involvement of Card9/Bcl10/Malt1 in the response of PRRs to pathogen-associated molecular patterns (PAMPs) is the activation of DCs and macrophages by the mycobacterial cell wall component TDM via recognition of the ITAM-coupled C-type lectin receptor Mincle (Schoenen et al. 2010). Furthermore, also activating NK cell receptors such as NK1.1 and ▶NKG2D couple to ITAM-containing signaling chains and signal to NF-κB in a Carma1/Bcl10/Malt1-dependent manner (Gross et al. 2008). The CBM complex has been described to also mediate NF-κB activation independently of upstream ITAM-Syk signaling. Tusche and colleagues reported that BAFF-induced alternative NF-κB signaling is dependent on Malt1 in B lymphocytes and that this BAFF pathway is essential for the survival and immune function of MZB but not of follicular B cells (Tusche et al. 2009). In nonimmune cells such as MEFs, Bcl10 and Malt1 were shown to be specifically required for NF-κB signaling upon activation of G protein-coupled receptors (GPCRs) by the phospholipid lysophosphatidic acid, LPA, which might be of relevance for tumorigenesis (Klemm et al. 2007).

MALT1 as a Potential Drug Target in Lymphoma Treatment

As mentioned above, *MALT1* had been initially identified as a gene that is involved in the t(11;18)(q21;q21) translocation in cases of MALT lymphoma. This translocation results in the expression of the API2-MALT1 fusion protein that independently of Bcl10 can auto-oligomerize and mediate ubiquitin ligase activity for deregulated NF-κB signaling in the process of lymphomagenesis. API2-MALT1 is known to activate the classical NF-κB pathway but Rosebeck and colleagues recently observed that also the alternative pathway is involved (Rosebeck et al. 2012). According to this report, the paracaspase activity of API2-MALT1 is directly responsible for the cleavage of the NF-κB-inducing kinase (NIK) behind its arginine residue R325, leading to the stabilization of NIK due to its rescue from proteasomal degradation. Cleavage-stabilized NIK was shown to result in enhanced processing of p100 to p52 and activation of the alternative NF-κB transcriptional program in t(11;18)-positive MALT lymphoma samples. Those data suggest that the inhibition of MALT1 paracaspase activity might offer a potential approach for the treatment of t(11;18)-positive MALT lymphoma. In contrast to the t(11;18)(q21;q21) translocation which generates an API2-MALT1 fusion protein, the recurrent translocation t(14;18)(q23;q21) brings *MALT1* into proximity of the immunoglobulin heavy-chain (*IGH*) locus and leads to high-level expression of MALT1 in the affected lymphoma cells. The mechanisms by which aberrant expression of *MALT1* contributes to NF-κB-dependent lymphomagenesis are not yet clear; nucleocytoplasmic shuttling of MALT1 and associated BCL10 might play a role. MALT1, BCL10, and CARMA1 were demonstrated to be indispensable for the survival of NF-κB-dependent diffuse large B-cell lymphoma (DLBCL) cell lines of the activated B cell (ABC) type and, therefore, might represent "Achilles' heels" that might be targeted for therapeutic intervention. Indeed, ABC-type DLBCL cell lines were shown to be selectively sensitive to treatment with the MALT1 paracaspase tetrapeptide inhibitor z-VRPR-fmk (Ferch et al. 2009). Thus, MALT1 as a component of the CBM complex with enzymatic paracaspase activity may be an attractive drug target for the treatment of lymphomas because inhibition of MALT1 paracaspase would not generally block NF-κB signaling but would only affect certain aspects of NF-κB signaling within a few cell types suggesting low side effects of such a therapeutic approach. However, the importance of MALT1 paracaspase activity in the physiological context of an organism is not known, and therefore, the consequences of MALT1 paracaspase inhibition remain to be investigated.

Summary

MALT1 was initially identified as a gene that is involved in chromosomal translocations in cases of MALT lymphoma. Soon it was recognized that MALT1 interacts and collaborates with BCL10, which also is translocated in MALT lymphoma, for the induction of NF-κB signaling. In response to the activation of adaptive and innate immune receptors MALT1 and BCL10 are recruited by CARD-containing proteins such as CARMA1 and CARD9 to form so-called CBM complexes. CBM complexes mediate the activation of the IKK complex and subsequent NF-κB signaling. Within the CBM complex, MALT1 functions as an adaptor protein that recruits further signaling molecules but also regulates CBM signaling via its paracaspase

protease activity. Regular CBM-mediated NF-κB signaling is essential for intact adaptive and innate immune functions. In contrast, aberrant CBM-mediated NF-κB signaling can contribute to and even might be essential for the development and/or maintenance of lymphomas. MALT1 as a component of the CBM complex with enzymatic paracaspase activity is an attractive drug target and first in vitro data indicate that inhibition of MALT1 paracaspase might indeed impair survival of specific subtypes of lymphoma cells. The physiological functions of MALT1 paracaspase activity, however, remain to be elucidated.

Acknowledgments We thank Frank Oliver Gorka for thoughtfully reading and discussing the manuscript.

Historical Background

Murine and human MK5 were initially isolated in 1998 in two independent screenings for proteins with sequence homology to the MK2 (New et al. 1998; Ni et al. 1998). This novel 54 kDa kinase displays 45% amino acid identity to MK2 and is ubiquitously expressed in all tissues. Both groups showed that MK5 could be phosphorylated and activated in vitro by the p38 MAP kinase, detected by 32P incorporation into peptide substrate (KKRPQRATSNVFS) or Hsp25 (Hspb1). New et al. named this kinase as p38-regulated and activated kinase or PRAK to emphasize its integration in p38 pathway. More recently, MK5 has also been shown to interact with the atypical MAP kinases ERK3 and ERK4 and this also results in phosphorylation and activation of MK5. The amino acid sequence of MK5 is most closely related to MK2 52% amino acid identity within kinase domains and MK3 50%, but MK5 is more distantly related to these kinases than they are to each other (77%). An MK5 gene does not appear to be present in either *C. elegans* or Drosophila, but orthologues are found in most vertebrates.

Structure, Activation, and Expression

According to the structure of the kinase domain, MK5 belong to the family of calcium/calmodulin-dependent protein kinases. The human MK5 mRNA could be spliced on the two slightly different ways, resulting in two isoforms differing in two additional amino acids within the C-terminal extension of MK5 of transcript coding for 473 aa (variant 2) compared to transcript variant 1. In mice, five MK5 isoforms have been

detected, representing combinations of the two amino acid changes found in humans with deletions of the N-terminal portion of the MK5 catalytic domain as well as truncated variant due to frame shift.

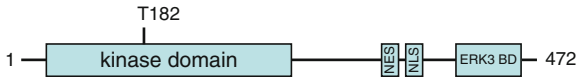
The functional significance of these different splice variants is not known. Similar to the other MKs MK5 contains a conserved LXTP site, where X is threonine for MK2, glutamine for MK3, and methionine for MK5, in the T-loop with the threonine as a phospho-acceptor site. The C-terminal region of MK5 contains a functional nuclear export sequence (NES) and a nuclear localization sequence (NLS). The NLS overlaps with a putative MAPK docking site (D motif) mediating interaction with p38 (Seternes et al. 2002). In contrast to MK2 and MK3, in MK5 NES and NLS are located in close proximity to each other. In addition, MK5 possesses a 100 amino acid extension C-terminal to the NLS, which is not present in other MKs. This extension is indispensible and sufficient for the interaction with phosphorylated MAPKs ERK3 and ERK4 and enables alternative way of MK5 activation. This activation mechanism via atypical MAPKs in addition to p38 is the unique feature of MK5, integrating it in two separate signaling pathways (Fig. 1).

MK5 is ubiquitously expressed in most tissues and cell lines that have been analyzed.

MK5 carries the phospho-acceptor site in the T-loop (T182), conserved of all other MKs (New et al. 1998) which is the only regulatory phosphorylation site in contrast to MK2 and MK3, requiring additional phosphorylation sites for full activation. Comparison of the MK5 sequence with that of MK2 and MK3 reveals that these additional regulatory MAPK phosphorylation sites are absent in MK5.

MK5 can be activated by p38 similar to MK2 (New et al. 1998, 2003; Seternes et al. 2002) at least in vitro and in the case of overexpression. Additionally, overexpressed p38 can bind MK5 leading to the cytoplasmic localization of resulting complex. However endogenous MK5 is not significantly activated by classical p38 stimuli, such as arsenite and sorbitol (Shi et al. 2003). Moreover, the phenotype of MK5-deficient mice does not resemble one of MK2/3-deficient animals, displaying a normal profile of cytokine production and no increased resistance to LPS challenge (Shi et al. 2003).

Recently, MK5 was shown to interact with atypical MAPKs ERK3 and ERK4. These kinases form a tight complex with MK5 resulting in mutual stabilization and phosphorylation. Moreover the expression of either ERK3 or ERK4 does only lead to phosphorylation and activation of MK5 but also cause the translocation of ERK3–MK5 from the nucleus to the cytoplasm (Seternes et al. 2004; Schumacher et al. 2004). However, the physiological conditions, leading to the activation of MK5 by ERK3 and ERK4 remain unknown.



Map Kinase-Activated Protein Kinase 5 (MK5), Fig. 1 Schematic structure of MK5. The phospho-acceptor site T182 in the T-loop nuclear export signal (NES), the D-domain/nuclear localization signal (NLS) and the ERK3 and ERK4 binding domain are shown

Protein kinase A (PKA) signaling also been postulated to influence the cellular distribution of MK5 (Gerits et al. 2007a). Treatment of cells with forskolin or overexpression of a nuclear-targeted PKA C alpha catalytic subunit was shown to induce the transient redistribution of MK5 from nucleus to cytoplasm in rat PC 12 cells.

Substrates

The optimal phosphorylation site motif for MK5 is identical to MK2/3 where it has been defined as (L,F,I)-X-R-(Q,S,T)-L-(pS,pT)-hydrophobic. MK5 is able to phosphorylate HSPB1, glycogen synthetase, tyrosine hydroxylase (preferentially on S19), and myosin heavy chain in vitro (New et al. 1998; Ni et al. 1998; Gaestel 2006; Toska et al. 2002) at the same sites as MK2.

It was shown that MK5 interact with Hspb1 and is responsible for the cAMP/cAMP-dependent protein kinase induced Hspb1 phosphorylation in PC12 cells (Kostenko et al. 2009).

However in MK5 knockout mice, stress-dependent HSPB1 phosphorylation under the stress conditions is not impaired (Shi et al. 2003). Instead, MK5 phosphorylates its interacting partners, atypical MAPKs ERK3 (Seternes et al. 2004; Schumacher et al. 2004) as well as homologous ERK4 (Kant et al. 2006; Aberg et al. 2006) and can also phosphorylate the transcription factor p53 on S37 (Sun et al. 2007).

Physiological Roles

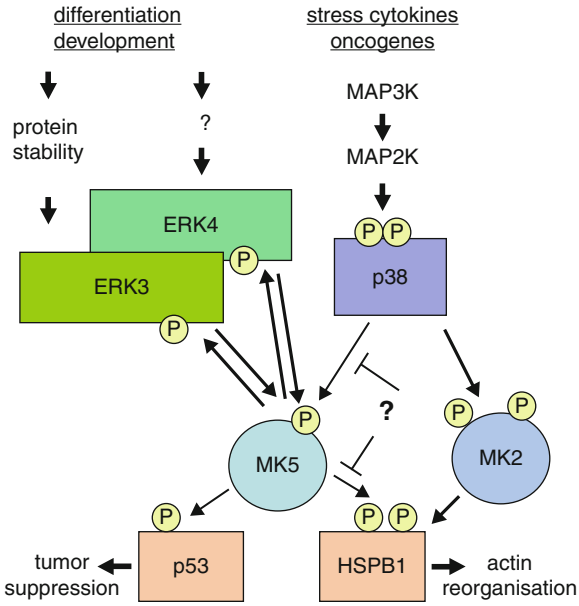
The exact biological function of MK5 is unknown. Originally, due to the high structural similarity and substrate consensus, MK5 was ascribed the same functions as MK2, which is involved in stress response and inflammation.

Generation of MK5-deficient mice challenged this assumption. Indeed, MK5-deficient mice do not display any of the phenotypic changes characteristic for MK2-deficient animals. Disruption of the MK5 gene in mice on mixed genetic background does not manifest in any phenotypic features. MK5 knockout backcrossed to C57Bl/6 genetic background resulted in lethality at E11.5 with incomplete penetrance, indicating the role of MK5 during embryogenesis.

In studies exploring the Ras-induced senescence in primary mouse and human fibroblasts, MK5 was shown to be indispensable for oncogene-induced senescence and hence can act as a tumor suppressor. Consistently, MK5-deficient mice were found to be more susceptible to skin carcinogenesis induced by the mutagen dimethylbenzanthracene. In the same study, the authors demonstrated that MK5 phosphorylates p53 at Ser37, a residue located in transactivation domain. Since this phosphorylation site is not within a perfect consensus for MAPKAP kinases, it could not be excluded that MK5-associated MAPK is responsible for this phosphorylarion.

Overexpression of MK5 in HeLa cells leads to an increase in both F-actin production and cell migration (Tak et al. 2007). Interestingly, MK5 was shown to interact with 14-3-3 epsilon resulting in inhibition of MK5 kinase activity. In another study, treatment of PC12 cells with forskolin caused a transient increase in F-actin levels and this was blocked in PC12 cells transfected with an siRNA against MK5 (Gerits et al. 2007a). How MK5 mediates cytoskeletal rearrangement is still unclear, and further studies are needed to address this.

Finally, a possible link between MK5 and neurological/cognitive function has been proposed based on behavioral analyses of a transgenic mouse that expresses a constitutively active mutant of MK5. This study revealed complex sex-specific changes in both anxiety-related traits and locomotor activity in MK5 expressing mice relative to WT controls (Gerits et al. 2007b) (Fig. 2).



Map Kinase-Activated Protein Kinase 5 (MK5), Fig. 2 ERK3 is an intrinsically instable protein and can be stabilized by differentiation or in development. Mechanism of ERK4 regulation is not revealed until now. ERK3 and ERK3 bind to MK5 and activate later through T182 phosphorylation. As a result of interaction, ERK3 and ERK4 become phosphorylated by MK5 either. P38 is able to phosphorylate MK5; however, MK5 phosphorylation is not essential result of p38 signaling as in the case of MK2/3 and this fact is indicated with inhibition symbol supplied with question mark. However, p53 phosphorylation on S37 stimulated by oncogenic Ras seems to proceed via p38–MK5 axis. Involvement of MK5 in the regulation of actin reorganization is described and could be mediated by MK5-dependent phosphorylation of F-actin capping proteins, shown here exemplary as small heat shock protein HSPB1, although HSPB1 phosphorylation is abrogated in MK2/3 but not MK5-deficient cell lines. The fact, that despite similarity to MK2, MK5 usually is not involved in MK2 substrate phosphorylation is indicated

Summary

MK5 is a MAPK-activated kinase integrated in p38 and ERK3/ERK4 signaling module. P38 was initially described as a MK5 activator, resulting in the name PRAK, which is acronym for p38 activating regulating kinase. However, p38 activation is not usually cause MK5 phosphorylation and activation. Moreover, MK5 – p38 interaction is rather weak, the significance of p38 in MK5 signaling is restricted and needs to be directly addressed in future studies. In the contrast, the involvement of ERK3 and ERK4 in MK5 functions is clearly documented in in vivo studies and supported by strong

interaction between these proteins, mutual stabilization and similar pattern of expression in embryogenesis. However, ERK3/ERK4 – MK5 remains "orphan" signaling module until now, since any physiological stimuli as well as regulatory mechanisms were revealed for it.

Future studies of available MK5 knockout animals and dissection of signaling events using genetic approach by crossing MK5-deficient animals with p38, ERK3/4, and MK2/3 as well as usage of emerging MK5 inhibitors.

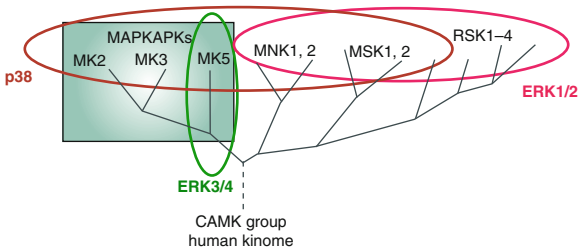
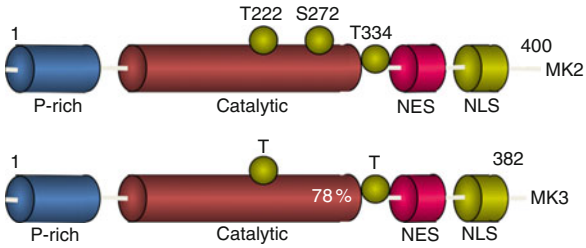
Historical Background

Formally, all protein kinases downstream to ▶ MAP kinases should be regarded as MAPK-activated protein kinases (MKs). This would include ribosomal S6-kinases (RSKs), mitogen- and stress-activated protein kinases (MSKs), MAP kinase-interacting kinases (MNKs), as well as MK2, MK3, and MK5/PRAK (Roux and Blenis 2004). However, due to the specificity of activation, this group of protein kinases is further subdivided (Fig. 1): RSKs are activated by classical ERKs (▶ Erk1/Erk2) and MSKs and MNKs are phosphorylated by both ERKs and p38 MAPK. MK2 and MK3 are the only MKs which are exclusively activated by p38 MAPK. MK5/PRAK has been described as a "p38-regulated and -activated kinase (PRAK)," but its activation by p38 MAPK is challenged and alternative activation by atypical MAPKs (Erk3/Erk4) is discussed (Gaestel 2006). For historical reasons RSK was designated MAPKAPK 1 (MK1) and the name MK4 was given to MK2 of sea urchin.

A stress-induced small heat shock protein-kinase activity was described as early as in 1983 (Kim et al. 1983), but identification of this activity as the protein kinases MK2 (Stokoe et al. 1992) and MK3 (McLaughlin et al. 1996) took more than 10 years. Characterization of the physiological roles of these protein kinases is still ongoing.



Mapkap Kinase 2/3 (MK2/3), Fig. 1 Classification of protein kinases downstream to MAPKs. For details, see text. Adapted from (Gaestel 2006) with modifications



Mapkap Kinase 2/3 (MK2/3), Fig. 2 Primary structure of MK2 and MK3. MK2 and MK3 display 78% identity in their amino acid sequence and contain N-terminal proline-rich domains (P-rich), central protein-kinase domains (catalytic), and C-terminal regulatory tails which contain a nuclear export signal (NES) and a bi-partide nuclear localization motif (NLS). The NLS overlaps with the p38 MAPK-docking site. At least two regulatory phosphorylation sites are present in both enzymes: One threonine within the catalytic domain at the activation loop (T222) and the other threonine in the hinge region between kinase domain and C-terminal tail

Structure, Activation, and Expression

According to their primary structure, MK2/3 belong to the family of calcium/calmodulin-dependent protein kinases (Camk). However, their activity does not depend on calcium, but on the phosphorylation of regulatory sites within the catalytic domain and in a hinge region between the catalytic domain and the C-terminus (Ben-Levy et al. 1995, Engel et al. 1995) (see Fig. 2). In human MK2, two phosphorylation sites are located within the catalytic domain, T222 and S272, and a further phosphorylation site is T334 in the hinge region. Similar sites were also identified in MK3. These are proline-directed sites which are phosphorylated by p38 MAPKα,β (Freshney et al. 1994, Rouse et al. 1994). The N-terminus of MK2/3 contains a proline-rich region which is able to bind to SH3 domain-containing proteins in vitro (Plath et al. 1994). The C-terminus of MK2/3 is a very interesting part, since it contains different signals for regulation of subcellular localization (nuclear export signal – NES; nuclear import signal – NLS). Furthermore, the C-terminus may have inhibitory effects on the catalytic domain (Engel et al. 1995) and tightly binds to the activator kinase p38 MAPKα (White et al. 2007). The binding specificity between MK2 and p38 MAPKα depends on two regions of p38, the common docking (CD) domain and the ED motif, and on the NLS of MK2 (Gum and Young 1999, Tanoue et al. 2001).

A variant of the cDNA of human MK2 that codes for an alternative C-terminus without NES and NLS has been described (Zu et al. 1994). MK2 also migrates as two (mouse, 46 and 54 kDa; human, 53 and 60 kDa) distinct bands in SDS–PAGE (Stokoe et al. 1992, Cano et al. 1996), which are both absent from MK2-knockout fibroblasts (Kotlyarov et al. 1999), and has two biochemically distinct forms (p43 and p49) in cardiac myocytes (Chevalier and Allen 2000). So far, it is not completely clear whether both bands detected for MK2 correspond to different proteins based on an alternatively spliced transcript or to posttranslational modification/processing of MK2.

MK2 and MK3 are highly expressed in heart and skeletal muscle, but their activity can also be detected in most other tissues and cell lines. Compared to expression of MK2, expression of MK3 is much lower, making it a "minor isoenzyme" of MK2. This explains the clear phenotype of the MK2-deletion (Kotlyarov et al. 1999), which cannot be compensated by MK3 because of its low expression (see below).

The regulation of MK2/3's subcellular localization is an interesting issue. GFP-tagged, overexpressed MK2/3 is mainly localized in the nucleus and translocated to the cytoplasm after activation (Engel et al. 1998). Whether this mechanism of coupled activation and translocation is of importance to the endogenous enzymes and whether this mechanism is modulated by complex formation of MK2/3 with p38 MAPK is so far not clear.

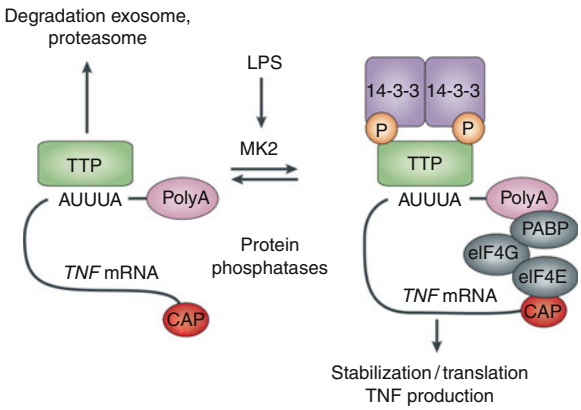
Substrates

The human kinome contains more than 500 protein kinases and the human proteome is thought to comprise more than 10,000 different phosphorylation sites.

Hence, an average protein kinase should phosphorylate more than 20 amino acid residues of various substrate proteins. Knowing the complete substrate spectrum of MK2/3 could be very helpful for understanding its downstream signaling in different cell types and physiological situations. The optimal phosphorylation site motif for MK2/3 has been defined as (L,F,I)-X-R-(Q,S,T)-L-(pS,pT)-hydrophobic. So far, no difference in substrate-specificity between MK2 and MK3 has been detected (Clifton et al. 1996). Several substrates of MK2/3 have been described. Besides the major substrate Hspb1, the following substrates have been identified: myosin II regulatory light chain, lymphocyte-specific protein 1, tyrosine hydroxylase, αB-crystallin, vimentin, serum response factor, transcription factors E47 and ER81, 5-lipoxygenase, poly (A)-binding protein 1, tuberin, hnRNP A0, p16-Arc, LIM-kinase 1 (▶ LIMK), 14-3-3ζ, tristetraproline (TTP), p66-Shc, Bcl-2-associated athanogene 2, polycomb-group protein Bmi 1, DNA-damage response protein phosphatase ▶ Cdc25B/C, and the p53 E3 ubiquitin ligase HDM2 (for references see supplementary table of (Gaestel 2006)). However, at the moment, only a few in vivo substrates of MK2/3, such as Hspb1, SRF, TTP, and keratin 20 (Menon et al. 2010), have been verified. The physiological function of phosphorylation of these substrates is far from being completely understood.

Physiological Roles

The physiological role of MK2 became mainly evident from the MK2-knockout mouse, which is viable and fertile but displays resistance against endotoxic shock (Kotlyarov et al. 1999) and collagen-induced arthritis (Hegen et al. 2006) as well as increased susceptibility in a *Listeria* infection model (Lehner et al. 2002). These phenotypes can be explained by MK2/3-dependent regulation of expression of the inflammatory master cytokine TNF at the posttranscriptional level of mRNA stability and translation (Kotlyarov et al. 1999, Neininger et al. 2002). Mechanistically, this regulation proceeds for AU-rich element (ARE)-containing mRNAs, such as TNF mRNA, via phosphorylation of ARE-binding proteins, such as hnRNP A0 (Rousseau et al. 2002) and TTP (Stoecklin et al. 2004) (Fig. 3). In a MK2-free genetic background deletion of MK3 leads to a further slight, but significant



Mapkap Kinase 2/3 (MK2/3), Fig. 3 Proposed mechanism of molecular action of MK2/3 in cytokine biosynthesis. MK2 phosphorylates AU-rich element (ARE – "AUUUA")-binding proteins such as hnRNP A0 or TTP. In the case of TTP, phosphorylation leads to 14-3-3 binding of the TNF mRNA-TTP complex, stabilization, and/or translation of the mRNA and increased TNF production. (From Gaestel 2006)

reduction of TNF production, indicating cooperative action of both enzymes (Ronkina et al. 2007). Apart from displaying catalytic activity, MK2/3 bind to p38 MAPK and mutually stabilize each other by protein complex formation. In MK2 knockout and MK2/3-double knockout mice, a significantly reduced p38 MAPK level is detected (Ronkina et al. 2007). Further physiological roles for MK2/3 include cell cycle checkpoint control, cell migration, and general stress response.

Because of its contribution to the production of inflammatory cytokines and because of the toxicity of p38 MAPK-inhibitors, MK2 becomes increasingly of interest as a target for anti-inflammatory therapy. First small molecule inhibitors of MK2 and/or MK3 have been reported. Of these, the orally available small molecule MK2 inhibitor of the benzothiophene type, PF-3644022, was demonstrated to be effective in a chronic streptococcal cell-wall-induced arthritis model in rats (Mourey et al. 2010).

Summary

MK2/3 are p38 MAPK-activated kinases that are stimulated by different stresses such as heat shock, hypo- and hyperosmolarity, and treatment with anisomycin or arsenite as well as by bacterial lipopolysaccharide (LPS) and chemotaxis-inducing formyl peptides. MK2 and MK3 show different levels of expression and

activity, making MK2 the major and MK3 the minor "isoform." MK2/3 are involved in stress and immune response by the modulation of cytokine production, mainly at the posttranscriptional level, regulating cytokine messenger RNA stability and translation. mRNA-binding substrates such as tristetraproline (TTP), hnRNP A0, and possibly also poly(A)-binding protein 1 are involved in this regulation. The existence of a wide variety of further substrates identified for MK2/3 indicates various other physiological functions for these protein kinases in vivo. One of the major substrates of MK2/3, the small heat shock protein Hspb1, contributes to stabilization of the actin cytoskeleton and acts as a molecular chaperone.

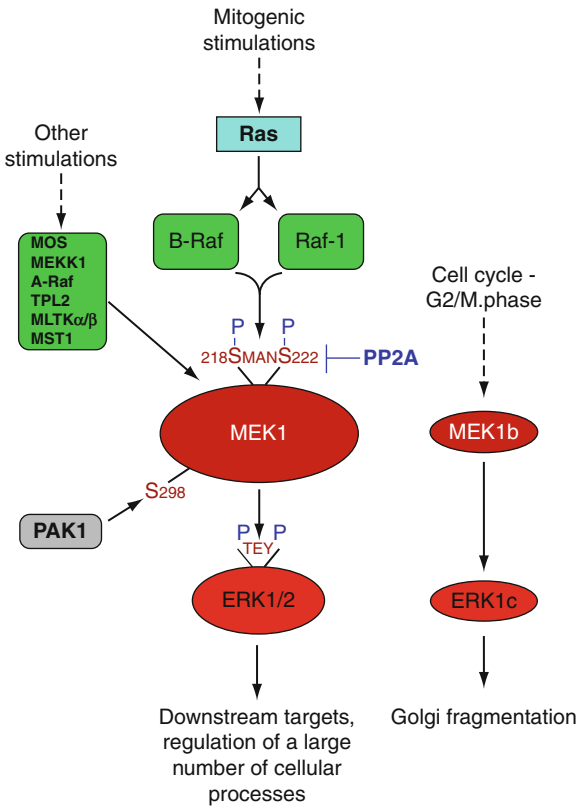
Historical Background

The transmission of extracellular signals to their intracellular targets is mediated by a network of interacting proteins that governs a large number of cellular processes including proliferation, differentiation, stress response, and apoptosis. One of the central components in the transmission network is the ERK cascade, which is composed of sequential phosphorylation and activation of the protein kinases Raf, MEK, ERK and ▶ MAPKAPKs. In turn, the latter two components of the cascade phosphorylate a large number of regulatory proteins, culminating in the induction and regulation of proper downstream cellular processes. This cascade was identified in the late 1980s and early 1990s of the previous century by several research groups that studied growth factor receptor signaling. At that time it was already known that growth factor receptors operate via an integral or associated protein tyrosine kinases that, upon stimulation, rapidly phosphorylate tyrosine residues on many substrates. It was also known that the initial Tyr phosphorylation is replaced by a Ser/Thr phosphorylation, which is found on a large number of Proteins, 15–60 min after stimulation. An important approach to study the role of these phosphorylations, was to establish a cellular event affected by growth factors, and identify components that regulate it up to the receptor (upstream approach; [Seger and Krebs 1995]). One protein that undergoes significant Ser/Thr phosphorylation shortly after growth factor stimulation is ribosomal protein S6, which became a useful readout for this upstream approach. Due to the work of several laboratories in

the 1980s it was found that the stimulated phosphorylation of S6 is mediated, in part, by RSK, which acts downstream of an enzyme that was initially termed microtubule-associated protein 2 (MAP-2) protein kinase, but later renamed mitogen-activated protein kinase (▶ MAP kinase; MAPK) and extracellular signal-regulated kinase (ERK; [Seger and Krebs 1995]).

As a central component in this novel pathway, ERK activation has attracted considerable attention. Soon after the cloning of ERK, it became clear that this protein kinase is activated due to phosphorylation of two residues in its activation loop (Thr183 and Tyr185 of ERK2). The phosphorylation of both these residues was found to be an essential step in ERK activation, as dephosphorylation of each of them completely abolished it. Initially, it was thought that the Tyr phosphorylation can be mediated by tyrosine kinases such as the growth factor receptors, while the Thr phosphorylation is mediated either by autophosphorylation or by another Ser/Thr kinase. However, this thought was rapidly changed due to studies by Ahn et al. (1991) who combined inactive ERK with fractions from growth factor–stimulated cells and looked for enhanced ERK activity. These studies led to the identification of two non-receptor ERK activating factors, which were able to induce phosphorylation of both activatory residues on ERK. Similar activators were then identified in NGF-stimulated PC-12 cells (Gomez and Cohen 1991), and later, in many other systems as well. Subsequently, the proteins were purified and cloned, giving rise to two main proteins and one alternatively spliced isoform that were eventually termed MEK1, MEK2, and MEK1b. These were shown to be protein kinases that catalyze Ser/Thr as well as Tyr phosphorylation, and therefore, belong to the small group of dual specificity protein kinases. These two kinases are also part of a group of MAPK kinases (MAPKKs) that are the specificity determinant of the MAPK signaling cascades in mammals and in other organisms. Finally, at that stage, it was important to elucidate the mechanism of MEK activation upon stimulation. Studies in that direction revealed that MEKs are activated by phosphorylation of two Ser residues in their activation loop. The main Ser/Thr kinase that executes this phosphorylation after stimulation was found to be the proto-oncogene Raf (Kyriakis et al. 1992), but other protein kinases were shown to act as activators (e.g., MOS, MEKK1) as well (see Fig. 1). In view of the above, it is clear today that



Mek, Fig. 1 Schematic representation of the ERK1/2 MAPK pathway. For more details, see text. MEK1 regulations are emphasized

MEK1/2 are the specificity determining component of the ERK cascade, and therefore, are central components in the regulation of proliferation and many other physiological processes (Seger and Krebs 1995).

The MEK1/2 Subfamily of MAPKKs

Key intracellular mediators of extracellular signals are the mitogen-activated protein kinase (MAPK) signaling cascades. They are evolutionarily conserved from yeast to mammals, and are expressed in nematodes, insects, slime molds, and plants as well. Each of the cascades is composed of three core protein kinases (MAP3K, MAPKK, and MAPK), which might be complemented in some cells and conditions by upstream MAP4K and downstream MAPK-activated protein kinase (MAPKAPK), giving rise to either 3, 4, or 5 tiered cascades. The transmission of signals

within the cascades is mediated by a sequential phosphorylation and activation of the components of the cascade, whereby the downstream components transmit the signal further by phosphorylating many regulatory proteins, which further governs an array of intracellular responses. Four such MAPK cascades are currently known in mammals, named according to the components of their MAPK tier: ERK1/2, JNK, p38 and ERK5 cascades. Main specificity determining components of the MAPK cascades are the MAPKK levels proteins, which are MEK1/2 for the ERK1/2 cascade, MKK3, 4, 6, 7 for the JNK and p38 cascades, and MEK5 for the ERK5 cascades. These kinases are unique in having a very stringent specificity toward Thr and Tyr residues in the activation loop of their cognate MAPKs. For that reason, the MAPKK are considered as the main specificity-determining components of their cognate cascades, and thereby are central regulatory components of essentially all stimulated cellular processes including proliferation, differentiation, adhesion, cellular morphology, stress response, and apoptosis.

The first identified and best-studied component of the MAPKK family is MEK1, which was shown to activate specifically ERK1/2 (Bendetz-Nezer and Seger 2005). This protein (45 kDa) is encoded by one gene (MAP2K1) that also encodes an alternatively spliced isoform termed MEK1b (43 kDa). The latter is very specific to the alternatively spliced isoform of ERK1 termed ERK1c (Shaul et al. 2009). Mammals contain another gene termed MAP2K2 that encodes the close homologue MEK2 (46 kDa), which phosphorylates and activates specifically ERK1/2 as well. This is an evolutionary conserved group of protein kinases, having very close orthologues in yeasts, worms, insects, and plants. MEK1/2, like other MAPKKs, are activated by many extracellular and intracellular stimuli. These stimuli usually transmit their signals to MEK1/2 via membranal receptors that recruit adaptor proteins together with nucleotide exchange factors, to consequently activate the small GTPase, Ras. Active Ras, in turn, recruits the protein kinases Raf1 and B-Raf (Rafs) to the plasma membrane, where they are activated via an unknown mechanism. The Rafs are the main MAP3Ks that activate MEK1/2 by phosphorylating them on two Ser residues (Ser218, 222 in human MEK1) in their activation loops. However, the ability to induce this MEK1/2 phosphorylation is not restricted to Rafs, since under different conditions, other kinases can serve as MEK kinases as well. For example, MOS acts as a MEK1/2 kinase in the reproductive system, and MEKK1 acts under stress conditions. A-Raf, ▶ MLTKα/β, ▶ TPL2 and MST1 have been implicated in the activation of MEK1/2 as well, but the conditions under which they operate are not fully understood.

MEK1/2 Activity and Its Regulation

As mentioned above, the main function of MEK1/2 is to phosphorylate and activate ERK1/2. In all species, MEK1/2 isoforms exhibit unique specificity toward the native forms of these two downstream targets, phosphorylating them non-processively on their activatory Thr and Tyr that are separated by Glu residue (Seger and Krebs 1995). This Thr-Glu-Tyr phosphorylation induces a big conformational change in the active pocket of ERK1/2, which consequently, results in the activation of the proteins and the rest of the cascade. Aside from this most important role of MEK1/2 in ERK1/2 activation, these MAPKKs were implicated in additional processes, including: (1) Association with ERK1/2 to induce either cytoplasmic localization of the latter in resting cells or their nuclear export at later time points after stimulation (Fukuda et al. 1997; Rubinfeld et al. 1999). (2) Direct binding to DNA in gene promoters that consequently results in a direct regulation of transcription (Perry et al. 2001). (3) Regulation of the subcellular localization of PPARγ (Burgermeister and Seger 2007). These additional functions, which are not directly dependent on the kinase activity of MEK1/2, indicate that these two MAPKKs may exert their activity in a kinase-independent manner. Furthermore, these additional activities demonstrate ERK-independent functions that seem to complement the main functions of ERK1/2 in the regulation of mitogenic signals.

Being important components of the central ERK cascade and other processes, MEK1/2 activation is well regulated by various mechanisms. Like many other components of signaling cascades, the activation of MEK1/2 is transient, as their activity usually peaks 2–4 min after stimulation and returns to basal levels within 10–90 min, dependent on the stimuli and conditions. The activation is mediated by the MAP3Ks described above, while the removal of the phosphates from the two activatory Ser residues, which

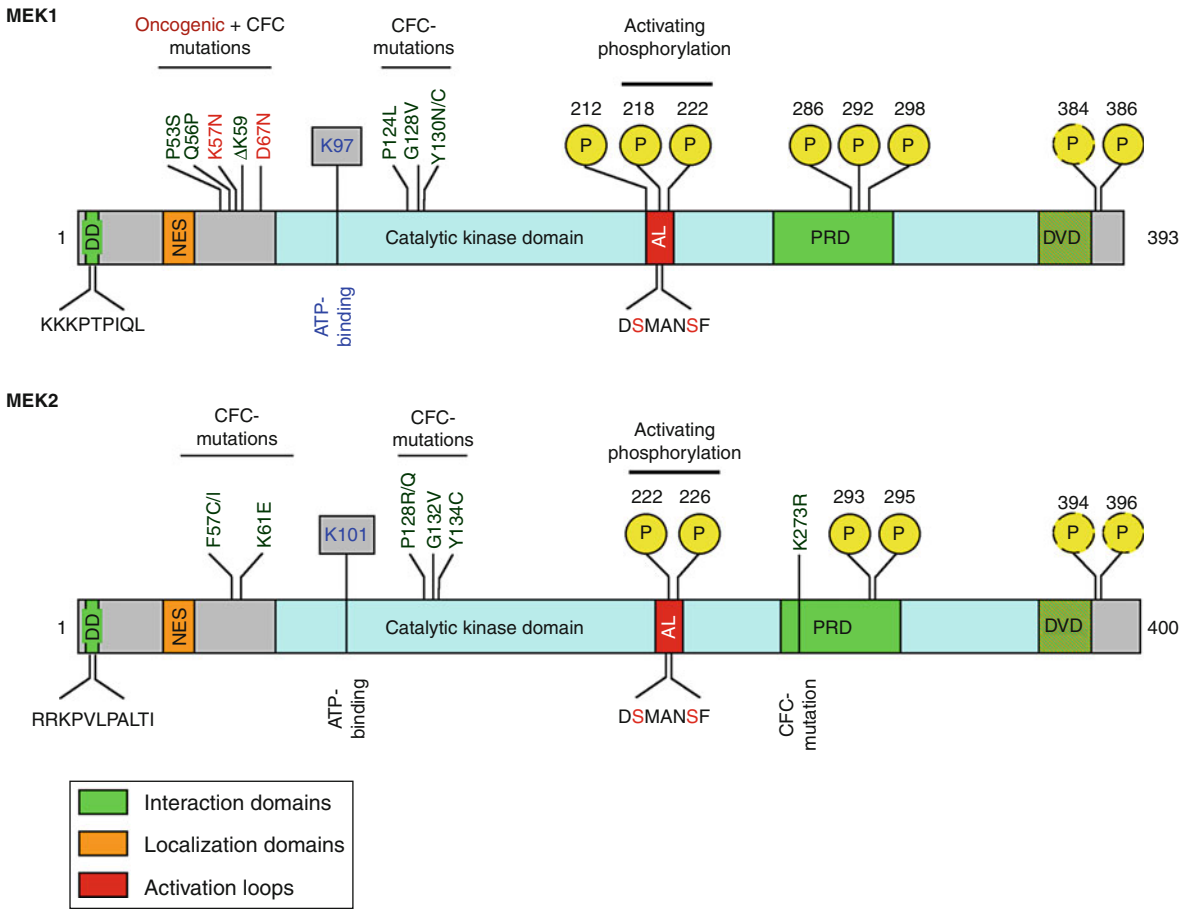
consequently leads to inactivation of MEK1/2, is mainly mediated by the Ser/Thr phosphatase PP2A. However, aside from the dynamic phosphorylation of the activatory Ser residues, MEK1/2 are regulated by additional phosphorylations. One such phosphorylation is that of Ser298 of MEK1 by the protein kinase ▶ Pak1, which acts downstream of the morphology regulator Rho. This phosphorylation does not activate MEK1 by itself, but seems to accelerate the Ser218/222-dependent activation, thereby serving as a convergence point of distinct signals. Other phosphorylations of MEK1 are inhibitory ones, including MEK1's Thr286 and Thr292, which seem to inhibit mainly Ser298 phosphorylation, and MEK1's Ser212 that inhibits the activity of MEK1/2 by an unknown mechanism. These, and other phosphorylations, as well as a few docking domains described below, induce better interactions of MEK1/2 with scaffold proteins such as Paxillin, MP1, and more. These interactions can bring MEK1/2 to close proximity to their upstream activators, to ERK1/2 and to their correct site of action, and therefore, may accelerate properly situated MEK activity. In addition, the activity of MEK1/2 is also regulated by their heterologous dimerization and by varying their subcellular localization. Finally, MEK1/2 are excellent targets for synthetic inhibitors, and many such small molecular weight inhibitors (e.g., PD98059, U0126, PD184352, and AZD6244) are currently being used either in the biochemical studies of the ERK cascade or in the development of anticancer drugs (see below).

Structure–Function Relationships

Most of the structure–function relationships have been conducted on MEK1, but because of their sequence (Seger and Krebs 1995) and conformation (Ohren et al. 2004) similarities, MEK1 and MEK2 probably share many of the features identified. Human MEK1 is a 393 amino acid protein kinase that contains all known kinase subdomains and residues, including ATP binding and catalytic sites. Indeed, this protein exhibits a significant phosphorylation activity that ranges from ~10 nmole/min/mg in basal state to ~1 mmole/min/mg in its active state. The significant change in MEK1 activity (10^5 fold) is mediated by two Ser phosphorylation, as described above. The phosphorylation of both residues is essential for full catalytic MEK1 activity, while phosphorylation of just one of the Ser residues is sufficient to induce only small MEK1 activation (up to ~15% of total activity for p-Ser222). Interestingly, phosphomimetic mutations of the two Ser residues induce a constitutive, but rather low MEK1 activity, which can be used to study MEK1 functions.

As central signaling components, the activity of MEK1/2 is well-regulated by interacting proteins, protein kinases, and protein phosphatases. In order to allow this regulation, MEK1/2 contain several docking domains, as well as phosphorylation sites that are spread all over the molecules (Fig. 2). Thus, the very N-terminus of MEK (residues 3–11) contains a docking domain (D-domain), which interacts specifically with the CRS/CD domain of ERK1/2, and thereby, directly determines ERK1/2 activation (Tanoue et al. 2000). This region is also important for other MEK1 activities, including its effects on PPARγ and ERK1/2 localization. Another important domain in the N-terminus of MEK1 lies within residues 31–68. Deletion of residues 31–51, or substitution of residues within this area, cause high constitutive activation of MEK1, which together with its phosphomimetic mutations, is used for functional MEK studies. In addition, few activatory oncogenic (see below) or Cardio-Facio-Cutaneous (CFC) syndrome–causing mutations were identified C-terminal to residue 51 (Phe53Ser, Gln56Pro, Lys57Asn, ΔLys59, and Asp67Asn). Therefore, it is likely that the 31–68 region is important for maintaining the low basal MEK1 activity. Finally, another important part in this region is its nuclear export signal (NES; residues 32–44), which determines its subcellular localization, as described below.

Based on sequence alignment, the core kinase domain of MEK1 starts at residue 74 with the ATP binding site, and is stretched all the way to residue 361. This catalytic region contains several regulatory parts, including the activation loop (residues 212–225) and a Pro reach domain (PRD; residues 271–307). First, CFC-causing mutations in residues 124–130 (Pro124Leu, Gly128Val and Tyr130Asn/Cys) indicate that similar to residues 31–68, this region participates in maintaining the low basal activity of MEK1. Another important functional region is the activation loop of MEK1 containing three phosphorylation sites, including the inhibitory Ser212, and activatory Ser218 and Ser222. Finally, the third functional region of the kinase domain is PRD, which unlike other domains is



Mek, Fig. 2 Schematic representations of MEK1 and MEK2. The docking domains (*DD*), nuclear export signals (*NES*), activation loops (*AL*), proline rich domain (*PRD*), domain of versatile docking (*DVD*, MAP3K binding), and ATP binding site are marked. MEK1's natural oncogenic (*red*), and CFC-causing (*green*) mutations and phosphorylation sites (*yellow*) are stated. Putative phosphorylation site is dashed

somewhat different between MEK1 and MEK2. This region mediates/regulates MEK1's interactions and activity, but the full scope of its activities still requires clarification.

The C-terminal region of MEK1 is, as yet, another regulatory part of MEK1/2. It contains the domain for versatile docking (DVD; residues 362–381), which is conserved among other MAPKKs, and seems to be important for interaction with upstream kinases (Takekawa et al. 2005). Interestingly, a region close to the DVD was also implicated in the determination of MEK1's localization in the cytoplasm (Bendetz-Nezer and Seger 2005). In addition, Thr386, very close to the C-terminal edge of MEK1, was identified as a robust phosphorylation site that regulates MEK1 interactions. This phosphorylation, together with that of the nearby Thr384, was recently implicated in mediating the short-term nuclear translocation of MEK1 (Chuderland et al. 2008). Finally, Thr23, Ser24/25, Ser218, and Ser299 in MEK1 also serve as phosphorylation/autophosphorylation sites, but their role is not fully understood yet.

Subcellular Localization

The downstream targets of the ERK cascade are localized in various cellular organelles, including the cytoplasm, nucleus, plasma membranes, cytoskeleton, mitochondria, Golgi, and ER. However, in resting cells, the inactive MEK1/2, ERK1/2, and most of their MAPKAPKs are localized primarily in the

cytoplasm (Yao and Seger 2009). This cytoplasmic localization of the various components is maintained mainly by binding to cytoplasmic anchoring proteins. In the case of MEK1/2, the anchoring proteins include KSR, β-arrestin, paxillin, MP1, Grb10, IQGAP1, and others that interact with either the D- or PR-domains of MEK1/2. These interactions also seem to be important for the rapid downstream signaling by the ERK cascade upon activation. Interestingly, MEK1/2 are localized in the cytoplasm not only by docking interactions, but also due to their N-terminal CRM-dependent NES, which rapidly exports any nuclear MEK1/2, making the nucleus completely devoid of MEK1/2 molecules at this stage. Since MEK1/2 are known to interact with inactive ERK1/2 via their D-domain, the cytoplasmic MEK1/2 molecules whose D-domain is not hindered by interacting proteins, can by themselves anchor ERK1/2 in the cytoplasm. Thus, it was proposed that MEK1/2 serve as main cytoplasmic anchoring proteins for ERK1/2 in non-stimulated cells, and therefore are responsible for a significant part of the cytoplasmic distribution of these protein kinases, as well as some of their interacting proteins.

The cytoplasmic distribution of MEK1/2 and the other ERK cascade components is dramatically changed upon cellular stimulations. It was shown that upon stimulation, Rafs rapidly translocate to the plasma membrane, while ERK1/2 and RSKs translocate to the nucleus and other cellular organelles. Unlike the other components, initial studies described MEK1 as a constant cytoplasm-resident protein, both in resting cells and after stimulation. It was even proposed that the nuclear translocation of MEK1/2 may be hazardous to cells, and therefore, the NES serves as a safety system to avoid this unwanted nuclear accumulation. However, it was later shown that MEK1, and presumably MEK2, could rapidly translocate into the nucleus upon cellular stimulation. Thus, initiation of signaling via the cascade causes MEK1/2 to detach from ERK1/2 and from other anchoring molecules, and translocate separately from ERK1/2 into the nucleus. Unlike ERK1/2 that can be retained in the nucleus for minutes to hours, most MEK1/2 molecules are rapidly exported back to the cytoplasm shortly after translocation due to their NES, giving rise to the apparent constant cytoplasmic distribution. The role of this rapid MEK1/2 shuttle in and out of the nucleus has not been fully resolved, but might include phosphorylation of nuclear ERK isoforms such as the alternatively spliced forms ERK1b and, to some extent, ERK1c. Another possibility is that the translocated MEK1/2 are involved in the export of ERK1/2 out of the nucleus at late stages after stimulation (Yao and Seger 2009). Finally, MEK1 can also interact with other nuclear proteins (e.g., PPARγ) via its D-domain and induce their nuclear export upon stimulation. Based on all the data described above, it is clear that the subcellular localization of MEK1/2 plays an important role in the regulation of function of the ERK1/2 cascade and probably additional signaling components upon various cellular stimulations.

MEK in Cancer

As soon as the ERK cascade was elucidated, it became clear that it plays a role in the induction and development of cancer. It was initially shown that the ERK cascade transmits signals of many oncogenes such as growth factors, growth factor receptors, and other signaling components. In particular, B-Raf that is a part of the ERK cascade is known as a potent oncogen, especially in melanoma. Today, activation of ERK1/2 was reported in more than 85% of cancer cases, even those that are transformed by oncogenes that are thought to act downstream of the cascade, indicating that downstream components may utilize a positive feedback loop to activate the ERK cascade. In all these cases, the ERK cascade is implicated mainly in mediating uncontrolled proliferation which is one of the key features that underlie oncogenic transformation. Since MEK1/2 are the sole activators of ERK1/2, it is very likely that these components are activated in cancer as well. Staining of a limited number of cancer samples indeed confirmed the phosphorylation of MEK1/2 in cancer, but a widespread screen for MEK1/2 phosphorylation in various cancer types has not been performed as yet.

Although activating mutations of MEK1/2 that can induce transformation of tissue culture cells have been identified already in the early 1990s, early studies failed to identify oncogenic forms of MEK1/2 in tumors. However, the extensive sequencing efforts of human cancers in the last few years did identify relatively rare oncogenic mutations of MEK1 in a limited number of human cancers. Thus, the activating mutation Lys57Asn was identified in lung cancer and Asp67Asn in ovarian and column cancers. Interestingly, mutations in two inhibitory regions of MEK1

(Gln56Pro and Pro124Leu) were shown to confer resistance to MEK1/2 and B-RAF inhibition, indicating the possible activating properties of these regions in human cancers. Although activating mutations have been identified in CFC, and despite large sequencing efforts, no activating MEK2 mutations were identified in human cancer so far. The reason for this is not fully understood, but may be derived from the fact that MEK1 seems to regulate MEK2 activity mainly by their heterodimerization (Catalanotti et al. 2009).

The involvement of the ERK cascade in cancer, and the ability of dominant negative mutants of Rafs and MEK1/2 to reverse oncogenic transformation, prompted many studies aimed to develop efficient inhibitors for components of this cascade. Indeed, several Raf inhibitors have been developed over the years, and one of them, Sorafinib, is already in clinical use for several cancer types. Efficient small molecular weight inhibitors of MEK1/2 have been developed as well. When applied to animal models, these inhibitors significantly reduced the phosphorylation of ERK1/2 and, as a consequence, inhibited the growth of tumors in these models (Sebolt-Leopold et al. 1999). Therefore, several such noncompetitive inhibitors have been used in clinical trials, and indeed demonstrated impressive inhibition of ERK1/2 activity, as well as a very low toxicity. Unfortunately, at present, the efficacy of the inhibitors examined is not sufficient, even in melanomas that are driven by the oncogenic form of the MEK1/2 upstream activator B-Raf. Although it seems that recent MEK inhibitors are somewhat more successful, and likely to be approved for clinical use, new generation of MEK inhibitors should still be developed to fully exploit the centrality of MEK1/2 activity in various types of cancer.

Summary

MEK1/2 are members of the MAPKK family of signaling protein kinases. They function within the ERK signaling cascade, constituting an evolutionarily conserved group with three mammalian isoforms: MEK1, MEK1b, and MEK2. MEK1/2 are activated via phosphorylation on two Ser residues in their activation loops, and when activated, they phosphorylate ERK1/2 on their regulatory Tyr and Thr residues, thereby causing their activation. Importantly, ERK1/2 are the only known phosphorylation substrates of MEK1/2, and therefore, the latter serve as specificity determinants of the ERK cascade. However, protein and DNA interactions of MEK1 also implicate it in the regulation of the subcellular localization of ERK1/2 and PPARγ and in regulating MyoD transcription. Upon activation MEK1/2 rapidly translocate into the nucleus, and then are rapidly exported back to the cytoplasm in a mechanism involving CRM1. Significantly, the centrality of MEK1/2 and the whole ERK cascade indicate that their dysregulation may result in various diseases. Indeed, activating mutations of MEK1/2 were shown to induce developmental disorders, and additional activating mutations of MEK1 were shown to act as oncogenes in a limited number of cancer. Furthermore, MEK1/2 are sensitive to synthetic inhibitors, and several of them are currently being developed as anticancer drugs mainly for melanoma.

Historical Background

Polymyxin B sensitivity (PBS) 2, a yeast homologue of mitogen-activated protein kinase kinase 3 (Mek3), was originally cloned as a gene that conferred polymyxin B resistance to yeast cells (Boguslawski and Polazzi 1987). The amino acid sequence of the *PBS2* gene product showed strong homology to the serine/threonine protein kinase family (Boguslawski and Polazzi 1987). In 1993, it was shown that *PBS2* and its downstream *HOG1* genes, which code for a Mek3 homologue and a ▶ p38 mitogen-activated protein kinase (MAPK) homologue, respectively, are necessary for yeast cells to grow at high osmolarity (Brewster et al. 1993). Two years after that study, *Mek3* was first amplified by degenerative PCR as a human homologue of yeast *PBS2*, and overexpression of its gene product was revealed to activate p38 MAPK in response to osmotic stress, UV irradiation, and inflammatory cytokines (interleukin (IL)-1 and ▶ tumor necrosis factor (TNF)) in COS-1 cells (Derijard et al. 1995).

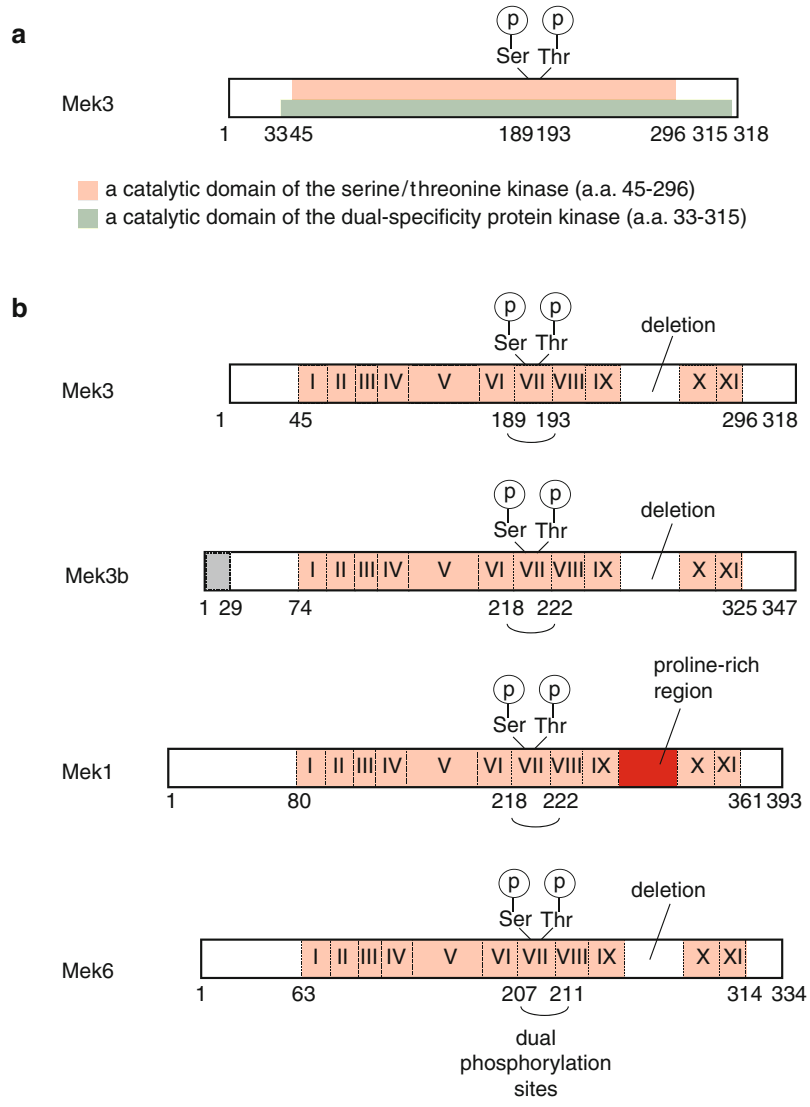
Protein and Gene Structure

The human *Mek3* gene has been mapped to 17q11.2 (Derijard et al. 1995). The *Mek3* gene has 12 exons and 11 introns, and its coding region contains 957 base pairs organized in nine exons (exons 2–10).

The human Mek3 protein consists of 318 amino acids, and its predicted molecular weight and isoelectric point are 36172.7 and 5.87, respectively. Mek3 contains two conserved motifs, a catalytic serine/threonine kinase domain (residues 45–296) and a catalytic dual-specificity protein kinase domain (residues 33–315) (Fig. 1a). Active Mek3 phosphorylates p38α, δ and γ MAPK and acts as a key mediator of various stress-mediated cellular responses (Cuadrado and Nebreda 2010).

The human ▶ Mek protein family contains seven kinases, Mek 1–7. Each member of the Mek family contains the Mek-kinase subdomains I–XI (Hanks et al. 1988) (Fig. 1b). Mek3, Mek4, and Mek6 phosphorylate p38 MAPK, whereas Mek1 and Mek2 phosphorylate extracellular signal-regulated kinase Erk1 and Erk2. Mek4 and Mek7 phosphorylate c-Jun N-terminal kinase (Jnk (1–3)). Mek5 is the only identified kinase upstream of Erk5.

Mek3 is approximately 50% and 80% homologous to Mek4 and Mek6, respectively (Derijard et al. 1995; Stein et al. 1996). In contrast to Mek1 and Mek2, all p38 MAPK stimulators include a large deletion that is located between subdomains IX and X (Fig. 1b). Both Mek1 and Mek2 contain a proline-rich region between these subdomains, which is required for the efficient activation of downstream Erk1 and Erk2 (Dang et al. 1998). Thus, the deletion could define the kinase substrate specificity of Mek3. A Mek3-specific inhibitor



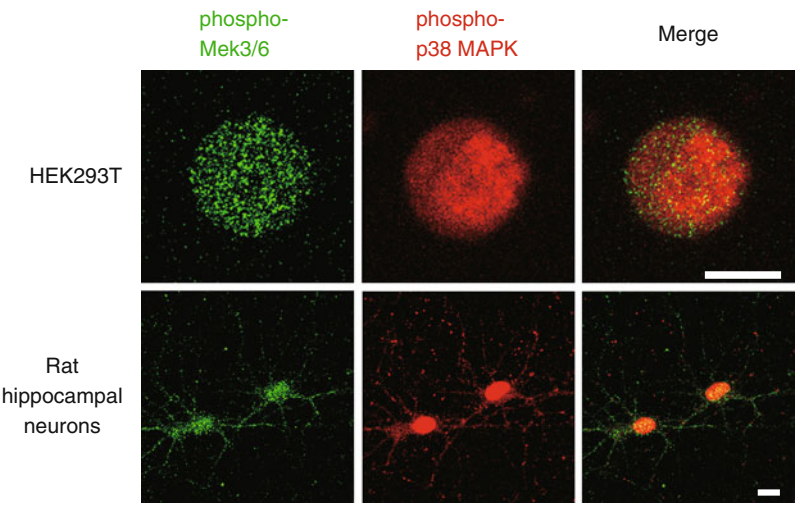
Mek3, Fig. 1 A deletion between subdomains IX and X may determine the kinase substrate specificity of Mek3. (**a**) Mek3 contains two catalytic domains. One is a serine/threonine kinase domain (residues 45–296), and the other is a dual-specificity protein kinase domain (residues 33–315). (**b**) Comparison of human Mek3 subdomains with those of human Mek3b, Mek1, and Mek6. The N-terminal extended region of MKK3b is shown in gray. Note that Mek3, Mek3b, or Mek6 do not contain a proline-rich region inserted between Mek-kinase subdomains IX and X of Mek1

has not yet been developed. UO126 is shown to weakly attenuate Mek3 activity. However, it preferentially suppresses Mek1 and Mek2.

Mek3b is an alternatively spliced form of Mek3. Mek3b is distinct from Mek3 at the 5′-end, encoding 29 extra amino acids at the N-terminus. Reminiscent of Mek3 and Mek6, Mek3b is activated by osmotic shock and phosphorylates p38 when expressed in cultured cells. Both Mek3 and Mek3b activate p38α, whereas only Mek3b phosphorylates p38β2, suggesting a role for the N-terminal region of Mek3 in the determination of substrate specificity (Enslen et al. 2000).

Localization

Mek3 is widely expressed, with its highest expression in skeletal muscle (Derijard et al. 1995). Immunostaining of HEK293T cells with Mek3-specific antibody indicates that this protein is localized to both the cytoplasm and the nucleus. Activated Mek3 and p38 MAPK are diffusely distributed in HEK293T cells and in hippocampal neurons. However, these phosphorylated proteins do not fully colocalize with each other (Fig. 2). There is no evidence for the subcellular translocation of Mek3 in response to cellular stresses.



Mek3, Fig. 2 Subcellular distribution of activated Mek3, Mek6, and p38 MAPK in HEK293T cells. Activated Mek3, Mek6, and p38 MAPK are widely distributed in HEK293T cells (*upper panel*) and rat cultured hippocampal neurons (*lower panel*) (P7). However, the localization of activated Mek3 does not necessarily correspond to that of activated p38 MAPK. The scale bar represents 10 μm

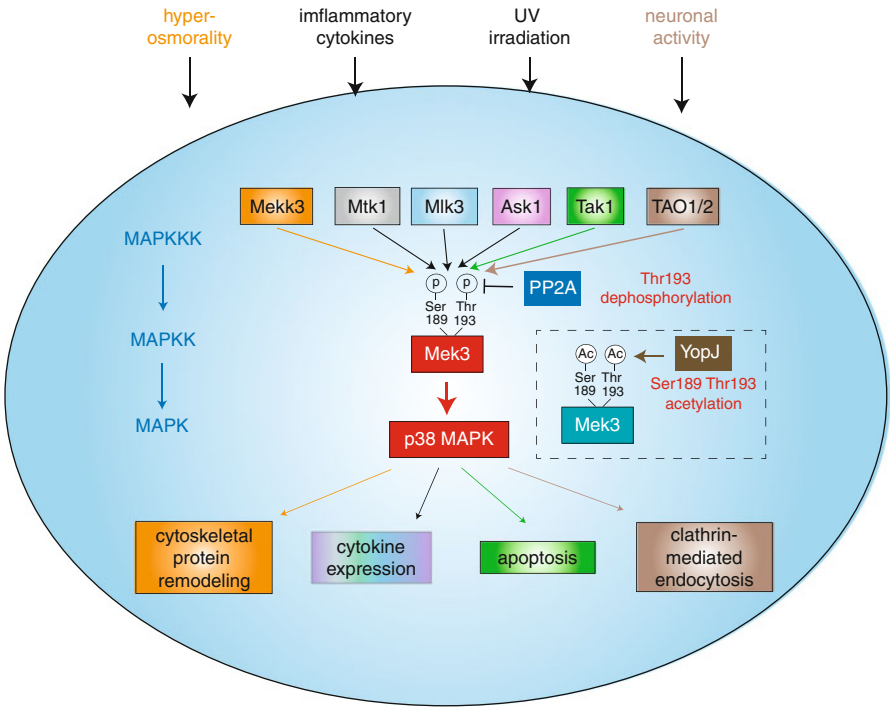
Interaction and Regulation

Mek3 binds to its upstream MAPKKKs, such as mitogen-activated protein/ERK kinase kinase (Mekk)3, Mekk4 (also known as MAP 3 Kinase 1; Mtk1), mixed lineage kinase (Mlk)3, apoptosis signal-regulating kinase (Ask)1, transforming growth factor (TGF)-beta-activated kinase (Tak)1, and thousand and one amino acid kinase (TAO)1/2 (Fig. 3). Through various external stimuli, such as hyperosmolarity, UV irradiation, inflammatory cytokine, and neuronal activity, MAPKKKs are first activated and then phosphorylate Mek3 at Ser189 and Thr193 in its activation loop (a region that lies outside the active-site cleft, residues 178–193 and 195–200) (Fig. 1) (Derijard et al. 1995). However, it is not well understood which MAPKKK is activated by each external stimulation.

Mek3 activity is down-regulated by phosphatases such as type 2 protein phosphatase (PP2A) (Prickett and Brautigan 2007). Phosphorylated Mek3 binds to alpha-4/immunoglobulin-binding protein 1 (Igbp1) and PP2A, which then enhances the site-specific dephosphorylation of Thr193 (but not Ser189) in the activation loop of Mek3 (Fig. 3). Moreover, Ser189 and Thr193 may be modified by an acetyltransferase, Yersinia outer protein (Yop) J (Fig. 3) (Mukherjee et al. 2006). This acetylation could consequently block phosphorylation of these residues, leading to the attenuation of Mek3 activity (Mukherjee et al. 2006). These results indicate that the level of Mek3 kinase activity is dependent on the phosphorylation, dephosphorylation, or acetylation state of its activation loop.

In addition, Mek3 binds to its own downstream proteins. For example, Mek3 is associated with Mirk (Minibrain-related kinase; also called Dyrk1B), which belongs to the Dyrk/minibrain family of dual-specificity tyrosine-regulated, arginine-directed protein kinases. The homophilic interaction of E-cadherin (a cell adhesion molecule) by cell-cell contact triggers the activation of a small G protein Rac and its downstream Mek3 (Jin et al. 2005). Phosphorylated Mek3 associates with and activates Mirk, which causes the phosphorylation and activation of transcriptional regulator hepatocyte nuclear factor (HNF)-1α. Mek3 up-regulates the Mirk kinase activity and the transcriptional activation of HNF1α, inducing gene expression associated with cell proliferation (Fig. 4a). Conversely, p38α and β-MAP kinases suppress Mirk by the dissociation of Mirk from Mek3. Mirk predominantly localizes in some carcinoma cell lines and may regulate cell proliferation by functioning at the junction between the p38 and Mirk signaling cascades (Fig. 4a).

Mek3 also binds to dynactin1 and microtubules. Dynactin1 binds to and cooperates with a microtubule-dependent motor protein, dynein, and this protein complex induces the movement of various cellular cargos, especially membranous vesicles. The disruption of dynactin1 or treatment with microtubule-disrupting drugs suppresses Mek3 and Mek6 phosphorylation in response to hyperosmolar stresses, suggesting that the



Mek3, Fig. 3 The MAPKKKs, Mek3, and p38 MAPK signaling pathways mediate various stress-dependent cellular functions

function of the dynein-dynactin complex may be to partly regulate the Mek3-p38 MAPK signaling cascade (Fig. 4b).

Apart from the interaction mentioned above, Mek3 is known to associate with several proteins including the osmosensing scaffold for Mekk (Osm), JNK-interacting protein 2 (Jip2), Smad7, c-Src, c-Met, phospholipase C (PLC)-β2, and Rho effector protein kinase N1 (Pkn1) (Yasuda et al. 2009). Such Mek3-interacting proteins are involved in various cellular functions. Details of Osm, Smad7, c-Src, and c-Met are described in the section Protein Function.

Protein Function

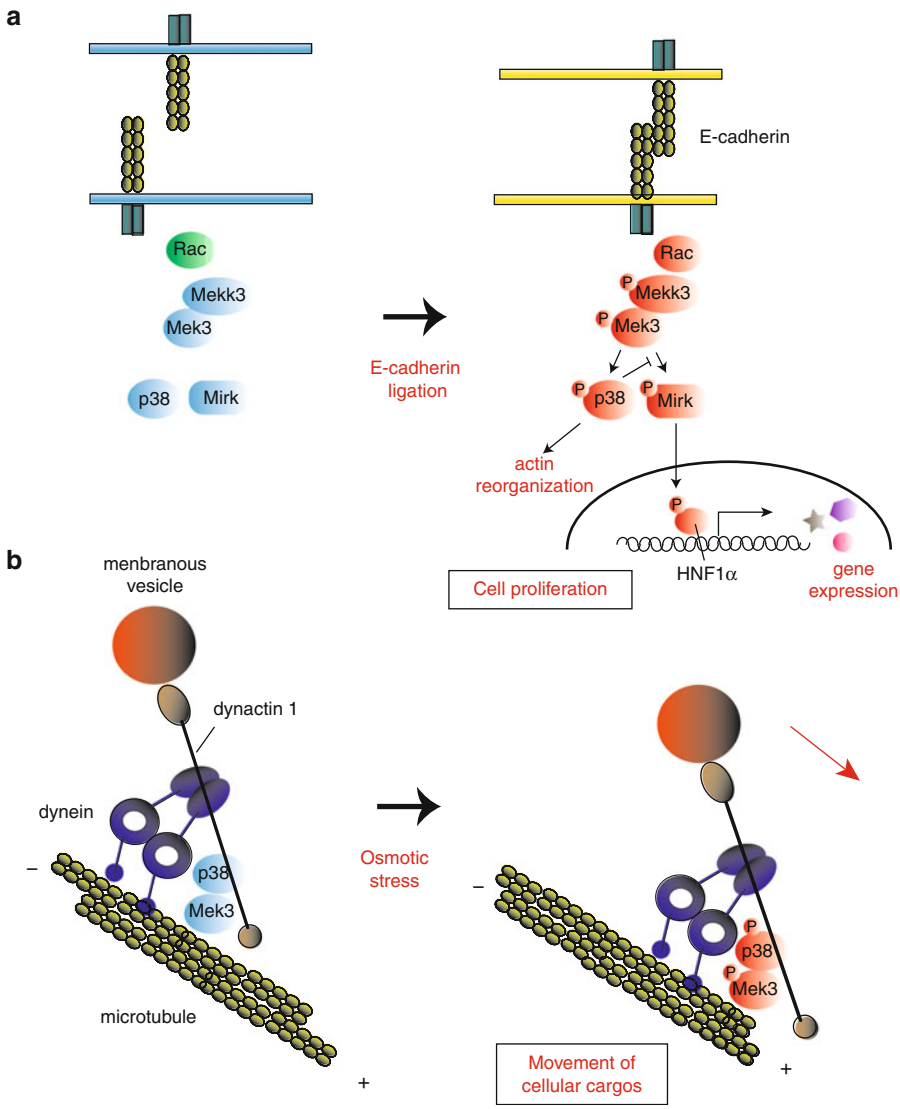
Whereas Mek6 activates all p38 isoforms, Mek3 is somewhat selective in that it preferentially phosphorylates the α, γ and δ subtypes of p38 MAPK at its regulatory Thr and Tyr residues (Cuadrado and Nebreda 2010). The activation of Mek3 and p38 MAPK is associated with several cellular functions, such as cytoskeletal protein remodeling, cytokine expression, apoptosis, and clathrin-mediated endocytosis.

Regulation of Cytoskeletal Proteins

Mek3 activation is involved in the stress-mediated remodeling of cytoskeletal proteins. For example, osmotic shock may activate the Mek3-p38 MAPK signal. Elevated Mek3 and p38 activities cause the recruitment of the scaffold protein Osm with Rac/Mekk3/Mek3/p38 to the actin cytoskeleton. This protein recruitment is likely to enhance the Mek3 and p38 interaction and kinase activity. Activated Mek3/p38 may consequently trigger actin polymerization and the formation of an actin-based ruffle structure (Fig. 5a).

Mek3 also regulates actin polymerization by binding to c-Met (a hepatocyte growth factor/scatter factor (HGF/SF) receptor) and its associated cytoplasmic binding protein kinase c-Src (a member of the cytoplasmic tyrosine kinase family). In this pathway, c-Met stimulates c-Src and its downstream molecule Rac1 that activates the Mek3-p38 MAPK signaling, leading to actin polymerization (Fig. 5a). The active forms of Rac, Mek3, and p38 MAPK are detected in signet-ring carcinoma cell lines (Kobayashi et al. 1999).

How does the activation of the Rac/Mek3/p38 MAPK pathway affect cytoskeletal reorganization? Hitherto, the p38 MAPK substrate, ▶ Mapkap kinase 2 (MK2), has been revealed to be involved in this mechanism. MK2 phosphorylates its downstream heat shock protein HSP27, which acts as an actin-capping protein. Phospho-HSP27 causes the release of free actin filament

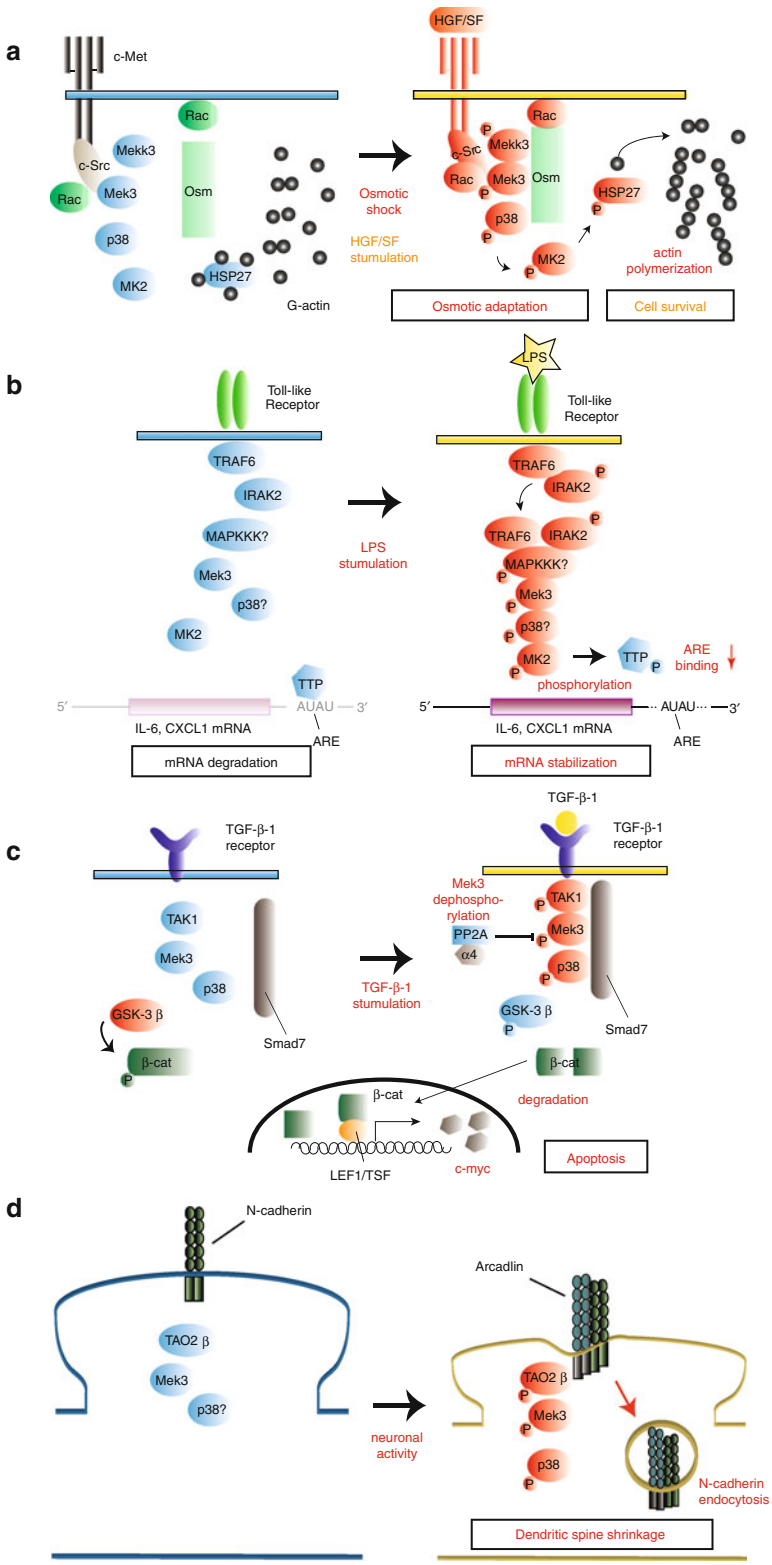


Mek3, Fig. 4 Mek3-interacting proteins. (**a**) Mek3 associates with its downstream protein Mirk. (**b**) Mek3 binds to dynactin 1, a component of the dynactin complex

barbed ends, which may result in actin polymerization (Fig. 5a) (Cuadrado and Nebreda 2010). Thus, Mek3 might control cell migration, cell adhesion, or cell shape by influencing cytoskeletal proteins under pathological conditions.

Cytokine Expression

The stress-mediated activation of Mek3 positively regulates the expression of several cytokines such as interleukin (IL)-1α, IL-1β, IL-6, and IL-12 (Cuadrado and Nebreda 2010). Mek3 knockdown shows selective defects in the response of fibroblasts to tumor necrosis factor (TNF)-α, including reduced p38 MAPK activation and cytokine expression (Cuadrado and Nebreda 2010). In addition, Mek3 mediates lipopolysaccharide (LPS)-triggered posttranscriptional control of cytokine and chemokine expression. LPS stimulation induces the formation of a complex consisting of Irak2 (a member of the IL-1 receptor-associated kinase (Irak) protein family), ▶ Traf6, MK2, and Mek3, and this interaction appears to regulate Toll-like receptor-mediated signaling (Fig. 5b). Elevated Mek3, p38, and MK2 activities cause the phosphorylation of its downstream mRNA destabilizing protein, tristetraprolin (TTP), which binds to the AU-rich element (ARE) of cytokine mRNA in the 3′-noncoding region. The phosphorylation of TTP leads to a reduction in the affinity to ARE and consequently stabilizes cytokine and chemokine mRNAs, such as IL-6



Mek3, Fig. 5 Mek3 plays a pivotal rote in various stress-mediated cellular functions. (**a**) Mek3 activity affects actin polymerization in response to stress. (**b**) LPS stimulation causes the activation of the Mek3-p38-MK2 signal, which may stabilize cytokine mRNAs. (**c**) Activated Mekm3/p38 signal may trigger TGF-β1-induced apoptosis. (**d**) Mek3/p38 activity regulates N-cadherin endocytosis, which causes dendritic spine shrinkage in a neural activity-dependent manner

and chemokine (C-X-C Motif) ligand 1 (CXCL1) (Fig. 5b) (Hitti et al. 2006). These findings indicate that Mek3 might contribute to the stabilization of cytokine mRNAs after exposure to various forms of stress.

Apoptosis

Activation of Mek3 also regulates the induction of apoptosis. That is, the Tak1-Mek3-p38 MAPK signaling complex mediates transforming growth factor (TGF) β1-induced apoptosis. In addition, Smad7 might facilitate this TGF-β-induced apoptosis as a scaffold protein by binding to Tak1, Mek3, and p38, and enhancing each interaction. As a downstream target of p38 MAPK, glycogen synthase kinase (GSK)-3 is phosphorylated and inactivated. The inactive form of GSK-3β causes dephosphorylation and degradation of ▶ β-catenin, which binds to a transcriptional regulator, lymphoid-enhancer binding factor 1 (LEF1)/T-cell-specific factor (TSF), and may increase the expression of some apoptotic inducers, such as ▶ *c-myc* (Fig. 5c) (Edlund et al. 2005). These results suggest that apoptosis may be regulated by Mek3 kinase activity.

Clathrin-Mediated Endocytosis

Activation of Mek3 is related to the mechanism of clathrin-mediated endocytosis. For instance, the endocytosis of N-cadherin is regulated by the Mek3-p38 MAPK activity in neurons. The cytoplasmic region of a neuronal activity-inducible protein, arcadlin, binds to the TAO2β/Mek3/p38 signalosome and initiates N-cadherin endocytosis, causing neuronal activity-dependent dendritic spine retraction in hippocampal neurons (Fig. 5d) (Yasuda et al. 2007). This is the only situation in which a specific external stimulation regulates the activity of Mek3. In addition, the activation of a signaling cascade containing Mek3 and p38 may also cause α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptor endocytosis in the dendritic spines of hippocampal neurons, suggesting that Mek3 may play a pivotal role in endocytosis in CNS neurons.

Phenotypes

Mek3-deficient mice appear to be viable and fertile (Cuadrado and Nebreda 2010). By contrast, the *Mek3*/*Mek6*-double knockout (KO) is lethal during midgestation at embryonic day 11.0–11.5 because of major defects during the development of the embryonic vasculature. The double KO mice also show developmental delay (Cuadrado and Nebreda 2010). This phenotype exhibited by *Mek3*/*Mek6* double KO mice is similar to that previously described for *p38α MAPK* KO embryos (Cuadrado and Nebreda 2010). Such a phenotypic difference between single and double KO mice suggests that some compensatory mechanisms can maintain p38 MAPK signaling. In fact, the amount of Mek6 protein is substantially increased in the unilateral ureteric obstruction kidney of *Mek3*-deficient mice (Ma et al. 2007).

Mek3-deficient mice show several phenotypes, including a reduction of cytokine production and impairment of immune responses (Cuadrado and Nebreda 2010). Additionally, *Mek3* KO mice exhibit a reduced progression of arthritis and type 1 diabetes (Fukuda et al. 2008; Inoue et al. 2006). Furthermore, mice with Mek3 deletions show a reduction of bone mass secondary to defective osteoblast differentiation (Greenblatt et al. 2010). Irrespective of the functional significance of Mek3, such minor phenotypes of its deficiency suggest the existence of possible redundant or compensatory mechanisms by Mek6 in vivo.

Summary

Mek3 is phosphorylated by various MAPKKKs, which become activated in response to various physical and chemical stresses, such as oxidative stress, UV irradiation, hypoxia, ischemia, and the presence of various cytokines. Activated Mek3 then specifically phosphorylates p38α, δ and γ MAPK. Conversely, Mek3 kinase activity is down-regulated by dephosphorylation or acetylation of the Ser and Thr residues in its activation loop. Although the crystal structure of Mek3 has not yet been determined, the primary structure indicates that it consists of Mek-kinase subdomains I–XI. An interesting structural characteristic of Mek3 is that it has a deletion between subdomain IX and X that could define the kinase substrate specificity for p38 MAPK. Mek3 converts diverse cellular stimuli into various stress responses, such as cytokine expression, cytoskeletal protein remodeling, apoptosis, and clathrin-mediated endocytosis. Further studies may be required to clarify the regulatory mechanism of Mek3 in response to various external stresses and the p38 MAPK activation machinery. The development of a Mek3-specific inhibitor is also needed to evaluate its pathophysiological significance of Mek3.

Synonyms

MEK5/ERK5: Mitogen-activated protein kinase 5/Extracellular signal-regulated kinase 5

Historical Background

► MEK5 is a dual-specificity protein kinase that belongs to the ► MAP kinase kinase family. MEK5 and ERK5 were first identified as the two components of a new protein kinase signaling cascade

(Zhou et al. 1995; English et al. 1995). MEK5 is the only identified immediate upstream MAP kinase kinase of ERK5. Alternative splicing of *mek5* at the 5'-end (NH_2-terminus) results in a 50 kDa (MEK5α) and a 40 kDa (MEK5β) isoforms. MEK5α acquires an extended NH_2-terminus with 89 amino acids longer than that of MEK5β and the longer NH_2-terminus endows MEK5α with unique features. This NH_2-terminus contains a Phox and Bem1 (PB1) protein dimerization/oligomerization domain, which is particular importance in the interaction between this kinase and other molecules. Besides an alternative splicing at 5'-end, both *mek5α* and *mek5β* appear to exhibit an additional alternative splicing at the 3'-end (COOH-terminus) where splicing at this 3'-end causes a deletion of ten amino acids in the catalytic domain. Thus, splicing at both 5'-end and 3'-end comprises four MEK5 alternative splice variants.

Functional difference between MEK5α and MEK5β due to the 5'-end splicing has been extensively examined (Cameron et al. 2004a; Nakamura and Johnson 2003; Nakamura and Johnson 2007; Nakamura et al. 2006; Seyfried et al. 2005). The constitutively active form of MEK5α (CA-MEK5α) but not CA-MEK5β activates ERK5 (Cameron et al. 2004a). Expression of CA-MEK5α but not CA-MEK5β promotes the nuclear translocation of ERK5, demonstrating the critical role of MEK5α NH_2-terminus in ERK5 activation. Deletion of 11 amino acids in the NH_2-terminus produces a mutant protein that is expressed but devoid of any kinase activity (Zhou et al. 1995). MEK5α and MEK5β have distinct tissue-wide distribution and cellular localization. MEK5α is highly expressed in liver and brain whereas MEK5β is ubiquitously present (English et al. 1995).

Null mice

ERK5 is not only a kinase but also a co-activator with a transcriptional domain in its COOH-terminus and this structure makes ERK5 different from ERK1/2. *Erk5*-null mutation results in embryonic lethality due to cardiovascular defects. Conditional *erk5*-knockout in cardiomyocytes, hepatocytes, and neuronal cells develops normally, but the depletion of ERK5 in Mx-1 Cre transgenic mice showed endothelial cell apoptosis and increased vascular permeability (Hayashi et al. 2004). *Mek5*-null mice are in a close phenocopy of *erk5*-null mice (Wang et al. 2005) providing indirect evidence that ERK5 is most likely a unique substrate of MEK5.

Physiological Roles in Different Cell Types

Epithelial Cells

MEK5/ERK5 signaling has been implicated in Epidermal Growth Factor (EGF)-mediated proliferation of epithelial cells (Kato et al. 1998). However, *mek5*-null embryo shows normal cell-cycle progression and the precise role of MEK5/ERK5 in epithelial cell proliferation is inconclusive. Rather, evidence supports an anti-apoptotic role of ERK5 (Squires et al. 2002; Wang et al. 2005) tipping the balance toward increase in viable cell number with an apparent increase in cell proliferation.

Endothelial Cells (ECs)

Steady laminar blood flow (s-flow) generates a frictional dragging force on the endothelium surface (fluid shear stress), which is known to possess anti-apoptotic and anti-atherosclerotic effects (Traub and Berk 1998). ERK5 is strongly activated by s-flow (Yan et al. 1999), and plays a key role in anti-apoptotic effects by increasing Bad phosphorylation, but the detailed mechanism remains unclear (Pi et al. 2004).

Due to its unique structure with a transcriptional domain on COOH-terminus, the activation of ERK5 by various stimuli is distinct from that of ERK1/2 (Abe et al. 1996). TNF-mediated JNK activation is inhibited by s-flow. This inhibition is completely reversed by treatment of ECs with BIX02188, a MEK5-selective inhibitor. However, treatment of ECs with PD184352, at a concentration that blocks ERK1/2 but not ERK5, shows no effect on flow inhibition of TNF-mediated JNK activation (Li et al. 2008). Moreover, s-flow can increase PPARγ1 activation which inhibits the expression of VCAM1 (vascular cellular adhesion molecule 1) and ICAM1 (intercellular adhesion molecule 1) (Pasceri et al. 2000).

Angiogenesis, the formation of new blood vessels from pre-existing ones, is a process that demands highly coordinated migration, proliferation, and differentiation of ECs (Carmeliet 2005). Activation of Epac, a cyclic adenosine 5'-monophosphate-activated guanine nucleotide exchange factor for Rap1, or Rap1 deteriorates angiogenesis via downregulation of ID1 (the inhibitor of differentiation 1). MEK5/ERK5 antagonizes the anti-angiogenic effect of Epac/Rap1 via upregulation of ID1 and increases angiogenesis (Biyashev et al. 2010; Doebele et al. 2009).

Studies on the effects of VEGF-mediated MEK5/ERK5 activation in primary human dermal microvascular

ECs (HDMECs) point out that the activation of MEK5/ERK5 is specifically essential for tubular morphogenesis but not for cellular proliferation. During tubular morphogenesis MEK5/ERK5 appears to be vital in mediating VEGF-stimulated Akt activation with a consequent suppression of caspase-3 activity and facilitation of EC survival (Roberts et al. 2010). However, the mechanism by which MEK5/ERK5 regulates Akt is still obscure.

FAK (focal adhesion kinase) is a central signaling molecule in focal contact turnover (Mitra et al. 2005). Constant hyper-activation of FAK and its downstream target p130Cas augments migration and motility, diminishes matrix-cell interaction, and stress fiber formation (Johnson et al. 2008; Kaneda et al. 2008). Constitutive activation of ERK5 by expressing MEK5DD not only phosphorylates FAK at Ser^{910} but also decreases p130Cas level, and blocks cell migration (Spiering et al. 2009).

Cardiomyocytes

MEK5/ERK5 cascade provides a critical link between extrinsic and intrinsic signals leading to cardiac hypertrophy (Nicol et al. 2001; Suzaki et al. 2002; Cameron et al. 2004b; Nadruz et al. 2003; Takahashi et al. 2005). To examine the impact of ERK5 in hypertrophic remodeling, cardiomyocyte-specific deletion of the *erk5* gene ($ERK5^{cko}$) was generated. Following hypertrophic stress, $ERK5^{cko}$ exhibits decreased hypertrophic growth and fibrosis than the control. However, cardiomyocyte apoptosis is increased in the absence of ERK5 (Kimura et al. 2010). Inhibition of ERK5 using BIX02189 (selective ERK5 inhibitor) or silencing ERK5 using siERK5 shows a reduction of MEF2 (myocyte enhancer factor 2) transcriptional activity and the attenuation of ERK5-mediated hypertrophic response. These observations provide clear evidence of the role of MEK5/ERK5 in hypertrophic remodeling via regulation of MEF2 activity (Nadruz et al. 2003; Kimura et al. 2010).

In addition to hypertrophic remodeling, MEK5/ERK5 can protect cardiomyocyte from apoptosis by regulating PDE3A (phosphodiesterase 3)/ICER (inducible cAMP early repressor) feedback loop (Ding et al. 2005; Yan et al. 2007; Kimura et al. 2010). Inhibition of PDE3 significantly increases cardiomyocyte apoptosis (Ding et al. 2005; Mongillo et al. 2004). Persistent downregulation of PDE3A and concomitant upregulation of ICER (PDE3A/ICER feedback loop) has been shown to play a key role in the pathogenesis of cardiomyocyte apoptosis. (Tomita et al. 2003; Ding et al. 2005). It has been reported that insulin-like growth factor-1 represses cardiomyocyte apoptosis via activation of ERK5 and inhibition of the PDE3A/ICER feedback loop (Yan et al. 2007). The cardio-protective effect of ERK5 activation also involves CHIP (ubiquitin ligase of the C terminus of Hsc-interacting protein). Upon activation, ERK5 binds to CHIP, increases CHIP ubiquitin E3 ligase activity, promotes degradation of ICER, and ultimately leads to apoptosis inhibition (Woo et al. 2010).

Embryonic Progenitor Cells (Myoblast)

Activated by the key fetal growth factor IGF-2, MEK5/ERK5 pathway is required for the pro-myogenic action of IGF-2 in myoblast differentiation (Carter et al. 2009).

Fibroblasts

Studies using fibroblasts derived from *erk5*- or *mek5*-null embryo suggest that MEK5/ERK5 is important for fibroblast cell survival. Bim, a protein of ▶ Bcl-2 family, is known to become hyper-phosphorylated upon apoptotic stress. Under basal condition, ERK5 is required to inhibit Bim phosphorylation, therefore repressing its pro-apoptotic activity (Puthalakath et al. 1999). The loss of ERK5 expression correlates with increased death of mouse embryonic fibroblasts under basal conditions. This phenomenon confirms the role of MEK5/ERK5 in fibroblast survival under basal condition via inhibition of the Bim pro-apoptotic effect. However, under an osmotic stress condition, MEK5/ERK5 uses a different mechanism to protect cells from apoptosis. Although the incubation of fibroblasts with sorbitol causes Bim phosphorylation, there is no significant difference in the ability of sorbitol to phosphorylate Bim between wild type and *erk5*−/− or *mek5*−/− mouse embryonic fibroblasts. Instead, in *erk5*−/− and *mek5*−/− mouse embryonic fibroblasts treated with sorbitol, the expression of death receptor FasL is elevated via upregulation of Foxo3a activity. This increase of FasL is responsible for enhanced cell death. This observation demonstrates that, under osmotic condition, MEK5/ERK5 prevents fibroblast cell death by suppressing the expression of FasL via downregulation of Foxo3a (Wang et al. 2006).

Prostate Cancer (PCa) Cells

Evidence supports the important role of MEK5/ERK5 cascade in PCa (Mehta et al. 2003; McCracken et al. 2008). Reduced ERK5 expression using siRNA, or

reduced EKR5 function using the MEK inhibitor leads to the inhibition of the motility and invasive capacity of human prostate cancer cell line PC3 both in vitro and in vivo (Ramsay et al. 2011).

Breast Cancer Cells

STAT3, a major member of the STAT family, has a role in cell proliferation and differentiation (Darnell et al. 1994; Schaefer et al. 1995; Buettner et al. 2002). STAT3 activation is detected in breast cancer specimens in patients with advanced disease and breast carcinoma cell lines, but not in normal breast epithelial cells (Watson and Miller 1995; Garcia et al. 1997, 2001). Similarly, increased MEK5 expression is noted in breast carcinoma cell lines and breast cancer tissues concomitant hyper- phosphorylation of STAT3 is present. Gene profile examination of apoptosis-resistant and -sensitive MCF-7 breast cancer cell lines identified a 22-fold increase in MEK5/ERK5. Overexpression of a constitutively active STAT3 results in a marked induction of MEK5 expression, whereas blocking of STAT3 activity inhibits MEK5 expression in breast cancer cells. Therefore, the role of STAT3 as an upstream regulator for MEK5 induction was proposed (Weldon et al. 2002; Song et al. 2004). However, details on how STAT3 regulates MEK5 expression are largely unexplored.

Hepatocytes

TGF-β (transforming growth factor β) is a multifunctional cytokine that is involved in the regulation of hepatic growth (Bissell et al. 2001; Zavadil and Bottinger 2005). Snail, a zinc-finger transcription factor, is an early TGF-β-responsive gene (Cicchini et al. 2008), with its activity controlled by various signaling pathways at multiple levels (Barrallo-Gimeno and Nieto, 2005). Previous studies show the role of GSK-3β (glycogen synthase kinase-3β) in inactivation and degradation of Snail through the proteasomal pathway (Bachelder et al. 2005; Zhou et al. 2004). The degradation of Snail mediated by GSK-3β occurs in a MAPK-dependent manner (Zhou et al. 2004). TGFβ-mediated activation of MEK5/ERK5 appears essential for the functional inactivation of GSK-3β, and stabilization of the snail protein expression (Marchetti et al. 2008).

Neuronal Cells

Peripheral target-derived neurotrophins acting on neurotrophin receptors on the nerve terminals results in endocytosis and transport of the neurotrophin-receptor complex through the axon to the cell body. This retrograde signaling by neurotrophins acts via activation of ERK5 in the cell soma (Watson et al. 2001). A recent review indicates that the MEK5/ERK5 pathway mediates the promotion of neuronal survival and differentiation both in vitro and in vivo (Obara and Nakahata 2010).

Regulation of MEK5/ERK5 Activity

PB1 Domain-Containing Molecules

MEK5/ERK5 interacts specifically with one another but does not interact with kinases in the MEK1/ERK1 signaling pathway. This specificity is likely due to MEK5 PB1 domain, which determines the binding partners for this kinase. Molecules contain a PB1 domain such as atypical PKCς (aPKCς), ▶ MEK kinase (MEKK)2/3, p62 (Sequestosome 1), and Par-6 (Partitioning defective 6 homolog a) (Moscat et al. 2006) can associate with MEK5 via the PB1 domain (Lamark et al. 2003).

aPKCζ aPKCς regulates MEK5/ERK5 activity in an enzymatic activity-independent manner. The interaction between aPKCς and MEK5 is needed for EGF-mediated ERK5 stimulation (Diaz-Meco and Moscat 2001). Upon activation of Gq-couple G protein-coupled receptors (GPCR), both aPKCς and MEK5 bind to Gαq thus forming a ternary complex that seems essential for ERK5 activation (Garcia-Hoz et al. 2010). A recent study reported that aPKCς directly associates with and phosphorylates ERK5, and these events are required to increase eNOS protein degradation in ECs (Nigro et al. 2010).

(MEKK)2/3 Unlike aPKCς, (MEKK)2/3 activates MEK5/ERK5 in an enzymatic activity-dependent manner (Diaz-Meco and Moscat 2001). Although both MEKK2 and MEKK3 specifically interact with MEK5 and activate ERK5, the activation of ERK5 by MEKK2 is more potent than that of MEKK3. MEKK2 associates with Lad, an SH2 domain-containing adaptor protein, and activates Src kinase that is necessary for ERK5 activation in response to EGF. Thus, the association between MEKK2 and Lad indicates an important role of Src–Lad in MEKK2–MEK5/ERK5 signaling (Sun et al. 2003).

p62 Depletion of p62 using antisense oligonucleotide inhibits MEK5-mediated MEF2C transactivation

presenting a possible functional role of the p62–MEK5/ERK5 interaction (Lamark et al. 2003).

Others

AMP-activated Protein Pinase (AMPK) AICAR (5-aminoimidazole-4-carboxamide ribonucleoside) is an agonist of AMPK. AICAR has been found to increase MEK5/ERK5 signaling. This increase is impeded by a dominant negative MEK5, thus rendering AMPK as an upstream regulator of MEK5 (Young et al. 2009). The exact regulatory mechanism between AMPK and MEK5 is unclear.

Epac1 (exchange factor for the small GTPase Rap1) The muscle-specific A kinase anchoring protein (mAKAP) signal transduction complex (mAKAP-PKA-PDE4D3) regulates cardiac hypertrophy. PDE3D3 acts as a scaffolding protein to recruit Epac1 to the mAKAP complex. ERK5-mediated PDE4D3 phosphorylation decreases phosphodiesterase activity and maintains a sustained peak of cAMP concentration (Hoffmann et al. 1999; Dodge-Kafka et al. 2005; Dodge-Kafka and Kapiloff 2006).

ERK5 SUMOylation

SUMOylation is a process of covalent attachment of SUMO (small ubiquitin-like modifier) proteins to specific lysine residues of target proteins (Johnson 2004). ERK5 has been reported to be SUMOylated at the NH_2-terminus (Lys-7 and Lys-22) when stimulated by ROS (reactive oxygen species) and AGE (Advanced Glycogen End product). The SUMOylation of ERK5 significantly inhibits ERK5 transcriptional activity (Woo et al. 2008). Inhibition of ERK5 SUMOylation by constitutively active (CA)-MEK5α is independent of ERK5 kinase activity, but dependent on the binding between MEK5-ERK5 (Shishido et al. 2008). Additionally, in diabetic hearts with exacerbation of left ventricular dysfunction after myocardial infarction, ERK5 SUMOylation is increased. Reduction of ERK5 SUMOylation using CA-MEK5α significantly improves cardiac function after myocardial infarction in diabetic mice, but not in nondiabetic mice. This observation implicates the crucial role of ERK5 SUMOylation in ROS-mediated ERK5 transcriptional repression and the contribution of this process to poor cardiac function after myocardial infarction in diabetics (Shishido et al. 2008).

Downstream Targets of MEK5/ERK5

Unlike other MAP kinases, ERK5 possesses not only a kinase domain that phosphorylates its substrates but also a transcriptional domain which is encoded by its long C-terminal region. Consequently, ERK5 transmits signals from MEK5 to downstream molecules either by phosphorylating or trans-activating. In the latter mechanism, ERK5 acts as a co-activator, binding to transcription factors and enhancing their activities (Akaike et al. 2004; Kasler et al. 2000). Furthermore, via direct or indirect protein–protein interaction, MEK5/ERK5 activates downstream signaling by phosphorylation.

Regulation via Phosphorylation

MEF2 (Myocyte Enhancer Factor 2) MEF2 belongs to a super family of transcription factors, consists of four *mef2* genes, referred to as MEF2A, – B,-C, and –D (Yang et al. 1998). MEK5/ERK5 specifically phosphorylate and activate MEF2A, –C, and –D but not MEF2B. MEK5/ERK5-induced MEF2 phosphorylation is necessary for the activation of MEF2 transcriptional activity by both ERK5 and growth factors (Kato et al. 1997; Kato et al. 2000). However, there is an alternative mechanism suggested that views the MEF2D transcriptional activity as predominantly regulated by ERK5 transcriptional activation domain and not by the kinase domain (Kasler et al. 2000). Members of the MEF2 family can bind to the endogenous KLF2 promoter and are crucial component of the transcriptional machinery required for the regulation of KLF2 expression (Parmar et al. 2006).

KLFs (Kruppel-Like Factors) KLF2: A mechano-activated transcription factor that control vasoprotective, anti-thrombotic, and anti-inflammatory responses to laminar flow (Dekker et al. 2002; SenBanerjee et al. 2004; Suzuki et al. 2005). KLF2 enhances endothelial nitric oxide synthase (eNOS) expression and reduces cytokine-mediated adhesion molecule expression (Lin et al. 2005; Parmar et al. 2006; SenBanerjee et al. 2004). The increase in KLF2 activity is triggered by steady laminar flow via the MEK5/ERK5/MEF2 signaling pathway.

KLF4: Likewise, *Klf4* has recently been reported as a shear stress-activated gene and an important regulator of inflammation in ECs. The activation of MEK5/ERK5 mediated by shear stress inhibits inflammatory responses in microvascular ECs, partly via ERK5-dependent induction of KLF4 (Clark et al. 2010). The expression

of KLF4 largely reproduces the protective phenotype in ECs. Overall, these results collectively underscore a major protective role of MEK5/ERK5/MEF2/KLF2 as well as -/KLF4 in ECs in response to pro-inflammatory stimuli (Parmar et al. 2006; Ohnesorge et al. 2010; Clark et al. 2010).

Cx43 (Connexin 43) MEK5/ERK5 activation is critical for EGF-mediated uncoupling of Cx43 gap junction, in which the activated ERK5 directly associates with, selectively phosphorylates Cx43 at Ser255, and regulates Cx43 gap junction uncoupling (Cameron et al. 2003).

Sap1a (TCF/Ets Transcription Factor SRF Accessory Protein-1a) The MEK5/ERK5 cascade activates the Serum Response Element (SRE) via Sap1a but not via the related transcription factor Elk1 and corroborated by the observation that MEK5/ERK5 can phosphorylate Sap1a but not Elk1. In contrast, ERK1/2 can phosphorylate and activate both Sap1a and Elk1. This difference proposes an overlapping but distinct function in regulating immediate early genes expression between the MEK5/ERK5 pathway and the ERK1/2 pathway (Kamakura et al. 1999).

Fos Family *c-Fos:* Activated MEK5/ERK5 augments the expression of oncogenic protein c-Fos (Kamakura et al. 1999), accounts for the phosphorylation and stabilization of c-Fos (Terasawa et al. 2003). Through the phosphorylation of c-Fos at Thr232 in the nuclear extraction signal (residues 221–233), MEK5/ERK5 inhibits c-Fos nuclear export. In addition, ERK5-mediated phosphorylation of c-Fos at Ser32 disrupts the interaction between c-Fos and the E3 ubiquitin ligase enzyme UBR1, and MEK5/ERK5 stabilizes c-Fos via phosphorylation of both Thr232 and Ser32 on c-Fos (Sasaki et al. 2006). ERK1/2 can also cause phosphorylation and stabilization of c-Fos. However, the activation of MEK5/ERK5 increases c-Fos transcriptional activity, but ERK1/2 does not. Both ERK5 kinase domain and transcriptional domain are required for the modulation of the transcriptional activity of c-Fos (Terasawa et al. 2003).

Fra-1: A member of the Fos family proteins, Fra-1 was previously found phosphorylated by ERK1/2. This phosphorylation is important for the activation of Fra-1 transcriptional activity (Young et al. 2002). Later, Terasawa et al. reported that the MEK5/ERK5 also regulates Fra-1 activity (Terasawa et al. 2003).

SGK (Serum- and Glucocorticoid-Inducible Kinase) Attempt to understand the role of MEK5/ERK5 in EGF-induced cell proliferation recognizes SGK as a cellular protein that interacts with ERK5. SGK, a serine/threonine kinase, is crucial for the G1/S cell cycle transition (Buse et al. 1999). Activated ERK5 phosphorylates SGK at Ser78 which is necessary for the activation of SGK and, more importantly, for cell proliferation (Hayashi et al. 2001).

p90RSK MEK5/ERK5 can phosphorylate p90RSK. However, physiological role of the p90RSK activation by ERK5 is controversial and may depend on the stimuli and cell type (Pi et al. 2005; Ranganathan et al. 2006).

Regulation via Interaction: PPARs (Peroxisome Proliferator-Activated Receptors)

PPARγ-1: Although activated MEK5/ERK5 mediates PPARγ-1 activation, a direct phosphorylation of PPARγ1 by ERK5 is not detected. Instead, association between the middle region (arginine-rich) on ERK5 and the hinge-helix region on PPARγ1 has been found (Akaike et al. 2004). The inactive N-terminal ERK5 kinase domain acts as a negative regulator of its middle region, and ERK5 activation induced by MEK5 disrupts this N-terminal inhibitory effect, leading to association of ERK5 with PPARγ1 and transactivation of PPARγ1.

PPARδ: MEK5/ERK5 also increases PPARδ transcriptional activity by a similar protein–protein association mechanism, but the binding site of ERK5 on PPARδ is different from that on PPARγ (Woo et al. 2006).

Nuclear Translocation

When ERK5 is non-phosphorylated the transcriptional activity in COOH-terminus is suppressed (Kondoh et al. 2006). Activation of ERK5 by MEK5 facilitates ERK5 auto-phosphorylation in the COOH-terminus and ERK5 is translocated from the cytoplasm to the nucleus (Mody et al. 2003; Carter et al. 2009).

Pharmacological Inhibitors

The unavailability of selective MEK5/ERK5 inhibitors is one of reasons why the number of studies for MEK5/ERK5 is limited compared to those for ERK1/2. In 2008, two novel selective MEK5 inhibitors, BIX02188 and BIX02189, were identified and these inhibitors were shown to inhibit the catalytic

function of purified MEK5 enzyme (Tatake et al. 2008). Availability of these selective MEK5/ERK5 inhibitors should contribute to further deciphering of the biological role of this signaling pathway.

Summary

Although strongly activated by s-flow which protects ECs from becoming dysfunctional (Ziegler et al. 1998; Gimbrone et al. 2000), the precise role of ERK5 in atherosclerosis is unknown. Depletion of ERK5 in Mx-1-Cre transgenic mice shows EC apoptosis and increased vascular permeability, but the role of ERK5 in other vessel functions such as vessel dilation and inflammation remains to be explored. Exposure of cultured ECs to s-flow potently activates the kinase and transcriptional activities of ERK5, and inhibits both leukocyte binding and adhesion molecule expression (Surapisitchat et al. 2001; Yamawaki et al. 2003). Identifying molecules that can negatively regulate ERK5 activity, and examining the interplay between those molecules and ERK5 might reveal a potential therapeutic venue for protecting ECs from becoming dysfunctional and treating vascular diseases.

Microtubule Affinity Regulating Kinases (MARK)

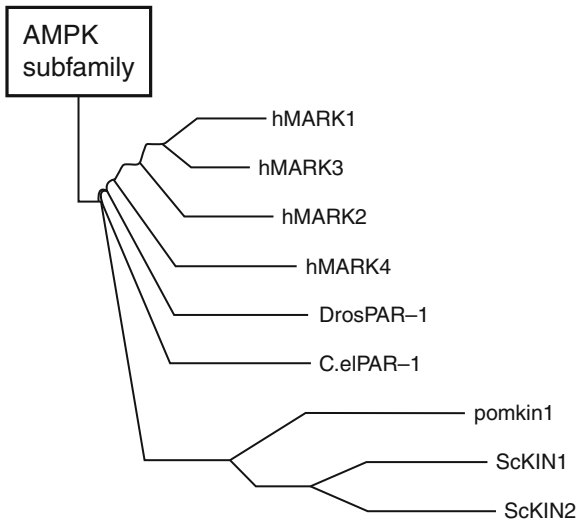
Gerard Drewes
Discovery Research, Cellzome AG, Heidelberg, Germany

Synonyms

MARK1: EMK3, hPAR-1c, KIAA1477; MARK2: EMK1, hPAR-1b; MARK3: EMK3, hPAR-1a, C-TAK1, KP78; MARK4: MARKL1, hPAR-1d, KIAA1860

Historical Background

Microtubule affinity regulating kinase (MARK) was first identified as an activity in brain extract with the ability to phosphorylate the microtubule-associated protein (MAP) tau and inhibit its binding to microtubules (MTs) (Drewes et al. 1995). All four human MARKs phosphorylate tau and the structurally related proteins MAP2 and MAP4 on their MT-binding domains, causing their dissociation from MTs in purified systems and in cells, which in turn leads to destabilization of MTs (Drewes et al. 1997, 1998). Since hyperphosphorylation and mislocalization of tau represent hallmarks of the neurofibrillar pathology of Alzheimer's disease (AD), MARKs have attracted interest as potential therapeutic targets early on (Drewes 2004). Other clues for the function of MARKs in cytoskeletal regulation and cell polarity resulted from studies in epithelial cells (Bohm et al. 1997) and from MARK orthologues in fission yeast (Drewes and Nurse 2003) and the extensive data from the nematode *Caenorhabditis elegans* (Kemphues 2000).

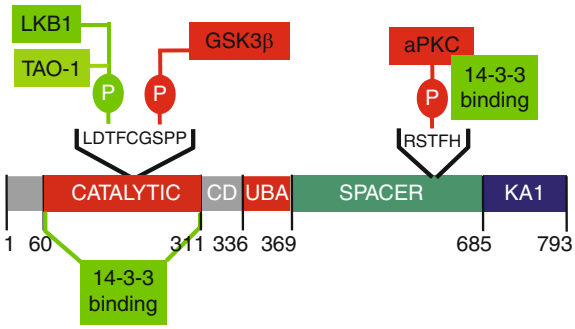


Microtubule Affinity Regulating Kinases (MARK), Fig. 1 MARK kinases are a part of the subfamily of the AMPK (AMP-dependent protein kinase)-related kinases. In humans, there are four MARK genes and 28 pseudogenes. The phylogenetic tree displays the relationship between the four human MARK gene products (GenBank numbers: MARK1; AB040910, MARK2; X97630, MARK3; U64205, MARK4; AY057448) and their orthologues from *Drosophila melanogaster* (PAR-1; AF258462), *Caenorhabditis elegans* (PAR-1; U22183), *Schizosaccharomyces pombe* (kin1; M64999), and *Saccharomyces cerevisiae* (KIN1; M69017, KIN2; M69018)

Phylogeny, Structure, and Regulation

Phylogeny: The MARK kinases represent a subgroup within the AMPK subfamily of the Ca^{2+}-calmodulin-dependent protein kinase branch of the human kinome. They are related to orthologous kinases in flies, worms, and yeast (Fig. 1). Humans express the four paralogous genes MARK1–MARK4 which undergo alternative splicing (Drewes et al. 1998). All paralogues comprise an N-terminal header (N), followed by a conserved catalytic domain and a ubiquitin-associated domain (UBA), which links via a more divergent spacer domain to the C-terminal "kinase associated domain" (KA1) (Fig. 2). The UBA and KA1 domains are only present in the AMPK-related protein kinases. The UBA domain plays a role in MARK activation (Jaleel et al. 2006).

Structure: Several crystal structures have been reported including the catalytic and UBA domains of MARK1, MARK2, and MARK3 (Marx et al. 2010), and the KA domain (Moravcevic et al. 2010). The structures of the catalytic domain are all in the inactive state and indicate a propensity for dimer formation. The overall structure of the kinase domain resembles that of other eukaryotic protein kinases consisting of a smaller N-terminal lobe and a larger C-terminal lobe with the active site pocket with the nucleotide located in between (Marx et al. 2010). The larger lobe contains the activation segment which, depending on its phosphorylation state, inhibits or permits the proper access of the peptidic substrate to the MgATP in the active site (see below). The UBA domain is located at the C-terminal end of the large lobe and may be able to confer autoinhibition by directly binding to the N-terminal lobe. The catalytic and UBA domains are connected via an acidic stretch of 15 amino acids, which bears similarity to the common docking domain in MAPK family kinases where it functions to bind upstream activating kinases and inactivating phosphatases. The C-terminus of MARK kinases folds into a compact domain ("KA1 domain") which is formed by five beta strands and two alpha helices and ends in an ELKL motif. This domain is less conserved in MARK4 which terminates with a DLEL sequence. The KA1 domain is a membrane association domain that binds acidic phospholipids like phosphatidylserine (Moravcevic et al. 2010).



Microtubule Affinity Regulating Kinases (MARK), Fig. 2 The domain structure of the four mammalian MARK/Par-1 kinases is conserved. A short diverse N-terminal sequence is followed by the catalytic domain, followed by a UBA (ubiquitin-associated) domain, which might be involved in the interaction with other proteins in a ubiquitin-dependent fashion. The C-terminal KA1 (kinase-associated) domain functions as a membrane anchor. All four human MARKs are activated by the phosphorylation of a conserved threonine residue by LKB1, and MARK2 can also be activated by TAO-1. The serine-proline motif nearby can be phosphorylated by GSK3b and this appears to confer inhibition. The serine in the spacer domain is phosphorylated by aPKC and regulates membrane localization. MARK/Par-1 can form complexes with 14-3-3 family proteins, which bind to the catalytic domain with a site on 14-3-3 outside the known phospholigand binding pocket

Regulation: MARK kinases are subject to diverse regulatory mechanisms including posttranslational modifications and the association with inhibitory proteins. The posttranslational modifications include phosphorylation and ubiquitination (Al-Hakim et al. 2008; Brajenovic et al. 2004; Lizcano et al. 2004; Timm et al. 2003). MARK2 purified from tissue is phosphorylated on T208 and S212 in the activation loop (Drewes et al. 1997). Phosphorylation of T208 (and the homologous sites on other MARKs) is required for activation and can be induced by LKB1, which constitutes a mammalian orthologue of *Drosophila melanogaster* and *C. elegans* PAR-4, and by TAO1/MAP3K16. Both upstream kinases increase MT dynamics through MARK activation (Kojima et al. 2007; Timm et al. 2003). Phosphorylation of S212 is mediated by GSK3β and leads to inactivation (Timm et al. 2008), although there is a conflicting report (Kosuga et al. 2005). Phosphorylation of S595 on MARK2 (and the homologous sites on other MARK isoforms) by aPKC (atypical PKC, a member of the Par-6 polarity complex) inactivates MARK by inducing its association with 14-3-3 proteins which in turn causes the delocalization from membranous compartments in polarized cells (Hurov and Piwnica-Worms 2007; Suzuki et al. 2004). MARK3 was shown to be inhibited by phosphorylation by ▶ Pim-1 (Bachmann et al. 2006) and MARK2 is inhibited by association with PAK5. It was proposed that the interplay between MARKs and the actin-modulating kinases PAK5 and TESK1 may provide a mechanism to route incoming signals to antagonistic MT network- or actin network-dependent cytoskeletal activity (Matenia et al. 2005). The proteomic analysis of MARK4 by tandem affinity purification revealed co-purification of several additional proteins including 14-3-3 proteins, the ubiquitin-dependent proteases USP7 and USP9x, subunits of protein phosphatase 2, and gamma-tubulin (Brajenovic et al. 2004). MARK4 and possibly other MARKs are subject to inhibitory polyubiquitination in vivo by unusual K29/K33-linked ubiquitin chains, which are regulated by USP9X (Al-Hakim et al. 2008). The interaction with 14-3-3 proteins appears to constitute a major function of MARKs (see below).

MARKs and Cell Morphology

MARKs and its orthologues in lower eukaryotes comprise protein kinases conserved from yeast to *C. elegans* and *Drosophila* to mammals, which are essential for cellular polarity, governing the establishment of the embryonic body axis and maintaining cell differentiation. The MARK/Par-1 kinase regulates the localization of structural PAR-proteins, and tightly regulated phosphorylation events provide a cellular regulatory mechanism governing important developmental decisions (Chen et al. 2006). In epithelial cells MARK2 is asymmetrically localized and knockdown or overexpression of inactive mutants perturbs the polarity in this cell line suggesting a conserved mechanism governing polarization from *C. elegans* embryos to mammalian cells (Cohen et al. 2007). Many of the effects of MARK on cell polarity are mediated by the MT system. In neurons, the phosphorylation of MAPs controls the binding to MTs, and bound MAPs stabilize the tubulin polymer, and their phosphorylation potentially provides a mechanism for regulating stability of MTs in a spatial and temporal fashion. MTs function as structural elements of cell morphology and as "tracks" for intracellular transport of vesicles and organelles (Matenia and Mandelkow 2009). Therefore, kinases that regulate MT stability may not only control cell shape and polarity but also cellular transport mediated

by the interplay of MAPs and motor proteins. In neurons, MARK2 and possibly MARK4 play role in neurite outgrowth and maintenance of neuronal polarity, a process requiring dynamic instability of MTs (Yoshimura et al. 2010; Trinczek et al. 2004). In hippocampal neurons, MARK2 overexpression inhibits axon formation whereas RNAi-mediated MARK2 knockdown induces multiple axons (Chen et al. 2006). MARK4 is absent from neuronal progenitor cells, but upregulated during neuronal differentiation (Moroni et al. 2006). MARK2 is also involved in the control of neuronal migration through the phosphorylation of doublecortin, a MAP present in the leading process of migrating neurons, which has been implied in neuronal migration disorders (Sapir et al. 2008). MARKs also impact body axis specification and morphogenic signaling via modulation of the Wnt signaling pathway by the phosphorylation of dishevelled (Dsh) which acts at a branching point for developmental decisions (Elbert et al. 2006).

Substrates of MARKs

Microtubule-associated proteins: Several of the effects of MARKs on the microtubule system are mediated via the phosphorylation of MAPs on serine and threonine residues. All four MARK isoforms can phosphorylate Tau and the related MAP2, MAP2c, and MARK4 at the repeated Lys-Xaa-Gly-Ser motifs in the MT-binding domain (Drewes et al. 1998). MARKs also phosphorylate other components of the MT system including doublecortins and motor proteins (Sapir et al. 2008; Yoshimura et al. 2010).

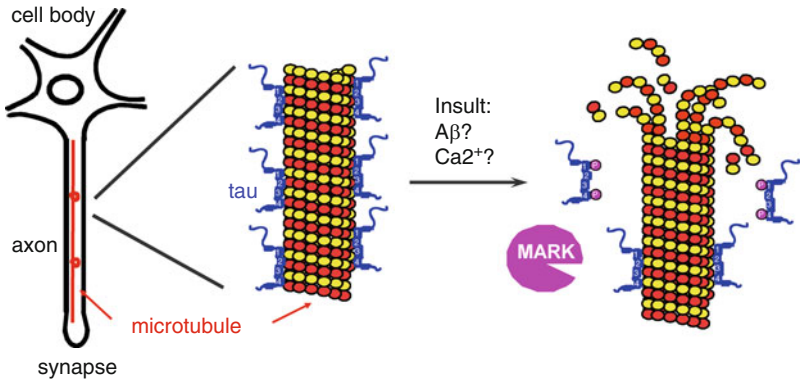
14-3-3 binding proteins: 14-3-3 proteins are phosphoserine adaptor proteins binding to multiple clients with pleiotropic cellular functions, e.g., in protein translocation and vesicle trafficking. MARK3 was shown to phosphorylate 14-3-3 binding motifs on different substrates: the phosphatases PTPH1 and CDC25; the suppressor of Ras/MAPK signaling KSR; the desmosomal protein plakophilin-2, and histone deacetylases. The phosphorylation of these substrates by MARK induces the formation of a complex between the substrate protein and 14-3-3, and changes the cellular localization and thus the function of the substrate (Matenia and Mandelkow 2009). 14-3-3 proteins also interact directly with the MARK catalytic domain, enabling the kinase to target substrates to 14-3-3 and re-phosphorylate sites quickly after dephosphorylation and disruption of 14-3-3 binding (Muller et al. 2003). Alternatively, the spacer domain of MARK2 can be phosphorylated by aPKC to generate a 14-3-3 binding motif leading to relocalization and inactivation (Hurov and Piwnica-Worms 2007).

Role of MARKs in Disease

Helicobacter infection: *Helicobacter pylori* is a pathogen associated with gastritis, ulcerations, and gastric adenocarcinoma. The virulence factor CagA can bind MARK2, inhibit its aPKC-dependent activation, and delocalize it from the membrane, causing junctional and polarity defects in gastric epithelial cells which results in mucosal damage, inflammation, and carcinogenesis (Saadat et al. 2007).

Neurodegenerative disease: The degeneration of neurons in AD and related diseases is characterized by filamentous aggregates of hyperphosphorylated proteins in neurons. Tau protein is the major component of these neurofibrillary tangles which cause neuronal death. Evidence implicating MARK in this process stems from models of tauopathies in the fruit fly *D. melanogaster* where the overexpression of the fly MARK orthologue PAR-1 causes neuronal degeneration dependent on both kinase activity and the presence of endogenous fly tau, and degeneration induced by exogenous expression of human tau was exacerbated by overexpression of PAR-1 (Nishimura et al. 2004). Taking together the biochemical studies on tau phosphorylation and function and the PAR-1 fly model, a cascade of events was proposed which is initiated by phosphorylation of microtubule-bound tau by MARK/Par-1 (Fig. 3) (Drewes 2004; Matenia and Mandelkow 2009). Both MARK4 and its upstream kinase LKB1 are rapidly upregulated in neurons after induced focal ischaemia in the mouse, a model for human stroke (Schneider et al. 2004). A genetic locus close to the MARK4 gene was reported to be associated with late-onset AD in a large genome-wide association study (Seshadri et al. 2010).

Metabolic syndrome: MARK2 knockout mice display growth retardation and dysfunctions in fertility, immune homeostasis, and learning and memory, but are lean, insulin hypersensitive, resistant to high-fat-diet-induced weight gain, and hypermetabolic (Hurov et al. 2007). MARK3 appears to have a related but



Microtubule Affinity Regulating Kinases (MARK), Fig. 3 Destabilization of microtubules by MARK. Axonal microtubules (*red*) function as tracks for synaptic vesicles. Microtubule function is regulated by bound tau protein (*blue*), which binds to the microtubules via the sequence repeats in its microtubule-binding domain. Activation of MARKs, possibly by an external insult to the cell such the disruption of intracellular calcium homeostasis by amyloid peptides, triggers phosphorylation of tau on its microtubule-binding domain. Phosphorylation triggers the dissociation of tau from the microtubule surface, changing the properties of the microtubule surface for transport processes and ultimately destabilizing the entire microtubule

nonredundant function as knockout mice exhibit increased energy expenditure, reduced adiposity with unaltered glucose handling, but normal insulin sensitivity. These mice were protected against diet-induced obesity and showed slow weight gain with resistance to fatty liver, with improved glucose handling and decreased insulin secretion. The crossing of MARK2 null mice with MARK3 null mice revealed that at least one allele is necessary for embryonic survival (Lennerz et al. 2010). The animal model data indicate that MARKs are important regulators of glucose and lipid metabolism and may be valuable drug target for the treatment of metabolic syndrome.

Summary

MARK genes are conserved in lower eukaryotic organisms like yeast, nematodes, and fruit flies where their function has been extensively studied by genetic means. From these studies MARKs have emerged as key regulators of cell polarity. Humans express four paralogous MARK genes encoding structurally related but functionally nonredundant protein serine/threonine kinases. MARKs are regulated by activating and inactivating phosphorylation events on distinct residues located in the activation loop and outside the catalytic domain. Key regulators of these pathways are the kinases LKB1 and aPKC which themselves constitute major regulators of cell polarity. MARK activity is also regulated by a tightly regulated interplay of 14-3-3 protein binding and membrane localization mediated by the C-terminal KA1-domain. Biochemical studies have proposed different classes of microtubule-binding proteins as substrates which are likely to transduce the effect of MARKs on cytoskeletal rearrangements during cellular transport processes and cell morphology. In disease, a deregulation of MARK activity may contribute to the loss of cell polarity in the affected highly polarized cell types including neurons (in Alzheimer's disease and other forms of dementia), gastric epithelial cells (in *H. pylori*-induced gastritis and in gastric cancer), and possibly in immune cell homeostasis.

MAP kinases; Microtubule-associated protein kinases

Historical Background

Mitogen-activated protein (MAP) kinases are a family of serine/threonine kinases that play a key role in transducing chemical and physical extracellular signals into a variety of intracellular responses. These protein kinases are among the most highly studied signaling molecules, as reflected by the more than 65,000 papers on "MAP kinase" listed in PubMed as of July 2011. This chapter provides a broad overview of the different subfamilies of MAP kinases. Each subfamily will then be treated in more detail in individual entries of this encyclopedia.

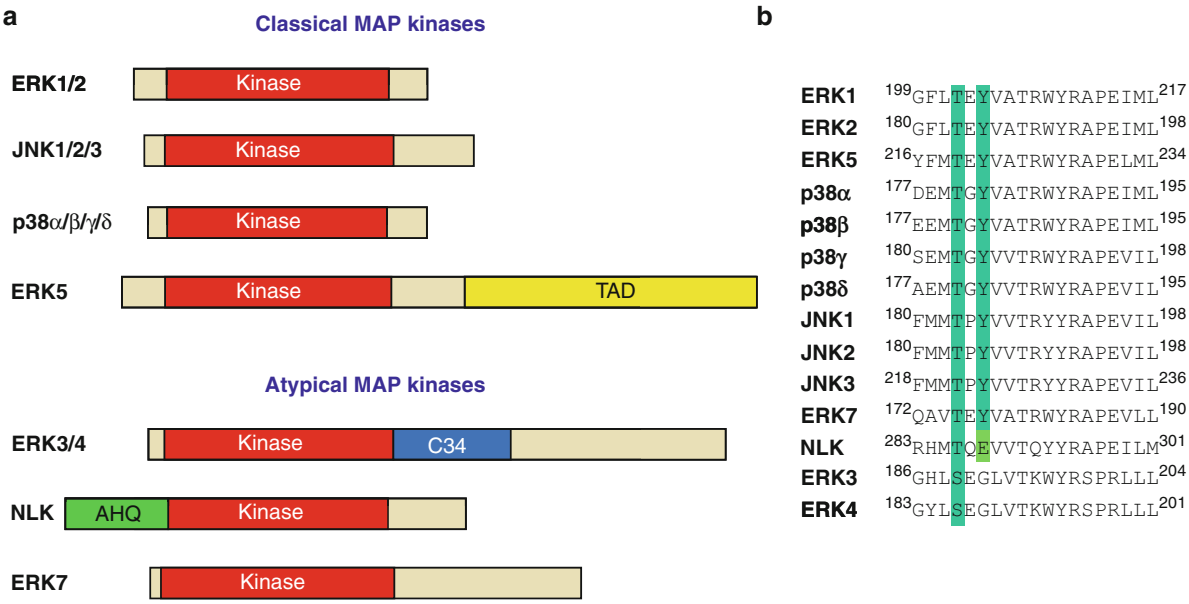
The discovery of MAP kinases goes back to 1987 when Ray and Sturgill reported the identification of a novel insulin-stimulated serine/threonine kinase activity from extracts of 3T3-L1 adipocytes that was capable of phosphorylating microtubule-associated protein-2 in vitro (Ray and Sturgill 1987). As a result, the enzyme was called microtubule-associated protein (MAP) kinase (Ray and Sturgill 1988). Partial purification of the novel kinase revealed that its activation was accompanied by phosphorylation on threonine and tyrosine residues, suggesting that it may be a direct substrate of the insulin receptor or another insulin-regulated tyrosine kinase (Ray and Sturgill 1988). Subsequent work indicated that the insulin-activated MAP kinase was identical to phosphoproteins of 41–43 kDa, previously shown to be phosphorylated on tyrosine in response to a variety of mitogens and growth factors (Rossomando et al. 1989). This led to the redesignation of the MAP acronym from microtubule-associated protein to mitogen-activated protein.

The first sequence of a mammalian MAP kinase, the insulin-stimulated MAP kinase named extracellular signal-regulated kinase 1 (Erk1), was reported in 1990 by the group of Melanie Cobb (Boulton et al. 1990). Interestingly, this protein kinase was found to be homologous to two recently identified budding yeast protein kinases, Kss1p and Fus3p, involved in cell cycle arrest in response to mating pheromones. This finding provided the first evidence for the conservation of MAP kinase functions across eukaryotic evolution. Later on, the discovery of additional MAP kinase pathways, first in yeast and then in mammalian cells, led to the concept of multiple MAP kinase subfamilies (Avruch 2007; Pearson et al. 2001; Widmann et al. 1999).

The initial observation that MAP kinase contains both phosphothreonine and phosphotyrosine, followed by the demonstration that dephosphorylation of either residue leads to inactivation of the kinase (Anderson et al. 1990) suggested that MAP kinase could serve to integrate information from two different signaling pathways. An intense effort was then made to identify these upstream MAP kinase kinase(s). Surprisingly, purification of a MAP kinase activator revealed that the threonine and tyrosine phosphorylation activities reside in the same polypeptide (Ahn et al. 1992). Shortly thereafter, a series of studies established that the MAP kinase kinases are themselves activated by phosphorylation by upstream MAP kinase kinase kinases, defining the basic architecture of MAP kinase pathways.

The Subfamilies of MAP Kinases

MAP kinases belong to the CMGC group of eukaryotic protein kinases, which also includes cyclin-dependent kinases (Cdks), glycogen synthase kinases, and Cdk-like kinases. They are proline-directed serine/threonine kinases, meaning that they phosphorylate substrates on Ser-Pro or Thr-Pro consensus motifs. In human, the MAP kinase family is encoded by 14 genes and is classified into 7 distinct subfamilies (Fig. 1)



Mitogen-Activated Protein Kinases, Fig. 1 Structure of MAP kinases. (**a**) Schematic representation of the structure of human MAP kinase subfamilies. Red, kinase domain; *TAD*, transactivation domain; *C34*, conserved in Erk3 and Erk4; *AHQ*, rich in alanine, histidine, glutamine. (**b**) Amino acid sequence of the activation loop of MAP kinase family members

(Coulombe and Meloche 2007). Many of the MAP kinase genes also encode alternatively spliced variants, further expanding the repertoire of these signaling enzymes.

Structure and Regulation of MAP Kinases

At the structural level, MAP kinases are composed of a catalytic kinase domain flanked by amino- and carboxy-terminal extensions of varying lengths (Fig. 1). All the family members display more than 40% identity to the founding member Erk1 in the kinase domain. One feature that distinguishes the different MAP kinase subfamilies is the sequence of the activation loop, which is the site of activating phosphorylation by upstream protein kinases. Several MAP kinases possess the motif Thr-Xxx-Tyr in the activation loop and are phosphorylated by a family of dual-specificity protein kinases known as MKKs (MAP kinase kinases) or ▶ MEKs (MAP kinase or ERK kinases). However, the Thr-Xxx-Tyr motif is absent in the MAP kinases Erk3, Erk4, and Nlk. Erk3 and Erk4 bear the motif Ser-Glu-Gly instead, whereas Nlk has a glutamic acid residue at the position of the tyrosine. The MAP kinase Erk7 has the Thr-Xxx-Tyr motif in its loop but is activated by a different mechanism. Based on these structural and regulatory features, it has been proposed to divide MAP kinases into classical and atypical enzymes (Coulombe and Meloche 2007). Classical MAP kinases, which are phosphorylated and activated by MKK family members, include the four subfamilies Erk1/2, Jnk1/2/3, p38α/β/γ/δ, and Erk5. Atypical MAP kinases, which are not substrates of MKKs, include the subfamilies Erk3/4, Erk7, and Nlk (Fig. 1).

Classical MAP kinases are organized into modules of three sequentially acting protein kinases (Pearson et al. 2001; Widmann et al. 1999). Typically, exposure to an extracellular stimulus induces the oligomerization and/or activation of a cell-surface receptor, often leading to the activation of a small GTPase of the Ras/Rho family, to a MAP kinase kinase kinase kinase, or to the binding of specialized adaptor proteins. These events ultimately lead to the activation of the upstream MAP kinase kinase kinase by a complex mechanism involving phosphorylation events and protein–protein interactions. The MAP kinase kinase kinase then phosphorylates and activates the MAP kinase kinase, which in turn activates the effector MAP kinase by dual phosphorylation of Thr and Tyr residues. Each MAP kinase kinase kinase confers responsiveness to

a distinct set of stimuli. Once activated, classical MAP kinases can phosphorylate a vast array of substrates present in all cellular compartments. The regulation of atypical MAP kinases is much less well understood (Coulombe and Meloche 2007).

MAP Kinases in Physiology and Disease

MAP kinases are activated in response to a variety of extracellular stimuli and cellular perturbations to regulate numerous cellular responses such as gene expression, cell proliferation and differentiation, cell survival, metabolism, motility, and adaptation (Coulombe and Meloche 2007; Cuadrado and Nebreda 2010; Hayashi and Lee 2004; Pearson et al. 2001; Weston and Davis 2007). Pharmacological and genetic studies have revealed that each of the MAP kinase subfamilies has distinct, but sometimes overlapping cellular functions. The best-characterized MAP kinase subfamilies are the Erk1/2, Jnk1/2/3, and p38α/β/γ/δ. The Erk1/2 MAP kinase pathway plays a major role in the regulation of cell proliferation in response to mitogenic factors. The Jnk pathway is involved in cell death signaling and metabolism, while the p38 pathway has been implicated in cytokine production and inflammatory responses.

Deregulated activity of MAP kinase pathways has been linked to many diseases, including cancer, inflammatory disorders, diabetes, and neurodegenerative diseases (Fremin and Meloche 2010; Kim and Choi 2010; Lawrence et al. 2008). For example, hyperactivation of the Ras-dependent Raf/▶ Mek/Erk1/2 pathway is frequently observed in human cancer as a result of aberrant activation of receptor tyrosine kinases or gain-of-function mutations in *RAS* or *RAF* genes (Schubbert et al. 2007). This has led to the clinical evaluation of small-molecule inhibitors of Mek1/2, the upstream activators of Erk1/2 MAP kinases, for the targeted therapy of cancer (Fremin and Meloche 2010). Inhibitors of p38 MAP kinase have also entered clinical trials to evaluate their efficacy in the management of rheumatoid arthritis. More recently, the p38δ MAP kinase inhibitor pirfenidone has been approved in Europe for the treatment of the fatal lung disease idiopathic pulmonary fibrosis. This represents the first small-molecule inhibitor of a MAP kinase to enter the market.

MAP kinases also play a causative role in certain congenital disorders. Indeed, germline mutations within components of the Erk1/2 MAP kinase signaling cascade have been associated with a number of clinical syndromes that are collectively termed "neuro-cardio-facial-cutaneous syndromes" (Bentires-Alj et al. 2006; Tidyman and Rauen 2009). Also, individuals with microdeletions encompassing the *Erk2* gene (*MAPK1*) in distal chromosome 22q11 exhibit a spectrum of craniofacial abnormalities, cardiac defects, and neurodevelopmental deficits (Ben-Shachar et al. 2008).

Summary

MAP kinases are components of evolutionarily conserved signaling modules that evolved to control a multitude of physiological responses required to maintain normal cellular and tissue homeostasis. Aberrant activity of MAP kinases has been observed in many human diseases, fostering the development of small-molecule inhibitors targeting these pathways. Considerable progress has been made over the last 20 years in identifying the core components of classical MAP kinase pathways and clarifying their mechanisms of regulation by extracellular stimuli. The physiological functions of classical MAP kinases have been extensively studied by the use of pharmacological inhibitors and genetic approaches. On the other hand, much less is known about the regulation and functions of atypical MAP kinases. Future challenges in the field include defining the individual contributions of MAP kinase isoforms using gene targeting and chemical genetic approaches, systematically characterizing the substrate profile of these enzymes by global proteomic strategies, further our understanding of the spatiotemporal regulation of MAP kinase pathways using mathematical modeling and synthetic biology, and exploiting the therapeutic potential of these enzymes.

Historical Background

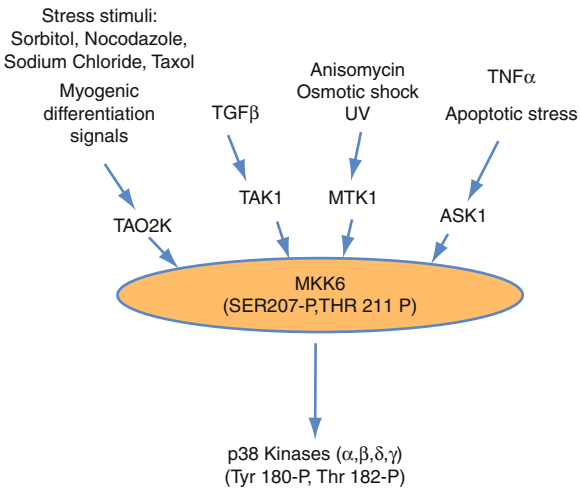
MKK6 is a dual specificity mitogen-activated protein kinase that was first cloned by PCR using degenerate primers for the conserved kinase domain of MKKs

(Han et al. 1996). MKK6 amino-acid sequence shares about 80% of similarity with MKK3 and 40% with MKK4 (Stein et al. 1996). Two MKK6 isoforms have been described in mouse and human (Cuenda et al. 1996; Han et al. 1996). The bigger form contains 334 amino acids and is highly expressed in heart, skeletal muscle, pancreas, and liver, while the smaller isoform of 278 amino acids has been detected only in skeletal muscle (Han et al. 1996).

Regulation of MKK6 Activity

Several extracellular stimuli initiate a cascade of upstream kinases that activate MKK6 by phosphorylation of two residues located in its activation loop domain (serine 207 and threonine 211) (Fig. 1). For instance, osmotic stress, ultraviolet light, and anisomycin activate MAP three kinase-1 (MTK1) which in turn phosphorylates MKK6 in a dose-dependent manner in COS and HeLa cells (Takekawa et al. 1997). Transforming growth factor beta–activated protein kinase 1 (TAK1) has been shown to phosphorylate and activate MKK6 in vitro and in vivo (Moriguchi et al. 1996) and to be required to activate MKK6-p38 pathway during myogenic differentiation (Bhatnagar et al. 2010). Thousand and one amino acid kinase-2 (TAO2) coimmunoprecipitates and phosphorylates MKK6 during myogenic differentiation in the presence of stress stimuli such as sorbitol, sodium chloride, taxol, and nocodazole (Chen and Cobb, 2001). Apoptosis signal-regulating kinase 1 (ASK1) activates MKK6-p38 in response to pro-inflammatory cytokines and apoptotic stress (Ichijo et al. 1997). PKNα (a fatty-acid-activated and rho-activated serine/threonine protein kinase) has been shown to play an activating role in the MKK6-p38 pathway as an upstream activator of MTK1 and as a scaffold protein, associating with each member of the p38γ MAPK signaling pathway (p38γ, MKK6 and MTK1) (Takahashi et al. 2003). MKK6 activation has also been shown to be mediated by microtubules and Dctn1, a component of the dynein-dynactin complex involved in organelle transportation along the microtubules (Cheung et al. 2004).

Upon activation, MKK6 phosphorylates ▶ p38α, p38β, p38γ, and p38δ on their regulatory threonine and tyrosine residues within a tripeptide motif (Thr–Gly–Tyr) located in the activation loop of p38 (Raingeaud et al. 1995). The specific recognition of



MKK6, Fig. 1 Activation of MKK6 by upstream kinases. Several extracellular stimuli activate MAPKKKs (MTK1, ASK1, TAK1, TAO2K) that phosphorylate MKK6, thereby activating it. Active MKK6 phosphorylates and activates p38 kinases alpha, beta, delta, and gamma

MKK6-p38 binding is mediated by a consensus docking domain (Lys/Arg–Xaa3–Leu/Ile–Xaa–Leu/Ile) present in the N-terminal region of MKK6 (Enslen et al. 2000).

MKK3 and MKK4, who share highly similar catalytic domains to MKK6, can also phosphorylate and activate p38 mitogen-activated protein kinase (MAPK) family members (Derijard et al. 1995). Genetic and biochemical evidence demonstrates nonredundant and selective functions for these MAPKKs in regulating the activity of p38 kinases in response to specific stimuli. For instance, p38α is activated by MKK6 and MKK3 in response to TNFα stimuli, while in response to UV light, p38α is phosphorylated and activated by MKK6, MKK3, and also MKK4. Environmental stress activates MKK6 and ▶ MKK3, which in turn activate p38β and p38γ. However, MKK6 activation by TNFα results in activation of p38γ, while MKK3 activation by TNFα, UV light, osmotic shock, and anisomycin results in activation of p38δ (Remy et al. 2010). The complexity of MAPKs' activation may reflect the ability to respond to multiple stimuli.

While phosphorylation of MKK6 in serine 207 and threonine 211 is an activatory event, MKK6 acetylation of these same residues by YopJ (Yersinia Outer protein J) has been shown to inhibit MKK6 activity. Therefore, MKK6 acetylation may be the mechanism by which YopJ blocks the innate immune response (Mukherjee et al. 2006).

MKK6 has major roles in several biological processes. The specificity of its action depends on the diversity of its activators, the selectivity of the available substrates, and the concomitant signaling pathways being activated or repressed in a particular situation. Because of its prominent signaling role in differentiation, inflammatory diseases, and cancer, the exploration of drugs targeting MKK6 activity is a challenging field to develop new therapeutic approaches.

Functional Roles of MKK6 Activity

Role of MKK6 in Differentiation

MKK6 plays a crucial role in promoting myogenesis through the activation of p38 pathway (Zetser et al. 1999). Myogenic differentiation stimuli such as cell-to-cell contact activate the CDO-JLP immunoglobulin-scaffold protein complex which in turn activates the MKK6-p38-α/β pathway (Takaesu et al. 2006). Other ligands, such as TNFα and amphoterin/RAGE, have been shown to induce myogenic differentiation through MKK6-p38 activation (Sorci et al. 2004). MKK6 exerts its pro-myogenic functions mainly through the p38 alpha kinase isoform (Perdiguero et al. 2007), which mediates the assembly of an active myogenic transcriptional complex by direct phosphorylation of its components: MEF2 myogenic transcriptional factors (Zhao et al. 1999; Rampalli et al. 2007), ▶ SWI/SNF (SWItch/Sucrose NonFermentable) chromatin remodeling subunits (Simone et al. 2004), and E47 (Lluís et al. 2005). p38 beta and gamma have been reported to promote and inhibit muscle gene expression by different groups (Wang et al. 2008; Gillespie et al. 2009).

The MKK6-p38 pathway has been shown to play a role in the survival of differentiated neurons. In response to calcium influx, the activation of MKK6-p38 pathway induces MEF2C phosphorylation in serine 387 and this event may activate the expression of survival genes and repress the expression of apoptotic genes (Mao et al. 1999).

Role of MKK6 in Heart Physiology

MKK6-p38 pathway plays an important cardioprotective role in the heart. In an in vivo model of infarction, transgenic mouse hearts overexpressing MKK6 show a better functional recovery and less injury than non-transgenic mice (Martindale et al. 2005). One possible mechanism could be that MKK6-p38 activation in these MKK6-transgenic mice induced the expression of the heat shock protein αB-crystallin and the antiapoptotic Bcl-2 protein, which have been shown to play important cardioprotective roles.

MKK6 Roles in the Immune System

MKK6 knockout (KO) mice are viable, fertile, and they do not show developmental or tissue abnormalities. However, these mice show impairment in double positive thymocyte apoptosis; therefore, MKK6 plays a role in thymocyte fate (Tanaka et al. 2002).

In macrophages, LPS induces MKK6 phosphorylation and its binding with IRAK2. This event is required for the posttranscriptional control of cytokine and chemokine expression involved in the innate immune response (Wan et al. 2009).

MKK6 Role in Cancer

A tumor suppressor role has been described by different groups for the MKK6-p38 pathway. Fibroblasts isolated from MKK6$^{-/-}$ mice show an increased proliferation rate in serum-free medium compared to WT fibroblasts, correlating with the maintained expression of D-cyclins and the presence of phosphorylated Rb. Subcutaneous injection of MKK6$^{-/-}$ fibroblasts into nude mice induces larger tumors compared to the WT fibroblasts (Brancho et al. 2003). A deficient MKK6-p38 signaling has been shown in certain types of rhabdomyosarcomas, where restoring a persistent activation of p38 MAPK pathway by a constitutively active mutant of MKK6 (MKK6EE) leads to tumor cell growth arrest and terminal differentiation (Puri et al. 2000). Activation of the MKK6-p38 pathway is sufficient to suppress in vivo tumorigenesis. Nude mice injected with HeLa (human cervical carcinoma) cells expressing a constitutively active MKK6 show a reduced tumor formation (Timofeev et al. 2005). In addition, an anti-metastatic effect has been attributed to the MKK6-p38 pathway. Ectopic expression of MKK6 in an ovarian carcinoma cell line prevented the metastatic process when these cells were injected intraperitoneally (Hickson et al. 2006). All these works show an important role of MKK6-p38 signaling pathway in the control of neoplastic growth.

MKK6 Role in Inflammation

MKK6 activation occurs in inflammatory diseases such as rheumatoid arthritis (RA) and osteoarthritis

(OA) (Chabaud-Riou and Firestein 2004). Blocking MKK6-p38 activity has been shown to attenuate these inflammatory diseases. For instance, a dominant negative MKK6 impairs the production of inflammatory cytokines (IL-6, IL-8) and the protease MMP-3 in IL-1 stimulated fibroblasts-like synoviocytes (Inoue et al. 2005). Furthermore, in a passive K/B × N mouse serum transfer model of arthritis, MKK6$^{-/-}$ mice show attenuation of arthritis, cartilage destruction, and bone erosion (Yoshizawa et al. 2009). In this study, MKK6 would be contributing to the colocalization of p38 with its substrate MK2 (MAPKAPK2).

Summary

Mitogen-activated protein kinase kinase-6 (MKK6) belongs to the MAPK kinase (MAPKK) family of enzymes, which specifically activates p38 MAPK. MKK6 has a similar sequence to MKK3 (80%) and to MKK4 (40%). Cellular stresses such as osmotic shock, UV irradiation, hypoxia, cytokine stimulation, and cell-to-cell contact activate the MKK6-p38 pathway by activating upstream kinases (MAPKKKs) including Ask1 (apoptosis signal-regulating kinase 1), Tak1 (transforming growth factor beta–activated kinase 1), Tao2 (1001 amino acids kinases 2), and Mtk1 (Mekk4/MAP three kinase 1). All of these protein kinases activate MKK6 by phosphorylating it on serine 207 and threonine 211 in its activation loop. Acetylation of these sites by acetyltransferase YopJ (Yersinia outer protein J) inhibits MKK6 activity, indicating that the phosphorylation and acetylation states of the activation loop are crucial to regulate MKK6 kinase activity. Active MKK6 phosphorylates p38α, β, δ, and γ MAPKs, on their regulatory threonine and tyrosine residues, activating p38 MAPK signaling. MKK6 is widely expressed in mammalian tissues with higher accumulation in skeletal muscle. MKK6 is a key mediator of many stress-responsive signaling cascades that are crucial for differentiation, inflammation, and tumorigenic processes.

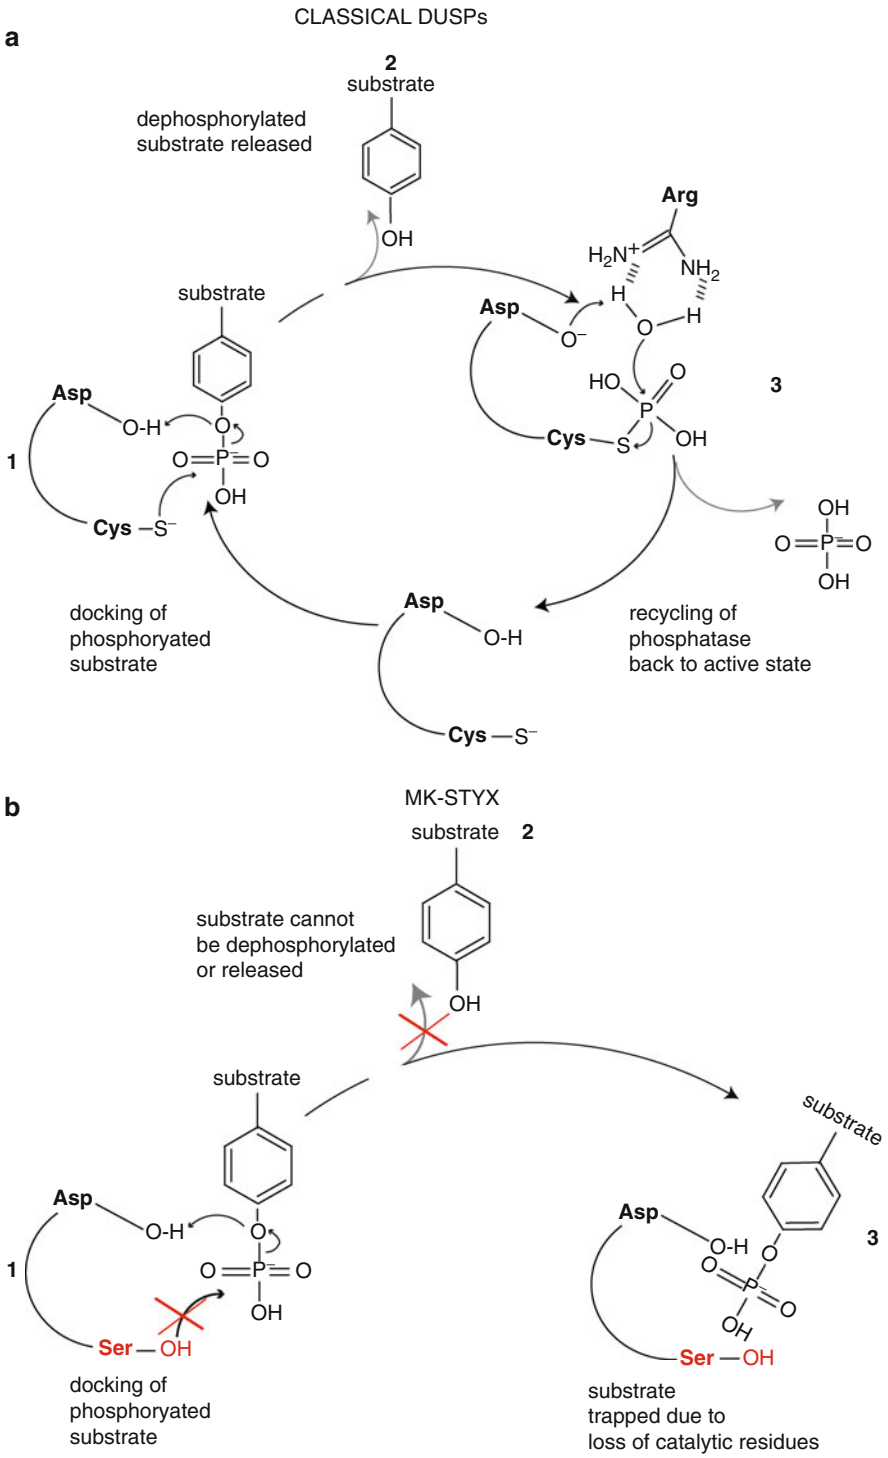
Historical Background

MK-STYX was first identified bioinformatically due to its homology with the dual specificity phosphatases (DUSPs), a family of enzymes known for their ability to dephosphorylate not only tyrosine residues but also serine and threonine residues (Wishart and Dixon 1998). Specifically, MK-STYX resembles a MAP kinase phosphatase (MKP), which contains a rhodenase or ▶ Cdc25 homology (CH2) domain in its N-terminus, while containing a DUSP domain in its C-terminus. The name of the protein reflects this similarity, as MK-STYX was coined from the phrase *M*AP *K*inase Phosphatase-like *S*erine *T*hreonine T*y*rosine inter*act*ion domain (Wishart and Dixon 1998). The Ser/Thr/Tyr interaction (STYX) domain was so named based on the observation that, though this domain shares significant homology to a DUSP domain, it lacks a critical cysteine residue necessary for catalysis; the conservative substitution of a serine in place of this residue renders this enzyme completely inactive. Mechanistically, this is explained though examination of the enzymatic reaction necessary for DUSPs to carry out the dephosphorylation reaction. After binding a phosphorylated substrate, a classical DUSP will utilize a conserved cysteine residue to nucleophilically attack the phosphate group which is to be removed from its substrate (Fig. 1a). This cysteine contains a thiolate intermediate, kept in its ionic state by an environment promoting an extremely low pKa within the pocket of the phosphatase. The substitution of a cysteine to a serine, however, abolishes this thiolate intermediate, and even the very low pKa of the phosphatase pocket is not sufficient to render the hydroxyl group on this serine as a potent nucleophile (Fig. 1b). Thus, the serine mutation does not affect the binding of the substrate, but rather the initiaton of the first step of catalysis. This Cys → Ser substitution has been exploited by researchers in the field of phosphatase biology to create what are known as "substrate-trapping mutants" (Flint et al. 1997). These mutants are utilized as a tool in which phosphatases bind their substrates in a more stable fashion, allowing for easier identification and characterization of binding partners and downstream effector molecules. Thus, MK-STYX is an endogenous "substrate-trapping mutant," although whether this molecule uses its STYX domain as a tool to bind phosphorylated residues on other molecules has yet to be determined.

MK-STYX is part of a family of two known proteins in humans with a STYX domain. The other protein, simply named STYX, is also catalytically inactive, due to a Cys → Gly mutation within its active site (Wishart and Dixon 1998). Reversion of the glycine back to a cysteine is sufficient to restore catalytic activity, demonstrating the preservation of the phosphatase domain and binding pocket in this protein (Wishart et al. 1995). Due to this structural preservation, it has been speculated that the STYX domain could bind to phosphorylated proteins, analogous to an SH2 domain binding phosphotyrosine residues. This would be a particularly interesting possibility, as DUSPs are able dephosphorylate both tyrosine residues, as well as serine/threonine residues due to a particularly shallow pocket which accommodates the active site. Indeed, a recent study demonstrated that the mutation of two residues within the active site, the serine → cysteine along with the −1 position, is sufficient to promote phosphatase activity of MK-STYX (Hinton et al. 2010). These data suggest that while the enzyme is catalytically inactive, it retains a phosphatase binding pocket that could be important in its cellular functions.

Another interesting possibility of MK-STYX function is to regulate the localization or enzymatic activity of an active phosphatase, presumably a DUSP. Surprisingly, there are numerous phosphatases present in the human genome which are rendered catalytically inactive due to mutations at various points within their active sites (Tonks 2006). This includes the D2 domains of many receptor protein tyrosine phosphatases (R-PTPs), which are implicated in controlling enzymatic activity. Interestingly, a family of lipid phosphatases, the myotubularins, consists of 14 different members, 6 of which are catalytically inactive (Begley and Dixon 2005). Importantly, these catalytically inactive myotubularins are critical for modulating enzymatic activity and/or cellular sublocalization of their active counterparts, creating an additional regulatory layer into lipid phosphatase biology (Begley et al. 2006; Robinson et al. 2008). While a phosphatase interactor for STYX and/or MK-STYX has yet to be found, the possibility that these proteins could be similar to a regulatory module for active phosphatases is an attractive model with clear precedence within the cell.



MK-STYX, Fig. 1 Catalytic mechanism of DUSPs and MK-STYX. All dual specificity phosphatases contain a consensus motif, DX_nCX_5R, which defines their phosphatase domain. The cysteine is critical for the initial nucleophilic attack of the phosphoryl group to be removed from the phosphorylated substrate (**a**, step 1). The phosphorylated residue is released from the enzyme, and the aspartate and arginine are involved in recycling the enzyme back to its active state (**a**, steps 2 and 3). In MK-STYX, the initial catalytic cysteine is substituted with a serine group, which is not a potent nucleophile (**b**, step 1). Due to the loss of this cysteine, the enzyme cannot instigate dephosphorylation of the substrate (**b**, steps 1 and 2). Instead, the phosphatase pocket creates a stable intermediate, with the inactive phosphatase "trapping" its substrate through docking in this binding pocket (**b**, step 3)

MK-STYX and STYX Domains Throughout Evolution

MK-STYX seems to be a relatively recent molecular addition in the evolution of animals, as definitive homologues of the protein can only be found within the phylum Chordata, which includes deuterosomes such as the sea cucumber as well as zebrafish, mice, and humans. It is not conserved, however, in insects, C. *elegans*, or yeast. It is interesting to note, however, that "STYX-domain" containing proteins do exist in these organisms (Wishart and Dixon 1998). While they are probably not direct homologues of MK-STYX, it is notable that catalytically inactive phosphatases have been utilized in even early life forms, though little is known about the functionality of these genes.

MK-STYX Regulation

As MK-STYX is relatively uncharacterized, it comes as no surprise that little is known about its regulation at a transcriptional or posttranscriptional level. There are multiple studies, however, that have demonstrated that MK-STYX transcript levels increase in the context of the Ewing's Sarcoma fusion product, EWS-FLI (Guillon et al. 2009; Siligan et al. 2005). EWS-FLI is a transcription factor with aberrant-binding capacities which is known to be sufficient in causing Ewing's Sarcoma. While MK-STYX transcript levels have been shown to increase to this aberrant fusion protein, presumably through transcriptional upregulation, little is known of the physiological significance of this observation, as MK-STYX has also been hypothesized to function as a tumor suppressor (see RNAi phenotypes, below).

MK-STYX has also been identified as being transcriptionally upregulated by the induction of the p21 protein (Chang et al. 2000), though this would have to be an indirect form of regulation, as p21 itself is not a direct transcriptional regulator. It is interesting, however, in light of the potential tumor suppressive functions of MK-STYX uncovered by MacKeigan et al., that p21 could upregulate MK-STYX to halt cell cycle progression or promote an apoptotic phenotype. The broad applicability p21-mediated control of MK-STYX expression will have to be confirmed and explored in much more detail before a clear understanding of these implications is uncovered.

RNAi-Mediated Phenotypes of MK-STYX Knockdown

Interestingly, MK-STYX has been identified as having numerous phenotypes in multiple RNAi screens designed to study very different cellular processes. The first study aimed to identify novel kinases and phosphatases involved in cellular survival or apoptotic potential (MacKeigan et al. 2005). The authors used siRNA sequences to all known and putative human kinases and phosphatases and transfected them into cancer cells. RNAi-mediated loss of MK-STYX promoted the most highly chemoresistant phenotype of all enzymes assayed. Importantly, this chemoresistance was shown in response to multiple drugs with different mechanisms of action, implicating a general cellular mechanism of chemoresistance. As chemoresistance is a highly significant clinical problem for patients with advanced and recurrent cancers, studies on the significance of this gene in treatment response and/or prediction of response rate could be an important future direction in oncology research.

A second RNAi-screening paper identified MK-STYX as potentially tumor suppressive in the context of breast cancer. This paper demonstrated that the RNAi-mediated loss of MK-STYX promoted a highly aberrant migratory phenotype in MCF-10A cells, a nontransformed mammary epithelial cell line (Simpson et al. 2008). This seemed to be coupled with a striking loss in cell polarity, which is a typical feature of cancer cells.

An additional independent study identified loss of MK-STYX within a set of genes whose downregulation is associated with breast cancer metastasis to the brain (Bos et al. 2009). In the study, two cell lines were passaged in vivo to create a daughter cell line which was highly metastatic to the brain. Importantly, both cell models had statistically significant downregulation of MK-STYX in the metastatic cell lines relative to the parental lines. This data, coupled with the RNAi-screening data, suggests that MK-STYX could be a potent tumor and/or metastasis suppressor in breast cancers.

While no molecular mechanism was worked out for either of these phenotypes, it is interesting to note that the loss of MK-STYX seems to promote both resistance to therapy, as well as a prometastatic phenotype. These data suggest that the loss of MK-STYX could be an important event in the later stages of cancer progression and could be a valuable therapeutic target if these observations validate in follow-up studies.

MK-STYX and Stress Granule Formation

Currently, the only known protein identified as an interaction partner of MK-STYX is the RNA-binding protein G3BP1. A recent study has shown that MK-STYX can bind to endogenous G3BP, a protein intimately involved in the formation and maintenance of stress granules within the cell (Hinton et al. 2010). Importantly, MK-STYX overexpression alleviated stress granule formation within cells, implicating a functional role to this interaction. Interestingly, the authors noted that the interaction between MK-STYX and G3BP is abrogated when MK-STYX is reverted to an active enzyme through the mutation of two key residues within its active site, suggesting that the MK-STYX-G3BP1 interaction axis is mediated through its STYX domain, potentially through a substrate-trapping mechanism. It will be interesting in the future to understand whether G3BP is phosphorylated and whether this phosphorylation is what mediates the interaction of these two proteins.

Summary and Future Directions

MK-STYX, while relatively uncharacterized, is suggested to have numerous independent and interesting cellular phenotypes. Many studies remain to be done to elucidate how a single gene could have such pleiotropic effects; subcellular localization, regulation, and turnover, as well as identification of interaction partners will be critical for these analyses. Although many facts remain to be uncovered about this gene, the few studies that have been done on this protein suggest that it could play a very interesting role in the etiology of diseases, such as cancer. As such, studies in the future should take note of this interesting gene, and efforts should be made to uncover its cellular function and what role it plays in the etiology of disease.

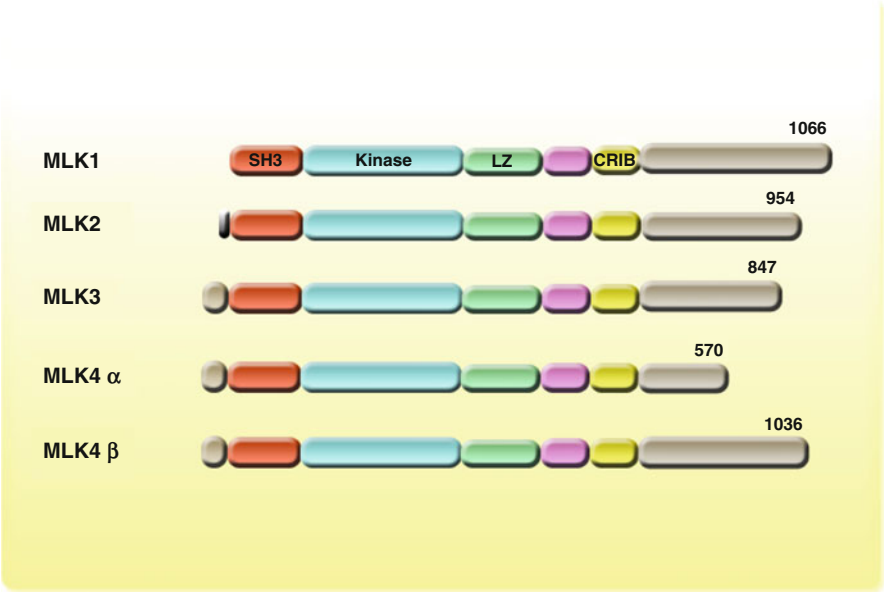
Historical Background

The mixed-lineage kinases are so named for their sequence similarity to both tyrosine kinases and serine/threonine kinases. However, based on biochemical assays, only serine/threonine kinase activity has been demonstrated for the MLKs. The three subfamilies of MLKs reside within the "tyrosine kinase-like" branch of the human kinome. Members of the MLK subfamily, comprised of MLK1-4, share a conserved domain arrangement and 75% identity within their catalytic domains (Fig. 1). The dual leucine zipper–bearing kinase (▶ DLK) subgroup of MLKs, which includes DLK/ZPK/MUK and LZK, is characterized by a kinase catalytic domain followed by two leucine zipper motifs. A third subgroup of MLKs represented by ZAK/▶ MLTK contains both a leucine zipper motif and a sterile-alpha motif. MLK3 has emerged as the paradigm for the MLK subfamily. There is no ortholog for MLK3 in yeast but in Drosophila, the MLK1-4 ortholog, Slipper, is critical for the cell sheet movement during dorsal closure in the fly embryo, which involves activation of the JNK pathway. MLK3-deficient mice are fully viable but have a reduced thickness of the dorsal epidermal tissue, which parallels the effects of disruption of Slipper in *Drosophila* (reviewed in Gallo and Johnson 2002; Schachter et al. 2006).

Regulation of MLK3 Activity

MLK3 contains several protein interaction domains that are important in regulating its activity. A short glycine-rich region is followed sequentially by a Src homology 3 (SH3) domain, a kinase catalytic domain, a leucine zipper region, and a Cdc42/Rac Interactive Binding (CRIB) motif (Fig. 1). The carboxyl terminal region of MLK3 is rich in proline, serine, and threonine residues (Gallo and Johnson 2002). Like many protein kinases, MLK3 activation involves phosphorylation within the activation loop of the kinase domain. Based on site-directed mutagenesis studies, Thr 277 and Ser 281 in the activation loop act as positive regulatory phosphorylation sites; and phospho-specific antibodies directed against these sites are widely used to monitor MLK3 activity. Notably these potential phosphorylation sites are conserved within the activation loops of MLK1-4, suggesting that they may serve a similar function. Leucine zippers form coiled coil dimers that are stabilized by the interaction of leucine or other nonaromatic aliphatic residues at the interface of the helices. Deletion of the entire zipper or introduction of a helix disrupting Pro residue for one of the conserved Leu residues prevents dimerization and activation loop phosphorylation of MLK3. Thus, leucine zipper–mediated dimerization can lead to MLK3 activation. These findings are consistent with the high MLK3 activity observed upon overexpression in many cultured cell lines. Presumably when MLK3 is expressed at high levels, a portion of MLK3 is dimerized in the absence of a physiologically appropriate stimulus, leading to high basal MLK3 activity.

MLK3 contains a CRIB motif, a short conserved sequence required for binding the Rho family GTPases, Cdc42 and Rac. Subsequent work demonstrated that the small GTPases, Cdc42 and Rac, are indeed capable of activating MLK3. Like other GTPase effector proteins, MLK3 interacts with the active, GTP-bound GTPase, but not the inactive, GDP-bound form. Binding of activated Cdc42 (or Rac) promotes MLK3 dimerization, activation loop phosphorylation, increases MLK3 catalytic activity, and translocates MLK3 to the cell



MLK3, Fig. 1 Conserved domains in the MLK subfamily. The number of amino acids in each kinase is shown. See text for details

periphery (Du et al. 2005). Posttranslational COOH-terminal prenylation (geranylgeranylation) of Cdc42 and Rac allows for membrane targeting. A prenylation-defective site-directed mutant of activated Cdc42 retains the ability to bind MLK3 and promote activation loop phosphorylation of MLK3, but fails to translocate MLK3 to membranes. Thus the physical interaction between the activated GTPase and MLK3 is the key mechanism by which it activates MLK3. However, membrane targeting by activated, prenylated Cdc42 is accompanied by additional phosphorylation events on MLK3 and further enhances MLK3 in vitro kinase and cellular signaling activities.

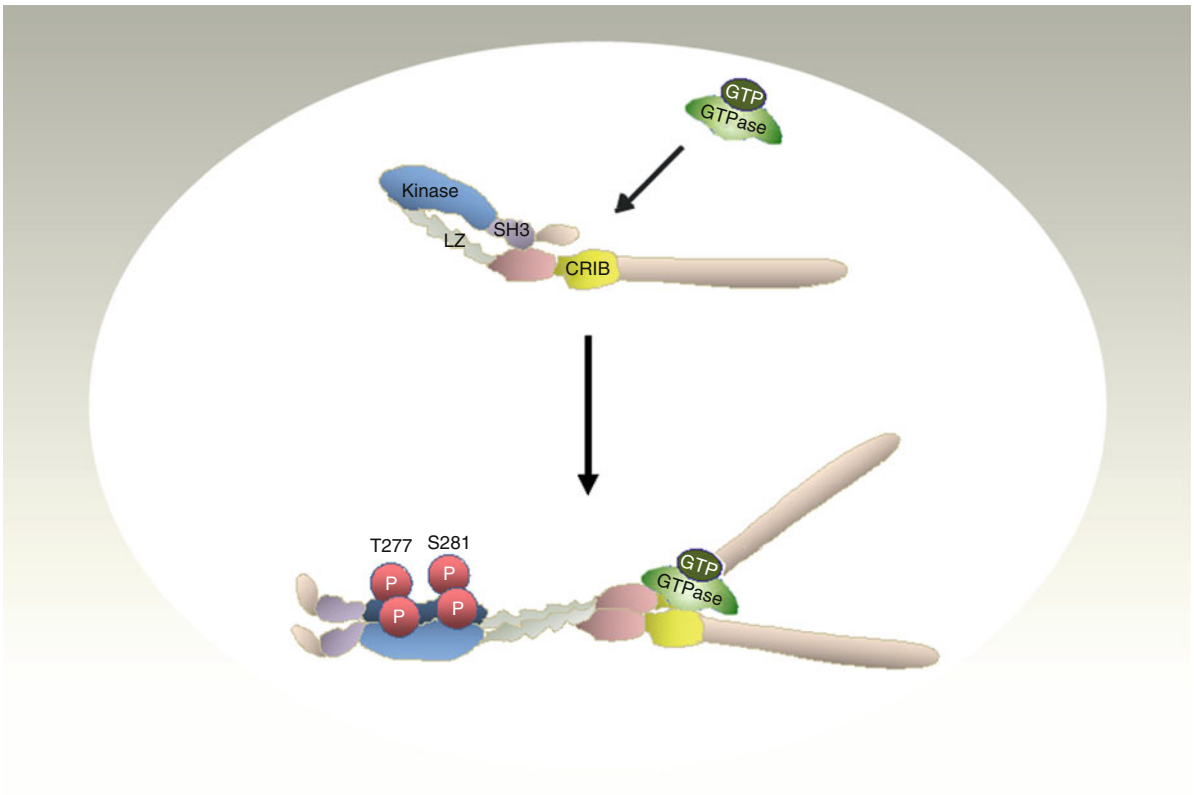
SH3 domains are modular domains of about 60 amino acids that typically bind proline-rich sequences to interact with intracellular signaling partners. The N-terminal SH3 domain of MLK3 functions as an autoinhibitory domain. A single Pro residue located between the leucine zipper and CRIB motif is required for the interaction with its SH3 domain. Though not formally shown, this autoinhibitory interaction is presumed to be intramolecular. Since this Pro residue is conserved in MLK1-4, it is likely that these MLKs are also regulated by SH3-mediated autoinhibition.

An integrated model for MLK3 activation by Cdc42 and Rac consistent with available data is shown in Fig. 2. Binding of the active, GTP-bound GTPase to MLK3 in a region containing the CRIB motif disrupts the SH3 autoinhibitory interaction, promoting leucine zipper–mediated dimerization and trans-autophosphorylation within the activation loop, yielding the active kinase at cell membranes (reviewed in Gallo and Johnson 2002; Schachter et al. 2006).

In addition to phosphorylation within the activation loop, numerous MLK3 phosphorylation sites have been identified through mass spectrometry, the majority of which are Ser or Thr residues followed immediately by Pro residues, conforming to the consensus sequence for proline-directed kinases. The downstream MAPK, JNK, has been shown to phosphorylate MLK3 at multiple proline-directed kinase sites within the COOH terminal region in a positive feedback loop that stabilizes MLK3 and/or redistributes MLK3 into Triton-soluble cellular fractions. Ser 674 has been identified as an Akt(PKB)-mediated phosphorylation site on MLK3 that inhibits MLK3-mediated apoptosis (reviewed in Handley et al. 2007; Schachter et al. 2006). In contrast, Ser 789 and Ser 793 have been identified as sites for GSK-3 beta-mediated phosphorylation on MLK3 that promote neuronal cell death (Mishra et al. 2007).

MLK3 Signaling Triggered by Cell-Surface Receptors

MLK3 signals through multiple mitogen-activated protein kinase (MAPK) pathways, including JNK, p38 MAPK, and ERK. MAPK pathways are three-tiered



MLK3, Fig. 2 Model for MLK3 activation by small GTPases, Cdc42 and Rac. Autoinhibition of MLK3 is maintained by an interaction between SH3 domain of MLK3 and a proline-containing sequence located between the LZ region and CRIB motif. The binding of GTP-bound GTPase(s) through the CRIB motif disrupts the autoinhibition, promotes dimerization and trans-autophosphorylation at Thr 277 and Ser 281 ensues

cascades wherein a MAP3K phosphorylates and activates a MAP2K which, in turn, phosphorylates and activates the terminal MAPK. Activated MAPKs have both nuclear and cytosolic substrates. MLK3, also known as MAP3K11, activates the JNK pathway by phosphorylation-mediated activation of MKK4/MKK7; it activates the p38 MAPK pathway through phosphorylation-mediated activation of MKK3/▶ MKK6. Whereas catalytic activity of MLK3 is required for activation of the JNK and p38 MAPK pathways, MLK3 acts as an indispensable scaffold required for B-Raf-mediated ERK activation (reviewed in Kyriakis 2007). Scaffold proteins, like the JIPs and POSH, are able to bind MLK3 as well as downstream MKKs and MAPKs, and may serve to localize, organize, or assemble MLK3 pathway complexes at specific subcellular locations (reviewed in Dhanasekaran et al. 2007).

Substantial evidence indicates that MLK3 can signal through multiple receptor types, including receptor tyrosine kinases, cytokine receptors, and G-protein-coupled receptors (GPCRs) (Fig. 3), but the details of these signaling pathways are largely unknown. The cytokine, tumor necrosis factor-alpha (TNF), is the best-described stimulus for activating MLK3 signaling to JNK. The TNF receptor-associated factor 2 (TRAF2) complexes with both the TNF receptor and MLK3 and is critical for TNF-induced JNK activation (Sondarva et al. 2010). It should be noted that other MAP3Ks, such as ASK, have also been implicated in TNF-induced JNK activation. Receptor tyrosine kinase signaling also involves MLK3, since silencing of MLK3 prevents epidermal growth factor (EGF)-induced activation of JNK, p38 MAPK, and ERK (reviewed in Kyriakis 2007). MLK3 can be activated by stimulation of cells with carbachol, a chemical ligand for G-protein-coupled acetylcholine receptors (Swenson-Fields et al. 2008). In this context, MLK3 complexes with the Rho guanine nucleotide

MLK3-mediated signaling pathways downstream of various receptors are shown. *EGFR* epidermal growth factor receptor, *TNFR* tumor necrosis factor receptor, *GPCR* G-protein-coupled receptor. Activated MAPKs can phosphorylate cytosolic substrates or enter the nucleus to phosphorylate nuclear substrates, including transcription factors that regulate gene expression. See text for details

exchange factor (GEF), p63RhoGEF, to inhibit RhoA activation. Finally free fatty acids can activate MLK3 and signaling to JNK, implicating MLK3 in insulin resistance (Jaeschke and Davis 2007).

MLK3 in Cancer

Deregulation of signal transduction pathways drives development of human malignancies. MLK3 has been shown to be overexpressed in breast cancer cell lines compared with non-tumorigenic mammary epithelial cells, suggesting that MLK3 might contribute to acquisition of malignant phenotypes in breast cancer (Chen et al. 2010). Ectopic expression of wild-type MLK3 causes cellular transformation of immortalized fibroblasts (reviewed in Kyriakis 2007) and promotes a malignant phenotype of mammary epithelial spheroids in 3D culture (Chen et al. 2010). MLK3 silencing or inhibition can inhibit proliferation in some, but not all, tumor cell lines, perhaps depending upon the oncogenic signaling signature in those cells (reviewed in Schachter et al. 2006; Kyriakis 2007).

Several lines of evidence demonstrate a critical role of MLK3 in migration and invasion of cancer cells of epithelial origin. Induced expression of MLK3 promotes migration of poorly invasive breast cancer cells and invasion of mammary epithelial cells (Chen et al. 2010). Small interfering RNA-mediated silencing of MLK3 blocks migration of highly invasive breast, lung, and gastric carcinoma cells, indicating an essential function for MLK3 in migration and/or invasion of a broad array of epithelial-derived tumor cells (Chen et al. 2010; Mishra et al. 2010; Swenson-Fields et al. 2008). A major mechanism by which MLK3 controls migration and invasion is through activation of JNK and its downstream transcription factor AP-1, leading to expression of genes that promote invasion or epithelial-to-mesenchymal transition, such as MMP-7, fra-1, vimentin, and N-cadherin (Chen et al. 2010; Mishra et al. 2010; Shintani et al. 2008). An AP-1-independent role in which MLK3 blocks activation of RhoA has been identified in lung carcinoma cells (Swenson-Fields et al. 2008). The inactivation of the neurofibromatosis-2 tumor suppressor gene is associated with the formation of benign brain tumors.

NF-2/merlin can interact with MLK3 to inhibit its activity, preventing proliferation and invasion of Schwann cells (Zhan et al. 2011).

Missense mutations in *mlk3* have been identified in human gastrointestinal cancers and are significantly associated with microsatellite instability (MSI) phenotype in mismatch repair-deficient gastrointestinal carcinomas. The identified mutations are found in different functional domains of MLK3, including the SH3 domain (Y99C), the kinase domain (A165S; P252H), and the COOH-terminal proline-rich region (R799C; P840L). When ectopically expressed in fibroblasts, these mutant forms of MLK3 are more transforming and tumorigenic than wild-type MLK3 (Velho et al. 2010). How these specific mutations affect MLK3 signaling activities is yet to been determined.

MLK3 Is Implicated in Neurodegenerative Diseases

Numerous neurotoxic insults can induce JNK activation and mitochondria-mediated apoptosis. MLK3 has been implicated as an upstream mediator of JNK in neuronal cell death in several experimental systems, primarily based on the use of dominant negative forms of MLK3 and the pan-MLK inhibitors, CEP-1347 and CEP-11004. For example, deprivation of nerve growth factor (NGF) induces JNK activation and apoptosis in PC12 cells and in cultured superior cervical rat ganglia, which can be attenuated by blocking MLK activity (reviewed in Wang et al. 2004). Studies in rodents support a role for MLK3 in apoptosis in response to cerebral ischemia-reperfusion, a model for stroke (Zhang et al. 2009). MLK3 has also been linked to JNK activation in kainate-induced neurotoxicity, with the scaffolding protein PSD-95 interacting with both the GluR6 receptor and MLK3 (reviewed in Gallo and Johnson 2002). Finally, substantial evidence has accumulated for MLK3 in JNK activation and neuronal death in cell-based and in vivo models of Parkinson's disease that use the dopaminergic selective neurotoxin MPTP or its derivative MPP+, respectively (reviewed in Wang et al. 2004). In response to treatment with MPTP/MPP+, the MLK inhibitor CEP-1347 was able to suppress JNK activation and increase survival of dopaminergic neurons. These studies suggested that CEP-1347 might be a promising therapeutic for treating patients with Parkinson's disease. CEP-1347 ultimately progressed to Stage II/III clinical trials, but failed to delay progression of patients with early stage Parkinson's disease (Parkinson Study Group PRECEPT Investigators 2007).

MLKs in Inflammation

MLK3 signaling is important in the production of pro-inflammatory proteins. In the context of ▶ interferon-gamma-activated macrophages, MLK signals to p38 MAPK increasing the mRNA levels of TNF-α and interferon inducible protein 10, presumably through increased mRNA stability. In microglia activated by the bacterial endotoxin, lipopolysaccharide (LPS), an MLK or JNK inhibitor reduces AP-1-mediated transcription of TNF-α (reviewed in Handley et al. 2007). In primary cortical astrocytes, activated by a mixture of pro-inflammatory cytokines, MLK signaling to both p38 MAPK and JNK has been implicated in the induction of inflammation-responsive genes (Falsig et al. 2004).

Thus, there is considerable interest in MLK inhibitors as anti-inflammatory drugs, particularly in attenuating neuroinflammation associated with HIV infection. Recently, the MLK inhibitor, CEP-1347, was shown to prevent the production of cytokines and chemokines in HIV-infected human macrophages and to elicit anti-inflammatory and neuroprotective effects in mouse models of HIV-1 encephalitis (Eggert et al. 2010).

Summary

MLK3 is an intracellular serine/threonine kinase, which belongs to a larger family of related kinases that are evolutionarily conserved in metazoans. The kinase activity of MLK3 is autoinhibited through its SH3 domain. The small GTPases, Cdc42 and Rac, can bind to MLK3, disrupting autoinhibition and promoting zipper-mediated dimerization and subsequent transphosphorylation within the kinase domain to yield active MLK3. MLK3 signals through multiple cell surface receptors, including receptor tyrosine kinases, cytokine receptors, and heterotrimeric G-protein-coupled

receptors. MLK3 contributes to the activation of multiple MAPK pathways, functioning as a MAP3K to activate the JNK and p38 MAPK pathways, and as a scaffold in B-Raf-mediated ERK activation. Although soon after its identification, MLK3 was implicated in neuronal apoptosis, emerging data indicates that MLK3 is a critical player in many pathophysiological processes, including cancer cell migration and invasion as well as inflammation. Thus MLK inhibitors may prove valuable in multiple therapeutic arenas.

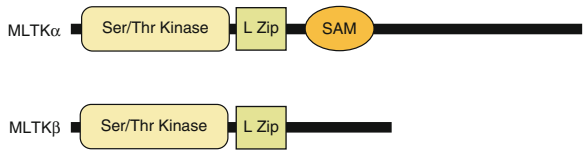
Synonyms

Mixed lineage kinase 7 (MLK7); MLK-like mitogen-activated protein triple kinase (MLTK); MLK-related kinase (MRK); Sterile-alpha motif and leucine zipper–containing kinase AZK (ZAK)

Historical Background

MLTK is a protein kinase that belongs to the family of mitogen-activated protein kinase kinase kinases (MAPKKK) with closer homology to the MLK proteins. It was isolated as ZAK by low-stringent hybridization to the Ste20 kinase (Liu et al. 2000): as MLK7, a gene highly expressed in the heart (Bloem et al. 2001); as MLTK, a gene induced by overexpression of active ERK (Gotoh et al. 2001); and as MRK, a human gene that acts as a MAPKKK in a yeast functional screen (Gross et al. 2002). The MLTK gene encodes two splice variants: MLTKα and MLTKβ of 91.7 kDa and 51.3 kDa calculated molecular mass, respectively. They share the N-terminus kinase and leucine zipper domains, while they diverge in the C-terminal region. MLTKα has a sterile α motif (SAM), whereas MLTKβ has a shorter C-terminus with a highly acidic region (Fig. 1).

The MLTK mRNAs are ubiquitously expressed, with higher levels in heart and skeletal muscle. With the exception of liver, MLTKβ is the more abundant of the two forms in most tissues (Gross et al. 2002). MLTK is found both in the cytoplasm and in the nucleus. Both splice forms have putative nuclear exclusion sequences, which suggest that the proteins shuttle between the cytoplasm and the nucleus. Blocking a nuclear export sequence receptor leads, in fact, to accumulation of MLTKβ in the nucleus (Gotoh et al. 2001). Activation of MLTK requires an autophosphorylation step (Gotoh et al. 2001), which occurs in the kinase loop region (Gross et al. 2002).

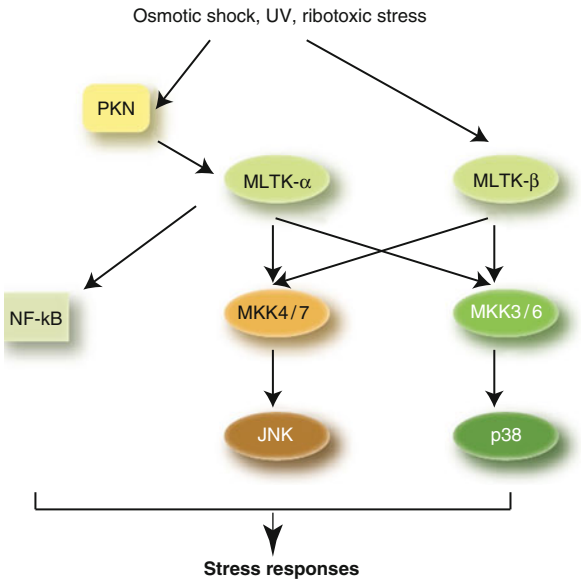


MLTK, Fig. 1 MLTK proteins structure. Schematic illustration of protein structure. *Ser/Thr kinase*, serine/threonine kinase; *L Zip*, Leucine Zipper; *SAM*, sterile α motif

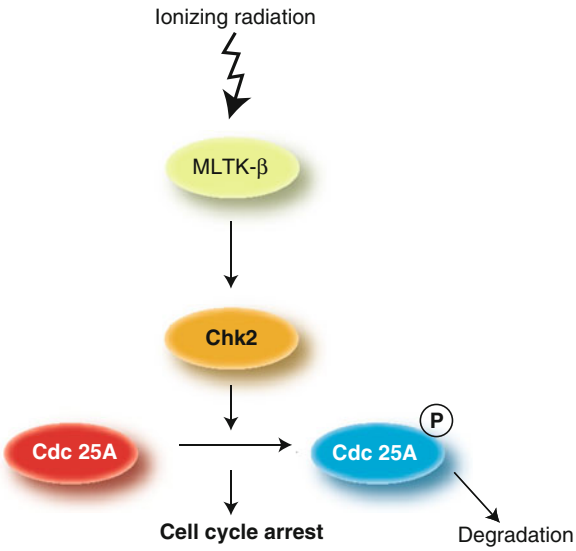
Despite sharing an identical kinase domain, there is some evidence suggesting that the two splice variants have distinct functions (see below).

Stress Response to IR, Anisomycin, UV, Osmotic Stress, Shiga Toxin, and Ricin

A variety of stressors activate both MLTKα and MLTKβ. They include osmotic stress (Gotoh et al. 2001; Takahashi et al. 2003; Mao et al. 2004), ultraviolet (UV) (Wang et al. 2005) and ionizing radiation (IR) (Gross et al. 2002; Tosti et al. 2004), and ribotoxic stress caused by anisomycin (Wang et al. 2005) and bacterial toxins like Shiga toxin and ricin (Jandhyala et al. 2008). When overexpressed in cells, both forms phosphorylate MKK4 and MKK7 to activate the Jun C-terminus kinase, JNK, and phosphorylate MKK3 and MKK6 to activate the p38 MAPK pathway (Gotoh et al. 2001, 2002; Yang 2002). The response to osmotic shock appears to be mediated by the protein kinase PKN, a member of the ▶ PKR family, upstream of MLTKα (Takahashi et al. 2003). A similar activation of MLTKβ has not been shown. Upon overexpression, MLTK also leads to activation of the MAP kinases ERK2 and ERK5 and the transcription factor ▶ NF-κB (Liu et al. 2000; Gotoh et al. 2001; Bloem et al. 2001; Gross et al. 2002) (Fig. 2). These responses may have protective and adaptive functions, unless the damage is too great, in which case, cell death is triggered. Apoptosis, a form of cell death, in fact, has been observed in some cases upon overexpression of MLTKα (Liu et al. 2000), and inhibition of MLTKβ improves cell viability after treatment with Shiga toxin and ricin (Jandhyala et al. 2008). MLTK proteins also mediate apoptotic responses following treatment with chemotherapeutic drugs like doxorubicin. This effect, however, appears to be limited only to normal cells and not to cancer cells (Sauter et al. 2010), which suggests that combining inhibition of MLTK with doxorubicin



MLTK, Fig. 2 MLTK signaling pathways stimulated by stress. Following treatment with the indicated stimuli, MLTK proteins activate the JNK and p38 MAP kinases and the transcription factor NF-κB, leading to stress responses



MLTK, Fig. 3 Role of MLTK-β in the response to DNA damage. Double-strand DNA damage induced by ionizing radiation activates MLTKβ, which in turn phosphorylates and activates Chk2. This protein phosphorylates and inactivates the phosphatase CDC25A, leading to cell cycle arrest

may increase the therapeutic window of this chemotherapeutic treatment.

In response to DNA damage caused by IR, MLTKβ phosphorylates the cell cycle check point protein Chk2 and contributes to cell cycle arrest in the S and G2 phases of the cell cycle (Tosti et al. 2004). Downregulation of MLTKβ by RNA interference, or by a dominant negative MLTKβ mutant, in irradiated cells prevents cell cycle arrest and leads to increased cell death (Gross et al. 2002; Tosti et al. 2004) (Fig. 3). MLTKα, but not MLTKβ, interacts with and phosphorylates histone H3, which is involved in chromatin remodeling (Choi et al. 2005).

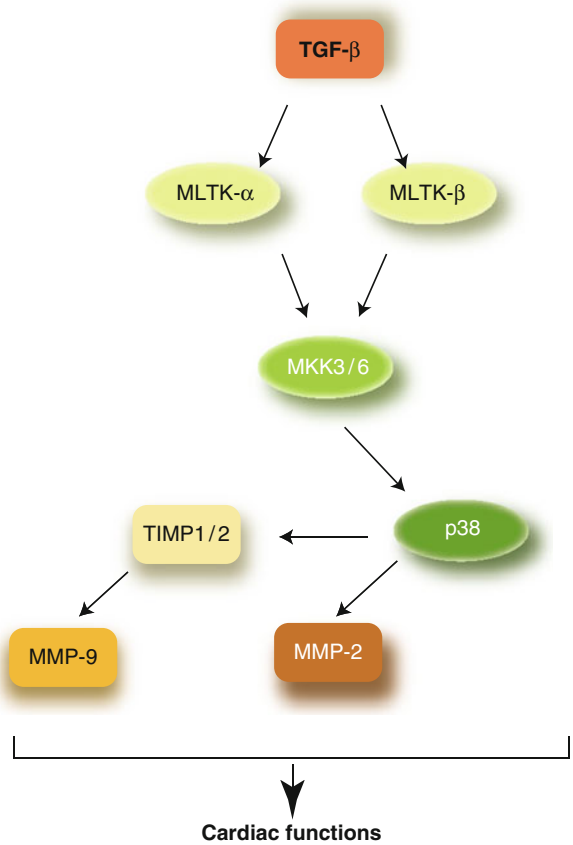
Cardiac Functions

The high levels of expression in heart and skeletal muscle suggest that MLTK proteins have an important role in these tissues. Overexpression of MLTK in cardiac myocytes or cardiomyoblasts causes hypertrophic growth, accompanied by increased protein synthesis and altered fetal gene expression (Bloem et al. 2001; Huang et al. 2004a). These effects are induced by TGF-β signals that are mediated by MLTK (Huang et al. 2004b). Overexpression of MLTKα in cardiomyoblasts increases metalloproteinase tissue inhibitor 1/2 (TIMP1/2) levels, which in turn reduce MMP-9 activity. MMP2 is also activated downstream of p38. These metalloproteinases have been suggested to contribute to cardiac fibrosis (Cheng et al. 2009) (Fig. 4).

The molecular events described above may explain the phenotypes observed in mice when MLTKβ is overexpressed in the heart. These animals, while they appear normal, show impaired cardiac functions under resting conditions and are less able to withstand cardiac stress. When challenged with β-adrenergic stress, provided by treatment with isoproterenol, the transgenic mice undergo a significant increase in mortality (Christe et al. 2004). Although these studies point to an important role for MLTK in the adaptive response to cardiac stress, mutations or alterations in expression levels of MLTK in the heart have not been investigated yet.

Regulation of the Actin Cytoskeleton

A clear distinction between MLTKα and MLTKβ functions has been observed upon overexpression of



MLTK, Fig. 4 MLTK pathway in the heart. Overexpression or stimulation of MLTK proteins by TGF-β leads to p38 activation, which contributes to cardiac changes via stimulation of the metalloproteases MMP2 and MMP9

these proteins in fibroblast cells. High levels of MLTKα, but not MLTKβ, cause disruption of the actin cytoskeleton that leads to cell rounding (Gotoh et al. 2001). As these proteins share an identical kinase domain, hence have the same enzymatic activity, it is likely that their different functions are mediated by their variant C-termini, which could be responsible for differential protein interactions and participation in different protein complexes.

Cancer

Conflicting observations have been reported regarding the role of MLTK proteins in cancer. In skin epidermal cells, overexpression of MLTKα induces proliferation and neoplastic transformation. These cells form fibrosarcoma tumors upon injection in athymic mice (Cho et al. 2004). In contrast, overexpression of MLTKα in lung cancer cells inhibits cell proliferation both in vitro and in vivo (Yang et al. 2010). Overexpression of MLTKα also causes cell cycle arrest in fibroblast cells (Yang 2002). The extent to which these opposite effects are caused by tissue-dependent responses or differences in expression levels used in the two studies is not clear. Elevated MLTK mRNA has been observed in multiple myeloma (Eisenberger et al. 2008); however, the relevance of this change to this disease is unclear.

Summary

The MLTK proteins are activated by a variety of stressors and may contribute to cellular adaptation to stress or cell death depending on the degree of damage. However, their role is not restricted to controlling apoptosis via the stress-activated MAP kinase proteins JNK and p38. Indeed, there is evidence that MLTK proteins are involved in additional functions like cell cycle arrest after ionizing radiation and cardiac adaptation to stress.

Destruction-box, D-box; Monopolar spindle 1, Mps1; Spindle assembly checkpoint, SAC; Spindle pole body, SPB

Historical Background

Mps1 was first identified in the budding yeast *Saccharomyces cerevisiae* and named for the monopolar spindles that form in the *mps1* mutant strain (reviewed in Fisk et al. 2004). These spindles are generated as a result of the absence of spindle pole body (SPB) duplication; mutant yeast cells consequently undergo a "monopolar" mitosis. Four years later, the *mps1* gene was shown to encode an essential dual-specificity protein kinase, and a fission yeast homolog, termed Mph1, was also identified in *Schizosaccharomyces pombe* (Fisk et al. 2004). Library screening with antibodies to phosphotyrosine also identified a human protein kinase termed TTK/PYT, and a mouse kinase termed Esk; these were later recognized as vertebrate Mps1 orthologs. In addition, *Xenopus*, zebrafish and *Drosophila* Mps1 orthologs have also been characterized (Fisk et al. 2004). Indeed, the Mps1 family of protein kinases has now recognized in all eukaryotic phyla for which sequence data exist, except in the *Caenorhabditis elegans* genome, where its function may be redundant or replaced by a distinct protein kinase (Winey and Huneycutt 2002; Fisk et al. 2004).

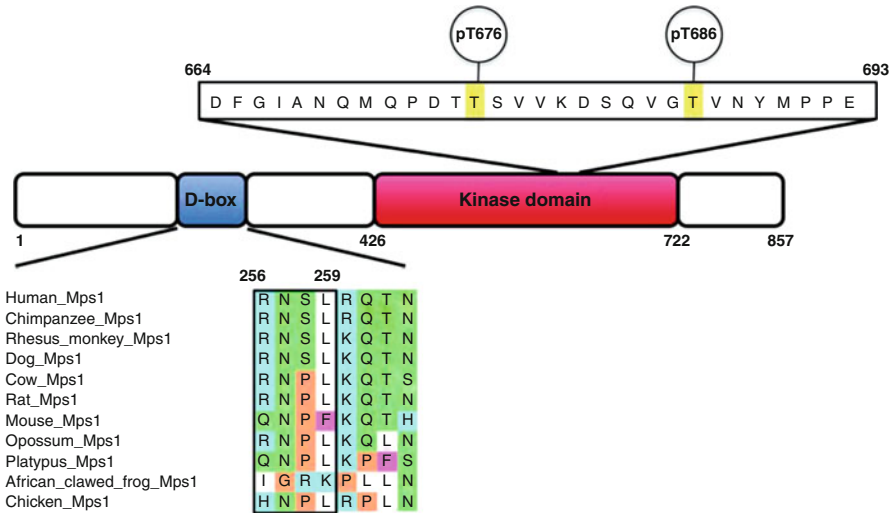
The domain structure of Mps1 is relatively simple (Fig. 1), with a large N-terminal region containing a Destruction- (D-) box, and a region that exhibits some homology to other mitotic kinases, likely to be important for subcellular targeting. The C-terminus harbors a kinase domain of the "non-RD" type, which exhibits dual-specificity kinase activity in vitro (Tyler et al. 2009).

Functions of Mps1

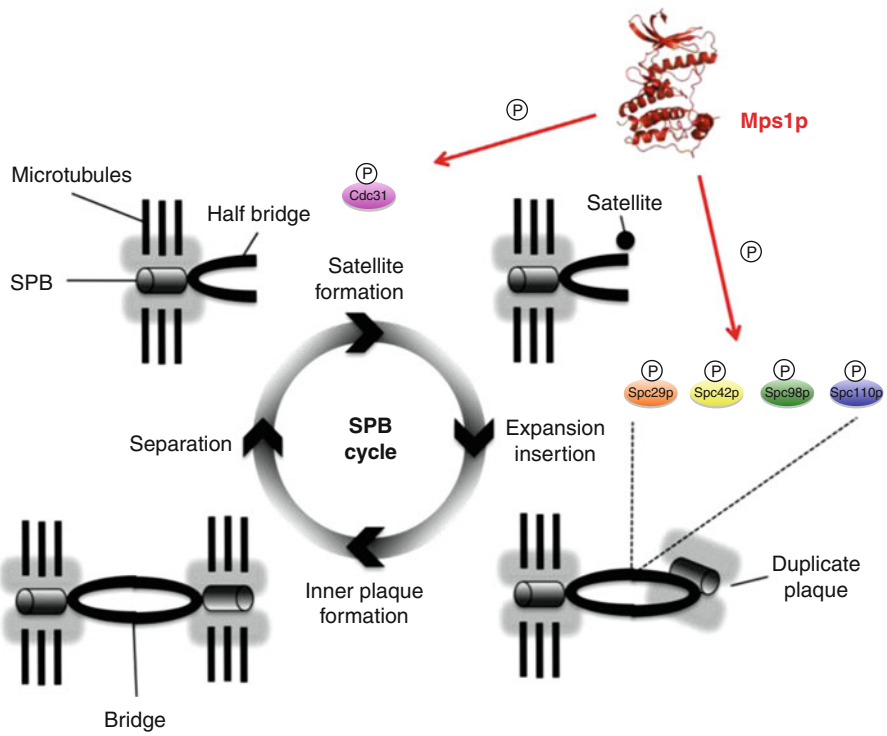
SPB duplication in budding yeast was the first identified function of Mps1p (Fisk et al. 2004). The SPB of yeast cells is duplicated during late G1 phase in the cell cycle to form the two poles of the mitotic spindle (Fig. 2). The *mps1p* gene is required for the transition from satellite-bearing to side-by-side SPBs. Loss of function caused by the original *mps1p* gene mutation (*mps1-1*) produces a single, large SPB with enlarged half-bridge (monopolar mitosis) (Fisk et al. 2004), and an additional series of alleles revealed that Mps1 has additional roles in SPB duplication (Winey and Huneycutt 2002). The unduplicated SPB observed by electron microscopy in *mps1-1* cells has a unique morphology, suggesting that Mps1p is required for SPB duplication (Fisk et al. 2004).

Furthermore, Mps1p localizes to SPBs (Fisk et al. 2004), and chemical genetic-induced inactivation of Mps1 revealed a defect in SPB duplication, suggesting that Mps1 has an important role in this process (Jones et al. 2005). Mps1p regulates SPB duplication by phosphorylating SPB components, including Spc98p, Spc110p, Spc42p, and Spc29p, which are all substrates of Mps1p in vitro and in vivo (Winey and Huneycutt 2002; Holinger et al. 2009; Fig. 2). Recently, the phosphorylation of Spc29p in G1/S phase was suggested to be required for recruiting the SPB membrane insertion machinery complex Mps2-Bbp1 to the newly formed SPB to facilitate its insertion into the nuclear envelope (Araki et al. 2010). An additional Mps1 substrate, the yeast centrin Cdc31, was also identified and its phosphorylation was shown to regulate its binding to the essential half bridge protein Kar1 (Araki et al. 2010). Although Mps1p is essential for SPB duplication in budding yeast, the fission yeast *S. pombe* Mps1 ortholog, Mph1, does not seem to have such a function (Winey and Huneycutt 2002).

The well-characterized requirement for Mps1p in SPB duplication in budding yeast implies that vertebrate Mps1 proteins might also function in centrosome duplication, analogous to those described for yeast Ipl (Aurora) and vertebrate Cdc5 (Polo) kinases. The mouse Mps1 enzyme was the first vertebrate Mps1 shown to regulate centrosome duplication. Mouse Mps1 localizes to the centrosome throughout the cell cycle in NIH 3T3 cells, and its overexpression induces centrosome reduplication, whereas overexpression of a catalytically inactive mutant (D637A) prevents centrosome duplication (reviewed in Fisk et al. 2004). Conflicting data have been reported as to the localization of human Mps1 and its possible roles in centrosome duplication. Stucke et al. demonstrated that human Mps1 is not required for centrosome duplication (Stucke et al. 2002), and did not find localization of human Mps1 at centrosomes or evidence that the kinase has a role in the centrosome cycle, despite the use of various functional analyses, including antibody microinjection, small interfering RNA (siRNA), and overexpression of wild-type and kinase-dead human Mps1. This result was unexpected owing to the very high sequence similarity (90%) between the mouse and human Mps1 proteins (Winey and Huneycutt 2002; Fisk et al. 2003). In contrast, separate studies showed



Monopolar Spindle 1 (Mps1), Fig. 1 Schematic representation of full-length human Mps1. Destruction-box (D-box) and kinase domain of Mps1 are denoted in *blue* and *red*, respectively. The D-box sequence (RNSL) is conserved in most mammalian species (bottom sequences, adapted from Cui et al. 2010). Conserved amino acids are indicated in *black* bars. The sequences were colored according to residue type: *Orange* small, *Red* negatively charged, *Blue* positively charged, *Green* polar, *White* hydrophobic, *Pink* aromatic. The activation segment sequence is indicated (*top*) and the important Mps1 autophosphorylation sites Thr 676 and Thr 686 (pT676 and pT686) are highlighted in *yellow*



Monopolar Spindle 1 (Mps1), Fig. 2 Mps1 regulates budding yeast spindle pole body (SPB) duplication. During the budding yeast cell cycle, the satellite appears on the cytoplasmic face of the half bridge during SPB duplication, and is thought to be the precursor of the new spindle pole body. The Mps1p gene is required for the transition from satellite-bearing to side-by-side SPBs and the phosphorylation of SPB components Cdc31, Spc29p, Spc42p, Spc98p, and Spc110p depend on Mps1p kinase activity

that human Mps1 does localize to centrosomes during interphase using distinct polyclonal Mps1 antibodies (reviewed in Fisk et al. 2004). Tyler et al. (2009) also reported centrosomal localization of phosphorylated human Mps1 in mitotic HeLa and DLD1 cells using RNA interference (RNAi)-validated phosphospecific

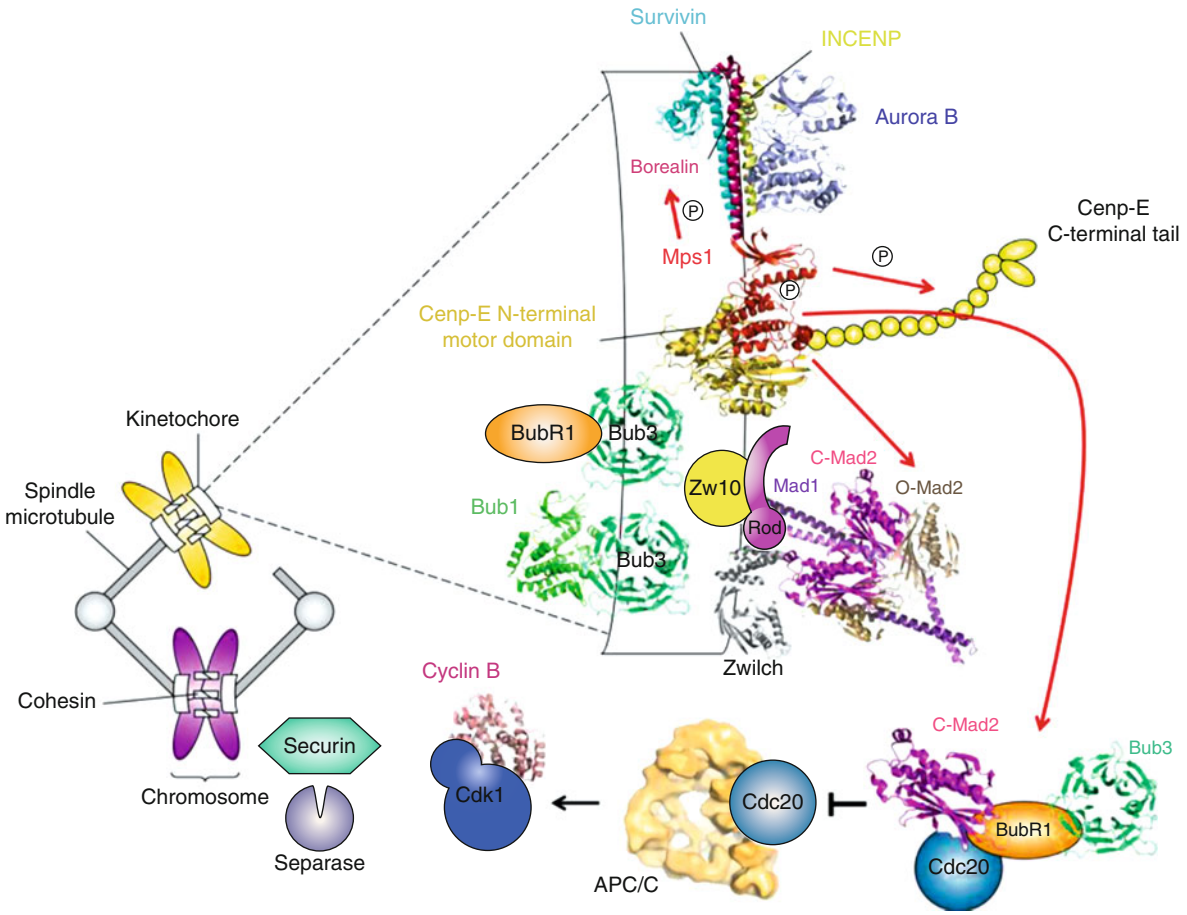
antibodies. Moreover, Fisk et al. showed that overexpression of human Mps1 causes centrosome reduplication, whereas overexpression of a kinase-dead mutant or siRNA depletion prevents normal centrosome duplication in various cell types, including NIH 3T3 cells (Fisk et al. 2003). Additional data further suggested that Mps1-dependent centrosome duplication lies downstream of Cyclin-Dependent Kinase-2 (CDK2) (Kasbek et al. 2007; Kasbek et al. 2009). Mps1-associated acceleration of centrosome duplication may also depend on the presence of phosphorylated mortalin (Kanai et al. 2007). Thus, despite controversy, vertebrate Mps1 protein kinases – including the human ortholog – do seem to regulate aspects of centrosome duplication.

The role of Mps1 in the SAC has been studied extensively. The checkpoint function of Mps1 was first reported when mutant *mps1-1* yeast cells were shown to inappropriately segregate their DNA (Fisk et al. 2004). The *mps1-1* mutant also overrides a nocodazole-induced mitotic checkpoint, further suggesting that Mps1p is essential in the SAC (Fisk et al. 2004). Mps1 localizes to the kinetochore through a complex series of protein-substrate interactions involving kinetochore components such as Mad1p, Ndc80-Hec1, and CENP-E (Fisk et al. 2004; Vigneron et al. 2004; Zhao and Chen 2006; Tighe et al. 2008). Notably, Mps1 also interacts with the APC and is destabilized by APC/C-Cdc20 for mitosis exit after anaphase in budding yeast (Palframan et al. 2006) and in human cells (Cui et al. 2010).

A chemical genetic study clearly revealed that inactivation of yeast Mps1 generates defects in the SAC (Jones et al. 2005). Moreover, the small-molecule inhibitor cincreasin blocks this checkpoint by inhibiting Mps1p (Dorer et al. 2005). The localization of Mps1p to kinetochores, observed by immunofluorescence and immunoelectron microscopy, is also consistent with its function in the SAC (Winey and Huneycutt 2002). Consistently, Mps1p phosphorylates a kinetochore protein termed Mad1p when the SAC is activated in yeast. The overexpression of Mps1p induces hyperphosphorylation of Mad1p and leads to cell cycle arrest in mitosis with morphologically normal spindles (Hardwick et al. 1996). In budding yeast, mutation in any of the checkpoint genes, *mad1-3* and *bub1-3*, blocks the ability of overexpressed Mps1p to arrest the cell cycle, indicating that Mps1p is involved in the Mad- and Bub-dependent SAC pathway and may lie "high up" in the cascade (Winey and Huneycutt 2002). Mps1p-dependent phosphorylation of Ndc80/HEC1 is also likely to be important for SAC activation at kinetochores (Kemmler et al. 2009).

Xenopus Mps1 is also required for the SAC and depletion of Mps1 leads to failure of the SAC in *Xenopus* egg extracts (reviewed in Fisk et al. 2004). Human Mps1 was subsequently shown by antibody microinjection and siRNA approaches to be required for mitotic checkpoint arrest in response to microtubule depolymerization (Fisk et al. 2003). Zebrafish Mps1 was also found to be required for SAC signaling during wound regeneration downstream of Fibroblast Growth Factor (FGF) (see Fisk et al. 2004). In fact, *Xenopus* Mps1, mouse Mps1, human Mps1, and *Drosophila* Mps1 all localize to kinetochores, probably through the noncatalytic N-terminus, implying a conserved N-terminal kinetochore function of vertebrate Mps1. Megator (Mtor), the *Drosophila* counterpart of the translocated promoter region of the human nuclear pore complex protein, promotes the recruitment of *Drosophila* Mps1 to unattached kinetochores and mediates normal mitotic duration and the SAC response (Lince-Faria et al. 2009). In *Xenopus* extracts, Mps1 is required for the recruitment of CENP-E, Mad1, and Mad2 to kinetochores. In human cells, the Hec1-Ndc80-Nuf2 complex is essential for the recruitment of human Mps1 to kinetochores (Fisk et al. 2004), as is the human PRP4 kinase, whose ablation by RNAi overrides the SAC (Montembault et al. 2007). In turn, human Mps1 is physically or catalytically required for the recruitment of the SAC components Mad1 and Mad2 (Fisk et al. 2003; Tighe et al. 2008; Xu et al. 2009).

Autophosphorylation of human Mps1 and modulation of its kinase activity have been extensively studied, and activity is required for SAC function (Mattison et al. 2007; Kang et al. 2007; Tighe et al. 2008; Jelluma et al. 2008a). Analysis using various chemical inhibitors demonstrated that Mps1 kinase activity is required to recruit other SAC components, including Bub1, BubR1, Bub3, Mad1, Mad2, and the Rod-Zw10-Zwilch complex (reviewed in Lan and Cleveland 2010) (Fig. 3). Mechanistically, Mps1 maintains the recruitment of the inactive open Mad2 conformer (O-Mad2) at unattached kinetochores to the stably bound Mad1-active closed Mad2 (C-Mad2) complex. Mps1 dimerizes and become activated by autophosphorylation at kinetochores followed by



Monopolar Spindle 1 (Mps1), Fig. 3 Mps1 functions in the SAC. Mps1 kinase activity is required to recruit the spindle assembly checkpoint proteins Aurora B, Bub1, Bub3, BubR1, CENP-E, Mad1, Mad2, and the Rod-Zw10-Zwilch complex to unattached kinetochores (white sections, expanded diagram indicated by *dashed lines*). The kinase activities of Aurora B, BubR1, and Mps1 are essential for checkpoint signaling. Aurora B binds and phosphorylates INCENP, which forms the chromosomal passenger complex with Survivin and Borealin. Mps1 phosphorylates Borealin and the CENP-E C-terminal tail; Mps1 also undergoes autophosphorylation. Mps1 maintains the recruitment of O-Mad2 at unattached kinetochores to the stably bound Mad1-C-Mad2 template. Activated C-Mad2, BubR1, and Bub3 form the mitotic checkpoint complex, which tightly associates with Cdc20, preventing it from activating the APC/C and thereby inhibiting ubiquitylation and degradation of securin and cyclin B. Separase, the protease that cleaves the securing that hold sister chromatids together, is inhibited by binding to securin. Thus, anaphase onset and mitotic exit are blocked. The crystal structures of some of these checkpoint proteins have been solved and are shown in the figure (produced using *Pymol*): Aurora B-INCENP – PDB ID 2BFX; Borealin-INCENP-Survivin – PDB ID 2QFA; Bub1 – PDB ID 3E7E; Bub3 – PDB ID 1YFQ; Cyclin B – PDB ID 2B9R; CENP-E N-terminal motor domain – PDB ID 1T5C; Mad1-Mad2 – PDB ID 1GO4; Mad2 – PDB ID 2V64; Mps1 – PDB ID 2ZMC; Zwilch – PDB ID 3IF8. The structure of the APC/C has recently been revealed using single-particle electron microcopy (EMD-1816) and is shown in the figure

rapid release into the cytosol (Kang et al. 2007). Cytosolic Mps1 kinase activity also promotes the assembly of the APC/C-Cdc20 inhibitory complex formed between BubR1, Bub3, and C-Mad2 (Lan and Cleveland 2010).

Mps1 was shown to phosphorylate Borealin (also called cell division cycle-associated protein-8, or Cdc8) to control the kinase activity of another mitotic kinase, Aurora B, thereby helping to coordinate kinetochore attachment and correct merotelic attachment error (only one kinetochore attached to both poles) alongside SAC signaling (Jelluma et al. 2008b). However, recent studies have also shown that the kinetochore localization of Mps1 may depend on Aurora

B activity, suggesting that Aurora B may indeed act upstream of Mps1 (Lan and Cleveland 2010). Mps1 also phosphorylates the kinesin-related motor protein CENP-E, which relieves its autoinhibition and is likely to contribute to M-phase chromosome congression (Espeut et al. 2008) (Fig. 3).

Like many other protein kinases that control mitotic progression, Mps1 has other functions beyond those described for centrosome duplication and the SAC. A chemical and genetic approach revealed that inactivation of Mps1p generates defects in mitotic spindle formation, sister kinetochore positioning at metaphase, and chromosome segregation during anaphase, implying a multifunctional requirement for Mps1p at the kinetochore in mitotic spindle assembly and function (Jones et al. 2005). Mutation analysis of a small subset of Mps1p phosphorylation sites on a kinetochore component, Dam1p, suggested that Mps1p and Ipl1p (Aurora B) are required for coupling kinetochores to plus ends of microtubules in budding yeast (Shimogawa et al. 2006). The analysis of Mps1p function in yeast meiosis further revealed that Mps1p is required for chromosome segregation and spore wall formation (Winey and Huneycutt 2002). Additionally, *Drosophila* Mps1 is required for the arrest of cell cycle progression in response to hypoxia (Pandey et al. 2007) and has an important role in meiosis in female flies by regulating processes that are crucial for ensuring the proper segregation of nonexchange chromosomes (Gilliland et al. 2005; Gilliland et al. 2007). A hypomorphic Mps1 mutation also causes aneuploidy in zebrafish embryos, indicating the disastrous consequences of defects in Mps1 function in vertebrate germ-cell meiosis (Poss et al. 2004). Notably, a more recent study has shown that Mps1 is a target of microRNA miR-133 in zebrafish, during fin regeneration downstream of the FGF receptor (Yin et al. 2008).

Depletion of human Mps1 by siRNA causes mitotic catastrophe in the absence of microtubule poisons, including a high incidence of unaligned chromosomes at metaphase, large numbers of lagging chromosomes in anaphase, and failure of cytokinesis (reviewed in Fisk et al. 2004). Recent studies also suggested that the kinase activity of human Mps1 is required for proper chromosome alignment and accurate chromosome segregation. Analysis using various chemical inhibitors showed that inhibition of Mps1 kinase activity prevents correction of syntelic attachments (both kinetochores of a mitotic chromatid pair are attached to the same pole) (reviewed in Lan and Cleveland 2010), which agree with the previous finding in Mps1-depleted cells using shRNA (Jelluma et al. 2008b; Tighe et al. 2008). Mps1 also phosphorylates the Bloom syndrome gene product BLM at Ser 144, which is important for ensuring accurate chromosome segregation, and its deregulation may contribute to cancer (Leng et al. 2006).

Interestingly, human Mps1 may also participate in regulation of the G2-M DNA structure checkpoint by directly phosphorylating CHK2 on Thr 68 (Wei et al. 2005). Studies have also shown that human Mps1 controls nuclear targeting of c-Abl tyrosine kinase by 14-3-3-coupled phosphorylation at Thr 735 of c-Abl in response to oxidative stress (Nihira et al. 2008), and that a constitutively active version of the oncogenic B-Raf protein could regulate the level of Mps1, thus influencing the spindle checkpoint, in human melanoma cells (Cui and Guadagno 2008). Mps1 might also influence p53-dependent postmitotic signaling mechanisms through phosphorylation of the tumor suppressor p53 (Huang et al. 2008).

Regulation of Mps1

In the context of yeast SPB duplication, genetic evidence indicates that Mps1p requires molecular chaperones for its function. The kinase activity of Mps1p is reduced in *cdc37*-mutant strains, implying that Cdc37 provides a client chaperone function that promotes Mps1p activity for SPB duplication (Winey and Huneycutt 2002). Cdc28 (CDK1) also phosphorylates Mps1p on Thr 29 to maintain Mps1p levels for regulating Spc42p phosphorylation and assembly during SPB duplication (Jaspersen et al. 2004). The regulation of vertebrate Mps1 function has been reported with respect to centrosome duplication during S phase. The kinase activity of the G1-S regulator CDK2 is believed to be required for regulating Mps1 activity. In particular, human Mps1 is phosphorylated by CDK2-cyclin E in vitro at Ser 436 and Thr 453; this observation has also been made with mouse and *Xenopus* Mps1 (Fisk et al. 2004; Grimison et al. 2006). Furthermore, one major function for CDK2 in centrosome duplication is to prevent the proteasome-mediated degradation of Mps1 during S phase (Fisk et al. 2004; Kasbek et al. 2007). Kasbek et al. (2007) further showed that phosphorylation at Thr 468 of

Mps1 by CDK2-cyclinA regulates the accumulation of Mps1 at centrosomes. Moreover, in *Xenopus*, mitogen-activated protein kinase (MAPK) phosphorylates *Xenopus* Mps1 on Ser 844, regulating its kinetochore localization (Zhao and Chen 2006). In human somatic cells or melanoma cells, B-Raf kinase signaling promotes phosphorylation and kinetochore localization of Mps1 through the MAPK pathway (Cui and Guadagno 2008; Borysova et al. 2008).

Studies in fission and budding yeast have shown that protein phosphatase-1 gamma regulates the SAC silencing mechanism by dephosphorylation of yeast checkpoint components, including Aurora B (Vanoosthuyse and Hardwick 2009; Pinsky et al. 2009). In human cells, Mps1 enzyme autoactivation (autophosphorylation) and substrate phosphorylation increases during G2, becoming maximal during mitosis (Stucke et al. 2002; Kang et al. 2007). Notably, Mps1 phosphorylation and activity are enhanced after activation of the SAC (Stucke et al. 2002), and Mps1 occupies an upstream position in the yeast SAC signaling cascade (Fisk et al. 2004). Identifying the protein phosphatase(s) that regulate Mps1 and/or inactivate the SAC in human cells is therefore an important challenge for the future. Human Mps1 phosphorylation and catalytic activity are enhanced by experimental activation of the SAC with nocodazole (Stucke et al. 2002). However, how these mitotic phosphorylation events contribute to the regulation of Mps1 activity during mitosis is not yet clear, although autophosphorylation may contribute to activation through changes in localization and/or substrate binding, or through the positioning of catalytic residues for productive catalysis. Recombinant Mps1 produced in bacteria is active when assessed by in vitro kinase assay and shows significant autophosphorylation and substrate phosphorylation when affinity-purified or immunopurified from prokaryotic or eukaryotic sources (Mattison et al. 2007; Kang et al. 2007; Jelluma et al. 2008b; Tyler et al. 2009).

The conserved activation-segment residues, Thr 676 and Thr 686, were identified as important autophosphorylation sites for the regulation of human Mps1 activity in vitro and in vivo (Mattison et al. 2007; Kang et al. 2007; Jelluma et al. 2008a; Tyler et al. 2009) (Fig. 1), and both of these sites are near-stoichiometrically modified in vitro (Johnson et al. 2009). Numerous other sites of autophosphorylation have been identified, including putative kinetochore targeting sites in the human N terminus at Thr 12 and Ser 15 (Xu et al. 2009). Tyler et al. (2009) used a combined mass-spectrometric, mutational, and phosphospecific antibody approach to identify a series of novel Mps1 autophosphorylation sites, several of which map to regions of the catalytic domain outside the activation segment. Although the in vivo function of many of these phosphorylation events is not yet known, they are important in regulating Mps1 autophosphorylation and activity in vitro (Kang et al. 2007; Tyler et al. 2009). In addition, a phosphorylated C-terminal extension is important for localization of *Xenopus* Mps1 to kinetochores in M-phase extracts (Zhao and Chen 2006); this conserved serine residue (Ser 844 in *Xenopus* Mps1 and Ser 794 in mouse Mps1) is also stoichiometrically autophosphorylated by Mps1 in vitro (Johnson et al. 2009) and highly phosphorylated on endogenous human Mps1 during mitosis (Tyler et al. 2009).

In addition to roles in centrosome duplication and the SAC, human Mps1 mRNA and protein expression are negatively regulated by the p53 protein after DNA damage (Bhonde et al. 2006). The lack of suppression of human Mps1 by p53 may contribute to DNA damage-induced apoptosis in cells (Bhonde et al. 2006). Human Mps1 activates CHK2 by phosphorylating CHK2 at Thr 68 after DNA damage. To maintain the DNA checkpoint control, activated CHK2 in turn phosphorylates Mps1 at Thr 288 and stabilizes the kinase, thus forming a positive regulatory loop (Yeh et al. 2009).

Mps1 protein levels are cell-cycle regulated and highest in rapidly proliferating tissues (Winey and Huneycutt 2002). CDK2 prevents the proteasome-mediated degradation of Mps1 during S phase (Fisk and Winey 2001), and phosphorylation of Mps1 at Thr 468 by CDK2-cyclinA regulates the accumulation of Mps1 at centrosomes in yeast (Kasbek et al. 2007). In addition, CHK2 phosphorylates Mps1 on Thr 288 and controls stability after DNA damage (Yeh et al. 2009). Several lines of indirect evidence suggest that the phosphorylation of Mps1 at Ser 844 is important for targeting and concentrating *Xenopus* Mps1 and Mad1 to the kinetochore and permitting M-phase checkpoint function (Zhao and Chen 2006), although this modification is clearly not important for *Xenopus* (Zhao and Chen 2006) or human (Tyler et al. 2009) Mps1 catalytic activity.

In anaphase, yeast Mps1p is regulated by the anaphase-promoting complex/cyclosome APC/C-Cdc20

complex. When the SAC is activated in metaphase, Mps1p acts through the checkpoint pathway to inhibit APC/C-Cdc20 activity and increase Mps1p stability, whereas in anaphase Mps1p is destabilized by APC/C-Cdc20 for mitosis exit (Palframan et al. 2006). Mps1p and APC/C-Cdc20 mutually inhibit each other to create this double-negative feedback loop (Palframan et al. 2006). However, it is still not known how yeast Mps1p localization is regulated. In human cells, Mps1 is also targeted for degradation by the APC/C-ubiquitin-proteasome pathway during late mitosis and G1 phase. A single D-box sequence, RNSL motif, was recently identified within the N-terminal region of human Mps1, which is recognized by APC/C-Cdc20 or APC/C-Cdh1 and is conserved in most mammalian species (Cui et al. 2010) (Fig. 1). The same study demonstrated that human Mps1 is a target of the APC/C-Cdc20 and APC/C-Cdh1 ubiquitin ligases, which undergoes proteolysis during anaphase through G1 phase to allow for proper centrosome duplication and cell cycle progression.

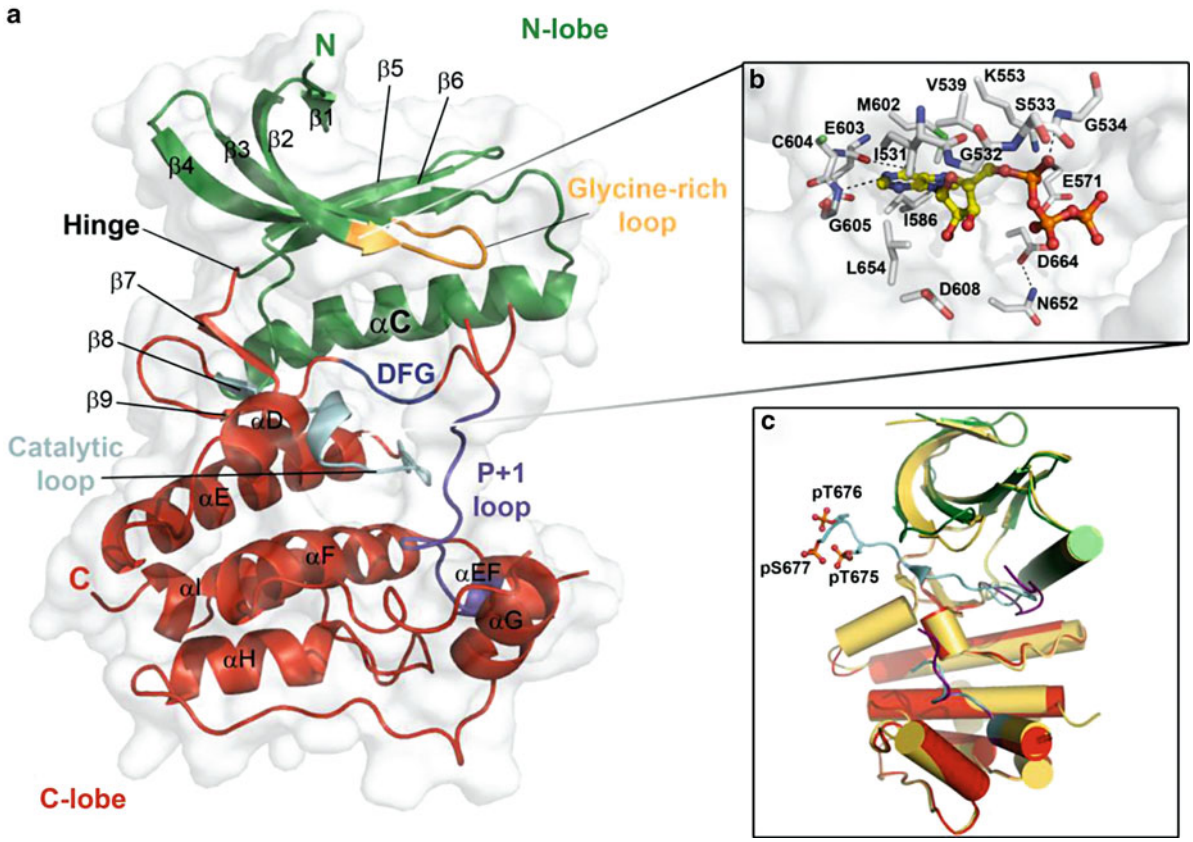
Mps1 and Disease

As a central mitotic kinase, it is not surprising that human Mps1 mRNA is found at high levels in freshly isolated malignant tissues and cancer cell lines, including breast cancer, cervical carcinoma, choriocarcinoma, hematopoietic cells, lung cancer, melanoma, neuroblastoma, ovarian cancer, and testicular tumors (Winey and Huneycutt 2002). The first data to implicate human Mps1 in tumorigenesis came with the observation that its mRNA is overexpressed in gastric cancer tissue, as well as in colon, kidney and lung cancers and bronchogenic carcinoma (Iwase et al. 1993). However, no studies have yet examined expression of Mps1 protein in parallel. Notably, Mps1 was identified in an siRNA screen of the human kinome as a modulator of cancer cell sensitivity to the microtubule-stabilizing agent, paclitaxel (Swanton et al. 2007). Dual roles of Mps1 in chromosome alignment and the SAC might be particularly important for its ability to synergize with therapeutic concentrations of paclitaxel in transformed cells (Janssen et al. 2009). These findings also indicate that Mps1 inhibition might be useful in treating patients with paclitaxel-resistant cancer, perhaps as part of a synthetic lethal strategy (Kaelin 2005). Notably, heterozygous Mps1 mutations have recently been identified in microsatellite-unstable colorectal cancers although these Mps1 mutants did not promote SAC weakening or override mitotic arrest (Niittymaki et al. 2011). By virtue of its importance in SAC signaling and its regulation of the Aurora B signaling pathway through Borealin (Jelluma et al. 2008b; Bourhis et al. 2009), Mps1 inhibition or modulation of its degradation kinetics might represent a way to sensitize or kill rapidly dividing cells (Kops et al. 2004; Kasbek et al. 2009).

Small Molecule Mps1 Inhibitors

Before 2010, only three small molecules – cincreasin (Dorer et al. 2005), SP600125 (Schmidt et al. 2005), and 1NM-PP1 (Jones et al. 2005; Tighe et al. 2008) – had been described to inhibit cellular yeast and human Mps1, respectively. Genetic and biochemical data suggest that Mps1p is a target of cincreasin, but this compound is a weak inhibitor of Mps1p, with a relatively high half-maximal inhibitory concentration of about 700 μm in an in vitro kinase assay (Dorer et al. 2005). The cell-permeant ATP analogue inhibitor 1NM-PP1 inhibits a modified M600G/A Mps1 allele and can be used to probe Mps1 function in yeast or human cells (Jones et al. 2005; Tighe et al. 2008). The ATP-competitive JNK1 inhibitor SP600125 is also a potent inhibitor of human Mps1 function. SP600125 completely inhibits Mps1 activity at 10 μm in vivo and in vitro (Schmidt et al. 2005); in contrast, it inhibits JNK1 at a half-maximal inhibitory concentration of 40 nM and is the first-choice JNK inhibitor for cellular studies (Bennett et al. 2001). Unfortunately, SP600125 also inhibits several other kinases in vitro, so its use as a specific inhibitor of Mps1 activity is prone to validation problems (Bain et al. 2007; Tighe et al. 2008). Nevertheless, SP600125 has also emerged as a potentially useful screening tool for the discovery of ATP-dependent Mps1 inhibitors through the development of fluorescent Mps1 ligand-displacement assays (Chu et al. 2010).

In 2010, six groups reported seven distinct small-molecule inhibitors of Mps1 (reviewed in Lan and Cleveland 2010; Colombo et al. 2010). Using these different chemical inhibitors, these studies demonstrated that Mps1 kinase activity is indispensable for accurate chromosome segregation through its recruitment of SAC proteins to kinetochores, formation of the



Monopolar Spindle 1 (Mps1), Fig. 4 Crystal structure of Mps1 catalytic domain. (**a**) Ribbon representation of the WT-apo Mps1 catalytic domain (PDB ID 2ZMC; Chu et al. 2008). Characteristic key features important for substrate binding and catalysis are labeled as follows: glycine loop (*orange*), aC helix, catalytic loop (*cyan*), activation segment with DFG motif (*blue*), and P + 1 loop (*purple*). (**b**) Detailed view of Mps1-ATP co-crystal structure, showing ATP bound in the hydrophobic cleft (PDB ID 3HMN; Chu et al. 2010). The residues that interact with ATP are depicted as *sticks* and ATP is depicted as *ball-and-sticks*. Catalytic residues are not in typical "active-form" orientations (conserved ion-pair Lys-553 and Glu-571 is disengaged, Asp-608 and Asn-652 in the catalytic loop, and Asp-664 at the DFG-motif do not interact with the ATP). (**c**) Superposition of unphosphorylated (*red* and *green*; PDB ID 3HMN; Chu et al. 2010) and phosphorylated Mps1 (*gold*, PDB ID 3H9F; Kwiatkowski et al. 2010) (90°-view of Fig. 4a). The activation segment of the unphosphorylated and phosphorylated Mps1 are colored in *purple* and *cyan*, respectively, and phospho-Thr-675, phospho-Thr-676, phospho-Ser-677 are shown as *ball-and-sticks*. The figure was produced using Pymol

APC/C-Cdc20 inhibitory mitotic checkpoint complex, and correction of erroneous microtubule attachments. However, contradictory results were described among the studies: two papers proposed that Mps1 acts upstream of Aurora B to correct syntelic attachments, while three other papers found that the kinetochore localization of Mps1 depends on Aurora B activity, suggesting that Aurora B acts upstream of Mps1 (reviewed by Lan and Cleveland 2010). An ultimate goal of Mps1 inhibitor discovery is the design of novel therapeutic agents for proliferative disorders such as cancer. Initial studies have shown that the purine analogues, 23-dMB-PP1, Mps1-IN-1, and Mps1-IN-2, all kill cultured tumor cells by direct targeting of Mps1. Colombo et al. (2010) have also described a selective, orally bioavailable, Mps1 inhibitor (NMS-P715) that reduces cancer cell proliferation and inhibits tumor growth in a preclinical model.

Crystal Structures of Human Mps1 Catalytic Domain: Insights into Mps1 Structural Biology

The first published crystal structures of the human Mps1 catalytic domain (amino acids 424–791) were

unphosphorylated catalytic domain deletions of a wild-type apo form (amino acids 510–857) and an inactive T686A mutant complexed with SP600125 at 3.14 Å and 2.88 Å, respectively (Chu et al. 2008). The catalytic domain of Mps1 adopts the classical fold of protein kinases, with the activation loop packing against the N-terminal lobe, where it induces conformational changes indicative of a catalytically inactive form of the enzyme (Fig. 4a). The structure of the complex with SP600125 shows the inhibitor bound in the ATP-binding site and highlights distinct structural features in the active-site cleft that might be exploited for rational drug design. Chu et al. (2010) also determined co-crystal structures with ATP (2.7 Å, Fig. 4b), the aspecific model kinase inhibitor staurosporine (2.4 Å) and a low-affinity quinazoline drug-like fragment termed Compound 4 (2.3 Å), which extended the knowledge of the Mps1 nucleotide binding site architecture. A 2.7-Å K553R Mps1 mutant apo-structure has also been reported (Wang et al. 2009). Despite the similar fold in other published Mps1 structures, Wang et al. identified two lysine residues, Lys 708 and Lys 710, in the loop between the αEF and αF helices that are essential for in vitro substrate recruitment and maintenance of high levels of kinase activity through Mps1 autophosphorylation. Although the C terminus of Mps1 is structurally disordered, Sun et al. (2010) recently showed that this tail is important for Mps1 substrate binding and transphosphorylation (but without affecting autophosphorylation). Most interestingly, it is also essential for SAC activation.

Most recently, Kwiatkowski et al. (2010) and Colombo et al. (2010) also reported Mps1 co-crystal structures with the kinase inhibitors, Mps1-IN-1 (2.74 Å), Mps1-IN-2 (2.6 Å), and NMS-P715 (3.1 Å), which give new insights for the design of Mps1-specific inhibitors. Significant structural difference is also found in the Mps1-IN-2 Mps1 complex. While the activation segments are absent in all other Mps1 crystal structures, it becomes ordered in the presence of this compound. Indeed, three phosphorylation sites can be observed, including Thr 675, Thr 676, and Ser 677, although the overall conformation of the catalytic domain is similar to those reported for unphosphorylated Mps1 structures (r.m.s.d. = 0.6 Å, Fig. 4c). This questions the function of the phosphorylation of these residues for Mps1 activation and the potential stabilization of a dimeric transphosphorylation complex.

Summary

Mps1 is a conserved eukaryotic dual-specificity protein kinase with an important role in centrosome duplication, SAC, chromosome alignment, and other critical cell cycle processes. Mps1 phosphorylates a growing family of cell cycle-modified proteins, and its own signaling function is controlled by phosphorylation, ubiquitination, and transient subcellular targetting. Inhibition of Mps1 activity by small molecules, either alone or as part of a multitherapy regime, might represent a novel therapeutic strategy for proliferative diseases such as cancer, where its central role as a cell cycle orchestrator makes it necessary for cell survival.

Synonyms

MOZ lysine acetyltransferase: MOZ; Monocytic leukemia zinc-finger protein; MYST3; Lysine (K) acetyltransferase 6A; KAT6A
MORF lysine acetyltransferase: MORF; MOZ-related factor; MYST4; Querkopf; Lysine (K) acetyltransferase 6B; KAT6B

Historical Background

MOZ is a founding member of the MYST (*MOZ*, *YBF2*, *SAS2*, and *TIP60*) family of lysine acetyltransferases (Borrow et al. 1996). It was identified in 1996 through positional cloning of the reciprocal chromosomal translocation t(8;16)(p11;p13) associated with a subset of acute myeloid leukemia (AML) (Borrow et al. 1996). A few years later, the acetyltransferase activity was formally demonstrated and mapped to the MYST domain (Champagne et al. 2001; Kitabayashi et al. 2001a). Human MORF was identified in BLAST search against expressed sequence tag databases for additional MYST proteins (Champagne et al. 1999). Mouse *Morf* was identified as *Querkopf*, a mutant allele causing craniofacial abnormalities (Thomas et al. 2000). MORF is highly homologous to MOZ (Fig. 1).

Domain Organization of MOZ and MORF

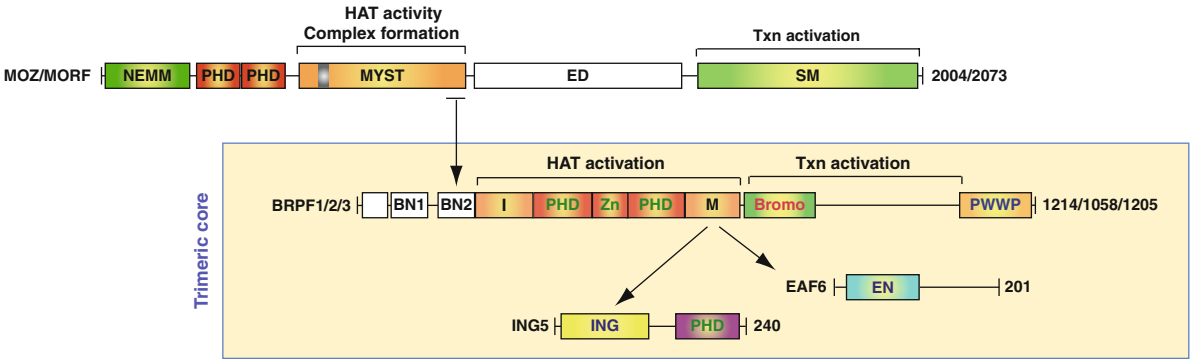
MOZ and MORF are large proteins (~250 kDa) with multiple functional domains (Fig. 1). The MYST domain contains a C2HC nucleosome-binding zinc finger and the histone acetyl transferase (HAT) core. The MYST domain of MOZ is able to acetylate histone H2A, H3 and H4, Runx1, and MOZ itself (Champagne et al. 2001; Kitabayashi et al. 2001a), but cannot acetylate nucleosomal histones (Champagne et al. 2001). MORF preferentially acetylates histones H3 and H4, and is capable to autoacetylate itself. When oligonucleosomes is used as substrates, MORF preferentially acetylated H4 (Champagne et al. 1999).

MOZ and MORF are members of the MYST family, which has five members in *Drosophila* or humans (Fig. 1). The MYST domain is the only structural feature common to all members of this family. MOZ and MORF show sequence similarity to the very N-terminal region and the MYST domain of Enok (Enoki mushroom), the most related *Drosophila* protein (Scott et al. 2001). Different from *Drosophila*, zebrafish possesses orthologs of MOZ and MORF. Thus, different from TIP60, MOF, and HBO1, both MOZ and MORF are vertebrate-specific.

Other protein domains of MOZ and MORF include an NEMM (N-terminal part of Enok, MOZ or MORF) domain, tandem PHD (plant homeodomain-linked) zinc fingers, a long acidic stretch, and a SM (serine/methionine-rich) region. The C-terminal part of the NEMM domain shows some sequence similarity to histones H1 and H5. The H15-like domain was shown to promote nuclear targeting (Kitabayashi et al. 2001a). The tandem PHD fingers are similar to those of Requiem and homologs (Borrow et al. 1996; Nabirochkina et al. 2002). The N terminal regions of MOZ and MORF possess strong transcriptional repression domains (Champagne et al. 1999). The SM domain constitutes an activation domain. The SM domain of MOZ is weaker than that of MORF, raising the interesting possibility that insertion of a PQ-stretch in the SM domain of MOZ reduces its activation potential (Champagne et al. 2001). The possession of multiple functional domains by MOZ and MORF suggests that they may regulate transcription in both acetylation-dependent and -independent manners.

MOZ and MORF Acetyltransferase Complexes

MOZ and MORF function as the catalytic subunits of an ING5 complexes (Doyon et al. 2006). ING5 is the



MOZ and MORF Lysine Acetyltransferases, Fig. 1 Schematic illustration of MOZ, MORF, and their association partners. A small region within the MYST domain of MOZ and MORF interacts with BRPF1 and paralogs, which utilize domain M for binding to ING5 and EAF6. ING5 and EAF6 form a trimeric core with BRPF1, -2, or -3. Association of ING5 with BRPF proteins promotes EAF6 interaction. The N-terminal domain of ING5 is sufficient for BRPF binding. The PHD fingers of ING5, BRPFs, MOZ, and MORF do not appear to be important for complex formation, but may mediate complex recruitment to specific chromatin domains. The bromodomain and PWWP domain of BRPF proteins may also recognize modified chromatin. *Txn*, transcription; *EN*, EAF6 N-terminal (Adapted from (Ullah et al. 2008)).

fifth member of the ING (inhibitor of growth) family of tumor suppressors (Soliman and Riabowol 2007). The other subunits of the complexes are EAF6 (homolog of yeast *E*sa1-*a*ssociated *f*actor 6) and BRPF1, -2, or -3 (*br*omodomain-*P*HD *f*inger protein 1, 2, or 3; Fig. 1) (Doyon et al. 2006). Different from MOZ and MORF alone, the complexes acetylate only histone H3 at lysine 14 (Doyon et al. 2006). BRPF1 binds to the MYST domains of MOZ and MORF, stimulates their acetyltransferase and coactivator activities, and bridges interaction with ING5 and EAF6 (Fig. 1) (Ullah et al. 2008). Coexpression of MOZ, BRPF1, and ING5 has a synergistic effect on the Runx2 promoter. The complexes may also be important for DNA replication (Doyon et al. 2006).

MOZ and MORF Act as Transcriptional Coactivators of Transcription Factors

Both MOZ and MORF are widely expressed in various mouse and human tissues (Borrow et al. 1996; Champagne et al. 1999; Katsumoto et al. 2006; Thomas et al. 2006), so similar to GCN5/PCAF and p300/CBP, they may function as coactivators for many transcription factors. Indeed, many lines of evidence have demonstrated that MOZ and MORF act as coactivators for different transcription factors such as Runxs, Hox, ETV6, PU.1, and p53; all of them play pivotal roles in different development and cellular processes. MOZ and MORF can bind to Runx2 (runt-related transcription factor 2) through the SM domain and potentiate Runx2-dependent transcriptional activation (Pelletier et al. 2002). Runx2 plays an important role in T cell lymphomagenesis (Pelletier et al. 2002), and is essential in controlling osteoblast differentiation and bone formation (Ducy et al. 2000).

MOZ and MORF in Animal Development

Consistent with the regulatory role of MOZ/MORF in regulating the activities of transcription factors that are essential in different developmental processes, studies on mutant fish and mouse models indicate that MOZ and MORF play key roles in hematopoiesis, skeletogenesis, neurogenesis, and other differentiation programs (Thomas et al. 2000, 2006; Miller et al. 2004; Crump et al. 2006; Katsumoto et al. 2006; Merson et al. 2006).

Homozygous *Moz* mutant mice lacking the Moz protein expression die at birth. Fetal liver hematopoietic cells from the *Moz* mutant fail to contribute to the hematopoietic system of recipients after transplantation, and display defects in the stem cell compartment (Thomas et al. 2006). $Moz^{-/-}$ mice without the expression of Moz generated by a separate group die around embryonic day 15 (E15). In $Moz^{-/-}$ E14.5 embryos, HSCs (hematopoietic stem cells) and progenitors are decreased, and maturation of erythroid cells is inhibited in Moz-deficient fetal liver that is due to the

synergistic effects of decreased expression of c-Mpl, HoxA9, and c-Kit (Katsumoto et al. 2006). Therefore, *Moz* is essential for the maintenance of hematopoietic stem cells.

A mouse strain carrying a point mutation that inactivates the HAT activity of the Moz protein remains alive during the gestation period, but about 40% of the homozygotes die within the first 6 months after birth. These mice exhibit significant defects in the number of HSCs and committed precursors and B-cell development defect. The reduced number of HSCs is caused by the failure of $HAT^{-/-}$ cells to expand. These results indicate that the HAT activity of Moz play a critical role in the proliferation and maintenance of hematopoietic precursors (Perez-Campo et al. 2009).

Studies on $Moz^{-/-}$ mutant mice (Thomas et al. 2006) also show that Moz is required for normal levels of H3K9 acetylation and gene expression at the Hox loci, and for correct specification of 19 body segments. In addition, Moz is required for recruitment of Ing5 and the H3 K4 methyltransferase Mll1 to the Hox loci (Voss et al. 2009). In zebrafish, it was found that Brpf1 and Moz cooperate to promote histone acetylation and maintenance of anterior Hox gene expression, and to determine pharyngeal segmental identities (Laue et al. 2008).

Homozygous mouse mutants for *Querkopf* fail to thrive in the postnatal period, display craniofacial abnormalities due to defects in the calvarial bones, and have defects in cerebral cortex development. (Thomas et al. 2000). Homozygous mice show smaller cerebral cortex, lack of large pyramidal cells in layer V of the cortex, and have reduction in the number of GAD67-positive interneurons throughout the cortex, suggesting that *Querkopf* is an essential in regulating cell differentiation in the cortex (Thomas et al. 2000). *Querkopf*-deficient mice also display defects in adult neurogenesis in vivo. Isolated neural stem/progenitor cells exhibit decreased self-renewal capacity and reduced ability to produce differentiated neurons. Thus, *Querkopf* is also essential for adult neurogenesis.

MOZ and MORF in Cancer and Other Diseases

MOZ fusion proteins caused by chromosomal rearrangement enable the transformation of non-self-renewing myeloid progenitors into leukemia stem cells (Huntly et al. 2004). Fusion partners of MOZ include (CREB-binding protein) CBP (Borrow et al. 1996), the CBP paralog p300 (Chaffanet et al. 2000; Kitabayashi et al. 2001b), the p300/CBP-interacting nuclear receptor coactivators TIF2 (transcription intermediary factor 2) (Carapeti et al. 1998; Liang et al. 1998), and nuclear receptor coactivators 2 (NCOA3) (Esteyries et al. 2008). *MORF* translocation is also associated with childhood AML or therapeutic myelodysplastic syndromes, in (Panagopoulos et al. 2001; Kojima et al. 2003). The *MORF* gene is also disrupted in multiple cases of uterine leiomyomata. *GCN5* is the fusion partner (Moore et al. 2004). Deregulation of gene expression resulting from these translocations may be involved in the pathogenesis. MOZ is involved in regulating cell cycle arrest in the G1 phase (Rokudai et al. 2009). DNA damage increases the level of a p53-MOZ complex. In $MOZ^{-/-}$ mouse fibroblasts, DNA damage fails to induce the expression of p21 and G1 cell cycle arrest. The leukemic fusion protein MOZ-CBP inhibits p53-mediated transcription. Thus, inhibition of p53/MOZ-mediated transcription contributes to leukemogenesis (Rokudai et al. 2009). In addition, the *MORF* gene has recently been shown to be mutated in three developmental disorders, including variants of Noonan syndrome and Ohdo syndrome, and Genitopatellar syndrome (Kraft et al. 2011; Clayton-Smith et al. 2011; Campeau et al. 2012). Strikingly, such patients all display characteristic bone defects, a phenotype that is somewhat consistent with what was observed in the *Querkopf* mutant mice (Thomas et al. 2000). It will be interesting to determine whether similar mutations are present in the *MOZ, BRPF* and *ING5* genes, and whether MOZ and MORF play a role in diseases other than cancer and bone defect disorders.

Summary

MOZ and MORF belong to the MYST family of histone acetyltransferases. Their multifunctional domains confer the function as co-regulators of transcription. They can regulate gene expression by acetylation-dependent and -independent manners. MOZ and MORF act as potential coactivators for different transcription factors such as Runxs, Hox, ETV6, PU.1, and p53, which play pivotal roles in different development and cellular processes. Accordingly, studies on mutant animal models indicate that MOZ and MORF are important for hematopoiesis, skeletogenesis, neurogenesis, body segment specification, and cell cycle control. MOZ and MORF are targets

of chromosome rearrangements that are associated with leukemia and other types of cancer. Deregulation of gene expression resulting from these translocations may be involved in tumor pathogenesis. Furthermore, the *MORF* gene is mutated in multiple syndromes with bone and various other abnormalities. Overall, both MOZ and MORF are enzymatic transcriptional coregulators that have important functions in various physiological and pathological processes.

Synonyms

CD280; Collagen-binding factor Endo180; C-type mannose receptor 2; Endo180; Endocytic receptor 180; Macrophage mannose receptor 2; Mannose receptor, C-type 2; Urokinase-type plasminogen activator receptor-associated protein (uPARAP)

Historical Background

The *MRC2* gene encodes the constitutively recycling type I transmembrane receptor Endo180 (Wu et al. 1996; Sheikh et al. 2000; Isacke et al. 1990), which is also cited in the literature as urokinase plasminogen activator receptor associated protein (uPARAP) following its identification as part of a trimolecular complex with pro-urokinase plasminogen activator (pro-uPA) and its receptor urokinase plasminogen activator receptor (► uPAR) (Behrendt et al. 2000). Endo180 is a member of the mannose receptor family, which also includes the mannose receptor (MR; CD206), M-type phospholipase A2 receptor, and DEC-205 (CD205) (East and Isacke 2002). The constitutive recycling of Endo180 between clathrin-coated pits at the plasma membrane and intracellular endosomal compartments is dependent on a dihydrophobic endocytosis motif and modulated by a conserved upstream acidic residue (Howard and Isacke 2002). Endo180 internalization is independent of a conserved tyrosine-based motif that is critical role for internalization to the other

three family members (Howard and Isacke 2002). Endo180 expression is regulated by transforming growth factor-beta receptor (TGF-beta Receptor) signaling via the Smad transcription factor pathway (Huijbers et al. 2010).

Endo180 functions as a signaling receptor that regulates the overall and tempero-spatial activation of the small Rho GTPases, Cdc42, Rac and Rho, which drive directed cell migration (chemotaxis) or random cell migration via pro-uPA-uPAR-dependent or independent mechanisms (Sturge et al. 2003, 2006). The factors responsible for Rho GTPase activation by Endo180 during its functional role as a chemotaxis receptor involves unidentified factors that promote guaninine nucleotide exchange (GDP → GTP) (see Fig. 1 and section "Endo180-Dependent Signaling in Cell Migration" for further details).

Endo180 Structure and Implications for Signaling

Endo180 has a similar domain structure to other members of the mannose receptor family and can be subdivided into 12 structural elements (see Fig. 1). The 150 kDa ectodomain of Endo180 is comprised of a cysteine-rich domain (CRD), a fibronectin type II–like domain (FNII) and eight repeated C-type lectin domains (CTLDs 1–8) and is modified by approximately 30 kDa of N-linked sugars (Wu et al. 1996; Sheikh et al. 2000; Behrendt et al. 2000). Following its transmembrane domain Endo180 has a short cytoplasmic tail, which in humans is comprised of 42 amino acid residues, including several putative phosphorylation sites (Isacke et al. 1990) (see Fig. 2 and section "Phosphorylation of Endo180" for more details). The three-dimensional structural arrangement of the amino terminal domains of Endo180 (CRD–FNII–CTLD1–2) has been modeled from single-particle electron microscopy analysis to reveal a hairpin loop structure (Rivera-Calzada et al. 2003) that is predicted to undergo conformational changes in response to ligand binding or microenvironmental factors (Boskovic et al. 2006) (see Fig. 1). The functional and biological context of these intramolecular alterations in Endo180 have not been determined but could modulate the intracellular signaling pathways activated downstream of Endo180. The identification of molecular partners that interact with the cytoplasmic tail of Endo180 and the receptor ectodomain will help to provide further insight about the biological context of the signaling events regulated by Endo180.

Endo180 Ligands and Implications for Signaling

Collagens

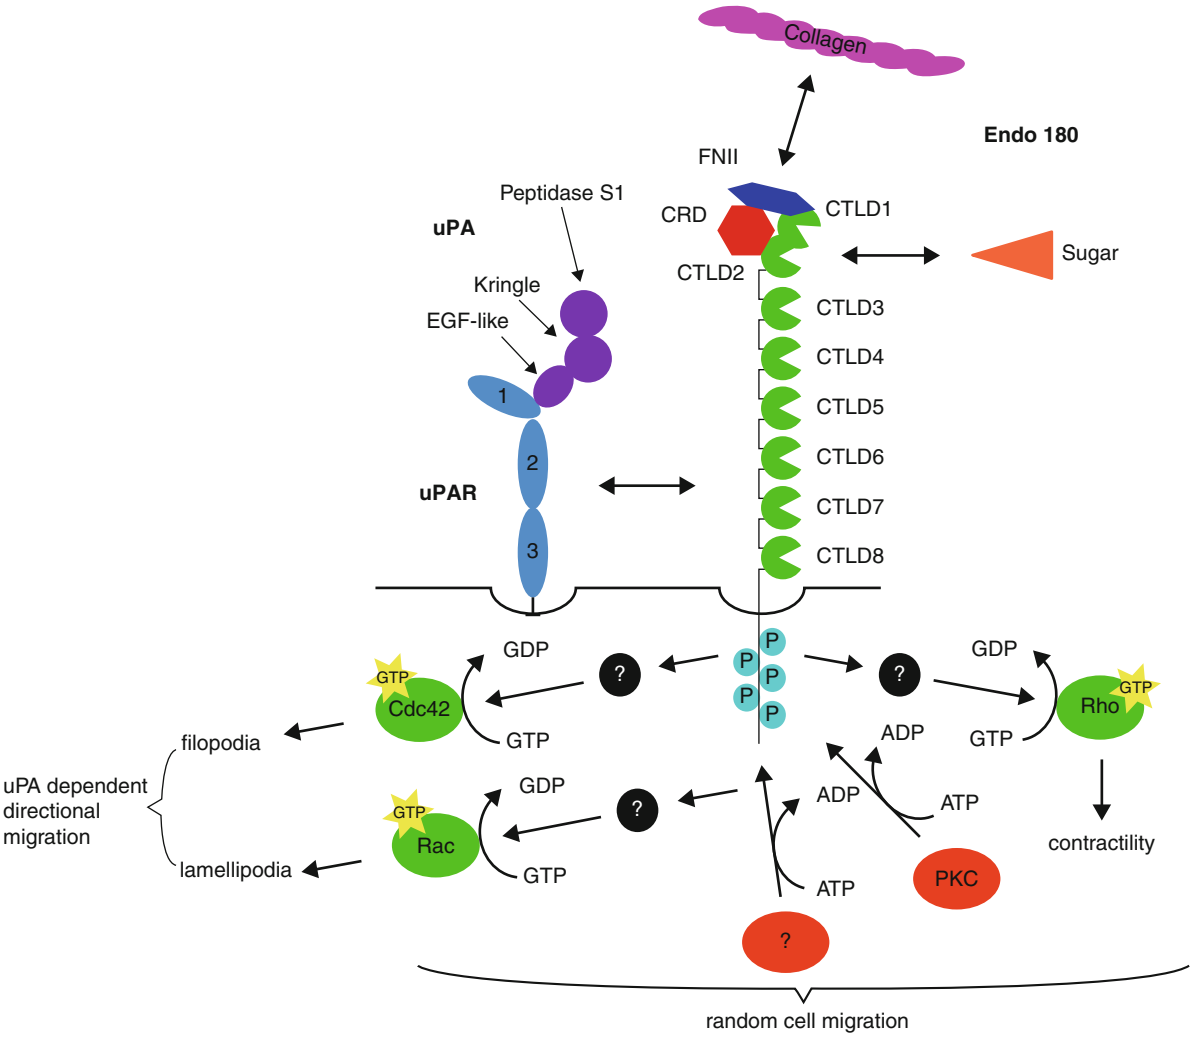
Endo180 interacts with different subtypes of collagen via its FNII domain (Wienke et al. 2003). For type I collagen this interaction occurs through the interaction of Endo180 with its C-terminal domain (Thomas et al. 2005). The binding of soluble collagen ligands at the cell surface results in their rapid internalization by Endo180 and subsequent transport to lysosomal compartments for degradation (Wienke et al. 2003; Engelholm et al. 2003; East et al. 2003), a function that has been implicated in the tissue remodeling process associated with cancer progression (Huijbers et al. 2010; Kogianni et al. 2009; Wienke et al. 2007) and tumor cell invasion (Huijbers et al. 2010). Another important function for this interaction is the promotion of cell-matrix adhesion (Sturge et al. 2006; Thomas et al. 2005). The intracellular signaling events activated by the engagement of Endo180 with either soluble or fibrillar forms of collagen have not been fully explored. To date, evidence suggests that the enhanced phosphorylation of ▶ myosin (regulatory) light chain-2 (MLC2) by the Endo180-Rho-Rho kinase (ROCK) signaling axis is independent of cell adhesion to collagen (Sturge et al. 2006).

Sugars

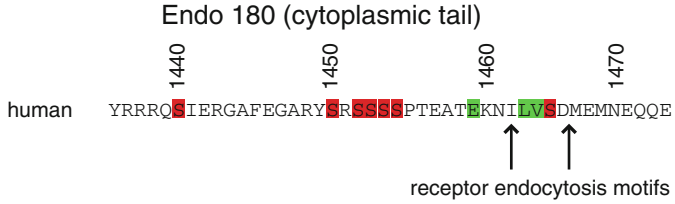
Endo180 has been shown to interact with various sugar moeities via calcium-dependent binding to its only functional C-type lectin-like domain, CTLD2 (East et al. 2002, 2003;). However, the impact of the lectin activity of Endo180 on its signaling function, or any of its other functions, has not yet been reported.

pro-uPA-uPAR

The trimolecular complex formed between Endo180, uPAR and pro-uPA on the cell surface (Behrendt et al. 2000) is implicated in the enhanced migratory behavior of tumor cells, during which, Endo180 can coordinate the activation of Rho GTPases (Cdc42, Rac, and Rho), cytoskeletal remodeling events



MRC2, Fig. 1 Endo180 domain structure, interaction partners, and signaling. Endo180 domains: N-terminal cysteine-rich domain (CRD); fibronectin type II domain (FNII); eight C-type lectin domains (CTLD1-8); a single transmembrane domain; and a short (42 amino acid residue) intracellular C-terminal domain. CRD, FNII, and CTLD1-2 form a hairpin loop structure at the receptor N-terminus. FNII binds collagen and CTLD2 binds sugars. Endo180 is a coreceptor of pro-uPA, which is comprised of a peptidase domain, kringle domain and EGF-like domain and uPAR, which is comprised of domains 1–3. Endo180 has at least five phosphorylation sites in its cytoplasmic tail with at least one of these sites characterized as a substrate for protein kinase C (PKC). Functional studies have shown that Endo180 regulates the overall and tempero-spatial activation of the small GTPases Cdc42, Rac, and Rho during pro-uPA dependent chemotaxis and random cell migration (Sturge et al. 2003, 2006)



MRC2, Fig. 2 Potential PKC-phosphorylation sites in Endo180. Potential serine targets for PKC-mediated phosphorylation are marked in red (Sheikh et al. 2000; Isacke et al. 1990). An E1464A mutation partially alters the internalization of Endo180, whereas L1468A/V1469A co-mutation blocks Endo180 internalization (Howard and Isacke 2002)

(filopodial, lamellipodial, and stress fiber dynamics), cell-matrix adhesion turnover and cell–cell adhesion disassembly (Sturge et al. 2003, 2006; Takahashi et al. 2010) (see section "Endo180-Dependent Signaling in Cell Migration" for further details). MR-dependent chemotactic responses in myoblasts (Jansen and Pavlath 2006) suggests that a common biological role exists for this related receptor; however, the molecular basis underlying the function of MR as a chemotaxis receptor and the chemotactic signaling events that are activated downstream of MR have not been determined.

Endo180–Dependent Signaling in Cell Migration

Ectopic overexpression of Endo180 in receptor null tumor cells results in their enhanced cell migration and chemotaxis (Sturge et al. 2003). In accordance, the genetic silencing of Endo180 by small interference RNA (siRNA) in invasive human tumor cell lines that express high endogenous levels of Endo180 (Sturge et al. 2003, 2006), or the targeted deletion of Endo180 in murine embryonic fibroblasts (Engelholm et al. 2003; East et al. 2003), results in reduced cell migration and adhesion. As stated previously there are three major signaling pathways that have been identified as downstream targets that can be modulated by Endo180 and can promote cell migration:

Endo180–Dependent Activation of Cdc42

The requirement for Endo180 in MDA-MB-231 metastatic breast cancer cells to sense a chemotactic gradient of pro-uPA was demonstrated by genetic silencing of Endo180 by siRNA in Dunn chemotaxis chamber assays (Sturge et al. 2003). The role of Endo180 in this chemotactic response was supported by a gain in directional migration toward a gradient of pro-uPA following its overexpression in non-invasive MCF7 breast cancer cells. These changes in chemotactic behavior are directly linked to altered dynamics of pro-uPA-dependent Cdc42 activation, which is suppressed by Endo180 silencing in MDA-MB-231 cells, enhanced in MCF7 cells that overexpress Endo180 and display increased filopodial protrusions in response to pro-uPA (Sturge et al. 2003). The activation of Cdc42 and detection of a pro-uPA gradient in cells that express an Endo180 mutant receptor that cannot be internalized indicates that the chemosensory function of Endo180 is independent of receptor endocytosis (Sturge et al. 2003).

Endo180–Dependent Activation of Rac

The rapid activation of Rac by uPA in MCF7 cells that overexpress Endo180 and the requirement for the internalization of Endo180 to activate Rac and promote an increase in migratory speed suggest the mechanism of Rac activation by Endo180 is distinct from that required for its activation of Cdc42 (Sturge et al. 2003). The localization of Endo180 to lamellipodia (Sturge et al. 2003) and the requirement of Endo180 for lamellipodial protrusion formation (Takahashi et al. 2010) indicates that it plays a critical role in Rac-dependent signaling, which drives cytoskeletal remodeling and cell migration.

Endo180–Dependent Activation of Rho-ROCK-MLC2

Endo180 is required for the diphosphorylation of serine 19/threonine 18 of MLC2 in MG63, MDA-MB-231, BE and HT-1080 cells and these signals are enhanced by the overexpression of Endo180 in MCF7 cells. Endo180 is also required for the phosphorylation of myosin light chain phosphatase-1 (MYPT1) and ▶ LIMK, which are common downstream targets of ROCK. Functional studies demonstrated that the Rho-ROCK-MLC2 diphosphorylation signaling axis is spatially localized by Endo180–containing endosomes for the promotion of focal adhesion disassembly at the rear of migrating cells (Sturge et al. 2006).

Phosphorylation of Endo180

Endo180 is phosphorylated by purified protein kinase C (PKC) in vitro and can be phosphorylated in vivo by treating cells with phorbol esters (Sheikh et al. 2000; Isacke et al. 1990). ^{32}Pi-labeling revealed that Endo180 contains at least three residues, which are constitutively phosphorylated in Flow 2000 embryonic lung diploid fibroblasts under normal growth conditions (Sheikh et al. 2000; Isacke et al. 1990). Treatment of Flow 2000 cells with phorbol 12-myristate 13-acetate (PMA) increased the phosphorylation of one of these sites and revealed two additional phosphorylation sites. All three PMA responsive phosphorylation sites have been identified as serine residues.

PKC purified from rat brain showed a strong preference to only one of these three phosphorylation sites in vitro. Endo180 has also been tested in vitro for a kinase activity against itself and a number of common substrates with negative results (Sheikh et al. 2000; Isacke et al. 1990). Endo180 has several putative phosphorylation sites in its cytoplasmic tail (see Fig. 2) but their functional role has not been confirmed.

Summary

Endo180 is an endocytic receptor that can signal to regulate the overall and tempero-spatial activation of the small Rho GTPases, Cdc42, Rac, and Rho (Sturge et al. 2003, 2006). Future work is required to: (a) elucidate the factors responsible for Rho GTPase activation by Endo180; (b) identify the intracellular partners of Endo180; (c) determine how conformational changes in the receptor ectodomain impact on receptor function and signaling, with a particular focus on the impact of collagen and uPA/uPAR-binding; and (d) investigate the influence of Endo180 phosphorylation on downstream signal transduction pathways.

90 kDa ribosomal protein S6 kinase 5; Mitogen- and stress-activated protein kinase 1; MSPK1; Nuclear mitogen- and stress-activated protein kinase-1; Ribosomal protein S6 kinase, 90kD, polypeptide 5; Ribosomal protein S6 kinase, polypeptide 5; RLPK; RLSK; Rps6ka5; Rsk-like (RSKL); Rsk-like protein kinase (RLPK)

Historical Background

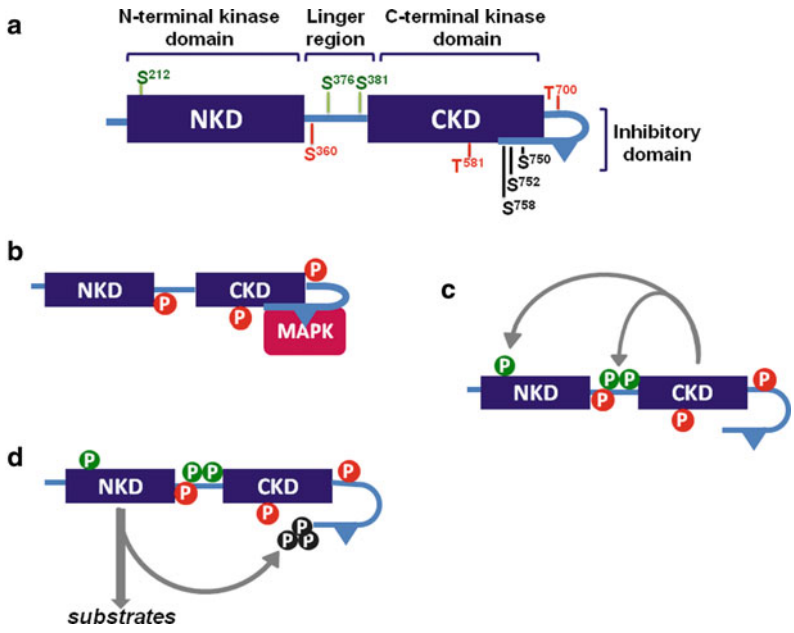
Mitogen- and stress-activated protein kinase (Msk) 1 and Msk2 are nuclear serine/threonine kinases that are widely expressed in tissues including heart, brain, placenta, lung, liver, kidney, and pancreas, with the highest levels observed in brain, muscle, and placenta (Deak et al. 1998). They belong to a group of structurally related kinases called the AGC kinase (cAMP-dependent, cGMP-dependent, and protein kinase C) family. This group includes p70 ribosomal S6 kinase (S6K), protein kinase B (PKB; also called Akt), protein kinase C-related kinase (Prk), ► p90 ribosomal S6 kinase (Rsk) and serum- and glucocorticoid-inducible kinase (Sgk) (Pearce et al. 2010).

Msk1 was identified through its homology to the N-terminal Rsk domain (Deak et al. 1998). Similarly to Rsk, Msk1 contains two kinase domains, connected with a linker region, in a single polypeptide (Deak et al. 1998). The N-terminal kinase domain is related to the AGC family of protein kinases (containing PKA, PKG, and PKC families), whereas the C-terminal kinase domain is related to the calmodulin-activated protein kinase family (Pearce et al. 2010). The C-terminal tail fulfills at least three functions: it contains a nuclear localization sequence and a mitogen-activated protein (MAP) kinase docking sequence, and can also act as an auto-inhibitory sequence (McCoy et al. 2007). Mutation of either the C- or N-terminal kinase domains in Msk1 is sufficient to block the phosphorylation of its substrates (Deak et al. 1998).

Because it can be activated through two different pathways (extracellular signal-regulated kinases 1 and 2 (ERK1/2) and p38 MAP kinase), Msk1 is able to integrate signals from growth factors, pro-inflammatory cytokines (tumor necrosis factor-α (► TNF-α)) and cellular stress (ultraviolet (UV)-irradiation, hydrogen peroxide). Msk1 is predominantly found in the nucleus and it contains a nuclear localization sequence in the C-terminal region, but a portion is localized to the cytosol of mouse fibroblasts and HEK 293 cells (Deak et al. 1998).

Regulation of Msk1 Activity

In cells, Msk1 is activated via a complex series of phosphorylation and autophosphorylation reactions downstream of ERK1/2 or p38α-MAP kinase. Many stimuli have been shown to activate Msk1 in cell cultures, including UV irradiation, anisomycin, nerve growth factor (NGF), ► TNF-α, interleukin (IL)-1, lysophosphatidic acid, endothelin-1, α_1-adrenergic stimulation, arsenic trioxide, and oxidative stress. In addition, exercise has been shown to induce Msk1 activation in animal skeletal muscle and light activates Msk1 in the suprachiasmatic nucleus in the brain



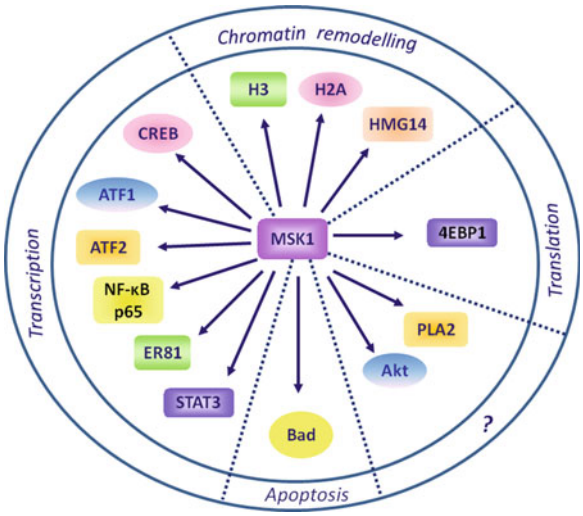
MSK1, Fig. 1 *Msk1 activation.* (**a**) Msk1 contains two kinase domains (C-terminal kinase domain, CKD and N-terminal kinase domaid, NKD) connected with a short linker region, and a C-terminal tail which contains a MAPK kinase docking sequence. Phosphorylation sites are shown. In the inactive Msk1, the C-terminal tail acts as an inhibitory domain of the CKD. (**b**) Active MAPKs (ERK1/2 or p38a-MAPK) bind to the docking domain in the C-terminal tail and phosphorylate S360, T581, and T700. (**c**) Phosphorylation of T700 promotes the dissociation of the inhibitory domain. The activated CKD phosphorylates S376 and S381 in the linker region and S212 in the NKD. (**d**) The NKD is activated and it is able to phosphorylate Msk1 substrates, or autophosphorylate Msk1 at S750, S752, and S758

(extensively reviewed in Arthur 2008; Vermeulen et al. 2009; Lazou and Markou 2010).

Msk1 is regulated by multiple phosphorylation sites (Fig. 1). In total, 13 phosphorylation sites have now been identified in Msk1 and six of these sites have significant roles in its activation. The role of the remaining sites is unclear, but phosphorylation of these residues may influence other processes such as localization or protein–protein interactions in vivo. Upstream ▶ MAP kinases, ERK1/2, and ▶ p38α, phosphorylate Msk1 on S360, T581, and T700 (Deak et al. 1998; McCoy et al. 2007). Phosphorylation of T581 is essential for Msk1 activation. On the other hand, mutation of S360 only partly reduces Msk1 activity and mutation of T700 does not affect it (McCoy et al. 2007). When phosphorylated at T581 and S360, the C-terminal kinase domain is activated and then autophosphorylates S376 and S381 in the linker region and S212 in N-terminal kinase domain. Of these three sites, S212 and S376 appear to be essential for Msk1 activation, as their mutation to alanine prevents kinase activation (McCoy et al. 2007). On the other hand, phosphorylation of S381 promotes N-terminal activation, probably through stabilization of phosphorylation of S376, but it is not essential for Msk1 activity. These autophosphorylation events activate the N-terminal kinase domain, allowing the phosphorylation of Msk1 substrates as well as the phosphorylation of S750, S752, and S758 in the C terminus of Msk1. Phosphorylation of the C-terminal sites is not required for Msk1 activation, and the function of this autophosphorylation is unknown (McCoy et al. 2007).

Msk1 Substrates

Msk1 is involved in the regulation of gene expression by phosphorylating transcription factors and chromatin-associated proteins. Furthermore, it has been shown that Msk1 phosphorylates proteins such as eukaryotic translation initiation factor 4E-binding protein 1 (4E-BP1) and Bad, thereby regulating translation initiation or apoptosis (Fig. 2; extensively reviewed in Arthur 2008; Vermeulen et al. 2009; Lazou and Markou 2010).



MSK1, Fig. 2 *Msk1 substrates*. ER81, H2A, and cPLA2 have not been validated in vivo

Transcription Factors

cAMP-responsive element (CRE) binding protein (► CREB) was the first Msk1 substrate to be identified (Deak et al. 1998). Since then, several studies using a variety of experimental settings, in vitro and in vivo, have shown phosphorylation of CREB (S133) and activation of its transcriptional activity by Msk1 in response to growth factors, phorbol esters, pro-inflammatory cytokines, G protein-coupled receptor agonists or cellular stresses (for review see Arthur 2008; Vermeulen et al. 2009; Lazou and Markou 2010). Phosphorylation of ► CREB by Msk1 leads to transcription of several immediate early genes that have CRE in their promoter including *c-fos*, *junB*, *Nur77*, *Mkp1*, *MUC5AC*, *Cox-2*, *IL-1β*, *ANF*, and *c-jun*. Msk1 also phosphorylates activating transcription factor 1 (ATF1) and activating transcription factor 2 (ATF2).

Another transcription factor that is a substrate for Msk1 is the nuclear factor (NF)-κB (Vermeulen et al. 2003; Vermeulen et al. 2009). In unstimulated cells NF-κB is found in the cytoplasm where it is kept inactive by binding to the inhibitory protein IκB. Stimulation with various agonists leads to the release of ► NF-κB and its translocation to the nucleus where further posttranslational modifications regulate its activity. Msk1 phosphorylates the p65/RelA subunit of NF-κB at S276 in response to ► TNF-α in fibroblasts, and in response to oxidative stress in skeletal myoblasts.

STAT3 (signal transducer and activator of transcription 3) and ER81 (E26 transformation-specific (ETS)-related protein 81; also called Ets transcript variant 1, Etv1) are also targeted by Msk1. Phosphorylation of STAT3 at S727 is mediated through Msk1 in JB6 cells in response to UVA irradiation and in erythroid cells in response to erythropoietin (Wierenga et al. 2003). The activity of the transcription factor ER81, which is involved in oncogenesis and breast tumor formation, is regulated by Msk1 via direct phosphorylation at S191 and S216. However, it should be noted that ER81 phosphorylation has not been validated in vivo.

Chromatin-Associated Proteins

Increasing evidence indicates an important role of Msk1 in remodeling chromatin structure and the epigenetic regulation of gene expression. Using H89 as an inhibitor of Msk1 activity, it has been shown that Msk1 phosphorylates histone H3 at S 10 and S 28 in response to phorbol esters (12-*O*-tetradecanoylphorbol-13-acetate (TPA)), epidermal growth factor (EGF), or anisomycin (Thomson et al. 1999). Studies using various types of cells from genetically modified animals provided further evidence for the role of Msk1 in H3 phosphorylation (for a review see Brami-Cherrier et al. 2009; Lazou and Markou 2010). However, the mechanism by which Msk1 is recruited to chromatin and directed to phosphorylated S10 or S28 in H3 is not known. It is not likely that Msk1 is pre-loaded onto immediate early gene promoters before induction, as it has been demonstrated that Msk1 is associated with the *IL-6* promoter after cells are stimulated (Vermeulen et al. 2003). Furthermore, E-26-like protein 1 (Elk-1) is required for the recruitment of ERK and Msk1 to the promoter of immediate early genes *c-fos* and *egr-1* (Zhang et al. 2008). On the other hand, using an in vitro system, it was recently shown that the recruitment of Msk1 and the subsequent phosphorylation of H3 on the *c-fos* chromatin requires CREB and, to a lesser extent, ATF1. Phosphorylation of CREB at S133 is essential for this process (Shimada et al. 2010).

In addition to H3, Msk1 also phosphorylates other chromatin-associated proteins such as nonhistone chromosomal protein HMGN1 (also called HMG-14) as well as histone H2A (Thomson et al. 1999; Brami-Cherrier et al. 2009).

Translation Factors

Msk1 has been implicated in the regulation of translational control by phosphorylating eukaryotic translation initiation factor 4E-BP1. 4E-BP1 binds to eIF4E in resting cells preventing formation of eIF-4 F complex which is essential for cap-dependent initiation of translation. UVB irradiation promotes phosphorylation of 4E-BP1 by Msk1 leading to the dissociation from eIF4E and the release of translational block after UVB irradiation (Liu et al. 2002).

Cell Death-Related Proteins

The ▶ Bcl-2 family member Bad has been also reported as Msk1 substrate. Bad is a pro-apoptotic protein and its phosphorylation promotes cell survival in many cell types. UVB irradiation promotes phosphorylation of Bad at S112 through Jnk1, Rsk2, and Msk1 (She et al. 2002). Furthermore, Msk1 mediates phosphorylation of neuronal Bad following Ca^{2+} influx (Clark et al. 2007).

Other Proteins

Msk1 phosphorylates ▶ cPLA2 at S727 in vitro and is also implicated in the translocation of cPLA2 to the membrane (Lazou and Markou 2010). However, it remains to be investigated whether cPLA2 is a real target of MSK1 in vivo. In mouse epidermal JB6 cells, the expression of Msk1 C-terminal kinase-dead mutant inhibited UVB-induced phosphorylation and activation of Akt, implicating Msk1 as the kinase responsible (Nomura et al. 2001).

Physiological Roles of Msk1

Inflammation

As mentioned above, Msk1 contributes to the transcriptional activation of ▶ NF-κB and ▶ CREB, two transcription factors with important roles in the regulation of inflammatory genes (Arthur 2008; Vermeulen et al. 2009). Furthermore, Msk1 controls the transcription of *COX-2* in response to TLR (toll-like receptor) signaling. Recently, it was reported that Msk1 induces the transcription of the MAP kinase phosphatase Dusp1 and the anti-inflammatory cytokines IL-10 and IL-1ra, which implies that Msk1 has a critical role in the negative feedback mechanisms required to reduce inflammation through TLR signaling (Ananieva et al. 2008).

Cell Death

There are controversial reports regarding the role of Msk1 in cell death. Activation of Msk1 by glutamatergic neurotransmission results in enhanced neuronal injury (Hughes et al. 2003). Furthermore, in human lymphoma B cells, the sequential activation of p38-MAP kinase and Msk1 leads to the Mn^{2+}-dependent activation of caspase-8 and cell death (El Mchichi et al. 2007). Although, expression of a dominant-negative mutant of Msk1 in these cells inhibits caspase-8 activation, the underlying mechanisms are not yet known. On the other hand, other studies suggest that Msk1 represents a pro-survival pathway. Decreased expression of Msk1 enhances arsenic trioxide-induced apoptosis of leukemic cells in vitro and in vivo (Kannan-Thulasiraman et al. 2006). Furthermore, Msk1 knockdown reduces Bad phosphorylation and enhances Noxa and Bim expression, leading to enhanced TGFβ-induced caspase-3 activity and cell death (van der Heide et al. 2011). In agreement with this latter study, Msk1 promotes cell survival by phosphorylating Bad in mouse epidermal cells (She et al. 2002). Thus, it is likely that the role of Msk1 is dependent on cell-type specific factors that are as yet undefined.

Cell Growth

Msk1 activity has also been implicated in cellular transformation. Using Msk1 dominant-negative mutants or small interfering RNA (siRNA) against Msk1, it was shown that Msk1 is required for TPA-induced or EGF-induced cellular transformation of JB6 Cl41 cells. This effect is mediated by phosphorylation of histone H3 at S 10 as well as AP-1 activation (Kim et al. 2008). Msk1 is also a positive regulator of epithelial cell proliferation (Schiller et al. 2006). Furthermore, pharmacological inhibition of Msk1 inhibits hypertrophic cell growth of cardiac myocytes (Lazou and Markou 2010).

Neuronal Plasticity

Several lines of evidence support the notion that Msk1 is involved in the mechanisms underlying neuronal plasticity in memory formation or as a response to drugs of abuse. It has been shown that Msk1 contributes to chromatin remodeling in striatal neurons and hippocampus resulting in long-term synaptic plasticity and memory formation (Brami-Cherrier et al. 2009). Furthermore, using Msk1-knockout mice, it was

demonstrated that Msk1 plays an important role in cocaine-induced transcriptional events and behavioral alterations. In these mice, phosphorylation of CREB and histone H3 as well as induction of c-*fos* and dynorphin in response to cocaine was prevented. In addition, a selective impairment of locomotor sensitization was observed. Msk1 deficiency was also shown to be responsible for the transcriptional dysregulation and striatal neurodegeneration in a mouse model of Huntington's disease (Brami-Cherrier et al. 2009).

Summary

Msk1 is a serine/threonine kinase that is activated in response to both growth factor and cellular stress stimuli. Msk1 belongs to a family of protein kinases that contain two protein kinase domains: an N-terminal kinase domain related to the AGC kinase family, and a C-terminal kinase domain related to the CaMK family, and it is activated via a complex series of phosphorylation and autophosphorylation reactions. Msk1 is predominantly located in the nucleus and has been shown to modulate gene expression by phosphorylating various substrates, including transcription factors and chromatin-associated proteins. Among the substrates that have been identified are CREB, ATF1, STAT3, the p65/RelA subunit of NF-κB and the immediate early genes *c-fos*, *junB*, *c-jun*, and *Nurr77*. In addition to transcription factors, Msk1 has been shown to phosphorylate the nucleosomal proteins histone H3 and nonhistone chromosomal protein HMG-14 as well as the eukaryotic translation initiation factor 4E-BP1 and the pro-apoptotic protein Bad. It seems that Msk1 plays a role in integrating the effects of diverse extracellular signals and it remains to be determined how it affects its downstream targets leading to the observed signal- and cell-type-dependent specificity. The full panoply of Msk1 physiological roles has not been elucidated yet, but substantial evidence implicates Msk1 in the regulation of cytokine production and the inflammatory response, as well as neuronal synaptic plasticity. In addition, recent work suggests that Msk1 can also be functionally involved in tumor initiation, cell growth, and cell death regulation. This evidence along with the growing number of newly identified Msk1 substrates makes this kinase a suitable target for therapeutic manipulation of several diseases.

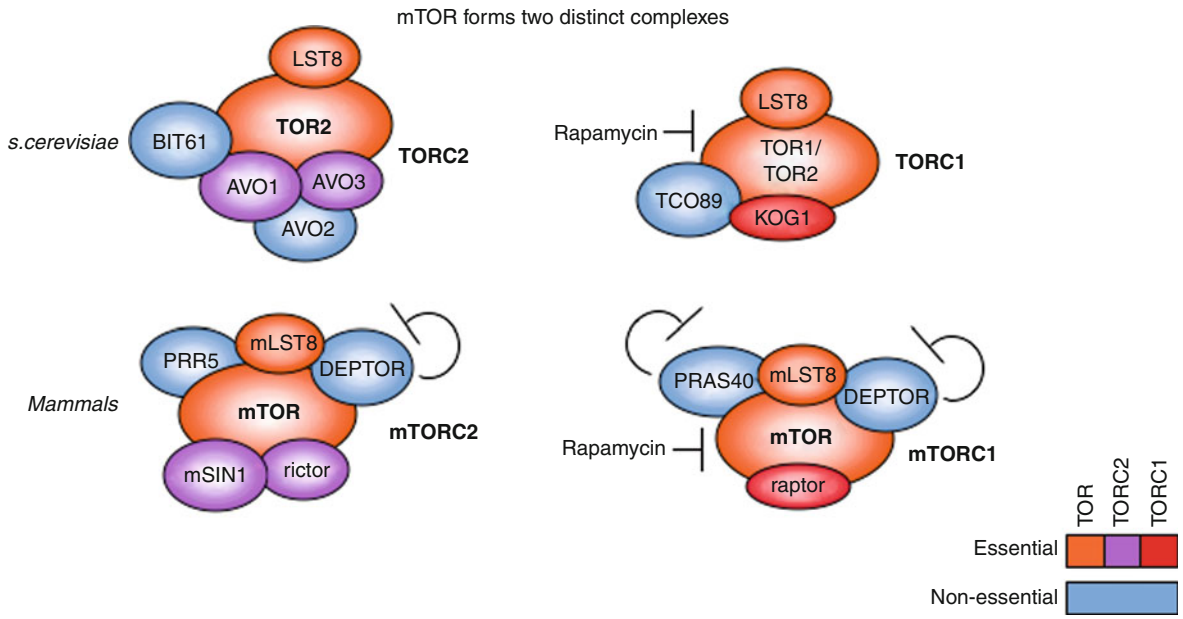
Historical Background

The mammalian target of rapamycin (mTOR) is a Ser/Thr kinase structurally and functionally conserved from yeast to humans that positively regulates cell growth, proliferation, and survival, while inhibition of mTOR signaling extends lifespan (Harrison et al. 2009). In eukaryotes, mTOR is ubiquitously expressed and whole-organism knockout has demonstrated that it is essential for cell growth and viability. mTOR forms two multiprotein complexes, namely, mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). The macrolide rapamycin acutely inhibits mTORC1 but not mTORC2. mTORC1 and mTORC2 regulate functionally distinct, yet partially overlapping, signaling networks that collectively control the spatial and temporal regulation of cell growth.

Nutrients and growth factors activate mTORC1, whereas low cellular energy levels or stress inhibits mTORC1. Under favorable conditions for growth, mTORC1 is activated to promote translation, ribosome biogenesis, and inhibit autophagy. Thus, mTORC1 regulates when a cell grows. mTORC2 is activated by growth factors to promote cell survival and actin cytoskeleton remodeling in yeast, dictyostelium, and mammals. Thus, in broad terms, mTORC2 regulates where a cell grows.

As primary regulators of cell growth, the mTORC1 and mTORC2 signaling networks function as key regulatory nodes whose functions are important for development, aging, and have been linked to cancer and metabolic disorders. These signaling networks will be discussed in detail below:



mTOR, Fig. 1 mTORC1 and mTORC2: mTOR forms two distinct, multiprotein complexes, mTORC1 and mTORC2, which are structurally and functionally conserved from yeast to human

mTOR Complexes

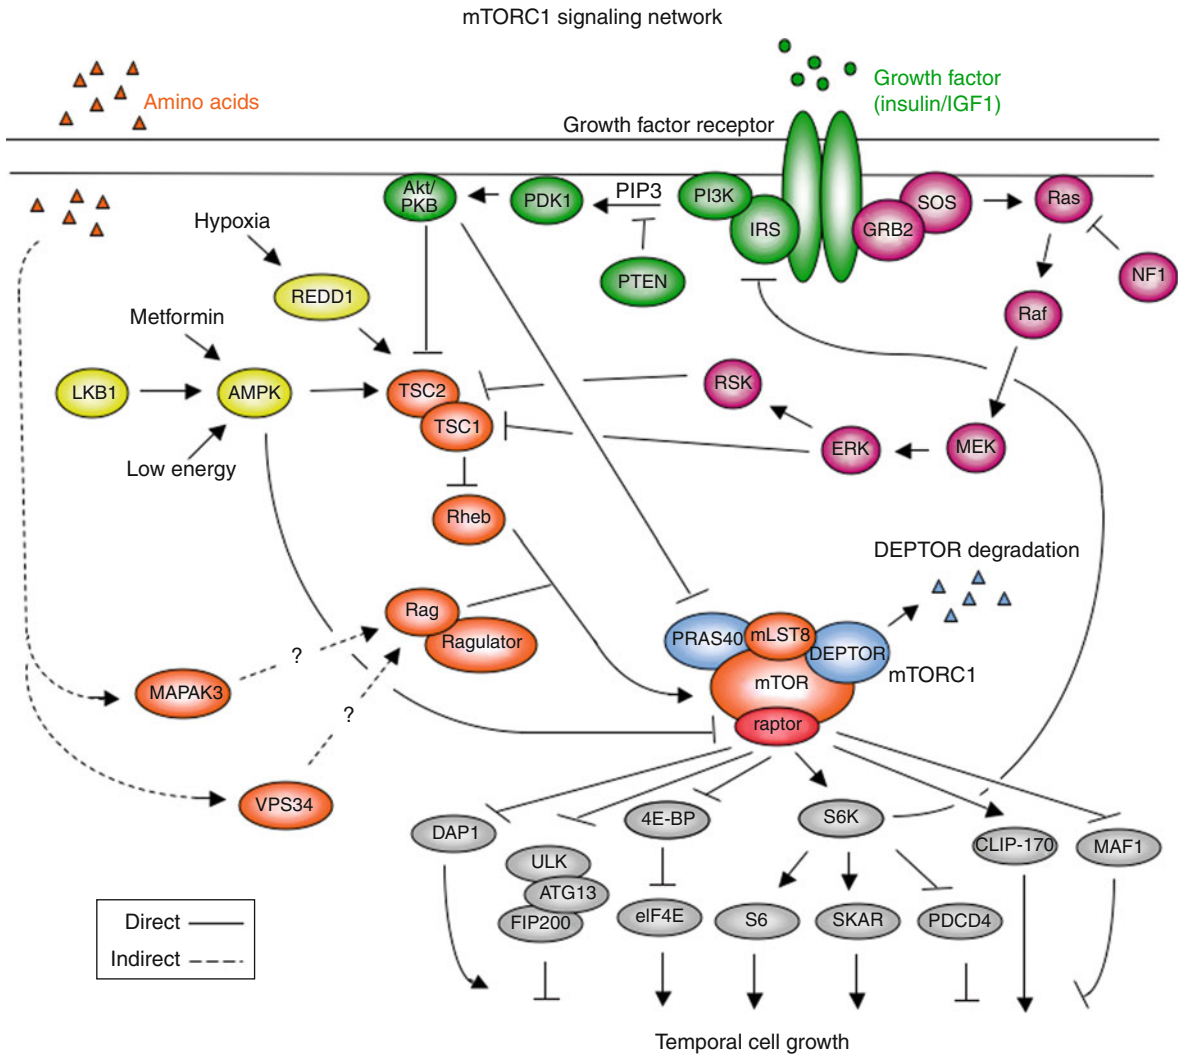
mTORC1 is multiprotein complex consisting of mTOR, Raptor, and mLST8 (also called GβL) (Fig. 1). Whole-body knockout of mTOR is embryonic lethal in mice. Homozygous mTOR−/− mice die at embryonic (E) day E5.5–E6. Similar to mTOR, Raptor−/− mice die at day E5.5–E6.5, suggesting that both mTORC1 components are required for progressing past the same stage of embryonic development. Additionally, mTORC1 associates with PRAS40 (proline-rich Akt/protein kinase B (PKB) substrate 40 kDa), and DEP-domain-containing mTOR-interacting protein (DEPTOR); ultimately this results in the negative regulation of mTORC1 activity (reviewed in Laplante and Sabatini 2009).

mTORC2 is composed of mTOR, Rictor, Sin1, mLST8, and PRR5/PRR5L (Protor 1/Protor 2) (reviewed in Cybulski and Hall 2009). PRR5 is not required for the interaction between mTOR, Rictor, Sin1, and mLST8. Deletion of Rictor or Sin1 is embryonic lethal, as mice die after day E10–E10.5. Loss of Sin1 disrupts Rictor's association with mTORC2. Interestingly, ablation of Rictor or Sin1 results in loss of Akt/PKB hydrophobic motif (HM) phosphorylation (at Ser473), yet the phosphorylation of several Akt/PKB targets is unaffected. This suggests either that phosphorylation of Ser473 may alter substrate specificity, or that in the absence of active Akt/PKB, other AGC kinases such as SGK, S6K, or RSK can phosphorylate a subset of Akt/PKB substrates. Surprisingly, although mLST8 is a component of both mTORC1 and mTORC2, mLST8 knockout mice die at day E10.5, phenotypically resembling Rictor−/− mice. Furthermore, mLST8 is required for Akt/PKB HM phosphorylation, but not S6K signaling. These data suggest that mLST8 has an essential role only in mTORC2.

In mice, tissue-specific knockouts of mTOR or mTORC1/mTORC2 components have demonstrated that mTOR plays a key role in regulating muscle atrophy, glucose metabolism, and lipid metabolism (reviewed in Polak and Hall 2009). mTORC1 and mTORC2 signal via distinct pathways to control a wide variety of cellular processes. These mTOR-regulated processes mediate the accumulation of cellular mass and, thereby, ultimately determine cell size.

The mTORC1 Signaling Network

Upstream regulation of mTORC1: Four major inputs control mTORC1: nutrients, such as amino acids; growth factors, such as insulin; cellular energy levels, such as the AMP: ATP ratio; and stress, such as



mTOR, Fig. 2 mTORC1 signaling network: amino acid and growth factor activation of mTORC1 promotes temporal cell growth and proliferation

hypoxia (reviewed in Taniguchi et al. 2006). mTORC1 integrates growth factors, cellular energy levels, and hypoxia through an upstream negative regulator called the tuberous sclerosis complex (TSC1/2), a heterodimeric GTPase-activating protein (Fig. 2). Growth factors inhibit TSC1/2 through the phosphoinositide 3-kinase (PI3K) pathway. Upon insulin stimuli, the insulin receptor substrate (IRS), and subsequently PI3K are recruited to the insulin receptor. The cellular level of phosphatidylinositol-3,4,5-triphosphate (PI(3,4,5)P3) is maintained by the antagonistic actions of PI3K and the lipid phosphatase PTEN. Akt/PKB and PDK1 are recruited to the plasma membrane via PI(3,4,5)P3, resulting in the phosphorylation and activation of Akt/PKB at the activation loop site by PDK1. TSC2 is then phosphorylated and functionally inactivated by Akt/PKB in response to insulin. In addition, Akt/PKB phosphorylates PRAS40 at Ser 247 and inactivates it, which leads to mTORC1 activation. mTORC1 can further phosphorylate PRAS40 at Ser 183 and Ser 221. Growth factor activation of mTORC1 also leads to the phosphorylation and subsequent degradation of DEPTOR, a negative regulation of mTORC1 activity (Peterson et al. 2009). The TSC1/2 complex is also inhibited by canonical MAPK signaling. Similar to Akt/PKB, active ERK or RSK can phosphorylate and inhibit TSC2 GAP activity.

In contrast to growth factors that inhibit TSC1/2, low cellular energy and stress activate TSC1/2 GTPase-activator protein (GAP) activity. Low energy (high AMP:ATP ratio) activates AMP-activated protein kinase (AMPK) to phosphorylate TSC2. This action inhibits mTORC1 by increasing TSC2 GAP activity toward Rheb, a Ras-like GTPase. In addition to phosphorylating TSC2, AMPK also inhibits mTORC1 by directly phosphorylating Raptor. Mutations of the AMPK upstream activating kinase, LKB1, result in hyperactive mTORC1 signaling, thereby linking LKB1 to the TSC1/2 mTORC1 pathway. Hypoxia inhibits mTORC1 signaling through the HIF1-mediated upregulation of two homologous proteins REDD1 and REDD2 (Regulated in Development and DNA damage response genes 1 and 2) REDD acts to activate TSC1/2, independently of LKB1-AMPK, in order to inhibit mTORC1. The stress and energy signaling pathways are likely to be further associated, as prolonged hypoxia leads to ATP depletion and activation of AMPK.

Inactivation of TSC1/2 then allows GTP-bound Rheb to activate mTORC1. However, amino acids are required for proper mTORC1 localization to a late endosome/lysosome compartment containing active Rheb. In contrast to growth factor stimulation, amino-acid activation of mTORC1 occurs independently of TSC1/2, as amino acid withdrawal also downregulates mTORC1 signaling in TSC2-deficient cells. Activation of mTORC1 by amino acids requires the Ras-like GTPases Rheb and Rag, both of which bind directly to mTORC1. The Rag GTPase heterodimer (RagA or RagB binding to RagC or RagD) mediates the localization of mTORC1 to a late endosomal/lysosomal compartment containing Rheb. Rag heterodimers are recruited to lysosomes via an aptly named protein complex, Ragulator, which is composed of the genes encoded by the MAPKSP1, ROBLD3, and c11orf59 (Sancak et al. 2010). Ragulator-to-Rag-to-mTORC1 binding then facilitates the activation of mTORC1 by GTP-bound Rheb. hVps34 has also been implicated in the amino-acid stimulation of mTORC1 in a TSC1/2-independent fashion. The hVps34 product phosphatidylinositol-3-phosphate (PI(3)P) may help recruit mTORC1 through an unidentified scaffold protein. However, in flies, Vps34 functions downstream of TOR. How amino acids GTP-load, and thereby activate the Rag GTPases to ultimately activate mTORC1 remains to be determined. Intriguingly, MAP4K3 acts upstream of Rag-mediated mTORC1 activation (Yan et al. 2010). Amino acids stimulate MAP4K3 activity to phosphorylate an unknown substrate upstream of the Rag/Ragulator complex, whereas under amino acid–starved conditions, PP2A T61 epsilon inhibits MAP4K3 and subsequent mTORC1 activation. Upon activation, mTORC1 controls protein synthesis, promotes ribosome biogenesis, and inhibits autophagy.

Downstream effectors of mTORC1: Translation: mTORC1 activates cap-dependent translation initiation and elongation by phosphorylating the eukaryotic initiation factor 4E (eIF4E)–binding protein 1 (4E-BP1) and the p70 ribosomal S6 kinase (S6K). The phosphorylation of 4E-BP1 prevents its binding to eIF4E, enabling eIF4E to then associate with eIF4G to stimulate translation initiation, whereas phosphorylation of S6K by mTORC1 and phosphoinositide-dependent kinase 1 (PDK1) is required for complete activation. Activated S6K promotes translation initiation by phosphorylating eIF4B, programmed cell death protein 4 (PDCD4), and eEF2 kinase (eEF2K). Phosphorylation of eIF4B and PDCD4 activates translation initiation, whereas phosphorylation of eEF2K upregulates translation elongation. S6K also promotes the translation efficiency of spliced mRNAs via S6K-Aly/REF-like substrate (SKAR) (Ma et al. 2008). SKAR associates with mRNAs in a splicing-dependent manner, where it then recruits activated S6K and thereby preferentially enhances translation of spliced mRNAs. Additionally, S6K phosphorylates 40S ribosomal protein S6, but the significance of this phosphorylation is unknown. mTORC1 associates with its substrates 4E-BP1 and S6K through Raptor and a TOR signaling (TOS) motif in 4E-BP1 and S6K. The TOS motif is a conserved five-amino-acid sequence (FEMDI and FDIDL in the C terminus of 4E-BP1 and in the N terminus of S6K, respectively) that is necessary for the phosphorylation of these proteins by mTORC1. However, TOS motifs have not been identified in recently discovered substrates, suggesting mTORC1 may bind to different substrates through distinct regions or alternative scaffold proteins.

Ribosome biogenesis: mTORC1 promotes the synthesis of ribosomes and transfer RNAs (tRNAs). Rapamycin blocks the biosynthesis of ribosomes by inhibiting transcription of RNA polymerase I (Pol I)–dependent rRNA genes, Pol II–dependent ribosomal protein genes (RP genes), and Pol III–dependent

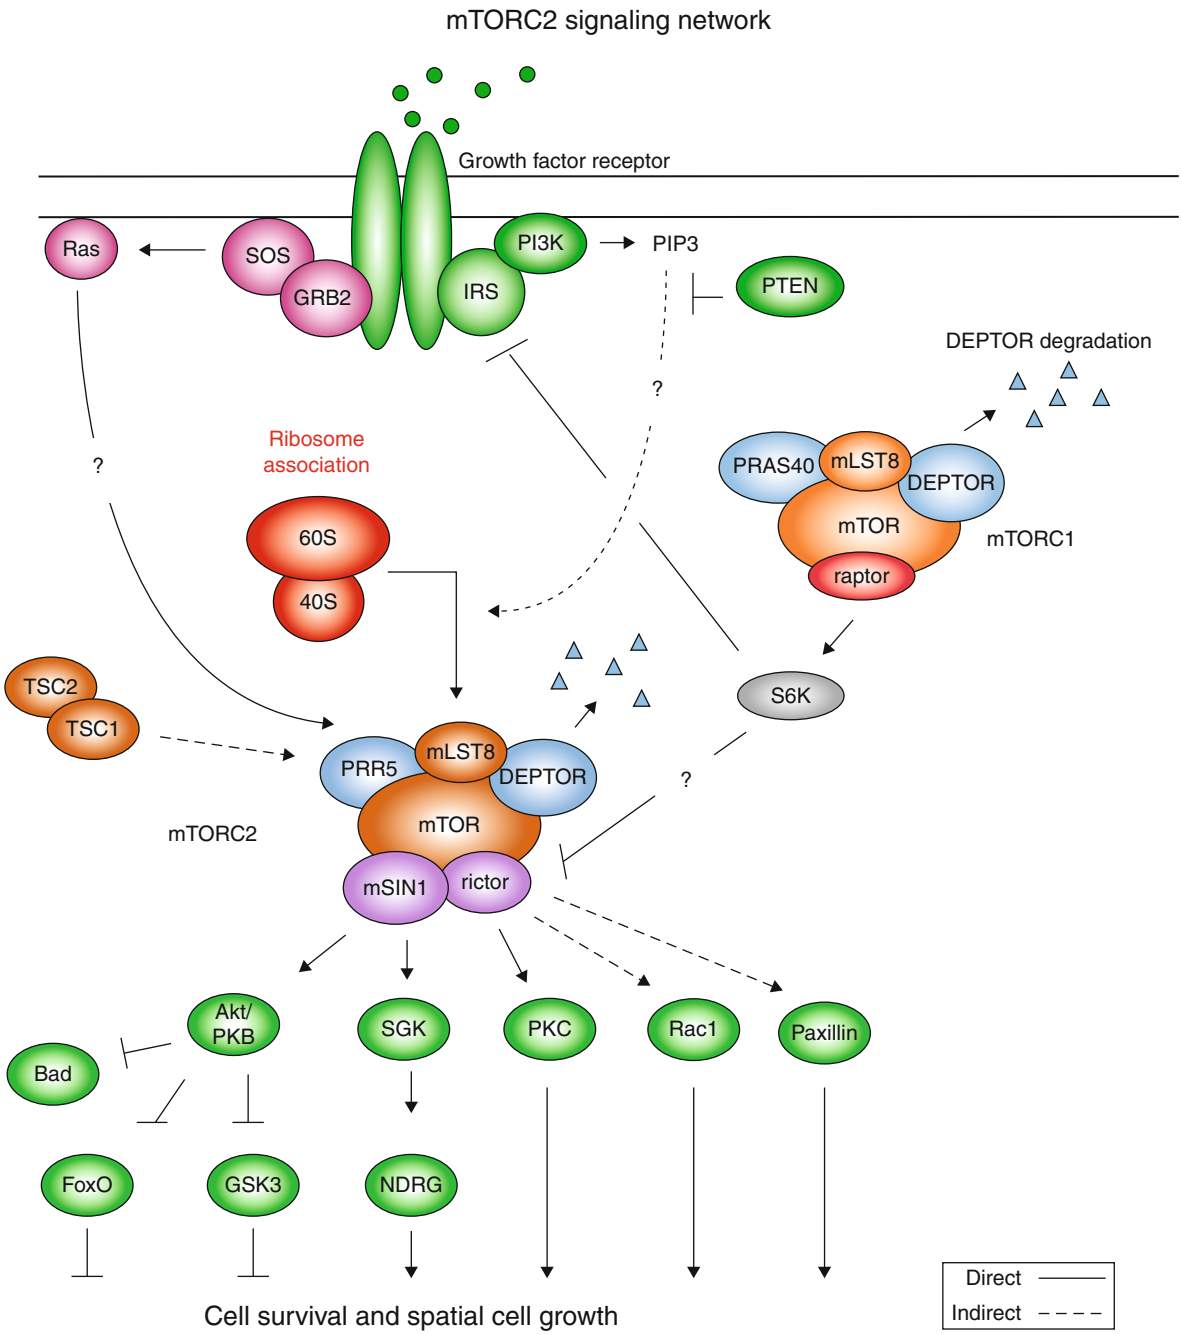
tRNA genes. mTOR controls Pol I via the essential transcription initiation factor TIF-1A (Transcriptional Intermediary Factor 1A). Rapamycin treatment leads to TIF-1A inactivation and thus impairs formation of the transcription initiation complex. Furthermore, TIF1A translocates from the nucleus to the cytoplasm upon rapamycin-mediated mTORC1 inactivation. In yeast, the forkhead-like transcription factor FHL1 functions as a TOR-dependent regulator of Pol II-dependent RP gene expression. mTORC1 regulates Pol III-mediated gene expression by directly phosphorylating and inhibiting MAF1, a Pol III transcriptional repressor. mTORC1 associates with TFIIIC, is recruited to Pol III-transcribed genes, and relieves MAF1-mediated repression, thus allowing Pol III transcription to occur (Michels et al. 2010).

Autophagy: mTORC1 negatively regulates macroautophagy, a starvation-induced catabolic process where bulk cytoplasm is enclosed in a double membrane structure and delivered to the vacuole for degradation. Rapamycin induces autophagy in yeast and human tissue culture, demonstrating the conserved role of mTORC1 as an inhibitor of autophagy. mTORC1 directly inhibits autophagy by phosphorylating and repressing a conserved protein complex composed of unc-51-like kinase 1 (ULK1), autophagy-related gene 13 (ATG13), and focal adhesion kinase family–interacting protein with a molecular weight of 200 kDa (FIP200) (Jung et al. 2009). mTORC1 also directly phosphorylates and represses DAP1 (Koren et al. 2010). Unlike the ULK1/ATG13/FIP200 complex, DAP1 is a negative regulator of autophagy. Thus via positive and negative regulation, mTORC1 activity tightly controls the absolute level of cellular autophagy. Additionally, dysregulation of mTORC1 may contribute to cancer cell survival, as tumor cells may temporarily activate autophagy to overcome nutrient deprivation under poor growth conditions. Through the mechanisms described above, mTORC1 regulates temporal cell growth.

The mTORC2 Signaling Network

Upstream regulation of mTORC2: In contrast to the detailed understanding of mTORC1 activation, a clear molecular mechanism underlying the activation of mTORC2 has been elusive until recently (reviewed in Robitaille and Hall 2008). In response to growth factors, mTORC2 promotes cell growth and proliferation by directly phosphorylating the hydrophobic motif of Akt/PKB and SGK. Growth factors signal to mTORC2 through the ▶ PI3K pathway (Fig. 3). Similar to the activation of mTORC1, upon insulin stimuli, the insulin receptor substrate (IRS) and subsequently PI3K are recruited to the insulin receptor. The cellular level of phosphatidylinositol-3,4,5-triphosphate (PI(3,4,5)P3) is maintained by the antagonistic actions of PI3K and the lipid phosphatase PTEN. Activation of PI3K promotes the association of mTORC2 with intact 80S ribosomes. The interaction between mTORC2 and the ribosome is required for mTORC2 activation, independent of protein translation (Zinzalla et al. 2011). How (PI(3,4,5)P3) promotes mTORC2 association with the ribosome and subsequent activation remains a mystery, but PI(3,4,5)P3-containing liposomes do not stimulate mTORC2's in vitro kinase activity. Growth factors activation of mTORC2 also leads to the phosphorylation and subsequent degradation of DEPTOR, a negative regulator of mTORC2 activity (Peterson et al. 2009). The TSC1/2 complex may also function upstream of mTORC2, but this activity is independent of TSC2 GAP activity. Loss of TSC1/2 inhibits the phosphorylation of mTORC2 substrates, while simultaneously hyperactivating mTORC1 and S6K. Active S6K can then directly phosphorylate Rictor and IRS, which is part of a negative feedback loop that attenuates insulin signaling. It is unclear to what degree the loss of TSC1/2, S6K-mediated Rictor phosphorylation, and IRS inhibition individually contribute to inhibition of mTORC2 activity. Recently, Ras has been shown to be upstream of mTORC2 independently of PI3K and conical MAPK signaling. In dictyostelium, RasC physically binds to TORC2 and activates it through an unknown mechanism (Charest et al. 2010). Mammalian Ras can also bind to Sin1 in vitro, but the physiological significance of this interaction has not been demonstrated. Additionally, mTORC2 and mTORC1 can bind phosphatidic acid (PA), suggesting that PA may mediate membrane localization of mTOR. Taken together, this data suggests that growth factors activate mTORC2 through multiple mechanisms, perhaps explaining why identifying a definitive upstream regulator has proven so elusive.

Downstream effectors of mTORC2: Unlike mTORC1, which can be specifically inhibited by rapamycin, mTORC2 is insensitive to acute rapamycin treatment. Thus, many of the downstream effectors and physiological functions of mTORC2 remain unknown.



mTOR, Fig. 3 mTORC2 signaling network: growth factor activation of mTORC2 promotes cell survival and spatial cell growth

Cell survival: mTORC2-deficient cells are sensitive to stress-induced apoptosis. mTORC2 promotes cell survival through the activation of Akt/PKB and serum and glucocorticoid-inducible kinase (SGK), two AGC kinases that have both distinct and overlapping substrates. Akt/PKB negatively regulates the pro-apoptotic protein BAD, while SGK regulates the phosphorylation of NDRG1, and both kinases negatively regulate FOXO. Interestingly, mTORC2 activity is required for prostrate tumorigenesis in PTEN null tumors, and not for normal prostate function (Guertin et al. 2009). This suggests that inhibiting

mTORC2-mediated cell survival would be attractive cancer therapeutic target with few side effects to healthy tissue.

Cytoskeleton remodeling: mTORC2 regulates actin cytoskeleton remodeling in yeast and is important for chemotaxis and cell migration in dictyostelium and mammals respectively (Charest et al. 2010). Furthermore, loss of mTORC2 alters actin polymerization and perturbs cell morphology. Thus, mTORC2 regulates where cell growth occurs. mTORC2-dependent cytoskeleton remodeling is likely mediated by the mTORC2 effectors PKCα, Paxillin, and Rac1, although the molecular mechanism by which mTORC2 regulates all these processes has not been determined.

AGC kinase activation and stability: mTORC1 and mTORC2 activate many members of the AGC kinase family (reviewed in Jacinto and Lorberg 2008). The AGC kinase activated by mTORC1 includes S6K, while mTORC2 regulates Akt/PKB, SGK, and PKCα. mTOR phosphorylates the hydrophobic motif (HM) in the AGC kinases to stimulate kinase activity. In S6K and SGK, phosphorylation of the HM creates a docking site for PDK1 and subsequent phosphorylation of the AGC kinase activation loop (reviewed in Pearce et al. 2010). mTOR also phosphorylates the turn motif (TM), at least in Akt/PKB and PKCα, to control stability of the kinase. In yeast, TOR phosphorylates and activates the AGC kinases Gad8, Ypk2, and Sch9. Future studies may reveal additional AGC kinases that are regulated by mTOR.

Open Questions and Summary

Expressional regulation of mTORC1: mTOR is classically thought to be ubiquitously expressed in eukaryotes. However, emerging research suggests mTORC1 may also be regulated at the level of expression. mTOR belongs to a subgroup of the atypical protein kinases, called [phosphoinositide 3-kinase]-related kinases (PIKK), which include Ataxia telangiectasia mutated (ATM); ATM and Rad3 related (ATR); DNA-dependent protein kinase (DNA-PK); suppressor with morphological effect on genitalia 1 (SMG1); and transformation/transcription domain–associated protein (TRRAP). All members of the PIKK family, including mTOR, interact with Tel2. These interactions positively regulate PIKK protein stability, but the physiological conditions under which Tel2 might regulate mTOR remain to be defined. Another recently identified regulator of mTOR protein stability is the tumor suppressor FBXW7. FBXW7 physically associates with mTOR and targets it for ubiquitination and degradation. Loss of FBXW7 increases the total amount of mTOR and subsequently the phosphorylation of S6K, indicating that FBXW7 is upstream of mTORC1. Depletion of FBXW7 did not affect the phosphorylation of Akt/PKB, suggesting that FBXW7 is not upstream of mTORC2. Further research is required to identify the physiological conditions when mTORC1 may be expressionally regulated.

Pharmacological inhibition of mTORC1 and mTORC2: Acute treatment with rapamycin, which forms a complex with FKBP12, binds to and allosterically inhibits mTORC1 but not mTORC2. In some cell lines, prolonged treatment with rapamycin (>24 h) indirectly inhibits mTORC2. Recently, several groups have independently developed active-site inhibitors of mTOR, which include PP242, Torin1, Ku-0063794, WAY-354, and AZD8055 (reviewed in Sparks and Guertin 2010). These compounds exhibit IC50 values in the low nanomolar range against mTORC1 and mTORC2. Furthermore, PP242 inhibited cancer cell proliferation to a greater extent than rapamycin (Janes et al. 2010). The increased antiproliferative affects of PP242 over rapamycin could be caused by inhibition of mTORC1 and mTORC2, rapamycin-resistant functions of mTORC1, or inhibition of an off-target kinase. mTOR active-site inhibitors will likely play an important role in the identification of novel mTOR functions and possibly as future cancer therapeutics.

mTORC1 and mTORC2 consensus motif: mTOR, as part of mTORC1 or mTORC2, can canonically phosphorylate two distinct target sites, a serine or threonine flanked by bulky hydrophobic (Φ) residues (Φ-pSer/Thr-Φ) and serine or threonine followed by a proline (pSer/Thr-Pro). Recent research in yeast and human cells to define the mTOR-regulated phosphoproteome revealed that mTORC1 can also phosphorylate serine followed by glutamine target sites (pSer-Gln) such as those in MAF1 (Huber et al. 2009 and Shor et al. 2010). Identification of additional mTORC1 and mTORC2 substrates may help to clarify the true mTOR consensus motif. Alternatively, mTOR may function as a promiscuous protein kinase to phosphorylate a wide variety of consensuses motifs. Under the latter model, a specific subunit of mTORC1 or mTORC2 would function as a scaffold protein to regulate substrate specificity.

Closing remarks: The mTORC1 and mTORC2 signaling networks have emerged as central controllers of cell growth that are important for development, aging, and diseases such as cancer and diabetes. The revelation that mTORC1 and mTORC2 regulate functionally distinct, yet partially overlapping signaling networks to collectively control the spatial and temporal cell growth has been a major conceptual advancement. Finally, the synthesis of mTORC1 and mTORC2 active-site inhibitors have the potential to be promising new therapeutic options to target mTOR dysregulation in cancer and metabolic disorders.

Acknowledgments I offer my regrets to our colleagues whose excellent work I could not described due to space limitations. I acknowledge the Werner-Siemens Foundation for funding support and M.N. Hall for advice and the general figure template.

Synonyms

Angiotensin II type 2 receptor interacting protein (ATIP); MTSG1, GK1, and AT2R binding protein of 50 kDa (ATBP50); MTUS1 isoform 1 (ATIP3); MTUS1 isoform 2 (ATIP3b); MTUS1 isoform 3 (ATIP4); MTUS1 isoform 4 (ATIP2); MTUS1 isoform 5 (ATIP1)

Historical Background

Following its initial identification in Japan in 1999 (Nagase et al. 1999), mitochondrial tumor suppressor 1 (MTUS1/ATIP) (2011), a putative tumor suppressor gene, has been independently identified by research groups from Japan (Kinjo et al. 2000), Germany (Seibold et al. 2003; Wruck et al. 2005), and France (Nouet et al. 2004). As a result, MTUS1/ATIP has been designated a variety of different names; therefore, the nomenclature used to describe MTUS1/ATIP in publications can be confusing.

MTUS1/ATIP was first identified in 1999 following the sequencing of 100 cDNA clones of unknown human genes from two sets of size-fractionated human adult and fetal brain cDNA libraries (Nagase et al. 1999). At this time, it was designated KIAA1288 (Genbank Accession Number: ABO33114).

In 2000, a second Japanese group independently identified MTUS1/ATIP following large-scale genomic DNA sequencing of chromosome 8p21.3 (Kinjo et al. 2000), where a loss of heterozygosity is associated with progression in a range of human cancers including breast, colorectal, hepatocellular, pancreatic, lung, and prostate cancers (Seibold et al. 2003). They designated the gene GK1 and following Northern blot analysis identified ubiquitous expression of 7.0- and 4.4-kb gene transcripts.

Then in 2003, a German group, who were investigating gene expression during induction of cellular differentiation and quiescence, using a combination of 3D collagen I cell culture and differential display reverse transcriptase-polymerase chain reaction (RT-PCR), identified that MTUS1, which they designated MTGS1, was transiently upregulated during initiation of cellular differentiation (Seibold et al. 2003).

In 2004, a group at the Cochin Institute in Paris (Nouet et al. 2004) identified a 354 bp insert that encoded an open reading frame of 118 amino acids using the yeast two-hybrid cDNA cloning system and the last 52 amino acids of the human AT2-receptor as a bait to screen a mouse fetal cDNA library. This was designated ATIP-ID, which stands for interacting domain of the AT2-receptor-interacting protein. ATIP-ID interacted with the C-terminal intracellular tail of the AT2-receptor, but not with the AT1-receptor or with the C-terminal domains of other G-coupled protein receptors such as β2-adrenergic or ▶ bradykinin receptor. In total, five MTUS1/ATIP variants, which are derived from a single gene by alternate promoter utilization and exon/intron splicing, were identified. Co-immunoprecipitation studies identified a constitutive interaction between the C-terminal end of the AT2-receptor and ATIP.

Finally in 2005, a second German group independently identified an interaction between the AT2-receptor and MTUS1, which they designated ATBP50 and described it as an AT2-receptor binding protein of 50 kDa.

Localization

The most commonly expressed MTUS1 transcripts, MTUS1 isoform 1 (ATIP3a), MTUS1 isoform 2 (ATIP3b), MTUS1 isoform 5 (ATIP1), and MTUS1 isoform 3 (ATIP4) are differentially distributed throughout the body (Table 1) and their translated sequences contain consensus motifs for localization to different subcellular compartments (cytosol, nucleus, and plasma membrane for isoform 5/ATIP1, isoforms 1 and 2 (ATIP3), and isoform 4/ATIP4, respectively), suggesting that the various transcripts may possess a wide range of physiological functions. By contrast, MTUS1 isoform 6/ATIP2 is expressed at very low levels or cannot be detected in all of the tissues examined to date (<1%) (Di Benedetto et al. 2006a).

MTUS1 isoform 5/ATIP1 is the major transcript found in the brain, excepting the cerebellum (Di Benedetto et al. 2006a). Moreover, it has also been detected in organs, which contain high levels of AT2-receptor expression, such as in the female reproductive (placenta breast ovary, uterus) and the heart.

MTUS1 isoforms 1 and 2 (ATIP3) are the major transcripts found in all other organs of the body. Both transcripts show a similar pattern of distribution in human tissues; however isoform 1 is the predominantly expressed isoform in most tissues (Di Benedetto et al. 2006a).

Expression of mRNA for MTUS1 isoform 4/ATIP4 is localized to the brain, predominantly in the fetal brain, and it is particularly abundant in the cerebellum (Di Benedetto et al. 2006a). Interestingly, the cerebellum is the only region in the brain where the AT2-receptor has been consistently detected.

Although MTUS1 isoform 5/ATIP1 has been previously localized to the mitochondrial region of the cytoplasm (Kinjo et al. 2000; Seibold et al. 2003), only recently has the cellular localization of MTUS1 isoform 1/ATIP3a been established. Using a combination of microtubule co-sedimentation assays and immunohistochemical techniques, isoform 1/ATIP3, in contrast to isoform 5/ATIP1, has been identified as a microtubule-associated protein (Rodrigues-Ferreira et al. 2009).

MTUS1/ATIP, Table 1 MTUS1 variants and the corresponding ATIP variant

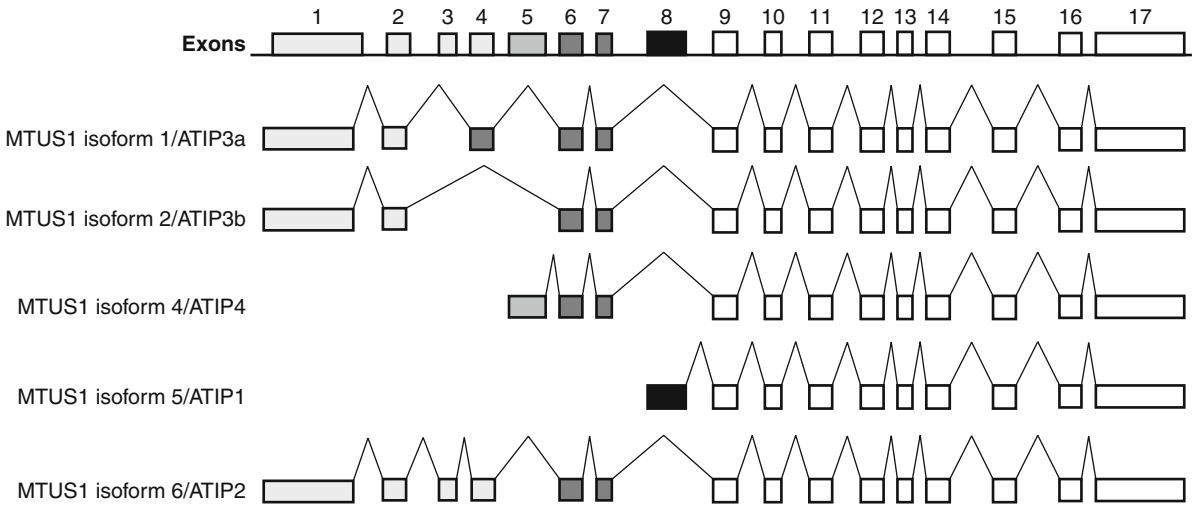
MTUS1 variant	Corresponding ATIP variant
MTUS1	ATIP
MTUS1 isoform 1	ATIP3a
MTUS1 isoform 2	ATIP3b
MTUS1 isoforms 1 and 2	ATIP3
MTUS1 isoform 4	ATIP4
MTUS1 isoform 5	ATIP1
MTUS1 isoform 6	ATIP2

Structure

Full-length human MTUS1 isoform 5/ATIP1, the first isoform fully characterized by the French group, comprises 1977 nucleotides (GenBank accession number AF293357) and encodes a 436-amino acid polypeptide and shares approximately 86% homology with mouse MTUS1 isoform 5/ATIP1 (Nouet et al. 2004).

The proteins encoded by mouse and human MTUS1 isoform 5/ATIP1 are mainly hydrophilic and contain no transmembrane domains. A major component of isoform 5/ATIP1 comprises a large coiled-coil domain, which contains two leucine zippers, and a high proportion of basic residues with a stretch of 30 C-terminal residues rich in proline, serine/threonine, and arginine. Protein analysis using an antibody-specific ATIP-ID revealed four apparent molecular weights of 30, 60, 120, and 180 kDa in a range of human tissues, which are thought to correspond to the various MTUS1/ATIP homologues (Nouet et al. 2004).

Comparison of the ATIP-ID nucleotide sequence in the Genbank database identified sequences that contained the homologous 354 bp region in uterus, brain, and fetal brain and these were designated ATIP2 (MTUS1 isoform 6), ATIP3 (isoforms 1 and 2), and ATIP4 (isoform 4), respectively, by the French group. Further structural analysis of the human MTUS1/ATIP gene (Genbank NT_030747) identified 17 coding exons encoding five transcripts through alternative splicing and these were designated ATIP1 (isoform 5), ATIP2 (isoform 6), ATIP3a (isoform 1), ATIP3b (isoform 2),



MTUS1/ATIP, Fig. 1 Schematic representation of the 17 coding exons of human MTUS1/ATIP and the corresponding exons contained in MTUS1 isoform 1 (ATIP3a), isoform 2 (ATIP3b), isoform 4 (ATIP4), isoform 5 (ATIP1), and isoform 6 (ATIP2) (Adapted from Di Beneditto et al. 2006a)

and ATIP4 (isoform 4) (Di Benedetto et al. 2006a) (Fig. 1).

All of the MTUS1/ATIP isoforms exhibit the same C-terminal domain capability to interact with the AT2-receptor (Nouet et al. 2004). MTUS1 isoform 5/ATIP1, isoforms 1/ATIP3a and 2/ATIP3b, and isoform 4/ATIP4, which correspond to murine ATBP50, ATBP135, and ATBP60, respectively (Wruck et al. 2005), share the same 3′ exons (exons 9–17) but contain differing 5′ exons (exons 8, 1, and 5, respectively). Moreover, isoforms 1/ATIP3a, 2/ATIP3b, and 4/ATIP4 are splice variants and all use exons 1, 2, 6, and 7, while in addition isoforms 1/ATIP3a and 4/ATIP4 contain exons 4 and 3, respectively.

The sequence of exon 4, which is present in human MTUS1 isoform 1/ATIP3a but not isoform 2/ATIP3b, does not exist in the coding region of either rat or mouse ATIP3, indicating that this gene, and the protein it encodes, are not present in these species (Krezel et al. 2011).

MTUS1 Function and Interaction with the AT2-Receptor

Initial studies examining the function of the most studied MTUS1 isoform, isoform 5/ATIP1, identified that recombinant expression of isoform 5/ATIP1 into MIA PaCa-2 pancreatic tumor cells, which did not endogenously express MTUS1/ATIP, inhibited cell proliferation, as measured by a 30% reduction in uptake of a thymidine analogue, bromodeoxyuridine (Seibold et al. 2003).

In 2004 it was reported, following parallel studies in wild-type monkey kidney fibroblasts (COS) cells and COS cells stably transfected with the AT2-receptor (COS-AT2), that transient transfection of isoform 5/ATIP1, into both cell lines resulted in a 50% reduction in EGF-induced ERK2 phosphorylation in AT2-receptor expressing cells but not in wild-type cells, suggesting that expression of the AT2-receptor is a necessary component of MTUS1 isoform 5 signaling cascade. Further studies, in stably transfected Chinese hamster ovary (CHO) cells, identified that overexpression of isoform 5/ATIP1 in the presence of AT2-receptors inhibited not only EGF-mediated ERK2 phosphorylation but also inhibited the effects of other growth factors, including insulin and basic fibroblast growth factor (Nouet et al. 2004). Additionally, following stimulation of isoform 5/AT2-receptor transfected CHO cells with insulin, autophosphorylation of the insulin receptor beta-chain migrating at 97 kDa was reduced compared with CHO cells transfected with an empty pcDNA3 vector (Nouet et al. 2004), i.e., it interferes at the initial step of insulin receptor signaling. It must also be noted that these studies were conducted in the absence of AT2-receptor activation, suggesting that overexpression of isoform 5/ATIP1 mimics the

activation of this receptor (Elbaz et al. 2000), while only slightly modifying the expression and affinity of AT2-receptors in these cells (Nouet et al. 2004).

Further evidence supporting the possible interdependence between MTUS1 isoform 5/ATIP1 and AT2-receptor function was provided in the form of siRNA studies in N1E-115 neuroblastoma cells (Wruck et al. 2005). These studies indicated that knockdown of MTUS1 isoform 5 not only reduced the ability of AT2-receptor activation to inhibit ERK2 phosphorylation and cell proliferation, which has recently been confirmed in studies of HVEC normal human umbilical vein epithelial cells (Zuern et al. 2010), it also increased AT2-receptor expression at the endoplasmic reticulum and significantly reduced the expression of these receptors at the cell surface, indicating that the receptor was not being transported to the cell surface(Wruck et al. 2005).

MTUS1 Other Potential Signaling Partners

As identified in the previous section, the activity of MTUS1 isoform 5/ATIP1, at least, is dependent on co-expression of the AT2-receptor. Beyond this little is known concerning the intracellular interactions of MTUS1/ATIP or the mechanism by which it inhibits ERK phosphorylation. Initially it was thought that MTUS1/ATIP did not act as a phosphatase (Nouet et al. 2004) or interact directly with protein tyrosine phosphatase 1 (SHP-l), a soluble protein tyrosine phosphatase that inhibits growth factor receptor signaling. However, more recently, it has been demonstrated that following activation of the AT2-receptor, ATIP interacts with SHP-1 to induce cell differentiation in primary cultures of rat neural cells (Li et al. 2007). Moreover, the ATIP/SHP-1 complex translocates into the nucleus and increases expression of one of the ubiquitin-conjugating enzyme variants, MMS2, which prevents neural damage and enhances neural cell differentiation (Li et al. 2007).

Pharmacological Regulation of MTUS1 Activity

In PC12W rat pheochromocytoma cells, which endogenously express both the AT2-receptor and MTUS1 isoform 5/ATIP1, AT2-receptor stimulation results in a "continuous increase" in isoform 5/ATIP1 mRNA levels, which commenced 30 min following receptor activation (Wruck et al. 2005).

Similarly, poly(ADP-ribose) polymerase-1 (PARP-1), which is implicated in the development of both cardiovascular and neuronal disease, is also thought to play a role in MTUS1 gene transcription, as PARP inhibition and PARP-1 ablation suppresses MTUS1 isoform 5/ATIP1 expression and promoter activity, whereas, they increased AT2-receptor expression at the plasma membrane (Reinemund et al. 2009). These findings appear to contradict the earlier work of Wruck et al. whereby isoform 5/ATIP1 knockdown decreased AT2-expression at the cell surface and this issue remains to be resolved.

EGF stimulation has also been shown to significantly decrease MTUS1/ATIP and MTUS1 isoform 5/ATIP1 mRNA expression by 45–65% in two prostate cancer cell lines (Louis et al. 2010).

MTUS1 in Cancer

Although MTUS1/ATIP was initially thought to be ubiquitously expressed (Kinjo et al. 2000), there is now a growing body of evidence indicating that a loss or downregulation of MTUS1/ATIP mRNA expression occurs with the development of a wide range of cancers, including cancers of the pancreas (Seibold et al. 2003), ovary (Pils et al. 2005), breast (Rodrigues-Ferreira et al. 2009; Frank et al. 2007; Chanrion et al. 2008), and colon (Zuern et al. 2010). For instance, Seibold *et al*. demonstrated an inverse correlation between MTUS1 mRNA expression and cellular differentiation and proliferation in pancreatic cancer cell lines and, as previously mentioned, demonstrated that recombinant expression of isoform 5 in MIA PaCa-2 cells inhibited cell proliferation (Seibold et al. 2003).

Similarly, QPCR studies examining control tissues containing ovarian tissues and cysts, 58 ovarian tumor biopsies, and 38 ovarian cancer cell lines identified that MTUS1 expression was significantly lower ($P = 0.004$) in primary ovarian carcinoma compared with control tissues (Pils et al. 2005).

Moreover, MTUS1 expression was also found to be significantly downregulated in cancers of the colon, compared to the corresponding normal tissues, at both the protein and mRNA level. However, no mutations in the MTUS1 coding or promoter sequences

could be identified. Similarly, only five nucleotide substitutions in the MTUS1/ATIP gene were detected in 109 primary hepatocellular carcinoma tumors and cell lines (Di Benedetto et al. 2006b), suggesting that the MTUS1/ATIP gene may not be a major target for mutation in either colon cancer or hepatocellular carcinoma. By contrast, a copy number variant, which lacks exon 4 of MTUS1/ATIP (i.e., MTUS1 isoform 2/ATIP3b), has been identified in breast cancers and this variation is significantly associated with a decreased risk for both familial and high-risk familial breast cancers (Frank et al. 2007; Hinds et al. 2006).

In addition, a recent study has identified that isoform 1/ATIP3a is the predominantly altered MTUS1/ATIP isoform in invasive breast cancer and that it is significantly reduced in highly proliferative breast carcinomas of poor clinical outcome. In addition, they have demonstrated that isoform 1/ATIP3a re-expression inhibits tumor cell proliferation both *in vitro* and *in vivo* and its overexpression delays the progression of mitosis by extension of the metaphase (Rodrigues-Ferreira et al. 2009).

Studies in human prostate cancer cell lines that express functional AT2-receptors (Chow et al. 2008) indicate that in a model of early stage, androgen-dependent prostate cancer, LNCaP cells, in which MTUS1/ATIP expression was knocked down using siRNA techniques the ability of EGF to stimulate DNA synthesis was potentiated, whereas, it had no effect on the basal rate of DNA synthesis. By contrast, MTUS1/ATIP knockdown in a model of late-stage, androgen-independent, prostate cancer, PC3 cells, resulted in a significantly increased basal rate of thymidine incorporation and stimulation of the cells with EGF did not increase DNA synthesis beyond this already heightened level of activation (Louis et al. 2010). Further studies examined the transient overexpression of MTUS1 isoform 5/ATIP1 in PC3 cells, as it expresses relatively low endogenous levels of ATIP. In these studies not only was the basal rate of ERK2 phosphorylation diminished but the ability of EGF to stimulate this pathway was also attenuated (Louis et al. 2010).

Of particular interest in prostate cancer however, is the re-expression of MTUS1/ATIP in the neoplastic epithelial cells in high-grade prostatic intraepithelial neoplasia, the premalignant phase of prostate cancer (Louis et al. 2007), suggesting that the downregulation of MTUS1/ATIP expression identified in other cancers may be preceded by an initial re-expression early in the malignant process, which may be of value in diagnosing the premalignant stage of a number of cancers in particular prostate cancer (Louis et al. 2011).

Summary

MTUS1/ATIP is a putative tumor suppressor gene, which localizes at 8p22 and encodes a family of five proteins as a result of alternate promoter utilization and exon/intron splicing. All five proteins contain a C-terminal domain which can interact with the AT2-receptor. MTUS 1 isoform 1/ATIP3a is the predominantly expressed variant throughout the body, excepting the brain where isoform 5/ATIP1 is the major transcript. The subcellular localization of MTUS1 isoform 1/ATIP3a has only recently been identified in the microtubules of SK-MES, HeLa, RPE1,MDA-MB-231, and MCF7 cells, whereas, isoform 5/ATIP1 has been identified in both the mitochondria and Golgi matrix. Relatively little is currently known concerning the action of MTUS1/ATIP; however, isoform 5/ATIP1, the most studied variant to date, has been shown to inhibit growth factor-induced ERK2 phosphorylation and cell proliferation in both normal and cancer cell lines; possibly by acting directly on growth factor receptors or via interaction with SHP-1. By contrast, isoform 1/ATIP3a inhibits tumor cell proliferation by extension of the metaphase, thereby, delaying the progression of mitosis. Studies indicate that MTUS1 isoform 5/ATIP1 and isoform 1/ATIP3a are downregulated in a range of human cancers and a mutation in isoform 1/ATIP3a has been associated with a decreased risk for both familial and high-risk familial breast cancers. Although there is much to be learned regarding the function and signaling pathways of MTUS1/ATIP, the information available indicates that it may play an important inhibitory role in cell proliferation and therefore may prove a potential therapeutic target in not only cancer but also cardiovascular disease.

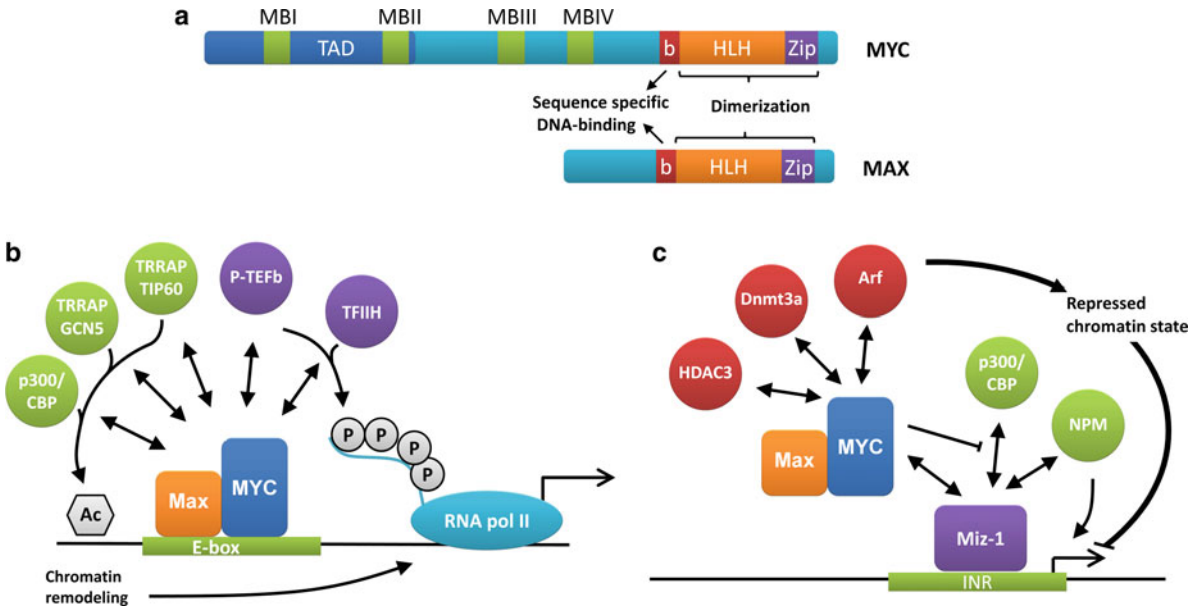
Historical Background

The first *MYC* gene was identified in the late 1970s in the avian acute leukemia virus MC29. This virus was known to cause a range of malignancies and the sequence in the viral genome responsible for the transforming capacity was named v-*myc* (short for viral myelocytomatosis, a leukemia caused by the virus). In 1979, a cellular homologue was identified in many species and was subsequently called c-*MYC*, where "c" denotes cellular. In contrast to other oncogenes known at the time, *MYC* did not seem to be activated by point mutations in the coding sequence. Instead studies in the early 1980s led to the identification of three novel mechanisms of oncogene activation: insertional mutagenesis (virus integration into the host genome at or near proto-oncogenes resulting in high levels of expression driven by the viral promoter), chromosomal translocation, and gene amplification (see also "MYC in Cancer" below). Following the discovery of c-*MYC*, it was realized that it was member of a larger family of oncogenes. In 1983, a new *MYC* gene was found to be amplified in neuroblastoma and was named *MYCN* where the "N" denotes neuroblastoma. Amplification of *MYCN* still remains one of the most important prognostic factors in neuroblastoma and is associated with aggressive disease and very poor prognosis. Two years later, yet another *MYC* family gene, *MYCL*, was identified in gene amplifications in small cell lung cancer. Since their discovery, studies of the MYC proteins have unveiled their fundamental roles in the development and function of normal tissues and have led to new knowledge about cancer biology (Wasylishen and Penn 2010).

The Transcription Factor MYC

Mammalian genomes contain three related genes, c-*MYC*, *MYCN*, and *MYCL* (here collectively referred to as *MYC*), which are structurally and functionally conserved. The founding member of the family, c-*MYC* is the best studied of the genes but many aspects of c-*MYC* biology and function hold true also for *MYCN* and *MYCL* (Eilers and Eisenman 2008). The MYC protein (MYC) is a transcription factor that can both activate and repress specific genes (Adhikary and Eilers 2005). It contains an N-terminal transactivation domain (TAD) and a C-terminal basic helix-loop-helix leucine zipper (bHLH-Zip) motif responsible for dimerization and DNA binding (Fig. 1a; Cowling and Cole 2006). To bind DNA MYC needs to heterodimerize with the small bHLH-Zip MYC-associated protein X (Max) (Lüscher and Larsson 1999). Max in turn can also interact with another group of bHLH-Zip-containing proteins, namely, Mxd1-4, Mnt, and Mga, but these heterodimers instead repress transcription and thus act



Myc, Fig. 1 *MYC structure and function in gene transactivation and repression.* (**a**) Schematic depiction of the structure of MYC and Max proteins indicating important functional domains. *MB* MYC box, *TAD* transactivation domain, *b* basic region, *HLH* helix-loop-helix, *Zip* Leucine-zipper. (**b**) Transactivation mediated by the MYC-Max dimer binding to the E-box sequence. Recruitment of HAT complexes leading to an open chromatin state, as well as MYC-promoted phoshphorylation of the C-terminal domain of RNA pol II, resulting in stimulated transcriptional elongation is shown. (**c**) MYC-mediated repression of Miz-1-induced transcription. The MYC-Max complex interacts with Miz-1 bound to the core promoter, resulting in displacement of co-activators of Miz-1 and instead recruiting factors mediating a repressed chromatin state

as antagonists of MYC. The MYC TAD contains two conserved regions, which are important for the transactivation and transforming activity of the protein referred to as MYC box (MB) I and MBII, respectively. MBII is mediating the interaction of MYC with several of its cofactors for transcriptional activation and repression, such as transformation/transcription domain-associated protein (TRAPP) and histone acetyl transferases (HATs). Located within MBI are residues that are important for regulation of MYC activity and turnover (see "Regulation of MYC Activity" below). Two additional conserved regions, MBIII and MBIV, are located in the central part of the MYC protein and are important for its full transforming activity (Cowling and Cole 2006).

To activate transcription, the MYC-Max heterodimer binds to the conserved E-box sequence core motif 5′-CANNTG, where 5′-CACGTG is the preferred sequence (Fig. 1b). MYC then recruits different cofactors in order to drive transcription and can stimulate histone acetylation at promoters by recruiting TRAPP-containing complexes with either GCN5 or TIP60 HATs or the CBP/p300 acetyl transferase (Fig. 1b). Histone acetylation opens the chromatin and provides docking sites for additional proteins that promote transcription (Cowling and Cole 2006). In addition, MYC also stimulates transcriptional elongation through recruitment of P-TEFb and TFII-H, which in turn phosphorylate the C-terminal domain of RNA pol II, allowing its release from the promoter and subsequent elongation (Fig. 1b; Cole and Cowling 2008). Furthermore, MYC can repress the transcription of specific genes by binding to other transcription factors in core promoters and inhibiting their transactivation activity (Herkert and Eilers 2010). The most studied example is the POZ-domain containing protein Miz-1, but other factors, including Sp1, can also be bound and inhibited by MYC. Several negative regulators of the cell cycle are among the transcriptional targets of Miz-1 including the cyclin-dependent kinase inhibitors (CKIs) p21 and p15. By binding to Miz-1, MYC can displace co-activators, such as CBP/p300 and instead recruit the DNA methylase Dnmt3, histone deacetylase 3 (HDAC3) and p14/ARF. This in turn leads to deacetylation of histones

as well as methylation of DNA and histones promoting a repressed chromatin state (Fig. 1c; Herkert and Eilers 2010). Recently it has also been recognized that regulation of specific microRNAs is another means whereby MYC indirectly regulates the expression of many genes (Bui and Mendell 2010). In addition to RNA pol II–mediated transcription of mRNA, MYC can also stimulate the transcription by RNA pol I and RNA pol III (Adhikary and Eilers 2005; van Riggelen et al. 2010). RNA pol I mediates the transcription of ribosomal RNA (rRNA) from rDNA. MYC promotes RNA pol I activity by binding E-boxes in rDNA promoter regions where it associates with the RNA pol I–specific promoter selectivity factor SL1. By binding to TFIIIB, an RNA pol III–specific transcription factor, MYC can also directly activate RNA pol III–mediated the transcription of 5S rRNA and tRNA.

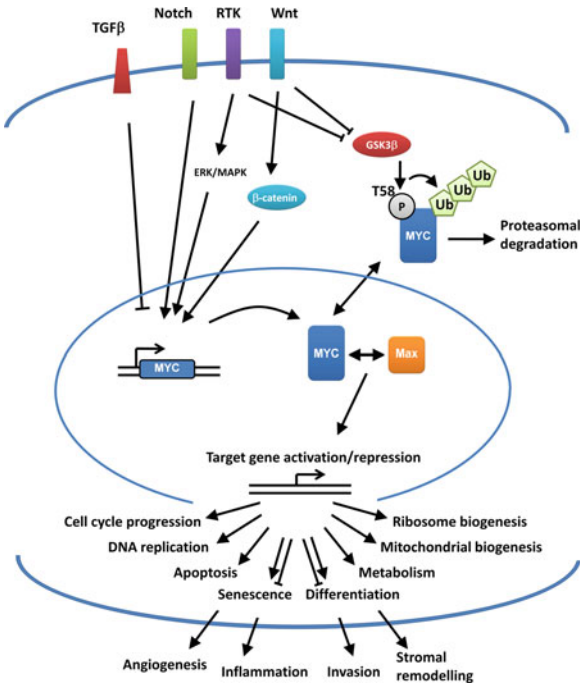
Several transcription-independent functions have been reported for MYC, including mRNA cap methylation and DNA replication (Cole and Cowling 2008). Cap methylation occurs during early stages of mRNA transcription, where the mRNA is first capped with an inverted guanosine and this cap is subsequently methylated. Uncapped mRNA is rapidly degraded and methylation of the cap is necessary for binding of translation factors. MYC stimulates the recruitment of enzymes responsible for both capping and methylation to specific mRNAs (Cole and Cowling 2008). In this way, the level of a protein can be increased by MYC, independent of any effects on transcription. A direct role for MYC at origins of replication has also been suggested. Defining the direct actions of MYC in regulating replication is not straightforward since MYC also stimulates DNA replication through transcription-dependent mechanisms. However, several components of the pre-replicative complex have been found to be direct interaction partners of MYC. Furthermore, MYC overexpression increased the number of origins of replication, even in the presence of transcription inhibitors, and could influence the rate of DNA synthesis in a *Xenopus* system, which supports cell cycle–regulated DNA replication in the absence of transcription and new protein synthesis (Herold et al. 2009). Recently, a cytosolic function of a cleavage product of the MYC protein was described (Conacci-Sorrell and Eisenman 2011). ▶ Calpain-mediated cleavage generates an N-terminal version of MYC, MYC-Nick, that lacks nuclear localization signal and was shown to promote differentiation of muscle cells.

MYC in Cell Biology

Although some transcription-independent activities have been reported for MYC, it acts primarily as a transcriptional regulator that exerts its biological properties through induction or repression of specific genes. The fact that MYC is a relatively poor transactivator and induces many of its targets only about twofold has complicated global analyses to identify target genes. This relatively weak MYC-induced gene regulation frequently drowns in the noise inherent to the methods applied, or fall below the cutoff values used. Still, MYC has profound effects on cell behavior and cell fate. This is likely achieved by modulation of the activity of an entire pathway or even of multiple cooperating pathways. MYC regulates specific groups of genes that are involved in metabolism, protein synthesis, cell cycle regulation, cell adhesion, and cytoskeleton composition (Fig. 2; Dang et al. 2006).

Early on, MYC's crucial role in driving cell proliferation was noted (Henriksson and Lüscher 1996; Wasylishen and Penn 2010). It was found to be an intermediate early response gene after serum stimulation and ectopic expression of MYC promoted cell cycle entry of quiescent cells. The effect of MYC on the cell cycle is achieved through repression of cell cycle checkpoint proteins and CKIs, including p21, p15, p27, and ▶ GADD45. MYC also activates several proteins that are important for the progression of the cell cycle including cyclins D1, D2, E1, A2 as well as CDK4, CDC25A E2F1 and E2F2 (Dang et al. 2006; Eilers and Eisenman 2008).

MYC drives cell division not only through regulation of cell cycle checkpoints but also by stimulating biosynthesis of macromolecules, allowing the doubling of cell mass required for every cell division. It is a direct regulator of ribosome biogenesis and thereby stimulates protein synthesis (van Riggelen et al. 2010). Through activation of the transcriptional activity of all three RNA polymerases, MYC stimulates synthesis of tRNAs, ribosomal RNAs (rRNA) and proteins, enzymes responsible for catalyzing the processing of rRNA, ribosome assembly, and export from the nucleus as well translation initiation and elongation factors. MYC also stimulates mitochondrial biogenesis and controls the activity of many metabolic pathways and the uptake of nutrients required to fuel these. Both glucose and glutamine transporters as well as several key enzymes in the glycolysis and glutaminolysis



Myc, Fig. 2 *MYC regulation and biological functions. MYC* gene expression is controlled downstream of a multitude of signaling pathways, including, Wnt/β-catenin, ▶ Notch, receptor tyrosine kinases (RTK), and tumor growth factor β (TGFβ). MYC activity is also regulated at the level of protein turnover. Through regulation of gene expression, MYC influences many intracellular and extracellular processes as indicated

pathways are direct transcriptional targets (Dang et al. 2006; Dang et al. 2009). Furthermore, MYC has a broad role in driving biosynthetic reactions that are required to supply macromolecules to support cell growth and stimulates the production of amino acids, ribose sugars, and purine nucleotides.

Somewhat surprising when it first was discovered, MYC overexpression can also cause apoptosis (Wasylishen and Penn 2010). This is the result if MYC overexpression is present together with anti-proliferative signals and can be rescued by specific survival factors (Hoffman and Liebermann 2008). Abrogation of the apoptotic signaling by MYC strongly contributes to cancer development. MYC can promote apoptosis through ▶ p53-dependent and p53-independent functions (Hoffman and Liebermann 2008). Overexpression of *MYC* can be sensed by ARF, which in turn activates ▶ p53 through inhibition of HDM2. High expression of *MYC* also promotes DNA damage and genomic instability. This may be the reason for activation of the ATM and ATR kinases, which also contributes to ▶ p53 activation in response to MYC. There is evidence showing that MYC can alter the balance of pro- and anti-apoptotic members of the Bcl2 family, in parallel with or independent of ▶ p53 activation. For example, the expression of the anti-apoptotic proteins Bcl2 and Bclx can be repressed, while the pro-apoptotic protein Bim can be induced by overexpression of *MYC* (Hoffman and Liebermann 2008). In addition, multiple proteins involved in the death-receptor pathway can be regulated directly or indirectly by MYC, resulting in increased sensitivity to apoptosis induced by ligation of death receptors such as the Fas and TRAIL receptors.

Regulation of MYC Activity

MYC activity is tightly regulated by developmental and mitogenic signals. The transcript and protein have short half-lives, allowing rapid adjustments of levels and thereby MYC activity. Many signaling pathways are involved in the transcriptional regulation of the gene. Transcription of *MYC* is, for example, induced downstream of signaling by ▶ Notch, Wnt/β-catenin, and receptors tyrosine kinases (Fig. 2). Several of these pathways interact with each other and there are multiple levels of regulation in each pathway. Thus *MYC* expression is controlled by a very complex network of intracellular signaling pathways allowing for tight regulation of gene activity. In addition, the cellular, developmental, and microenvironmental context will affect expression (see Wierstra and Alves 2008 for an extensive review).

Protein turnover is another means of regulating the expression level of MYC. Phosphorylation of two N-terminal sites, Serine 62 (S62) and Threonine 58 (T58) within the MBI has been shown to have an important regulatory function for protein stability (Hann 2006; Vervoorts et al. 2006). Importantly, mutations of these residues have been found in Burkitt lymphomas and other lymphomas and are associated with stabilized MYC protein, increased transforming activity and impaired ability to induce apoptosis (Hann 2006). Phosphorylation of S62 and T58 are interdependent since T58 require prior S62 phosphorylation. S62 phosphorylation stabilizes the MYC protein while phosphorylation of T58 promotes its degradation. Several kinases have been implicated in the phosphorylation of S62 including MEK/ERK, JNK, and CDK1 (Hann 2006). Once S62 is phosphorylated, MYC can

be recognized by GSK3β, which phosphorylates T58 resulting in the targeting of MYC for proteasomal degradation. Upon T58 phosphorylation, S62 is dephosphorylated. T58 phosphorylated MYC can then be recognized by the F-box protein FBW7, which is a subunit of the SKP1-CUL1-F-box protein (SCF) complex that stimulates polyubiquitylation and subsequent proteasomal degradation of MYC (Hann 2006; Vervoorts et al. 2006). Ras signaling is believed to stabilize MYC through activation of Raf/► MEK/ERK leading to S62 phosphorylation, and at the same time inhibiting T58 phosphorylation through activation of ► PI3K signaling, which in turn inhibits the activity of GSK3β (Hann 2006). Another ubiquitin ligase, SKP2, can when recruited to MYC-regulated promoters mediate the ubiquitylation of MYC. This results first in transcriptional activation followed by proteasomal degradation of MYC. Furthermore, MYC can be phosphorylated at multiple additional sites, be ubiquitylated by HectH9, and is also subject to acetylation (Vervoorts et al. 2006).

Development, Differentiation, and Stem Cells

The importance of MYC activity during development has been demonstrated by gene targeting in mice, where loss of either c-*myc* or *mycn* is embryonic lethal. c-$myc^{-/-}$ embryos die at embryonic day 10.5 due to severe hematopoietic as well as placental defects, while $mycn^{-/-}$ embryos succumb to neuroectodermal and heart abnormalities between embryonic day 10.5 and 11.5. Mice lacking *mycl* on the other hand appear normal (Laurenti et al. 2009). It is likely that c-*myc* and *mycn* can at least partly compensate for the absence of each other during development since $max^{-/-}$ mice die already at embryonic day 6.5 (Laurenti et al. 2009).

It was early recognized that MYC expression negatively correlated with terminal differentiation of tissues and that MYC expression could prevent terminal differentiation. The role of MYC in differentiation now appears more complex and the presence of MYC is important for many steps in differentiation in various tissues, including the hematopoietic system and the skin (Eilers and Eisenman 2008; Laurenti et al. 2009).

Furthermore, MYC function seems to be required for embryonic stem (ES) cell self-renewal. MYC was also one of the factors in the first described four-factor reprogramming of somatic cells to induced pluripotent stem (iPS) cells. While not strictly necessary for iPS generation, MYC has been found to enhance the reprogramming of cells. This has been linked to its capabilities to stimulate proliferation and to inhibit differentiation as well as to its ability to modify epigenetic patterns. Taken together, MYC can promote an open chromatin state and an ES cell-like chromatin landscape (Laurenti et al. 2009).

MYC in Cancer

Deregulated expression of one of the *MYC* family genes is detected in a wide range of human cancers and has in many instances been associated with aggressive, poorly differentiated tumors. Activation of *MYC* in cancers can be achieved through different means and is in most cases not the consequence of activating point mutations, but rather through increased expression. At the genomic level translocations or amplifications of the *MYC* genes occur. Translocation of *MYC* to one of the immunoglobulin loci is the hallmark of Burkitt lymphoma, but also occurs at variable frequency in other lymphomas and leukemias (Vita and Henriksson 2006). Amplification of one of the *MYC* genes is found in a range of solid tumors, including breast cancer, prostate cancer, neuroblastoma, and lung cancer (Vita and Henriksson 2006; Albihn et al. 2010). Overexpression of MYC can also be achieved through deregulation of upstream signaling pathways, which regulate *MYC* transcription and/or MYC protein stability. Furthermore, mutations leading to enhanced translation, or mutations affecting specific residues in MYC, such as T58, which are involved in the regulation of MYC protein turnover can be the cause of enhanced MYC protein levels in tumors. In fact overexpression of MYC is one of the most common events coupled with tumorigenesis (Pelengaris and Khan 2003; Albihn et al. 2010).

Early in vitro experiments defining the oncogenic properties of MYC revealed that its constitutive overexpression in rat embryo fibroblasts (REFs) lead to immortalization and prevented exit from cell cycle. MYC's contribution to tumorigenesis has been attributed mainly to its ability to promote tumor cell proliferation without the requirements of exogenous mitogenic signals resulting in uncontrolled proliferation. Overexpression of MYC can also promote

tumorigenesis through its effects on metabolism, cell growth, and metastasis as well as on the tumor microenvironment, for example, through the regulation of angiogenic factors (Pelengaris and Khan 2003; Sodir and Evan 2009). The tumor promoting effect of MYC was also verified in vivo in transgenic mice, first in the *Eμ-myc* model where MYC is overexpressed in B cells resulting in lymphoma, and then in many other tissues (Pelengaris and Khan 2003).

High levels of MYC expression promote apoptosis. While contradictory to its tumor promoting function, this has come to be viewed as an intrinsic tumor suppressor function to guard against uncontrolled proliferation. The same holds true for other oncogenes, such as E2F. Cooperation in transformation is seen between MYC and other oncoproteins, for example, Ras and Bcl2 or loss of tumor suppressor proteins such as ▶ p53 and ARF that counteracts the apoptosis signaling induced by MYC. Another tumor suppressor function that can be affected by MYC is senescence. MYC can suppress senescence induced by oncoproteins such as Ras and BRAF. However, under certain circumstances, MYC can also induce senescence (Larsson and Henriksson 2010).

Conditional transgenic models where *MYC* overexpression can be turned on and off have shown that inactivation of MYC can lead to tumor regression (Felsher 2010). Some tumors are dependent on the sustained expression of MYC, so-called oncogene addiction, which implicates MYC as a therapeutic target at least in some tumor types. MYC inactivation in tumors can lead to proliferative arrest, differentiation, senescence, and/or apoptosis. In addition, inhibition of MYC can also affect the tissue microenvironment and tumor-induced angiogenesis. Studies in a collection of conditional transgenic models of MYC-driven tumors of various tissue origins have shown that the efficiency and reversibility of the effects of MYC inhibition depends on the cellular, genetic, and epigenetic contexts (Felsher 2010). Approaches to target MYC include strategies that interfere with MYC expression such as antisense and RNA interference, inhibition of downstream MYC target genes and small molecules that disrupt MYC-Max interaction (Vita and Henriksson 2006; Larsson and Henriksson 2010; Prochownik and Vogt 2010). MYC has for several reasons been regarded as an impossible target for therapy and development of small targeting molecules has lagged behind. Interfering with protein-protein interactions instead of the classical targeting strategy of gain-of-function mutants in cancer-associated kinases has been deemed difficult. Recent development of other protein interaction–targeting small molecule compounds, including nutlins, which disrupts the ▶ p53-HDM2 interaction, and ABT-737 that targets the interaction between specific Bcl2 family members, shows however that this strategy indeed is possible and can be successful (Prochownik and Vogt 2010). Concerns have also been raised regarding the effect of inhibition of MYC in normal tissues. One recent study of systemic MYC inhibition in mice with the conditional expression of the MYC inhibitor Omomyc indicates, however, that the effects on normal tissues are mild and can be tolerated (Sodir and Evan 2009). Different screening strategies have lead to the identification of MYC-Max disrupting small molecules (Prochownik and Vogt 2010). Although these compounds need to be further developed, they give hope for the continued efforts to develop compounds that could be used clinically to target MYC in human cancer.

Summary

The MYC protein is a transcription factor, which appears to act as a global regulator of gene transcription that controls many important normal and neoplastic cellular processes. The studies of MYC have in fact greatly contributed to our understanding of fundamental mechanisms of cell growth, cell death, and development and will likely continue to do so. Furthermore, the oncogenic role of MYC in tumor development is well established and deregulated *MYC* is involved in many human cancers. This has stimulated the idea that inhibition of MYC could be an attractive strategy for development of novel cancer therapies. This notion is further encouraged by recent progress in the development of MYC-targeting small molecules.

Synonyms

MyD88; Myeloid differentiation primary response gene 88

Historical Background

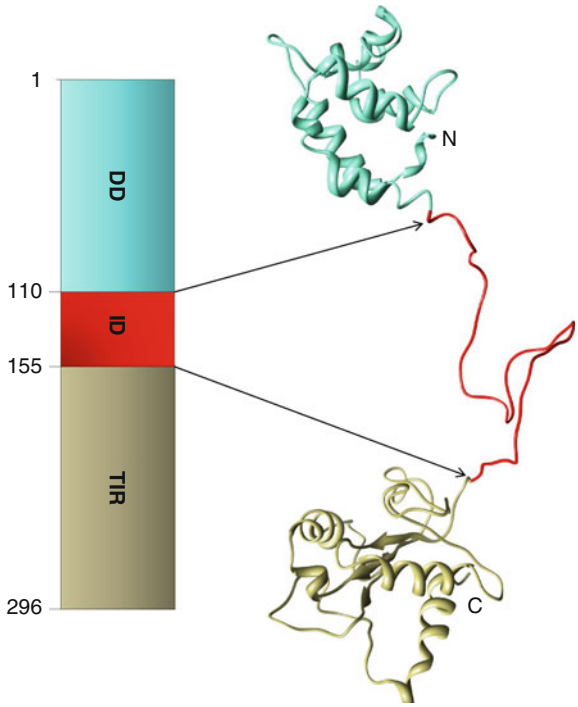
Myeloid differentiation primary response gene 88 (MyD88) was originally discovered and cloned by Liebermann and Hoffman in 1990 as one of 12 different mRNA transcripts that were induced in M1 myeloblastic leukemia cells upon activation with lung-conditioned medium or recombinant interleukin (IL)-6 (Lord et al. 1990). The "MyD" portion of the name stands for myeloid differentiation, while "88" refers to the gene number in the list of induced genes (Lord et al. 1990). At the time of its discovery, the MyD88 sequence showed no homology with other sequences available in the databases and contained no recognizable protein motifs. In 1994, the C-terminal portion of MyD88 was found to be similar to a conserved stretch of ~200 amino acids in the intracellular regions of the *Drosophila* Toll receptor and the mammalian interleukin-1 receptor (IL-1R) (Hultmark 1994), and was thus referred to as the TLR (Toll-like receptor)- and IL-1R-related (TIR) domain. The N-terminal portion of MyD88 encodes the death domain (DD) (Feinstein et al. 1995) that was originally identified in apoptosis-promoting proteins. By 1997,

the function of MyD88 had been determined. Specifically, MyD88 was first shown to be involved in type 1 interleukin-1 receptor (IL-1R1) signaling and subsequently in all TLRs (Hultmark 1994) signaling except for TLR3 response and ▶ TLR4-mediated late response. The MyD88 adapter protein links members of the TLR and IL-1R superfamily to the downstream activation of nuclear factor-κB (▶ NF-κB) and mitogen-activated protein kinases (MAPKs). Although originally identified as a myeloid-differentiation marker, MyD88 is known to play an essential role in the innate immune response of insects and mammals. The generation of MyD88-deficient mice as well as the identification of MyD88-related proteins and regulators of MyD88 signaling have revealed new and important insights into the functions of MyD88 (Janssens and Beyaert 2002).

MyD88 Localization and Structure

MyD88 transcript is detected in most tissues including the heart, brain, spleen, lung, liver, muscle, kidney, and testis, as well as in the T, B, and myeloid cell lines. MyD88 is localized in distinct condensed particles scattered throughout the cytoplasm, reportedly in organelles yet to be identified (Nishiya et al. 2007).

MyD88 is a 296 amino acid cytoplasmic adaptor protein that relays signals from IL-1, IL-18, IFNγ, IL-33, and most TLRs. MyD88 has a clear-cut modular structure composed of three main domains that are encoded by five exons (Hardiman et al. 1997). The first exon encodes the N-terminal DD, which mediates downstream interactions with the IRAK family of kinases. Exon 2 encodes the short linker ID, while the last three exons encode the C-terminal TIR domain, which mediates the interaction of MyD88 with other TIR domain receptors. The N-terminal DD is related to a motif that was originally defined as the region of similarity between the cytoplasmic tails of the FAS/Apol/CD95 and TNF (tumor necrosis factor) receptors that is required for cytotoxic signaling by the so-called death receptors (Tartaglia et al. 1993). Conversely, the MyD88 C-terminal TIR domain is homologous with the cytoplasmic signaling regions of the *Drosophila* Toll receptor and the IL-1 receptor complex. To date, the entire structure of MyD88 has not been solved. However, the crystal structure of the MyD88 DD in complex with DDs of IRAK4 (interleukin-1 receptor associated kinase 4)-IRAK2 (PDB ID: 3MOP) was recently solved by Chang et al. (Lin et al. 2010) and the NMR solution structures of the TIR domain of MyD88 (PDB ID: 2Z5V and 2J67) were solved by two independent research groups (Ohnishi et al. 2009). The entire structure of MyD88 is depicted in Fig. 1.



MyD88, Myeloid Differentiation Primary Response Gene 88, Fig. 1 *Representation of protein domains found in the MyD88 adaptor protein*. (**a**). Schematic representation of MyD88 protein domains. MyD88 contains a Toll/interleukin-1 receptor (TIR) domain, an intermediary domain (ID), and a death domain (DD). The N-terminal (N) DD is shown in *aquamarine color*, ID is shown in *red color*, and the C-terminal (C) TIR domain is represented by *khaki color*. (**b**). *Ribbon* representation of the entire structure of MyD88, where the N-terminal DD represents the crystal structure solved by Chang et al. (Lin et al. 2010) and the C-terminal TIR domain represents the NMR solution structure solved by Ohnishi et al. (2009). The ID domain shown is the modeled structure generated using the MOE program (Molecular Operating Environment: http://www.chemcomp.com/software.htm)

The importance of the MyD88 DD is that it interacts with IRAKs, including IRAK1, IRAK2, IRAK4, and IRAK-M (IL-1R-associated kinase M), which are characterized by an N-terminal DD and a carboxy-terminal Ser/Thr kinase or kinase-like domain. The ensuing pathway eventually activates transcription factors NF-κB, activator protein (AP)-1 and interferon regulatory factors (IRFs) to elicit anti-pathogen

responses and inflammation (Akira et al. 2006). The crystal structure of the DD of MyD88 consists of six helices (H1–H6) with a short H3 and an extraordinarily long H6 from residue 99 to the end of the construct at residue 117, which includes part of the ID (residues 110–154). For the loop regions, MyD88 has the longest H1–H2 loop, shortest H3–H4 loop, and longest H4–H5 loop (Lin et al. 2010). The MyD88 DD structure explains the disruptive phenotypes of mutations ΔE52 and L93P in children suffering from life-threatening pyogenic bacterial infections (von Bernuth et al. 2008). Structure-based mutagenesis studies identified critical residues of MyD88 DD (V43, A44, E52, Y58, I61, and R62). In particular, E52 and Y58 were found to be involved in IRAK4 recruitment and NF-κB signaling (Loiarro et al. 2009).

Following the MyD88 DD is an ID. Alternative splicing of MyD88 results in a variant that lacks the ID – MyD88 short (MyD88s), which is only expressed in the spleen and brain. When overexpressed in HEK293 cells, MyD88s is able to bind IRAK, but it does not activate NF-κB because it cannot induce IRAK phosphorylation. Hence, it has been suggested that MyD88 ID plays a potent role in the differential activation of distinct (NF-κB versus JNK-dependent) transcriptional programs (Janssens et al. 2003).

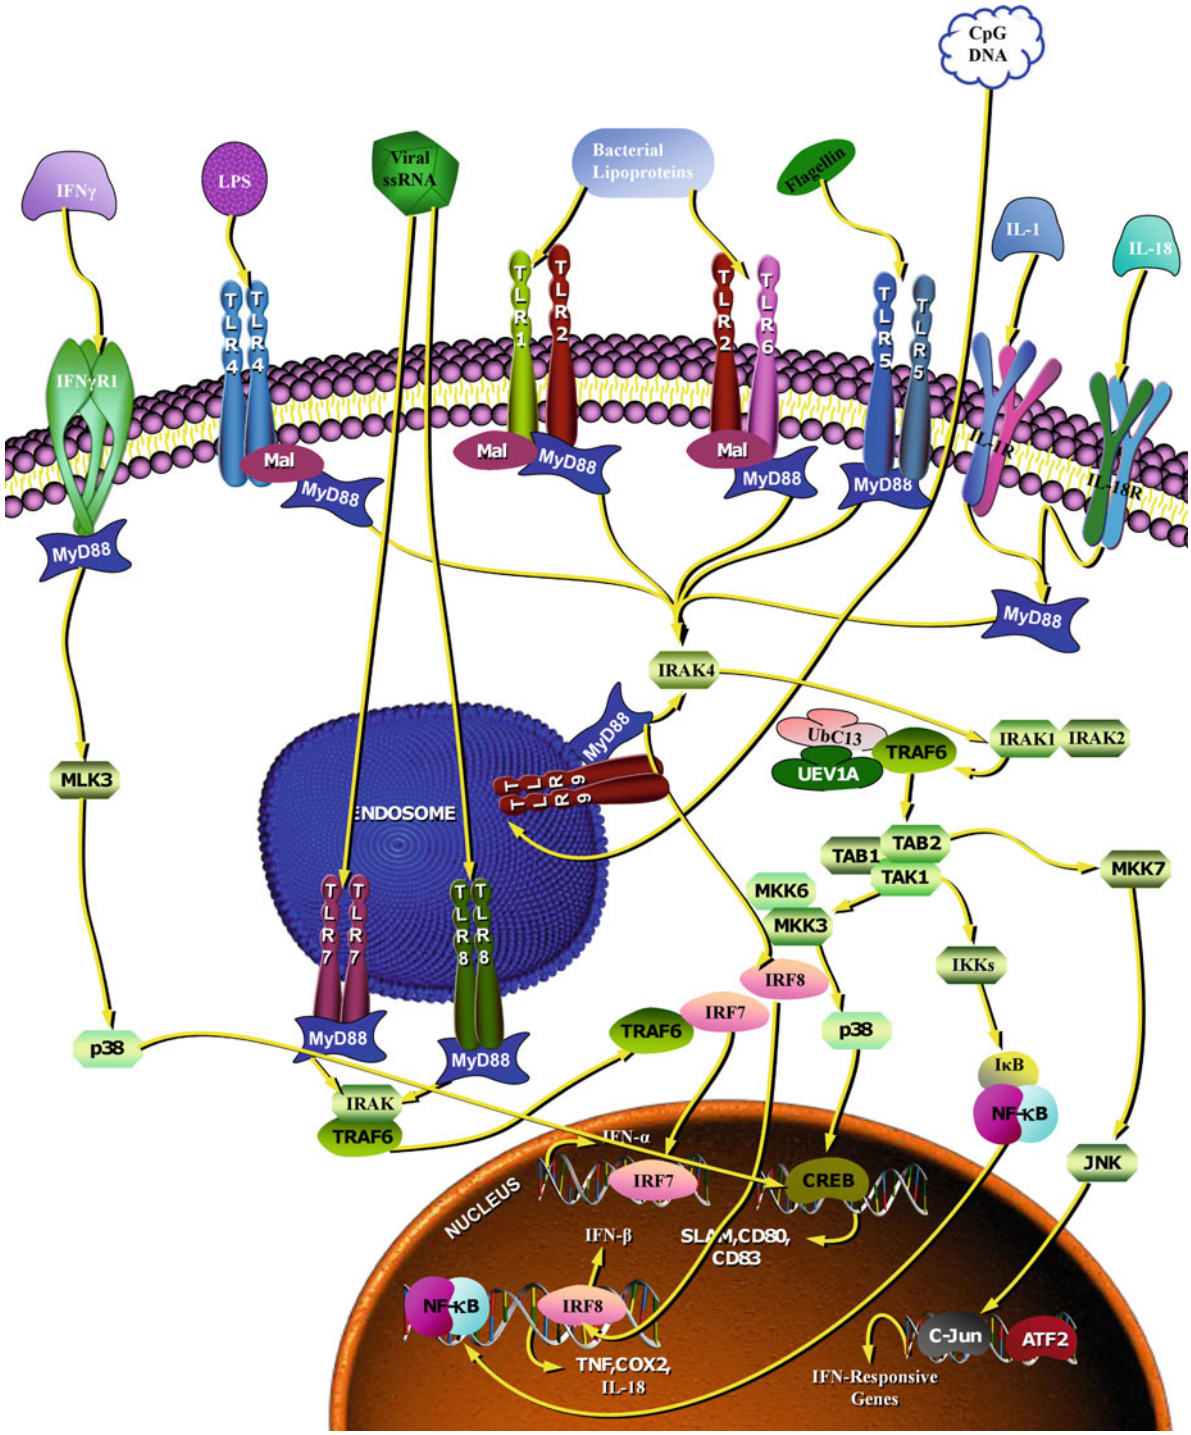
The C-terminal portion of MyD88 contains a TIR domain that mediates homo- and heterotypic protein interactions during signal transduction. The NMR solution structure of the MyD88 TIR domain (residues 157–296) identified by Ohnishi et al. comprised a central five-stranded parallel β-sheet (βA-βE) surrounded by four α-helices (αA-αC and αE) (Ohnishi et al. 2009). Rossi et al. also released the solution structure of the TIR domain of human MyD88 in the Protein Data Bank (PDB). The overall folding was identical to that reported by Ohnishi, despite minor differences. MyD88-TIR was found to reside in a monomeric state, as determined by the size-exclusion chromatography. However, the DD including the ID of MyD88 existed in a dimeric state. Therefore, the reported MyD88 dimerization was likely mediated by DD + ID and not by the TIR domain. TIR domains in TLRs, IL receptors, and the adaptors MyD88 and ▶ Mal (MyD88-adaptor like protein)/TIRAP (TIR domain containing adaptor protein) contain three conserved boxes (boxes 1, 2 and 3), which are required for signaling (Li et al. 2005). A mutagenesis study conducted by Jiang et al. in conjunction with previous docking studies revealed that the BB loop and Poc site (I179N) in the TIR domain are critical for responses to most TLR ligands and for all other MyD88-dependent TIR signaling events (Jiang et al. 2006).

Universal Role of MyD88 in Signaling

A great deal has been learnt about the role of MyD88 in signaling pathways. In terms of signaling, the situation regarding MyD88 has become more complex. MyD88 is considered to be a critical component in the signaling cascades mediated by all TLRs, IL-1R, IL-18R, IFNγ, and IL-33 (Kakkar and Lee 2008; Wesche et al. 1997; Muzio et al. 1997; Burns et al. 1998; Medzhitov et al. 1998) (Fig. 2).

MyD88 adapter protein links members of the TLR and IL-1R superfamily to the downstream activation of NF-κB and MAPKs. The extracellular domains of the TLRs and IL-1Rs are divergent; however, their intracellular domains share a high degree of similarity and activate similar signaling cascades upon stimulation. It is generally accepted that MyD88 is recruited to all members of the TLR/IL-1R family. The signaling in IL-1R and TLRs is initiated by the direct recruitment of MyD88 to the activated receptor complex. However, in the case of TLR2 and 4 signaling, a bridging adaptor, Mal, is required for MyD88 recruitment. Members of the IRAK family are recruited immediately downstream of MyD88. IRAK4 appears to be the MyD88-proximal kinase, which in turn recruits IRAK1. IRAK2 can also be found in the MyD88 complex (although this has only been shown when IRAK2 is overexpressed). A key downstream target for IRAK1 is believed to be TNF-receptor-associated factor 6 (▶ TRAF6) which, through the recruitment of transforming-growth-factor-β-activated kinase 1 (TAK1) and TAK1-binding protein 2 (TAB2), and the ubiquitylating factors, ubiquitin-conjugating enzyme E2 variant 1 isoform A (UEV1A) and ubiquitin-conjugating enzyme 13 (UBC13), ultimately engages with the upstream kinases for p38 and JNK and with the inhibitor of NF-κB kinase (IKK) complex, leading to NF-κB activation.

In addition to the MyD88 pathway, which results in NF-κB translocation, there is a cell-specific pathway that is required for the induction of type I IFNs by TLR7, 8 and 9. MyD88 has also been shown to be essential for activation of IRF7 by these TLRs, which leads to IFNα production (Honda et al. 2005). Furthermore, a complex comprising MyD88, IRAK1, IRAK4,



MyD88, Myeloid Differentiation Primary Response Gene 88, Fig. 2 *Overview of MyD88-dependent signaling pathways*. The MyD88-dependent signaling pathway is utilized by all TLRs (with the exception of TLR3 and certain signals of TLR4), IL-1R, IL-18R, and IL-33. As the name suggests, the adapter molecule, MyD88 is the key mediator of this pathway, and its main role is activation of NF-κB (a hallmark of MyD88 signaling). MyD88 possesses its own C-terminal TIR domain, which drives the heterodimerization of the adaptor with the activated receptor. The N-terminal DD of MyD88 then recruits the IRAK1 and IRAK4 kinases. IRAK4 phosphorylates and activates IRAK1, which in turn initiates autophosphorylation

TRAF6, and IRF7 has been detected, with IRF7 being phosphorylated by IRAK1. This phosphorylation appears to be a key role of IRAK1 in TLR7, 8 and 9 signaling, as the IRF7 response is totally abolished in IRAK1-deficient cells, whereas NF-κB activation is only partially impaired (Uematsu et al. 2005). In the case of ▶ TLR9, IRF7 activation seems to require a stable interaction between MyD88 and the TIR domain of TLR9, which occurs on the cytosolic side of endosomes (Honda et al. 2005). These studies have expanded our understanding of the role of MyD88 in signaling during the host defense response.

MyD88 also interacts with ▶ IRF5 and IRF1 and is required for the activation of these IRFs. IRF5 was found to be crucial for the induction of pro-inflammatory cytokines and type I IFNs by all TLRs tested (Takaoka et al. 2005). The association of MyD88 with IRF1 appears to be required for the translocation of IRF1 to the nucleus in myeloid DCs, and IRF1 is required for the induction of several TLR-dependent genes in these cells. IFNγ is required to induce IRF1, which might be the basis for the priming effect of IFNγ on TLR action. Another intriguing link to the IFNγ system is the reported association between MyD88 and IFNγ receptor 1 (IFNγR1) (Sun and Ding 2006). MyD88 recruits mixed-lineage kinase 3 (MLK3) downstream of IFNγR1, which in turn activates p38. Therefore, an alternative signaling pathway for MyD88 that does not involve TIR-domain-containing receptors has been revealed.

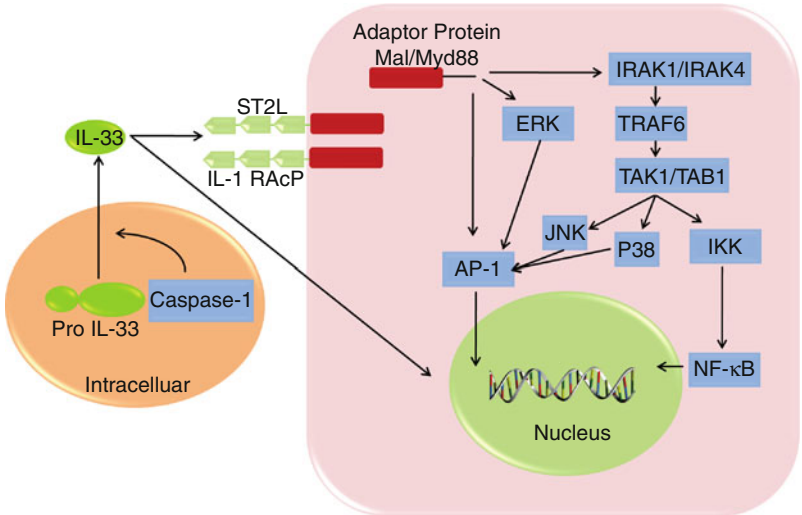
Involvement of MyD88 in IL-33 signaling has recently been clarified (Fig. 3). IL-33 appears to bind a receptor complex composed of ST2L (transmembrane bound form of ST2) and IL-1RAcP (IL-1 receptor accessory protein). In general, upon activation of a Toll-like receptor/IL-1-receptor superfamily member, the transmembrane receptor's TIR domain dimerizes with the TIR domain of cytosolic adaptor molecules. The adaptor proteins, MyD88 and the associated protein IRAKs activate downstream MAPKs through TRAF6 signaling, which in turn activates AP-1 through c-Jun N-terminal kinases (JNKs). TRAF6 also activates the inhibitor of NF-κB kinase (IKK) complex, leading to the downstream liberation of active NF-κB from the complex. IL-33 signaling appears to share many of these properties, and events downstream of IL-33 stimulation may include phosphorylation of extracellular signal-regulated kinase (ERK) 1/2, p38 MAPK, JNKs, and activation of NF-κB (Kakkar and Lee 2008).

An additional TLR-independent function of MyD88 was reported in CD95 (also known as FAS) signaling. CD95 signaling enhances IL-1R1 signaling by redirecting FADD (FAS-associated death domain) from a complex with MyD88 to the death domain of CD95, thereby allowing IL-1R1 to signal through MyD88 (Ma et al. 2004).

Antagonists of MyD88 Signaling

Although positive regulation of NF-κB, AP1, and IRFs via MyD88-dependent signaling has been extensively studied, recent studies have begun to unravel how these pathways are negatively regulated. The molecules that have been shown to negatively regulate MyD88-dependent signaling include MyD88s, transforming growth factor-β (TGF-β), IRAK-M, SIGIRR (single immunoglobulin IL-1-receptor-related molecule), and ST2L (Fig. 4).

MyD88, Myeloid Differentiation Primary Response Gene 88, Fig. 2 (continued) and recruits TRAF6. TRAF6 together with IRAK dissociates from the activated receptor and binds to the preformed complex of TAK1/TAB1/TAB2. TAK1 is a MAP3K involved in the activation of IκB kinase (IKK). Activation of IKK appears to require atypical polyubiquitination. The TRAF6/TAK1/TAB1/TAB2 complex associates with the heterodimeric ubiquitin-conjugating-enzyme UBC13/UEV1A. This results in modification of TRAF6 with the lysin63-linked polyubiquitin chain, which leads to IKK activation, IκB phosphorylation, ubiquitination, and degradation. NF-κB released from IκB translocates to the nucleus and switches on the transcription of a large number of proinflammatory genes. TAK1 is also responsible for activation of p38 and JNKs. MyD88 also couples to IRF5 and IRF1. In the case of TLR2 and TLR4 signaling, a bridging adaptor, Mal, is required for MyD88 recruitment. In the case of TLR7, 8 and 9, the MyD88-IRAK4 pathway also leads through TRAF6 to the activation of IRF7. Finally, IFNγR1 can also engage with MyD88, leading to activation of p38 through MLK3. MyD88, Myeloid differentiation primary response gene 88; IL-1R, Interleukin-1 receptor; NF-κB, nuclear factor-κB; IRAK4, IL-1R-associated kinase 4; TRAF6, tumor-necrosis-factor-receptor-associated factor 6; TAK1, transforming-growth-factor-β-activated kinase; TAB1, TAK1 binding protein; MAP3K, mitogen-activated-protein 3 kinase; UEV1A, ubiquitin-conjugating enzyme E2 variant 1 isoform A; UBC13, ubiquitin-conjugating enzyme 13; IFNγR1, interferon-γ-receptor 1; MLK3, mixed-lineage kinase 3

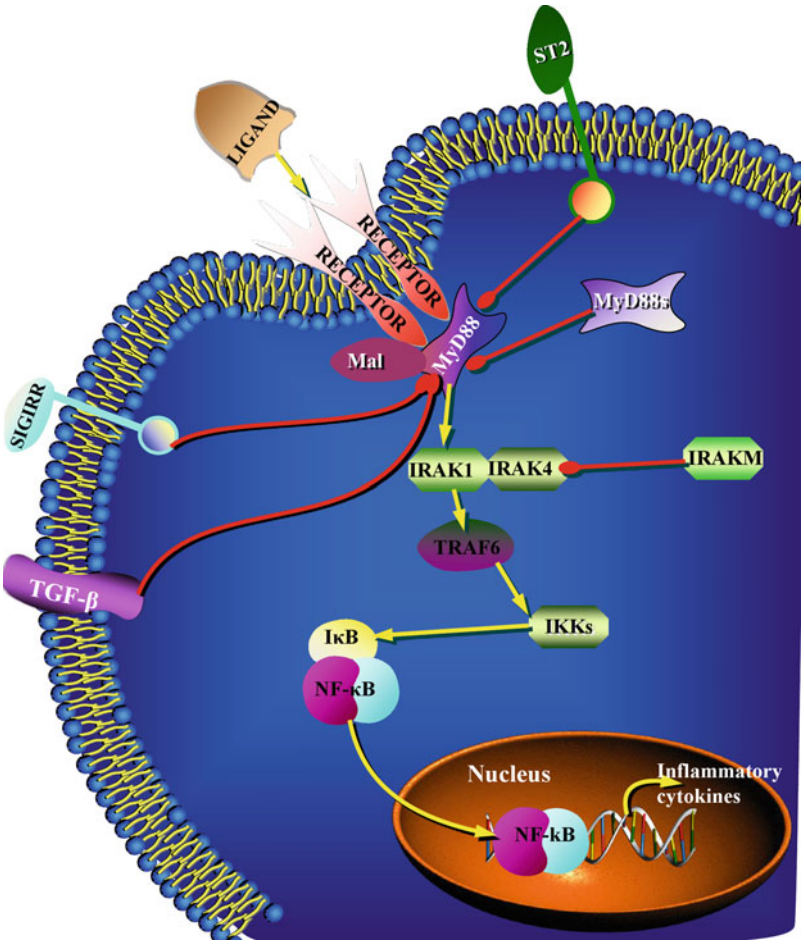


MyD88, Myeloid Differentiation Primary Response Gene 88, Fig. 3 *A model for IL-33/ST2 signaling*. MyD88-dependent pathway of Toll-like receptor signaling involves TIR dimerization between the receptor and the Mal. Recruitment of MyD88 and downstream activation of TRAF6 via IRAK proteins results in TRAF6-mediated activation of the IKK complex and liberation of NF-κB from the complex. Free NF-κB is then able to bind DNA and act as a gene transcription regulator. IL-33 signaling appears to share many of these properties, and events downstream of IL-33 stimulation may include phosphorylation of ERK 1/2, p38 MAPK, and JNKs and activation of NF-κB. IL-33 binds to its receptor complex, which is composed of ST2L and IL-1RAcP. Subsequent sequestering of the adaptor proteins, MyD88 and Mal, results in modulation of IRAK-mediated TRAF6 activation and subsequent MAPK and IKK/NF-κB activation. The nature of this modulation of NF-κB activity by IL-33 is complex. MyD88, Myeloid differentiation primary response gene 88; IL-33, Interleukin-33 receptor; NF-κB, nuclear factor-κB; IKK, inhibitor of NF-κB kinase; IRAK, IL-1R-associated kinase; TRAF6, tumor-necrosis-factor-receptor-associated factor 6; MAPK, mitogen-activated-protein kinase; IL-1RAcP, Interleukin-1 receptor accessory protein

MyD88s, an alternatively spliced variant form of MyD88 that lacks the ID, is induced in monocytes following stimulation with LPS (lipopolysaccharide). Overexpression of MyD88s inhibits IL-1- and LPS-induced NF-κB activation, but not TNF-induced NF-κB activation (Janssens et al. 2002). The mechanism of inhibition has been elucidated and shown to involve altered interactions in the downstream signaling pathway. Overexpression of MyD88s favors formation of MyD88s-MyD88 heterodimers, which are recruited to the receptor in favor of full-length MyD88 homodimers; however, the mechanism responsible for this process is not clear. In the presence of MyD88s-MyD88 heterodimers, IRAK1 was still recruited, presumably through a DD interaction with MyD88s, but was no longer phosphorylated. IRAK4 causes IRAK1 phosphorylation, and the presence of MyD88 is essential for this effect. MyD88s inhibits the ability of IRAK4 to phosphorylate IRAK1 because, unlike full-length MyD88, MyD88s does not interact with IRAK4. Although IRAK4 recruitment primarily requires the DD of MyD88, it also requires the ID for its binding with MyD88; therefore, the kinase is not recruited to the receptor complex (Janssens et al. 2003). This indicates that MyD88s might be involved in a negative-feedback regulatory mechanism to control excessive TLR-mediated signaling. Although MyD88s is inhibitory with respect to NF-κB signaling, overexpression of this adaptor still activates transcription factor AP1, implying an important role for alternative splicing in the fine-tuning of TLR responses (Janssens et al. 2003).

Another molecule that has been shown to negatively regulate MyD88-dependent signaling is TGF-β. Naiki et al. showed that TGF-β blocked NF-κB activation and cytokine production in response to TLR2, 4 and 5 ligands by decreasing MyD88 protein, but not mRNA levels (Naiki et al. 2005). TGF-β was found to cause the ubiquitination of MyD88 and an observed decrease in MyD88 protein levels. Furthermore, a protease inhibitor was found to abolish this effect, suggesting that TGF-β causes the polyubiquitination of MyD88, resulting in its proteasomal degradation.

Another negative regulator of MyD88 signaling is IRAK-M, which is primarily found in cells of



MyD88, Myeloid Differentiation Primary Response Gene 88,

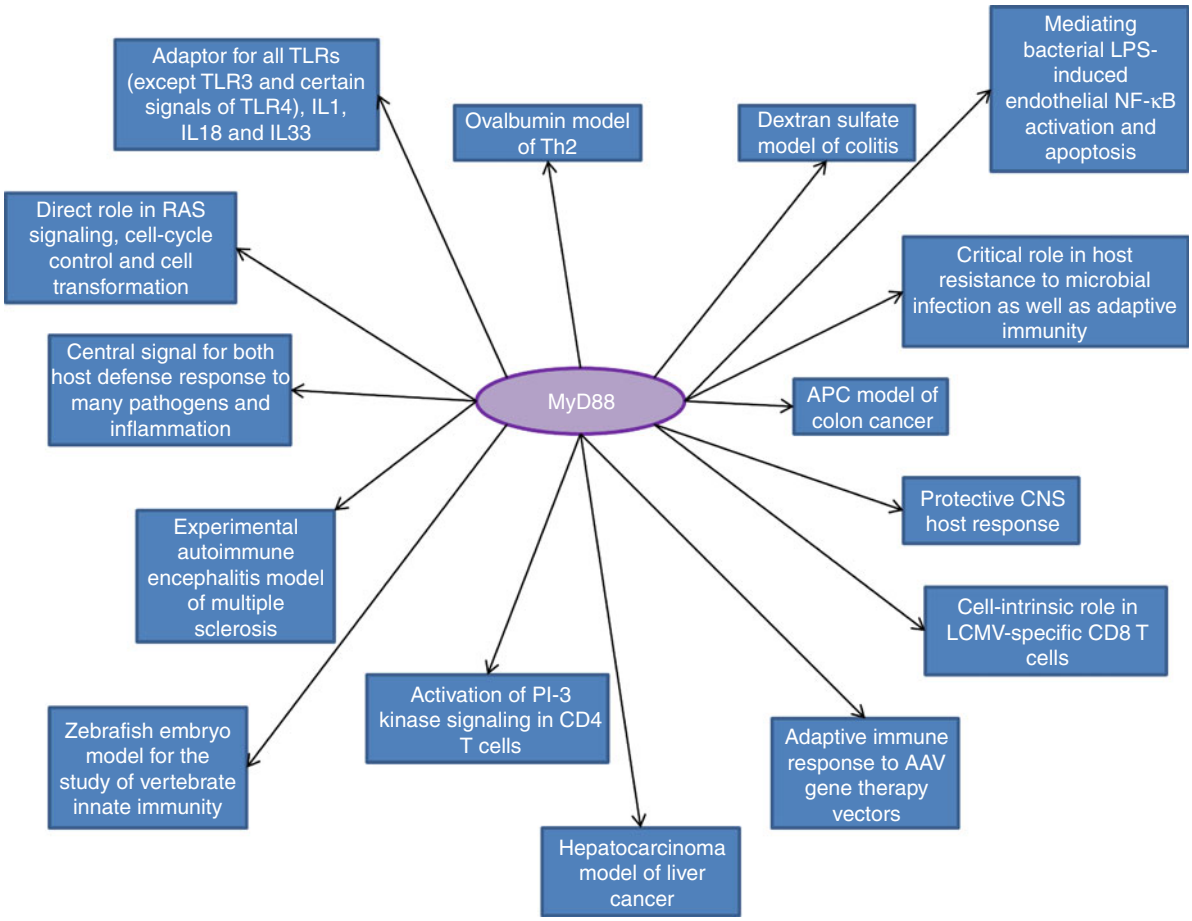
Fig. 4 *Negative regulation of MyD88-dependent signaling.* MyD88-dependent signaling pathways are negatively regulated by several molecules that are induced by the stimulation of receptors. IRAK-M inhibits the dissociation of the IRAK1-IRAK4 complex from the receptor. MyD88s blocks the association of IRAK4 with MyD88. TGF-β blocks NF-κB activation and cytokine production in response to TLR2, 4 and 5 ligands by decreasing MyD88 protein. The TIR-domain-containing receptors, SIGIRR and ST2L, have also been shown to negatively regulate MyD88-dependent signaling. IRAK-M, IL-1R-associated kinase M; MyD88s, MyD88 short; TGF-β, transforming growth factor-β; SIGIRR, single immunoglobulin IL-1-receptor-related molecule; ST2L, transmembrane bound form of ST2

monomyeloic origin such as monocytes and is induced upon TLR stimulation (Wesche et al. 1999). IRAK-M acts to prevent the dissociation of IRAK1 and IRAK4, which results in IRAK1 being unable to interact with TRAF6 and therefore unable to induce a signaling cascade. IRAK-M deficient cells exhibited increased cytokine production upon TLR/IL-1 stimulation and bacterial challenge.

Another important negative regulatory mechanism for MyD88-dependent signaling involves the transmembrane proteins, ST2L and SIGIRR (both members of the TIR superfamily). ST2L interacts with MyD88 and Mal and sequesters MyD88-dependent NF-κB activation by TLR2, 4 and 9 signaling pathways (Brint et al. 2004). SIGIRR binds to TLR4 and IRAK and terminates the downstream TLR signaling pathways (Wald et al. 2003). These findings indicate that MyD88 serves as an important point of control for signaling through various receptors.

Multiple Roles of MyD88

Studies conducted in the past few years have firmly established the central role of MyD88 adaptor in inflammation and immunity (Fig. 5). As mentioned above, much of the recent scientific literature has focused on the role of MyD88 with respect to TLR signaling leading to the activation of several signaling cascades including the NF-κB pathway, resulting in the production of proinflammatory cytokines/chemokines and upregulation of co-stimulatory and adhesion molecules involved in both innate and adaptive immune responses. MyD88 is also essential for transducing signals from IL-1R family members, including IL-1R, IL-18R, and several other receptors. Furthermore, Andrew et al. identified the role of MyD88 in the activation of PI-3 kinase signaling in $CD4^+$ T cells, thereby enabling CpG oligodeoxynucleotide-mediated co-stimulation (Gelman et al. 2006).



MyD88, Myeloid Differentiation Primary Response Gene 88, Fig. 5 *Diverse roles of MyD88.* MyD88 is essential for signaling by IL-1, IL-18, IL-33, and all TLRs (except TLR3 and certain TLR4 signals) and is a central signal for many processes involving host defense to infection, inflammation, and cancer. MyD88 is required for inflammation in the ovalbumin model of Th2 responses, the collagen-induced arthritis model of rheumatoid arthritis (RA), the dextran sulfate model of colitis, the APC model of colon cancer, a hepatocarcinoma model, and the experimental autoimmune encephalitis model of multiple sclerosis (MS). MyD88 plays a potent cell-intrinsic role in lymphocytic *choriomeningitis* virus (LCMV)-specific CD8 T cells, activation of PI-3 kinase signaling in $CD4^+$ T cells, and a direct role in RAS signaling, cell cycle control, and cell transformation, implicating its role in tumorigenesis via proinflammatory mechanisms. MyD88 also plays an important role in innate immune signaling mechanisms during vertebrate embryogenesis in a zebrafish embryo model. TLR9-MyD88 pathway is known to be critical for adaptive immune responses to adeno-associated virus (AAV) gene therapy vectors in mice. Bovine Mal and MyD88 are essential to mediation of bacterial LPS-induced endothelial NF-κB activation and apoptosis. MyD88 also establishes a protective CNS host response during the early stages of brain abscess development, thus exhibiting its central role in the responses of microglia to PAMPs

The overall importance of MyD88 is demonstrated by the results of many studies involving MyD88-deficient mice. Targeted disruption of the MyD88 gene results in loss of TLR, IL-1, IL-33, and IL-18-mediated functions (Adachi et al. 1998). MyD88-deficient mice have been subjected to many models of infection, inflammation, and recently cancer (Takeuchi et al. 2000a; Naugler et al. 2007; Rakoff-Nahoum and Medzhitov 2007), and the results have shown that MyD88 is essential for the inflammation seen in models of airway hyperreactivity, colitis, and APC model of colon cancer and hepatocarcinoma (Naugler et al. 2007; Rakoff-Nahoum and Medzhitov 2007; Araki et al. 2005; Piggott et al. 2005). MyD88-deficient mice fail to generate pro-inflammatory and Th1 responses when stimulated with TLR ligands (Schnare et al. 2001). Additionally, these mice are highly susceptible to infection by a wide variety of different pathogens, including *Staphylococcus aureus*

(Takeuchi et al. 2000b), *Listeria monocytogenes* (Seki et al. 2002), *Toxoplasma gondii* (Scanga et al. 2002), and *Mycobacterium tuberculosis* (Shi et al. 2003). MyD88-deficient mice are also highly susceptible to *Leishmania major* infection associated with a polarized Th2 response (Muraille et al. 2003). An impaired production of proinflammatory cytokines and host resistance to acute infection with *Trypanosoma cruzi* is conspicuous in mice lacking functional MyD88 (Campos et al. 2004). MyD88 has generally been considered to indirectly regulate adaptive immune responses by controlling inflammatory cytokine production and antigen (Ag) presentation in innate immune cells; however, Rahman et al. identified an unappreciated cell-intrinsic role of MyD88 in lymphocytic *choriomeningitis* virus (LCMV)-specific CD8 T cells (Rahman et al. 2008). Their results demonstrated the importance of MyD88-dependent signals for supporting the survival of the cells and sustained accumulation. MyD88-dependent signaling is also required for the control of *ehrlichial* infection via a potent role in immediate activation of the innate immune system and inflammatory cytokine production, as well as in activation of the adaptive immune system at a later stage by providing for optimal Th1 immune responses (Koh et al. 2010).

MyD88 contributes to regulation of cell proliferation and differentiation in human adipose tissue-derived mesenchymal stem cells (hASCs) (Yu et al. 2008). Astrid et al. demonstrated that the innate immune response of the developing embryo involves MyD88-dependent signaling by utilizing the zebrafish embryo as a model for a study of vertebrate innate immunity (van der Sar et al. 2006). The TLR9-MyD88 pathway has also been shown to be critical for adaptive immune responses to adeno-associated virus (AAV) gene therapy vectors in mice (Zhu et al. 2009). Both MAVS and MyD88 are known to be essential for innate immunity, but not cytotoxic T lymphocyte response against respiratory *syncytial* virus (Bhoj et al. 2008), thereby providing an example of a normal and effective adaptive immune response in the absence of innate immunity. Cates et al. demonstrated that bovine Mal and MyD88 are essential for mediation of bacterial LPS-induced endothelial NF-κB activation and apoptosis (Cates et al. 2009). Furthermore, Tammy et al. showed an essential role enacted by MyD88 in establishment of a protective CNS host response during the early stages of brain abscess development (Esen and Kielian 2006), thus exhibiting a central role for MyD88 in the responses of microglia to pathogen-associated molecular patterns (PAMPs).

Recently, Isabelle et al. demonstrated that, in addition to its role in inflammation, MyD88 played a crucial direct role in RAS signaling, cell cycle control, and cell transformation, thus demonstrating its potent role in tumorigenesis via proinflammatory mechanisms (Coste et al. 2010). Bettina et al. showed that both MyD88 and TRIF are nonredundant signaling pathways involved in early endotoxin-induced rodent ileus, and that MyD88 is the essential adaptor molecule involved in the transduction of early TLR4-induced ileus and inflammatory signaling (Buchholz et al. 2010). These findings have led to the conclusion that MyD88 plays a critical role in host resistance to microbial infection, inflammation, and innate and adaptive immunity.

Summary

Numerous reports conducted in the past few years have established MyD88 as a universal and essential signaling adaptor molecule that is critical for an effective immune response against a wide range of microbial pathogens. MyD88 fulfills important functions in both innate and adaptive immunity, inflammation, and programmed cell death. However, much remains to be learned about the in vivo functions of MyD88 in higher organisms. Future studies should address the prospect of a detailed molecular account of the MyD88 interaction at the DD, ID, and TIR levels with receptors and adaptor proteins. Moreover, the underlying factors involved in MyD88 direct/indirect (via the use of other adaptors) interaction with receptors following ligand stimulation have yet to be elucidated. Joined efforts among researchers will help us to understand the molecular mechanisms by which MyD88 functions in cellular processes. MyD88-related findings have proven to be fruitful in terms of improving our knowledge of the molecular basis for innate immunity and inflammation, and thus we can anticipate further discoveries in the coming years.

Synonyms

MLCK; MLCK108; MLCK210; MYLK1; Nonmuscle myosin light chain kinase; smMLCK; Smooth muscle myosin light chain kinase

Historical Background

The gene for myosin light chain kinase encodes three proteins: MLCK210, MLCK108, and -telokin/kinase-related protein (KRP). The first protein discovered was MLCK108 (Mr = 110–140 kDa) as a major cytoplasmic component of smooth muscle and responsible for smooth muscle contractility through the phoshorylation of the regulatory light chain of myosin (Kamm and Stull 2001; Lukas et al. 1998). MLCK210 (Mr = 210–220 kDa) has an amino-terminal extension containing additional protein-binding elements (Fig. 1). It was discovered ~15 years later before the gene for MYLK was characterized from chicken (Birukov et al. 1998) and humans (Lazar and Garcia 1999). Both MLCKs are Ca^{2+} -calmodulin-dependent enzymes. Telokin/KRP is an independently expressed non-kinase gene product containing the C-terminus of MLCK, and functions as a ▶ myosin-binding and filament-stabilizing protein (Shirinsky et al. 1993). Telokin/KRP is primarily expressed in smooth muscle and modulates contractility by regulating the access of protein kinases to myosin light chains (Shcherbakova et al. 2010). It has also been implicated in activation of the myosin light chain phosphatase by an unknown mechanism (Choudhury et al. 2004).

MLCK-Domain Structure and Human Genetics

As shown in Fig. 1, MLCK is a multidomain protein. MLCK108 has amino-terminal actin-binding motifs, a protein kinase catalytic domain, calmodulin regulatory domain, and the myosin-binding (telokin/KRP) domain. Within the amino-terminal domains are IgG C2-like domain motifs and fibronectin-like motifs that may be mediators of other protein–protein interactions within the cell. Similarly, the amino-terminal extension found in the MLCK210 isoform has six additional IgG domains and actin-binding motifs (Kamm and Stull 2001). The additional actin-binding motifs in MLCK210 allow stronger interactions with the actin cytoskeleton (Kamm and Stull 2001), while the expanded IgG domain motifs may be associated with binding to other proteins such as tubulin (Kudryashov et al. 2004), Macrophage migration inhibition factor (MIF) (Wadgaonkar et al. 2005), Arrested in development 1(ARD1) (Shin et al. 2009), and Supervillin (Takizawa et al. 2007).

Single nucleotide polymorphisms (SNPs) in the MYLK gene (Human chromosome 3q21) have been associated with two conditions: severe inflammatory lung disease, including asthma, and sepsis (Gao et al. 2007). It is interesting that African-derived and Caucasian populations differ in the frequency of various polymorphisms, which may make them risk factors in one population, but not the other. For example, a haplotype containing SNP rs9361070, which is within the promoter region of MLCK108, was negatively associated with asthma (Decreased risk) in both American and Caribbean families. However, the same haplotype conferred risk for severe sepsis (Gao et al. 2007). Microarray studies of mRNA from blood cells in the various patient population indicated that there was a decrease in MLCK expression associated with the minor allele of SNP rs9361070. This may explain the reduced risk of asthma, because MLCK expression is upregulated in asthmatic airway tissue (Stephens et al. 2007). African Americans are also at higher risk for glaucoma and there is an increased expression of MLCK108 in the optic nerve head astrocytes of African Americans compared to Caucasian populations, although specific polymorphisms have not been identified with disease. On the other hand, MLCK210 is upregulated in glaucomatous astrocytes of both populations (Lukas et al. 2008). Finally, upregulation of MLCK210 is associated with inflammatory bowel disease, but as with glaucoma, no polymorphisms have been associated with disease (Blair et al. 2006).

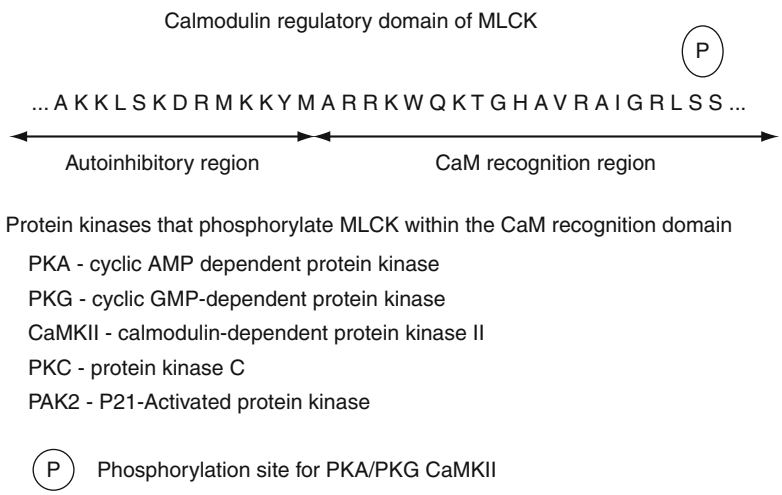
MYLK (Myosin Light Chain Kinase), Fig. 2 Promoters within the myosin light chain kinase gene. *Upper* part of the figure describes where the four promoters are located. The *bottom* part of the figure has the approximate location of transcription factor binding motifs within MLCK210 and MLCK108 promoters

Expression of MLCK Isoforms

MLCK108 is expressed in most tissues, with lower levels appearing in embryonic cells and precursors. MLCK210 specific expression occurs predominantly in endothelial cells of blood vessels and epithelial cells of the intestine and lung (Blue et al. 2002). Primary cells such as those from smooth muscle often exhibit decreased expression of MLCK108 when placed in tissue culture (Blue et al. 2002).

MLCK108, MLCK210, and telokin/KRP expression are independently regulated. Figure 2 illustrates the relationships among the transcripts produced from the MYLK. The promoter for MLCK108 contains several serum response factor (SRF) elements that are often associated with smooth muscle gene expression. Promoter analysis indicates that myocardin, an SRF activator, is necessary for high-level expression of MLCK108 and telokin/KRP in smooth muscle. GATA-6, an SRF repressor may be responsible for the downregulation of MLCK108 and telokin/KRP in nonmuscle tissues (Herring et al. 2006). In addition to SRF other trans-acting factors that affect MLCK108 and/or telokin/KRP expression include thyrotroph

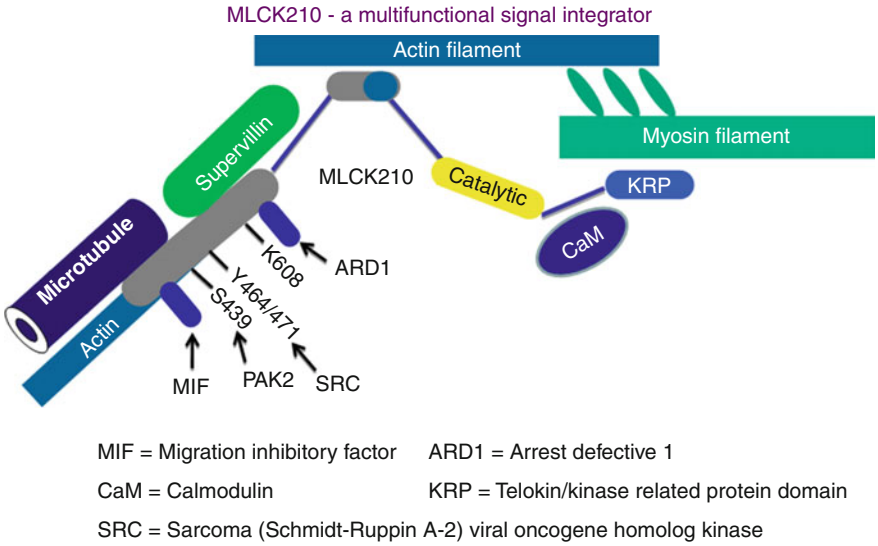


MYLK (Myosin Light Chain Kinase), Fig. 3 Calmodulin regulatory domain of MLCK. This domain contains the autoinhibitory and calmodulin recognition region and a listing of protein kinases that modulate Ca^{2+} -calmodulin binding through phosphorylation at the C-terminal end of this region. The legend indicates the protein kinases that phosphorylate one of the two serines within the RLSS sequence

embryonic factor (TEFB), FoxQ1 and Hox proteins. These factors bind to AT-rich regions adjacent to the SRF sites (Herring et al. 2006). In the case of MLCK210, the promoter is more complex because there are two alternate start sites for exon 1 each containing its own upstream promoter (Fig. 2). MLCK210 expression in epithelial cell types is inducible by tissue necrosis factor alpha (▶ TNFα) (Graham et al. 2006). However, two types of transcriptional motifs are involved. In the upstream promoter sequence of MLCK210 (Transcript #1 –Exon 1A) there are at least two NFκB motifs and at least four AP-1 sites in either promoter region (Fig. 2). These are important for the induction of MLCK210 by ▶ TNFα in epithelial cells. However, the relative importance of NFκB compared to AP-1 transcriptional activity is dependent on the extent of cell differentiation with NFκB declining and AP-1 increasing with cell confluence (Graham et al. 2006). The promoter for MLCK210 transcript #1 also contains two SP1 motifs at −275 and −218 bp upstream of the transcriptional start site that are responsible for basal MLCK210 promoter activity (Graham et al. 2006). Detailed promoter activity analysis for transcript #2 (Exon 1B) has not yet been reported but the presence of a common set of transcription factor binding motifs suggests that this activity will be similar to the Exon 1 promoter.

MLCK and Signal Transduction

As mentioned earlier, MLCK108 is one of the kinases responsible for Ca^{2+}-stimulated contraction of smooth muscle (Kamm and Stull 2001). Ca^{2+} calmodulin-dependent activation is further modulated by phosphorylation at serine residues within the calmodulin regulatory region (Fig. 3). This region has two subdomains that function to maintain the kinase in an autoinhibited state that is released when calmodulin binds and activates the enzyme (Lukas et al. 1998). Site-directed mutagenesis studies established the importance of selected charged residues within the autoinhibitory- and calmodulin-binding domains with respect to autoinhibition and calmodulin binding. Calmodulin-dependent protein kinase II, ▶ PAK2, and cyclic nucleotide (cyclic AMP, cyclic GMP)-dependent protein kinases are capable of phosphorylating sites within the calmodulin-binding domain (Fig. 3) and decrease the Ca^{2+} sensitivity of MLCK activation (Kamm and Stull 2001). MLCK210 is also phosphorylated by PAK2 at Ser-439, but this has not been associated with decreased MLCK activity (Kamm and Stull 2001). On the other hand, phosphorylation of MLCK by MAP Kinase stimulates activity in cultured tumor cells. A unique tyrosine phosphorylation site (Y464) is found in one splice form of MLCK210 and tyrosine phosphorylation of MLCK210 in cultured cells has been observed after stimulation with a tyrosine phosphatase inhibitor or constitutively activated epidermal growth factor (EGF) receptor (Kamm and Stull 2001). Although this site is distal from the calmodulin and kinase catalytic domains, tyrosine phosphorylation slightly increases MLCK210 activity (Kamm and Stull 2001).



MYLK (Myosin Light Chain Kinase), Fig. 4 MLCK210 contains multiple interaction sites for cytoskeletal and regulatory proteins. Shown in this figure are selected binding partners for MLCK210 that interact with MLCK210 as well as those shared by MLCK108 (Actin, CaM, and myosin)

MLCK210 as a Signal Integrator

The interactions of MLCK210 with various kinases as well as with specific proteins within the amino-terminal tail suggest that MLCK210 may coordinate (integrate) signaling from other cellular processes (Kudryashov et al. 2004). This may be particularly important in the cell types that express MLCK210 and contain mostly actin and little myosin, so that MLCK catalytic activity contributes toward changes in cell morphology and/or migration rather than a contractile event as found in smooth muscle. A summary of such signal integrations is illustrated in Fig. 4. Clearly, not all of these interactions happen in every tissue/cell type. However, selected sets of interactions and signaling events that regulate MLCK localization and activity are likely to play a role in specific cellular processes.

Interactions between MLCK210, MIF, and actomyosin fibers of the cytoskeleton may be important in endothelial cells involved in an inflammatory response (Wadgaonkar et al. 2005). Likewise, recruitment and activation of Pyk2 tyrosine kinase by MLCK210 amino-terminal tail is required for full activation of β_2 integrins and neutrophil transmigration through microvascular wall in sepsis-induced lung inflammation model (Xu et al. 2008). Membrane-associated scaffolding protein supervillin also directly interacts with MLCK210 N-terminus as well as with myosin II. Through these interactions, supervillin apparently modulates myosin II activation by MLCK210 and contributes to myosin II assembly during cell spreading (Takizawa et al. 2007).

MYLK (Myosin Light Chain Kinase), Table 1 Predicted Serine (S) and Threonine (T) phosphrylation sites in MLCK210

Site	Kinase	Score
S-10	PKC	0.81
T-185	PKC	0.71
S-239	PKC	0.86
S-298	PKC	0.71
S-324	PKC	0.84
T-430	PKC	0.82
S-482	PKA	0.72
T-599	PKC	0.89
S-605	PKC	0.86
S-609	PKA	0.80
T-643	PKC	0.73
S-733	PKC	0.76

Sites were found by analyzing the MLCK210 amino acid sequence using the NetPhos 1.0 Web site (http://www.cbs.dtu.dk/services/NetPhosK/) using a cutoff of 0.7 and no additional filtering. Only predicted sites within the N-terminal extension domain are shown

In addition to the identified sites at tyrosine 464/471, and serine 439 (Fig. 4), MLCK210 has multiple predicted phosphorylation sites in the N-terminal tail domain that may dynamically regulate localization and function of this protein (Table 1). For example, phosphorylation of an MLCK210 N-terminal tail construct in vitro alters the actin filament binding and phosphomimiking mutant of MLCK210 N-terminal tail has reduced binding to the cytoskeleton in cultured

cells (V.P. Shirinsky, unpublished data). In another study, the N-terminal domain of MLCK210 is differentially phosphorylated and localized in mitotic and interphase cultured cells suggesting that phosphorylation (by the kinase Aurora B) may impact MLCK210 cellular localization (Dulyaninova and Bresnick 2004). Similarly, ARD1 is a lysine acetylase that targets a site (Lys-608) in a Ca^{2+}-dependent fashion (Shin et al. 2009). Acetylation of MLCK210 reduces myosin light chain phosphorylation (Shin et al. 2009). Therefore, the signal integrating functions of MLCK210 are likely to by dynamically regulated through post-translational modifications such as acetylation and phosphorylation.

Summary: Future Work on MLCK Function

Details of the involvement of MLCK, particularly MLCK210 in cellular processes that mediate cell migration, epithelial, and endothelial barrier functions are still emerging. Population genetics studies are needed to determine whether specific variants in MLCK210 are associated with increased risk for specific conditions such as glaucoma and inflammatory bowel disease. Two complex promoters for MLCK210 are suggestive that tight regulation of its expression is key to cellular homeostasis in particular cell phenotypes. Alterations of MLCK210 expression in multiple human diseases such as cancer, lung injury, glaucoma, and inflammatory bowel disease indicate that MLCK210 is a potential target for pharmacological and/or genetic intervention. Additionally, cell interactions of the unique N-terminal tail region in MLCK210 with multiple cytoskeletal and signal transduction proteins offers opportunities for specific intervention at the level of protein–protein interactions. Finally, the posttranscriptional regulation of MLCK gene product expression through reagents such as siRNA and endogenous miRNAs will contribute to the array of tools used to modulate MLCK210 activities.

Nomenclature

The nomenclature of myosins I is confusing, although there is general agreement in the naming of myosins I in vertebrates (Gillespie et al. 2001). The names used in vertebrates, however, do not correspond to those used in lower organisms. The following names have been used to refer to class I myosins:

In yeast: Myo3, Myo5

In *Acanthamoeba*: Myosin IA-C

In *Dictyostelium*: MyoA-F, K

In *Caenorhabditis elegans*: Myo1A or HUM-1; HUM-5

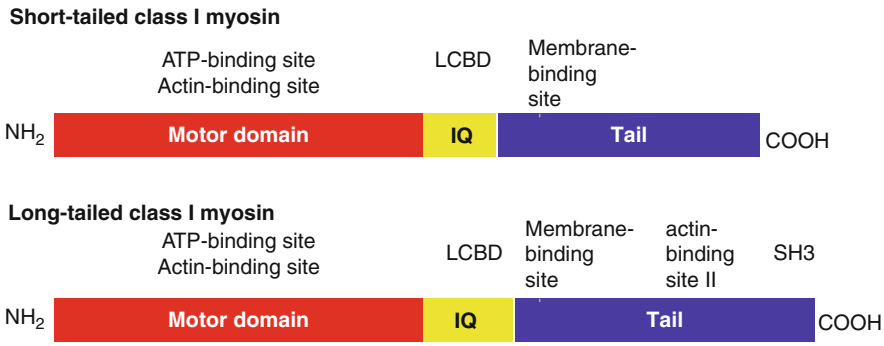
In *Drosophila:* Myo1A (Myo31DF, CG7438); Myo1B (Myo61F, CG9155)

In vertebrates: Myo1a-h; (MyoA-H in humans)

Myo1a (Brush border myosin I, 110kDa-calmodulin complex)
Myo1b (myr 1, myosin-Iα, 130-kDa myosin I)
Myo1c (myr 2, myosin-Iβ,110-kDa myosin I)
Myo1d (myr 4, myosin-Iγ, 105-kDa myosin I)
Myo1e (myr 3, human myosin-1C)
Myo1f
Myo1g
Myo1h

Historical Background

Myosin 1 is the largest of ~35 different classes of proteins that comprise the myosin superfamily, a collection of actin-associated molecular motor proteins that use the energy from ATP hydrolysis to translocate actin filaments. In the early 1970s Pollard and Korn identified in the soil amoeba, *Acanthamoeba,* the first myosin I, a relatively short, single polypeptide chain with an actin-activated ATPase activity resembling that of thick filament-forming myosin (II) from skeletal muscle, which was already known. A major difference was that unlike muscle myosin, the *Acanthamoeba* protein was single-headed and nonfilamentous. Subsequently, the first myosin I in vertebrates, the 110K-calmodulin complex or brush border myosin I (renamed Myo1a), was identified by several different research groups. In vertebrates, Myo1a forms lateral links that connect the core bundle of actin filaments in intestinal microvilli to the microvillar membrane. It is now known that multiple class I myosins are expressed in cells including two class I myosins in yeast (Myo3 and Myo5); three class I myosins in *Acanthamoeba* (myosin IA-C); 7 class I myosins in the slime mold, *Dictyostelium* (MyoA-F, K); 2 in the nematode, *Caenorhabditis elegans* (Myo1A or HUM-1; HUM-5); 2 class I myosins in the fly, *Drosophila melanogaster*



Myosin I (Myo1), Fig. 1 Schematic of short-tailed and long-tailed class I myosins showing the differences in tail domains. In addition to the membrane-binding domain found in short-tailed myosins I, long-tailed class I myosins contain in some cases an ATP-insensitive actin-binding site and an SH3 domain found in signaling proteins

(Myo1A and Myo1B); and 8 class I myosins in humans (Myo1A-H), and that these myosins are involved in a variety of different cellular events. More comprehensive recent reviews with extensive references are available (Coluccio 2008; Kim and Flavell 2008).

Myosin Structure

Myosins I are single polypeptide chains of 110–140 kDa containing a motor domain, a light-chain-binding domain (LCBD), and a tail region.

As with all myosins, the motor domains of class I myosins contain the nucleotide- and actin-binding sites. They share many of the highly conserved amino acid residues found in myosin II and other myosins. So far, the only available atomic structure of a class I myosin is that of the motor domain of *Dictyostelium* MyoE (Kollmar et al. 2002), which resembles the available solved structures of other myosin motor domains, although the surface loops differ in length and the position of the lever arm is 30° further up.

The LCBD of class I myosins is an alpha-helical region containing one or more repeats of ~29 amino acids called IQ regions for the isoleucine and glutamine residues that are normally present. The LCBDs of class I myosins bind calmodulin or light chains that resemble calmodulin. Alternate splicing can occur in the LCBD, e.g., mammalian Myo1b has 6 IQ regions, but is alternatively spliced in the cell to 4-IQ and 5-IQ forms. The sequences of the IQ domains vary among isoforms, as does the affinity of the light chains for the specific IQ domain, suggesting that the myosins might not have a full complement of light chains under all intracellular conditions.

Although the C-terminal tails of class I myosins are diverse, they all contain a membrane-binding domain with different affinities for specific phosphoinositides, which might account for differential localization of myosins I in cells (Fig. 1). Unlike short-tailed myosins I which contain only the membrane-binding domain, other class I myosins are long-tailed, which contain in some cases an ATP-insensitive actin-binding site and a Src-homology 3 (SH3) domain common to many proteins involved in signal transduction. In yeast, the SH3 domain binds proline-rich regions in the WASP-like adapter protein, Bee1p/Las17, and the actin-binding protein, verpolin (Vrp1p), which is analogous to human WASP-interacting protein (WIP). Verpolin is important in the localization of the yeast class I myosins, Myo3 and Myo5, to cortical structures found at sites of polarized growth and actin organization. Myo3/Myo5 and Bee1p bind and stimulate the actin-nucleating properties of the Arp2/3 complex (Anderson et al. 1998). The amoeboid myosins I also regulate actin assembly, but through a mechanism different from that of yeast. The SH3 domains of MyoB and MyoC from *Dictyostelium* bind a linker protein known as CARMIL (an analogous protein, Acan125, is found in *Acanthamoeba*), which associates with the Arp2/3 complex and capping protein to mediate actin assembly (Jung et al. 2001).

Phylogenetic trees show that class I myosins, which probably resemble the first myosin, are related evolutionarily and can be divided into four subclasses based on the amino acid sequences of their motor

domains. The amoeboid myosins I and long-tailed vertebrate Myo1e and Myo1f constitute subclass 1. Vertebrate Myo1a and Myo1b constitute subclass 2. Vertebrate Myo1c and Myo1h constitute subclass 3. Vertebrate Myo1d and Myo1g, along with *Drosophila* 1A and *C. elegans* HUM-1 and HUM-5, constitute subclass 4.

Biochemical and Mechanical Properties

Actin activates the Mg^{2+}-ATPase activity of the lower eukaryotic class I myosins 60-fold to a level similar to that of rabbit skeletal muscle myosin II; however, the ATPase activity of vertebrate class I myosins is only modestly activated by actin. Kinetic analyses indicate that class I myosins spend most of their time weakly bound to actin (i.e., they have a low duty ratio). Activation of the steady-state ATPase activity of myosins I can show a hyperbolic relationship with increasing actin concentration (e.g., Myo1a, Myo1b, Myo1c) or be triphasic (e.g., *Acanthamoeba* IA and IB, vertebrate Myo1e) with activation at low actin concentrations, inhibition at moderate actin concentrations, and further activation at high actin concentrations. This triphasic behavior was originally attributed to the presence of an ATP-insensitive actin-binding site in the tail; however, Myo1e does not have an ATP-insensitive actin-binding site, so the reason for this triphasic behavior remains unclear (see El-Mezgueldi and Bagshaw 2008).

Single-molecule mechanical studies showed that the interaction of myosin I with actin occurs in two parts representing release of inorganic phosphate followed by ADP release (Veigel et al. 1999; Batters et al. 2004). These results together with results from structural studies showing that class I myosins undergo an ADP-induced conformational change and kinetic studies showing that the change in fluorescence when ATP is added to pyrene actin-myosin I is biphasic, consisting of a fast phase followed by a slow phase, led to the hypothesis that some class I myosins are sensitive to strain (Coluccio and Geeves 1999). This hypothesis is supported by other single-molecule studies showing that the rate of detachment of Myo1b from actin decreases 75-fold under tension (Laakso et al. 2008). Furthermore, membrane tension increases in cells overexpressing class I myosins (Nambiar et al. 2009).

Regulation

Phosphorylation of a single serine or threonine between the ATP- and actin-binding sites in the heavy chain of the *Acanthamoeba* and *Dictyostelium* myosins I regulates their actin-activated Mg^{2+}-ATPase and motor activities. Phosphorylation by the myosin I heavy chain kinase, MIHCK, which is a p21-activated kinase (PAK) enhances the ATPase activity 40–80 fold (Brzeska et al. 1997). In vertebrate myosins I, negatively charged glutamate or aspartate is present at the corresponding site, known as the TEDS site after the one-letter codes for the amino acids found at the site, indicating that these myosins I are constitutively active (Bement and Mooseker 1995).

The vertebrate class I myosins translocate actin filaments in vitro albeit slowly. Although the ATPase activity is higher in calcium vs. EGTA, the rate of actin translocation is less in buffers containing calcium. This inhibition is reversed in the presence of exogenous calmodulin suggesting that calcium causes calmodulin dissociation from the LCBD thereby compromising its function as a lever arm and ability to support motility. In the case of Myo1c, calmodulin dissociation might reveal sites that are then available to interact with receptors on hair cells in the inner ear (Cyr et al. 2002).

The steady-state ATPase activity of a fragment of mammalian Myo1c consisting of the motor domain and first IQ domain, $Myo1c^{1IQ}$, is relatively insensitive to calcium; however, individual steps in the cyclic interaction of $Myo1c^{1IQ}$ with actin including the ATP hydrolysis step (7-fold inhibition) and ADP release (10-fold acceleration) are sensitive to calcium, which would result in acceleration in the detachment of the Myo1c crossbridge and lengthening of the lifetime of the detached M-ATP state (Adamek et al. 2008). This modulation by calcium could have important implications, especially for Myo1c function in the inner ear, where mechanotransduction involves changes in free calcium concentration as channels open and close in response to sound and vibration.

Function

Yeast in which one of the two class I myosins, Myo3 and Myo5, is deleted have no phenotype, although cells in which both myosins are deleted round up and exhibit an accumulation of intracellular vesicles and

sensitivity to osmotic shock. The three myosin I isoforms from *Acanthamoeba* – myosin 1A, 1B, and 1C – have both distinct and overlapping localization patterns and functions. Each is associated with the cell membrane, but only myosin 1C is found at contractile vacuoles. Amoebae loaded with anti-myosin 1C, but not anti-myosin 1B, become large with vacuoles and lyse in response to osmotic shock suggesting that myosin 1C is involved in the expulsion of water from contractile vacuoles. *Dictyostelium* amoebae are viable when any one of the seven myosin I genes expressed in that organism is deleted demonstrating functional redundancy among the isoforms. Amoebae lacking MyoA or MyoB show defects in speed of locomotion, formation of pseudopods, and directionality of movement. Cells, in which two or three isoforms are deleted, are deficient in pseudopod formation, motility, pinocytosis, membrane ruffling, endocytosis, secretion, and cortical tension (Ostap and Pollard 1996).

The two myosin I isoforms in *Drosophila*, Myo1A and Myo1B, are most closely related to mammalian Myo1d and Myo1c, respectively and are implicated in left-right symmetry (Hozumi et al. 2006; Spéder et al. 2006). Although both isoforms are expressed in brush border of the midgut, Myo1b is found along the length of the apical microvilli and is required for integrity of the brush border and resistance to bacterial infection (Hegan et al. 2007).

Significant progress in understanding the roles of the class I myosins in mammalian cells is being made. Although there are defects in the morphology of the microvillar membrane, mice in which expression of Myo1a is knocked out show little change in phenotype indicating that other myosins substitute for the loss of Myo1a (Benesh et al. 2010). Unlike Myo1a, which is found predominantly in intestine, Myo1b, which is most closely related to Myo1a, is ubiquitously expressed. Overexpression of Myo1b affects the distribution of endocytotic compartments suggesting that Myo1b plays a role in endocytosis (Raposo et al. 1999). Myo1c, also found in a variety of different cell types, supports the insulin-induced exocytic fusion of vesicles containing GLUT4 in adipocytes (Bose et al. 2002). In the specialized hair cells of the inner ear, Myo1c mediates adaptation, a process by which stimulated cells remain sensitive to new stimuli (Holt et al. 2002). In *Xenopus* eggs Myo1c plays a role in the compensatory endocytosis of cortical granule membranes after secretion (Sokac et al. 2006). Nuclear Myo1c, which differs from Myo1c by the presence of an N-terminal extension, supports RNA synthesis (Hofmann et al. 2006), although the exact mechanism is unknown. Myo1d plays a role in endocytic membrane trafficking (Huber et al. 2000). Mice in which Myo1e, which is associated with podocytes in kidney, is knocked out show signs of kidney disease (Krendel et al. 2009). Myo1f is expressed predominantly in the spleen, lymph, thymus, and lung; and neutrophils from Myo1f knockout mice exhibit decreased motility and increased adhesion making the mice more susceptible to infection (Kim et al. 2006). Knock-down experiments show that Myo1g, which is expressed exclusively in hematopoietic cells, regulates cell elasticity (Olety et al. 2009).

Summary

Myosins I are a diverse group of single-headed, actin- and membrane-associated molecular motors with roles in a variety of cytoskeletal-membrane events.

Myosin II, "Conventional" Myosin

► Myosins

Myosin III

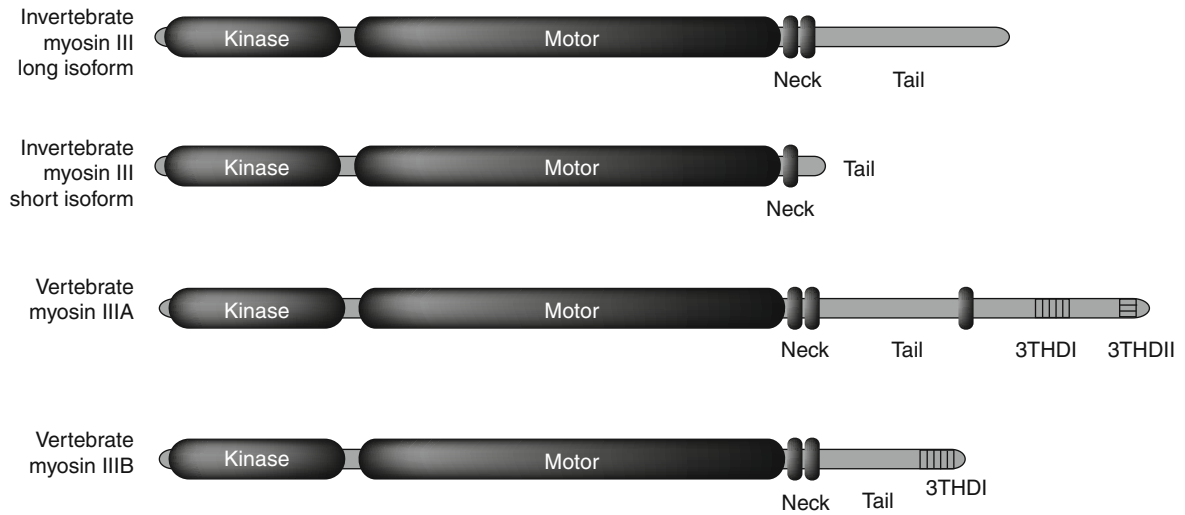
Shigeru Komaba
Boston Biomedical Research Institute, Watertown, MA, USA

Synonyms

LpMYO3; MYO3A; MYO3B; myoIII$_{Lim}$; NINAC (p174, p132)

Historical Background

Class III myosins are one of many classes of ► myosin motor proteins. The first class III myosin, *ninaC* (neither inactivation nor afterpotential C), was identified in *Drosophila* as a gene responsible for abnormal phototransduction (Montell and Rubin 1988). This novel class of myosin is unique in having an N-terminal putative kinase domain joined to a myosin motor domain. The second class III myosin was isolated from the horseshoe crab *Limulus polyphemus* as a phosphoprotein regulated by a circadian clock; it is exclusively expressed in photoreceptors (Battelle et al. 1998). Subsequently, human class III myosin, MYO3A, was isolated by degenerated polymerase chain reaction (PCR) and rapid amplification of cDNA ends PCR from retina and a retinal pigment epithelial cell line (Dose and Burnside 2000).



Myosin III, Fig. 1 Diagram of invertebrate myosin III, vertebrate myosin IIIA, and vertebrate myosin IIIB. Class III myosin consists of a kinase domain, a motor domain, a neck domain with IQ motifs, and a tail domain

A shorter class III isoform, MYO3B, encoded by a different gene from MYO3A, was also identified (Dose and Burnside 2002).

Structure

Drosophila has a single myosin III gene that expresses two alternative isoforms, p174 (long isoform) and p132 (short isoform) (Fig. 1). The long isoform has two IQ motifs, whereas the short isoform has a single IQ motif. The myosin III gene in horseshoe crab encodes a single isoform with a single IQ motif and a short tail. Vertebrates possess two genes that code for two distinct isoforms, myosin IIIA and myosin IIIB (Fig. 1). Similar to other myosin classes, myosin III consists of a motor domain, a neck domain, and a tail domain in addition to an N-terminal kinase domain. There is a large diversity in amino acid sequence of the motor domain among class III myosins, e.g., there is only 30% homology between myosin III from human and *Drosophila*. The neck region binds 1–4 light chains such as calmodulin. Vertebrate myosin IIIA has an additional 1–5 calmodulin-binding site in the tail. There are two conserved sequences in the tail domain of vertebrate myosin III, class III tail homology domain I (3THDI), and class III tail homology domain II (3THDII) (Dose et al. 2003). 3THDI is present in both myosin IIIA and myosin IIIB. 3THDII is located at the C-terminus of myosin IIIA and is an ATP-independent actin-binding domain, which is found in ▶ myosin light chain kinase (Erickson et al. 2003). Heavy meromyosin-like human myosin III consisting of a kinase domain, a motor domain, a neck region, and a partial tail domain is monomeric (Komaba et al. 2003), which is consistent with the observation that human myosin III does not have a long coiled-coil region with which to form dimers.

Biochemical and Biophysical Properties

Given its sequence similarity to other myosins, it was predicted that class III myosins function as molecular motors, enzymes characterized by the ability to interact with actin to produce mechanical force by hydrolyzing ATP. Hicks et al. demonstrated that *Drosophila* myosin III in the soluble fraction of a retinal homogenate binds to actin in an ATP-sensitive manner (Hicks et al. 1996), although to date there has been no report demonstrating that purified *Drosophila* myosin III has ATPase activity. The sequence of the phosphate-binding loop or P-loop, known as a nucleotide-binding motif, consists of GESGAGKT in many myosins; however, the sequence of *Drosophila* myosin III is

GESYSGKS. Indeed, myosin III from horseshoe crab binds actin, but lacks ATPase activity (Kempler et al. 2007). Amino acids which form a salt bridge, E^{459}-R^{238} in the case of *Dictiostelium* myosin II, are essential for ATP hydrolysis. Horseshoe crab myosin III has H^{487} at the equivalent position for R^{238}. The first experimental evidence to demonstrate that myosin III is an actual motor protein was reported in 2003 (Komaba et al. 2003). The authors showed that human myosin IIIA missing the tail domain has an ATPase activity with Vmax of 0.34 s^{-1} and is capable of gliding actin filament at 0.11 μm/s, which is relatively slower compared to many other myosins. Kinetic analysis demonstrated that the dephosphorylated motor domain of human myosin IIIA spends the majority of its time during the ATP hydrolysis cycle attached to actin suggesting that myosin III moves along actin cables without dissociating (Kambara et al. 2006).

Phosphorylation/Regulation

Kinase activity in a class III myosin was originally observed in expressed myosin III from *Drosophila*, where the kinase domain phosphorylates various substrates including itself (Ng et al. 1996); however, the biochemical or physiological role of autophosphorylation of *Drosophila* myosin III remains unclear. *Drosophila* myosin III is phosphorylated in the p174 tail domain by protein kinase C and this phosphorylation is required for normal phototransduction, although the effect of phosphorylation on the biochemical properties of myosin III has not been shown (Li et al. 1998).

Horseshoe crab myosin III is also autophosphorylated and phosphorylated by protein kinase A (PKA) in loop 2, which is at the interface of actin binding (Kempler et al. 2007), suggesting that the interaction between myosin III and actin is modulated by cAMP-mediated phosphorylation and/or autophosphorylation.

Human myosin IIIA also undergoes autophosphorylation in the motor domain, which significantly reduces its affinity for actin (Kambara et al. 2006) resulting in a decrease in the duty ratio (Komaba et al. 2009). Deletion of the kinase domain affects both the biochemical and cell biological properties of myosin IIIA. A kinase domain-deletion mutant has a twofold higher Vmax and fivefold higher affinity for actin, compared to that of myosin IIIA with the kinase domain (Dose et al. 2008). Erickson et al. reported that striped bass myosin IIIA localizes to the cytoplasm and to the tip of filopodia in HeLa cells and that deletion of the kinase domain reduced cytoplasmic localization while enhancing localization at the tips of filopodia, suggesting that the kinase domain inhibits localization to filopodial tips (Erickson et al. 2003).

Physiological Function

Deletion of *Drosophila ninaC* causes abnormal phototransduction and light- and age-dependent retinal degeneration (Porter et al. 1992). Deletion of the motor domain leads to a change in the subcellular distribution of myosin III and a phenotype indistinguishable from that of a null mutant, while mutations in the kinase domain result in defects in normal phototransduction, but no retinal degeneration (Porter and Montell 1993). The study using temperature-sensitive mutants demonstrated that the motor domain is required for maintenance of the retinal structure, but not for normal phototransduction (Porter and Montell 1993).

Myosin III is a major calmodulin-binding protein and the distribution of calmodulin in the retina of *Drosophila* is dependent on myosin III expression (Porter et al. 1993). In the mutant lacking p174, which is specifically localized to rhabdomeres, microvilli-packed structures in photoreceptor cells, calmodulin does not concentrate in rhabdomeres, whereas deletion of p132, the cell body–specific isoform, results in a decrease in cytoplasmic calmodulin.

Recent studies suggested that myosin III is involved in the transport of signaling molecules that undergo light-dependent translocation between the rhabdomere and the cell body in *Drosophila* photoreceptors. Upon light illumination, visual arrestin Arr2 translocates into rhabdomeres from the cell body and inactivates rhodopsin. Arr2 binds to myosin III mediated by phosphoinositides and this translocation is hindered in myosin III null and p132-lacking mutants (Lee and Montell 2004). However, another group demonstrated that light-dependent translocation of Arr2 does not require myosin III (Satoh and Ready 2005).

$G_q\alpha$, an activator of phospholipase Cβ, translocates from the rhabdomere to the cell body in response to light stimulation and returns to the rhabdomere in the

dark. The rate of translocation from the rhabdomere to the cell body in myosin III null mutants is similar to that of wild type; however, upon return to the dark, transport to the rhabdomere is significantly slower in myosin III mutants (Cronin et al. 2004).

Localization of transient receptor potential-like (TRPL) channels in the rhabdomere of myosin III mutants raised in the dark resembles that of wild type, whereas in orange light translocation to the cell body is partially inhibited in myosin III null mutants (Meyer et al. 2006).

One of the binding partners of myosin III in *Drosophila* is INAD, a scaffolding protein for signalplex consisting of phospholipase C, protein kinase C, and calmodulin. Disruption of binding between myosin III and INAD leads to defects in the termination of the photoresponse (Wes et al. 1999).

Vertebrate myosin IIIA is expressed at high levels in the retina and at lower level in the brain and testis. It localizes to the calycal processes of rod and cone photoreceptors (Dose et al. 2003).

Transgene expression of GFP-tagged myosin IIIA in *Xenopus* rod photoreceptors produces abnormal calycal processes and causes subsequent rod degeneration (Lin-Jones et al. 2004). Transgene-induced long and thick calycal processes contain a larger number of actin bundles, suggesting that myosin III regulates the organization of the actin-cytoskeleton in the rod photoreceptors.

Mutations in myosin III found in an Israeli family cause nonsyndromic progressive hearing loss, but have no effect on vision, although myosin III is strongly expressed in retina (Walsh et al. 2002). Myosin IIIA localizes at the tip of stereocilia, which are actin protrusions found on the sensory hair cells in the inner ear, in the thimble-like pattern (Schneider et al. 2006). Overexpression of GFP-tagged full-length myosin IIIA localizes similar to endogenous myosin IIIA and does not change stereocilia structure; however a mutant lacking the kinase domain accumulates at a higher level at the tip and leads to elongation of the stereocilia and bulging of the tip (Schneider et al. 2006). Myosin IIIA colocalizes with espin 1, an actin-bundling protein, at stereocilia tips (Salles et al. 2009). Espin 1 interacts with 3THD1 of myosin IIIA and when coexpressed with myosin IIIA produces longer stereocilia suggesting that myosin IIIA regulates the length of stereocilia together with espin 1. Normal vision and late-onset deafness in patients with myosin IIIA mutations suggests that myosin IIIB, which has 3THDI but not 3THDII compensates for myosin IIIA in photoreceptors and partially in the inner ear.

Summary

Myosin III is a unique myosin in that it has a kinase domain at the N-terminus of its motor domain. Physiological functions of class III myosins have not been fully uncovered, especially in vertebrates; however, the production of model animals such as myosin III knockout or transgenic mice will provide key information regarding the roles of myosin III.

Myosin X

Hiroshi Tokuo
Boston Biomedical Research Institute, Watertown, MA, USA

Synonyms

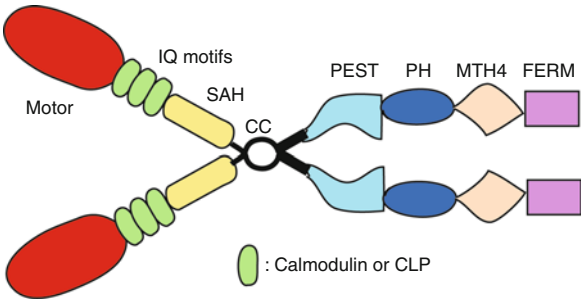
Myosin-10; Myo10

Historical Background

In 1994, myoX was first identified in a PCR screen designed to find novel ▶ myosins in the inner ear (Solc et al. 1994). The full-length cDNA sequences of myoX were determined in 2000 in mouse (Yonezawa et al. 2000), human, and cow (Berg et al. 2000), and the molecular structure and ubiquitous expression in tissues were reported (Berg et al. 2000, Yonezawa et al. 2000). The unique localization pattern of myoX in cultured cells at the tips of filopodia and in lamellipodia was identified in the same reports (Berg et al. 2000, Yonezawa et al. 2000). Subsequently, in 2001, it was shown that the head domain of myoX binds actin and hydrolyzes ATP to induce movement and force (Homma et al. 2001). In 2002, myoX was shown to participate in intrafilopodial movement and filopodia formation (Berg and Cheney 2002), and in phagocytosis (Cox et al. 2002). After these breakthroughs, studies of myoX were expanded to many different aspects by precise biochemical analyses or by identifying binding partners critical for exploring its functions in cells.

Molecular Structure

The N-terminal domain of myoX functions as a motor domain: It binds actin and hydrolyzes ATP to produce



Myosin X, Fig. 1 Schematic diagram of MyoX protein. The N-terminus of myoX functions as a motor domain. The motor domain is followed by a neck region. The predicted coiled-coil segment is present at the C-terminus of the neck region [22]; however, a recent study suggests that instead of forming a stable coiled-coil, this domain forms a stable α-helix (SAH) [23]. The C-terminus of the molecule, or tail, consists of four different domains: a PEST domain; three pleckstrin homology (PH) domains; a myosin tail homology 4 (MTH4) domain; and a band 4.1, Ezrin, Radixin, Moesin (FERM) domain

movement and force (Homma et al. 2001). The motor domain is followed by a neck region that contains three IQ motifs, which bind calmodulin or calmodulin-like light chains (Berg et al. 2000). In epithelial cells, myoX binds calmodulin-like protein (CLP), an epithelial-specific light chain that is expressed during differentiation. CLP expression increases myoX protein levels by stabilizing the molecule (Bennett et al. 2007). A predicted coiled-coil segment is present at the C-terminus of the neck region (Berg et al. 2000); however, it has been suggested that this domain does not form a stable coiled-coil, but instead forms a stable α-helix (SAH) (Knight et al. 2005). The C-terminal end of the molecule is the tail domain, which consists of four different domains: PEST, PH, MTH4, and FERM (Fig. 1). Classes VII, X, XII, and XV myosins share a conserved structural feature in their tail domains – a myosin tail homology 4 (MTH4) domain followed by a band 4.1, Ezrin, Radixin, Moesin (FERM) domain. Together, the myosins containing these domains comprise the MTH4-FERM superclass of myosins (Berg et al. 2001).

In addition to this full-length myoX, brain expresses a shorter form that lacks a motor domain (Sousa et al. 2006). This "headless" myoX might have a possible role as a natural dominant-negative regulator to suppress the function of full-length myoX in neurons.

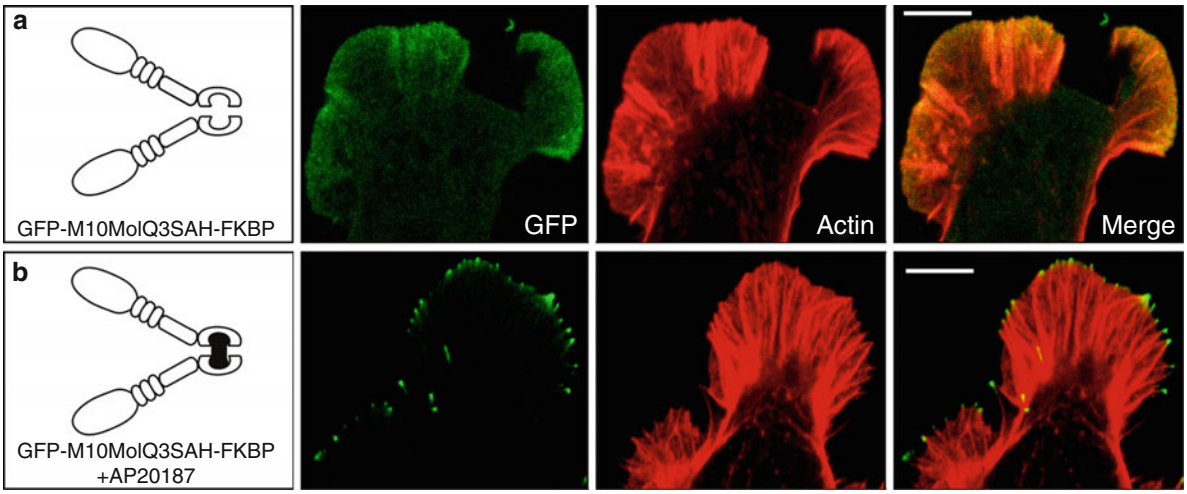
Intrafilopodial Motility

One of the most striking properties of myoX is its forward and rearward movements within filopodia (Berg and Cheney 2002). Recently, the velocity of the forward movement was calculated as ~600 nm/s in living cells using TIRF microscopy (Kerber et al. 2009), similar to the 340–780 nm/s reported for movement of individual myoX molecules on artificial actin bundles (Nagy et al. 2008). The rearward movement of myoX in filopodia is slow at 10–20 nm/s (Berg and Cheney 2002), presumably the rate of retrograde actin flow in filopodia. In these studies, only dimerized myoX showed intrafilopodial motility, suggesting that dimer formation of myoX is necessary for its proper movement in cells.

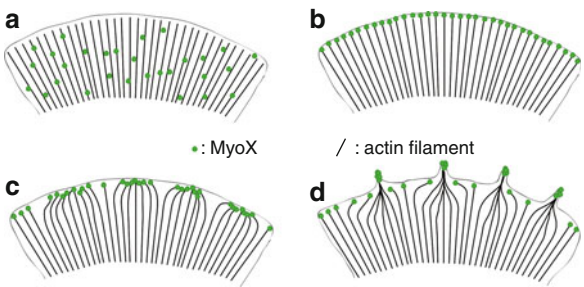
A forced dimer construct of tail-less myoX was first reported to preferentially select bundled actin for motility and showed poor processivity on single filaments in vitro (Nagy et al. 2008). The selectivity of actin tracks (single filaments or bundled) by myoX is controversial because a recent report shows the robust processivity of myoX on individual actin filaments (Sun et al. 2010). Sun et al. also report that myoX moves processively in a hand-over-hand manner with a left-hand helical walking path using single-molecule fluorescence techniques such as polTIRF, FIONA, and Parallax.

Filopodia Formation

MyoX has an important role in the formation of filopodia (Berg et al. 2000, Tokuo and Ikebe 2004, Bohil et al. 2006, Tokuo et al. 2007, Zhu et al. 2007), but the mechanism of filopodia induction by myoX is still largely unknown. Using a regulated dimerization technique (Tokuo et al. 2007), it was shown that the motor activity of myoX is itself critical for the initiation of filopodia formation. The regulated dimerization system (Ariad Pharmaceuticals) was based on the human FK506-binding protein variant (FKBP) and its small molecular ligands. An EGFP-tagged myoX construct was produced by fusing FKBP to the C-terminal end of the SAH domain (EGFP-M10MoIQ3SAH-FKBP, Fig. 2a). If two FKBPs are present, the dimer-inducing drug, AP20187, binds to both FKBPs, thus creating a dimer of the target molecule (Fig. 2b). After addition of dimerizer, EGFP-M10MoIQ3SAH-FKBP induced filopodia in transfected cells (Fig. 2b). These results support the following model (Fig. 3): (a) MyoX is present as a dimer and monomer in cells. Monomeric



Myosin X, Fig. 2 Dimerization of myoX is critical for filopodia formation. NIH3T3 cells were transfected with GFP-M10MoIQ3SAH-FKBP (*green*) and replated on fibronectin-coated cover slips with (**b**) or without (**a**) the dimerizer AP20187. *Red*: rhodamine-phalloidin staining



Myosin X, Fig. 3 The filopodia initiation model by dimerization of myoX. (**a**) MyoX is present as a dimer and a monomer in cells. Monomeric (single-headed) myoX does not localize at the edge of lamellipodia. (**b**) Once the dimer is produced, myoX moves to and concentrates at the tip of actin filaments presumably due to its ability to walk toward the barbed end of actin filaments. (**c**) The tips move laterally along the leading edge with actin filaments, and myoX motor activity plays a role in this process. (**d**) The lateral movement of myoX causes the barbed end of the actin filaments to converge, thus producing the base of filopodia, where actin polymerization might induce formation of parallel actin bundles

(single-headed) myoX does not localize at the edge of lamellipodia. (b) Once dimerization occurs, myoX moves to the tip of the actin filaments, presumably as a result of its ability to walk toward the barbed ends of actin filaments. (c) The tips move laterally along the leading edge with actin filaments, and the mechanical activity of myoX plays a role in this process. (d) The clustering of myoX causes convergence of the actin filaments into parallel bundles, thus producing the base of the filopodia. This hypothetical model is elicited from the observation that dimerized tail-less myoX induces microspikes or short unstable filopodia which is thought to be an initial step in filopodia formation. On the other hand, deletion of the MTH4-FERM region abolishes the formation of stable and elongated dorsal filopodia by myoX (Bohil et al. 2006). From these results, it is plausible that monomer-to-dimer transition of the motor and neck region controls initiation, and the tail region controls elongation and stabilization of filopodia formation.

TIRF microscopy was used to clarify the role of the tail domain in the mechanism of myoX-induced filopodia formation (Watanabe et al. 2010). MyoX was recruited to discrete sites at the leading edge where it assembles with exponential kinetics before filopodia extension. MyoX-induced filopodia showed repeated extension–retraction cycles with each extension of 2.4 μm, which was critical to produce long filopodia. FERM domain–deleted myoX moved to the tip as in wild type, but it was transported toward the cell body during filopodia retraction, did not undergo multiple extension–retraction cycles, and failed to produce long filopodia. Deletion of the FERM domain did not change movement at the single-molecule level with the same velocity of approximately 600 nm/s as wild type, suggesting that the myoX in filopodia moves without interacting with the attached membrane via the FERM domain. These

results suggest that the interaction of myoX and substrate-engaged integrin is necessary for phased elongation.

Regulating Molecules and Other Functions

Recent studies implicate myoX in a variety of cellular functions through its interactions with other molecules:

PIP_3: In leukocytes, myoX localizes to phagocytic cups with phosphatidylinositol-3,4,5-triphosphate (PIP_3) in a PI3K-dependent manner. Expression in macrophages of a tail domain of myoX inhibits phagocytosis (Cox et al. 2002). MyoX might provide a molecular link between PI3K and pseudopod extension during phagocytosis.

Ena/VASP: MyoX and VASP bind in vitro and in vivo, colocalize at the tips of filopodia, move together in filopodia, and there is a correlation between the length of filopodia and the concentration of VASP/myoX at the tips of filopodia (Tokuo and Ikebe 2004). These results suggest that myoX transports VASP to the tips of filopodia to support elongation by actin incorporation.

Microtubules: Through its MTH4-FERM domain, MyoX associates with microtubules. Expression of the tail domain or microinjection of anti-myoX antibodies disrupts nuclear anchoring, spindle assembly, and spindle-F-actin association in *Xenopus laevis* (Weber et al. 2004). These results indicate that during meiosis, myoX has a critical role in integrating the F-actin and microtubule cytoskeletons. MyoX is also essential for mitotic-spindle function (Woolner et al. 2008). Interaction with microtubules is also important in osteoclast function (McMichael et al. 2010). MyoX suppression by RNAi or overexpression of dominant-negative myoX (MTH4-FERM) leads to decreased sealing zone perimeter, motility, and resorptive capacity of osteoclasts. These results suggest that myoX plays a role in osteoclast attachment and podosome positioning by direct linkage of actin to the microtubule network.

Integrins: The FERM domain of myoX interacts with an NPXY motif within the cytoplasmic domain of β-integrin (Zhang et al. 2004). Knockdown of myoX results in decreased integrin-mediated cell adhesion to the extracellular matrix, and myoX is responsible for localization of integrins in filopodia. Localization of integrin at filopodial tips and filopodia elongation did not occur with myoX mutants deficient in integrin binding or with a β-integrin mutant deficient in myoX binding. These results suggest that binding of myoX to integrins allows tethering of the filopodial actin filaments to the extracellular matrix for stabilizing the structure of filopodia and elongation.

BMP6: In endothelial cells, myoX is a target gene of bone morphogenetic protein (BMP), and myoX colocalizes with the BMP6 receptor, ALK6, in a BMP6-dependent fashion. Other data indicate that myoX is required to guide endothelial migration toward BMP6 gradients via the regulation of filopodial function and amplification of BMP signals (Pi et al. 2007).

Netrin receptor: The FERM domain of myoX interacts with the cytoplasmic tail of the netrin receptors, DCC (deleted in colorectal cancer) and neogenin (Zhu et al. 2007). Netrins regulate axon path-finding, which is essential for proper wiring in the brain. Cortical explants derived from mouse embryos expressing dominant-negative myoX exhibit reduced neurite outgrowth in response to netrin-1. Inhibition of myoX in embryos causes impaired commissural neuronal axon projections in chicken brain. These results indicate that myoX regulates axon outgrowth and guidance in response to netrins (Zhu et al. 2007).

Using *Xenopus* as a model system to study the function of myoX in neurons, two reports show that knock-down of myoX expression results in retarded migration of cranial neural crest cells (Hwang et al. 2009, Nie et al. 2009). These results suggest that myoX has an essential function in neuronal development in vertebrates.

VE–cadherin: MyoX is directly associated with the VE–cadherin complex via a FERM domain. It colocalizes and moves synchronously with filopodial VE–cadherin. Expression of the FERM domain blocks the transportation of VE–cadherin along actin fibers, resulting in an almost total depletion of VE–cadherin at the cell edge. VE–cadherin trafficking along filopodia by myoX may be a pre-requisite for cell–cell junction formation in endothelial cells (Almagro et al. 2010).

Summary

MyoX functions both as a molecular transporter and a cytoskeletal regulator in cells.

Synonyms

Myosin II, "conventional" myosin; other myosins, "unconventional" myosins

Historical Background

In 1864, Kühne named a protein extracted from nematode muscle in high salt *myosin* and in 1939, Engelhardt and Ljubimowa determined that this protein possessed an ATPase activity. Later studies

would determine that myosin is the major component of muscle thick filaments, and that its cyclic interactions with actin-containing thin filaments are the basis for muscle contraction. It would eventually be renamed myosin II to signify that the molecule is a dimer consisting of two polypeptide chains each with a globular head region and a long α-helical tail (Szent-Györgyi 2004). In 1969, a molecule resembling muscle myosin II was identified in slime mold, showing that myosin is a component of nonmuscle cells, too (Adelman and Taylor 1969). Subsequently, in 1973 a molecule with actin-activated ATPase activity resembling skeletal muscle myosin, although smaller in molecular weight and monomeric rather than filamentous, was isolated from *Acanthamoeba* and named ▶ myosin I (Pollard and Korn 1973). This would be the first of many studies leading to the recognition that myosins constitute a large structurally and functionally diverse family of actin-associated molecular motor proteins that use the energy from ATP hydrolysis to translocate actin filaments usually toward the preferred (or pointed) end of actin filaments (the exception is myosin VI). In fact phylogenetic analyses based on the N-terminal domains of 328 organisms show that there are as many as 35 different myosin classes (Odronitz and Kollmar 2007). After myosin I and myosin II, the different classes that constitute the myosin superfamily are named in order of discovery usually with Roman numerals. The largest class is that of the single-headed class I myosins, which probably most closely resemble the first myosin I, a molecule predicted to have consisted of only a motor domain with a nucleotide-binding site and an actin-binding site. Humans express myosins I, II, III, V, VI, VII, IX, X, XV, XVI, XVIII, and XIX, and mutations in myosins are associated with diseases including cardiac hypertrophic myopathies, deafness, and blindness. As of mid-2010, representatives from only a small subset of the 35 different myosin classes have been either purified from tissues or expressed in vitro and studied with biochemical and biophysical approaches. Some have been expressed in cells exogenously and studied with cell biological methods.

Structure

In general, myosins have an N-terminal head or motor domain consisting of a nucleotide-binding site and an actin-binding site, a neck or light-chain-binding domain (LCBD), which binds calmodulin or calmodulin-like molecules, and a C-terminal tail domain, which is highly diverse among myosins and is the site of regions involved in dimerization as well as membrane and cargo binding. The crystal structures of the motor domains of several different classes of myosins have been solved beginning with that of chicken skeletal muscle myosin II and are similar consisting of four main subdomains: the upper 50 kDa domain, the lower 50 kDa domain, a 7-stranded β-sheet known as the transducer, and the converter region (Holmes 2008; Sweeney and Houdusse 2010). These subdomains are surrounded by several structural elements that coordinate communication among the subunits. The upper and lower 50 kDa domains form a cleft that opens and closes as a function of nucleotide binding. The nucleotide-binding pocket, highly conserved among myosins, kinesins, and G-proteins, comprises the purine-binding, or P, loop on one side and the switch 1/P-loop on the other side. Myosin motor domains have surface loops, including loop 1, near the nucleotide-binding region, and loop 2, near the actin-binding face, that differ in length and overall charge among myosins and when mutated affect a variety of kinetic properties. The C-terminal end of the motor domain is the converter region, which rotates 60° in response to ATP binding and attaches to the LCBD. Several classes of myosins, such as myosins III, IX, XV, XVI, XVIII, and XVa, contain an N-terminal extension, which contains, e.g., a serine/threonine kinase domain in the case of myosin III and several ankyrin repeats in the case of myosin XVI.

The LCBD is an α-helical region containing one or more repeats of ~29 amino acids called IQ domains for the isoleucine and glutamine residues that are normally present. Myosins can have as few as one and as many as 17 IQ domains as in the case of the type 2 myosin from *Phytophthora ramorum*. The LCBD of myosin II binds a regulatory and essential light chain. The light chain of many myosins is the calcium-binding molecule calmodulin. The LCBD serves as a lever arm amplifying small structural changes in the motor domain. Myosin VI has a unique 53-amino-acid insert containing an unusual calmodulin-binding site between the motor domain and LCBD, which is responsible for redirecting the lever arm toward the minus end of actin resulting in the movement of myosin VI on actin in the direction opposite to that of other myosins (Bahloul et al. 2004).

The tail domains of myosins are highly variable in sequence and length and are involved in cargo and membrane binding as well as oligomerization of myosins (Mooseker and Foth 2008). As a consequence of long coiled-coil regions in their tails, myosins II associate to form bipolar filaments. Class V, VI, and X myosins dimerize to form two-headed molecules that move processively, i.e., take several steps along actin filaments without detaching, a property critical for carrying cargo long distances within the cell. In the case of myosin VI, dimerization is induced by binding to its adaptor proteins, optineurin and Dab2, following a conformational change that exposes dimerization sites within the myosin VI monomers (Phichith et al. 2009).

The tails of myosins contain different kinds of protein modules including those involved in protein–protein interactions such as SH3 (Src homology 3), MyTH4 and FERM, dilute, and PDZ-binding; and membrane-binding domains, such as PH domains. Myosins VII, X, XII, and XV are MYTH4-FERM myosins, defined by the presence in the tail of a Myosin Tail Homology 4 (MyTH4) domain followed by a band 4.1, Ezrin, Radixin, Moesin (FERM) domain. MyTH4-FERM myosins are implicated in mediating membrane-cytoskeleton interactions. The FERM domain in *Drosophila* myosin VIIa regulates its activity (Yang et al. 2009). In ATP, the tail of myosin VIIa is bent toward and interacts with the motor domain, but the molecule unfolds in the absence of ATP presumably as a consequence of actin binding by the FERM domain.

Biochemical and Mechanical Properties

Due to the similarity in structure of their motor domains, all myosins are Mg^{2+}-ATPases believed to operate by a common mechanism (El-Mezgueldi and Bagshaw 2008). The interaction of myosin with nucleotide, defined in the 1970s by Bagshaw and Trentham, is described by a seven-step scheme in which ATP binding to myosin occurs in two steps as monitored by tryptophan fluorescence (a binding step and a protein conformational change) followed by reversible ATP hydrolysis. Phosphate (Pi) release and ADP release then occur sequentially, each dissociation event preceded by a protein conformational change. The release of phosphate is activated by the presence of actin. Kinetic differences among myosins are due primarily to differences in rates of Pi and ADP release.

The kinetic interaction of ATP with the mammalian class I myosins when bound to actin is biphasic consisting of both a fast phase and a slow phase. The studies suggest that vertebrate myosins I must undergo a conformational change before ADP release can occur, which is supported by cryo-electron microscopy studies showing that myosins I undergo an ADP-induced conformational change. These data coupled with those from studies done with optical-tweezers transducers showing that the mechanical interaction of myosin I with actin occurs in two parts led to the idea that myosins I are strain-sensitive and complete their cycle only when strain is reduced (Coluccio and Geeves 1999). This notion is supported by single-molecule studies in which the rate of detachment from actin of mammalian Myo1b decreases 75-fold under tension (Laakso et al. 2008). Although first detected in vertebrate myosins I as a consequence of their slow kinetics (Veigel et al. 1999), the interaction with actin in two mechanical parts has now been seen with other myosins.

The ability of myosins to bind and move cargo long distances along actin filaments is crucial for intracellular transport and certain myosins are specially adapted structurally and functionally for this role. Processivity, the ability to take several steps along actin before dissociating, is usually associated with motors that have a high duty ratio, i.e., they spend most of their time attached to actin. Myosin V moves processively along actin filaments because of its high affinity for actin, which ensures that one of its two heads stays associated with the actin filament while the other is detached so that the motor does not diffuse away. Strain on the lead head causes it to stall until the rear head can detach from actin. Processivity of myosin V is also supported by its long LCBD, which allows the heads to bind actin at 36 nm intervals so that the molecule can walk along the longitudinal axis of the actin filament without the viscous drag that would occur if it had to spiral around the filament (Sellers and Weisman 2008). Myosin VI also moves processively (although in the opposite direction), but its step size varies from 25 to 36 nm, and although it carries cargo along the longitudinal axis of the actin filament like myosin V, it can move on a right-handed spiral (Sun et al. 2007).

Single-headed myosins are non-processive motors, which make only one interaction with actin, then detach. In general these myosins have low duty ratios. Clustering of single-headed myosins could make them act as processive motors. Curiously, although Myo9B is monomeric, it can take multiple steps along actin before dissociating; the mechanism is currently unknown (Bähler 2008).

Regulation

Myosins can be regulated by phosphorylation of either the heavy or light chain. Regulation of class I myosins is varied; however, phosphorylation of a single serine or threonine between the ATP- and actin-binding sites in the heavy chain of the *Acanthamoeba* and *Dictyostelium* myosins I regulates their actin-activated Mg^{2+}-ATPase activity and motor activity. Phosphorylation by the myosin I heavy chain kinase, MIHCK, which is a p21-activated kinase (PAK), enhances the ATPase activity 40- to 80-fold (Brzeska and Korn 1996). In vertebrate myosins I, negatively charged glutamate or aspartate is present at the corresponding site, known as the TEDS site after the one-letter codes for the amino acids found at the site, indicating that they are constitutively active (Bement and Mooseker 1995).

The actin-activated Mg^{2+}-ATPase activities of smooth and nonmuscle class II myosins are regulated by phosphorylation of Ser^{19} of the regulatory light chain, which causes unfolding of the molecule. Autophosphorylation of class III myosins leads to a decrease in the affinity for actin (Kambara et al. 2006).

Calcium plays a role in the regulation of some myosins. Although the actin-activated Mg^{2+}-ATPase activity is higher in calcium vs. EGTA, the rate of actin translocation by vertebrate myosins I is less in buffers containing calcium (Coluccio 2008). This inhibition is reversed in the presence of exogenous calmodulin, suggesting that calcium causes calmodulin dissociation from the LCBD thereby compromising its function as a lever arm. In the case of Myo1c, calmodulin dissociation might reveal sites that are then available to interact with receptors on hair cells on the sensory epithelia of the inner ear (Cyr et al. 2002). Calcium indirectly regulates myosin II activity in skeletal muscle by binding to the thin filament-associated protein, troponin, which causes a conformational change in a second thin filament-associated protein, tropomyosin, which shifts position thereby exposing sights on the thin filaments to which myosin heads can bind. The conformation of myosin V in vitro is affected by calcium with it adopting an extended form in calcium, and a folded form in buffers containing no calcium (Wang et al. 2004).

Function

The large number of myosin classes present in eukaryotes correlates with tremendous diversity in cellular function including maintenance of cortical tension, intracellular transport, the extension of actin-containing membrane structures, and cell movement. Class I myosins in single-cell organisms contribute to pseudopod formation, motility, pinocytosis, membrane ruffling, endocytosis, secretion, and cortical tension. In vertebrates, myosins I maintain cortical tension and play specialized roles such as supporting the structure and function of intestinal microvilli, supporting adaptation in hair cells of the inner ear, and mediating the transport of GLUT4-containing vesicles in adipocytes (Coluccio 2008). Membrane tension has been shown to increase in cells overexpressing class I myosins (Nambiar et al. 2009). In skeletal and smooth muscle, myosin II-containing thick filaments slide relative to actin-containing thin filaments to effect muscle contraction (Cremo and Hartshorne 2008, Reggiani and Bottinelli 2008). In *Dictyostelium* amoebae, myosin II is required for cytokinesis, and cells in which expression of myosin II is knocked out cease dividing and become multinucleate (Knecht and Loomis 1987). In mice, each of the three nonmuscle myosin II isoforms is critical to normal organ development (Conti et al. 2008). ▶ Myosin III is expressed primarily in sensory cells including the stereocilia of the hair cells of the inner ear. In hair cells, myosin III transports espin 1 to the tips of stereocilia and supports their elongation (Salles et al. 2009). Class V myosins, found in many different organisms, bind various types of cargo through their tail domains, including melanosomes, endoplasmic reticulum, and secretory vesicles and carry them long distances within cells (Sellers and Weisman 2008). Mutations in myosin V give rise to mutant coat colors in mice because the transport of melanosomes in melanocytes is compromised. In humans, the neurological disease, Griscelli's Syndrome, is associated with mutations in myosin V. The plant-specific class XI myosins, responsible for

intracellular transport in characean algae, are similar to that of class V myosins and translocate actin in vitro at speeds of ~40–60 μm/s (Ito et al. 2007). Class VI myosins are found in membrane ruffles, at the Golgi and in endocytic and exocytic vesicles (Buss and Kendrick-Jones 2008). Multiple binding partners for myosin VI have been identified suggesting that it plays a variety of cellular roles. Snell's Waltzer mice, which lack functional myosin VI, are deaf. In the hair cells of the sensory epithelium of the inner ear, myosin VI is located at the base of stereocilia where it may play a role in assembling and anchoring the stereocilia. Myosin VII is widely expressed, but most of what is known about its cellular role centers on its location in vertebrates in the hair cells of the inner ear, where it is found in both the cell body and the hair bundle; and in the retina, where it is found in the retinal pigment epithelium and rod and cone photoreceptors cells. In humans, mutations in the myosin VII gene cause Usher syndrome type 1, characterized by profound congenital deafness, vestibular dysfunction, and retinitis pigmentosis leading to blindness. Roles for myosin VII in both maintenance of tension and transportation of cargo have been suggested (El-Amraoui et al. 2008). The class IX myosins in vertebrates, Myo9a and Myo9b, are Rho GTPase-activating proteins, which are negative regulators of Rho signaling. In melanoma cells, Myo9b accumulates in lamellipodia, membrane ruffles, and filopodia. Myo9b might control actin polymerization induced by the Rho proteins, cdc42 and Rac, to prevent undesired cell extension (Bähler 2008). ▶ Myosin X, found at the tips of filopodia, binds and transports VASP, which mediates actin assembly along filopodia, and there is a correlation between the length of filopodia and the concentration of VASP and myoX at the tips (Tokuo and Ikebe 2004). Like myosins I, III, VI, and VII, the class XV myosin, myosin XVa, is important in hearing (Boger et al. 2008). In the shaker-2 mouse, a missense mutation in myosin XVa causes deafness and circling behavior. Myosin XVa binds and transfers the scaffolding protein, whirlin, to the tips of stereocilia and is responsible for elongation of hair bundles on the sensory epithelia of the inner ear.

Summary

Myosins are a large and diverse group of actin-associated molecular motor proteins that participate in cytoskeletal functions in nearly all cells.

Historical Background

Cell–cell interactions via cell adhesion are the basis for the evolution of all multicellular organisms. The first experiments to understand cell adhesion were performed at the beginning of the last century by Wilson (1907), who dissociated sponges and allowed them to fuse and to reconstitute. Fifty years later, Townes and Holtfreter (1955) demonstrated that dissociated cells from amphibian embryos adhere to form random aggregates of their origin, with ectoderm forming an outer surface layer, endoderm forming a compact central ball, and mesoderm producing a loose array of cells. In 1963, Roger Sperry (1963) proposed that different cells bear distinct cell surface proteins that serve as markers or tags. One of these markers, the Neural Cell Adhesion Molecule (NCAM) was first described in 1974 by Elizabeth Bock (Jacque et al. 1974) and designated as D2 antigen. Three years later, the group of Edelman (Thiery et al. 1977) approved that NCAM mediates cell–cell adhesion and established it as one of the first cell adhesion molecules. When NCAM was sequenced and cloned during the mid-1980s, it became obvious that NCAM belongs to the immunoglobulin superfamily

Please note that there exist a close relative to NCAM, the Neural Cell Adhesion Molecule 2; also called OCAM or RNCAM. The overall similarity to NCAM is 45%. However, this entry is a summary only on the Neural Cell Adhesion Molecule.

NCAM1, Fig. 1 Schematic representation of the three major isoforms of NCAM

(Barthels et al. 1987) and that NCAM is not only responsible for static adhesion, but also transmits signals across the cell membrane. With the help of transgenic knockout techniques, Cremer and colleagues could demonstrate 1994 (Cremer et al. 1994) that NCAM is involved in learning and memory.

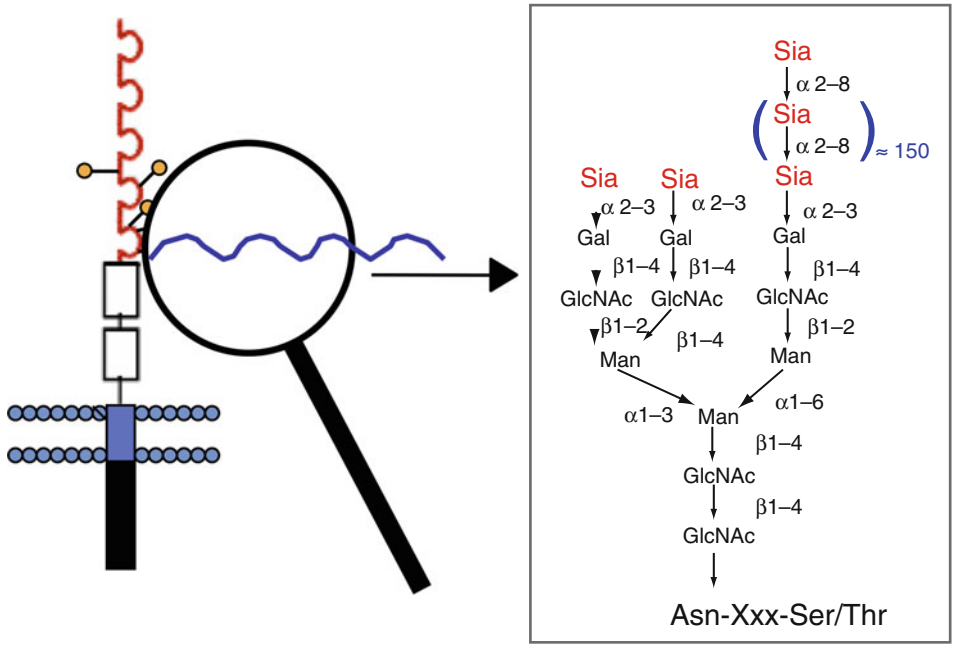
Structure and Function

NCAM is a glycoprotein belonging to the immunoglobulin superfamily. All members of this protein superfamily have in common the presence of at least one immunoglobulin-like domain, which received their name from immunoglobulins (antibodies). There are more than 750 proteins known with immunoglobulin-like domains. An immunoglobulin-like domain usually consists of 70–110 amino acids with a defined secondary structure including one disulfide bridge. NCAM consists of five immunoglobulin domains in its extracellular domain. Furthermore NCAM has two membrane proximal fibronectin type III (F3) homologous repeats. There exist three major isoforms of NCAM, which are generated by alternative splicing from one single gene (Barbas et al. 1988). The isoforms are named according their apparent molecular weight as NCAM120 (gylcosylphosphatidyl inositol anchor = GPI-anchored) or NCAM140 and NCAM180 (transmembrane-anchored). NCAM140 and NCAM180 differ in the intracellular domain in that NCAM180 has an additional insert of 267 amino acids (see Fig. 1). Although identified in the nervous system, NCAM is expressed in many other cell types or tissues, such as muscle cells or immune cells. This is underlined by the fact that NCAM corresponds to CD56 and is a marker of natural killer cells.

NCAM mediates preferentially homophilic NCAM–NCAM interactions, which are Ca^{2+}-independent. The homophilic NCAM–NCAM interactions mediate adhesion between neurons and neurons, neurons and glia cells, and between glia cells and glia cells. NCAM140 is known to be responsible for the fasciculation of axons or neurites and for promotion of axonal regeneration after injury. NCAM-deficient mice have defects in learning and memory and have a smaller brain compared to wild-type animals. Furthermore, the nervous system–specific NCAM180 is thought to stabilize cell–cell contacts at synapses. A recent model of NCAM–NCAM interaction suggests that two NCAMs form dimers on the cell curface (cis-interaction) and that these dimers bind to existing dimers on opposing cells (trans-interaction) via their Ig-domains 2 and 3 in antiparallel orientation ("zipper"-like) (Soroka et al. 2003).

Posttranslational Modification

NCAM is notable for several posttranslational modifications. Like many other proteins involved in signal transduction, NCAM was demonstrated to be phosphorylated. NCAM contains numerous (depending on its isoform) potential phosphorylation sites on Serine or Threonine residues but only one on a Thyrosine residue. In addition, NCAM has five N-glycosylation sites and nearly 30% of its apparent molecular weight is represented by glycans. It is of special interest that NCAM bears a very unique type of glycosylation, namely, polysialylation (Finne et al. 1983).



NCAM1, Fig. 2 Polysialylation of NCAM. Note that polysialylation of NCAM results in the introduction of more than 100 negatively charged sialic acids on a classical Aspargine-linked glycan structure

Polysialylation is characterized by the presence of up to 150 monomers of sialic acid on the outer chains of the N-glycans of the fifth immunoglobulin-like domain (see Fig. 2). Polysialylation on NCAM represents more than 95% of all polysialylation of a specific organism. The addition of polysialic acids introduce one negative charge per sialic acid and alter dramatically the function of NCAM. Polysialylated NCAM is much less adhesive compared to non-polysialylated NCAM. The expression of polysialic acid is strongly regulated. It is high during development and drops during lifetime. Adult mammals (including humans) express high levels of polysialylated NCAM only at sites of plasticity, such as hippocampus, the place of learning and memory.

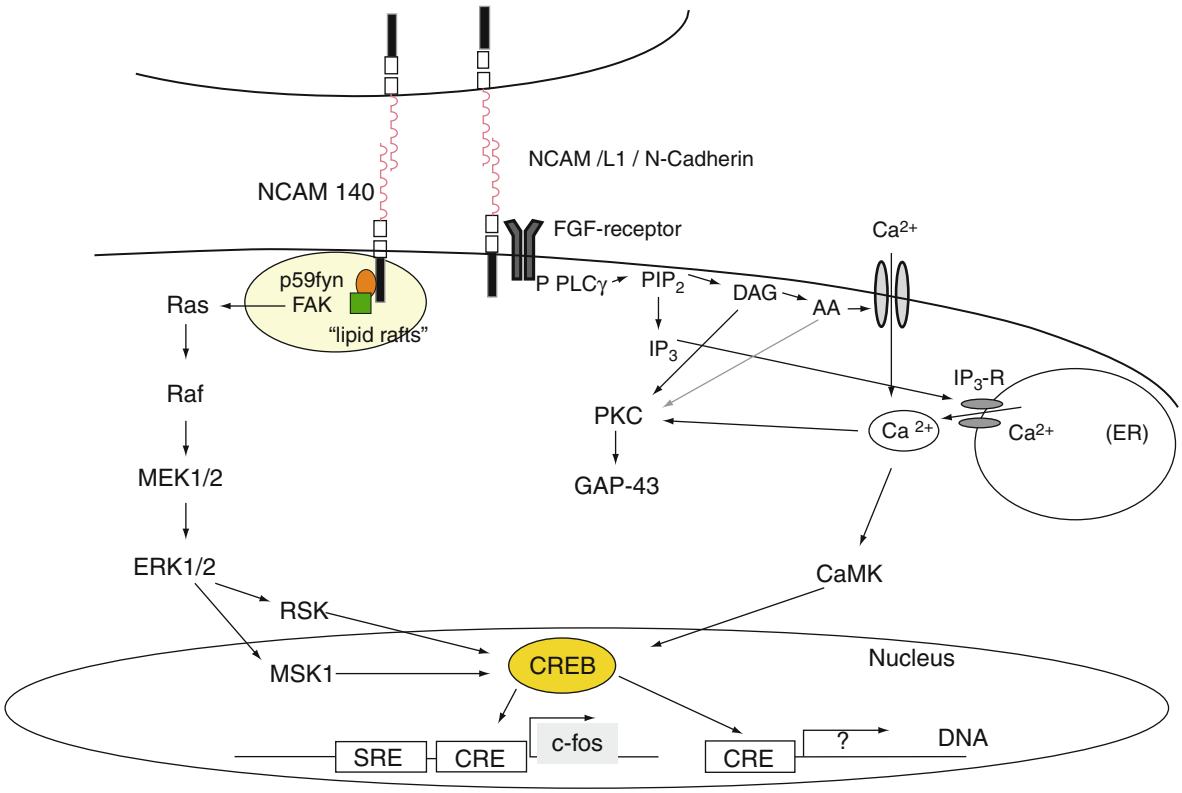
Please note that there are several and sometimes confusing abbreviations for polysialic acid or polysialylated NCAM used in the literature (PSA = polysialic acid; E-NCAM = embryonic NCAM; polySia = polysialic acid).

Signaling

The last two decades of research on NCAM-mediated signal transduction focuses mainly on NCAM-mediated promotion of neurite outgrowth, which will be discussed in the following. One central pathway of the NCAM-mediated signal transduction is the mitogen-activated protein kinase pathway (MAPK pathway). The MAPK pathway can be activated by two mechanisms: First, via the Fibroblast Growth Factor Receptor (FGF-receptor) (Doherty and Walsh 1996) and second via non-receptor kinases such as FAK and Fyn (Beggs et al. 1997).

The Mitogen-Activated Protein Kinase Pathway

It has been demonstrated that NCAM interacts directly with the FGF-receptor on one cell membrane (cis-interaction) via the F3 modules 1 and 2 (Kiselyov et al. 2003). NCAM binding is capable of activating the FGF-receptor upon NCAM–NCAM interaction. The FGF-receptor activation leads to recruitment of the adaptor proteins Shc and Grb-2, which then activate Ras as key enzyme of the MAPK pathway. Final target of the MAPK pathway is the transcription factor ▶ CREB (Jessen et al. 2001), which activates transcription of genes, which are responsible for neurite outgrowth. The NCAM-mediated FGF-receptor activation and neurite outgrowth can be inhibited by ATP, which could be explained by an overlapping ATP and FGF-receptor binding sites in the second F3 module of



NCAM1, Fig. 3 Simplified scheme of the NCAM-mediated signal transduction (For details see text or for review see Maness and Schachner (2007))

NCAM (Skladchikova et al. 1999). However, the also close polysialylation at the Ig module 5 of NCAM is essential for NCAM-dependent neurite outgrowth (Doherty et al. 1990). Another possibility to activate the MAPK pathway is via the recruitment of the non-receptor kinases FAK and Fyn. It has been demonstrated in several studies that NCAM is also associated with the receptor protein tyrosine phosphatase-alpha (RPTP-alpha). NCAM–NACM interaction leads to the activation of RPTP-alpha and to recruitment of Fyn and FAK, which then are responsible for further activation of the MAPK pathway (see Fig. 3).

Phospholipase C and Calcium

NCAM-mediated signaling has been demonstrated to involve an increase in intracellular Ca^{2+}-concentration (Kolkova et al. 2000). Several studies suggested that phospholipase Cγ (PLCγ) is responsible for the NCAM-mediated increase in Ca^{2+}-concentration. Upon NCAM–NCAM interaction, PLCγ cleaves PIP2 into inositol trisphosphate (IP3) and diacylglycerol (DAG). ▶ IP_3 Receptors binds to its intracellular receptor at the ER-membrane and releases Ca^{2+} from the ER store. Furthermore ▶ arachidonic acid (AA) might be released from DAG by the DAG lipase, which further activates Ca^{2+}-channels at the plasma membrane. All this leads to an increase of intracellular Ca^{2+}. The increased Ca^{2+} binds to calmodulin and this leads to the activation of the Ca^{2+}-calmodulin-dependent protein kinase II. Ca^{2+}-calmodulin-dependent protein kinase II phosphorylates several target proteins, which are involved in neurite outgrowth (see Fig. 3).

Cyclic Adenosine Monophosphate and Cyclic Guanosine Monophosphate

The involvement of the two second messengers cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) in NCAM signaling has been demonstrated in several studies by the use of specific inhibitors (Shimomura et al. 1998). However, the exact role of the respective heterotrimeric G-proteins (in the case of cAMP) or nitric oxid synthases (in the case of cGMP) is not clear yet.

Summary

NCAM may transmit signals into the cell by several mechanisms. This is, like in many other cases, a complex network of signal transduction pathways. The MAPK pathway seems to be very crucial for NCAM-mediated signal transduction. However, little is known about relative roles of the individual players and further research is necessary to elucidate the total network of NCAM signaling.

Historical Background

The NIMA-related kinase, or "Nek," family constitutes approximately 2% of all human kinases. They are related in sequence, as their name suggests, to NIMA (699 residues, 80 kDa), a serine/threonine protein kinase present in the filamentous fungus, *Aspergillus nidulans*. Ron Morris identified the gene, nimA, through analysis of a temperature-sensitive loss-of-function mutant that was never in mitosis (nim) when cells were incubated at the restrictive temperature (Morris 1975). Loss of NIMA activity led to G2 arrest, while overexpression of NIMA drove cells into a premature mitosis from any point in the cell cycle (Oakley and Morris 1983; Osmani et al. 1988, 1991). Mechanistically, NIMA is likely to regulate multiple aspects of mitotic entry, with evidence that its activity is required for nuclear pore disassembly, relocalization of the master regulator, cdc2-cyclin B, to the nucleus and spindle pole body (SPB), and chromatin condensation. NIMA is subsequently degraded in

an anaphase-promoting complex/cyclosome (APC/C)-dependent manner and this is necessary for mitotic exit (reviewed in O'Connell et al. 2003; O'Regan et al. 2007).

Aspergillus cells are syncytial and undertake a semi-closed mitosis. It may therefore have evolved control mechanisms that are specific for this form of cell division. However, an early suggestion that NIMA-related kinases might be conserved in other eukaryotes came from expressing *Aspergillus* NIMA in cells from diverse species, including humans, and observing cell cycle defects (Lu and Hunter 1995; O'Connell et al. 1994). With the complete sequencing of many genomes, it is now clear that kinases related to NIMA by sequence are indeed present in most eukaryotes (Parker et al. 2007). However, so far, only the NIM-1 protein from the highly related filamentous fungus, *Neurospora crassa*, has been proven to be a functional homologue of NIMA capable of rescuing an *Aspergillus nimA* mutant suggesting the possibility of functional divergence. Indeed, the budding yeast, *Saccharomyces cerevisiae*, and fission yeast, *Schizosaccharomyces pombe*, each have one NIMA-related kinase in their genome, Kin3 and Fin1, respectively, but these are not essential for mitotic entry. However, careful studies revealed that Fin1 does contribute to the timing of mitotic onset through regulating the localization of the polo-like kinase, Plo1, to the SPB, which in turn promotes activation of cdc2-cyclin B (Grallert and Hagan 2002). Fin1 also contributes to mitotic spindle formation and mitotic exit (Grallert and Hagan 2002; Grallert et al. 2004). Thus, Neks from different species do play roles in mitotic progression.

Surprisingly, some lower eukaryotes have many genes encoding Nek kinases. For example, the unicellular organisms *Chlamydomonas* and *Tetrahymena* have 10 and 39 Nek genes, respectively. The key to this expansion of Nek genes appears to lie in an alternative non-mitotic function for Nek kinases, that is, in ciliogenesis. *Chlamydomonas* produce two elongated cilia, or flagella, that allow the organism to swim in response to environmental stimuli. To date, only two of the *Chlamydomonas* Nek genes have been studied in depth, Fa2p and Cnk2p, but loss of either protein affects both flagella disassembly and cell cycle progression (Bradley and Quarmby 2005; Mahjoub et al. 2002). Meanwhile, *Tetrahymena* has hundreds of cilia that fall into different classes depending on their location and length, and all of the Neks tested so far in this organism localize to cilia and regulate cilia length (Wloga et al. 2006).

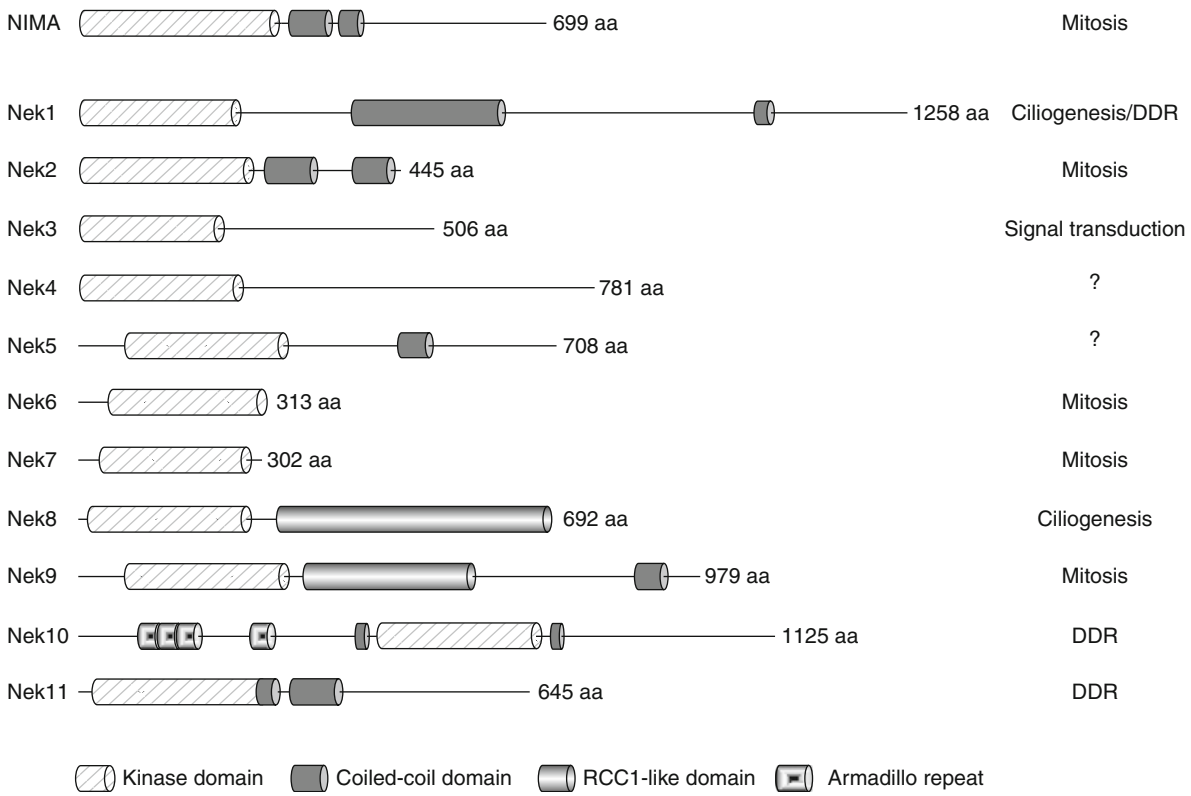
The human NIMA-related kinase family consists of 11 proteins, named Nek1 to Nek11, that are encoded by distinct genes (Fig. 1). Apart from Nek10, these share a common protein domain structure with an N-terminal catalytic kinase domain, containing all the signature motifs of a serine/threonine kinase, and a C-terminal regulatory domain that is highly variable in length and sequence. These differences in the non-catalytic regions contribute to the distinct patterns of expression, localization, activation, and regulation that are seen across this family. Functionally, though, studies performed across many systems including humans, support the hypothesis that the majority of Neks contribute in one way or another to cell cycle progression and/or ciliogenesis (O'Connell et al. 2003; O'Regan et al. 2007; Quarmby and Mahjoub 2005). Thus, altered expression or mutation of Neks can interfere with these key processes, implicating them in both human cancer and inherited ciliopathies.

Specifically, research on the human proteins has demonstrated a role for Nek2, Nek6, Nek7, and Nek9 in mitotic regulation, Nek10 and Nek11 in the DNA damage response, Nek1 and Nek8 in ciliogenesis, and Nek3 in signal transduction (Fig. 2). At the time of writing, little is known about the function of Nek4 and Nek5. A brief summary of findings to date on the regulation and function of each mammalian Nek is presented below.

Mitotic Neks: Nek2, Nek6, Nek7, and Nek9

Of all the human Nek kinases, **Nek2** is the most closely related by sequence to NIMA being 48% identical within the catalytic domain. For this reason, it is to date the most well-studied member of this family. It also shares a number of other important properties with NIMA, including cell cycle–dependent expression, APC/C-dependent degradation and localization to the centrosome, the higher eukaryotic microtubule organizing center and equivalent of the fungal SPB (Fry 2002; Hayward and Fry 2006). However, like the yeast Neks and unlike *Aspergillus* NIMA, human Nek2, as far as one can tell, is not essential for mitotic entry.

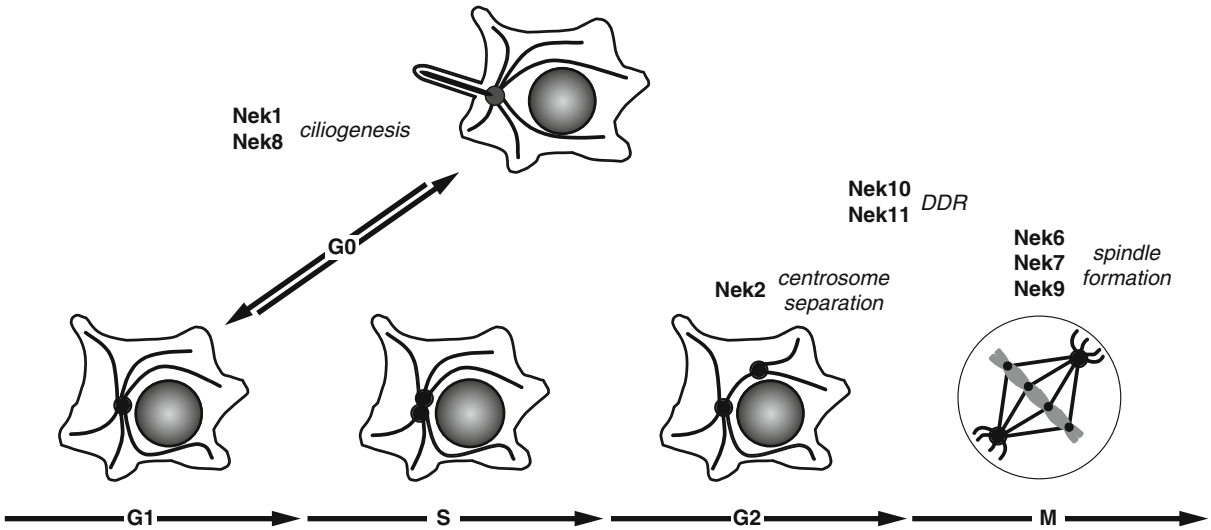
Nek2 is a ubiquitous protein with at least three splice variants, Nek2A (445 residues; 51 kDa), Nek2B (384 residues; 44 kDa), and Nek2C (437



NEKs, NIMA-Related Kinases, Fig. 1 *The human NIMA-related kinase family*. The schematic diagram shows the domain organization of the 11 human NIMA-related kinases, Nek1 to Nek11, below that of the *Aspergillus* NIMA kinase. These generally have an N-terminal catalytic domain followed by a C-terminal non-catalytic region containing potential regulatory motifs. Several Neks have putative coiled-coil sequences; in the case of Nek2 the first of these is an atypical leucine zipper that promotes dimerization, whereas the second has been identified as a SARAH domain that mediates interaction with Hippo pathway components. The length of each kinase is indicated (amino acid number) together with its best understood function

residues; 50 kDa; also called Nek2A-T). These all share the N-terminal kinase domain followed by a leucine zipper coiled-coil motif that promotes dimerization and activation. Nek2A then contains a second coiled-coil motif at its C-terminus. Nek2B is somewhat shorter than Nek2A and lacks the second coiled-coil, whereas Nek2C is identical to Nek2A apart from missing an 8 residue sequence that lies between the leucine zipper and C-terminal coiled-coil. The relative expression of the three variants differs depending on cell type and developmental stage, although generally Nek2A appears to be the predominant isoform. The major function of Nek2A is to regulate centrosome organization through the cell cycle, as described below. Similarly, Nek2B is required for assembly and maintenance of centrosome structure and this may be particularly important during early embryonic development as, in *Xenopus*, it is the only variant expressed at this stage (Uto and Sagata 2000). Interestingly, a role for Nek2B has been proposed in mitotic exit in human cells where its depletion leads to cytokinesis failure (Fletcher et al. 2005). The 8 residue deletion that leads to Nek2C creates a functional nuclear localization signal not present in Nek2A or Nek2B, raising the possibility of nuclear-specific functions for this variant (Wu et al. 2007).

Overall, Nek2 expression and activity are regulated in a cell cycle–dependent manner (Fry et al. 1995; Schultz et al. 1994). The protein is almost undetectable during G1 but accumulates abruptly at the G1/S transition and remains high until late G2. This is a combined result of transcriptional repression and



NEKs, NIMA-Related Kinases, Fig. 2 *Functions of NIMA-related kinases in the cell cycle*. The majority of human Neks play roles in cell cycle progression. A schematic view of cells progressing through the cell cycle with the point at which the Neks act and their best understood function is indicated. However, it should be stressed that each of these Neks is likely to have multiple functions beyond those indicated, for example, Nek6 and Nek7 are also implicated in nuclear pore complex disassembly and cytokinesis, while Nek1 may have functions in the DDR as well as ciliogenesis. The roles of Nek4 and Nek5 remain unknown at the time of writing, while Nek3 is involved in prolactin-mediated cell migration

APC/C-mediated degradation in G1 and transcriptional upregulation in S/G2 (Hayward and Fry 2006). However, Nek2A activity is further regulated by a number of key structural and sequence-specific features of the kinase. The N-terminal kinase domain contains a number of sites which undergo autophosphorylation upon dimerization through the leucine zipper (Rellos et al. 2007). It is likely that phosphorylation at least at some of these sites, particularly those in the activation loop, is required for kinase activation. The C-terminal non-catalytic domain also contains autophosphorylation sites, although the functions of these remain unclear. The C-terminal coiled-coil motif has recently been defined as a putative SARAH domain, which enables interaction with the Hippo pathway proteins, hSav1 and the Mst2 kinase (Mardin et al. 2010). Mst2 acts as an upstream activator of Nek2, phosphorylating sites in the C-terminal region that regulate localization of Nek2 to the centrosome. The C-terminal domain also contains a site that mediates direct interaction of Nek2 with the phosphatase, PP1 (Helps et al. 2000). PP1 negatively regulates Nek2 through dephosphorylation, while Nek2 may be able to inhibit PP1 by phosphorylation. This creates a very sensitive bistable switch that allows rapid Nek2 activation, once PP1 activity starts to decrease at the onset of mitosis (Eto et al. 2002). Nek2 is also negatively regulated by the focal adhesion scaffolding protein, HEF1, although the mechanism is not known (Pugacheva and Golemis 2005). Finally, the C-terminal domain of Nek2 contains two destruction motifs that target it for APC/C-mediated degradation in early mitosis (Hayes et al. 2006).

Nek2 localizes to the centrosome throughout the cell cycle (Fry et al. 1998b). An additional fraction is present in the cytoplasm where it colocalizes with and is trafficked along microtubules (Hames et al. 2005). This localization is dependent on the region between the leucine zipper and SARAH domain that encompasses sites phosphorylated by Mst2 (Hames et al. 2005; Mardin et al. 2010). The primary role of Nek2 at the centrosome is as a regulator of centrosome cohesion. Overexpression of active Nek2 induces premature centrosome splitting during interphase (Fry et al. 1998b), while expression of inactive Nek2 or depletion by RNAi inhibits centrosome separation and promotes monopolar spindle formation (Faragher and Fry 2003; Fletcher et al. 2005; Mardin et al. 2010). Nek2 promotes loss of cohesion or "disjunction" of centrosomes through phosphorylation of C-Nap1 and,

possibly rootletin and ▶ β-catenin (Bahmanyar et al. 2008; Fry et al. 1998a). These proteins, together with Cep68, form a flexible linker structure that extends between the proximal ends of the parental centrioles and which must be dismantled at the onset of mitosis to allow centrosome separation and spindle formation to occur. In addition to the role of Nek2 in centrosome separation, Nek2 has been implicated in regulating the microtubule organizing capacity of the centrosome through phosphorylation of Nlp and centrobin, chromatin condensation through phosphorylation of HMGA2, spindle checkpoint signaling through phosphorylation of Hec1, and nuclear pore complex disassembly through phosphorylation of Nup98 (Laurell et al. 2011; O'Regan et al. 2007).

Nek9 is a 979 residue protein of 113 kDa that, following its N-terminal catalytic domain, has a C-terminal regulatory region comprising a central Regulator of Chromosome Condensation 1 (RCC1)-like domain and a C-terminal coiled-coil motif. It is expressed throughout the cell cycle, but becomes phosphorylated and activated specifically in mitosis (Roig et al. 2002). Nek9 is subject to complex but, as yet, poorly understood regulation. It is thought that during interphase Nek9 adopts an autoinhibited conformation with the RCC1-like domain blocking access to the catalytic site. However, at the G2/M transition, a number of events lead to release of this conformation and activation of the kinase. These are likely to include dimerization, autophosphorylation (especially on T210 in the activation loop), and, potentially, activation by upstream kinases such as Cdk1 and Plk1 (Roig et al. 2002; Bertran et al. 2011). In terms of localization, Nek9 is mainly cytoplasmic, although it can also be found in the nucleus. However, its activated form appears to be specifically concentrated on spindle poles during mitosis (Roig et al. 2005).

Early functional studies on Nek9 by overexpression of wild-type or mutant constructs, or by inhibition through antibody microinjection, led to the hypothesis that Nek9 activity contributes to mitotic spindle formation (Roig et al. 2002). How exactly it does this remains unclear, but Nek9 can interact with the γ-tubulin ring complex (γ-TuRC) that nucleates microtubules both from the centrosome and within the spindle (Roig et al. 2005). Hence, one is tempted to speculate that Nek9 directly contributes to microtubule nucleation in mitosis. However, depletion of Nek9 from *Xenopus* egg extracts prevents the formation of spindles via either the centrosome- or chromatin-mediated pathways (Roig et al. 2005). This suggests that Nek9 function is unlikely to be restricted to regulating the microtubule nucleating activity of γ-tubulin. Nek9 also interacts with BICD2, a protein associated with microtubule-dependent motor proteins, raising the possibility that BICD2 might target Nek9 to microtubules, as well as potentially being a substrate (Holland et al. 2002). Furthermore, the presence of the RCC1-like domain, together with the demonstration that the ▶ Ran GTPase can bind to Nek9, points to a potential role in Ran-mediated spindle formation (Roig et al. 2002). Some reports suggest that Nek9 could have functions outside of mitosis. For example, Nek9 was reported to associate with the FACT complex, a chromatin modifying complex involved in replication and transcription (Tan and Lee 2004). This could explain the presence of a nuclear fraction of Nek9 in interphase and, although not consistent with the timing of bulk Nek9 activation, it is possible that the FACT complex activates a restricted pool of Nek9 in the nucleus, which in turn might be inhibited by the adenovirus E1A protein.

One major route through which Nek9 almost certainly regulates mitotic spindle organization is through interaction, phosphorylation, and activation of two other NIMA-related kinases, Nek6 and Nek7. Indeed, Nek9 was first identified through its association with Nek6 (Roig et al. 2002). Subsequently, Nek9 was shown to phosphorylate sites within the activation loop of Nek6 and this, together with the high degree of similarity between Nek6 and Nek7, led to the proposal that these three Neks form a mitotic cascade in which Nek9 acts upstream of Nek6 and Nek7 (Belham et al. 2003). Lately, it has been demonstrated that Nek9 may also activate Nek7, and by analogy Nek6, through an allosteric mechanism independent of phosphorylation (Richards et al. 2009).

Nek6 and **Nek7** are the smallest family members being only 313 (36 kDa) and 302 (35 kDa) residues, respectively. As a result they comprise little more than a catalytic domain with only a short (30–40 residue) N-terminal extension. By sequence, they are highly related to each other, sharing 86% amino acid identity within the catalytic domain, although the N-termini of the two proteins are not conserved. Often considered as a pair because of their similarity, both Nek6 and Nek7 are, like their upstream activator Nek9, cell cycle

regulated with maximal activity in mitosis. Moreover, while they give slightly different localization patterns, with Nek6 weakly associated to spindle fibers and Nek7 more concentrated on spindle poles, RNAi depletion experiments demonstrate that they are both essential not only for assembly of a robust mitotic spindle, but also potentially for completion of cytokinesis and cell abscission (Kim et al. 2007; O'Regan and Fry 2009; Yin et al. 2003; Yissachar et al. 2006). In support of a late mitotic role for these kinases, Nek6 activation, judged with a phosphospecific antibody against a key activation loop residue, peaks at the time of cytokinesis (Rapley et al. 2008), while mouse embryonic fibroblasts derived from Nek7$^{-/-}$ embryos show defects indicative of cytokinesis failure (Salem et al. 2010).

How these kinases regulate spindle formation and cytokinesis remains to be defined. However, despite their sequence similarity and requirement for both events, it is likely that their respective roles and substrates differ. Systems approaches have identified a large number of putative interacting partners and substrates for Nek6 (Ewing et al. 2007; Vaz Meirelles et al. 2010). These include proteins involved in chromatin condensation, microtubule binding, and nuclear pore complex organization. On this basis, Nek6 has been proposed to be a high confidence hub kinase with an expansive network of substrates involved in diverse cellular processes. Moreover, a number of these interactions depend on the N-terminal extension of Nek6 explaining why Nek6 and Nek7 may target different proteins (Vaz Meirelles et al. 2010). However, to date, the only substrates that have been studied in any detail for Nek6 and Nek7 are the kinesin motor, Eg5, which is phosphorylated by Nek6 promoting spindle pole separation (Rapley et al. 2008), and the nuclear pore complex component, Nup98, whose combined phosphorylation by Cdk1 and potentially multiple Neks, including Nek2, Nek6, and Nek7, promotes nuclear pore complex disassembly upon mitotic entry (Laurell et al. 2011).

Checkpoint Neks: Nek10 and Nek11

Nek10 is a protein of 1,125 residues in length (129 kDa) that is unique in this family, in that unlike the other Neks, Nek10 has its catalytic domain in the center of the protein with long N- and C-terminal non-catalytic regions. The catalytic domain is flanked by two coiled-coil motifs, while in addition the N-terminal region contains four armadillo repeats. Nek10 is one of the least characterized members of the family at the present time with, for example, no data yet on its localization. However, the first report into its function has placed Nek10 within the G2/M DNA damage checkpoint, suggesting that Nek10 is required for Erk1/2 activation in response to UV-induced damage (Moniz and Stambolic 2011). In unperturbed cells, Nek10 forms a trimeric complex, interacting with Mek1 via ▶ Raf-1. In response to UV treatment, Mek1 undergoes autophosphorylation and activation in a Nek10-dependent manner; this leads to phosphorylation of Erk1/2 and G2/M arrest. Importantly, though, UV treatment increases neither association of Nek10 with Raf-1 and Mek1, nor Nek10 activity, and there is no evidence that Nek10 directly phosphorylates Raf-1 or Mek1. Hence, it seems likely that other factors or events contribute to the mechanism by which Nek10 modulates Mek1 signaling.

Nek11 exists as at least four splice variants: Nek11 Long (Nek11L; 645 residues, 74 kDa), Nek11 Short (Nek11S; 470 residues, 54 kDa), and two isoforms that are present in databases but have yet to be reported, Nek11C (482 residues, 55 kDa) and Nek11D (599 residues, 69 kDa). Expression of at least the Nek11L isoform is cell cycle regulated being highest from S through to the G2/M phases of the cell cycle (Noguchi et al. 2002). Localization studies revealed that Nek11 localizes to the nucleus, and possibly nucleolus, in interphase cells, as well as spindle microtubules in prometaphase and metaphase cells (Noguchi et al. 2002, 2004). It was also suggested that Nek11 might be phosphorylated by the Nek2 kinase, converting Nek11 into an active conformation (Noguchi et al. 2004); however, this has yet to be verified. More convincingly, Nek11 is implicated in the DNA damage response (DDR). Nek11 activity is increased in response to stalled DNA replication and genotoxic stresses, such as ionizing radiation (IR), and this activation is blocked by caffeine, an inhibitor of the DDR kinases, ATM and ATR (Melixetian et al. 2009; Noguchi et al. 2002). The role of Nek11 in the G2/M DNA damage checkpoint appears to be a central one. Upon DNA damage, ATM and ATR phosphorylate and activate Chk1; this in turn activates Nek11 by phosphorylation of Ser273 (Melixetian et al. 2009).

Both Chk1 and Nek11 then phosphorylate Cdc25A on residues that promote binding of the β-TrCP E3 ubiquitin ligase. Ultimately, this results in the proteasomal degradation of Cdc25A arresting the cell in G2. While this model is highly attractive, it has been argued that casein kinase 1, and not Nek11, is the major kinase that regulates the phospho-dependent recruitment of β-TrCP. It is also worth noting that, in *Xenopus*, Erk1/2 can target Cdc25A for degradation through the β-TrCP pathway following genotoxic stress. Clearly, further work is required to determine the relative importance of these kinases in mediating G2/M arrest in response to different forms of DNA damage.

Ciliary Neks: Nek1 and Nek8

Nek1 was the first Nek to be identified in mammals and is also the largest member of the family, being composed of 1,258 residues (145 kDa). It was initially reported to have dual serine-threonine and tyrosine kinase activity in vitro, although this is unlikely to be the case in vivo (Letwin et al. 1992). The first clue to its function came almost a decade later when, completely unexpectedly, mutations of the gene encoding Nek1 were found to be causative in two mouse models for polycystic kidney disease (PKD), named *kat* (for kidney, anemia, testis) and kat^{2J} (Upadhya et al. 2000; Vogler et al. 1999). Cystic kidney diseases are now known to be common hallmarks of ciliopathies, whereby the underlying defect is in the formation or function of the primary cilium. Indeed, this was the first indication that Nek kinases may have some role in ciliogenesis. Since then, Nek1 has been localized to the primary cilia in a number of different cell types (Mahjoub et al. 2005; Shalom et al. 2008; White and Quarmby 2008). Here, it is proposed to negatively regulate ciliogenesis, as overexpression of wild-type and certain truncated forms of Nek1 inhibit ciliogenesis, whereas overexpression of mutants predicted to be catalytically inactive do not (White and Quarmby 2008). Interestingly, Nek1 may also be involved in cell cycle control and, specifically, the DDR. Like Nek11, Nek1 activity is elevated in response to IR and Nek1-deficient cells are sensitive to DNA damage (Polci et al. 2004). Furthermore, although to date no *bona fide* substrates have been identified for Nek1, a number of proteins involved in DNA double-strand break repair were found as Nek1 binding partners (Surpili et al. 2003).

Nek8 is a smaller protein than Nek1, being 692 residues in length (80 kDa). Interestingly, Nek8 shares a very similar domain organization to Nek9, with Nek8 also having an RCC1-like domain. On this basis, one might expect that Nek8 would have a role in mitosis. However, subsequent to identification of the mouse Nek1 PKD model, a missense mutation in the RCC1-like domain of Nek8 was identified in the *jck* mouse model of autosomal recessive juvenile PKD (Liu et al. 2002). Consistent with this, Nek8 was also found to localize to the primary cilia (Quarmby and Mahjoub 2005; Sohara et al. 2008). In fact, Nek8 concentrates in the proximal region of the cilia, known as the inversin compartment, a localization that is dependent on the inversin protein (Shiba et al. 2010). Inversin is a protein encoded by a gene that is mutated in the human childhood kidney disorder, nephronophthisis (NPHP). This disease is a typical ciliopathy with at least nine candidate Nphp genes identified so far. Importantly, Nek8 turns out to be Nphp9, thus implicating the Neks in human inherited disease for the first time (Otto et al. 2008). Mutations in Nek8 found in NPHP patients lead to loss of Nek8 localization from the cilia (Trapp et al. 2008). Nek8 has also been found to interact with ▶ polycystin-2 (PC-2), a causative gene for human autosomal dominant PKD (ADPKD), with abnormal phosphorylation of PC-2 detected in cells from the *jck* mouse (Sohara et al. 2008). To date, though, much still remains to be learnt about the cellular basis of renal cyst formation. Thus, it remains unclear whether defects in Nek1 and Nek8 cause cystic kidney disease directly, by interfering with the structure of the primary cilium itself, or more indirectly, by abrogating cilia-dependent signaling. It is also formally possible that these Neks somehow relay signals between the cilium, at the time when the cell is quiescent, and the mitotic spindle, once it reenters the cell cycle.

Signal Transduction Neks: Nek3

In contrast to most other Neks, there is no clear indication that **Nek3** (506 residues, 58 kDa) is a cell cycle–dependent kinase with conflicting reports over whether Nek3 expression in elevated in dividing or quiescent cells. Localization studies indicate that Nek3 is

predominantly cytoplasmic, with no evidence to date that Nek3 associates with centrosomes (Tanaka and Nigg 1999). Unexpectedly, however, yeast two-hybrid and co-immunoprecipitation studies found a direct interaction between Nek3 and members of the ► Vav family of guanine nucleotide exchange factors that was enhanced in response to signaling from the prolactin receptor (Miller et al. 2005). These studies suggested that prolactin receptor stimulation induces Nek3 kinase activity causing Vav2 to interact with the kinase domain of Nek3 and become phosphorylated. Phosphorylated Vav proteins then activate downstream signaling targets involved in tumor progression. Indeed, overexpression of Nek3 potentiated prolactin-mediated cytoskeletal reorganization of cells; however, if Nek3 was depleted then cytoskeletal reorganization was attenuated, as was cell migration and invasion. This is therefore the first report of a Nek kinase being involved in growth-related signaling events. However, Nek3 has also been reported to more directly regulate cytoskeletal dynamics in neurons by altering levels of acetylated tubulin, thus raising the possibility of a role for Nek3 in neuronal disorders (Chang et al. 2009).

Nek4 and Nek5

Little research has been carried out on **Nek4** (781 residues, 90 kDa). However, a recent study implies that this kinase might also play a role in microtubule regulation, as changes in Nek4 expression led to altered sensitivity of cells to microtubule poisons (Doles and Hemann 2010). There is no specific published data yet on **Nek5** (708 residues, 81 kDa). Intriguingly, though, Nek5 was identified in a microarray analysis of FOXJ1 target genes. This transcription factor governs motile cilia assembly by regulating genes involved in cilia biogenesis and function, suggesting that Nek5 may contribute to ciliogenesis in multiciliated cells.

Nek Kinases and Cancer

There is increasing evidence implicating Nek kinases in cancer. Most commonly, this involves upregulated expression, although a few rare mutations have been identified in cancer genome screens. However, whether elevated expression or mutation contributes to the transformed phenotype remains an important but currently unanswered question. The current data on Nek kinases and cancer can be summarized as follows. Nek1 may be required to protect genome stability as cells deficient in Nek1 form tumors in mice (Chen et al. 2011); this would be consistent with it having a role in the DNA damage checkpoint. Nek2 expression levels are frequently upregulated in a wide range of cancer cell lines and primary tumors, and the Nek2 gene has been reported to be amplified in breast and gastric cancers (Hayward and Fry 2006; Kokuryo et al. 2007; Suzuki et al. 2010; Tsunoda et al. 2009). Nek3 is enriched in breast carcinomas (Miller et al. 2005, 2007), while the Nek3 gene is located in a chromosomal region that is frequently deleted in several types of human cancer and a polymorphism in the Nek3 gene is linked to prostate cancer. Nek4 appears to be frequently deleted in lung cancer, although interestingly this might make tumors more sensitive to particular microtubule poisons (Doles and Hemann 2010). The Nek6 gene is found at a locus for which loss of heterozygosity is associated with several cancers, while, like Nek2, the expression of Nek6 is widely elevated in cancer cell lines and tumors (Nassirpour et al. 2010). Nek7 is also overexpressed in breast, colon, and larynx cancers (Capra et al. 2006), and mutations in Nek7 have been identified in lung and ovarian cancers. Nek8, although primarily associated with ciliogenesis, is upregulated in some breast tumors. Although this could suggest that Nek8 has alternative functions in cell cycle control, a link between cilia-dependent signaling and tumorigenesis is beginning to emerge. A few point mutations have been identified in Nek9, although their relevance remains unclear, and a link between Nek9 expression and human cancers is not yet well established. On the other hand, Nek10 has been identified as a candidate breast cancer susceptibility gene and mutations of this kinase have been reported in several human cancers, including lung. Finally, Nek11 expression is increased during colorectal cancer development suggesting that this kinase too is implicated in cancer progression (Sørensen et al. 2010).

Summary

In summary, of the 11 human Nek kinases, Nek2, Nek6, Nek7, and Nek9 function in mitotic regulation,

Nek10 and Nek11 in the DDR, Nek3 in signal transduction, and Nek1 and Nek8 in ciliogenesis. Currently, Nek4 and Nek5 have no assigned function. Hence, although these kinases are related to each other in sequence, it is clear that they are regulated in quite different manners and function in diverse processes. However, based on studies in both lower and higher eukaryotes, the common underlying theme is that many, albeit perhaps not all, Neks contribute to microtubule organization during cell cycle progression and/or ciliogenesis. Importantly, advances in understanding how this family contributes to cell cycle events make these kinases attractive targets for therapeutic interventions in human cancer. RNAi-mediated depletion of Nek2 and Nek6, for example, has been found to inhibit proliferation of cancer cell lines and tumor xenografts, and selective pharmacological inhibitors are beginning to be generated (Hayward et al. 2010; Jeon et al. 2010; Jin et al. 2006; Kokuryo et al. 2007; Nassirpour et al. 2010; Qiu et al. 2009; Suzuki et al. 2010; Tsunoda et al. 2009; Whelligan et al. 2010; Wu et al. 2008). Hence, although a better understanding of the basic biology of NIMA-related kinases is still required, there is growing evidence that Neks could serve as important targets for the management of cancers. Finally, the identification of mutations in Nek8 as causative for an inherited human disease emphasizes the need for further research into the processes and pathways in which this family of kinases operate.

NES (Nuclear Export Sequence)

► p38 MAPK Family of Signal Transduction Proteins

Net1 (Neuroepithelial Cell Transforming Gene 1 Protein)

Jeffrey A. Frost
Department of Integrative Biology and Pharmacology, University of Texas Health Science Center at Houston, Houston, TX, USA

Synonyms

ARHGEF8

Historical Background

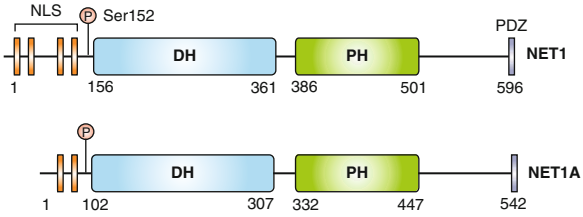
Rho family small GTPases control multiple cell functions, including organization of the actin cytoskeletal, cell motility and invasion, and cell cycle progression. They act as molecular switches, cycling between their active GTP-bound and inactive GDP-bound states. When bound to GTP, Rho GTPases initiate intracellular signaling by binding to downstream proteins known as effectors. The activation state of Rho GTPases is controlled by three families of proteins, known as GDP exchange factors (Rho GEFs), GTPase activating proteins (Rho GAPs), and guanine nucleotide dissociation inhibitors (Rho GDIs). Rho GEFs activate Rho proteins by stimulating the release of GDP, thereby allowing the binding of GTP. Rho GAPs accelerate the intrinsic GTPase activity of Rho proteins to hydrolyze GTP to GDP. Rho GDIs sequester inactive, GDP-bound Rho GTPases in the cytosol, thereby maintaining and stabilizing a ready pool of Rho proteins for subsequent activation. Within this regulatory network, it is the Rho GEFs that are primarily responsible for translating upstream signaling events into Rho protein activation.

During the mid-1990s a number of groups used NIH 3T3 cell focus formation assays to identify candidate oncogenes. In this type of screen, 3T3 cells are made to express a cDNA expression library derived from cancer cells, and then tested for subsequent loss of contact inhibition. This can be observed through the formation of cell foci, which are essentially masses of transformed cells. The neuroepithelial transforming gene 1 (Net1) was discovered in this way using a cDNA library derived from neuroepithelioma cells (Chan et al. 1996). The Net1 cDNA initially cloned from this screen lacked the coding sequence for the first 145 amino acids of full length Net1, which was subsequently found to be critical to its transforming activity. NIH 3T3 cells expressing truncated Net1 were found to exhibit anchorage-independent growth in soft agar assays, and were tumorigenic when injected into nude mice. Thus, Net1 fit the requirements for a putative oncogene.

Since that time it has become appreciated that Net1 belongs to a large family of Rho GEFs containing tandem Diffuse B cell lymphoma (Dbl) and Pleckstrin homology (PH) domains. There are nearly 70 members within the Rho GEF family that exhibit different specificities for Rho proteins, distinct regulatory mechanisms, and unique tissue distributions. Net1 was originally described as being ubiquitously expressed, with lower levels of expression in the heart, brain, and pancreas (Chan et al. 1996). However, a detailed study of its expression in different tissues has not been published. Two isoforms of Net1 exist, Net1 and Net1A, which are identical except for their N-terminal regulatory domains (Fig. 1). The unique portion of the N-terminus corresponding to the Net1 isoform consists of an 85 amino acid span that contains two nuclear localization signal (NLS) sequences (Schmidt and Hall 2002), while the unique 31 amino acid portion of Net1A has no identified function. The rest of the N-terminus is shared between Net1 isoforms, and this region contains two additional predicted NLS sequences. The DH domain of Net1 proteins binds to RhoA and in conjunction with the PH domain mediates RhoA activation. Although PH domains were originally characterized as phosphoinositide binding domains, the PH domain of Net1 has not been shown to bind phospholipids. The shared C-terminus of Net1 isoforms is 93 amino acids in length. Its only characterized function to date is mediated by its C-terminal PDZ domain–binding site.

Regulation of Net1 Activity

Net1 activity in the cell is regulated at the levels of transcription, subcellular localization, and posttranslational modification. Transcription of Net1 isoforms is controlled by alternate promoters which allows for



Net1 (Neuroepithelial Cell Transforming Gene 1 Protein), Fig. 1 Domain organization of Net1 proteins. Nuclear localization signal (*NLS*) sequences are shown in *orange*. The catalytic Dbl homology (*DH*) domain is shown in *light blue*. The Pleckstrin Homology (*PH*) domain is shown in *light green*. The C-terminal PDZ domain–binding site (*PDZ*) is shown in *dark blue*. Serine 152 is the negative regulatory Pak1 phosphorylation site. Numbers refer to amino acids within human Net1 and Net1A

their differential expression under certain circumstances (Dutertre et al. 2010). For example, in MCF7 breast cancer cells estrogen potently stimulates Net1 transcription and weakly downregulates Net1A transcription. On the other hand, progesterone stimulates the transcription of both Net1 and Net1A in MCF7 and T47D breast cancer cells (Dutertre et al. 2010). Most studies to date have not differentiated between Net1 isoforms when studying Net1 expression. Thus, TGFβ has been reported to stimulate Net1 transcription in human keratinocytes (Shen et al. 2001). IL-2 stimulation increases Net1 expression in Kit 225 human lymphocytes (Mzali et al. 2005), and both ▶ TNFα and LPA stimulate Net1 expression in AGS gastric cancer cells (Leyden et al. 2006; Murray et al. 2008).

Apart from transcriptional regulation, the cellular activity of Net1 proteins is also highly regulated. One important mode of regulation is by control of subcellular localization. Both Net1 isoforms contain multiple NLS sequences in their amino-termini, and when overexpressed in cells they accumulate in the nucleus (Schmidt and Hall 2002; Qin et al. 2005). Since RhoA activation is thought to occur only at the plasma membrane, this means that nuclear sequestration of Net1 isoforms is a mechanism to negatively regulate their activities. Regulatory signals that control the nuclear export of either Net1 isoforms are unknown at present. Both Net1 isoforms contain possible nuclear export signal (NES) sequences in their common PH domain, and treatment of cells with the CRM1 inhibitor leptomycin B has been shown to cause an increased accumulation of the N-terminal truncation mutant Net1ΔN in the nucleus (Schmidt and Hall 2002). However, since this was only a partial effect, it is possible that there are additional, leptomycin B–resistant exportins that control the nuclear exit of Net1 proteins.

The catalytic activity of Net1 is also regulated within the cell. Specifically, phosphorylation by the Rac and Cdc42 regulated kinase ▶ Pak1 negatively regulates Net1 catalytic activity (Alberts et al. 2005). Pak1 has been shown to phosphorylate Net1 on serines 152, 153, and 538 in vitro, and on serine 152 in cells. Serines 152 and 153 are contained within an amino-terminal extension of the DH domain that is restricted to a subset of RhoA-specific GEFs (Alberts and Treisman 1998). Substitution of serines 152 and 153 with the phosphorylation mimetic glutamate inhibits the ability of Net1 to catalyze GDP exchange on RhoA in vitro, and also blocks the ability of expressed Net1ΔN to cause actin stress fiber formation in cells. Similarly, overexpression of constitutively active Pak1 blocks stress fiber formation caused by co-expression of wild type Net1, but not by a Net1 mutant containing alanine substitutions at serines 152 and 153 (Alberts et al. 2005).

The cellular activity of Net1A is also tightly regulated by ubiquitylation (Carr et al. 2009). Net1 isoforms contain a C-terminal PDZ domain–binding site that mediates interaction with proteins within the Dlg1 family. Interaction of Net1A with Dlg1 prevents its ubiquitylation in MCF7 breast cancer cells, and increases the half-life of Net1A from 25 min to 10^5 h. This effect was specific for Dlg1, since co-expression of the Net1 interacting, PDZ domain containing protein Magi-1b did not significantly stabilize Net1A (Carr et al. 2009). Interestingly, the interaction of endogenous Net1A with Dlg1 in these cells is dependent on the formation of E-cadherin-mediated cell contacts, since disruption of these contacts causes a rapid and dramatic increase in Net1A ubiquitylation. In this same study, it was determined that Net1ΔN is stable when expressed in MCF7 cells, indicating that the amino-terminus of Net1A is important for regulating its degradation (Carr et al. 2009). The enhanced stability of Net1ΔN may also account for its strong transforming ability relative to full length Net1 isoforms.

Regulation of Actin Cytoskeletal Organization by Net1

Net1 has been shown to act as a GEF for RhoA, but not Rac1 or Cdc42 (Alberts et al. 1998). By analogy with

other RhoA-specific GEFs, Net1 may also have activity toward the RhoA subfamily members RhoB and RhoC, although this has not been tested. When overexpressed in mouse fibroblasts, Net1 stimulates the formation of actin stress fibers that are a hallmark of RhoA activation (Alberts et al. 1998). In this regard, the N-terminal truncation mutant Net1ΔN is far more efficient at stimulating stress fiber formation than full length Net1, which is most likely due to the enhanced localization of Net1ΔN outside the nucleus. Net1 has also been reported to mediate actin stress fiber formation in human keratinocytes following stimulation with TGFβ (Shen et al. 2001). Similar to other RhoA-specific GEFs, the ability of Net1ΔN to stimulate actin stress fiber formation is dependent on downstream activation of the RhoA effector kinases ▶ ROCK1 and ▶ ROCK2 (Tran et al. 2000).

Additional Physiological Roles of Net1

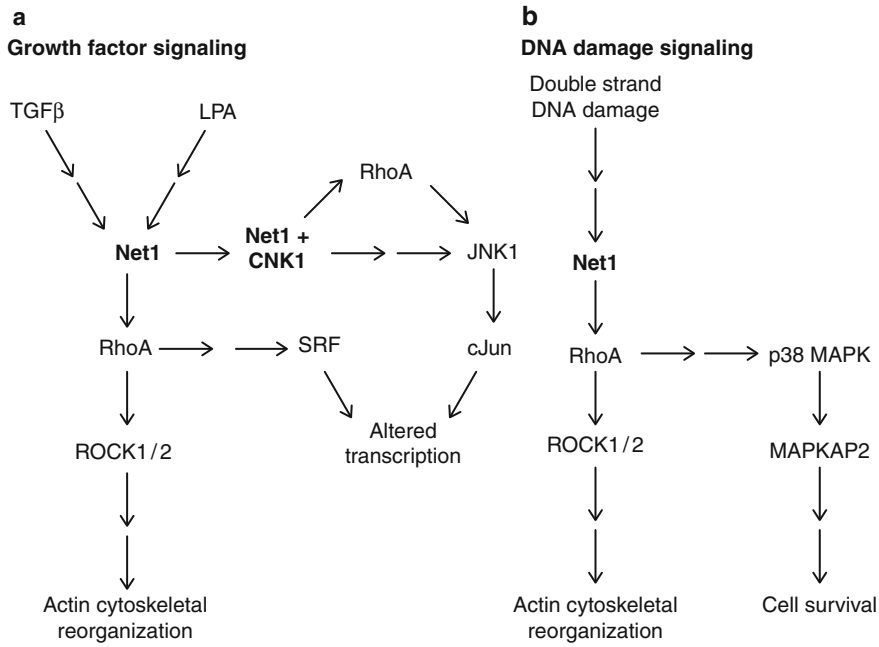
Net1 likely plays important roles during development and differentiation. For example, in chicken epiblasts Net1A expression is required for RhoA activation at the basal surface and maintenance of the integrity of the basement membrane (Nakaya et al. 2008). During gastrulation, epiblasts undergo an epithelial to mesenchymal transition (EMT) that is accompanied by loss of Net1A expression on the basal membrane, and enforced expression of RhoA or Net1A in these cells prevents basement membrane breakdown and EMT (Nakaya et al. 2008). Similarly, overexpression of xNet1A in *Xenopus* embryos inhibits gastrulation movements (Miyakoshi et al. 2004). Net1A expression is also strongly upregulated during mouse osteoclast differentiation in vitro, and inhibition of Net1A expression in these cells prevents cell fusion that is required for osteoclast formation (Brazier et al. 2006). All of these processes are associated with dramatic changes in actin cytoskeletal organization and altered cell motility, both of which are RhoA-regulated events.

By regulating the activation of RhoA and ▶ MAP Kinases, Net1 also impacts transcription factor activation. For example, overexpression of the N-terminal deletion mutant Net1ΔN in NIH 3T3 cells stimulates serum response factor (SRF) activation. This requires activation of both RhoA and the stress-activated protein kinase/Jun N-terminal kinase (SAPK/JNK) pathway (Alberts et al. 1998). In Hela cells, Net1ΔN expression stimulates SAPK/JNK activation through interaction with the scaffold protein Connector Enhancer of KSR 1 (CNK1), which results in efficient activation of the transcription factor c-Jun (Jaffe et al. 2005). Stimulation of c-Jun activity by Net1ΔN requires both RhoA and SAPK/JNK activation, and stimulation of c-Jun activity by the extracellular ligand LPA requires endogenous CNK1 expression. However, it is unknown whether LPA-stimulated c-Jun activity also requires endogenous Net1. Taken as a whole, these data suggest that Net1 controls RhoA and SAPK/JNK activation to regulate transcription factors such as SRF and c-Jun, which are associated with cell proliferation and transformation (Fig. 2a).

Net1 may also play a role in protecting cells from death following DNA damage (Guerra et al. 2008). It has recently been shown that Net1 is dephosphorylated on the negative regulatory phosphorylation site serine 152 following exposure of Hela cells to ionizing radiation (IR), suggesting that it is activated by IR treatment. In addition, RNAi-mediated knockdown of Net1 expression sensitizes these cells to IR-induced apoptosis. Knockdown of Net1 expression also prevents RhoA activation following IR, which has previously been shown to be required for protection from IR. Similarly, inhibition of Net1 expression in these cells blocks the activation of p38 MAPK and its downstream substrate MAPKAP2, both of which are required for cell survival following IR exposure (Fig. 2b). Thus, these data indicate that Net1 plays an important role in the survival response of cells to IR, which may have important consequences for cancer therapy approaches.

Net1 and Cancer

Net1 was originally identified as a potential oncogene in mouse fibroblasts, and subsequent work suggests that it may play an important role in human cancer. For example, using differential display and real time PCR, Net1 transcripts have been shown to be overexpressed in human gastric cancers. In addition, transfection of siRNA targeting both Net1 isoforms into AGS gastric cancer cells inhibited both their proliferation and their ability to invade a Matrigel extracellular matrix (Leyden et al. 2006). In a separate study, RNAi-mediated knockdown of both Net1 isoforms in AGS gastric cancer cells dramatically attenuated basal levels of RhoA activation and prevented their migration



Net1 (Neuroepithelial Cell Transforming Gene 1 Protein), Fig. 2 Regulation of cell signaling by Net1. Net1 proteins respond to diverse stimuli to contribute to intracellular signaling following exposure to (**a**) extracellular growth factors or (**b**) double-strand DNA damage

in wound healing and transwell assays. In this study Net1 was also shown to be required for migration and invasion of cells in response to the extracellular ligand LPA (Murray et al. 2008).

Unfortunately, few studies have focused on whether individual Net1 isoforms are differentially regulated, or control different aspects of cancer cell behavior. Thus, it is difficult to predict whether one or both Net1 isoforms contribute to human cancer. However, in a recent study evidence was presented suggesting that Net1 isoforms do play different roles in the cell and may uniquely contribute to cell transformation. Specifically, it was shown in MCF7 breast cancer cells that estrogen treatment strongly upregulated Net1 transcription and weakly repressed Net1A transcription (Dutertre et al. 2010). This was likely to be important for the ability of these cells to proliferate in response to estrogen, since transfection with siRNA specific for the Net1 isoform inhibited their proliferation. On the other hand, transfection of these cells with Net1A-specific siRNA did not significantly block proliferation, but adversely affected cell adherence. Thus, these data are the first to report divergent roles for Net1 isoforms in any cell type, and suggest that Net1 isoforms may make distinct contributions to cell cycle progression and cytoskeletal organization.

Evidence is also accumulating in translational studies to indicate that Net1 expression may be an important factor in predicting cancer outcome. For example, Net1 has been reported to be overexpressed in human gliomas (Tu et al. 2010). Importantly, in this study elevated Net1 expression correlated with higher grade cancers and was prognostic of lower overall survival. Similarly, in a separate study of breast cancer patients, co-expression of Net1 with alpha6beta4 integrin was predictive of decreased distant metastasis-free survival (Gilcrease et al. 2009). Because antibodies specific for individual Net1 isoforms are not available, neither of these studies differentiated between Net1 isoforms. However, when expression of transcripts for each Net1 isoform was examined in breast cancers, high expression of Net1 mRNA, but not Net1A, was prognostic for decreased metastasis-free survival (Dutertre et al. 2010). Clearly, more detailed studies will be required in the future to determine whether a particular Net1 isoform is more closely associated with oncogenesis. However, taken together these data seem to indicate that increased expression of Net1 as a whole is associated with more aggressive cancers and poor patient prognosis.

Summary

Net1 is a Rho GEF that is specific for the RhoA subfamily of small G proteins. Two isoforms exist in

most cells that exhibit differential subcellular distributions and that may play distinct roles in the cell. The activities of Net1 proteins are tightly regulated by phosphorylation and ubiquitylation. Net1 proteins play important roles in gastrulation and also contribute to cellular differentiation. Net1 proteins may also be aberrantly expressed in human cancers and contribute to cancer initiation and/or progression.

University of Manitoba, Winnipeg, MB, Canada

Synonyms

NTR; NTS

Historical Background

Neurotensin was originally isolated from bovine hypothalamus by Carraway and Leeman in 1973 and was identified as a 13 amino acid peptide (Carraway and Leeman 1973). It was named "neurotensin" in view of its hypotensive activity. Neurotensin is produced by neurons in the central nervous system (CNS) and N cells of the gastrointestinal tract. It was later discovered that neurotensin is also present in several types of tumors. Neurotensin acts as a hormone and a neurotransmitter or neuromodulator in the periphery and in the CNS, respectively. Neurotensin is involved in the regulation of a number of physiological functions such as analgesia, neurodegeneration, thermal regulation, metabolic regulation, pituitary hormone secretion, and gastrointestinal motility. Thus, signaling pathways downstream of neurotensin could be a potential drug target for the treatment of a variety of diseases. However, we had to wait 17 years to see the first receptor for neurotensin (neurotensin receptor 1, NTSR1). Subsequently, two additional subtypes of the neurotensin receptor (NTSR2 and NTSR3) and a candidate for NTSR4 have been identified. Development of subtype-selective neurotensin analogs facilitated investigations of the role of neurotensin receptors in mediating the effects of neurotensin.

Neurotensin Receptor Subtypes

Neurotensin exerts its effects primarily through two neurotensin receptor subtypes, NTSR1 and NTSR2. NTSR1 is a high-affinity (0.1–0.3 nM) neurotensin receptor which is not sensitive to levocabastine, a nonpeptide H1 histamine antagonist. NTSR2 has a low affinity (Kd = 3–5 nM) for neurotensin and is sensitive to levocabastine. Both NTSR1 and NTSR2 are 7-transmembrane G-protein-coupled receptors (GPCRs). The human *NTSR1* gene, encoding a 418 amino acid protein, is located on the long arm of chromosome 20 (20q13). The human *NTSR2* gene encodes a 410 amino acid protein and is located on chromosome 2 (2p25.1). Separate NTSR subtypes display distinctive tissue distribution patterns (Table 1). NTSR1 is distributed widely throughout the CNS and is also found in the small and large intestines as well as the liver. NTSR2 is located more diffusely in the CNS than NTSR1. Two additional receptors have been shown to bind neurotensin among other ligands. Both receptors are single transmembrane domain receptors of the type I family. The NTSR3 was originally identified as the intracellular sorting protein sortilin. The human *SORT1* gene, encoding an 831 amino acid protein, is located on the short arm of chromosome 1 (1p21.3-p13.1). NTSR3/sortilin, like NTSR1, binds neurotensin with high affinity once converted to its mature form upon cleavage. Sorting protein-related receptor (SorLA, also known as LR11) has been proposed as a fourth neurotensin receptor. The human *SorLA* gene, encoding a 2214 amino acid peptide, was mapped to chromosome 11 (11q 23.3-24). NTSR3/sortilin and SorLA/LR11 are located primarily in the CNS, but also in nonneuronal tissues (Table 1) (Vincent et al. 1999; Dobner 2005; St-Gelais et al. 2006).

Signal Transduction of NTSR Receptors

Stimulation of NTSR1 leads to the activation of multiple signaling pathways. The major signal transduction event associated with the activation of NTSR1 is the stimulation of phospholipase C (PLC), which is responsible for the production of inositol 1,4,5-triphosphate, Ca^{2+} mobilization, and activation of extracellular signal-regulated kinase 1/2 (ERK1/2), a member of ▶ mitogen activating protein kinase (MAPK) in a variety of tissues and cells. Neurotensin-induced ERK1/2 activation is also mediated via the activation of small GTPase Ras protein and epidermal growth factor receptor (EGFR) in human colonial epithelial cells. NTSR1 activation stimulates ▶ nuclear factor kappaB (NF-κB) which is dependent on intracellular calcium release. Neurotensin activates the Rho family proteins RhoA, Rac1, and Cdc42 and neurotensin-induced ▶ NF-κB activation, but not ERK1/2 activation, is mediated through the activation of RhoA, Rac1, and Cdc42. Little is known about the signaling pathways activated by the other three receptor subtypes. When NTSR2 is challenged with neurotensin, internalization of receptor–ligand complexes occurs through the activation of ERK1/2. Stimulation of NTSR3/sortilin activates ERK1/2 and ▶ phosphoinositide 3-kinase (PI3K)-dependent pathways in microglial cell lines (Martin et al. 2005; Zhao and Pothoulakis 2006; Ferraro et al. 2009). Homodimer and/or heterodimer of GPCRs play

Neurotensin Receptor (NTSR), Table 1 Tissue distribution of neurotensin receptors

NTSR1	NTSR2	NTSR3/sortilin	SorLA/LR11 (NTSR4)

Gastrointestinal tract	Pancreas	Pancreas	Lymph node
Carotid body		Adipose tissue	
Liver		Skeletal muscle	
		Placenta	
		Testis	

important roles in receptor-trafficking, agonist-binding, and signal transduction. Heterodimerization/oligomerization alters receptor functions by forming new receptor complexes that exhibit ligand-binding properties distinct from monomeric receptors. NTSR1 and NTSR2 can form heterodimers, and NTSR2 suppresses neurotensin-induced NTSR1 activity (Hwang et al. 2009). The formation of NTSR1/NTSR2 heterodimers may provide additional functional resources to the cells.

Physiological Relevance of CNS NTSR Signaling

Neurotensin-containing neurons are neuroanatomically associated with the brain dopamine system, and neurotensin acts as a neuromodulator of dopamine transmission in several areas of the brain, including the nigrostriatal and mesolimbic pathways. Neurotensin increases the activity of dopaminergic neurons and dopamine release by antagonizing dopamine D_2 receptor function through NTSR1-mediated increases in intracellular Ca^{2+} and an interaction between NTSR1 and D_2 receptors. Neurotensin levels are increased and NTSR1 mRNA levels are lower in the substantia nigra of Parkinson's disease patients than in controls. Treatment with neurotensin analogs reduces tremor and muscle rigidity in animal models of Parkinson's disease. These findings argue for the possibility that enhanced signaling through substantia nigra NTSR1 supplements dopaminergic agonists to augment the function of the remaining dopaminergic neurons in Parkinson's disease. However, activation of NTSR1 by neurotensin enhances N-methyl-D-aspartate (NMDA)-induced increase in extracellular glutamate levels. The neurotensin-mediated potentiation of NMDA receptor signaling may be mediated by phosphorylation of the NMDA receptors by protein kinase C. Glutamate is the major excitatory neurotransmitter, and the excessive activation of glutamate receptors, especially NMDA receptors, has been postulated to contribute to the neuronal injury. In cultured dopaminergic neurons, neurotensin enhances the neurotoxic effects of glutamate on dopaminergic neurons via NTSR1 activation. Thus, treatment with selective NTSR1 antagonists may be beneficial in improving the symptoms of Parkinson's disease (Antonelli et al. 2007; Mustain et al. 2011). Abnormal neurotensin-NTSR1 signaling has been also found in the brain of Alzheimer's disease patients. Regardless of whether CNS neurotensin-NTSR1 signaling is beneficial or deleterious in neurodegenerative processes, this signaling pathway is likely to be involved in the etiology of neurodegenerative diseases.

Centrally administered neurotensin causes a variety of effects similar to those exhibited by antipsychotic drugs. Reduced signaling capacity through NTSR1 contributes to psychotic symptom in schizophrenia. Cerebrospinal fluid levels of neurotensin are lower in schizophrenic patients than in control subjects, whereas increased levels of neurotensin are associated with improvement in symptoms during treatment. The density of neurotensin receptors (primarily NTSR1) is decreased in the intermediate entorhinal cortex of schizophrenia patients. Both NTSR1-deficient mice and NTSR2-deficient mice show schizophrenia-like signs, such as amphetamine-induced hyperlocomotion and lower basal glutamate levels. Lack of neurotensin causes diminished prepulse inhibition (PPI), a schizophrenia-like sign, while NTSR1 deficiency does not

alter PPI and NTSR2-deficient mice have elevated PPI (Mustain et al. 2011). These findings support the idea that enhanced neurotensin-NTSR signaling is beneficial in improving schizophrenia symptoms. It is presently unclear what NTSR subtype is involved in this process. Brain-region-specific alterations in neurotensin-NTSR signaling may play a role in the etiology of schizophrenia.

Neurotensin has analgesic effects that are μ-opioid independent. Although NTSR2 was initially considered as a main receptor subtype mediating the antinociceptive effect of neurotensin, NTSR1 is also involved in neurotensin-induced analgesia. Both NTSR1 and NTSR2 are required for different aspects of neurotensin-induced analgesia and these two receptors modulate the pain-induced behavior responses by suppressing activity of distinct spinal and/or supraspinal neural circuits (Dobner 2005; St-Gelais et al. 2006; Roussy et al. 2009).

CNS neurotensin-NTSR signaling plays a role in neuroendocrine function via modulation of the activity of the hypothalamus-pituitary axis. Neurotensin stimulates secretion of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH), and inhibits thyroid-stimulating hormone (TSH) secretion. Hypothalamic action of neurotensin increases prolactin secretion, while neurotensin action on the adenohypophysis causes a reduction in prolactin secretion. The direct hypothalamic effect of neurotensin in reducing prolactin secretion may be mediated by dopamine release into the portal system. It is unclear whether these effects of neurotensin are mediated via NTSR1 and/or NTSR2. Both receptors are expressed in the hypothalamus and anterior pituitary. Neurotensin has been implicated in the mediation of the pre-ovulatory positive feedback of estradiol on GnRH release via NTSR2 activation. NTSR2 also mediates neurotensin-induced increase in CRH and corticosterone secretion in response to stress (Lafrance et al. 2010; Stolakis et al. 2010; Mustain et al. 2011).

Neurotensin participates in the regulation of metabolism. Central administration of neurotensin reduces food intake via NTSR1. NTSR1 also mediates effects of other anorexigenic hormones, leptin and xenin. Genetic deletion of NTSR2 did not cause any metabolic abnormalities in mice, while NTSR1-deficient mice have increased body weight, food intake, and adiposity, implicating NTSR1 in metabolic regulation (Mustain et al. 2011).

CNS action of neurotensin reduces body temperature. NTSR1-deficient mice have increased body temperature and do not respond to the hypothermic effect of neurotensin, implicating neurotensin-NTSR1 signaling in thermal control.

Physiological Relevance of Peripheral NTSR Signaling

The effects of neurotensin in the gastrointestinal tract are mediated by both neural and hormonal mechanisms. Neurotensin elicits a relaxing effect on duodenal longitudinal muscle and induces contraction of the ileal muscle and the proximal colon. These neurotensin-induced alterations in gastrointestinal motilities were blocked by NTSR1 antagonist and were absent in NTSR1-deficient mice. Neurotensin-related peptide, xenin, also affects gastrointestinal motility partly via activation of NTSR1. These findings indicate that neurotensin regulates gastrointestinal motility via NTSR1 (Zhao and Pothoulakis 2006).

Neurotensin-NTSR1 signaling is associated with the progression and differentiation of tumors. NTSR1 is expressed in tumors of the ovary, pancreas, colon, prostate, and breast. High NTSR1 expression is associated with a larger tumor size, and the size of tumor becomes smaller in the presence of NTSR1 antagonist. In human breast cancer cell lines, functionally expressed NTSR1 receptor coordinated a series of transforming events, including cellular migration and invasion. The NTSR1 gene is a target of oncogenic pathways known to activate genes involved in cancer cell proliferation and transformation. When NTSR1 is challenged with neurotensin, a variety of signaling pathways are activated. For example, activation of NTSR1 promotes growth of colon tumors through NF-κB activation. Neurotensin also increased the activity of PI3K signaling by increasing specific microRNA species via NTSR1 in colon epithelial cells. During prolonged neurotensin agonist stimulation, NTSR1 receptors are recycled to the cell surface, leading to the long-term activation of ERK1/2, an oncogenic signaling pathway. These findings place NTSR1 at a major nexus between neurotensin and tumorigenesis. Although NTSR3 is also present in several types of cancer cells, the role of NTSR3 in cancer is presently unknown (St-Gelais et al. 2006; Bakirtzi et al. 2011; Mustain et al. 2011).

Physiological Relevance of Non-GPCR NTSRs

Whereas both NTSR3/sortilin and SorLA/LR11 are capable of binding neurotensin, the physiological relevance of these receptors is largely unclear. NTSR3/sortilin is predominantly expressed in regions of the CNS that neither synthesize nor respond to neurotensin. It binds a variety of ligands such as the receptor-associated protein (RAP) and lipoprotein lipase (LPL), and nerve growth factor precursor (proNGF) (St-Gelais et al. 2006). It is thus possible that NTSR3/sortilin subserves non-neurotensin-related functions in the CNS. NTSR3/sortilin may be involved in the neurotensin-induced migration of human microglial cells via the activation of both MAPK and ▶ PI3K signaling pathways (Martin et al. 2005). NTSR3/sortilin may also play a role in the regulation of metabolism. Levels of NTSR3/sortilin mRNA and protein were reduced in adipose tissue and skeletal muscle of obese mice and patients. NTSR3/sortilin promotes the formation of insulin-responsive glucose transporter 4 (GLUT4) storage vesicles in adipocyte cell line. Palmitate reduces the expression of NTSR3/sortilin in adipocytes and skeletal muscle cells (Tsuchiya et al. 2010). These recent findings suggest that NTSR3/sortilin plays a role in glucose homeostasis by modulating GLUT4 trafficking in adipose tissue and skeletal muscle and mediates FFAs-induced insulin resistance in these tissues.

It has been suggested that SorLA/LR11 regulates the processing of the amyloid precursor protein and levels of SorLA/LR11 are reduced in the brains of Alzheimer disease patients, suggesting a possible role of SorLA/LR11 in the pathogenesis of this disease (Andersen et al. 2005).

Summary

Neurotensin exerts diverse actions through NTSR receptors in the CNS and in the periphery. Alterations in NTSR signaling have been implicated in a wide range of pathologic conditions such as schizophrenia, Parkinson's disease, metabolic disorders, and cancer. Signaling pathways involving NTSR receptors and their downstream mediators could be potential drug targets for the treatment of these impairments. Pharmacological tools and genetically engineered animal models enabled us to manipulate NTSR signaling and we have begun to elucidate specific role for each NTSR subtype. Creation of animal models with cell type–specific ablation of specific NTSR subtype should help clarify the role of NTSR subtypes in the mediation of neurotensin action. Development of additional subtype-selective agonistic and antagonistic neurotensin analogs that cross the blood-brain barrier may offer new avenues for the treatment of disorders associated with altered NTSR receptor signaling.

NFAT

Rut Valdor, Brian T. Abe and Fernando Macian
Department of Pathology, Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

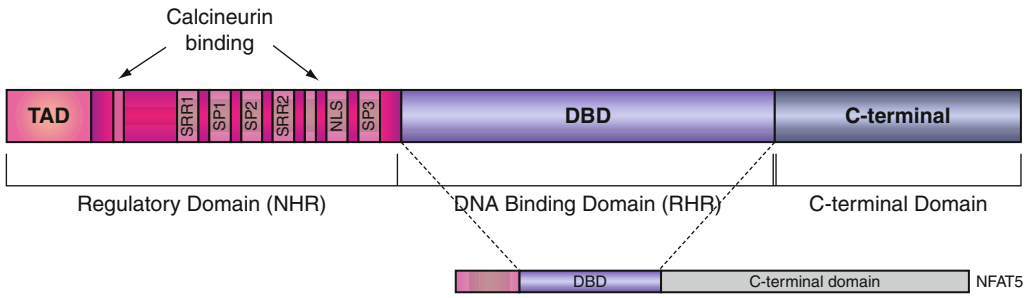
NFAT1 (Nuclear factor of activated T-cells 1, NFATp, NFAT preexisting, NFATc2, NFAT cytosolic 2); NFAT2 (Nuclear factor of activated T-cells 2, NFATc, NFAT cytosolic, NFATc1, NFAT cytosolic 1); NFAT3 (Nuclear factor of activated T-cells 3, NFATc4, NFAT cytosolic 4); NFAT4 (Nuclear factor of activated T-cells 4, NFATx, NFATc3, NFAT cytosolic 3); NFAT5 (Nuclear factor of activated T-cells 5, TonEBP, Tonicity-responsive enhancer binding protein, NFATz, OREBP, Osmotic response element-binding protein, NFATz, NFAT-L1, NFAT-related protein 1)

Historical Background

Initially defined as a factor that bound the interleukin (IL)-2 promoter in activated T cells, the first Nuclear Factor of Activated T cells (NFAT) protein was isolated almost 20 years ago and termed NFATp, as it was shown to be "preexistent" in the cytosol of resting cells. In activated T cells, NFATp interacted in the nucleus with Fos and Jun proteins to induce the expression of IL-2 (Jain et al. 1993; McCaffrey et al. 1993). Soon after that, new members of the NFAT family were also identified and the characterization of the calcineurin-mediated dephosphorylation and activation of NFAT proteins allowed establishing them as the targets of the immunosuppressive effects of cyclosporine A. Although initial efforts were focused in studying the role of NFAT proteins in the regulation of T cell activation, it soon became clear that this ubiquitously expressed family of transcription factors was also involved in the regulation of a multitude of programs of development and differentiation in many other cell types. This chapter reviews the current understanding on the mechanisms that regulate the activity of NFAT proteins and the functions that these proteins have in different cells and tissues.

Family and Structure

The NFAT family of transcription factors comprises five different members: NFAT1 (also known as NFATp or NFATc2), NFAT2 (NFATc or NFATc1), NFAT3 (NFATc4), NFAT4 (NFATx or NFATc3), and NFAT5. The activation of NFAT1, NFAT2, NFAT3, and NFAT4 is regulated by the calcium/calmodulin-activated phosphatase calcineurin, whereas NFAT5 is the only NFAT protein that is not regulated by calcium (Macian 2005). NFAT5, which was also identified as the Tonicity-responsive Enhancer-Binding Protein, has been shown to regulate the expression of osmoprotective genes in mammalian cells in response to osmotic stress (Lopez-Rodriguez et al. 2001). All NFAT family members share a conserved DNA-binding domain, which in turn shares structural homology with the Rel domain found in the NF-κB family of transcription factors. The DNA-binding domain confers specific DNA binding and mediates interactions with many transcriptional partners, including Fos and Jun proteins (Chen et al. 1998). With the exception of NFAT5, NFAT proteins have also an N-terminal regulatory domain, known as the NFAT homology region (NHR). The NHR contains transactivation and regulatory domains, which include interaction sites for calcineurin and several kinases that regulate NFAT activation by modifying the phosphorylation status of multiple serine-containing motifs (Fig. 1) (Hogan et al. 2003). NFAT5 also contains a Rel domain as a conserved DNA-binding and dimerization domain but it lacks a NHR (Lopez-Rodriguez et al. 2001). The C-terminal region is not conserved among the different NFAT proteins and has been shown to contain sites that may allow interactions with transcriptional co-activators.



NFAT, Fig. 1 NFAT1, 2, 3, and 4 contain a regulatory domain (NHR or NFAT-homology domain), which comprises a transactivation domain (TAD), several target phosphorylation motifs for NFAT-kinases (SRR1, SRR2, SP1, SP2, and SP3), calcineurin-binding sites, and the nuclear localization signal (NLS); and a DNA-binding domain (DBD or Rel-homology region, RHR), which also contains residues required to interact with Fos and Jun proteins. NFAT5 shares a conserved DNA-binding domain but differs in the rest of its structure for the other NFAT family members

Regulation

NFAT activation is mainly regulated by its subcellular localization. The net result of the rate of nuclear import and export of NFAT proteins, which is controlled by their phosphorylation status, determines the overall level of activation of NFAT. Moreover, several other mechanisms have also been described to contribute to the fine regulation of the transcriptional activity of NFAT.

Regulation by calcium and calcineurin: Engagement of calcium-coupled receptors, such as the T cell receptor (TCR), induces the activation of the calcium/calmodulin-dependent phosphatase calcineurin, which binds NFAT proteins and directly dephosphorylates them, inducing their translocation into the nucleus. In T cells, where this complex regulation has been better characterized, engagement of the TCR induces activation of the phospholipase Cγ, which hydrolyzes phosphatidylinositol 4,5-biphosphate into inositol-1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 binds IP_3 receptors in the endoplasmic reticulum and induces calcium-release from intracellular calcium stores. STIM proteins sense this depletion and activate calcium entry through interaction with ORA1, an integral component of the calcium-release activated calcium (CRAC) channels in the plasma membrane, causing a further increase in the intracellular calcium levels (Feske et al. 2006; Oh-hora and Rao 2008). In response to the increase in the intracellular calcium concentration, calcineurin is activated and binds to NFAT and dephosphorylates NFAT proteins, which are heavily phosphorylated and localized in the cytosol in resting cells (Fig. 2). At least 13 different phosphorylation sites located in serine-rich motifs and SPxx repeat motifs in the regulatory domain are dephosphorylated by calcineurin. Dephosphorylation of these residues causes a conformational change in NFAT that exposes a nuclear localization signal, allowing NFAT import into the nucleus, where it binds specific sites and cooperates with other transcription factors to activate the expression of distinct sets of genes (Hogan et al. 2003).

NFAT-kinases: Phosphorylation of NFAT proteins is required to promote nuclear export and to maintain cytosolic localization in resting conditions. Several kinases have been reported to be responsible for the phosphorylation of different serine-containing motifs in NFAT. Casein kinase1 (CK1) binds the N-terminal region of NFAT and regulates its nuclear export and cytosolic retention through phosphorylation of a serine-rich motif. Glycogen synthase kinase 3 (GSK3) phosphorylates serine-proline motives in NFAT1 and NFAT2, promoting NFAT nuclear export. These phosphorylation sites appear to be created by previous priming by cyclic-AMP dependent Protein Kinase-mediated phosphorylation of NFAT. Activation of the AKT kinase negatively regulates GSK3 and prolongs NFAT residence time in the nucleus. The dual-specificity tyrosine-(Y)-phosphorylation-regulated kinases DYRK1A and DYRK2 also regulate NFAT nuclear export through phosphorylation of an SP motif that primes for subsequent phosphorylation by CK1 or GSK3. There is evidence that other kinases, such as p38 and JNK, PIM1, or Cot, may also phosphorylate NFAT proteins and contribute to their regulation (Macian 2005; Muller and Rao 2010).

Pathways involved in the activation of NFAT by nuclear import and modulation of its transcriptional activity are represented with solid arrows, whereas the pathways involved in NFAT nuclear export or cytosolic retention are depicted with dashed arrows. *APC* antigen presenting cell, *TCR* T cell receptor, *MHC* major histocompatibility complex, *PLC-γ* phospholipase Cγ, *P* phosphate, Ptdins(4,5)P_2, phosphatidylinositol 4,5-biphosphate, *IP3* inositol-1,4,5-triphosphate, *DAG* diacylglycerol, *IP3R* inositol-1,4,5-triphosphate receptor, Ca^{2+} calcium, *CRAC* calcium release activated calcium channel, *STIM* stromal interaction molecule, *NFAT* nuclear factor of activated T cells, *CM* calmodulin, *Cn* calcineurin, *CK1* casein kinase1, *NLS* nuclear localization signal, *NES* nuclear export signal, *PIM1* proto-oncogene serine/threonine-protein kinase 1, *Cot* cancer Osaka thyroid oncogene 1, *DYRK* dual-specificity tyrosine-(Y)-phosphorylation-regulated kinase 1, 2, *GSK3* glycogen synthase kinase 3, *CRM1* exportin 1, *JNK* C-Jun N-terminal kinase, *AP-1* activator protein 1, *PKC* protein kinase C, *IKK* inhibitor of kappa B kinase

Transcriptional regulation of NFAT: NFAT2A is an isoform of NFAT2 that is regulated at a transcriptional level by an auto-regulatory loop under the control of an inducible NFAT-dependent promoter. In T cells, it has been shown that the activation of constitutively expressed isoforms of NFAT2 and NFAT1, induces the expression and accumulation of this inducible NFAT2A isoform (Serfling et al. 2006).

Posttranslational regulation: Several posttranslational mechanisms that also contribute to the regulation of NFAT activity have recently been described. Sumoylation of NFAT has been characterized as a NFAT nuclear retention mechanism, which might also regulate NFAT transcriptional activity. Recently, evidence has also been presented that poly(ADP-ribose) polymerase-1 (Parp-1) interacts with NFAT1 and NFAT2, regulating NFAT nuclear export and its transcriptional activity. NFAT1 has also been characterized to be ubiquitinated by the E3 ubiquitin ligase MDM2 in breast cancer cells, which leads to its proteasome-mediated degradation (Mancini and Toker 2009; Muller and Rao 2010).

Transcriptional Activity

Numerous reports have shown that NFAT proteins form transcriptional complexes cooperating with many other transcription factors to activate or repress the expression of specific genes. This allows cells to integrate calcium signaling with other signaling pathways to regulate the expression of specific programs of gene expression. Initially identified as the nuclear component of the NFAT activity that was responsible for the expression of IL-2 in activated T cells, Activator protein 1 (AP-1) complexes are the best characterized NFAT partners, and one of the main families of transcription factors that interacts with NFAT during T cell activation. In response to the engagement of the TCR and co-stimulatory receptors, calcium signaling and the Ras-MAPK pathway converge in the activation of NFAT and Fos and Jun proteins, which form the AP-1 complex. The DNA-binding domain of NFAT interacts with AP-1, forming a quaternary complex on DNA that activates the expression of activation-induced genes, including numerous cytokines. The number of transcription factors that have been identified to cooperate with NFAT has grown in the last few years. In many cases these interactions occur in specific cells of tissues and are responsible for the regulation of different programs of activation, differentiation, or development. A list of transcription factors that cooperate with NFAT to activate or inhibit the expression of particular genes is shown in Table 1. NFAT proteins are also able to form homodimers. These complexes bind to κB-like sites that contain two tandem NFAT-binding sites separated by one or two bases. NFAT dimers have been reported to bind the promoter of several genes to positively regulate their expression. Recently, dimers formed by NFAT1 have been implicated in regulating the expression of genes that are responsible for the induction of an unresponsive state in anergic T helper cells (Soto-Nieves et al. 2009). In addition, NFAT5 is a constitutive dimer and needs to form homodimers to bind to DNA and exert its transcriptional activity (Lopez-Rodriguez et al. 2001).

Functions

The innate immune system is our first line of defense against invading pathogens and, therefore, it must react quickly and efficiently. Cell types involved in this process include eosinophils, neutrophils, mast cells, and macrophages. NFAT proteins have been shown to be expressed in all these cell types and serve a pivotal role in transforming molecular signals to expression of genes. For instance, fungal infections are commonly seen in cyclosporine A treated individuals and appear to respond to impaired killing of fungi caused by inhibition of NFAT-mediated gene expression in neutrophils (Greenblatt et al. 2010). NFAT expression also plays an integral part of the mast cell response, as ligation of the FcεR with IgE results in intracellular calcium fluxes, causing mast cells to release histamine containing granules and to produce cytokines (Turner and Kinet 1999). Calcineurin has also been shown to regulate the toll-like receptor pathway and, therefore, blocking calcineurin activity and NFAT activation leads to altered innate and inflammatory responses.

The adaptive immune response is highly specific and efficient at targeting pathogens and infected cells for elimination. This arm of the immune system involves the uptake and processing of foreign material by antigen presenting cells and the presentation of this material to effector cells. The activation of effector cells is governed by the recognition of an antigen by the B cell Receptor (BCR) or its presentation in the context of an MHC molecule to cognate TCRs on T cells. NFAT has been most extensively studied in T cells, although roles in the regulation of B cell have also been characterized. NFAT proteins are activated in B cells in response to BCR engagement and have been shown to be involved in the induction of the programs of gene expression that regulate B cell activation and differentiation. As described in detail above, in T cells, TCR triggering by the recognition of antigen: MHC complexes induces the calcineurin-mediated dephosphorylation of NFAT proteins, which causes nuclear localization of these transcription factors and leads to the expression of genes involved in a productive immune response (Wu et al. 2007; Muller and Rao 2010). Coordinated engagement of the TCR and the co-stimulatory receptor CD28 leads to the nuclear presence of the NFAT transcriptional partners Fos and Jun, which are necessary for IL-2 production and proper T cell activation and proliferation. In the absence of co-stimulation, TCR triggering still leads to NFAT nuclear localization, however, without the opportunity to cooperate with Fos and Jun, NFAT proteins form homodimers that regulate the expression of

NFAT, Table 1 NFAT transcriptional partners

NFAT transcriptional partners	Interaction site	Effect of cooperation with NFAT
AP-1(Fos, Jun)	Cytokine promoters, *Rorgt*	Activating
ICER	*Il2* promoter	Inhibiting
$P21^{SNFT}$	*Il2* promoter	Inhibiting
Foxp3/Runx1	*Il2* promoter or *Gitr, Cd25, Ctla4* promoters	Inhibiting or activating, respectively
PPAR-γ	Cytokine promoters	Inhibiting
Mina	*Il4* promoter	Inhibiting
t-bet	*Ifng* enhancer	Activating
c-MAF/IRF4	*Il4* promoter	Activating
IRF4	Cytokine promoters and *Rorgt*	Activating
BRG1	*Il4* promoter	Activating
GATA3	*Il4 3'* enhancer	Activating
MEF2	*Nur77* promoter	Activating
Smad3	*Foxp3 promoter*	Activating
EGR1 and EGR4	*Tnf* promoter	Activating
C/EBP	*Pparg* promoter	Activating
OCT	*Il3* enhancer	Activating
MITF	*Cathepsin K* promoter	Activating
Osterix	*Col1a1 promoter*	Activating
NIP45	*Il4 promoter*	Activating
Pu.1	*Beta3 integrin* promoter	Activating

genes involved in keeping T cells in a nonresponsive state termed anergy. Several genes, such as Grail, Caspase3, Ikaros, Deltex1, and Egr2, are required for the induction of anergy and their expression depends on the activation of NFAT in T cells that receive tolerizing stimuli (Macian et al. 2002; Baine et al. 2009). The involvement of NFAT proteins in the regulation of immune tolerance is also mediated through their role in the development of regulatory T cells (Treg), a distinct population of T cells that express the transcription factor FoxP3 and have the capacity to suppress the activation of other T cell populations. NFAT proteins not only regulate the expression of FoxP3 but also cooperate with this transcription factor to activate (CTLA-4, CD25, and GITR) or inhibit (IL-2) the expression of genes in Tregs and, therefore, regulate the differentiation and function of these suppressor cells (Wu et al. 2006).

T cell development is also dependent on NFAT activity. The development of thymocytes in the thymus involves their maturation into CD4+ and CD8+ T cells that can interact with MHC molecules. In the thymus, immature T cells rearrange both the α and β chains of the TCR and mature from a double negative (CD4-CD8-) thymocyte into a double positive thymocyte that expresses both CD4 and CD8 co-receptors. From here, T cells undergo a rigorous process that involves being positively selected for the presence of a TCR that can interact with MHC molecules, but negatively selected for self-reactive TCR that can recognize self-antigens. The lack of calcineurin activity in immature thymocytes leads to a block in positive selection, suggesting a role for NFAT proteins in thymocyte development. Recent evidence has shown that NFAT1 and NFAT4 are responsible for regulating the thresholds for the transduction of signals that are

necessary to induce positive selection in the thymus (Gallo et al. 2007).

CD4+ T cells can differentiate into many different effector subsets, and NFAT proteins are involved in these processes. Naïve T helper cells can differentiate into Th1, Th2, and Th17 cells, depending on the cytokine profile of the extracellular environment. In all these differentiation events, NFAT regulates the transcription of genes that help define the particular T cell subtype, which depends on the choice of transcriptional partners. For instance, T-bet is an integral co-transcriptional partner for NFAT in the development of Th1 cells and the secretion of their signature cytokine IFN-γ. Likewise, GATA3–NFAT interactions are necessary for IL-4 expression and the maturation into Th2 cells. Similarly, the presence of IL-6 in the extracellular milieu induces the expression of Rorgt, which synergizes with NFAT in the expression of IL-17, IL-21, and IL-22 to allow Th17 differentiation (Muller and Rao 2010).

Outside of the immune system, NFAT expression has been reported in almost all tissues, although the expression of any individual NFAT protein is often limited to specific tissues. For instance, whereas NFAT1, NFAT2, and NFAT4 are expressed in cells of the immune system and in several nonlymphoid cells and tissues, NFAT3 expression has not been reported in immune cells. During the last few years an increasing number of reports have characterized the role that different NFAT proteins have as regulators of development, differentiation, and function in many cells and tissues, including, skeletal muscle differentiation, myocardial hypertrophy, control of heart valve formation, vascular development, cartilage formation, neuronal development, and the regulation of stem cell quiescence (Wu et al. 2007). The expression of different NFAT proteins is developmentally regulated in skeletal muscle and these proteins control progression from immature precursors to mature myocytes and contribute to the specification of muscle fiber type. NFAT proteins also regulate cartilage growth and bone remodeling. The role that NFAT proteins play in the regulation of osteoclast differentiation has been amply documented. In these cells, RANKL-mediated activation of NFAT2 directs the expression of a set of genes required for osteoclast differentiation. Initial characterization of a mouse model that lacked expression of NFAT2 unequivocally showed that NFAT2 played a key role in the formation of the heart's valves. In the adult heart, NFAT proteins partner with members of the GATA and MEF2 families of transcription factors to regulate myocardial hypertrophy. NFAT3 and NFAT4 are expressed in perivascular mesenchymal cells, which regulate the assembly of blood vessels during embryogenesis, and mice that lack those NFAT proteins present an abnormal vascular development. Vascular endothelial growth factor is a major activator of NFAT proteins in endothelial cells, and engagement of its receptor leads to the activation of NFAT-dependent genes such as COX2. NFAT proteins also regulate neuronal axon growth and are essential for neuronal development and the differentiation of Schwann cells. NFAT has also been shown to control beta cell growth in the endocrine pancreas and regulate insulin-signaling pathways and adipogenesis. Recently, NFAT2 has also been implicated in the maintenance of stem cell quiescence in the skin follicle by repressing the expression of the cell cycle kinase CDK4 (Wu et al. 2007; Aliprantis and Glimcher 2010).

As discussed above, NFAT proteins are key regulators that control cell development and differentiation in part by modulating proliferation and cell death. As such, altered NFAT signaling has been described associated with cancer. As expected due to their pivotal role in lymphocyte development, altered NFAT activity have been associated with several forms of B and T cell lymphoma and leukemia. Furthermore, different NFAT family members have been shown to be involved in the regulation of different properties of many cancer cell types. For instance, NFAT1 and NFAT5 appear to positively regulate migration and invasion of breast cancer cells. Given their role in angiogenesis, NFAT proteins have also been proposed to regulate tumor-associated angiogenesis. Furthermore, NFAT may also directly activate the expression of oncogenes, such as *Myc* (Mancini and Toker 2009; Muller and Rao 2010).

Pharmacological Modulation of NFAT Activity

Pharmacological agents currently used to modulate NFAT activity have found tremendous benefit in the clinic. These agents, which inhibit the activation of T cells and act as immunosuppressants, are widely used in therapies ranging from treatment of autoimmune disease to prevention of organ transplant rejection. However, their widespread use is limited by their

costly side effects, such as nephrotoxicity. The activation of NFAT is dependent on its dephosphorylation, and, therefore, the phosphatase calcineurin has been an important area of focus for inhibitor development. Nevertheless, the specificity of NFAT inhibition is limited by the fact that NFAT is not the only target of calcineurin. Cyclosporine A and FK506 are the most widely used and studied suppressors of NFAT activity. Both are calcineurin inhibitors whose mechanism of action is quite similar. They bind separate intracellular peptidyl prolyl isomerases (cyclosporine A-cyclophilin; FK506-FKBP12). These complexes then bind to distinct regions of calcineurin and inhibit its phosphatase activity. The fact that these compounds not only affect calcineurin but also the activity of their endogenous targets also limits their use as specific NFAT inhibitors. The search for more specific inhibitors has centered on targeting specifically the interaction of NFAT and calcineurin. Calcineurin-binding sites on NFAT have been mapped to the N-terminal regulatory domain and include the amino acid sequence SPRIET. A closer analysis of this sequence among NFAT family members revealed the consensus-binding sequence PxIxIT, which laid the groundwork for the discovery using combinatorial libraries of the highly potent VIVIT peptide (Hogan et al. 2003). This peptide has been successfully used in mouse models of graft rejection and tumor progression. The major benefit of the VIVIT peptide is in its higher specificity for the inhibition of NFAT function; however, this sequence is still conserved in other proteins, such as AKAP79, Cabin1, or MCIP1, that have calcineurin-binding activity. Due to the long term side effects of cyclosporine A and FK506, finding inhibitors with more specificity for inhibiting NFAT functions and less on calcineurin has been also pursued. A number of natural and synthetic compounds have been discovered and developed over the last years. Some small compounds have been shown to covalently bind to calcineurin and disrupt more specifically the calcineurin–NFAT interaction. Similarly, disrupting the ability of NFAT to bind DNA or enhancing the nuclear export of NFAT has also been explored. As binding partners and gene targets of NFAT are being discovered, further inhibitors with higher specificity could be developed. This should lead to a higher degree of precision to specifically alter NFAT activity.

Summary

Members of the NFAT family of transcription factors have been established as crucial regulators of numerous programs of development, differentiation, and activation in many cell types and tissues. NFAT activation is induced by the engagement of calcium-coupled receptors that eventually leads to the translocation of this transcription factor into the nucleus, where it cooperates with several transcriptional partners so that signals that emanate from different inputs can be integrated to ensure specific regulation of distinct program of gene expression. Circuits of regulation that fine-tune NFAT activation have also been proposed and are likely to play important roles in the regulation of NFAT activity. Given the wide range of tissue expression of NFAT proteins, it is clear that novel functions and targets of these transcription factors still remain to be discovered. The identification of specific functions for individual NFAT family members and the characterization of the differential spatial and temporal expression of specific NFAT proteins during unique programs of development should also enhance our understanding on how NFAT-regulated programs of development are orchestrated. The development of new more specific inhibitors of NFAT activity is also a pending issue that should resolve the inherent toxic effect associated with the use of calcineurin inhibitors. Given the increasing amount of evidence that clearly involves NFAT signaling in oncogenesis and cancer progression, these new therapeutic approaches should prove of great value not only to suppress NFAT-regulated immune responses, but also to design new interventions for the treatment of certain types of cancer and other pathologies controlled by this family of transcription factors.

Historical Background: Discovery and Structure

NF-κB (nuclear factor-kappa-light-chain-enhancer of activated B-cells) is a collective term for a family of transcription factors. NFκB has a complex regulation, modulates the expression of a wide set of genes and biological responses and is involved in a variety of diseases. The dysfunction of NF-κB is associated with inflammatory disease, cardiovascular injury, cancer, diabetes, kidney injury, viral infections, and human genetic disorders, among others (Kumar et al. 2004).

NF-κB was identified as a protein that bound to a specific decameric DNA sequence (ggg ACT TTC C), within the intronic enhancer of the immunoglobulin kappa light chain in mature B- and plasma cells but not pre B-cells (Sen and Baltimore 1986). Later, it was demonstrated that NF-κB DNA-binding activity is induced by a variety of exogenous stimuli, that this activation is independent from de novo protein synthesis and that it binds to several DNA sequences.

NF-κB family members share structural homology with the retroviral oncoprotein v-Rel, resulting in their classification as NF-κB/Rel proteins (Gilmore 2006). There are five proteins in the mammalian NF-κB family: RelA (p65), RelB, c-Rel, p50 (NFκB1, generated from p105), and p52 (NFκB2, generated from p100). All of them may form homo- and heterodimeric complexes. The most common and best characterized active forms the RelA/p50 heterodimer (Hayden and Ghosh 2004).

Each member of the NF-κB family has a conserved N-terminal region termed the Rel homology domain (RHD). The Rel homology domain mediates the DNA binding, dimerization, and nuclear transport of the NF-κB proteins (Li and Verma 2002). However, the transcription activator domain (TAD) necessary for target gene expression is present only in the carboxyl terminus of RelA, c-Rel, and RelB subunits. Large precursors, p105 and p100, undergo processing to generate mature p50 and p52, respectively. The p50 and p52 NF-κB subunits do not contain transactivation

domains. However, they participate in target gene transactivation by forming heterodimers with RelA, RelB, or c-Rel (Li and Verma 2002). The p50 and p52 homodimers also bind to the nuclear protein Bcl-3, and such complexes can function as transcriptional activators.

NF-κB Activation

Activation of NF-κB requires a number of discrete steps (Fig. 1). There is a long list of known inducers of NF-κB activity, including many inflammatory cytokines such as TNF-α superfamily cytokines and IL-1, T-cell activation signals, growth factors, reactive oxygen species (ROS), bacterial lipopolysaccharide (LPS), and other stress inducers (http://people.bu.edu/gilmore/nf-kb/inducers/index.html).

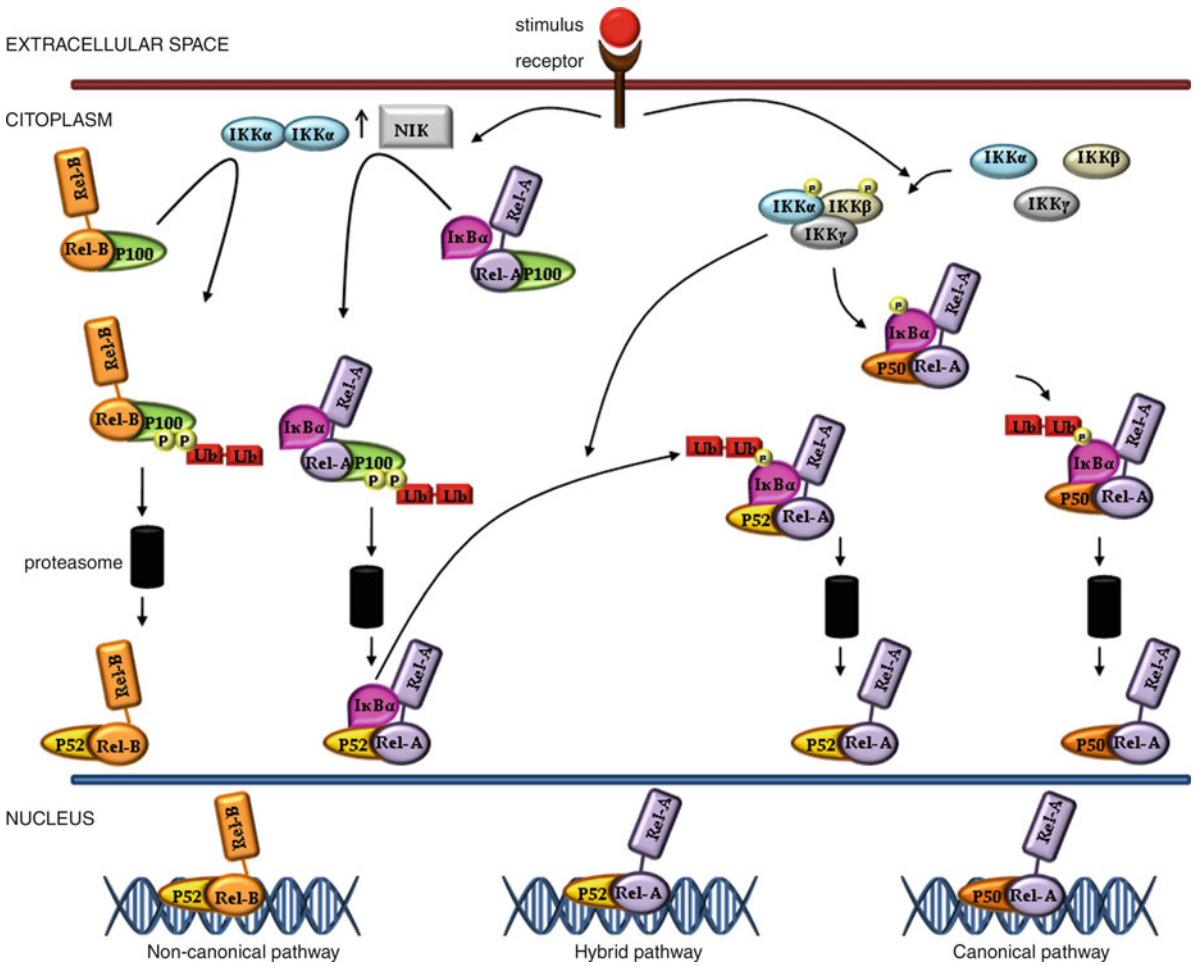
In the cytoplasm of almost all cell types inactive NF-κB is associated with inhibitory κB proteins (IκBs) that regulate NF-κB nuclear translocation and DNA binding (Sanz et al. 2010a). IκBs, are a class of inhibitor proteins that contain an N-terminal regulatory domain, followed by multiple copies of a sequence called ankyrin repeats and a COOH-terminal PEST domain that is important in regulating IκB turnover. The ankyrin repeats mediate the association between IκBs and NF-κB dimers and mask the nuclear localization signals (NLS) of NF-κB proteins, thus preventing nuclear translocation and keeping them in an inactive state in the cytoplasm. The most important IκBs are IκBα (associated with transient NF-κB activation), IκBβ (involved in sustained activation), and IκBε. Additional IκBs are Bcl-3, p100, and p105. Bcl-3 is the only that does not induce cytoplasmic retention of NF-κB, but regulates gene expression as a transcriptional co-activator for p50 and p52 homodimers in the nucleus. The phosphorylation, ubiquitination, and subsequent degradation by the 26S proteasome of IκB proteins is a key step in NF-κB activation that release active NF-κB (Karin and Delhase 2000). NF-κB activation is initiated by a signal-induced phosphorylation of IκBs, mediated by a high molecular weight complex that contains a serine-specific IκB kinase (IKK). IKKs have 52% amino acid identity and a similar structural organization, which includes kinase, leucine zipper, and helix-loop-helix domains. IKKs form both homo- and heterodimers. Gene disruption studies of the IKK genes in mice indicate that IKKβ is the critical kinase involved in activating the NF-κB pathway, while IKKα likely plays an accessory role (Yamamoto and Gaynor 2001). The IKK complex consists of three subunits, including the kinases IKK-α and IKK-β (catalytic subunits also called IKK-1 and IKK-2, respectively) (Sanz et al. 2010a), and the regulatory nonenzymatic subunit IKK-γ (NEMO, NF-κB essential modulator) (Sanz et al. 2010a). IKKs are key convergence steps for multiple signaling pathways that lead to NF-κB activation.

There is a temporal and selective control of NF-κB target gene activation. Some genes are transcribed following a short stimulation of NF-κB. These include negative regulators of NF-κB activity such as IκBα and inflammatory cytokines such as IL-6 and MCP-1. Other genes are transcribed only when NF-κB activation occurs for at least 1 h such as cell-surface receptors, adhesion molecules, and some chemokines such as RANTES/CCL5 (Hoffmann et al. 2002). DNA accessibility contributes in part to these temporal patterns.

NF-κB activation and nuclear translocation can proceed either through the classical/canonical pathway, that is a rapid and transient response of stimuli involving mainly RelA/p50, or the alternative/noncanonical NF-κB pathway, that involves slow activation of the RelB/p52 heterodimer leading to prolonged activation of NF-κB target genes (Sanz et al. 2010a) (Figs. 1 and 2). These pathways are activated by often distinct stimuli, require different IKK complexes, activate different NF-κB complexes and may have different target genes.

Canonical pathway: The classical NF-κB pathway is triggered by most of the stimuli shown to activate NF-κB. In this pathway, the activated IKK complex IKKα, IKKβ, and NEMO phosphorylates two specific serines near the N terminus of IκBα to trigger its ubiquitin-dependent degradation by the 26S proteasome, allowing nuclear migration of RelA/p50 and other NF-κB dimers (Haas 2009).

Noncanonical pathway: The alternative pathway results in nuclear translocation of the heterodimer RelB/p52 leading to prolonged activation of NF-κB target genes (Senftleben et al. 2001). Only a small number of stimuli are known to activate NF-κB via this pathway, including TNF superfamily members such as TWEAK, but also lymphotoxin-α, BAFF or RANKL (Sanz et al. 2010b). This pathway requires IKKα phosphorylation by NF-κB-inducing kinase



NF-κB Family, Fig. 1 *Schematic representation of canonical and noncanonical NF-κB pathway activation*. In the canonical pathway IKK activation leads to proteasomal IκB degradation, which allows nuclear migration of RelA/p50 and other complexes. In the noncanonical pathway NIK and IKKα recruitment lead to proteasomal processing of p100 to p52, allowing nuclear migration of RelB/p52 complexes. p100 may also retain in the cytoplasm RelA, c-Rel, and p50. Thus, proteasomal processing of p100 to p52 also generates RelA/p52, c-Rel/p52, or p52/p50 complexes. IκB molecules weakly sequester RelB/p52 complexes and they are free for nuclear translocation upon p100 processing. In the hybrid pathway noncanonical p100 processing generates RelA/p52 and c-Rel/p52 complexes that are retained in the cytosol by IκB proteins. Classical pathway degradation of IκB proteins allows nuclear migration of these complexes. *P* phosphorylation, *Ub* Ubiquitin

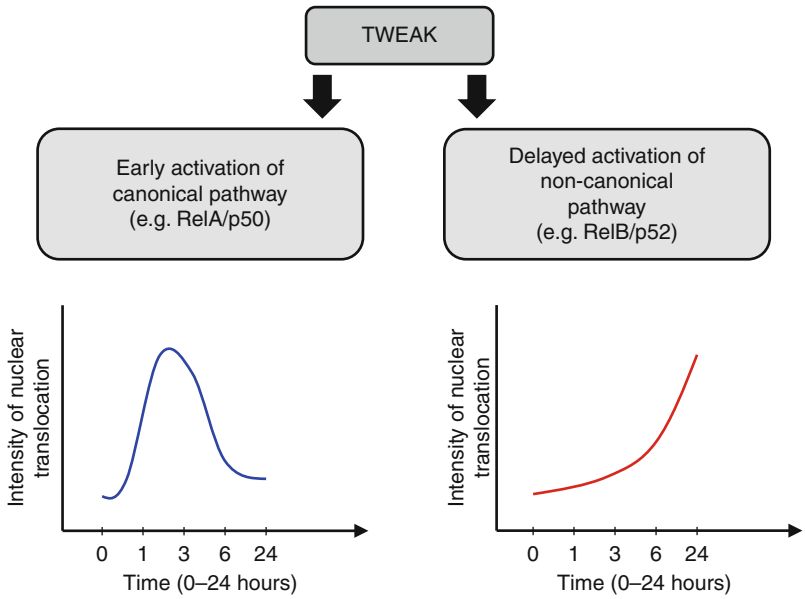
(NIK). IKKα phosphorylates p100 leading its polyubiquitination and promoting the proteasomal processing to p52, freeing the active p52/RelB dimers that migrate to the nucleus (Senftleben et al. 2001).

The noncanonical IKKε (IKKi) is a serine/threonine kinase inducible by inflammatory mediators that activates IRF-7, phosphorylates IκBα, NF-κB p65, and c-Rel and is required for activation of an NF-κB complex containing p52 and p65 (Wietek et al. 2006; Harris et al. 2006). However, mice bearing a deletion of the IKKε gene activate NF-κB normally in response to lipopolysaccharide.

Hybrid pathway: The hybrid pathway of NF-κB activation requires the contribution of both pathways: the NF-κB complex is generated by the alternative pathway and activated by the classical pathway (Sanz et al. 2010a).

Finalization of NF-κB Activation

NF-κB activation is regulated by negative feedback loops which control the duration of NF-κB nuclear localization in response to a stimulus. Negative



NF-κB Family, Fig. 2 *Temporal pattern profile of TWEAK-induced canonical and noncanonical NF-κB pathway activation in renal proximal tubular epithelial cells.* TWEAK is one of a handful of TNF superfamily cytokines that activates both the canonical NF-κB pathway, leading to early transient nuclear translocation of RelA/p50 and the noncanonical NF-κB pathway, leading to delayed nuclear translocation of RelB/p52

feedback mechanisms include NF-κB-dependent induction of IκBα, A20, and cezanne. Newly formed IκBα sequesters NF-κB subunits and terminates transcriptional activity unless a persistent activation signal is present. Deubiquitinating enzymes CYLD (cylindromatosis gene), A20, and cezanne induced by proinflammatory signaling can block IKK activation by removing polyubiquitin chains (Van der Heiden et al. 2010).

Target Genes

NF-κB complexes regulate the transcription of multiple genes related to inflammation, immunity, apoptosis, cell proliferation, and differentiation. At http://people.bu.edu/gilmore/nf-kb/ the reader can find updated lists of NF-κB gene targets classified by function as cytokines/chemokines and their modulators, immunoreceptors proteins involved in antigen presentation, cell adhesion molecules, acute phase proteins, stress response genes, cell-surface receptors, regulators of apoptosis, growth factors, ligands and their modulators, early response genes, transcription factors and regulators, viruses, enzymes, and others.

While NF-κB frequently promotes gene transcription, it may also function as a repressor of gene expression. Thus, anti-inflammatory cytokines may induce the synthesis of nuclear-located atypical IκB proteins, which bind to DNA-bound NF-κB dimers and repress transcription of inflammatory genes (Ghosh and Hayden 2008). Additional mechanism involve competition of RelA with co-activators of transcription, posttranslational modifications of RelA, and posttranslational modification of histones near the NF-κB target genes (Sanz et al. 2010a).

No clearcut differences in DNA-binding sequences have been observed for the different NF-κB complexes and considerable promiscuity is thought to occur.

The Role of NF-κB Signaling in Disease

Studies in knockout mice revealed specific functions of each NF-κB family proteins in the regulation of disease. Deletion of RelA or IKK-β genes in mice causes embryonic lethality due to high apoptosis in the liver indicating that their function is indispensable during development (Beg et al. 1995; Li et al. 1999). On the other hand, mice lacking RelB are immunodeficient but develop normally to adulthood (Sha et al. 1995). Mice lacking c-Rel or p52 have defective immune functions (Caamano et al. 1998).

Dysregulated activation of the NF-κB pathway is involved in the pathogenesis of a number of human diseases. The NF-κB family controls multiple processes, including immunity, inflammation, cell survival, differentiation and proliferation, and regulates

cellular responses to stress, hypoxia, stretch, and ischemia. Activation of the NF-κB pathway is involved in the pathogenesis of chronic inflammatory disease, kidney disease, atherosclerosis, viral infections, neurological diseases, cancer and aging, among others. Evidence for the involvement of NF-κB in disease often comes from functional studies in experimental cell and animal models as well as descriptive data from animal models and human samples. We will provide some examples of NF-κB involvement in disease processes.

Inflammation

NF-κB is involved in the pathophysiology of autoimmune and inflammatory disorders, such as rheumatoid arthritis, asthma, and others.

NF-κB is activated in the inflamed synovium of rheumatoid arthritis patients as well as in the synovium of animal models in this disease.. Intra-articular gene transfer of IKK-β into the joints of normal rats resulted in synovial inflammation, while arthritis dominant-negative adenoviral IKK-β construct ameliorated the severity of adjuvant. NF-κB "decoy" or RelA antisense oligodeoxynucleotides prevented the development of arthritis in rats (Neurath et al. 1996).

Asthma is characterized by the lung infiltration of inflammatory cells. Increased NF-κB and is evident in biopsies from asthmatic patients (Kumar et al. 2004). Treatment with steroids decreases NF-κB activity in mice, cultured cells (Kumar et al. 2004), and in asthmatic patients as well as reducing the symptoms of the disease.

Kidney Disease and Aging

The role and regulation of NF-κB in kidney disease was recently reviewed and includes functional studies showing improvement of kidney disease outcomes when targeting NF-κB in experimental models (Sanz et al. 2010a). Many drugs used in kidney disease target NF-κB, including steroids, calcineurin inhibitors, drugs targeting the renin-angiotensin system and statins, but no functional studies of therapies specifically targeting NF-κB are available in humans. The recent observation that inflammation downregulates klotho mRNA expression and protein via NF-κB activation provides a link between inflammation, kidney disease, NF-κB, and accelerated aging (Moreno et al. 2011 accepted). Klotho is a kidney-secreted hormone with antiaging properties and Klotho knockout mice die prematurely from accelerated aging.

Cardiovascular Disease

NF-κB has been linked to both cardiovascular health and disease. NF-κB can protect cardiovascular tissues from injury or contribute to pathogenesis depending on the cellular and physiological context.

Atherosclerosis is a chronic lipid-driven inflammatory disease characterized by accumulation of lipids in arterial walls, which can lead to a heart attack or stroke. Recruitment of monocytes and their extravasation into the subendothelial space, a key event in atherogenesis, is regulated by NF-κB. Activated NF-κB has been identified in situ in human atherosclerotic plaques (Collins and Cybulsky 2001). Interestingly, dietary compounds that block the initiation of atherogenesis are known to inhibit NF-κB activation.

One consequence of atherosclerosis is tissue ischemia. Ischemia-reperfusion promotes alterations in oxygen availability leading to NF-κB activation through proinflammatory cytokines and endogenous ligands for toll-like receptors. Blocking NF-κB using pharmacological inhibitors or decoy oligonucleotides can reduce myocardial infarction in animal models. However in a murine myocardial infarction model NF-κB activation was essential for the protection of cardiomyocytes from apoptosis via induction of cytoprotective genes (Van Der Heiden et al. 2010). This illustrates the "good and evil" aspects of NF-κB.

Human Immunodeficiency Virus (HIV) and Other Viral Infections

Most viruses encode proteins that are capable of activating NF-κB. HIV infection induces NF-κB activation that allows evading the immune response. HIV has two NF-κB binding sites called long terminal repeat (LTR) that are involved in viral transcription. NF-κB activation by viral infection is required for viruses to induce proliferative responses, like expression of cyclin D1, replicate their genetic material, and induce pathogenic responses.

Neurological Diseases

NF-κB is associated with antiapoptotic as well as proapoptotic mechanisms. Consistent with its role in regulating apoptosis, NF-κB serves a cell survival role in stressed neurons through the upregulation of antiapoptotic and antioxidant genes. NF-κB activation may also be involved in the initiation of neuritic plaques and neuronal apoptosis during the early phases of Alzheimer's disease, whereas mature plaque types

show mainly reduced NF-κB activity (Kumar et al. 2004).

Cancer

Constitutive NF-κB activation is involved in some forms of cancer and the inhibition of NF-κB abrogates cell proliferation in these tumors (Kumar et al. 2004). Genes encoding RelA, c-Rel, p105/p50, and p100/p52 proteins are located within regions of the genome involved in oncogenic rearrangements or amplifications. Mutations that can lead to tumors include those that inactivate IκB proteins as well as amplifications of genes encoding NF-κB. In tumor models, NF-κB is activated in tumor cells in response to chemotherapy, and inhibition of NF-κB by viral expression of IκB leads to enhancement in the apoptotic response of the chemotherapy.

Therapeutic Targeting of NF-κB

The identification of NF-κB as a key player in the pathogenesis of the disease suggests that NF-κB-targeting drugs aimed at blocking NF-κB activity might be effective in the clinic. Suppression of NF-κB activation has potential therapeutic applications. In fact, some well known commercially available drugs, such as glucocorticoids, nonsteroidal anti-inflammatory drugs, and calcineurin inhibitors, modulate NF-κB activity.

Repression of NF-κB-dependent gene expression is one of the major elements of immunosuppression and anti-inflammation by glucocorticoids. Glucocorticoids induce IκBα synthesis and enhance the cytosolic retention of NF-κB in monocytes and lymphocytes (Yamamoto and Gaynor 2001). However glucocorticoids block NF-κB activation by different mechanisms in different cell types.

Nonsteroidal anti-inflammatory drugs are used in the treatment of chronic inflammatory disease. Most of them also target NF-κB. Both aspirin and salicylate inhibit NF-κB activation in patients with chronic inflammatory conditions by inhibiting ATP binding to IKKβ.

Cyclosporin A (CsA) and tacrolimus (FK-506) are calcineurin inhibitor immunosuppressive agents used in organ transplantation to prevent rejection. Both inhibit the NF-κB pathway in lymphocytes by distinct mechanisms: preventing IκBα degradation and translocation of c-Rel from the cytoplasm to the nucleus, respectively (Yamamoto and Gaynor 2001).

Proteasome inhibitors may prevent NF-κB activation function by reducing IκB degradation. There are a variety of proteasome inhibitors, some in clinical use, like bortezomib.

Since oxygen radical species promote NF-κB activation, drugs with antioxidant properties may inhibit NF-κB activation.

A variety of other approaches has been used to inhibit NF-κB activation in cell culture or experimental animal models (http://people.bu.edu/gilmore/nf-kb/inhibitors/index.html). These include small molecules, siRNA, oligodeoxynucleotides, degradation-resistant IκBs, and other specific NF-κB inhibitors, whose efficacy has been shown in animal models of inflammatory disease. Since NF-κB may have dualistic roles in disease, specific NF-κB inhibition might result in unintended side effects. As an example, NF-κB may promote both cell survival and inflammation in cells stimulated with certain cytokines, such as TNF and NF-κB inhibition in these circumstances may result both in less secretion of inflammatory mediators and cell death.

Summary

NF-κB is a term used for a family of transcription factors composed of homo- or heterodimeric DNA-binding protein complexes that may be activated in response to a wide variety of stimulus inducing cell stress. NF-κB, in turn, promotes the transcription or repression of a wide array of genes involved in many key cell biology processes. As a result, NF-κB contributes to the pathogenesis of many diseases. Specific NF-κB inhibition is promising in experimental animal models, but experience in humans is limited. By contrast, many commonly used drugs may target NF-κB directly or indirectly as one of several mechanisms of action.

NHERF

Byong Kwon Yoo and C. Chris Yun
Emory University School of Medicine, Division of Digestive Diseases, Department of Medicine, Atlanta, GA, USA

Synonyms

NHERF (N^+/H^+ Exchange Regulating Factor); SLC9A3R1 (Solute carrier family 9 member 3 regulator 1); EBP50 (Ezrin-radixin-moesin-Binding phosphoprotein 50 kDa)

Historical Background

The functional presence of NHERF-1 was implicated in the late 1980s from a series of studies of inhibition of Na^+/H^+ exchange in rabbit kidney brush border membrane by cyclic AMP-dependent protein kinase (PKA). It took almost another decade before the cloning and molecular identification of NHERF-1 (Weinman et al. 1995). Shortly after, NHERF-2 was cloned from a yeast two-hybrid screen as an NHE3 interacting protein and was initially named E3KARP based on its ability to mediate PKA-dependent inhibition of Na^+/H^+ exchanger 3 (NHE3) in PS120 fibroblasts (Yun et al. 1997). NHERF-3 was initially identified as a protein that is upregulated in low dietary phosphate and was later shown to interact with the type II Na/P_i cotransporter (Npt2a) (Gisler et al. 2001). NHERF-4 was shown to interact with the intestinal receptor guanylyl cyclase C to inhibit the catalytic

activity of the receptor in response to heat-stable enterotoxin (Scott et al. 2002).

Introduction

The NHERF family consists of four related proteins that are present in the brush border membrane of the mammalian intestine, colon, and renal proximal tubules. These proteins contain 2 or 4 PSD-95/Dlg/ZO-1 (PDZ) domains (Fig. 1) (Weinman et al. 1995; Yun et al. 1997; Gisler et al. 2001; Scott et al. 2002). NHERF-1 and NHERF-2 contain two PDZ domains as well as an ezrin-radixin-moesin-merlin (ERM) binding domain at the carboxyl terminus (Lamprecht et al. 1998). NHERF-3 and NHERF-4 have four PDZ domains without ERM binding domain (Gisler et al. 2001; Scott et al. 2002). PDZ domain interaction with their interacting ligands or proteins generally occurs at the ligand COOH terminus although non-canonical interaction with an internal motif has been reported. NHERFs are able to interact with multiple proteins through their PDZ domains, including transporters, channels, transmembrane receptors, and other cytoskeleton proteins localized at or below the plasma membrane (Table 1). NHERFs play significant roles in maintenance and regulation of a broad range of cellular functions in a variety of tissues through the interactions with multiple target proteins.

NHERF Basics

Localization

NHERF-1 and NHERF-2 are expressed in a broad range of tissues and organs (Yun et al. 1997). NHERF-3 and NHERF-4 show highest expression in the kidney and gastrointestinal tract (Gisler et al. 2001; Scott et al. 2002). Immunofluorescent confocal microscopic analysis of NHERF proteins shows that NHERF proteins have different subcellular localization in polarized epithelial cells. NHERF-1 and NHERF-3 are located in the brush border membrane under basal conditions. The brush border localization of NHERF-2 was shown, but it is predominantly in the intermicrovillar clefts just below the brush border membrane. NHERF-4 is primarily distributed in the cytosol as well as in the subapical region, but not in the brush border membrane (Donowitz et al. 2005). NHERF expression in non-epithelial cells is less well documented, but the expression of NHERF-1 and NHERF-2 in neurons and astrocytes, where these proteins show a membranous expression, has been reported.

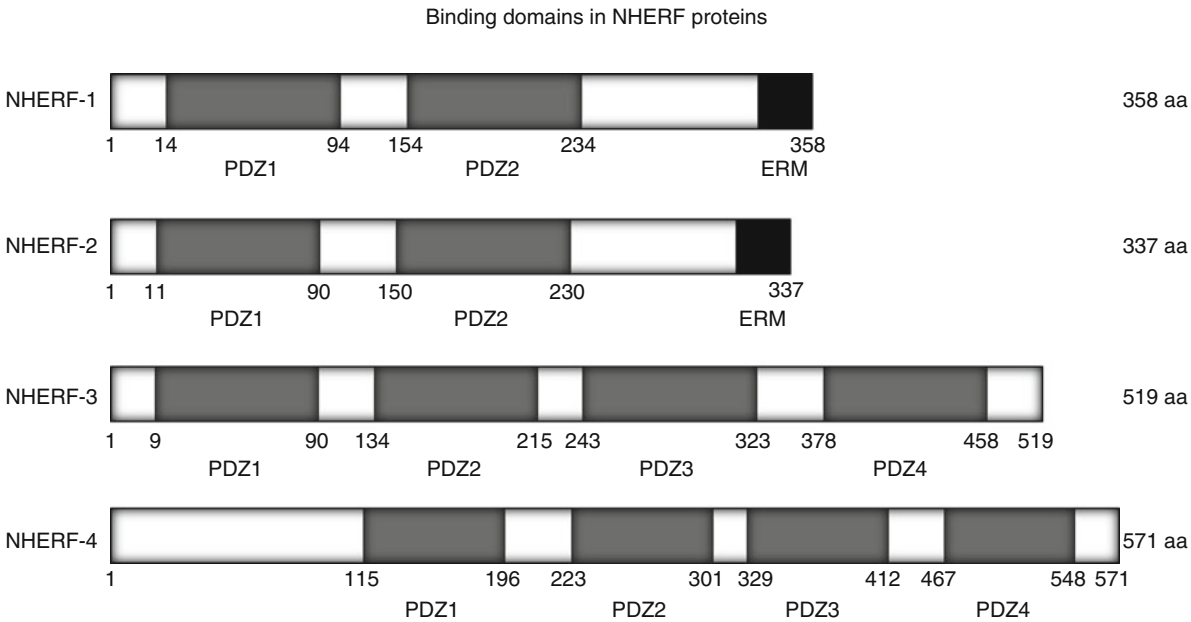
Regulation of NHERF

NHERF-1 is regulated by phosphorylation. NHERF-1 is constitutively phosphorylated on Ser 289 by G protein–coupled receptor kinase 6 (GRK 6), which enhances oligomerization of NHERF-1 (He and Yun 2010). Furthermore, NHERF-1 is phosphorylated by the cyclin-dependent kinase Cdc2 at Ser279 and Ser301, which impair oligomerization, and at S77 by protein kinase C, which interferes with parathyroid hormone (PTH)-induced signaling (Weinman et al. 2007). In contrast to NHERF-1, NHERF-2 does not appear to be regulated by phosphorylation (Lamprecht et al. 1998). Both NHERF-1 and NHERF-2 have been shown to form homotypic as well as heterotypic dimers. Dimerization of NHERF is thought to affect their interaction with other proteins. NHERF-3 mRNA expression is regulated by peroxisome proliferator-activated receptor alpha (PPARα), a ligand-activated transcription factor that plays an important role in the regulation of lipid homeostasis (Tachibana et al. 2008). Regulatory mechanism of NHERF-4 has not yet been studied.

Association with Cell Surface Proteins

Transporters and Channels

The majority of functional characterization of the NHERF family came from heterologous expression of these proteins. In addition to the importance of NHERF-1 and NHERF-2 in regulation of NHE3 by PKA, these studies have provided evidence for the importance of NHERFs for trafficking, membrane retention, and dimerization of the cystic fibrosis transmembrane regulator (CFTR) (Singh et al. 2009). Although initial studies suggested redundancy in the functions of the NHERF family, studies of rodents that are genetically targeted to delete one or more of the NHERF family members have helped to reveal distinct physiological roles of NHERF proteins. NHERF-1 is essential for cAMP- and parathyroid hormone (PTH)-induced inhibition of renal NHE3, but not intestinal



NHERF, Fig.1 Binding domains in NHERF proteins. Four members of NHERF family (NHERF1-4) are shown with PDZ domains and ERM binding regions. Numerical numbers denote lengths of amino acids

NHE3 (Weinman et al. 2005). Ablation of NHERF-1 decreases forskolin-induced secretion of bicarbonate by CFTR (Singh et al. 2009). NHERF-1 is also essential for the recruitment of Npt2a to the brush border membrane of renal proximal tubule cells (Weinman et al. 2005). NHERF-2 appears to play a dual role in regulation of NHE3. Glucocorticoid- or lysophosphatidic acid (LPA)-mediated stimulation of NHE3 is dependent on the presence of NHERF-2 (He and Yun 2010). Similarly, NHERF-2 is necessary for inhibition of NHE4 by cyclic GMP kinase II (cGKII), protein kinase C (PKC), and Ca^{2+}-mediated signaling (He and Yun 2010). NHERF-3 ablation in mouse colon abolishes cAMP- and Ca^{2+}-induced inhibition of NHE3 (Donowitz et al. 2005). NHERF-3 is also involved in the localization of organic cation/cartinin transporter (OCTN2, Slc22a5) and H^+/dipeptide transporter (PepT1, Slc15a1) in the brush border membrane (Sugiura et al. 2008). NHERF-4 activates NHE3 via a Ca^{2+}-dependent mechanism (Zachos et al. 2008).

G Protein–Coupled Receptors

NHERF proteins interact with several G protein–coupled receptors (GPCRs), including the β_2-adrenergic receptor (β_2-AR), κ-opioid receptor, PTH type 1 receptor (PTH1R), P2Y receptor, and lysophosphatidic acid receptor (Ritter and Hall 2009). The first insight into the role of NHERF in GPCR-mediated signaling came from the finding that agonist-promoted association of NHERF-1 with the carboxyl terminus of β_2-AR displays NHERF-1 from NHE3 blocking the inhibition of NHE3 by PKA (Ritter and Hall 2009). Evidence shows that NHERF-1 regulates β_2-AR trafficking by regulating agonist-promoted recycling of receptor proteins, which can be perturbed by interruption of NHERF-1 binding, and hence directing the receptor to lysosome (Ritter and Hall 2009). In addition, the NHERF proteins regulate GPCR-mediated signaling through selective recruitment of signaling proteins, including phospholipase C and G proteins, which could potentiate or redirect G protein–mediated signaling (Mahon et al. 2002).

Receptor Tyrosine Kinases

In addition to GPCRs, NHERFs associate with receptor tyrosine kinases, including platelet-derived growth factor receptor (PDGFR) and epidermal growth factor receptor (EGFR). The binding of NHERF-1 to the carboxyl terminus of PDGFR potentiates receptor activity only when NHERF-1 is allowed to oligomerize (Maudsley et al. 2000). Evidence shows that the interaction between PDGFR and NHERF-1

can be disrupted by phosphorylation of the carboxyl terminus of PDGFR by GRK2 (Hildreth et al. 2004). Recent study showed that NHERF-1 facilitates actin cytoskeletal reorganization mediated by PDGFR (Theisen et al. 2007). Unlike PDGFR, EGFR lacks the carboxyl terminal PDZ binding sequence, but yet it was shown that EGFR interacts with NHERF-1 involving a non-canonical internal PDZ binding motif (Lazar et al. 2004). This interaction appears to stabilize EGFR at the cell surface by restricting EGF-induced receptor degradation, which causes EGFR to remain longer at the cell surface.

NHERF as a Signaling Molecule

Cellular Signals

PDGFR is activated through dimerization and autophosphorylation upon ligand binding. NHERF-1 dimers enhance dimerization of PDGFR to potentiate mitogenic signals transduced by extracellular signal-regulated kinase (Erk) 1/2. Similarly, transient receptor potential 4 (TRP4) calcium channel associates with phospholipase C (PLC) β isoforms to activate protein kinase C signals by binding to NHERF PDZ1 domain. NHERF-1 has significant importance in PTH-mediated signaling as evidenced by the defective PTH signaling in NHERF-1-deficient mice (Weinman et al. 2005). NHERF-1 modulates PTH signaling by affecting PTH receptor recycling, membrane retention, and desensitization.

In addition to the regulation of the membrane receptors and channels, NHERF-1 interacts with Akt and inhibits PKA-mediated Erk1/2 activation by decreasing the stimulatory effect of 14-3-3 binding to B-Raf (Wang et al. 2008).

Cancer

Overexpression of NHERF-1 in breast cancer cells and the transcriptional regulation of NHERF-1 by estrogen suggested a potential role of NHERF-1 in cancer. In addition, unpublished data in our lab show the elevated expression of NHERF-2 in colon adenocarcinoma. However, the mechanism and effects of NHERFs in tumorigenesis are unclear. The interaction of NHERF-1 with PDGFR and EGFR appears to suggest an oncogenic role of NHERF-1. In addition, NHERF-1 expression is elevated in hepatocellular carcinoma where NHERF-1 complexes with β-catenin to promote Wnt signaling (Shibata et al. 2003). On the other hand, NHERF-1 or NHERF-2 recruits phosphatase and tensin homolog (▶ PTEN) tumor suppressor to restrict the activation of the PI3K (Georgescu et al. 2008). Therefore, NHERFs appear to play a dual role in tumorigenesis and their role in cancer requires additional studies.

Summary

From the uncertain identity as a cofactor of cAMP-induced regulation of NHE3, NHERF proteins have firmly rooted their identity as the major molecular scaffolds. The role of the NHERF proteins extends beyond the regulation of ion transporters. Growing evidence links NHERF to cancer, inflammatory diseases, hypertension, and neurological disorder. However, the functional roles and the underlying mechanisms of NHERF-mediated regulation are incompletely understood. A combination of biochemical and cellular approaches along with physiological studies using animal models lacking one or more of the NHERF proteins should advance the understanding of the physiological and pathophysiological functions of the NHERF proteins.

NK Receptor

Bin Xu, Mesfin Gewe, Kathryn Finton and Roland K. Strong
Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Synonyms

Killer immunoglobulin-like receptors (KIR); Killer lectin-like receptors (KLR); Natural cytotoxicity receptors (NCR); Natural killer cell group (NKG)

Historical Background

Natural Killer (NK) cells are a major component of the innate immune system, providing surveillance against infected or transformed cells without the requirement of prior host sensitization. NK cells were first discovered by their cytotoxic potency against tumor cells (Kiessling et al. 1975), and their importance was

demonstrated early on in herpes viral infections, usually mild or localized, which become severe and life-threatening in NK-deficient patients. NK cell effector functions are governed by the balance of potentially opposing signals from a diverse array of both activating and inhibitory receptors on the cell surface that are not rearranged from germ-line receptor segments, unlike B and T cell receptors (BCRs, TCRs) on lymphocytes. While NK cells are now well characterized in terms of their origin, differentiation, and receptor repertoire, advances are still being made in NK cell receptor modulation, ligand recognition, and signaling and activation mechanisms which greatly enrich our understanding of NK cell biology: an important component of a complex immune system that remains incompletely understood.

Function and Signaling

Because of their potent cytolytic activity, the function of NK cells needs to be tightly regulated to limit potential autoreactivity. Molecular events driving activation occur at the NK immune synapse (NKIS), the surface of contact between NK and potential target cells. The NKIS comprises an array of molecular interactions including receptor–ligand pairs, adhesion molecules, signaling adaptors, signaling effectors, membrane lipid rafts, and cytoskeletal molecules (MacFarlane and Campbell 2006). NK cells kill sensitive target cells by release of cytotoxic granules that contain perforin and granzymes; perforin polymerizes and forms a transmembrane pore that allows the delivery of granzymes and associated molecules into the cytosol where they initiate various apoptotic death pathways. NK cells express a variety of receptors that serve either to activate or to suppress their cytolytic activity (Lanier 2005). NK cell surface receptors are commonly divided into activating and inhibitory receptors, but they can also be structurally classified into C-type lectin-like receptors and immunoglobulin (Ig)-type receptors.

The functional response of an NK cell is the result of the integration of signals transduced by the set of activating and inhibitory receptors engaged upon target cell interrogation (Bryceson and Long 2008). The majority of known activating receptors transduce signals through their association with one or two of four transmembrane-spanning accessory proteins: the DNAX-activating proteins with molecular weights of 10 kDa (DAP10) or 12 kDa (DAP12), ▶ CD3ζ, or the Fcε-receptor γ-chain (FcεRIγ; Table 1). All four accessory adaptor proteins exist as disulfide-linked homodimers, but CD3ζ and FcεRIγ can also form disulfide-linked heterodimers. Electrostatic interactions link activating receptors and accessory adaptor molecules through either an arginine or lysine residue in the receptor or an aspartic or glutamic acid residue on the accessory protein. The cytoplasmic domains of DAP12, CD3ζ, and FcεRIγ all contain one or more immunoreceptor tyrosine-based activation motifs (ITAMs) containing a sequence signature: YxxL/I (x denotes any amino acid). Two of these motifs are typically separated by six to eight amino acids in the tail of the molecule [YxxL/Ix(6–8)YxxL/I]. Receptor–ligand binding leads to phosphorylation of tyrosine residues within these motifs by membrane proximal Src kinase family molecules. This in turn leads to recruitment of protein tyrosine kinases (PTKs) of the spleen tyrosine kinase (Syk) family, such as Syk and ζ-associated protein of 70 kDa (▶ ZAP-70). Subsequent downstream signaling pathways can involve phosphatidylinositol 3 kinase (▶ PI3K), Vav, phospholipase Cγ (PLCγ), protein kinase C (PKC), and extracellular signal-regulated kinase (ERK). PLCγ activation leads to intracellular calcium flux. Activation of PLCγ, PKC, Vav, and PI3K, as well as elevation of cytosolic calcium concentrations is an important event for initiation of the cytolytic functions by NK cells. Activation of ERK is important for granule-mediated cytotoxicity and ▶ IFN-γ production.

Alternatively, the cytoplasmic signaling domain of DAP10 contains a YINM motif, which may lead to the association of DAP10 with PI3K or the adaptor molecule Grb2, as opposed to Syk or ZAP70. Significant differences have emerged that distinguish DAP10-mediated activation signals from those downstream of ITAMs (Billadeau et al. 2003). This may lead to divergent effector functions: DAP10 can stimulate cytotoxicity, but not IFN-γ production by NK cells, whereas DAP12 can trigger both responses. Multiplicity of activating signals results in complex functional cross talk, leading to the integration of different receptor–ligand interactions directing NK-mediated cell killing.

NK cells are also activated in response to interferons or macrophage-derived cytokines, including IL-2, IL-12, and IL-15. Activated NK cells in turn release cytokines such as ▶ TNF-α and IFN-γ, which

NK Receptor, Table 1 Ectodomain structure, ligand information and endodomain signaling motifs are catalogued for a series of NKRs

Activating	Structure	Ligand	Signaling

can promote cellular resistance to infection and influence adaptive immunity resulting in infection clearance. NK cells also express the Fc receptor (FcR) molecule (CD16), an activating receptor that binds the Fc portion of antibodies. This allows NK cells to target cells against which a humoral response has been mobilized and to lyse cells through antibody-dependent cellular cytotoxicity (ADCC).

Although the extracellular domains of NK cell inhibitory receptors are diverse, the cytoplasmic signaling motifs of these transmembrane receptors are remarkably similar. The cytoplasmic tails of inhibitory receptors have one or more copies of conserved sequence motifs (V/IxYxxL/V) known as immunoreceptor tyrosine-based inhibitory motifs (ITIMs). Binding of ligands to inhibitory receptors activates ▶ Src family kinases that phosphorylate ITIM tyrosine residues, leading to the recruitment of other enzymes, such as SH2 domain-containing protein tyrosine phosphatases SHP-1 and SHP-2, or the inositol phosphatase, ▶ SHIP. These tyrosine phosphatases are able to dephosphorylate protein substrates of tyrosine kinases linked to activating NK cell receptors. Recruitment and activation of SHP-1 by some inhibitory receptors has been functionally implicated in delivery of the dominant inhibitory signal in human NK cells. NK cells tolerate normal, autologous cells by sensing appropriate levels of surface-expressed self-MHC class I molecules that induce an inhibitory signal. Infection or transformation often alters MHC class I cell surface expression, typically as part of a strategy to evade T cell responses, which is then detected by NK cells. This "missing-self" hypothesis

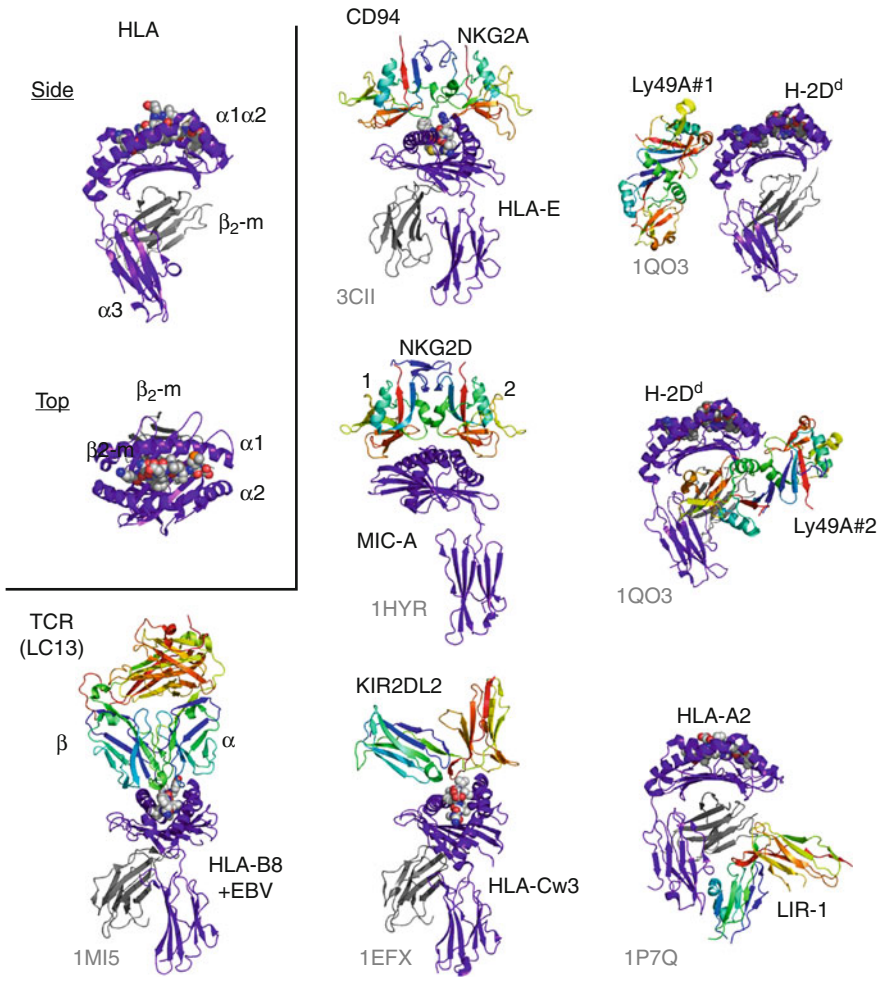
was first proposed by Karre and colleagues (Karre et al. 1986) and subsequently demonstrated by Yokoyama and colleagues (Karlhofer et al. 1992). MHC class I–mediated inhibition is therefore crucial to the role played by NK cells.

Specificities and Recognition Mechanisms: Inhibitory Receptors

Major inhibitory NK receptors in humans include inhibitory isoforms of the Killer Immunoglobulin Receptors (KIRs, also CD158), the lectin-like receptor CD94/NKG2A, and the Leukocyte Immunoglobulin-like Receptors (LIRs, also CD85), which all recognize classical or nonclassical MHC class I molecules, and some less well-characterized inhibitory receptors that bind non-MHC class I molecules, such as the lectin-like receptor Natural Killer Receptor P1 (NKR-P1, also KLRB1 or CD161). In mice, the KIRs are replaced with the structurally distinct, C-type lectin-like Ly49 family of NK receptors. Inhibitory receptors that recognize classical and nonclassical MHC class I proteins limit signals through activating receptors. In this way, recognition of normal MHC class I expression dominantly suppresses NK attack of normal cells, whereas a lack of self-MHC class I shifts the balance toward targeted cell killing. Structural and functional studies of inhibitory Ly49 and H-2 complexes provided among the first detailed insights into NK cell recognition (Tormo et al. 1999). The homodimeric Ly49A receptor binds to H-2D^d at two distinct sites, one of which involves the α1 and α2 domains of MHC class I, whereas the second interaction site spans the underside of the platform domain (α1 and α2), α3 domain and β_2-microglobulin (Figs. 1 and 2). The second site is considerably more extensive than the first site and also overlaps the CD8 binding site on MHC class I molecules. The first binding site is consistent with *trans* interaction between NK and target cells where the second, more extensive contact site is likely a regulatory *cis* interaction between Ly49 and class I molecules on the same NK cell. Both binding sites are distinct from that of the TCR.

The highly polymorphic KIR family of human NK receptors consists of at least fifteen active genes and two pseudogenes. KIRs are either activating or inhibitory and contain either two or three extracellular Ig-like domains (named D0, D1, and D2). KIR nomenclature is based on the number of extracellular Ig domains (2D versus 3D) and the size of their cytoplasmic tails. Receptors possessing an ITIM-containing long cytoplasmic tail are designated by an L, whereas activating receptors with a short cytoplasmic tail are designated by an S. The cytoplasmic region of activating receptors does not contain an ITIM, but instead contains a positively charged residue that can interact with adaptor molecules such as DAP12. The KIRs are known to show allotypic specificity toward different HLA alleles (Table 1). The best characterized KIR–ligand interactions come from two complex crystal structures of two-domain inhibitory KIRs: KIR2DL2/HLA-Cw3 and KIR2DL1/HLA-Cw4 (Boyington et al. 2000; Fan et al. 2001). KIR2DL1/2 binds to HLA-C with a similar docking orientation as TCRs, with the D1/D2 domains contacting the α1/α2 helices of the MHC peptide–binding cleft and positions P7 and P8 of the bound peptide (Figs. 1 and 2). The KIR2DL1/2/HLA-C interface is dominated by charge complementarity and is mediated by six loops; three loops from D1 contact the α1 helix and bound peptide while one hinge loop and two loops from D2 contact the α2 helix. Allotypic specificity of KIR2D toward HLA-C alleles is determined by a dimorphism at residues 77 and 80 of HLA and a reciprocal dimorphism in KIR2D at position 44. For example, KIR2DL1 (M44) will recognize the C2 epitope (N77/K80) of HLA-C, whereas KIR2DL2 (K44) will recognize the C1 epitope (S77/N80). In the absence of any KIR3D structures, a KIR3DL1/ligand complex model has been proposed, but remains to be confirmed. Analogous to the KIR2D complex structure, the D1/D2 domains contact the α1/α2 helices of HLA and position 8 of the bound peptide. The D0 domain contacts the α1 helix, stabilized by hydrophobic contacts with D1 and D2, consistent with the finding that D0 contributes to avidity. KIR3DL1 is known to recognize HLA-A and -B molecules with the Bw4 epitope (residues 77–83). Several lines of evidence also point to the importance of residue 80 of the Bw4 epitope for KIR interaction.

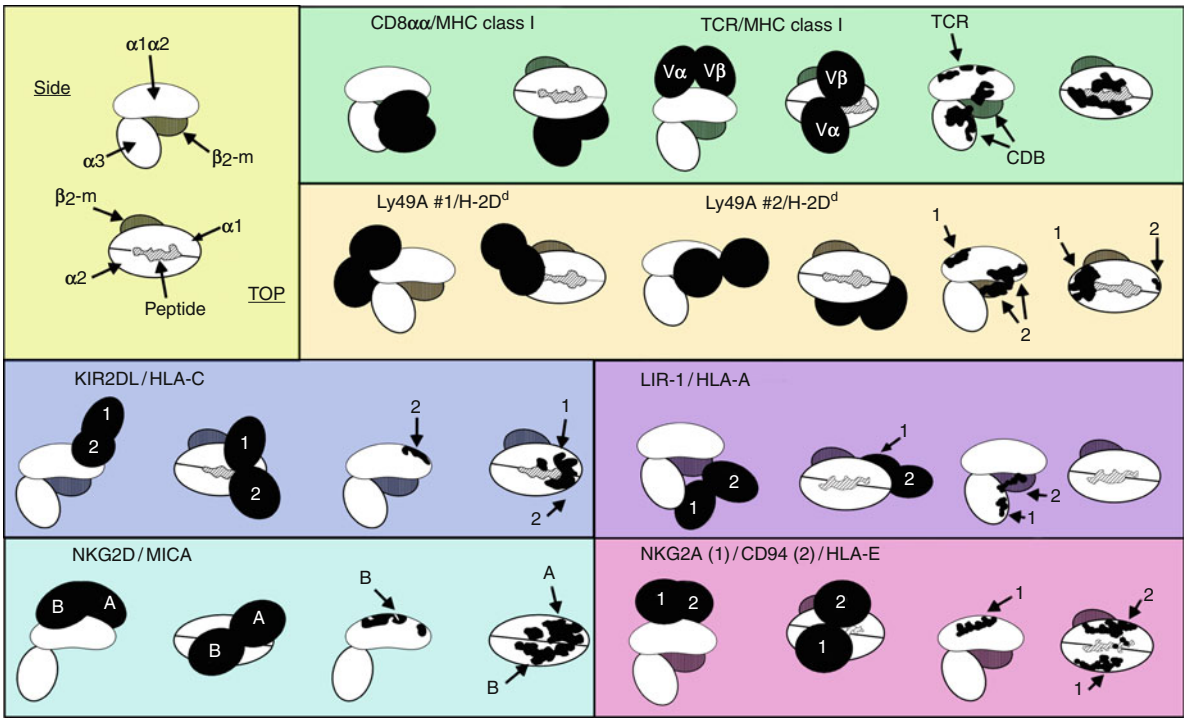
Besides receptors for classical MHC class I molecules, NK cells can indirectly gauge MHC class I expression on target cells through the NKG2x/CD94 receptor complexes. The NKG2x/CD94 receptors, which include both the inhibitory NKG2A/CD94 and activating NKG2C/CD94 receptors, contain C-type lectin-like ectodomains and recognize HLA-E, a nonclassical MHC class I molecule that presents



NK Receptor, Fig. 1 NK receptor–ligand complex structures. Ribbon representations of an αβ TCR/MHC class I complex and several NK receptor–ligand structures. MHC class I molecules are shown in *purple*. Receptors are colored in *rainbow spectrum*; β_2m is shown in *gray*. Class I–bound peptides are shown in *solid spheres* and colored by element. PDB accession codes for the coordinate files used to generate the figure are indicated in *gray*

MHC class I leader peptides. As with the KIR and Ly49 receptors, the inhibitory NKG2A/CD94 receptor binds the ligand with a higher affinity than the activating NKG2C/CD94 receptor. There are few conformational changes in either CD94-NKG2A or HLA-E upon binding, which reflects a typical "lock and key" recognition in innate receptor–ligand interactions (Petrie et al. 2008). A patch of amino acids (residues 167–170) of NKG2A account for the approximately sixfold-higher affinity of the inhibitory NKG2A/CD94 receptor compared to its activating counterpart. These residues do not contact HLA-E or peptide directly but instead form part of the heterodimer interface with CD94. An evolutionary analysis reveals that residues at the CD94 interface have evolved under positive selection, suggesting that the evolution of these genes is driven by an interaction with pathogen-derived ligands. Consistent with this possibility, data show that NKG2C/CD94, but not NKG2A/CD94, weakly but specifically binds to the CMV MHC-homologue UL18 (Kaiser et al. 2008).

NK cells can also be inhibited by members of the LIR (or immunoglobulin-like transcript (ILT)) family. Some members of LIRs (including LIR1-3) are inhibitory receptors with intracellular ITIM motifs, while others (including LIR6-7) are activating receptors associated with adaptor proteins for signaling. LIR-1 and LIR-2 are receptors for a broad range of class I molecules, including nonclassical molecule HLA-G. HLA-G is highly expressed in the trophoblast, and the inhibitory function of LIR-HLA-G interaction has been implicated in immunological tolerance of the fetus. The LIRs show a distinct recognition mode with regard to its class I HLA-A2 or nonclassical



NK Receptor, Fig. 2 NK receptor–ligand complex schematics. Schematic representations of an αβ TCR/MHC class I complex and several NK receptor–ligand structures to highlight interaction surfaces. Each row shows two views of a receptor–ligand complex, first showing the organization of domains in the complex (receptor domains in *black*, labeled where a distinction between domains is significant; MHC class I ligand heavy chains in *white* and β_2m in *dark gray*). The arrangement of domains in the ligands is detailed in the inset; the approximate solvent-accessible surface area of the bound peptide, if present, is shown as a *cross-hatched* area. The two *right*-most columns show approximate footprints of receptors and co-receptors on the ligands as *black hatches*, labeled by receptor component, subsite or domain as appropriate

MHC HLA-G ligand (Figs. 1 and 2). Both complex structures of HLA-A2 bound to LIR-1 and HLA-G bound to LIR-2 (Willcox et al. 2003; Shiroishi et al. 2006) showed the LIR binds at a site bridging the α3 and β_2m domains. The overall orientation of the MHC molecules with regard to LIR receptors resembles somewhat the *cis* binding site of Ly49A on H-2D^d, though none of the LIR domains are in contact with the underside of the platform domain of the MHC molecules (Figs. 1 and 2). The LIR-1 binding site on HLA-A2 overlaps with the CMV UL18 binding site. Binding sites on LIR-1 and LIR-2 similarly comprise residues at the interdomain hinge and a patch at the tip of domain 1. The overall geometry of the LIR receptor–MHC ligand complex is most consistent with a *trans* interaction involving recognition of an MHC class I protein on a target cell by a LIR receptor on an opposing NK cell.

Although the binding of an inhibitory receptor to MHC class I represents the major mechanism for inhibition and prevention of NK cell autoreactivity, there are other inhibitory receptors which bind to non-MHC class I ligands. NKR-P1 binds to lectin-like LLT1 molecules in humans. More information on the regulation of NKR-P1 ligands expression is required to determine the functional implications of this receptor–ligand interaction. Leukocyte-associated immunoglobulin-like receptor 1 (LAIR-1) is an inhibitory receptor that binds to collagen and is widely expressed on immune cells. Several members of the sialic acid binding Ig-like lectin (Siglec) family of receptors, which bind sialyl groups with various specificities, carry ITIMs in their cytoplasmic tail. Presumably, Siglec molecules function as inhibitory receptors; yet, the biological significance remains elusive.

Specificities and Recognition Mechanisms: Activating Receptors

Activating receptors include ▶ NKG2D, CD16, natural cytotoxicity receptors (NCRs), activating KIRs, the signaling lymphocyte-activation molecules (SLAM) family of receptors, and DNAX accessory molecule-1 (DNAM-1). One of the best characterized NK-activating receptors is NKG2D (Gonzalez et al. 2006). It is a type II integral membrane protein associated with the adaptor protein DAP10. NKG2D binds several ligands, including MHC class I chain–related A/B (MICA/B) and the UL16-binding proteins, 1-6 (ULBP1-6). Expression of these ligands is upregulated in a variety of epithelially derived tumors and virally infected cells. Currently, the mechanisms that upregulate NKG2D ligand expression on cancer cells are not well understood. While NKG2D provides an important defense mechanism against tumors and viral infection, it can also contribute to autoimmunity. For example, MICA and MICB are dramatically upregulated in rheumatoid arthritis synoviocytes and are capable of activating autoreactive autologous T cells in an NKG2D-dependent manner. MICA/B and ULBP1-6 are class I homologs that are not encoded by genes in the MHC complex and do not function as peptide-binding structures to present antigens to T cells. Multiple crystal structures of the receptor alone and three complexes (human NKG2D/MICA, NKG2D/ULBP3, and murine NKG2D/Rae-1β) show that NKG2D interacts with its MHC class I homologs in a manner very similar to how TCRs interact with classical MHC class I molecules (Strong and McFarland 2004; Figs. 1 and 2). Unlike KIR and Ly49A interactions at the first binding site, the NKG2D binding sites are much less dominated by charge–charge interactions. Both homodimer-related binding sites on NKG2D contribute approximately equally to the interactions in both complexes, reflecting a binding site that has evolved to bind multiple target sites without side-chain rearrangements. The considerable recognition degeneracy of NKG2D, accommodating structurally divergent, polymorphic families of ligands, is enabled not by a conformationally plastic binding site ("induced fit" or "conformer selection"), but rather by a "rigid adaptation" mechanism.

Another NK-activating receptor is the low-affinity receptor for IgG, CD16, which mediates ADCC and signals through adaptors containing cytoplasmic ITAMs. Several receptors, which activate antibody-independent, natural cytotoxicity are also associated with ITAM-containing signaling adaptors (Table 1). These receptors include NKp30, NKp44, and ▶ NKp46, which are referred to as NCRs (Biassoni 2009). CD16, NKp30, and NKp46, all use both FcεRIγ and CD3ζ as signaling adaptors. NKp44, on the other hand, partners with DAP12. Both NKp46 and NKp44 have been reported to bind viral hemagglutinin on infected cells while their cellular ligands have not been identified. NKp46 also contributes to enhanced killing of mitotic cells by NK cells, suggesting a role of NK cells in controlling the expansion of rapidly dividing cells. A recent study identified a tumor cell surface molecule that belongs to the B7 family that triggers NKp30-mediated activation of human NK cells (Brandt et al. 2009). This molecule, designated as B7H6, was not detected in normal human tissues but was expressed on human tumor cells. The expression of stress-induced self-molecules such as MICA/B and B7H6 associated with cell transformation serves as a mode of cell recognition in innate immunity. NKp30 also mediates killing of immature dendritic cells by NK cells. A nuclear factor, human leukocyte antigen-B-associated transcript 3 (BAT3), was also described as a ligand for NKp30. This ligand is released from tumor cells and plays an important role in tumor rejection in a multiple myeloma model via NKp30-mediated cytotoxicity. In addition, the main tegument protein (pp65) of human cytomegalovirus (HCMV) was proposed as an exogenous viral ligand as it inhibits NKp30-mediated cytotoxicity.

The specificity of the activating KIR family members has not been extensively characterized as compared with those of the inhibitory ones (Lanier 2005). KIR2DS1 and KIR2DS4 recognize HLA-C or HLA-A molecules weakly and KIR3DS1 is thought to recognize HLA-B with the Bw4 epitope, while ligands for other activating KIR receptors are undefined. The high sequence similarity between several pairs of activating and inhibitory KIR suggests they arose by gene duplication. However, in general, the activating KIRs either do not bind the cognate HLA class I, or bind with an affinity much weaker than that of the paired inhibitory KIR. The activating KIR receptors all have short cytoplasmic tails, and they transduce signals and trigger function through the ITAM-bearing adaptor DAP12. The exception is KIR2DL4. It has a functional ITIM in its cytoplasmic tail, yet it also associates with the

FcεRIγ adaptor protein, a feature for an activating receptor. Despite the presence of an ITIM, ligation of KIR2DL4 with its specific monoclonal antibody (mAb) leads to cytotoxicity and IFN-γ production in IL-2-activated NK cells. Soluble HLA-G has been described as its ligand.

Other activating receptors signal through motifs in their own cytoplasmic tail, or through pathways that have not been well characterized. 2B4, NK-T-B-antigen (NTB-A), and CD2-like receptor-activating cytotoxic cells (CRACC), all belong to the SLAM family of receptors (Veillette 2006). They are predominantly expressed on hematopoietic cells and regulate both innate and adaptive immunity. They are members of the Ig superfamily that consist of multiple Ig-like domains in the extracellular region, a transmembrane segment, and a cytoplasmic domain containing multiple tyrosine-based motifs. Comparing with other ITAM-based activating receptors, SLAM receptors have distinct activation pathways. In humans, activation through these receptors is accompanied by the phosphorylation of unique TxYxxV/L/I sequence–based immunoreceptor tyrosine-based switch motifs (ITSMs) in their cytoplasmic tails and the recruitment of SLAM-associated protein (SAP) as adaptors. SAP couples SLAM family receptors to FYNT, a Src-related PTK that is expressed by hematopoietic cells. In mice, however, 2B4 apparently functions as an inhibitory receptor. It is unclear if 2B4 itself can independently trigger effector functions or rather serves as a costimulatory receptor. The strongest evidence supporting an activating role in human NK cells comes from the demonstration that transfection of CD48, its ligand, into certain NK-resistant target cells renders them susceptible to NK-mediated cytotoxicity and triggers the production of IFN-γ by the human NK cells. Such action can be blocked by anti-CD48 mAb and anti-human 2B4 mAb. Adaptor protein SAPs appears to play important roles in SLAM receptor functions. In patients with certain mutations in SAP, NK cells can no longer be activated through the 2B4 receptor. Furthermore, immature human NK cells express 2B4 receptors that mediate inhibitory function, presumably because these immature NK cells lack SAP. 2B4 may, therefore, be a multifunctional receptor in both human and mice, displaying different functions depending on factors such as NK cell differentiation and activation. The complex crystal structure between the N-terminal domains of mouse 2B4 and CD48 reveals that they interact in a mode related to, yet distinct from, that of the homophilic NTB-A dimer of the same SLAM family. Binding is accompanied by the rigidification of flexible 2B4 regions containing most of the polymorphic residues across different species and receptor isoforms (Velikovsky et al. 2007).

Other activating NK receptors, such as DNAM-1 and NKp80, have been implicated in various immune functions. DNAM-1 receptor is a member of the Ig superfamily that is expressed in a variety of human lymphocytes including NK cells. It has been implicated in cell adhesion and in triggering NK- and T-cell-mediated cytolysis. CD112 and CD155, which are components of cellular adherens junctions, have been identified as ligands for DNAM-1. These ligands are frequently upregulated, and interaction between DNAM-1 on NK cells and CD112 and CD155 on tumor cells augments NK cell–mediated cytotoxicity and cytokine production. The interaction of NK cell receptors with members of the nectin-like molecules indicates the importance of adhesion in the triggering of NK cell function. Physical association of DNAM-1 with LFA-1 is necessary for NK and T cell triggering. NKp80 is another NK-activating receptor with unknown signaling properties. The cellular ligand of NKp80 was recently identified as activation-induced C-type lectin (AICL). AICL is expressed on myeloid cells, and is upregulated by inflammatory stimuli. Thus, NKp80–AICL interactions may be important for NK cell-myeloid cell cross talk during inflammation.

Tumor and Viral Evasion Mechanisms

Tumors use several mechanisms to evade the immune system, including NK-mediated responses. Aberrant loss of the activating receptor NKG2D in cancer is a key mechanism of immune evasion (Groh et al. 2002). Production of soluble, secreted NKG2D ligands or growth factors, such as TGF-β released from tumors, is a mechanism for downregulating NKG2D expression. TGF-β may also play an important role in the conversion of normal T cells into regulatory T cells (T_{reg}), a population of T cells that is found in high levels in the tumor microenvironment. T_{reg} cells reduce NKG2D expression, suppress NKG2D-mediated NK cell cytotoxicity, and accelerate the progression of tumors.

Although the expression of MICA/B may result in tumor elimination, MICA shedding, through directed proteolysis from the surface of tumor cells, into the

plasma is a common characteristic of many epithelially derived tumors. The process of shedding is mediated by interactions between MICA and a protein disulphide isomerase, endoplasmic reticulum protein 5 (ERp5 or PDI-P5). ERp5 forms a transitory complex with MICA and reduces an inaccessible disulfide bond in the α3 domain, which must induce a conformational change that is essential for the proteolytic cleavage of MICA (Kaiser et al. 2007).

Epigenetic repression of NKG2D ligand transcription, such as limiting the accessibility of promoter sequences to transcription factors or micro-RNA-induced repression of gene expression, is another tumor evasion mechanism. Transcription of MICA/B and ULBP1 is mainly regulated by ubiquitous transcription factors including Sp1, Sp3, and NFY. However, the binding of these transcription factors to their promoters may be regulated by the histone deacetylases (HDACs) and the structure of chromatin. HDACs remove the acetyl groups of histone to form compacted chromatin, which restrains the accessibility of promoter sequences to transcription factors. HDACs are overexpressed in many cancer types, and they participate in the repression of numerous proteins with tumor-suppression activities (Lopez-Soto et al. 2009). Micro-RNAs may also target the MICA/B 3'-untranslated region to repress expression (Stern-Ginossar et al. 2007).

Viral immune modulatory mechanisms also manipulate NK receptor and ligand expression (Wilkinson et al. 2008), and virus-derived decoy ligands for inhibitory receptors are used as viral evasion mechanisms. HCMV encodes an inhibitory decoy glycoprotein ligand, UL18, which is structurally similar to MHC class I proteins, including a peptide-binding groove and association with host β_2-microglobulin. UL18 is used to evade NK detection by binding to the inhibitory NK receptor LIR-1 with high affinity. Selective upregulation of inhibitory MHC class I antigens is another viral evasion mechanism; viral proteins that bind MHC class Ib proteins and upregulate their expression, while differentially downregulating CD8 + T cell activating MHC class Ia antigens, include HCMV-encoded UL40, US2, US11, and HIV-encoded Nef. A nine amino acid sequence (VAMPRTLIL) in HCMV UL40, identical to HLA-C leader sequences, binds to HLA-E and allows its surface expression when MHC class I expression is repressed by other viral mechanisms. On the other hand, HCMV-encoded US2 and US11 have been shown to selectively downregulate HLA-A surface expression without interfering with HLA-E expression. Similar evasion mechanisms are also observed with the HIV-encoded Nef protein, which directs HLA-A and B for lysosomal degradation while sparing HLA-C and HLA-E.

Viral proteins that directly interact with NK-activating ligands are also deployed by viruses to evade NK surveillance by sequestering and retaining ligands intracellularly. HCMV UL16 sequesters the NKG2D ligands MICB, ULBP1, and ULBP2 and downregulates their surface expression. Another HCMV-encoded protein, UL142, uses similar mechanism to downregulate MICA. Various serotypes of human adenovirus also encode proteins that are used to modulate surface expression of NK-activating receptors: The E3/19 K protein sequesters MICA/B proteins in the ER, downregulating surface expression. Expression of NK-activating ligands is also modulated by virus-derived micro-RNAs. The HCMV-encoded miRNA, hcmv-miR-UL112, selectively downregulates the NKG2D ligand MICB (Stern-Ginossar et al. 2007). Viruses also manipulate components of the host ubiquitin pathway to protect infected cells from NK responses. The KSHV-encoded immune evasion proteins, K3 and K5, have E3 ubiquitin ligase activity, possess a variant RING domain, and downregulate surface expression of NKG2D ligands MICA/B by ubiquitination of conserved lysine residues in the cytoplasmic tail of MICA/B which result in its trafficking from the cell surface to an intracellular compartment.

Summary

NK cells are capable of recognizing and destroying multiple pathogenic cell targets. This broad specificity is mediated by multiple activating and inhibitory surface receptors and intracellular signal transduction molecules. NK receptors are regulated in a spatial and temporal fashion at the NK synapse where adhesion molecules and NK receptors interact with their ligands on the target cell. Healthy cells expressing MHC class I will engage NK inhibitory receptors and thus be spared, whereas infected or transformed cells, that have an aberrant expression of MHC class I and cell stress markers, become susceptible to attack. Significant progress has been made in the identification of many activating and inhibitory receptors, their ligands,

and signaling pathways. However, many receptors, such as NCRs and activating KIRs, have poorly defined or unknown ligands. The signaling mechanisms of receptors such as NKp80 and many of the mechanisms governing the regulation of receptor expression also remain unknown. Furthermore, the interplay between the complex array of activating and inhibitory receptors leading to NK cell function needs to be defined. Future studies aimed toward identifying unknown ligands and understanding the dynamic interactions between receptor signaling and its effect on cellular function will help in the understanding of NK cell biology and the role that NK cells play in the immune system.

Historical Background

Natural killer (NK) cells are key components of the innate immune response and can mediate cellular cytotoxicity without previous antigen exposure. The mechanisms underlying NK cell activation have been uncovered in a stepwise fashion from the early 1980s (for a detailed review of the field and its development see (Lanier 2008)). The role of the CD16 FcγRIII cell surface receptor in antibody-dependent NK cell activation was described in 1983. In 1986, Karre and colleagues proposed the "missing self hypothesis" hypothesis, and demonstrated the presence of inhibitory NK cell surface receptors responsive to the self-MHC (major histocompatibility complex) molecules on normal host cells. The search for antibody-independent NK cell activating receptors led to the identification of the NKG2 family of NK cell receptors in 1991. Among these was NKG2D, a molecule that shared limited homology with other NKG2 family members and was expressed in both NK and T cells as a predicted type 2 transmembrane C-type lectin receptor. In 1994, Bahram et al. identified two polymorphic genes encoding molecules related to classical MHC class I molecules which they named major histocompatibility complex I chain-related genes A and B (MICA, MICB) (Bahram et al. 1994). In 1999, NKG2D was identified as the activating receptor for MICA and MICB (Bauer et al. 1999).

NKG2D is recognized as a dominant activating NK cell receptor, capable of activating NK cells (Bauer et al. 1999), and influencing T cell activation. It is expressed constitutively in human NK cells, γδ T cells, and $CD8^+$ T cells, and may also be found in some invariant natural killer T (iNKT) cell and $CD4^+$ T cell populations. In mice, NKG2D is constitutively expressed in NK cells, but is only expressed in $CD8^+$ T cells when they have been activated. NKG2D has been identified in a wide range of mammals, including nonhuman primates, pigs, cattle, and rats.

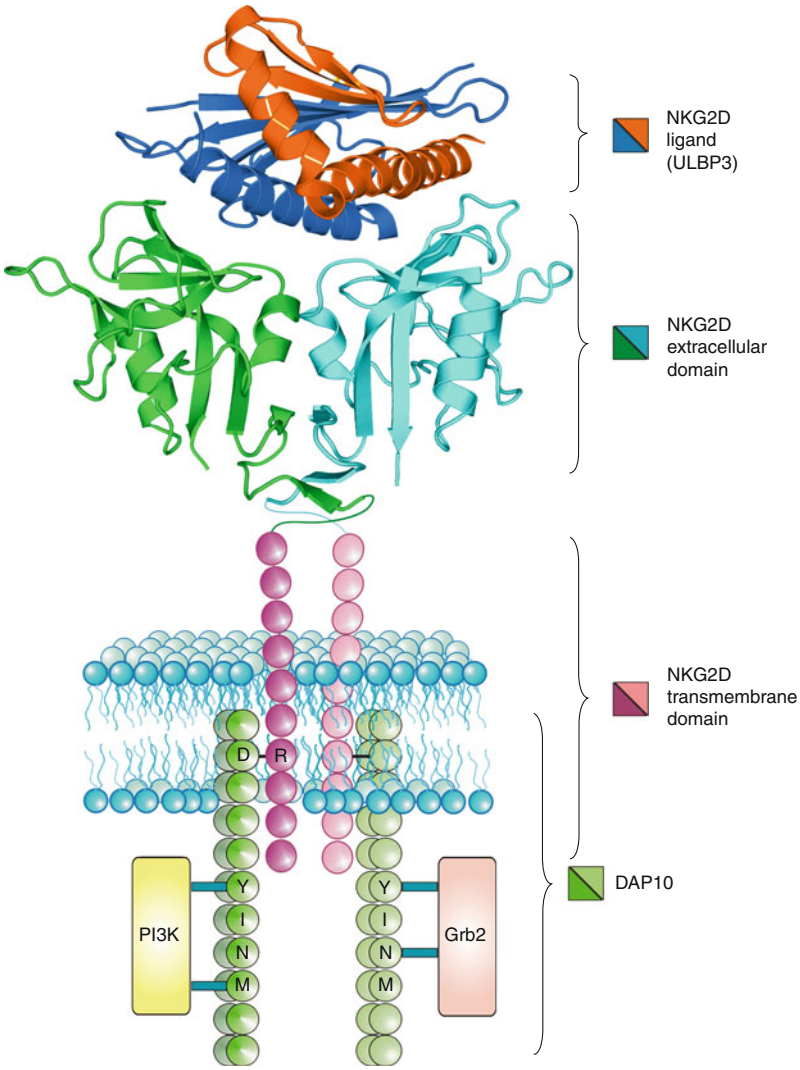
NKG2D Structure

Human NKG2D is a 316 amino acid type 2 transmembrane C-type lectin-like protein encoded by the KLRK1 gene (Killer cell Lectin-like Receptor subfamily K-1) within the NK gene complex at chromosome 12p13.2-12.3. Structural studies show that human NKG2D exists as a dimer and lacks functional calcium coordinating carbohydrate binding domains (Fig. 1) (Li et al. 2001). Each NKG2D monomer contains two β sheets and two helical elements, with four intrachain disulphide bonds. Murine NKG2D is structurally similar to human NKG2D (Wolan et al. 2001), but unlike human NKG2D, it exists in two isoforms: a long isoform of 232 amino acids (NKG2D-L, isoform A), and a short 219 amino acid isoform (NKG2D-S, isoform B) (Diefenbach et al. 2002).

The cytoplasmic portion of human NKG2D does not possess intrinsic signaling capability. Instead, a charged amino acid (arginine) in the transmembrane portion of NKG2D interacts with an aspartate residue in the adaptor molecule DAP10 (DNAX-activation protein 10). Each NKG2D molecule binds to a DAP10 dimer in this fashion to form a hexameric structure capable of signal transduction. The YINM motif in the cytoplasmic region of DAP10 recruits downstream signaling molecules. Murine NKG2D interacts with both DAP10 and DAP12, an ITAM (immunoreceptor tyrosine-based activation motifs)-containing adaptor molecule, through similar transmembrane region interactions. Both long and short NKG2D isoforms are capable of interacting with and signaling through either DAP10 or DAP12 in vitro, but in vivo the long form of NKG2D only interacts with DAP10 (O'Callaghan 2009). Human NKG2D does not interact with DAP12.

NKG2D Signaling

Signal transduction from NKG2D is complex (Fig. 1). A critical early event in the NKG2D-DAP10 signal cascade is tyrosine phosphorylation of the YINM motif in DAP10 by the src family tyrosine kinase, Lck and src kinase inhibitors abrogate downstream signal transduction. The phosphorylated YINM motif recruits further intermediates: the p85 subunit of ► PI3K (phosphatidylinositide-3 kinase) and the adaptor protein Grb-2 (growth factor receptor-bound protein 2). Both binding events are essential for signal transmission. The GNEF (guanine nucleotide exchange factor) ► Vav1, which plays an important role in actin reorganization, is recruited to Grb-2, where it is phosphorylated and activated. From here, signal transmission diverges, but it is known that Vav1 acts in part by binding the γ2 isoform of phospholipase C (PLCγ2), which amongst other downstream targets



NKG2D, Fig. 1 Human NKG2D ligand binding and signaling. The NKG2D extracellular domain and ULBP3 are shown in cartoon form based on the crystal structure of the complex. Each NKG2D molecule interacts with a DAP10 dimer through an association between an arginine residue (R) in the transmembrane region of NKG2D, and an aspartate residue (D) in the transmembrane domain of DAP10. Upon ligand binding, signaling from NKG2D is transmitted through DAP10. Key interactions with DAP10 include binding of the p85 subunit of PI3K to the YXXM motif in DAP10, while Grb2 recognizes YXNX, following the phosphorylation of DAP10 by src family tyrosine kinases

activates MAPK8 (mitogen-activated protein kinase 8, JNK1). In contrast, MAPK1 (ERK2) appears to be an important downstream target of PI3K. These signaling pathways are reviewed by Lanier (2008).

While human NKG2D does not interact with DAP12, NKG2D-DAP12 signaling remains an important consideration in murine NKG2D models. Unlike DAP10, NKG2D-DAP12 signaling is dependent on the ITAM domain of the cytoplasmic portion of DAP12. Engagement of ligand by NKG2D leads to the phosphorylation of two tyrosine residues in the DAP12 ITAM by src family tyrosine kinases. This enables recruitment of the syk tyrosine kinase, which is necessary for NKG2D-DAP12 function. It is likely that the downstream components of this pathway are similar to those in other ITAM-associated receptors, which have been studied in greater detail in different contexts.

NKG2D Ligands

A striking characteristic of NKG2D is the wide range of distinct ligands with which it can productively interact. Such ligand diversity indicates that NKG2D has evolved as an important receptor receiving input from the various stimuli which act through the upregulation of the different ligands. For further detailed reviews, see Mistry and O'Callaghan (2007) and Champsaur and Lanier (2010).

Humans express eight distinct functional NKG2D ligands: MICA and MICB (major histocompatibility complex I chain-related genes A and B), and the UL16 binding proteins (ULBP) 1–6. MICA and MICB are distant homologues of classical MHC class I molecules. Both are highly polymorphic, a feature of much interest, with 71 and 30 known alleles respectively identified to date. MICA and MICB are transmembrane molecules with MHC class I-like α1, α2, and α3 domains. However, in contrast to classical MHC class I molecules they do not associate with β2-microglobulin, and the cleft separating the α2 and α3 domains is closed and does not bind peptides.

In contrast, the ULBPs have limited polymorphism and lack an α3 domain. ULBP 1–3 were originally identified as proteins that were bound by the cytomegalovirus protein UL16 and that interacted with NKG2D to induce NK cell cytokine secretion and cytotoxicity. Seven related gene sequences were subsequently described in the same region of chromosome 6q. Three of these encode functional molecules, ULBP 4 (RAET1E, LETAL), ULBP 5 (RAET1G), and ULBP 6 (RAET1L). ULBPs 1–3 and ULBP 6 are GPI-linked cell surface proteins, while ULBP 4 and 5 exist principally in transmembrane forms. A GPI-linked splice variant of ULBP 5 has been described, while ULBP 4 has three functional splice variants, each encoding transmembrane receptors.

Mice do not have MICA or MICB genes. There are three families of murine NKG2D ligands: the retinoic acid early (RAE) 1 family including α, β, γ, δ and ε; H60 a, b and c; and murine ULBP-like transcript 1 (Mult1). RAE1 α, β, and γ were described in 1996 as glycophoshatidyl-inositol (GPI)-linked cell surface molecules of unknown function, isolated from retinoic acid–treated mouse embryonal carcinoma cells. The murine NKG2D ligands show limited homology with murine classical MHC class I molecules and have an α1, α2 domain structure which does not present peptide, and does not associate with β2 microglobulin. H60a, H60b, and Mult1 are transmembrane proteins, while H60c is a GPI-linked cell surface protein. The binding reactions between murine NKG2D and its ligands have been studied in detail, and binding affinities vary distinctly between NKG2D and its various ligands (O'Callaghan et al. 2001; Mistry and O'Callaghan 2007).

The ligands for NKG2D are expressed on some normal cells, including gastrointestinal epithelial cells, and activated T cells, but are primarily displayed in pathological settings, notably in response to viral infection, some intracellular bacterial infections, and in many cancers. While several stimuli, broadly described as physiological stressors, are known to increase cell surface expression of NKG2D ligands on target cells, the mechanisms underlying regulation of NKG2D ligand expression remains poorly understood (Mistry and O'Callaghan 2007).

NKG2D Function

NKG2D may play significant roles in viral immunity, tumor immunity, autoimmune diseases, and transplant rejection (Ogasawara and Lanier 2005). These roles are mediated through specific cellular processes, especially the induction of natural killer cell cytotoxicity and cytokine production. The role of NKG2D in T cell costimulation remains unclear (Lopez-Larrea et al. 2008; O'Callaghan 2009).

Natural cytotoxicity. Natural cytotoxicity involves the coordination of several complex cellular processes including cytoskeletal reorganization, immune synapse formation, and perforin translocation. Freshly isolated human NK cells are capable of mounting a cytotoxic response to a target expressing NKG2D ligands without further experimental manipulation. Signaling through NKG2D can override inhibitory signaling through the interaction of HLA-E with CD94/NKG2A (Bauer et al. 1999) although in vivo NK cell activation is likely to reflect a broad balance between activating and inhibitory signaling. NKG2D may mediate TCR-independent cytotoxicity in IL-2 treated $CD8^+$ T cells, γδ-TCR T cells, and some $CD4^+$ T cell populations, but the *in vivo* significance of this is less certain and remains to be firmly established.

Cytokine and chemokine production. Early studies suggested that isolated ligation of NKG2D on NK cells and γδ-TCR T cells is sufficient to induce secretion of cytokines, primarily IFNγ, TNFα and to a lesser extent, GMCSF and TNFβ (Fauriat et al. 2010). In one study, isolated human NKG2D ligation induced little cytokine secretion, but IFNγ and TNFα, prototypical NK cell cytokines, in addition to MIP-1α, MIP-1β, and RANTES, were produced when NKG2D was triggered together with CD16 (FCγRIII), natural cytotoxicity receptors, 2B4 or LFA-1 (Fauriat et al. 2010).

Costimulation. CD28 is the prototypical TCR costimulatory molecule, and signals through the p85

subunit of PI3K, which is recruited to a YMNM motif in the cytoplasmic domain of CD28. Given this shared signaling pathway with NKG2D, it was hypothesized that NKG2D might costimulate TCR-dependent T cell activation. Cytotoxicity, cytokine production (IFNγ, TNFα, IL-2, and IL-4) and proliferation was enhanced by the MICA-NKG2D interaction in cytomegalovirus-specific $CD8^+$ T cells (Groh et al. 2001). Similar findings have been demonstrated in freshly isolated naïve ($CD62L^+$, $CD45RO^-$) human αβ TCR $CD8^+$ T cells (Maasho et al. 2005). Both these studies used cytokine (IL-2 or IL-15) supported T cells in their experiments. When the T cell costimulatory capacity of NKG2D was compared to that of CD28, in the absence of cytokine support, NKG2D ligation did not mediate costimulation (Ehrlich et al. 2005).

Murine knockouts. NKG2D knockout mice have provided further insights into NKG2D function (Guerra et al. 2008; Zafirova et al. 2009). Crossbreeding of NKG2D deficient mice with mice which develop prostate cancer or lymphoma demonstrate earlier and more rapid progression of these cancers in NKG2D-deficient mice (Guerra et al. 2008). Furthermore, NK cells from NKG2D-deficient mice have a diminished ability to kill NKG2D ligand expressing target tumor cells (Zafirova et al. 2009). NK cell development also appears to be affected, with more rapid NK cell division, and enhanced cytokine responses to NK cell stimulation (Zafirova et al. 2009).

NKG2D Regulation

Several factors modify the cell surface expression of NKG2D (Mistry and O'Callaghan 2007; O'Callaghan 2009). Cytokines appear to be the principle regulators of NKG2D cell surface concentration on both NK cells and T cells. Altering NKG2D cell surface density may alter the influence of NKG2D on cellular activation. TGFβ decreases cell surface NKG2D expression in NK cells, while IL-21 decreases NKG2D cell surface expression in both NK cells and $CD8^+$ T cells. IL-15 increases NKG2D expression on $CD8^+$ T cells, $CD4^+$ T cells, and NK cells, while IL-2, IL-12, and IFNα have been shown to increase NKG2D expression on NK cells.

Excessive exposure to NKG2D ligands is reported to lower NKG2D cell surface concentrations in both physiological and pathological settings. In pregnancy, syncytiotrophoblast cells of the placenta produce exosomes containing soluble NKG2D ligands, which decrease NK cell NKG2D cell surface expression and reduce NK cell cytotoxicity (Hedlund et al. 2009). Tumor cells have been shown to downregulate NKG2D cell surface concentration in a similar fashion (Groh et al. 2002).

Summary

NKG2D is a homodimeric C-type lectin like molecule which acts as an activating receptor in NK cells, and can play an activating and potentially costimulating role in γδ T cells and $CD8^+$ T cells, and some $CD4^+$ T cell and iNKT cell populations. It is widely conserved in mammals suggesting an important immune role. It is a promiscuous receptor with multiple diverse ligands, which are now well characterized in humans and mice. Future work is needed to further elucidate NKG2D signaling mechanisms, define functional interactions between NKG2D and other immune signaling molecules, and to identify regulatory mechanisms that govern NKG2D ligand expression in target cells.

Historical Background

NK cell function is finely regulated by a series of inhibitory or activating receptors. The inhibitory receptors, specific for major histocompatibility complex (MHC) class I molecules, allow NK cells to discriminate between normal cells and cells that have lost the expression of MHC class I (e.g., tumor cells). In the absence of sufficient signaling by their HLA class I-specific inhibitory receptors, human natural killer (NK) cells become activated and display potent cytotoxicity against cells that are HLA class I negative. This indicates that the NK receptors responsible for the induction of cytotoxicity recognize ligands on target cells different from HLA class I molecules. These receptors have been termed natural cytotoxicity receptors (NCR) and include NKp46, together with NKp44 and NKp30 (Bottino et al. 2000). A direct correlation exists between the surface density of NCR and the ability of NK cells to kill various target cells (Sivori et al. 1999). Importantly, mAb-mediated blocking of these receptors has been shown to suppress cytotoxicity against most NK-susceptible target cells. However, the process of NK-cell triggering during target cell lysis may also depend on the concerted action of NCR and other triggering receptors, such as ▶ NKG2D, or surface molecules, including 2B4 and NKp80, that appear to function as co-receptors rather than as true receptors.

Distribution and Molecular/Biochemical Characterization of NKp46

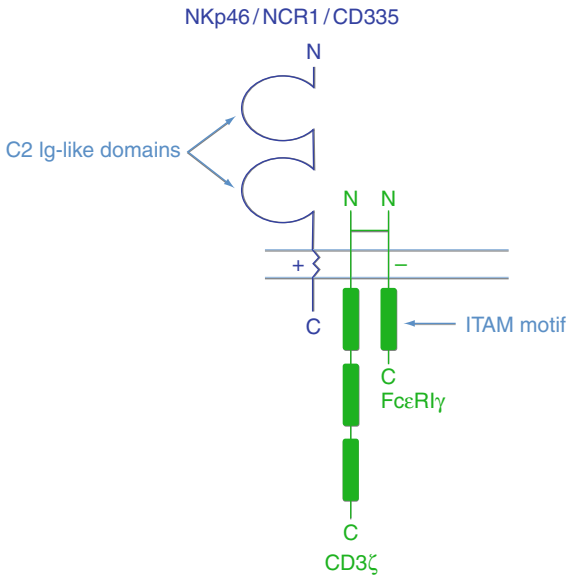
NKp46 is a surface molecule of 46 kDa expressed by all human NK cells (including the $CD56^{bright}$ $CD16^{-}$ subset) irrespective of their state of activation. It is mostly confined to NK cells and its engagement induces a strong activation of NK-mediated cytolysis, Ca^{++} mobilization, and cytokine release (Moretta et al. 2001; Sivori et al. 1997).

NKp46 is encoded by the NCR1 gene, which maps in the telomeric region of "leukocyte receptor complex" (LRC) on human chromosome 19q13.42 (Kelley et al. 2005; Pessino et al. 1998). The NCR1 gene is conserved during speciation, at least in rodents, bovine, and primates (Biassoni 2008).

NKp46 is a type I transmembrane glycoprotein belonging to the Ig superfamily. It is characterized by two extracellular Ig-like domains of the C2 type

(about 190 aa), connected by a short peptide (25 aa) to the transmembrane domain (about 20 aa) and by a small cytoplasmic domain (about 30 aa) (Fig.1). The amino-terminal portion of the transmembrane region of NKp46 contains the positively charged amino acid arginine, which likely forms a salt bridge with the aspartic acid residue located in a similar topological context of the transmembrane domains of CD3ζ or FcεRIγ. The cytoplasmic tail does not contain immunoreceptor tyrosine-based activation motifs (ITAM), typically involved in the activation of the signal cascade(s) (Moretta et al. 2001; Pessino et al. 1998). NKp46 can transduce positive signaling thanks to its association with CD3ζ or FcεRIγ, two small polypeptides characterized by short extracellular portions and by cytoplasmic tails containing three and one ITAM, respectively, that become tyrosine phosphorylated upon receptor engagement. In NK cells, CD3ζ and FcεRIγ are also involved in intracellular signaling via CD16 and have been shown to be phoshorylated by tyrosine kinases of the ▶ Src family, such as p56lck, followed by the recruitment of Syk and ▶ ZAP-70 tyrosine kinases (Moretta et al. 2001).

The crystal structure of NKp46 indicates a certain degree of structural conservation with KIR2DL2, CD89, glycoprotein VI platelet collagen receptor, LILRB1 (LIR-1/ILT2/CD85j), and LILRB2 (LIR2/ILT4/CD85d) molecules, which are encoded by genes that map close to each other on chromosome 19q13.42 (Ponassi et al. 2003).



NKp46, Fig. 1 *NKp46 structure*. NKp46 is a type I glycoprotein belonging to the Ig-superfamily. It contains, in its transmembrane portion, a positively charged amino acid involved in the association with signal-transducing molecules characterized by negatively charged residues in their transmembrane portion and tyrosine-based motifs in their cytoplasmic tails

NKp46 Ligands

The identification of the NKp46 ligand(s) on cancer cells is still being investigated. At this regard, it has been suggested that membrane-associated heparan sulfate proteoglycans (HSPGs) might be involved in the recognition of tumor cells by NKp46 and NKp30 (Bloushtain et al. 2004). These results have been not confirmed by other studies, at least for NKp30-mediated killing (Warren et al. 2005). Moreover, since heparan sulfate is also found on normal cells that are not killed by NK cells, it is likely that it does not represent a specific ligand of NKp46 or NKp30. Indeed, heparan sulfate is already known as a co-ligand for different growth factors, chemokines, lipid-binding proteins, and adhesion proteins (Capila and Linhardt 2002).

NKp46 is also involved in the killing of virus-infected cells and it has been described to recognize the hemagglutinin of influenza virus (IV-HA) and the hemagglutinin-neuraminidase of Sendai virus (SV-HN) (Arnon et al. 2004; Gazit et al. 2006; Mandelboim et al. 2001). This recognition seems to depend on the sialylation of NKp46 receptor, in particular on α2,6-linked sialic acid carried by Thr-225 residue (located into the membrane proximal domain of NKp46) (Arnon et al. 2004). The Thr-225 of NKp46 plays a critical role in interaction not only with viral hemagglutinins, but also with unknown tumor cellular ligands, probably via different mechanisms not involving its sialylation (Arnon et al. 2004).

Other authors have suggested that vimentin, expressed on the surface of *Mycobacterium tuberculosis*–infected monocyte cell lines, mediates NKp46 binding to these cells and contributes to their lysis (Garg et al. 2006).

It has been suggested that the positively charged amino acids K133, R136, H139, R142, and K146 present in the membrane proximal domain may be involved in ligand interaction. Indeed mutagenesis of these amino acids on NKp46 to noncharged amino

acids decreases the affinity of interaction with tumor cells at least 10–100 times, without affecting the interaction with viral ligands (Zilka et al. 2005).

NKp46 on CTL

Although the cell-surface expression of NKp46 is the most selective marker for human and mouse NK cells described so far, there are non-NK populations that also express NKp46, including discrete subsets of γδ T cells in mice and subsets of intraepithelial lymphocytes in patients with celiac disease. In various chronic infectious and inflammatory diseases (such as celiac disease or citomegalovirus infection), human CTLs can aberrantly express NKp46 as well as other activating NK receptors, such as NKG2C or NKp44. These activating NK receptors, thanks to their association with ITAM-bearing molecules (DAP12, CD3ζ or FcεRIγ), could interfere with normal T cell tolerance mechanisms by both inducing the expansion and unleashing the effector function of CTL, independently of TCR signaling (Meresse et al. 2006).

NKp46 on NK-22 Cells

NKp46 is also expressed on a cell subset found in the lamina propria of mouse small intestine and characterized by constitutive production of interleukin (IL)-22. This cell subpopulation seems to play a role in protecting mucosa and controlling inflammation (Satoh-Takayama et al. 2008). Constitutive IL-22 production by NKp46$^+$ cells is abolished in germ-free mice and infection of mice with enteric pathogens increases both NKp46$^+$ cell numbers and their IL-22 expression. These cells display greatly reduced cytotoxic activity and IFN-γ production, but produce large amounts of IL-22 in response to IL-23.

A similar subpopulation has been found also in tonsils and Peyer's patches in humans, although these cells displayed the NCR NKp44 rather than NKp46 (Cella et al. 2009). Mouse IL-22$^+$ NKp46$^+$ cells and human IL-22$^+$ NKp44$^+$ cells have been collectively called NK-22 cells (Cella et al. 2009). Human NK-22 cells also produce IL-26 and LIF (Cella et al. 2009).

More recently the phenotype of human NK-22 cells has been refined. In particular, the revised phenotype of the human IL-22-producing NKp44$^+$ cells is the following: RORγt$^+$, NKp46$^+$, NKp44$^+$, NKG2D$^+$, CD56$^+$, CD127$^+$ (IL-7 receptor α chain), CD117$^+$, KIR$^-$, perforin$^-$, and granzyme$^-$ (Vivier et al. 2009).

Summary

NKp46 is a surface molecule of 46 kDa expressed by all human NK cells irrespective of their state of activation. It is mostly confined to NK cells and its engagement induces a strong activation of NK function. In particular, NKp46 plays an important role in the killing of virus-infected and tumor cells. The identification of the NKp46 ligand(s) on cancer cells is still being investigated. Indeed it is important to understand whether NKp46 ligand(s) down-modulation or loss can be involved in tumor resistance to NK-mediated cytolysis. Moreover this identification will allow designing strategies to increase tumor susceptibility to NK-mediated killing by manipulating the NKp46 ligand(s) expression at the tumor cell surface. Although NKp46 is the most selective marker for human and mouse NK cells described so far, there are non-NK populations that also express NKp46, including discrete subsets of γδ T cells in mice, human CTLs in various chronic infectious and inflammatory diseases, and mucosal RORγt$^+$ IL-22-producing cells.

Glycylpeptide N-tetradecanoyltransferase; Myristoyl CoA:protein N-myristoyltransferase; NMT; N-myristoyltransferase; Peptide N-myristoyltransferase.

Historical Background

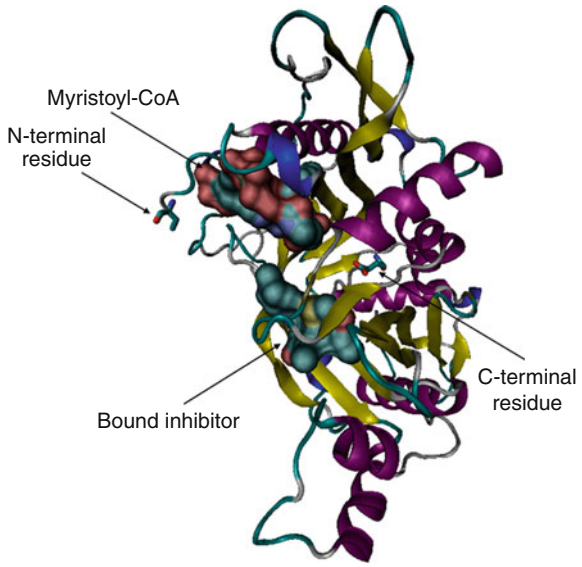
Protein functions are coordinated by a variety of secondary modifications which include the addition of chemical moieties of low molecular weight such as phosphate, acetate, and formate as well as of high molecular weight which includes carbohydrate and lipid molecules. In particular, the addition and removal of lipophilic moieties to proteins influences membrane targeting, signaling, and their functions. However, the current understanding of the roles and biological significance of fatty acid modifications in the regulation of protein functions is in a state of infancy. The three prevalent forms of lipid modification in eukaryotes are addition of glycosylphosphatidylinositols (GPIs),

isoprenoids, and fatty acids (myristoylation and palmitoylation) (Hannoush and Sun 2010). The protein modification by GPIs is a post-translational process which involves anchoring of a complex structure involving both lipids and carbohydrates to the carboxy terminus of protein molecules, whereas protein prenylation involves the post-translational irreversible attachment of a 15-carbon (farensyl) or a 20-carbon (geranylgeranyl) by a thioester bond to one or more cysteines located at or near to the carboxy terminus of the proteins (Hannoush and Sun 2010). Among the two fatty acid alteration processes, palmitoylation is a reversible change which occurs post-translationally and involves the addition of a 16-carbon chain palmitic acid to internal cysteine (S-acylation) residues via a thioester bond. However, sometimes palmitoylation can also occur via formation of an amide linkage (N-acylation) or an oxyester linkage (O-acylation) (Hannoush and Sun 2010). The protein myristoylation process on the other hand is an irreversible lipidic modification that refers to the covalent attachment of myristate, a 14-carbon saturated fatty acid, generally to the N-terminal glycine residue of proteins (Boutin 1997; Resh 1999; Farazi et al. 2001; Selvakumar et al. 2007; Wright et al. 2010; Hannoush and Sun 2010). The very first myristoylated protein to be discovered was catalytic subunit of cAMP-dependent protein kinase from bovine cardiac muscle which was found to be blocked at the N-terminus by n-tetradecanoic acid and a similar modification was very soon reported in the β-subunit of calcineurin (Boutin 1997; Selvakumar et al. 2007). Protein myristoylation was at very first thought to be a co-translational protein modification occurring after removal of the initiator methionine residue by methionine aminopeptidases (Wilcox et al. 1987); however, it is now reported to occur post-translationally as well (Farazi et al. 2001; Wright et al. 2010; Hannoush and Sun 2010). With subsequent studies, it has now been shown that myristoylation is not restricted to the N-terminal glycine but it can also occur on the internal lysine and cysteine residues (Boutin 1997). However, myristoylation other than at the N-terminal glycine is restricted to a very small fraction of the reported myristome. Myrisitic acid is considered a rare fatty acid in the cells and constitutes less than 1% of the total fatty acid pool (Boutin 1997). However, it is estimated that at least approximately 0.5% of the eukaryotic proteins are myristoylated (Hannoush and Sun 2010; Wright et al. 2010). This suggests a special role for myristoylation which cannot be substituted by other lipidic modifications of proteins. However, the myristoylation process so far has received less attention than the other related lipid modification processes, namely, prenylation and palmitoylation.

Myristoyl-CoA:Protein N-Myristoyltransferase (NMT) and Its Isoforms

The transfer of myristate to the N-terminal glycine of proteins is catalyzed by the enzyme myristoyl-CoA: protein N-myristoyltransferase (NMT) which is found ubiquitiously among lower and higher eukaryotes (Boutin 1997; Resh 1999; Selvakumar et al. 2007; Wright et al. 2010; Farazi et al. 2001). The enzyme follows an ordered Bi Bi reaction mechanism in which the apoenzyme binds myristoyl-CoA to form a NMT-myristoyl-CoA binary complex which subsequently binds to protein/peptide substrates. The catalytic conversion (N-myristoylation) is via direct nucleophilic addition–elimination reaction. The sequential release of CoA and myristoyl peptide follows the formation of enzyme–product complex from the enzyme–substrate complex (Resh 1999; Farazi et al. 2001; Wright et al. 2010). The enzyme is highly selective for myristoyl-CoA in vitro and in vivo (Farazi et al. 2001; Wright et al. 2010). The protein belongs to GNAT superfamily of enzymes and consists of saddle-shaped β-sheet flanked by α helices. There is pseudo twofold symmetry with regions corresponding to N- and C-terminal portions of the enzyme. The N-terminal half forms the myristoyl-CoA binding site whereas the C-terminal half forms the major portion of the peptide binding site (Fig. 1) (Farazi et al. 2001; Wright et al. 2010). NMTs have a very high common preference for myristoyl-CoA but have varying peptide substrate specificities (Farazi et al. 2001; Wright et al. 2010).

There is substantial biochemical evidence that suggests that these enzymes exist as isozymes in vivo, varying in either apparent molecular weight and/or subcellular distribution (Boutin 1997; Wright et al. 2010). The first report on the multiple isoforms of NMT came from studies on bovine brain NMT (King and Sharma 1992) and further isozymes varying in size and tissue distribution have been reported from



NMT (N-Myristoyltransferase), Fig. 1 Structural model of human NMT1 bound to myristoyl-CoA and an inhibitor (generated from PDB code 3IU2). The distinct myristoyl-CoA and the inhibitor binding sites are shown in proximity to the N-terminal and C-terminal portion of the molecule, respectively. This image was made with VMD (ver 1.8.7). VMD is developed with NIH support by the Theoretical and Computational Biophysics group at the Beckman Institute, University of Illinois at Urbana-Champaign

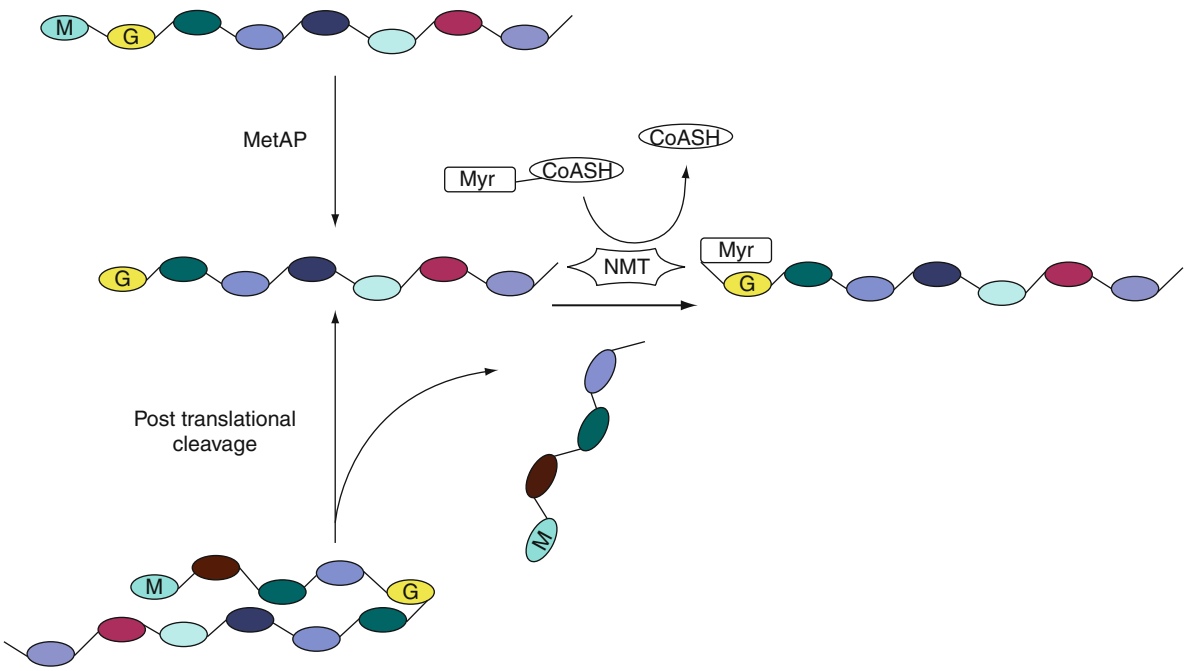
a variety of sources (Boutin 1997; Selvakumar et al. 2007; Wright et al. 2010). Five isoforms of NMT were shown to exist in the murine leukemia cell line L1210 whereas two isoforms were reported to exist in the bovine brain cortex (Boutin 1997; Selvakumar et al. 2007; Wright et al. 2010). Later it was shown that the bovine brain contains a heterogenous mixture of NMT subunits (Glover et al. 1997). Subsequently it has been established now that NMT exists as two isoforms generally termed as NMT1 and NMT2 (Giang and Cravatt 1998). While NMT2 appears as a single 65 kDa protein, NMT1 is processed to exist as four distinct isoforms ranging from 49–68 kDa in size (Giang and Cravatt 1998). The two isoforms NMT1 and NMT2 have an overall sequence identity of 76–77% with most divergence at their N termini indicating that these are two distinct families of NMTs. These isoforms are conserved well across higher eukaryotes (Giang and Cravatt 1998). However, to the best of our knowledge, among the lower eukaryotes only NMT1 has been reported so far. Out of the two NMT isoforms NMT1 has been studied in great detail from a variety of hosts and there is a great wealth of information regarding NMT1 as compared to NMT2 and hereafter we would be referring NMT1 as NMT unless otherwise stated.

Myristoylation and Its Biological Significance

Myristoylation catalyzed by NMT is linking of myristate via an amide bond to the glycine residue at the N-terminus of protein molecules (Boutin 1997; Resh 1999; Farazi et al. 2001; Selvakumar et al. 2007; Wright et al. 2010; Hannoush and Sun 2010). The availability of amino terminal glycine is an absolute requirement and the modification occurs on a general consensus motif of GXXXS/T (where X is any amino acid) (Boutin 1997; Resh 1999; Farazi et al. 2001; Wright et al. 2010; Hannoush and Sun 2010). N-Myristoylation can take place in either of the two ways (Fig. 2):

1. Co-translational protein myristoylation takes place while the protein chain is being synthesized by the ribosome (Wilcox et al. 1987). After the few initial amino acid residues (within 100) have been synthesized by the ribosome and the initiator methionine is removed by a methionine aminopeptidase to expose an available N-terminal glycine
2. Post-translational myristoylation occurs when an internal glycine within a polypeptide is exposed following a proteloyic cleavage (Farazi et al. 2001; Wright et al. 2010; Hannoush and Sun 2010)

N-myristoylation is reported in *Dictoystelium* amoeboid cells, in wheat germ, and among several eukaryotes and thus is a ubiquitious process (Boutin 1997; Farazi et al. 2001; Selvakumar et al. 2007; Wright et al. 2010). The N-terminal glycine myristoylation of various key proteins is inevitable for normal cell functioning and thus NMT is essential for survival and growth in a number of organisms (Boutin 1997; Farazi et al. 2001; Wright et al. 2010). Targeting the endogenous NMT functions of the individual organisms has therefore been a candidate choice for the treatment of many human pathogens including *Candida albicans, Cryptococcus neoformans, Leishmania major, Trypanosoma brucei, and Plasmodium falciparum* (Boutin 1997; Farazi et al. 2001; Wright et al. 2010; Frearson et al. 2010). Comparative analysis of the various NMTs has shown that the peptide binding pocket is more divergent than the myristoyl-CoA-binding site and thus the identification and



NMT (N-Myristoyltransferase), Fig. 2 Schematic representation of the co-translational and posttranslational N-myristoylation process. Abbreviations: *CoASH* coenzymeA, *Myr-CoASH* myristoyl coenzymeA, *Myr* myristate, *M* methionine, *G* glycine, *MetAP* methionine aminopeptidase

development of specific inhibitors focus on exploiting substrate specificities and targeting the peptide-binding pocket of NMT (Wright et al. 2010). A large number of moieties of diverse structures (generally grouped into four structural classes: analogs of myristate and myristoyl-CoA, myristoylpeptide derivatives, histidine analogs, and other synthetic compounds) have been shown to inhibit NMT activity and have been discussed elsewhere (Boutin 1997; Farazi et al. 2001; Selvakumar et al. 2007).

The substrates of myristoylation among higher eukaryotes including humans are the regular endogenous, physiological enzymes and proteins such as protein kinase A, protein kinase G, the NADH-cytochrome b5 reductase, nitric oxide synthase, recoverin, members of the Ras family of proteins, and most of the G protein alpha subunit. The detailed list of the substrate proteins is available in a number of reviews elsewhere (Boutin 1997; Resh 1999; Maurer-Stroh et al. 2004; Selvakumar et al. 2007). N-Myristoylation of proteins ensures their diverse functional roles such as specific protein–protein and protein–lipid interactions; ligand-induced conformational changes and subcellular targeting (Resh 1999; Farazi et al. 2001; Wright et al. 2010). On the other hand, N-myristoylation also controls the functional roles of several proteins involved in a disease condition and thus many pathogenic states are linked to undesired myristoylation activity (Boutin 1997; Resh 1999; Selvakumar et al. 2007; Wright et al. 2010). The enzymes involved in signaling process such as the non-receptor tyrosine kinases fyn, lyn, src are myristoylated and associated with the undesired states linked to myristoylation (Boutin 1997; Resh 1999; Selvakumar et al. 2007; Wright et al. 2010). Among the two human isozymes NMT1 and NMT2, the various undesired myristoylation processes linked to the disease condition can be broadly grouped into two categories:

1. The first category includes the myristoylation of viral proteins by the host NMT after the infection of proteins to the host (Maurer-Stroh and Eisenhower 2004). The myristoylation of structural and various other proteins of viruses is required for the maturation and infectivity of the viral particles (Boutin 1997; Resh 1999; Wright et al. 2010).

The inhibition of the myristoylation process targeting specific isoforms of the NMT can thus target the virus infectivity. The viruses requiring myristoylation of their proteins for infectivity include the dreaded human pathogens HIV, poliovirus, hepatitis B virus, and many more (Boutin 1997; Resh 1999; Maurer-Stroh and Eisenhower 2004). Many of the oncogenes from viruses are homologues of tyrosine kinases and require N-myristoylation for the infectivity of viral particles. Myristoylation is required for transformation by ▶ Src (a tyrosine kinase) and for its activation. Mutation of the N-terminal glycine of the viral oncogenes with tyrosine kinase activity blocks the transformation ability by interfering with the proper localization to plasma membrane and cell attachment (Boutin 1997; Wright et al. 2010). In the case of HIV infections, viral proteins Gag and Nef require myristoylation by host cell NMT to carry out their function properly (Wright et al. 2010). Gag is the precursor polyprotein for structural components of viral capsids and requires myristoylation for intracellular localization and its targeting to the lipid rafts in the plasma membrane during virus assembly. Nef on the other hand comprises many virulence factors to modify the cellular environment of infected cells to facilitate viral replication and evade detection by cells of the immune system. Among the two human NMT isozymes, NMT2 has increased affinity for the viral proteins and drugs, specifically targeting the distinct substrate profile of human NMT isozymes has been proposed to be developed as anti-HIV molecules (Wright et al. 2010). However, it has also been reported that NMT1 myristoylates Gag in vivo and inhibiting NMT1 but not NMT2 negatively affects HIV production (Wright et al. 2010).

2. The second group of pathogenic states attached to morbid myristoylation is linked to the upregulated NMT acitivity in hyperproliferative cells. It has been reported that in the mammary epithelial cells the proliferative capacity correlates with NMT activity (Wright et al. 2010). Elevated NMT activity has been observed in human colorectal cancer, adenocarcinoma, gallbladder cancer, and various other carcinomas (Boutin 1997; Selvakumar et al. 2007; Wright et al. 2010). Several protein kinases of the Src family have established roles in oncogenesis and a number of studies have shown that c-Src is a critical regulator of human cancers (Boutin 1997; Wright et al. 2010). Myristoylated tyrosine kinases, $pp60^{c\text{-}src}$ and $pp60^{c\text{-}yes}$ are several fold higher in colonic pre-neoplastic lesions and neoplasms compared with normal colon cells (Bolen et al. 1987; Wright et al. 2010). Differential expression of $pp60^{c\text{-}src}$ has been observed in colonic tumor-derived cell lines and colonic polyps prone to developing cancer (Cartwright et al. 1990). Higher levels of cytoskeletal-associated $pp60^{c\text{-}src}$ protein tyrosine kinase activity have been observed in intestinal crypt cells along with higher expression of $pp60^{c\text{-}yes}$ in the normal intestinal epithelium. Studies have revealed that $pp60^{c\text{-}src}$ is overexpressed in human colon carcinoma and it has enhanced kinase activity in progressive stages and metastases of human colorectal cancer (Bolen et al. 1987). Furthermore, it has been shown that Src kinase activity is positively regulated by myristoylation and the non-myristoylated c-Src exhibited has reduced kinase activity (Patwardhan and Resh 2010). The elevated NMT activity during carcinogenesis may be due to the higher demand for myristoylation of various proteins/oncoproteins (src, ras, etc.) which are overexpressed and activated during tumorogenesis. A direct relationship between elevations of NMT expression and activity in colon cancer progression has been reported (Magnuson et al. 1995). It has also been demonstrated that in colon cancer cell lines, elevated expression of NMT correlates with high levels of c-Src levels (Rajala et al. 2000). Blockage of N-myristoylation in colonic cell lines compromises colony formation and proliferation and also reduces localization of $pp60^{c\text{-}src}$ to plasma membrane (Rajala et al. 2000). The studies have been suggestive that NMT represents both a valuable clinical marker and therapeutic target for cancer (Boutin 1997; Selvakumar et al. 2007; Ducker et al. 2005; Wright et al. 2010). A several fold increase in NMT activity in polyps and stage B1 tumors compared to normal colonic mucosa have been proposed to be used as a diagnostic/prognostic tool for colorectal cancer (Shrivastav et al. 2007; Magnuson et al. 1995). siRNA-mediated NMT knockdown shows that among the two human NMT isoforms, silencing NMT1 strongly inhibits tumor growth in a mouse model mainly through loss of c-Src activation and its target FAK as well as reduction of various protein

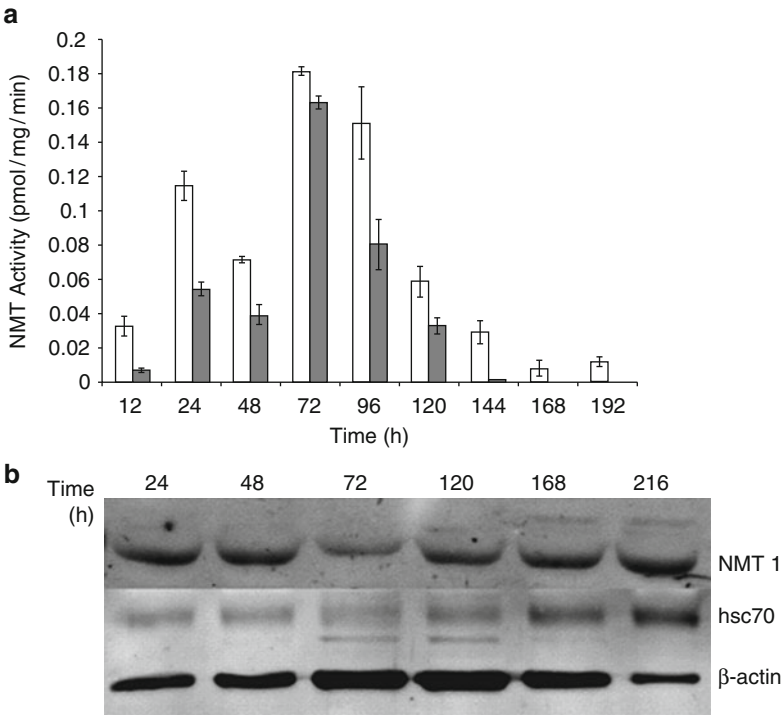
kinase–regulated pathways. It has been concluded that NMT1 and NMT2 have only partially overlapping functions and that NMT1 is critical for tumor cell proliferation further suggesting that isoform-specific inhibitors might be developed as potential anticancer agents (Ducker et al. 2005). Therefore, the specific inhibition or regulation of either NMT in vivo may in turn allow for the selective control of particular myristoylation-dependent cellular functions. It has been observed that NMT1 and NMT2 interact differentially with the apoptotic-related proteins. NMT2 has been found to interact with both Bcl2 and ▶ p53 while NMT1 interacts only with p53 (Selvakumar et al. 2007). Further it has also been noted that the proteases *m*-calpain and caspase-3 interact differently with NMT isoforms (Selvakumar et al. 2007).

Regulation of N-Myristoyltransferase

The process of N-myristoylation appears to be a tightly regulated reaction which involves the coordinated action of several different enzymes (e.g., N-methionylaminopeptidase, fatty acid synthetase, long chain acyl-CoA synthetase, acyl-CoA-binding proteins, etc.), access of the NMT to the limited pools of myristoyl-CoA, and the timely N-myristoylation of nascent polypeptide substrates to ensure proper functional roles and avoid potential interfering reactions (e.g., N-acetylation and polypeptide misfolding) (Wilcox et al. 1987; Boutin 1997; Glover et al. 1997; Resh 1999; Farazi et al. 2001; Wright et al. 2010). This implies the existence of mechanisms designed to ensure the regulated activity of NMT in a timely manner. From the available evidences to date, it is believed that NMT activity is regulated by at least three mechanisms in mammalian cells. The first one involves the targeting of the NMT to the ribosomes which involves N-terminal domain of NMT (Glover et al. 1997). Targeting to ribosomes appears to be consistent with its role as a co-translational protein modifier. It was earlier proposed that the N-terminal domain of NMT has no catalytic roles (Farazi et al. 2001). However, no information is available regarding the catalytic regulation of NMT in terms of the interaction of the N-terminus residues with other parts of the molecule from higher eukaryotes. The available crystal structure of NMT from *S. cerevisise* shows that the extended N-terminus is located close to the myristoyl-CoA binding site as well as the peptide binding site and it has been proposed that this region plays an important role in coordinated control of catalytic activity of NMT (Wu et al. 2007). Furthermore, the identification of two isoforms (NMT1 and NMT2) in higher eukaryotes with divergent N-terminus have raised the possibility that this region might be involved in regulating enzyme activity by modulating regulation/interaction with targets substrates or intracellular locations of NMT (Farazi et al. 2001). The establishment of the catalytic role of the N-terminus of NMT from mammalian counterparts is precluded unless further studies in this direction are carried out.

The second regulatory process controlling the functions of NMT in vivo is via the phosphorylation-mediated regulation of NMT activity. It has been observed that Akt/PKB-mediated phosphorylation of NMT in HepG2 cells attenuates NMT activity (Shrivastav et al. 2009). Further, the downregulation of NMT activity in several breast cancer cell lines has been correlated to the phosphorylation of NMT. Studies so far in this direction have been few and this is the only report showing in vivo phosphorylation of NMT in metastatic cell lines (Shrivastav et al. 2009). In earlier reports, it was noted that in cases of colorectal cancer both NMT expression levels and activity are significantly upregulated (Selvakumar et al. 2007; Magnuson et al. 1995; Rajala et al. 2000). Furthermore, in cases of colorectal cancer, calcineurin expression levels are also high compared to normal colonic epithelial tissue (Lakshmikuttyamma et al. 2005). In cases of colorectal cancer, the NMT activity is high presumably because of the dephosphorylation of NMT by the elevated levels of calcineurin, a ser/thr phosphatase. In other words, dephosphorylation of NMT upregulates its activity. This hypothesis is supported by earlier findings which show that in the presence of the phosphatase inhibitor sodium orthovanadate, NMT activity is reduced (King et al. 1995). It has also been identified in human phospho-proteome analysis studies that in normal cell lines NMT is phosphorylated in vivo at serine 47 (Olsen et al. 2006). However, detailed studies are required to discern the in vivo modulations of NMT by its phosphorylation.

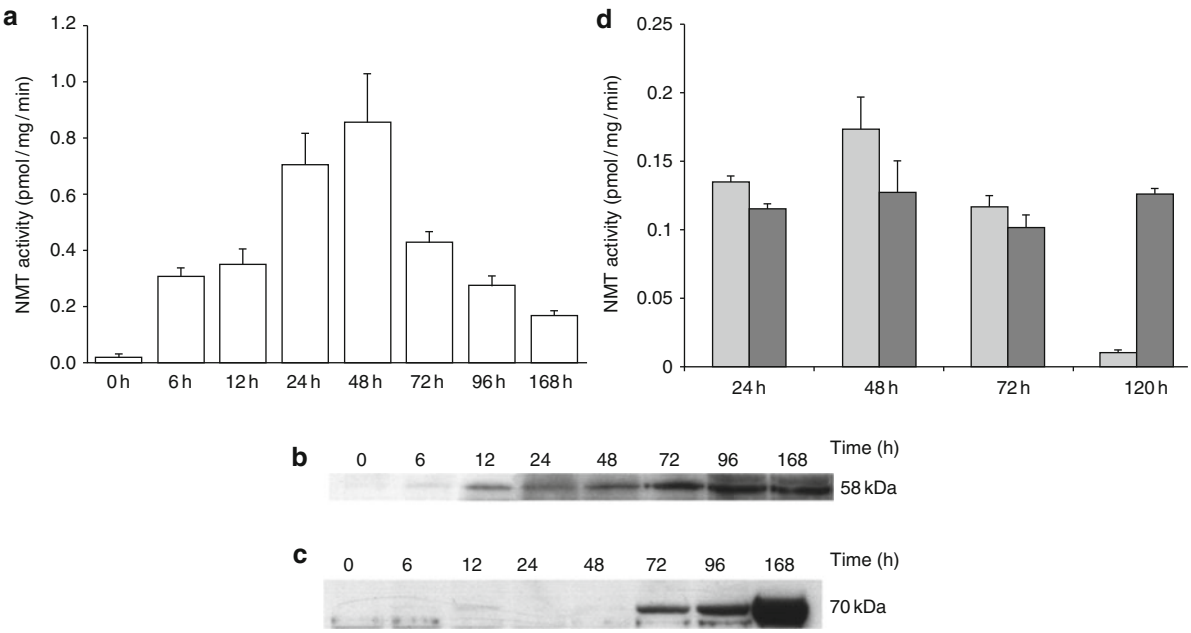
The most well-documented regulatory process controlling NMT functions is the modulation of NMT activity by its interaction with heat shock cognate protein 70. Initially it was identified as a monomeric



NMT (N-Myristoyltransferase), Fig. 3 NMT activity and hsc70 profile during the maturation of BMDM. (**a**) NMT activity in BMDM from the bone marrow of wild-type mice (□) or heterozygous (+/−) *Nmt1*-deficient mice (■) at indicated time points using $pp60^{c-Src}$ derived peptide substrate. (**b**) Expression of NMT and hsc70 during the differentiation of BMC (Adapted from Shrivastav et al. 2008. Copyright 2008. The American Association of Immunologist, Inc.)

NMT inhibitor protein of molecular mass 71 kDa (NIP71) (King and Sharma 1993). It was observed that during subcellular fractionation of the bovine brain tissue NMT activity resides both in the cytosolic as well as particulate fraction of the cells. However, the separation of the particulate fraction from the total cellular lysate enhanced NMT activity of the remaining soluble fraction. These findings indicated the existence of an inhibitor protein associated with the membranous fraction which was purified and characterized and was termed NIP71. In studies on colon cancer cell lines, it has been observed that the upregulation of NMT is accompanied by increase in c-src levels and a decrease in the expression levels of NMT inhibitor protein (NIP71) (Rajala et al. 2000). Later it was shown that the purified NIP71 and Hsc70 cross react with each other's specific antibody and have similar IC_{50} values for NMT inhibition in vitro (Selvakumar et al. 2007). Based on MS-MALDI and sequence similarity analysis, NIP71 was reported to be homologous to the Hsc70 (Selvakumar et al. 2007). NMT is essential for growth and development of many organisms (Farazi et al. 2001; Wright et al. 2010) and it has been shown that it is essential for the early development of the mouse and is the main enzyme in early embryonic development (Yang et al. 2005). Studies on NMT regulation in developmental processes using wild type and heterozygous (+/−) and homozygous (−/−) *Nmt1*-deficient mice have shown that NMT is essential for monocytic differentiation of bone marrow–derived macrophages (BMDM) (Shrivastav et al. 2008). It has been observed that during the stages of macrophagic differentiation of bone marrow cells from the wild type and heterozygous (+/−)*Nmt1*-deficient mice NMT activity rises in the early stages reaching a maximum at 72 h and then decreases for the remaining time exhibiting a parabolic activity profile for NMT (Fig. 3a). It was also noticed that in bone marrow cells, the expression levels of NMT remain constant over time; however there is an increase in the expression levels of Hsc70 which is concomitant with the time point for the decreased NMT activity (Fig. 3b).

The NMT activity follows a very similar parabolic activity profile during in vitro studies on macrophagic differentiation process using promonocytic cell lines. However, the maximum activity is achieved at 48 h which then dramatically falls over the remaining time



NMT (N-Myristoyltransferase), Fig. 4 NMT activity and protein expression in U937 cells treated with PMA for different time periods. course (Fig. 4a). The NMT expression levels do not decline over time; however there is an increase in the level of inhibitor protein NIP71 which accounts for the downregulation of NMT activity (Fig. 4b, c). The roles of Hsc70 in NMT regulation in vivo has been further established by siRNA knockdown of Hsc70 in the PMA-treated U937 promonocytic cell lines (Shrivastav et al. 2008). It has been observed that upon the knockdown of Hsc70, the NMT activity profile remains almost constant with time (Fig. 4d).

Taken together, the modulation of NMT activity seems to be regulated by a variety of mechanisms which involves its specific targeting to particular subcellular location, protein modification, and interaction with other cellular proteins. NMT activity is modulated in various situations including in mononuclear phagocytes by IFN gamma and tumor necrosis factor (TNF), in HL60 cells by retinoic acid and TPA, and in rat liver by 3-methylcholanthrene treatment (Boutin 1997). Myristoylation is a long-lasting process however not without exceptions (Hannoush and Sun 2010). There are reports on demyristoylation of the modified substrate proteins (Boutin 1997; Wright et al. 2010). Furthermore in vitro studies have suggested that NMT activity can be enhanced by a variety of organic solvents and various other solutes and molecules (Boutin 1997; Selvakumar et al. 2007). However, a mechanistic understanding of these processes is still lacking.

Summary

N-myristoylation is a key process in cellular pathways which regulates the functioning of many proteins often in conjugation with other protein modifications. The enzyme is an important target for the treatment of many infectious diseases. The roles played by NMT (both isoforms NMT1 and NMT2) in maintaining cellular homeostasis are diverse and many new proteins are now known to undergo this lipidic modification (Maurer-Stroh et al. 2004; Martin et al. 2008). The roles of myristoylation in controlling the functions of the newly identified proteins are not yet well understood. Many of these proteins are linked to pathological states and thus myristoylation may play a part in

pathogenesis. Currently the other lipid modifications (palmitoylation and prenylation) are of intense interest as targets of therapeutic interventions; however, despite the fact that NMT plays a key role in growth and developmental processes and is also associated with various pathological states, the regulation of this enzyme has not been studied in much detail. Further studies are definitely warranted not only to understand the regulatory mechanism of NMT but also on the roles of various myristoylated proteins implicated in signaling and other cellular pathways. Understanding the roles of myristoylated proteins and the regulation of myristoylation process will clarify the roles of myristoylation in modulating cellular function and thus help in establishing new modalities and novel targets for the therapeutic intervention of many health disorders.

Historical Background

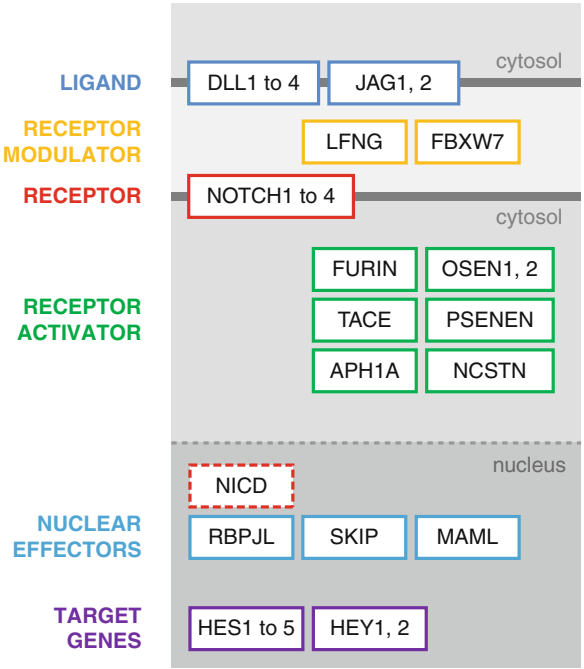
Notch mutants in *Drosophila melanogaster* were originally reported in 1919 (Morgan and Bridges 1919). Notch was named based on the *Drosophila melanogaster* mutants that exhibited irregular notches of missing tissue at the tips of their wing blades. This phenotype was caused by heterozygous loss-of-function mutations in a gene subsequently named "Notch" that was cloned in 1983 (Artavanis-Tsakonas et al. 1983).

Notch and Notch Signaling

Notch proteins are single-pass transmembrane receptors that mediate cell-to-cell communications for the regulation of cell fate decisions during developmental stages and also adult life. Notch receptors are highly conserved in throughout evolution and are found in a diverse range of organisms from worms to humans. The Notch family includes four receptors, NOTCH1, NOTCH2, NOTCH3, and NOTCH4. These receptors have an extracellular domain that contains multiple epidermal growth factor (EGF)-like repeats and an intracellular region that contains a RAM domain, ankyrin repeats, and a C-terminal PEST domain (Fig. 1).

The Notch receptor is synthesized as a 300-kDa precursor and is cleaved in the trans-Golgi compartment. The resulting extracellular and lumenal N-terminal fragment and the transmembrane domain and intracellular domain C-terminal fragment are assembled into the mature heterodimer receptor through a noncovalent linkage. The extracellular and lumenal portion of Notch undergoes extensive N- and O-linked glycosylation during synthesis and secretion, which is critical for proper folding of the receptor and its subsequent interactions with ligands (Fortini 2009).

Canonical Notch signaling is activated by binding of a ligand from the DSL family, that includes Delta and the Serrate/Jagged subfamily that is located on the adjacent cell's surface. Ligand binding activates proteolysis of Notch between gly1743 and val1744 (termed site 3 or S3) by γ-secretase. One fragment is the Notch intracellular domain (NICD) that is translocated to the nucleus. NICD functions in transcriptional regulation of the Hairy/E(spl) family (*Hes* genes in mammals, *her* genes in zebrafish), that codes for inhibitory basic helix-loop-helix (bHLH) transcriptional regulators that control many different secondary targets, including Notch ligand genes and



Notch (Notch1, Notch2, Notch3, Notch4), Fig. 1 Notch activation and signaling pathway

the *Hes*/*her* genes themselves. The other fragment is the Notch extracellular domain (NECD) that is endocytosed by the ligand-expressing cell.

Lateral inhibition is a feedback loop in which adjacent and developmentally equivalent cells assume completely different fates. Binding of Delta and Notch across the two cells in the opposite direction generates transcriptional feedback. Delta expression by the signal-sending cell is stronger than by the signal-receiving cell, therefore, Notch signaling by the signal-receiving cell is activated. This signaling results in transcription of *Hes*/*her* genes, thereby producing an achaete-scute complex (AS-C) to block expression of differentiation genes and Delta transcription. Decreased Delta expression by the signal-receiving cell diminishes the Delta-Notch binding from the signal-receiving to signal-sending cell, thus inactivating Notch signaling by the signal-sending cell. As a result, the *Hes*/*her* genes are not transcribed by the signal-sending cells, enhancing differentiation and upregulating Delta expression. The final outcome of this feedback loop is that the signal-receiving cell maintains strong expression of the Notch receptor Notch expression and Notch signaling through *Hes*/*her*-dependent transcriptional feedback, while the signal-sending cell maintains strong ligand expression and repressed Notch signaling through AS-C-dependent transcriptional feedback (Lewis et al. 2009).

Physiological Roles of Notch Signaling

Notch and Development and Differentiation

The Notch pathway, with TGF-β, Wnt, and Hedgehog, is a representative pathway that regulates developmental and differentiation gene expression programs, so that at the correct time and place, cells with the same propensity for a particular cell fate can give rise to daughters that exhibit differences in morphology and protein expression.

A variety of strategies are used to achieve developmental goals. One strategy is to form gradients of signaling proteins either on cell surfaces or in extracellular spaces that help determine cell fates when they activate cellular receptors. These signaling proteins are known as morphogens. Another strategy is to utilize hierarchical sequences of gene expression so that over time different progeny will become different types of cells. Notch signaling is involved with these strategies to achieve proper cell development and differentiation (Beckerman 2005).

Somitogenesis

Notch signaling coordinates and synchronizes the cell clocks of individual cells when somites form. Segmentation and antero-posterior polarity of somites are formed under the control of Notch signaling and its associated pathways.

Somites are musculoskeletal segments, derived from presomitic mesoderm (PSM). Wnt and FGF are produced at the tail end of the PSM and spread to the anterior portion, generating a morphogen gradient. Anteriorly, somites form in response to lowered Wnt and FGF levels, and at the tail PSM grows caudally, expanding the embryo. This growth is a rhythmic process that results in segmentation, and originates from cell-intrinsic oscillation. The oscillation is paced by autoregulation of *Hes*/*her* genes, which results in a negative feedback loop. Delays in transcription and translation within the feedback loop determine the period of oscillation.

Blocking of Notch signaling disrupts segmentation. However, Notch signaling does not produce oscillation itself, but rather functions in the coordination. Even

Notch-dissociated cells show oscillating expression, though in a less regular pattern (Lewis et al. 2009).

Mesp2 is a central mediator of Notch signaling in the somite mesoderm, generating antero-posterior polarity in the presumptive somite via a complex signaling network involving Dll1- and Dll3-Notch signaling and the Notch regulator presenilin 1 (Kuan et al. 2004).

Neural Development

Notch signaling controls neural cell fates, both the early-fate decisions between neural and epidermal and the late-fate decisions between different subtypes of neural cells (Cau and Blader 2009). Proneural clusters are developed in neural cells or epidermal cells. Following several iterations of the lateral inhibition feedback loop as cluster communication, only one cell of the cluster downregulates the Notch pathway and becomes a neural precursor. The remaining cells are blocked from reaching the neural fate and, are either reselected during a second wave of neurogenesis or secondarily adopt an epidermal fate.

Notch is also required during the specification between two different neural subtypes. These binary decisions can either involve sister cells, as during the formation of *Drosophila* sense organs, or cells that are not linearly related, such as the R3 and R4 photoreceptors of the *Drosophila* eye. Once specified as a neural progenitor, the sensory organ precursor (SOP or pI) divides to generate two cells, pIIa and pIIb, which communicate via Notch. Subsequent divisions generate the four cells of the sensory organs, as well as a glial cell that undergoes apoptosis.

Hematopoietic System

Canonical Notch signaling is essential for the generation of definitive embryonic hematopoietic stem cells, but is dispensable for their maintenance during adult life (Sandy and Maillard 2009). Notch controls several early steps of T-cell development, as well as specific cell fate and differentiation decisions in other hematopoietic lineages. In addition, emerging evidence indicates that Notch is a potent, context-specific regulator of T-cell immune responses, which includes several disease models relevant to patients.

Notch signaling intensity varies throughout T-cell development. The Notch target genes *Deltex1* and *Hes1* are expressed at very low levels in bone marrow hematopoietic stem cells (HSCs). Upon arrival in the thymic environment, early T progenitors (ETPs) strongly upregulate the expression of Notch target genes. Expression levels of Notch target genes gradually increase during development from the ETP stage to the double negative 3a (DN3a) stage. After the β-selection checkpoint, during which Notch signaling is significantly downregulated, the intensity of Notch signaling steadily decreases from the DN3b stage to the CD4+/CD8+ double positive (DP) stage. Thymic single positive (SP) CD4+ and CD8+ T cells, as well as naive peripheral T cells, express low amounts of Notch target genes. Upon T-cell activation in the periphery, Notch signaling increases sharply in a context-dependent manner.

Notch and Cancer

The highly conserved Notch signaling pathway plays pleiotropic roles during embryonic development and is important for the regulation of self-renewing tissues (Koch and Radtke 2007). The physiological functions of this signaling cascade range from stem cell maintenance and influencing cell fate decisions of slightly differentiated progenitor cells, to the induction of terminal differentiation processes, all of which are recapitulated in different forms of cancers. Although Notch signaling is mainly associated with oncogenic and growth-promoting roles, depending on the tissue type, it can also function as a tumor suppressor.

Oncogenic Function

The first data describing the oncogenic consequences of aberrant Notch signaling in solid tumors were derived from animal studies characterizing a frequent insertion site, named int3, of the mouse mammary tumor virus (MMTV). The int3 site was later identified as the Notch4 locus. MMTV insertions have also been found in the Notch1 locus, albeit with a lower frequency. Together, these result on aberrant Notch signaling and mouse mammary tumorigenesis lead to the question of how significant aberrant Notch signaling is for human breast cancer. To date, only correlative evidence for the involvement of Notch signaling in human breast cancer is available.

Medulloblastoma has primarily been associated with aberrant ▶ sonic hedgehog signaling (Shh), which induces N-▶ MYC expression. The primitive nature of medulloblastoma tumor cells and the fact

that Notch signaling is involved in the maintenance of neural stem and progenitor cells motivated several groups to investigate the potential role of Notch in medulloblastoma. Expression studies using primary medulloblastoma tumor samples showed increased mRNA expression of NOTCH2, but not of NOTCH1. Increased expression of the target gene *Hes1* correlated with a poor patient survival prognosis. Blocking of Notch signaling resulted in increased apoptosis and a reduction of viable cell in tumor cells.

While the causative role of aberrant Wnt signaling for the development of colorectal cancer is well established, it is currently less clear whether Notch signaling might have a similar oncogenic function within the gut. Since gene expression profiles of crypt cells and colorectal cancer cell lines appear to be very similar, colorectal cancer cells may represent the transformed counter part of crypt cells. Since Notch is a gate keeper of crypt cells, it is likely that Notch and Wnt signaling occur simultaneously in adenomas and crypt cells. Indeed, expression of the Notch target gene *Hes1* has been observed in adenomas of APC^{Min} mice, as well as in primary human colorectal tumors.

Notch signaling has been shown to play an important role during embryonic pancreas development by maintaining an undifferentiated precursor cell type. Notch receptors, ligands, and downstream targets, such as *Hes1*, were found to be upregulated in preneoplastic lesions, as well as in invasive pancreatic cancers in humans and mice. This suggests that Notch signaling in pancreatic cancers might be an early event leading to the accumulation of undifferentiated precursor cells.

Global gene expression profiling and immunohistochemistry have revealed the expression of multiple Notch receptors and ligands in primary lesions of human malignant melanomas, therefore, expanding the list of possible pathways involved in melanoma development. Subsequent studies using established melanoma cell lines showed that pharmacological blocking of Notch signaling can have growth suppressive effects. The oncogenic function of Notch signaling within these cell lines was linked to increased ► β-catenin-mediated signaling, as well as increased MAPK and AKT signaling.

Historically, human NOTCH was identified at the chromosomal breakpoint of a subset of T cell lymphoblastic leukemias/lymphomas containing a t(7;9)(q34; q34.3) chromosomal translocation. The translocation fuses the 3′ portion of NOTCH1 to the T-cell receptor Jb locus. This translocation results in a truncated NOTCH1 protein (N1ICD) that is constitutively active and aberrantly expressed. However, this seminal discovery did not reveal the full oncogenic potential of the truncated version of N1ICD. Less than 1% of all human T-cell leukemias or lymphomas contain this translocation. However, more importantly, aberrant Notch signaling was subsequently found in several human leukemias and lymphomas that lacked genomic rearrangements, signifying that upregulated Notch signaling might have a common role in human leukemogenesis.

Definitive proof for a central role of NOTCH1 in human T-cell acute lymphoblastic leukemia (T-ALL) cell lines came from a recent study that identified somatic activating mutations in the NOTCH1 receptor independent of the t(7;9) translocation. These mutations were detected in more than 50% of human T-ALL cases. Additionally, these mutations were found in all previously defined T-ALL subtypes.

Notch signaling was constitutively active in human clear cell renal cell carcinoma (CCRCC) cell lines. Blocking Notch signaling attenuated proliferation and restrained anchorage-independent growth of CCRCC cell lines and inhibited growth of xenotransplanted CCRCC cells in nude mice. Notch1 knockdown was accompanied by elevated levels of the negative cell-cycle regulators p21(Cip1) and/or p27(Kip1). Moreover, Notch1 and the Notch ligand Jagged1 were expressed at significantly higher levels in CCRCC tumors than in normal human renal tissues. Growth of primary CCRCC cells was attenuated upon inhibition of Notch signaling.

In adults, blood vessels in most organs are quiescent, but the growth of solid tumors requires specific embryonic signaling pathways to direct new blood vessels to grow around and into the tumor. VEGF is important in this process. Notch signaling has a strong effect on angiogenesis as seen in gain- or loss-of-function studies of Notch1, Notch1/4, Jagged1, Dll1, Dll4, Hey1/Hey2, and Presenilins (PS1 and PS2) (Iso et al. 2003; Li and Harris 2005).

By examining the whole-genome transcriptome profile of a xenograft model of breast cancer and its metastasis form to brain, activation of Notch signaling was found to be crucial in brain metastasis. Over 2,000 genes were differentially expressed in brain metastatic cells, which included various metastasis-related genes

and many genes related to angiogenesis, migration, tumorigenesis, and cell-cycle regulation. Interestingly, the Notch signaling pathway was activated in correlation with increased Jag2 mRNA expression, activated NICD, and NICD/CLS promoter-luciferase activity. Increased migration and invasion of brain metastatic cells as compared with primary breast cancer cells were inhibited by inactivation of Notch signaling using DAPT, a γ-secretase inhibitor, and RNAi-mediated knockdown of Jag2 and Notch1 (Nam et al. 2008; Jeon et al. 2008).

Tumor Suppressor Function

Instead of maintaining progenitor cells in an undifferentiated state, or influencing their cell fate decisions, in some tissues such as skin, prostatic epithelium, hepatocellular carcinoma, and small-cell lung cancer, Notch can also induce differentiation that is associated with growth suppression (Koch and Radtke 2007). However, the growth inhibitory role of Notch has mainly (with the exception of the prostate) been based on activated Notch1 overexpression studies. Thus, further experiments are needed in these tissues and cancer types to clarify whether Notch indeed has tumor suppressive functions.

Cancer Stem Cells (CSCs)

The strongest evidence to date for a role of Notch in CSCs is in breast cancer, embryonal brain tumors, and gliomas. γ-secretase inhibitors (GSIs) abolish the formation of secondary mammospheres from a variety of human breast cancer cell lines, as well as in primary patient specimens. In breast ductal carcinoma in situ (DCIS), the ability to form multilineage spheroids termed "mammospheres," indicators of stem-like cells, is dramatically decreased by GSIs, Notch-4 monoclonal antibodies, or Gefitinib. This finding suggests cooperation between epidermal growth factor receptor (EGFR) and Notch-4 in DCIS "stem cell" maintenance. There is evidence for a feedback loop between Her2/Neu and Notch, which may maintain CSCs in Her2/Neu-overexpressing tumors. Sansone and colleagues showed that in mammospheres from human breast cancers, IL-6 induces Notch-3 signaling, increases expression of Jagged-1, and, through Notch-3, promotes a hypoxia-resistant phenotype. The same group described the p66Shc-Notch-3 pathway as essential for maintaining the hypoxia-resistant phenotype of human breast cancer mammospheres. Fan and colleagues showed that Notch inhibition selectively depletes medulloblastoma CSCs as determined by CD133-high status or dye exclusion. The same group has described very similar findings in glioblastoma CSCs. Importantly, in gliomas, Notch confers radioresistance to CSCs. GSI treatment selectively enhanced radiation-induced death of glioma CSCs, but not bulk glioma cells. This effect was replicated by Notch-1 or Notch-2 knockdown, and was accompanied by AKT inhibition and reduced Mcl-1 expression. Other malignancies are being actively investigated. A role of Notch, STAT3, and TGF-β in hepatocellular carcinoma CSC maintenance has been suggested. In Gemcitabine-resistant pancreatic carcinoma cells, EMT (epithelial-mesenchymal transition) is associated with activation of Notch signaling, potentially linking Notch to the "Weinberg model" of stemness acquisition through EMT and to treatment resistance. Inhibition of Notch signaling through GSIs or Delta-4 monoclonal antibodies decreased the number of CSC and/or their tumorigenicity in some preclinical models (Pannuti et al. 2010).

Drug Development

The Notch signaling pathway in various cancers can be targeted at various levels, including receptor-ligand binding, release of NICD, as well as the coactivator complex. A promising strategy to block receptor-ligand binding employs inhibitory antibodies directed against Jagged1 or DLL4. Blocking DLL4 led to dysfunctional neovascularization and inhibition of tumor growth. The most promising results have been achieved using small-molecule inhibitors of the γ-secretase complex (GSI) that prevented the release of NICD. A phase I clinical trial using the GSI MK0752 inhibitor was initiated in 2005. The third protein component of the Notch signaling complex that may possibly provide a suitable drug target is the coactivator complex consisting of CSL, MAML, and CBP/p300. Small inhibitory peptides acting as dominant negative forms of MAML or CLS decrease the transcriptional activation of target genes (Koch and Radtke 2007).

Even targeting developmental pathways such as Notch, will most likely not give the elusive "magic bullet," and will require the development of rational drug combinations. Such cocktails will be made

possible only through a thorough understanding of cross-talk between Notch and other developmental and nondevelopmental pathways that may play roles in CSCs in specific malignancies. Our knowledge is rapidly evolving, but there is evidence to support some combinations of treatments. The following examples are not meant to be all-inclusive. However, these classes of agents are reasonable candidates for combination with Notch inhibitors: (1) Inhibitors of the PI3-kinase-AKT-mTOR pathway; (2) ▶ NF-κB inhibitors; and (3) Her2/Neu inhibitors, platinum compounds, EGFR inhibitors, and Hedgehog inhibitors. In breast cancer, a newly discovered feedback loop between Notch and ERα supports combining Notch inhibitors with antiestrogens. Antiestrogens plus GSI and Hedgehog-inhibitors plus GSI combinations are being investigated in ongoing clinical trials. In the case of the Hedgehog inhibitor-GSI combination, anti-CSC effects are being specifically measured.

Ultimately, the best use of Notch inhibitors and other CSC-targeted agents will be in the context of personalized medicine. To that end, it must be determined: (1) which cancers and specific cancer subtypes contain Notch-dependent CSCs; (2) what role specific components of Notch signaling play in these CSCs; (3) what pathways cross-talk with Notch in specific CSCs; and (4) how Notch activity can be measured in CSCs from individual patients (e.g., in biopsy material).

The design of clinical trials for CSC-targeted agents will have to consider that anti-CSC effects will not necessarily translate into rapid tumor volume changes. Disease-free or recurrence-free survival will be the most informative endpoints. For situations when this would require prohibitively long follow-ups, it will be important to develop accurate surrogate biomarkers that reflect anti-CSC effects. These may include spheroid formation assays, flow cytometry, and molecular tests, but posttreatment tumor tissue will be required in most cases. A question of potentially great interest is whether it is possible to assess CSC numbers or the relative "stemness" of individual tumors by studying CTCs. These cells can be isolated from patient blood by several methods, one of which is US Food and Drug Administration approved. Although these trials may be challenging, the payoff may be novel treatments that eliminate or greatly reduce treatment resistance in a broad range of malignancies (Pannuti et al. 2010).

Notch and Genetic Diseases

Loss of function of Notch pathway components can cause inherited genetic diseases such as Alagille syndrome, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), and spondylocostal dysostosis (SCD) (Fiuza and Arias 2007).

Mutations in the *Jagged1* gene are responsible for Alagille syndrome, which is normally diagnosed in the first 2 years of life. This is an autosomal dominant mutation that causes defects in bile duct formation leading to liver problems, and is also responsible for kidney, eye, heart, and skeleton development problems. The great diversity of the disease presentation suggests that other factors may influence the outcome, such as genetic properties of Notch signaling regulators.

Mutations in human Notch 1 and 3 are responsible for CADASIL syndrome. These mutations lead to an autosomal vascular disorder resulting in the loss of the arteriolar vascular smooth muscle cells that are substituted by granular eosinophilic material. One specific feature of CADASIL syndrome is its late onset around the age of 45 years. This disease is linked with a variety of symptoms ranging from migraines and subcortical ischemic strokes to progressive dementia and premature death.

SCD is a family of diseases that results in vertebral defects. Essentially, SCD is caused by mutations in Dll3 resulting in rib defects that lead to abnormalities in vertebral segmentation and trunk size. Understanding the mechanisms of Notch signaling regulation is crucial in the development of therapeutic approaches for the treatment of these diseases.

Notch and Other Diseases

Alzheimer's Disease

Notch is expressed by neurons in the adult brain where it is present at particularly high levels in the hippocampus. The prospect that Notch is the substrate of γ-secretase/presenilin and plays a role in learning and memory suggests a potential link between Notch signaling and the pathogenesis of Alzheimer's disease (Woo et al. 2009). In post-mitotic neurons, Notch proteins interact with PSs (presenilins) and with APP (amyloid precursor protein), which have roles in the

memory deficits associated with Alzheimer's disease. In some cases, mutations in the genes encoding APP, PS1, and PS2 are responsible for early-onset Alzheimer's disease. The phenotype of PS1 deletion mice is similar to that observed in Notch knockout mice. The PS1/PS2 double knockout phenotype is even more similar, suggesting closely related functions for these proteins. Indeed, knockouts of any one of several c-secretase components cause developmental abnormalities that are similar to those caused by Notch 1 and Notch 2 knockouts.

Glomerular Disease

Albuminuria associated with sclerosis of the glomerulus affects millions of people and leads to a progressive decline in renal function. Activation of the Notch pathway, which is critical to glomerular patterning, contributes to the development of glomerular disease. Expression of the intracellular domain of Notch1 (ICN1) was increased in glomerular epithelial cells in diabetic nephropathy and in focal segmental glomerulosclerosis. Conditional in vivo re-expression of ICN1 exclusively in podocytes caused proteinuria and glomerulosclerosis. In vitro and in vivo studies showed that ICN1 induced apoptosis of podocytes through the activation of p53. Genetic deletion of a Notch transcriptional partner (Rbpj) specifically in podocytes or pharmacological inhibition of the Notch pathway (with a c-secretase inhibitor) protected rats with proteinuric kidney diseases (Niranjan et al. 2008).

Connection to Other Signaling Pathways

The *Drosophila* Disheveled gene, which encodes a component of the Wingless signaling pathway, interacts antagonistically with Notch and one of its ligands, Delta. Notch1 activation induced p21 in differentiating mouse keratinocytes. The induction was associated with the targeting of Rbpjk (RBPSUH) to the p21 promoter. Notch1 also activated p21 through a calcineurin-dependent mechanism acting on the p21 TATA box-proximal region. Notch signaling through the calcineurin/► NFAT pathway also involved calcipressin and Hes1.

Oncogenic Ras activates Notch signaling. Wild-type Notch1 is necessary to maintain the neoplastic phenotype in Ras-transformed human cells in vitro and in vivo. The oncogenic effect of NOTCH1 on primary melanoma cells was mediated by ► beta-catenin, which was upregulated following NOTCH1 activation. Inhibiting ► beta-catenin expression reversed NOTCH1-enhanced tumor growth and metastasis.

Microarray studies of the mouse presomitic mesoderm transcriptome demonstrated that the segmentation clock drives the periodic expression of a large network of cyclic genes involved in cell signaling. Mutually exclusive activation of the Notch-fibroblast growth factor (► FGF) and Wnt pathways during each cycle suggested that coordinated regulation of these 3 pathways underlies the clock oscillator. Another study identified two clusters, the first cluster contains the known cyclic genes of the Notch pathway: Hes1, Hes5, Hey1, Id1, and Nrarp, a direct target of Notch signaling. In the same cluster as the Notch pathway were members of the FGF-MAPK pathway, including Spry2 and Dusp6. The second cluster of periodic genes contained genes cycling in an opposite phase to the Notch-► FGF cluster. This cluster included a majority of the cyclic genes associated with Wnt signaling, including Dkk1, c► Myc, Axin2, Sp5, and ► Tnfrsf19.

NOTCH and MYC regulate two interconnected transcriptional programs containing common target genes that regulate cell growth in primary human T-cell lymphoblastic leukemias. In bone marrow progenitor cells and T-cell acute lymphoblastic leukemia (T-ALL) cell lines, constitutively active NOTCH1 transcriptionally activated the NFKB pathway via the IKK complex, thereby causing increased expression of NFKB target genes.

Expression of NOTCH1 in human keratinocytes was under the control of ► P53. NOTCH1 suppressed tumor formation through negative regulation of ROCK1/ROCK2 and MRCK-α (CDC42BPA), which are effectors of small RHO GTPases implicated in neoplastic progression.

Some T-ALL cells show resistance to γ-secretase inhibitors that act by blocking NOTCH1 activation. Using microarray analysis, ► PTEN was identified as the gene most consistently downregulated in γ-secretase inhibitor-resistant T-cell lines. Studies in normal mouse thymocytes indicated that Notch1 regulated ► Pten expression downstream.

Genes in the Notch pathway were expressed in mature podocytes in humans and in rodent models of diabetic nephropathy and focal segmental glomerulosclerosis.

Summary

Notch activity via cell–cell contacts generates molecular differences between adjacent cells. The Notch pathway can mediate both instructive and lateral signaling in neural differentiation and tumorigenesis. Many Notch regulatory processes have been identified, but are not yet truly characterized. Notch activity regulation by ligand inhibitory effects is well described, but its mechanism of action is still unclear. The role and mechanisms of Notch and ligand trafficking are not well understood. CSL-independent Notch signaling remains undefined, both as a molecular pathway and in its effects. Further work is necessary to understand Notch signaling in all its complexity, and to provide insight into how to tackle Notch signaling in a more specific way to better approach different clinical contexts.

Historical Background

Nrf2 was found as a member of nuclear factor erythroid 2 (NF-E2) transcription factor family in 1994 (Moi et al. 1994). Nrf2 is a basic Leucine Zipper (bZIP) transcription factor that belongs to the Cap'n'Collar (CNC) family (p45-NFE2, Nrf1, Nrf2, and Nrf3) and is expressed ubiquitously in various tissues (Moi et al. 1994). Yamamoto and his colleagues showed that Nrf2 forms a heterodimer with small Mafs and induces phase-II detoxifying enzymes through antioxidant response elements (AREs) in the promoter regions of the target genes (Tong et al. 2006). A myriad of studies have identified Nrf2 as a sensor that acts against oxidative stress or electrophilic chemicals. In spite of the similarity in nucleotide sequences between Nrf2 and NF-E2, it was not involved in erythropoiesis and development in a murine model.

Oxidative stress is featured by high levels of reactive oxygen species (ROS), which exerts a harmful effect on cellular components and induces defensive responses. ROS originates from hydrogen peroxide (H_2O_2), superoxide ($O_2^{\bullet -}$), and peroxynitrite ($ONOO^-$) form powerful oxidants in the cell. Thus, ROS generation is the fate of aerobic organisms as a natural by-product of oxygen metabolism. In order to avoid cellular damage inflicted by oxidative perturbation, aerobic organisms have developed novel antioxidant defense systems. Among these, Nrf2 and its cytoplasmic repressor kelch-like ECH-associated protein 1 (Keap1) serve sulfhydryl-containing sensors that respond to oxidative stress (Tong et al. 2006); oxidative stress modifies reactive cysteine residues in Keap1 and/or Nrf2. Under no oxidative stimuli, Keap1 binds to the amino-terminal Nrf2-ECH homology 2 (Neh2) domain of Nrf2 and provokes its ubiquitin/proteasomal degradation (Tong et al. 2006). In cells challenged with oxidative stimuli, Keap1 dissociates from Nrf2 and thereby ubiquitin/proteasomal degradation of Nrf2 is hampered. Hence, mice deficient in Nrf2 exacerbate sensitivity to carcinogens or tumorigens, which supports the concept that Nrf2-mediated gene transcription is necessary for the prevention of chemical carcinogenesis by cytoprotective agents (Kensler and Wakabayashi 2010).

An increasing number of studies have described a series of synthetic and phytochemical compounds that activate Nrf2 in cell or animal models (Eggler et al. 2008) (Table 1). Because most of these agents have beneficial effects in a variety of disease models, current pharmacological interventions that target the activity of Nrf2 are expected to advance into novel drug discovery for human diseases.

Regulation of Nrf2 Activity

Domain Structure of Nrf2

Nrf2-ECH homology (Neh) domains are highly conserved in mammalian cells; Nrf2 has six Neh domains (Fig. 1). The domain structure of Nrf2 has been extensively studied by Yamamoto group. Each Neh domains has a distinct role in regulating the activity of Nrf2. First, Neh1 domain contains CNC-bZIP domain that

Nrf2 (NF-E2-Related Factor2), Table 1 Nrf2-activating compounds

Categories	Nrf2 activators
Aromatic organic compounds	BHT (butylated hydroxytoluene)
	tBHQ(tert-butylhydroquinone)
	BHA (butylated hydroxyanisole)
Dithiolethiones	oltipraz, D3T (1,2-dithiole-3-thione)
Isothiocyantes	sulforaphane
Oleanoic triterpenoids	CDDO-Im (2-cyano-3,12-dioxooleana-1,9-dien-28-imidazolide)
Flavonoids	genistein, isoliquiritigenin
Cyclopentenone prostaglandin	15-deoxy-$\Delta^{12,14}$-prostaglandin J_2
Polyphenols	EGCG ((−)-epigallocatechin-3-gallate), resveratrol

leads to the formation of heterodimer with small Mafs lacking a transactivation domain. Using yeast two hybrid analysis, it has been shown that the Neh2 domain of Nrf2 interacts with Kelch/DGR domain of Keap1, and which induces ubiquitin/proteasomal degradation of Nrf2 via Cul3 ubiquitin ligase (Tong et al. 2006). Whereas Neh2 degron is redox-sensitive, Neh6 degron is not and is required for maximal turnover of Nrf2. Studies have shown that Neh4 and Neh5 domains cooperatively bind with either CREB-binding protein (CBP) or silencing mediator of retinoid and thyroid receptors (SMRT)(Ki et al. 2005) and enhance target gene transactivation (Li and Kong 2009). In addition, the carboxy-terminal Neh3 domain of Nrf2 contributes to Nrf2 transactivation activity.

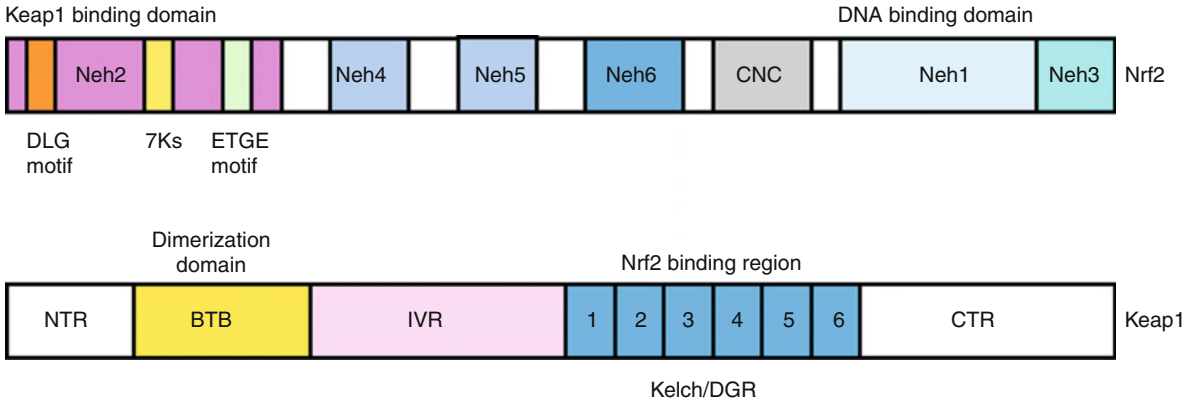
Degradation of Nrf2 Protein

In normal cells, Nrf2 is short-lived but is rapidly stabilized by oxidative stress. In this process, Keap1 has been recognized as a key repressor molecule that causes ubiquitination/proteasomal degradation. Keap1 is a cysteine-rich protein and serves an oxidative sensor molecule in response to free radical stress. The sulfhydryl modifications of cysteine residues of Keap1 affect Nrf2 degradation (Keap1 has nine reactive cysteine residues that respond to oxidative stress) (Fig. 1). Among them, C273 and C288 are located in the intervening region (IVR) of Keap1, and thus these mutations abrogated the basal inhibitory activity of Nrf2. So, oxidative stress supposedly causes the intermolecular disulfide bond formation of C273 and C288 and, thereby, downregulates Keap1 activity.

Keap1 has two functional domains called Kelch/DGR and broad complex, tramtrack, bric-a-brac (BTB) (Fig. 1) that are involved in Nrf2 degradation. Kelch/DGR domain interacts with Neh2 of Nrf2. BTB domain of Keap1 recruits ubiquitin-ligase complex components and also forms a homodimer of Keap1. Neh2 domain of Nrf2 contains two distinct binding motifs with Kelch/DGR domain of Keap1. One is ETGE motif (formulated as D/N-X-E-T/S-G-E) that has a high affinity ($K_a = 20 \times 10^7\ M^{-1}$) to Kelch/DGR domain of Keap1, whereas the other is DLG motif (formulated as L-X-X-Q-D-X-D-L-G) that has a low affinity ($K_a = 0.1 \times 10^7\ M^{-1}$). X-ray crystallography unraveled that Kelch/DGR domain is a shape of six-bladed β-propeller and each Kelch domain consists of four antiparallel β-strands. Kelch/DGR domain possesses arginine triad (R380, R415 and R483), and these amino acids explain why ETGE motif of Neh2 exerts higher binding affinity than that of DLG. Between these two motifs, 7 lysine residues (7Ks) are located and ubiquitinated by E3 ligase. In addition, the results of nuclear magnetic resonance analysis indicated that the binding ratio of Keap1/Neh2 domain is 2:1 (Li and Kong 2009), suggesting that Keap1 makes homodimer formation.

In addition to Keap1, the ubiquitin-proteasome system is responsible for Nrf2 degradation (Tong et al. 2006). Ubiquitin consists of 76 amino acids and is a highly conserved regulatory protein which designates certain proteins subjected to degradation. E1, an ubiquitin-activating enzyme, generates an ubiquitin-adenylate intermediate using ATP, and then transfers ubiquitin to the active cysteine residue of E1. E2, an ubiquitin-conjugating enzyme, and E3, ubiquitin ligase, cooperatively accomplish the ubiquitination of target proteins. Lysine residue of target protein and C-terminal glycine of ubiquitin forms isopeptide bond by E3 ubiquitin ligase complex. Nrf2 is ubiquitinated by Cul3-BTB^{keap1} E3 ligase which belongs to the members of RING domain E3 ligases (Tong et al. 2006). Cul3-BTB^{keap1} E3 ligase is composed of Keap1, Rbx1, Cullin3, and Ubc5 (E2 enzyme). As the member of E3 ligase complex, Kelch/DGR domain of Keap1 binds to Nrf2 and the BTB domain recruits the components of E3 ligase complex.

According to these results, Yamamoto's group proposed "hinge and latch model-two-sites binding mechanism" that describes Keap1-Nrf2 system (Tong et al. 2006). ETGE motif serves "hinge" since it forms a strong binding complex with the Kelch/DGR domain



Nrf2 (NF-E2-Related Factor2), Fig. 1 The domain structures of Nrf2 and Keap1

of Keap1 even under oxidative stress. In contrast, DLG motif works as a "latch" which allows Nrf2 to be disoriented under oxidative stress and impedes Nrf2 ubiquitination by Cul3-BTB^{keap1} E3 ligase. Reactive cysteines in the IVR domain of Keap1 are modified by oxidative stress. It is postulated that these sulfhydryl modifications may change the conformation of Nrf2 structure (Tong et al. 2006). "Hinge and latch model" successfully accounts for the mode of actions of various Nrf2 activators, including ROS, reactive nitrogen species (RNS), 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2, and sulforaphane. Recently, the direct interaction between ^{154}KRR motif in p21 and DLG/ETGE motifs in Nrf2 hampers ubiquitination of Nrf2 by competitively binding with Keap1 (Chen et al. 2009), which supports the model of Yamamoto's group. Collectively, "hinge and latch model" may account for redox-sensitive Nrf2 activity regulation in association with Keap1.

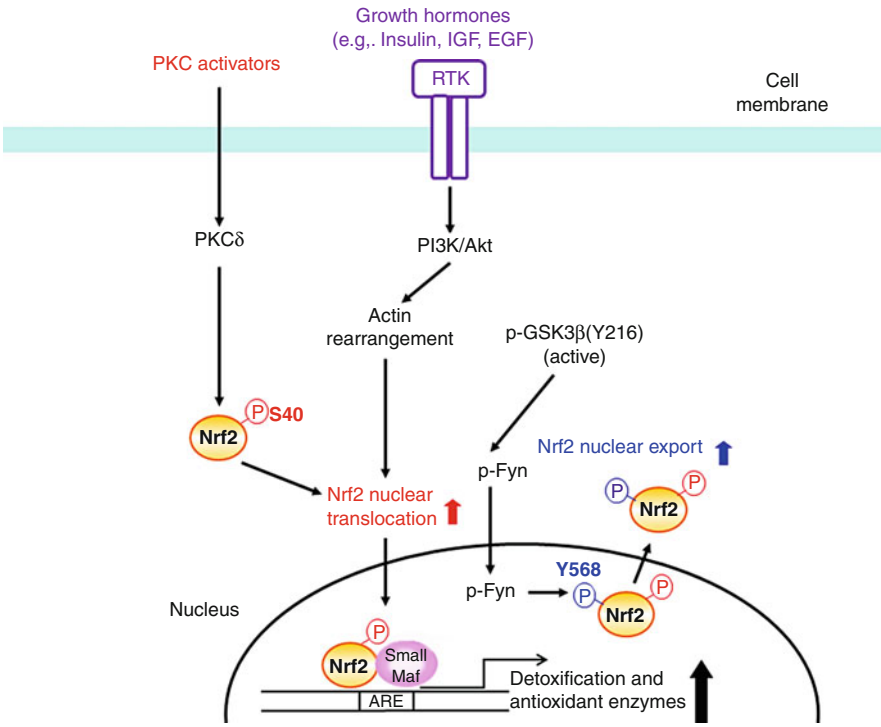
Nuclear Localization of Nrf2

Nrf2 contains three nuclear localization signal (NLS) motifs and two nuclear export signal (NES) motifs (Li et al. 2006; Li and Kong 2009). NLS_N was identified at the amino-terminus, whereas NLS_C was at the carboxy-terminus. bNLS is characterized at the basic region of Nrf2. NES_{TA} is localized at the Neh5 transactivation domain, whereas NES_{zip} is at the ZIP domain of Nrf2. Li et al. discovered NES_{TA} motif (^{175}LLSIPELQCLNI^{186}) of Neh5 domain based on the consensus leucine-rich NES motif that is formulated as $\Phi^4(X)_{2-3}\Phi^3(X)_{2-3}\Phi^2X\Phi^1$ (Φ represents hydrophobic amino acids and X represents any amino acids). EGFP-NES_{TA} chimeric protein (a truncated form of Nrf2) promoted cytoplasmic distribution of Nrf2. So, mutation of C183 of NES_{TA} abrogated oxidant-induced ARE activity. The fluorescence resonance energy transfer (FRET) assay failed to show direct interaction between NES_{TA} and Keap1, indicating that nuclear localization of Nrf2 might be modulated by NES_{TA} motif independently of Keap1. Li and Kong have proposed another Nrf2 signaling model in association with Keap1-independent Nrf2 regulation (Li and Kong 2009); in this model, the balance between NLSs and NESs determines the subcellular localization of Nrf2 in response to oxidative stress or antioxidants. NES_{TA} and bNLS motifs possess similar strong driving force for the translocation of Nrf2. Since the driving forces among the motifs are well balanced under normal condition, Nrf2 is expelled to cytoplasm. Nrf2 is translocated into the nucleus when redox-sensitive NES_{TA} is halted by oxidative stress (i.e., NES_{zip} is redox-insensitive).

The Signals of Nrf2 Regulation

Phosphatidylinositol 3-Kinase

Phosphatidylinositol 3-kinase (PI3K) phosphorylates phosphatidylinositol-4,5-trisphosphate [PtdIns(4,5)P2] into phosphatidylinositol-3,4,5-trisphosphate [PtdIns(3,4,5)P3], which is the secondary messenger for other kinases such as serine-threonine Akt kinase. ▶ PI3K regulates microfilaments and translocation of actin-associated proteins (Fig. 2). In response to oxidative stress, PI3K activation induces actin cytoskeleton rearrangement. Actin depolymerization promotes translocation of a complex of Nrf2 and actin into the nucleus and enables activating Nrf2 to bind to the ARE for phase II enzyme induction by oxidative stress (Kang et al. 2005).



Nrf2 (NF-E2-Related Factor2), Fig. 2 The signaling pathways for Nrf2 activity regulation

Protein Kinase C Delta

Protein kinase C (PKC) disseminates signals into target molecules in response to extracellular stimuli. PKC pathway may be an initial triggering step for recognizing cellular redox state transition. Pickett's group revealed that Nrf2 activation requires phosphorylation at S40 by PKCδ critical for nuclear translocation of Nrf2 (Fig. 2) (Kaspar et al. 2009). Recently, both phosphorylation of Nrf2 S40 by PKCδ and antioxidant-induced modification of Keap1 C151 contribute to stabilization and nuclear translocation of Nrf2 (Niture et al. 2009).

Glycogen Synthase Kinase-3β

It has been shown that tyrosine kinase Fyn phosphorylated Y568 of Nrf2 and regulates chromosomal region maintenance 1 (Crm1/exportin 1)-mediated nuclear export of Nrf2 (Fig. 2). Glycogen synthase kinase-3β (GSK-3β) was identified as an upstream kinase of Fyn (Kaspar et al. 2009). Inhibition of GSK-3β induces nuclear accumulation of Nrf2 and transcriptionally activates the induction of Nrf2 target genes (i.e., phase-II enzymes). Hydrogen peroxide directly phosphorylates Y216 of GSK-3β, which leads to GSK-3β activation, implying that ROS affects GSK-3β-mediated Nrf2 activity regulation (Kaspar et al. 2009).

Nrf2 Target Genes and Biological Functions

The Genes That Contain ARE(s)

The induction of phase-II detoxification enzymes and phase-III efflux transporters through ARE depends on the activity of Nrf2. Major antioxidant enzymes contain one or more functional ARE(s) in their promoter regions (Table 2). Once Nrf2 dissociates from its Keap1 binding in response to oxidative stress, the activating Nrf2 translocates into the nucleus and binds ARE comprised in the promoters of target genes. Unlike canonical bZIP proteins, Nrf2 has no ability to form homodimer (Li and Kong 2009). Instead, Nrf2 forms heterodimer with small Maf proteins such as MafF/G/K which lack canonical transactivation domain. In addition, Nrf2 is directly acetylated by p300/CREB-binding protein (CBP) under the condition of arsenite-induced stress (Sun et al. 2009). Eighteen lysine residues were identified as acetylation sites in Neh1 DNA-binding domain. Intriguingly, combined lysine-to-arginine mutations

Nrf2 (NF-E2-Related Factor2), Table 2 Nrf2 target genes

Functions	Target genes
Phase-I enzymes	None
Phase-II enzymes	GSTA2
	NQO1
	heme oxygenase-1
	UDP-glucuronosyltransferases (UGT) 1A6
	glutamate-cysteine ligase modifier (GCLM)
	glutamate-cysteine ligase catalytic subunits (GCLC)

Iron-binding protein	Ferritin H

on the acetylation sites unaffected the stability of Nrf2, but compromised its DNA-binding activity (Sun et al. 2009). Nrf2 activation and target gene transcription contribute to the detoxification and excretion of detrimental xenobiotics. Phytochemicals and synthetic compounds may have cytoprotective and chemopreventive effects through Nrf2 activation (Eggler et al. 2008). Hence, a deficiency of Nrf2 abrogates the abilities of these agents to protect cells against toxic chemicals or physical stresses, as shown in the experiments using animals or cells.

As the cores of energy metabolism, mitochondria regulate the balance between constitutive and excessive levels of cellular ROS. The mitochondrial respiratory chain not only produces ROS under a basal condition, but also serves a major ROS source under pathological situations. Oxidative stress causes mitochondrial permeability transition, mitochondrial dysfunction, and apoptosis. Hence, the maintenance of mitochondrial function is crucial in protecting cells or organs from toxicants. Compared to nuclear DNA, mitochondria DNA are vulnerable to oxidative stress because of two reasons: (1) mitochondria are the organelles that produce ROS via electron transport chain, and (2) mitochondria DNA repair mechanisms are insufficient. Therefore, the induction of phase-II detoxifying enzymes by Nrf2 might be closely associated with cytoprotective effect against toxicant-induced injury, which may result from not only a decrease in cellular ROS, but protection of mitochondria (Kensler et al. 2007). Collectively, it is hypothesized that the roles of Nrf2 in apoptosis include regulation of redox-homeostasis, increase in adaptive antioxidant capacity, activation of phase-II detoxifying enzymes, and mitochondrial protection, all of which contribute to cell viability.

Cancer

Exposure to toxic external stimuli such as xenobiotics and viral infections might cause genetic defects and thus increase cancer incidence. Carcinogenesis is induced by complex mechanisms which are characterized as multiple genetic defects and uncontrolled growth. These genetically defected genes often have effects on signal transduction pathways regarding cell survival, proliferation, and trans-differentiation. In particular, excess ROS provokes DNA damage such as point mutation, deletion-insertion, and microsatellite instability. Thus, it is a reasonable prediction that antioxidants and antioxidative enzymes contribute to preventing genetic defects of cells from radical stress. Various experimental models have shown that induction of antioxidative and cytoprotective enzymes by chemicals contributes to cancer chemoprevention, and which accompanies Nrf2 activation in most cases.

Many research groups have made a huge effort to develop Nrf2 activators as chemopreventive agents. However, it is now accepted that constitutive Nrf2 activation may also contribute to malignancy and radiation/drug resistance in cancer. The mutations in Keap1 and overwhelming expression of Nrf2 occur in the tissue of lung cancer patients (Lau et al. 2008). Mutated Keap1 possesses substantially impeded binding affinity with Nrf2, leading to augmented anti-apoptotic and antioxidative effects. Therefore, some cancer cells with Keap1 mutations acquire the capacity to survive from harsh tumor microenvironment through Nrf2 activation. Recently, Kensler and Wakabayashi proposed "U-Shaped model" that describes the modulation of cancer risk in terms of the Keap1-Nrf2 pathway (Kensler and Wakabayashi 2010). Nrf2 activation is clinically practical only between the biologically effective dose (BED) and a maximal-tolerated dose (MTD). Low level of Nrf2 expression makes cells susceptible to carcinogenesis or toxicity, whereas high level of Nrf2 expression in tumor might attribute to cancer malignancy.

Lately, epigenetic regulatory pathway of Nrf2-Keap1 has been underscored in cancer cells by several research groups. Hypermethylation of CpG islands of Keap1 was discovered in lung adenocarcinoma.

In addition, CpG island methylations in the promoter region of Nrf2 gene was identified in transgenic adenocarcinoma of mouse prostate, but not in normal tissue (Yu et al. 2010). Thus, Nrf2 level and its downstream target gene expression are substantially repressed in this prostate tumor model. These results suggest that the epigenetic approach is also necessary for the understanding of Nrf2 role in cancer.

Cardiovascular Diseases

ROS is involved in the pathologic processes of cardiovascular diseases such as atherosclerosis, hypertension, and coronary heart disease. In cardiovascular diseases, ROS production (H_2O_2 and O_2^-) is increased due to NAD(P)H oxidase, peroxidase, and cyclooxygenase. In particular, vascular smooth muscle cells (VSMCs) and endothelial cells are the major sources of ROS. Nrf2 is a potential target for the intervention of cardiovascular diseases. Studies have shown that the Nrf2/heme oxygenase-1 (HO-1) pathway is associated with the inhibition of VSMC proliferation and migration, and which helps provide a condition for obtaining anti-atherosclerotic activity (Li et al. 2009). After balloon angioplasty in rabbit aorta, local adenoviral transfer of Nrf2 contributes to reducing VSMC proliferation, oxidative stress, and inflammatory responses (Li et al. 2009). However, the lack of change in neointimal hyperplasia by ectopic Nrf2 expression implies that Nrf2 may induce anti-apoptosis of VSMCs. In human aortic endothelial cells, laminar flow, but not oscillatory flow, induces Nrf2 activation and its target gene transactivation (Li et al. 2009); the degree of Nrf2 activation differs between atherosclerosis-resistant and atherosclerosis-susceptible regions of the mouse aorta. Although Nrf2 regulates antioxidant defense system, it still remains elusive what the exact molecular mechanism of Nrf2 is in cardiovascular system.

Summary

Oxidative stress is critical in homeostasis and survival of aerobic organisms. Nrf2 target gene induction plays a role in antioxidant defense systems. In cells challenged with oxidative stimuli, Keap1 is not able to degrade Nrf2 so that antioxidative and cytoprotective enzymes are activated. So, Nrf2-mediated gene induction by pharmacological agents may account for cancer chemoprevention, and amelioration of hepatic and cardiovascular diseases. However, incremental Nrf2 activation was observed in cancer tissues, implying that it may also contribute to invoking cancer malignancy and chemoresistance. The exact role and mechanism of Nrf2 regulation and its functional consequences are still elusive, and further molecular and clinical investigation is requisite.

nrip1 (Nuclear Receptor-Interacting Protein 1)

Ping-Chih Ho and Li-Na Wei
Department of Pharmacology, University of Minnesota Medical School, Minneapolis, MN, USA

Synonyms

RIP140 (Receptor-Interacting Protein 140)

Historical Background

Determining the regulatory mechanisms of nuclear receptor action was one major focal topic of research in the 1990s. During this period, many nuclear receptor-associated proteins were identified as transcriptional coregulators, which were broadly categorized as coactivators and corepressors. Human receptor interacting protein 140 (RIP140) was identified as a ligand-dependent interacting protein of estrogen receptor α (ERα) by far-western blotting, and mouse RIP140 was isolated as a corepressor of orphan receptor TR2 from a yeast two-hybrid screening and later found to also interact with ▶ retinoic acid receptor (RAR) in a ligand-enhanced manner (Cavailles et al. 1995; Lee et al. 1998; Lee and Wei 1999). An official gene name *nrip1* was established for RIP140 by the HUGO gene nomenclature committee. The mouse gene is located on chromosome 16, in region C3.1; whereas the human gene is located on q11.2 of chromosome 21. DNA sequence analyses conclude that this gene is conserved in all vertebrate species examined. Experimental data have validated its interaction and gene coregulatory activity for all the nuclear receptors examined, as well as several transcription factors. The list includes AR, ER, GR, RARα/β, RXRα/β, PPARα/γ/δ, PXR, LXRα/β, ▶ VDR, AhR, ERRα/β/γ, RORβ, HNF4α, TR2, ▶ TR4, c-jun, SF-1, RelA, and ▶ GRIP1. Most experimental data in the past have demonstrated its ligand-enhanced gene repressive activity. Recent studies have begun to elucidate its other functions beyond the nucleus, such as modulation of signal transduction and biological processes in the cytoplasm.

Major sites of RIP140 expression

Sites	Detection method
Ovary	Western blotting and reporter
Muscle	Western blotting
White Adipose tissue	Western blotting

nrip1 (Nuclear Receptor-Interacting Protein 1), Fig. 1 Expression of RIP140 in the mouse and detection methods

Expression of RIP140 and Its Regulation

RIP140 expression in the mouse can be detected as early as embryonic stage E12.5. In studies using promoter-driven reporters, Northern blotting, or Western blotting, RIP140 is detected in various organs and cell types (Fig. 1). Its expression level, based upon Western blot results, is higher in ovary and metabolic tissues such as adipose tissue, muscle, and liver. Regulation of its expression involves transcriptional regulation through several binding sites for hormone receptors

nrip1 (Nuclear Receptor-Interacting Protein 1), Fig. 2 Regulatory mechanisms of RIP140 expression, including the stimuli, underlying mechanisms, and cells/tissues in which stimuli are identified

such as ER (Thenot et al. 1999) and RAR (Kerley et al. 2001), translational regulation through the action of a microRNA miR-346 (Tsai et al. 2009), and ubiquitin-mediated protein degradation (Ho and Wei, unpublished) (Fig. 2). In hormone sensitive lipase-null mice, its expression is altered in adipose tissues. In mice fed a short-term high-fat diet, it is up-regulated in the epididymal adipose tissue (Strom et al. 2008; Ho et al. 2009). These findings suggest that the whole-body metabolic status can affect the regulatory machineries for RIP140 expression. In the brain, a novel form of RIP140 mRNA, which possesses an alternatively spliced 5'UTR, has been detected. Because miR-346 is generated from glutamate receptor ionotropic delta 1 gene that has been proposed to be involved in certain neurological diseases, translational regulation of RIP140 by miR-346 would suggest a potential link between RIP140 and brain disorders.

Posttranslational Modifications of RIP140

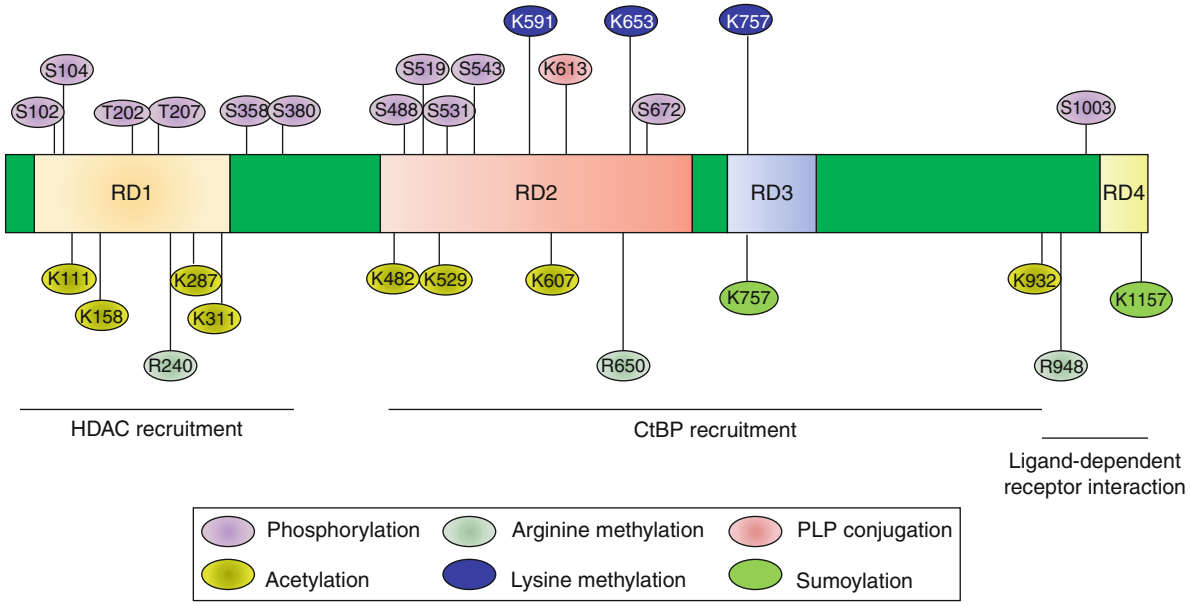
Posttranslational modifications (PTMs) provide an important regulatory mechanism to control or modulate the function, location, interaction, and stability of proteins in response to extracellular and/or intracellular stimuli. Using mass spectroscopy (MS) analyses, many PTMs have been found on RIP140, and most of these PTMs appear to affect RIP140's interaction with other proteins, which ultimately affects its stability, sub-cellular distribution, and biological activities. Figure 3 shows the established PTMs of RIP140.

Phosphorylation

RIP140 can be phosphorylated at nine serine and two threonine residues. Phosphorylation at Thr202 and Thr207 by ERK2 facilitates its recruiting p300 which in turn acetylates RIP140 at Lys158 and Lys287 (Ho et al. 2008). These sequential PTMs enhance RIP140's gene repressive activity by enhancing the recruitment of HDAC3. Phosphorylation at Ser102 and Ser1003 is catalyzed by Protein kinase C epsilon (PKCε), which promotes PRMT1-mediated methylation at Arg240, Arg650, and Arg948 (Gupta et al. 2008). These sequential PTMs lead to the recruitment of exportin 1, which would facilitate its nuclear export (see following). Interestingly, a high-fat diet can initiate this nuclear export pathway in adipocytes by activating nuclear PKCε activity.

Acetylation

Nine lysine residues on RIP140 can be modified by acetylation. Acetylation at Lys482, Lys 529, and Lys607 in repressive domain 2 (RD2)/RD3 region promotes nuclear export and reduces its gene repressive activity; whereas acetylation at Lys158 and Lys287 in RD1 region leads to a stronger gene repressive



nrip1 (Nuclear Receptor-Interacting Protein 1), Fig. 3 Posttranslational modifications (PTMs) of RIP140. The boxes show the full length protein with four repressive domains (RDs 1–4)

activity and nuclear retention (Huq et al. 2009). Acetylation at Lys158 and Lys287 is catalyzed by p300 following ERK2-mediated phosphorylation (see above). Interestingly, this is elevated in the adipocyte differentiation process of the 3 T3-L1 model indicating that RIP140's gene repressive activity is increasingly needed in later stages of adipocyte differentiation.

Methylation

Methylation can occur at either arginine or lysine residues of RIP140. Arginine methylation at Arg240, Arg650, and Arg946 is mediated by PRMT1, which promotes the interaction of RIP140 with the exportin 1 subunit CRM1, thereby stimulating RIP140's nuclear export and reducing its nuclear activity in transcriptional repression. On the other hand, lysine methylation at Lys591, Lys653, and Lys757 elevates its gene repressive activity by unknown mechanisms (Huq et al. 2009). Interestingly, demethylation at these three lysine residues of RIP140 is required for its methylation at the three arginine residues. This suggests a signal crosstalk among various protein methylation enzyme machineries in the nucleus in order to coordinate RIP140's PTMs and, as a result, its interacting partners, subcellular localization, and biological activity.

PLP Conjugation

PLP (pyridoxal 5′-phosphoate) conjugation is found at Lys613 of RIP140, which elevates its gene repressive activity (Huq et al. 2007). This modification is regulated by the cellular status of PLP level, the active form of vitamin B6. This finding suggests that RIP140 may sense PLP or other nutritional factors through PTMs, which then modulates its property and biological activity.

Sumoylation

Sumo-1 conjugation is found for the human protein at Lys 756 and Lys 1154 (Lys757 and Lys 1157 for the mouse RIP140), which may regulate its gene repressive activity and nuclear distribution. The sumoylation enzyme for RIP140 has not been identified. Interestingly, Lys757 on the mouse protein can be methylated, but its relationship with potential Lys757 sumoylation is unclear.

Functional Roles of RIP140

The ubiquitous expression profile of RIP140 suggests its role in many biological processes. Based on the phenotype of RIP140-null mice, this gene is essential for normal ovulation in female animals, and metabolism in general. At the molecular level, RIP140 is known,

mostly, for its corepressive activity in gene transcription through its four RDs which mediate its interaction with HDAC, CtBP, and other chromatin remodeling proteins. Recent studies indicate that RIP140 can also function as a coactivator for transcription of certain genes, including fatty acid synthase (FAS) in hepatocytes and several proinflammatory genes in macrophages. The demonstrated opposing activities, with regards to gene transcriptional control, of RIP140 would indicate that the coregulatory function of RIP140 in transcription might be gene-, transcription factor-, and/or cell context-specific. A hypothesis for its diverse functions was first proposed based upon its extensive PTMs (Huq et al. 2005). This hypothesis has been validated in several studies which examined the functional significance of specific PTMs of RIP140 as detailed above (Mostaqul et al. 2008). In addition, its tightly regulated nuclear export and cytoplasmic distribution strongly suggest other functional roles for RIP140 outside the nucleus. This has also begun to be established in more recent studies, including its activity in modulating insulin-stimulated glucose uptake in adipocytes (Ho et al. 2009) and adipokine secretion (Ho and Wei, unpublished). It is clear that its biological activity is intimately regulated by its PTMs, which are stimulated by certain extracellular/intracellular cues or stimuli. The functional roles of RIP140 in animals have been demonstrated using, primarily, genetically manipulated mice. However, animal phenotypes are the manifestation of multiple defects in various tissues/organs, and therefore should not be simply interpreted as the direct consequence of a single gene defect in a specific tissue, organ, or cell. Further, recent demonstration of cytoplasmic functions of RIP140 has complicated the interpretation of data generated from studying genetically altered animals. In the following, its functional roles deduced from studying whole animals or cell cultures are summarized.

Role in Ovulation

Depletion of RIP140 in mouse revealed its essential role in female fertility, particularly for the control of ovulation. The absence of RIP140 impacts many steps including follicular rupture, cumulus cell-oocyte complex expansion, and oocyte release (White et al. 2000). Further studies indicate that RIP140 is also critical for the expression of EGF-like factors which are essential in cumulus expansion and, possibly, follicular rupture.

Role in Adipocyte

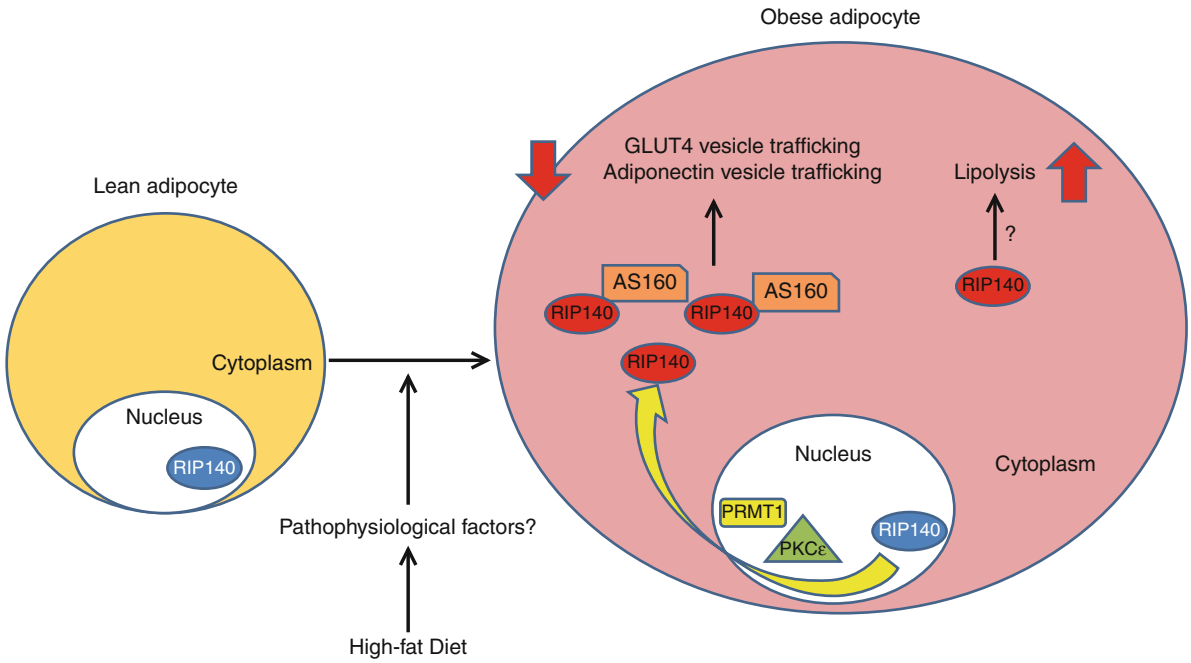
RIP140-null mice exhibit a lower fat content and are resistant to diet-induced metabolic disorders. In the 3T3-L1 adipocyte differentiation model, depletion of RIP140 can substantially change lipid accumulation, fatty acid oxidation, glycolysis, glucose uptake, and mitochondria biogenesis in these cells. These results demonstrate RIP140's activity in modulating metabolism in adipocytes. Among potential target genes of RIP140 in adipocytes, UCP-1 is important for energy metabolism. In brown adipocytes that express a higher level of coactivator PGC-1, UCP-1 is up-regulated to enhance thermogenesis. In white adipocytes where RIP140 is detected at a higher level, UCP-1 is down-regulated to reduce thermogenesis. Importantly, in RIP140-null animals, white adipose tissue gains certain brown adipocyte features, indicating potential antagonism between RIP140 and PGC-1 in adipocyte metabolism. Recently, RIP140 is also found to have specific functions in the cytoplasm of adipocytes (see later section).

Role in Hepatocytes

In liver cells, RIP140 can function as a corepressor or coactivator for LXR. As a corepressor of LXR, RIP140 suppresses PEPCK expression to reduce gluconeogenesis. As a coactivator of LXR, RIP140 enhances SREBP-1c and FAS expression to increase lipogenesis. Interestingly, RIP140-null mice are resistant to the development of hepatic steatosis under a high-fat diet (Fritah et al. 2010b). In studying these animals, RIP140 has also been identified as an important regulator for triglyceride storage in sepsis, starvation, and cancer cachexia (Diaz et al. 2008). These results indicate a potential role for RIP140 in liver lipogenesis and triglyceride storage.

Role in Muscle Cells

RIP140 is differentially expressed in muscle cells: glycolytic fibers express a higher level, but oxidative fibers express a lower level, of RIP140 (Fritah et al. 2010b; Seth et al. 2007). Microarray and metabolic analyses of muscle cells reveal that depleting RIP140 enhances the expression of genes involved in oxidative phosphorylation, fatty acid oxidation, and mitochondria biogenesis. This study demonstrates the role of RIP140 in controlling muscle metabolism and provides a clue for the defect of cardiac function in



nrip1 (Nuclear Receptor-Interacting Protein 1), Fig. 4 The activities of cytoplasmic RIP140 related to adipocyte dysfunctions. In a normal state, adipocytes are lean and RIP140 is mainly localized within nuclei. After a short-term high-fat diet, certain pathophysiological factors up-regulate nuclear PKCε activity and promote nuclear export of RIP140 by a PKCε-PRMT1-dependent pathway. Cytoplasmic RIP140 interacts with AS160 to reduce GLUT4 and adiponectin vesicle trafficking and promote lipolysis by unknown mechanisms

RIP140 overexpressed transgenic mice (see later sections).

Role in Macrophages

For macrophages, RIP140 can function by interacting with ▶ NF-κB and CBP (Zschiedrich et al. 2008). This is important for LPS-stimulated transcription of several inflammatory genes. Depleting RIP140 in macrophages impairs LPS-stimulated proinflammatory cytokine production, because NF-κB transcriptional activity is reduced. This study demonstrates a regulatory role for RIP140 in classic (M1) macrophage activation and suggests that RIP140 may be involved in inflammation and/or inflammation-related diseases. Interestingly, PGC-1 beta has been demonstrated as an important activator for anti-inflammatory (M2) activation of macrophages. This also suggests a potentially antagonistic relationship between PGC-1 and RIP140 in regulating macrophage activation.

Role in Cardiomyocytes

In studying whole-body RIP140-overexpressing transgenic mice, a role for RIP140 in cardiac hypertrophy and functions was identified (Fritah et al. 2010a). This finding suggests a need to control the expression level of RIP140 in cardiomyocytes. However, it remains unclear if the cardiac defects are results directly from the expression of RIP140 in cardiomyocytes, or that may be caused by systemic changes in whole body metabolism. However, since lipid usage in cardiomyocytes can significantly impact cardiac functions, it is important to evaluate the specific functions of RIP140 in cardiomyocytes.

Cytoplasmic RIP140: Player in Pathophysiology of Metabolic Diseases

The finding that PTMs dramatically alter RIP140's property and subcellular distribution (nuclear export) would suggest certain functions for RIP140 in the cytoplasm. Recently, studies have shown that a short-term high-fat diet can promote cytoplasmic accumulation of RIP140 in epididymal adipose tissue, accompanied by the up-regulation of nuclear PKCε activity which provides the initial trigger for

RIP140's nuclear export (Ho et al. 2009). Detailed molecular studies show that RIP140 interacts with AS160, which blocks AS160 inactivation by Akt/PKB and retards GLUT4 vesicle trafficking (Fig. 4). These studies establish the first cytoplasmic function of RIP140. In addition, cytoplasmic RIP140 can also retard adiponectin secretion through its action on AS160, and enhance lipolysis by an unknown mechanism (Fig. 4). These adipocyte defects could have severe pathological consequences. For instance, increased lipolysis in adipocytes causes high circulating fatty acid levels, and these fatty acids can accumulate in muscle cells, hepatocytes, and cardiomyocytes to trigger apoptosis. Adiponectin is the most abundant and protective adipokine that is known to modulate systemic glucose homeostasis and lipid metabolism. Reduction in adiponectin secretion is an important feature in diabetic mice and human patients.

The findings that cytoplasmic accumulation of RIP140 in adipocytes may contribute to their dysfunctions such as impaired glucose uptake, adipokine secretion, and lipolysis would strongly support its functional role in regulating systemic metabolism as demonstrated in whole-body knockout mice, which, in part, is attributable to the cytoplasmic RIP140. In animals, a high-fat diet promotes RIP140's nuclear export in adipocytes. From a clinical point of view, targeting cytoplasmic RIP140, or blocking signaling pathways that promote RIP140's cytoplasmic accumulation, may provide a more specific, beneficial/protective effect in the management of metabolic disorders.

Summary

RIP140 was first identified as an universal gene transcriptional corepressor that acts, primarily, on nuclear receptors in a ligand-enhanced manner. Its gene repressive activity is mediated by its four RDs that recruit various corepressive factors and histone modifying enzymes. RIP140 can be extensively modified by PTMs, which drastically affect its ability to recruit its interacting partners and alter its subcellular distribution, stability, and functions. Studies of whole-body gene knockout and over-expression transgenic mice provide insights into its physiological role, which is to modulate metabolic, inflammatory, and reproductive activities in animals. Studies of its PTMs reveal its cytoplasmic distribution and novel functions in the cytoplasm, which is to modulate insulin sensitivity, glucose homeostasis, and lipid metabolism through interacting with various signaling molecules and adaptors in the cytoplasm. In the nuclei, it acts, primarily, to antagonize coactivators' activity such as that of PGC-1. In the cytoplasm, it acts also to antagonize specific signaling pathways such as insulin signaling, glucose uptake, and lipolysis control. In the context of system biology, RIP140 seems to provide one counteracting mechanism to modulate most of the stimulating or activating signals including hormones and cytokines. It is tempting to speculate a Yin-Yang regulatory principle manifested through RIP140, both in the nucleus and the cytoplasm, to counteract most of the stimulating or activating including hormones and cytokines.

This would suggest that targeting RIP140 might be a promising strategy in treating metabolic disorders that are mostly due to disturbance in hormone or cytokine signals that disrupt normal biological processes. However, the promiscuous feature of RIP140's antagonistic activity toward a wide variety of hormonal inputs or cytokine signals may undermine the application of this strategy. To this end, a careful dissection of its extensive PTMs to understand the regulation of its specific biological activity can be very helpful. Additionally, studying its regulation specifically through degradation may provide new clues.

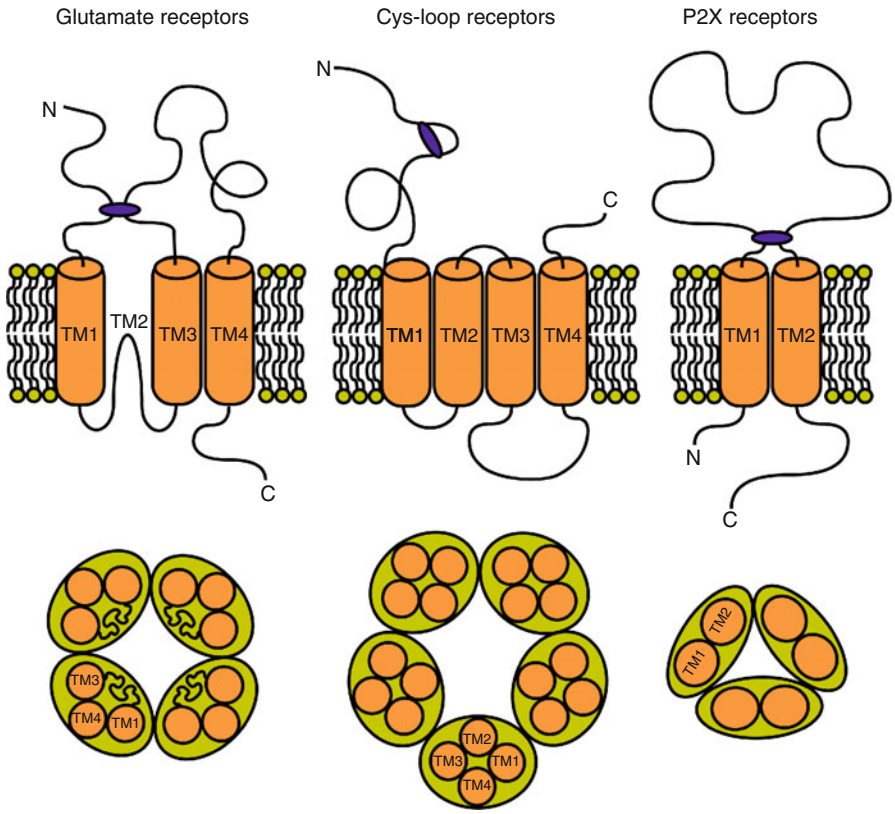
Historical Background

The first evidence of purinergic signaling was described in 1929, when purines were found to underlie physiological responses in the circulatory and digestive system. After 50 years and a wealth of data supporting purine mediated effects in different systems, Burnstock presented the first direct evidence that ATP acts as a transmitter and introduced the concept of purinergic neurotransmission (Burnstock et al. 2010). Thus, ATP was recognized as both an intracellular energy source and an extracellular signaling molecule. Extracellular ATP has been implicated in intercellular communication in a wide variety of cells from different organisms and associated with a diverse array of biological effects. ATP is an ideal molecule for extracellular signaling, it is small, rapidly diffusing, highly unstable due to the presence of extracellular degrading enzymes and not abundant in the extracellular environment at resting conditions (Soto et al. 1997). ATP exerts it actions by binding to cell surface receptors called P2 receptors. P2 receptors are subsequently divided into two different families: P2Y receptors are metabotropic G-protein-coupled receptors while P2X receptors are ligand-gated ion channels (North 2002). Binding of ATP to P2X receptors opens within milliseconds an integral ion channel. While P2X receptors are functional homologues to the Cys-loop and glutamate receptor families of ligand-gated ion channels, they form a structurally distinct group of membrane receptors. Purinergic signaling via P2X receptors has a remarkably wide range of action, influencing epithelia and endocrine cell secretion, immune and inflammatory processes, cardiovascular performance, skeletal and smooth muscle contraction, and glial and neuronal function (Surprenant and North 2009). This chapter is devoted to the molecular and functional properties of P2X receptors and their involvement in physiological and pathological processes.

Molecular Properties of P2X Subunits

The first two P2X subunits (P2X1 and P2X2) were isolated from rat vas deferens smooth muscle and from PC12 cells by expression cloning. Based on sequence similarity, five additional subunits were identified in the rat and shortly after in human and mouse tissues (North 2002). The sequence identity between subunits (approx. 30–50%) and the lack of similarity to other cloned ligand-gated ion channels indicated they constitute a new family of membrane receptors. P2X subunits have been isolated and characterized from additional vertebrate classes (e.g., aves) and are present in all vertebrate species. They have also been found in fish, protozoa, trematode, fungi, and algae. In contrast, no P2X subunits have been identified in the genomes of the nematode worm (*Caenorhabditis elegans*), the fruit fly (*Drosophila melanogaster*), or in prokaryotes (Fountain and Burnstock 2009). Mammalian P2X receptor subunits are 379–595 amino acids long. Multiple splice variants of the originally cloned P2X subunits have been described, showing different amino acid lengths and properties. It was predicted using hydrophobicity plots that each subunit has two transmembrane domains linked by an



Nucleotide Receptor P2x, Fig. 1 *Ligand-gated receptor membrane topology and stoichiometry*. The membrane topology of a single subunit belonging to the three main families of ligand-gated ion channels is shown. The place of agonist interaction for the three types of receptors is shown in *purple*. In the lower part of the Figure, the arrangement of subunits around the channel pore to form a functional receptor is depicted. TM: transmembrane domain. The membrane topology and stoichoimetry is shared between the P2X receptor family and the degenerins/ENaC/ASIC family

extracellular loop comprising between 50% and 70% of the total protein length (Fig. 1). This extracellular loop contains 10 cysteine residues conserved in all cloned vertebrate P2X subunits. Both N- and C-terminus were suggested to be intracellular, with the length of the C-terminal domain being the main source of structure variation between the different subunits. The predicted membrane topology has been confirmed using multiple approaches, including mutating the extracellular domain, use of extracellular antibodies, concatemers and chimeric constructs (North 2002). The proposed membrane topology differs from that of the members of Cys-loop receptors superfamily and glutamate ionotropic receptors family but closely resembles that of the degenerins/ENaC/ASIC family (Fig. 1) (North 2006). P2X receptors are trimeric combinations of P2X subunits. Questions about the membrane topology of P2X subunits as well as the quaternary structure of P2X receptors were recently and definitely answered by X-ray crystallography (Kawate et al. 2009). The authors solved the crystal structure of zebrafish P2X4 receptor in its closed stated, as a symmetrical assembly of three P2X subunits surrounding a central ionic channel pore. This study confirms the proposed membrane structure and will further the understanding about the protein domains involved in P2X receptor function.

Genomic Organization and Splicing

The chromosomal localization (obtained from the Ensembl database, www.ensembl.org) of the seven P2X subunit genes is summarized in Table 1. Several P2X genes are localized in the same human chromosome. Thus, P2X4 and P2X7 genes are located in the long arm of chromosome 12. Similarly, P2X1 and P2X5 genes are located within 1 Mb in the short arm of chromosome 17. A co-localization of paralog genes in chromosomes could arise from tandem duplication. However, it might also indicate the formation of a gene cluster, in which the expression of functionally related genes is co-regulated (Makino and McLysaght 2008). This could be the case for P2X subunits since

Nucleotide Receptor P2x, Table 1 Chromosomal location and length of human P2X subunit genes

Gene	Chromosomal location	Gene length (Kb)
P2RX1	17p13.2	20.1
P2RX2	12q24.3	3.7
P2RX3	11q12.1	31.6
P2XR4	12q24.3	24.2
P2XR5	17p13.2	23.9
P2XR6	22q11.2	13.8
P2XR7	12q24.3	53.2

Data obtained from the Emsembl database at http://uswest.ensembl.org/index.html.

co-expression of P2X4 and P2X7 has been detected in many different tissues and cell types, including microglia, vascular endothelium, ciliated epithelium, and the immune system. Moreover, P2X1 and P2X5 subunits co-express and heteromerize to form the P2X receptor in astrocytes (Surprenant and North 2009).

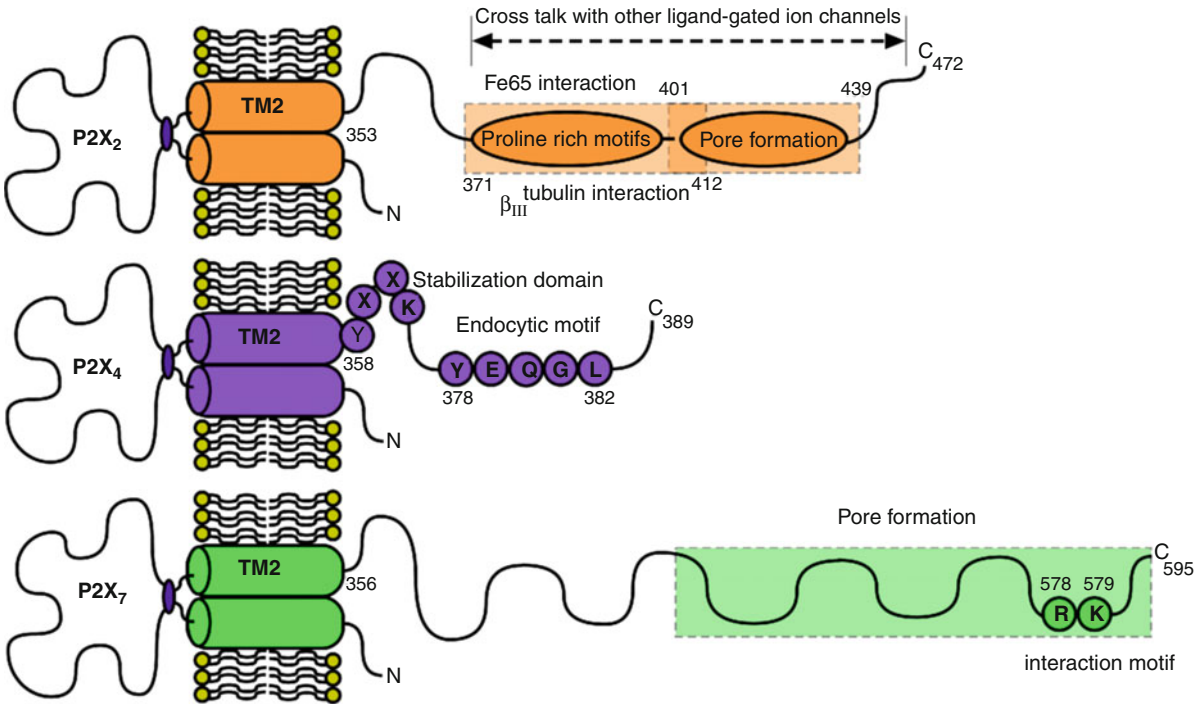
The number of exons comprising the sequence of P2X subunits varies between 11 for P2X2 and 15 for P2X7 (Cheewatrakoolpong et al. 2005, Nicke et al. 2009), while the remaining P2X genes contain 12 identified exons. Most exon–intron borders are conserved between the different genes, indicating, as expected, a common evolutionary origin. In contrast, intronic length varies largely between genes, as reflected by the differences in gene length listed in Table 1. Splice variants have been identified for all P2X subunits. Many of the isolated splice variants lack transmembrane domains or part of the extracellular domain giving rise to truncated P2X subunits that are not able to assemble in functional receptors. In addition, several subunits present a shorter version of their C-terminal domain due to the use of cryptic splice sites inside exon sequences or of inclusion of intron sequences in the corresponding DNA (Cheewatrakoolpong et al. 2005, Koshimizu and Tsujimoto 2006). The importance of this splicing in the receptor function will be described in the next section in more detail.

Regulation of P2X Receptors via Their C-terminal Domain

The C-terminal domain of P2X subunits is the least conserved part of the protein both in length and amino acid composition (North 2002), indicating that it might confer subunit specific properties. Moreover, the intracellular location of the domain makes it a candidate for interaction with intracellular adaptor and cytoskeletal proteins. Indeed, it has been shown that the P2X2 C-terminus interacts with the adaptor protein Fe65, a cytosolic protein containing several protein-binding domains (Fig. 2). P2X subunits and Fe65 colocalize in brain synapses and Fe65 has been shown to modify the functional properties of P2X2 receptors upon co-expression in heterologous systems (Masin et al. 2006). A splice variant of P2X2 with a 69 amino acid deletion in the C-terminal domain, assemble into a membrane receptor with different kinetic properties, and it does not interact with Fe65 (Masin et al. 2006).

A role for the cytosolic C-terminal domain of the P2X4 subunit in trafficking of the receptor in and out of the plasma membrane has been described. Thus, a tyrosine-based non-canonical sorting signal in the C-terminal tail of P2X4 subunits (YXXGL, Fig. 2) that directly binds to the AP2 adaptor protein has been identified. When the interaction was disrupted by mutations in the sorting signal, an increase in the surface expression of $P2X_4$ receptors in transfected neurons was observed (Murrell-Lagnado and Qureshi 2008). In addition, another tyrosine-containing domain (YXXXK) present in the proximal C-terminus of all P2X subunits was shown to be involved in membrane stabilization of P2X receptors (Murrell-Lagnado and Qureshi 2008).

Arguably, the best studied C-terminal domain is that of P2X7 receptors. In the immune system, P2X7 receptors mediate ATP-induced inflammatory responses by activating caspase-1 and the subsequent release of interleukins. Macrophages of a mouse line in which the C-terminal domain of P2X7 has been deleted by knock-in methods lack the immune response elicited by ATP. Moreover, efficient caspase-1 activation by ATP requires priming by bacterial membrane lipopolysaccharides (LPS) and an LPS binding domain has been identified in the distal C-terminal sequence (Surprenant and North 2009) (Fig. 2). P2X7 receptors have been shown to interact with many intracellular proteins, including pannexin-1, protein tyrosin-phosphatase β, heat shock, and epithelial membrane proteins (Surprenant and North 2009); however, the domains mediating the interaction are not known. In addition to playing a role in protein interaction and intracellular signaling, the C-terminal domain is modulating the channel properties of P2X7 receptors.



Nucleotide Receptor P2x, Fig. 2 *Carboxy terminus of P2X subunits.* Representation of the functional and interacting domains present in the C-termini of P2X2, P2X4, and P2X7 subunits. The surface stabilization sequence YXXK present in all P2X subunits C-terminus proximal domain is represented only for P2X4

Thus, the increases in permeability to big cations or fluorescent dyes of P2X7 receptors upon repetitive application of ATP also depend on the C-terminal domain (North 2002).

Pharmacology, Tissue Expression, and Physiological Roles of P2X Receptors

In considering the pharmacology and P2X receptors (P2XR), a number of considerations are needed. First, P2X receptors are ligand-gated ion channels, and as such serve as both cell-surface receptors and ion channels. The natural agonist is extracellular ATP or adenine nucleotides. A number of nucleotide and non-nucleotide antagonists have been developed with selectivity at each of the seven P2X receptors. Most of the agonists are relatively nonselective while the antagonists with a high degree of selectivity have been developed. Second, the endogenous or native P2XR may be homomeric or heteromeric. Each P2X channel is a subunit of the trimeric channel. Each P2X receptor is capable of complexing with itself to form a homotrimeric channel or with another P2X receptor as a heterotrimer. A total of seven heterotrimers have been demonstrated. P2X1/2, P2X1/4, P2X1/5, P2X2/3, P2X2/6, P2X4/6, P2X4/7. Pharmacology of heterologously expressed P2XR subtype in oocytes or HEK293 cells is often different from that of P2XR in native tissues. Third, agonist and antagonist selectivity is different at homomeric vs. heteromeric receptors. Individual P2X subunit of a heterotrimeric P2XR retains some of its selective characteristic response to agonist, antagonist, extracellular zinc, pH, or desensitization kinetics. Fourth, heteromers can exhibit unique pharmacology of agonist and/or antagonist actions or other properties that are different from those for homomeric receptors. In some heteromers, the individual characteristic properties specific to one of its subunit can become dominant and make the heteromer more like the homomeric assembly of the "dominant" subunit. Table 2 summarizes the EC50s of known agonists and IC50 of antagonists at both homomeric and heteromeric receptors (Ralevic and burnstock 1998; Gever et al. 2006; North 2002; Jarvis and Khakh 2009; Roberts et al. 2006; Burnstock and Knight 2004). summarizes the tissue expression pattern of both homomeric and heteromeric P2X receptors (Ralevic and burnstock 1998; Gever et al. 2006; North 2002; Burnstock and Knight 2004; Surprenant and North 2009). Each homomeric or heteromeric receptor will be discussed in the following sections.

Homomeric P2X1R

P2X1 mRNA and protein are detected in a fairly broad range of tissues, such as urinary bladder, smooth muscle of small arteries and vas deferens, brain, spinal cord and several neuron ganglions, and platelets. Low levels of P2X1 are also found in lungs, spleen, and heart. Notably, P2X1R is the significant P2X subtypes in smooth muscle of blood vessels and other hollow organs including bladder, intestine, and vas deferens. Studies demonstrated that ATP or α,β-meATP could elicite an inward current and membrane depolarization, induce the contraction in a variety of smooth muscle tissues. These effects of that ATP or α,β-meATP in smooth muscle are eliminated or reduced in P2X1R knockout (KO) mice, confirming the significant role of P2X1R in the regulation of native smooth muscle contractility (Ralevic and burnstock 1998; Gever et al. 2006).

P2X1R can also regulate platelet functions as the main ATP-gated ion channel in platelets and megakaryocytes. The endogenous platelet P2XR has a similar pharmacology as that of the heterologously expressed recombinant P2X1R. In P2X1R KO mice, functions of platelets, such as aggregation, secretion, adhesion, and thrombus formation, are impaired. Vascular disease superimposed on P2X1R KO mice showed reduced mortality in the presence of systemic thromoembolism and laser-induced vessel injury. On the other hand, hypersensitive ex vivo platelet response and increased mortality in vivo secondary to increased thromboembolism were observed in transgenic mice overexpressing human P2X1R in megakaryocytic cell line (Gever et al. 2006).

Homomeric P2X2R

P2X2R is expressed throughout the central and peripheral nervous (CNS) systems as well as other non-neuron cell types, such as in bladder, adrenal medulla, endothelial and epithelial cells, skeletal, cardiac and smooth muscles, lymphocytes, intestine, and vas deferens (see Table 3). In the heart, P2X2R mRNA was detected in smooth muscle cells of coronary artery and only in atrium myocardium. Homemeric P2X2R appears to play a significant role in ATP-mediated fast synaptic transmission at both nerve terminals and interneuronal synapses. Thus, P2X2R is likely involved in memory, learning, motor function, autonomic coordination, and sensory integration in CNS as well as afferent and efferent signal pathway in peripheral nervous system (PNS). P2X2R is also expressed in many other non-neuron tissues in which its function is still not clear, although it may have a role in autocrine/paracrine hormone release, exocytosis/endocytosis, smoother muscle contractility, and pacemaker activity.

Heteromeric P2X1/2R

Phenotypically, heteromeric P2X1/2R is identical to homomeric P2X1R except the different sensitivity to pH changes. Furthermore, Aschrafi et al. found that assembly of heteromeric P2X1//P2X2R is favored over the respective homomeric P2X1R. It suggested that ATP-stimulated currents originally attributed to homomeric P2X1R in native tissue may actually be mediated by heteromeric P2X1/2R (Aschrafi et al. 2004). Using pharmacology profile and specific P2X subunit gene knockout mice, Calvert JA et al. confirmed existence of functional heteromeric P2X1/2R in sympathetic neurons from the superior cervical ganglion and it is implied that heteromeric P2X1/2R may have a broad role in regulation of the neuron function. Although the dominant phenotype of endogenous P2XR in sympathetic neurons is P2X2-like, a subpopulation of neurons showed $P2X_1$ property such as α,β-meATP responsiveness that was reduced in P2X1R KO mice. P2X2-like means slow desensitization, sensitivity to blockade by antagonists, potentiation by acidic pH (this property is unique to P2X2 receptor) and extracellular zinc, and partial inhibition by high extracellular calcium. It is of interest that the α,β-meATP responsiveness was abrogated by high extracellular calcium and alkaline pH; the latter two properties are more characteristic of P2X2R. Thus, a presumed heteromeric P2X1/2 native receptor includes properties of both subunits (Calvert and Evans 2004).

Homomeric P2X3R

Homomeric P2X3R has restricted distribution and is only expressed in peripheral terminals of unmyelinated C-fiber and thinly myelinated afferent neurons, such as trigeminal and dorsal root ganglions. These receptors

are mainly expressed on nociceptive sensory neurons. P2X3R can be activated by both α,β-meATP and 2-methylthioATP and are sensitive to blockade by suramin, PPADS, and TNP-ATP and is selectively antagonized by NF023. The functional role of homomeric P2X3R in these neurons is to mediate the sensory neurotransmission.

Heteromeric P2X2/3R

These heteromeric receptors have a mixed property that incorporates that of both P2X2 and P2X3 receptors. Thus, they can be activated by α,β-meATP and high sensitivity by TNP-ATP (P2X3-like), and show slow desensitization and potentiation by acidic pH (P2X2-like). A feature unique to this heteromer is that diinosine pentaphosphate is a much more potent blocker at homomeric P2X3 than at heteromeric P2X2/3R. This feature is useful in characterizing whether any of the native tissue P2XR is a P2X2/3R heteromer. These heteromers are expressed in subpopulations of sensory neurons, sympathetic ganglion cells, and brain neurons. They are thought to be important in initiating sensory signaling in pathways for taste, chemocreception, visceral distension, and neuropathic pain (Ralevic and Burnstock 1998). Heteromeric P2X2/3R is the first heteromeric channel to be studied following gene knockout confirmed the role of heteromeric P2X2/3R in several sensory signaling (Roberts et al. 2006).

Homomeric P2X4R

Homomeric P2X4R is not activated by α,β-meATP but is responsive to ATP and 2-methylthioATP. Of all the P2X receptors, it is the only receptor that can be potentiated by ivermectin via allosteric enhancement. Another unique feature is its lack of sensitivity to blockade by suramin or PPADS (North 2002). It has a desensitization kinetics intermediate between that for P2X1 and P2X2 receptors. It may be the most widely distributed of all the P2X receptors with expression in brain and spinal cord, automatic and sensory ganglions, arterial smooth muscle, osteoclasts, parotid acinar cells, kidney, lung, heart, bladder, thymus, colon, pancreas, and B lymphocytes (Gever et al. 2006; Burnstock and Knight 2004). However, the functional roles in some of these tissues are not clearly defined yet. However, recent studies showed that P2X4R are expressed in microglial cells and their activation can mediate neuropathic pain. P2X4R are also expressed in the endothelium in which activation can mediate nitric oxide-mediated vasorelaxation/vasodilatation. Global P2X4R KO mice showed hypertension and smaller arteries. Recent studies have also implicated P2X4 receptor as an important subunit of the endogenous cardiac myocyte P2X receptors. Increased expression of cardiac P2X4R by cardiac myocyte-specific transgenic overexpression or by stimulation with hydrolysis-resistant P2X agonist can confer a protected phenotype in models of both ischemic and non-ischemic heart failure (Zhou et al. 2010). Expression of a P2X4-like contractile phenotype in human atrial myocardium was recently described. P2X4R may also interact with P2X7 receptors in inflammatory responses such as pain signaling (see P2X7 receptors).

Heteromeric P2X1/4R

Both the P2X1R and P2X4R are expressed in the smooth muscle in renal resistance arteries. α,β -meATP evoked a spike-like membrane depolarization followed by a sustained depolarization which could be partially blocked by nanomolar P2X1 selective antagonist, NF279. The residual current could further be blocked by millimolar NF279, consistent with the existence of heteromeric P2X1/4R. Thus, heteromeric P2X1/4R showed both agonist and antagonist pharmacology that are more P2X1-like. TNP-ATP can block this heteromer with affinity that is higher than but closer to that for the homomeric P2X1 receptor. The P2X1/4R heteromer participates in the sympathetic control and paracrine regulation of renal blood flow (Harhun et al. 2010).

Homomeric P2X5R

Homomeric P2X5R is expressed in brain, spinal cord, heart, and eye. These homomeric receptors have pharmacology and desensitization kinetics similar to those of P2X2 receptors. The current mediated by rat P2X5R has a smaller amplitude than that induced by P2X1, P2X2, P2X3, or P2X4 receptors. P2X5 channels have a uniquely high chloride conductance. Recently, high levels of homomeric P2X5R are found in differentiating tissues, such as skeletal muscle, epithelial cells of nasal mucosa, gut, bladder, utter, and skin. Activation of homomeric P2X5R inhibits proliferation while increases the differentiation of rat skeletal muscle satellite cells. Homomeric P2X5R may be also involved in the regulation of proliferation and differentiation of certain type of cancer cells in skin and prostate.

Heteromeric P2X1/5R

P2X1R and P2X5R can assemble into a heteromeric P2X1/5R. A defining property of this heteromer is its activation by α,β-meATP, which cannot activate P2X5R. Other characteristic properties of this heteromer is a greater sensitivity to activation by ATP, a biphasic response to ATP with a transient peak current followed by a sustained plateau current, and a sensitivity to TNP-ATP intermediate between the sensitive homomeric P2X1 and the insensitive homomeric P2X5 receptors. Further, this heteromer does not appear to dilate to a larger pore on prolonged ATP exposure. Although the physiological role of heteromeric P2X1/5R is not defined, it has been postulated that it may mediate excitatory junction potentials at arterial neuroeffector junctions in guinea pig (Gever et al. 2006; North 2002). Recently, Ase et al. identified the heteromeric P2X1/5R in astrocytes from mouse brain and implied that it might participate in the astroglial Ca^{2+} signaling and excitability (Ase et al. 2010).

Homomeric P2X6R

P2X6R is expressed mainly in CNS. However, P2X6R is the only P2X receptor that usually does not form the functional homomeric P2X6R without extensive glycosylation. When such functional homomeric P2X6R are formed (after glycosylation), the heteromer has significantly higher responsiveness to α,β-meATP. Since P2X4R and P2X2R are the other two P2X subunits that usually coexist with P2X6R, the physiological role of the P2X6R is mediated either by the heteromeric P2X2/6R or heteromeric P2X4/6R (Gever et al. 2006; North 2002).

Heteromeric P2X2/6R

The P2X2R and P2X6R can be co-immunoprecipitated after co-expression in HEK293 cells or oocytes. The P2X2/6R heteromer showed a hybrid sensitivity to blockade by suramin at pH 6.5. There was a bi-phasic inhibition with a high sensitivity P2X2-like component and a lower sensitivity portion that is more P2X6-like. In general, the pharmacology of P2X2/6R heteromer is similar to that of P2X2 receptors (much less like that of homomeric P2X6 receptors). A subtle difference is that the P2X2/6R heteromer has a greater sensitivity to pH and to α,β-meATP. This heteromer is expressed by respiratory neurons in the brain stem (Gever et al. 2006; North 2002).

Heteromeric P2X4/6R

P2X4 receptors can also form a heteromer with P2X6 receptors. The pharmacology of this heteromer is similar to that of the homomeric P2X4 receptor. The heteromer, like the homomeric P2X4 receptor, is relatively insensitive to blockade by PPADS or suramin or reactive blue-2. The heteromeric P2X4/6R is similar to homomeric P2X4 receptors in its potentiation by the P2X4-specific allosteric enhancer and by zinc. In fact, the P2X4/6R heteromer appears more sensitive to the potentiation effect of ivermectin. The incorporation of P2X6 receptor in this heteromer also modestly increases the sensitivity to 2-meSATP and α,β-meATP(Gever et al. 2006; North 2002). On tissue expression and function of P2X2/6R and P2X4/6R heteromers, Antonio et al. confirmed the presence of the heteromeric P2X2/6R and P2X4/6R in mouse Leydig cells using immunofluorescence and pharmacologic profiles. Both heteromers are involved in regulating testosterone secretion (Antonio et al. 2009). Heteromeric P2X2/6R and P2X4/6R are also found in rat dorsal root ganglion neuron where they contribute to the transmission of nociceptive message, especially under inflammatory condition (De Roo et al. 2003).

Homomeric P2X7R

Homomeric P2X7R is mainly localized on glia and immune cells such as mast cells, macrophages lymphocytes, erythrocytes, and erythroleumemia. With prolonged exposure to high extracellular ATP concentrations, the homomeric P2X7R becomes open to larger size molecules such as ethidium and YO-PRO-1, leading to cell death. At low ATP concentration, the receptor is a cation channel like the other P2X receptor. Activation of homomeric P2X7R has been associated with the processing and releasing of active interleukin-1β and interleukin-18 from immune cells and glia. Selective P2X7R antagonist KN-62 (known to be selective at human P2X7R) could block the release of interleukin-1 β in macrophages and microglia. This function of P2X7R is further confirmed in experiment in P2X7R KO mice, which fail to release interleukin-1 β when challenged by ATP or BzATP. P2X7R also has a role in mediating the release of cytokine, reactive oxygen species, and neurotransmitter in microglia and astrocytes. Other roles implicated include apoptosis around β-amyloid plaques in Alzheimer's disease model and neurodegeneration and cell death in models of spine

cord injury or cerebral ischemia (Gever et al. 2006; North 2002).

Heteromeric P2X4/7R

Homomeric P2X7R is structurally similar to other P2XR except its significantly longer intracellular C-terminal. Originally, P2X7R was thought not able to heteropolymorize with any other P2XR. However, Guo et al. reported a functional heteromeric P2X4/7R in macrophages, representing the latest example of heteromeric P2X receptors (Guo et al. 2007). The two P2X receptors can be co-immunoprecipitated in detergent extracts from co-transfected HEK293 cells and from murine macrophages that express endogenous P2X4 and $P2X_7$ receptors. A mutant P2X4R lacks ATP-gated channel activity but is capable of trafficking to the plasma membrane. When this mutant P2X4R (Named S341W) was co-expressed with P2X7R, ivermectin was able to potentiate the ATP-induced current in cells co-expressing these receptors. Since ivermectin could not potentiate homomeric P2X7R - mediated current, the potentiation by ivermectin of the co-expressed S341W P2X4R and P2X7R is most likely due to allosteric enhancement of the heteromer via the S341W P2X4 receptor. The overlapping expression of P2X4R and P2X7R have been identified in a number of tissues including some non-excitatory cells such as epithelial cells from salivary glands, exocrine pancreas, airway, leukocytes, microglial cells, and osteoclasts. The possible presence of heteromeric P2X4/7R in these tissues or cells raises the question that heteromeric P2X4/7R may mediate important physiological function(s) in these tissues (Dubyak 2007).

Future Directions

Further systematic examination of the effect of each agonist and antagonist will be needed at heteromeric P2X receptors. This can be performed in cells co-expressing individual P2X subunits using heterologous systems such as HEK293 cells or oocytes. Features including pharmacology, desensitization kinetics, and sensitivity to pH, extracellular calcium, or zinc will all need to be determined. Once characterized, these features should be compared to those obtained in the native tissues to ascertain whether they are similar. Similarity of features would support the particular heteromer as the native tissue receptor. Another possibility is that a heteromer may comprise three different P2X receptor subtypes. If true, this possibility will add further complexity.

Summary

P2X receptors are a family of ligand-gated ion channels. The natural agonist ligands are ATP. There are seven P2X receptors (P2X1-7) and each receptor is a subunit of the trimeric channel. Each subunit can complex with itself to form a homotrimeric channel or with other subunits to form a heterotrimeric channel. Evidence points to existence of both homo- and hetero-trimeric channels as endogenous channels in the tissue. In the heterotrimeric channel, molecular and pharmacological properties of the constituent subunit can both dominate or become masked. Evidence is accumulating to indicate potentially important biological and pathophysiolgical roles of these receptor channels. It is expected that many of these homo- or heterotrimeric channels will become novel therapeutic targets for various diseases. Much more work is needed.

Synonyms

Nucleotide receptors; Purinergic receptors

Historical Background

Signaling by extracellular ATP was first reported in 1929 (Drury and Szent-Györgyi 1929). Subdivision of purinergic receptors between P1 (adenosine) and P2 (ATP, ADP) was proposed in 1978 (Burnstock 1978), and further subdivision of P2 receptors between P2Y and P2X was made in 1985 (Burnstock and Kennedy 1985). The $P2Y_1$ and $P2Y_2$ receptors were the first P2Y receptors to be cloned in 1993 (Webb et al. 1993; Lustig et al. 1993).

Release of Nucleotides in the Extracellular Fluids

Although nucleotides, such as ATP and UTP, are mainly intracellular, they are released in the extracellular fluids by various mechanisms. One of them is cell damage: both necrotic and apoptotic cells release ATP and other nucleotides that thus constitute "danger signals" or DAMP (damage-associated molecular pattern) (Elliott et al. 2009). But they can also be released without cell lysis by specific mechanisms: exocytosis of secretory granules, vesicular transport, and membrane channels, such as ABC transporters, pannexins, and connexins (Abbracchio et al. 2006). Nucleotides are released by exocytosis during platelet aggregation and synaptic transmission. They are also released in response to various types of stress: mechanical stimulation (stretch, shear stress), hypoxia, or pathogen invasion. Extracellular nucleotides are rapidly degraded by a variety of ectonucleotidases such as the ENTDPases that degrade ATP into ADP and ADP into AMP, and 5'-nucleotidase that converts AMP into adenosine (Abbracchio et al. 2006). Signaling by extracellular nucleotides is mediated by two families of receptors: metabotropic G protein–coupled P2Y receptors and ionotropic P2X receptors.

Structure and Signaling Properties of P2Y Receptors

The P2Y family is composed of eight members encoded by distinct genes that can be subdivided into two groups based on their coupling to specific G proteins, as well as structural features (Abbracchio et al. 2006).

Whereas the P2X receptors are all receptors for ATP, the various P2Y receptors differ by their selectivity for distinct nucleotides (Table 1). $P2Y_{11}$ is primarily an ATP receptor, whereas $P2Y_1$, $P2Y_{12}$, and $P2Y_{13}$ are ADP receptors. $P2Y_4$ and $P2Y_6$ are pyrimidinergic receptors activated by UTP and UDP respectively. $P2Y_2$ is a dual ATP and UTP receptor. $P2Y_{14}$ is a receptor for UDP-glucose and other nucleotide sugars as well as for UDP itself.

Comparisons of the structural characteristics and functionally important amino acid residues within the family have been performed using mutagenesis and

Nucleotide Receptor P2Y, Table 1 Properties of P2Y receptors

Group	Receptor	Chromosome (human)	Agonist (human)	G protein
A	$P2Y_1$	3q24-25	ADP	G_q
	$P2Y_2$	11q13.5	ATP = UTP	G_q (+ G_i)
	$P2Y_4$	Xq13	UTP	G_q (+ G_i)
	$P2Y_6$	11q13.5	UDP	G_q
	$P2Y_{11}$	19p31	ATP	G_q + G_s
B	$P2Y_{12}$	3q21-25	ADP	G_i
	$P2Y_{13}$	3q24-25	ADP	G_i
	$P2Y_{14}$	3q24-25	UDP-glucose UDP	G_i

modeling (Abbracchio et al. 2006). Conserved cationic residues that interact with the negatively charged phosphate groups have been identified in transmembrane domains 3, 6, and 7. The 8 P2Y receptors have a H-X-X-R/K motif in TM6. The $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptors share a Y-Q/K-X-X-R motif in TM7, whereas another motif, K-E-X-X-L is found in $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$. This last motif is not specific for P2Y receptors since it is also found in GPR87, a lysophosphatidic acid receptor.

The $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptors couple mainly to G_q and the $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$ receptors couple to G_i (Table 1). This coupling has been demonstrated directly in reconstitution experiments: ADP-activated GTP hydrolysis in vesicles containing either $P2Y_1$ and $G\alpha_q$ or $P2Y_{12}$ and $G\alpha_{i2}$ (Waldo et al. 2004). However, the dichotomy between G_q- and G_i-coupled P2Y receptors is an oversimplification. Indeed, the $P2Y_{11}$ receptor has the unique property to couple through both G_q and G_s. It is also unique by its late appearance during evolution since no $P2Y_{11}$ gene can be identified in the genome of rodents (Communi et al. 2001a). Furthermore, the $P2Y_2$ and $P2Y_4$ receptors are also coupled to G_i, as shown inter alia by a sensitivity of the responses mediated by those receptors to inhibition by pertussis toxin.

There is limited evidence for non-G-protein-mediated signaling by P2Y receptors. In particular, the $P2Y_2$ receptor has been shown to transactivate the VEGF receptor-2, by a mechanism involving the binding of ▶ Src tyrosine kinase to SH3 binding sites in the C-terminal domain of $P2Y_2$ (Seye et al. 2004).

The pharmacology of some P2Y receptors exhibits species differences: while the human $P2Y_4$ is a UTP receptor, the rat and mouse $P2Y_4$ receptors are activated equipotently by ATP and UTP.

The missing numbers in the classification represent either nonmammalian orthologs or receptors having some sequence homology to P2Y receptors, but for which there is no functional evidence of responsiveness to nucleotides.

Primary references are as follows : $P2Y_1$ (Webb et al. 1993), $P2Y_2$ (Lustig et al. 1993), $P2Y_4$ (Communi et al. 1995), $P2Y_6$ (Communi et al. 1996), $P2Y_{11}$ (Communi et al. 1997), $P2Y_{12}$ (Hollopeter et al. 2001), $P2Y_{13}$ (Communi et al. 2001b), $P2Y_{14}$ (Chambers et al. 2000).

Functions of P2Y Receptors

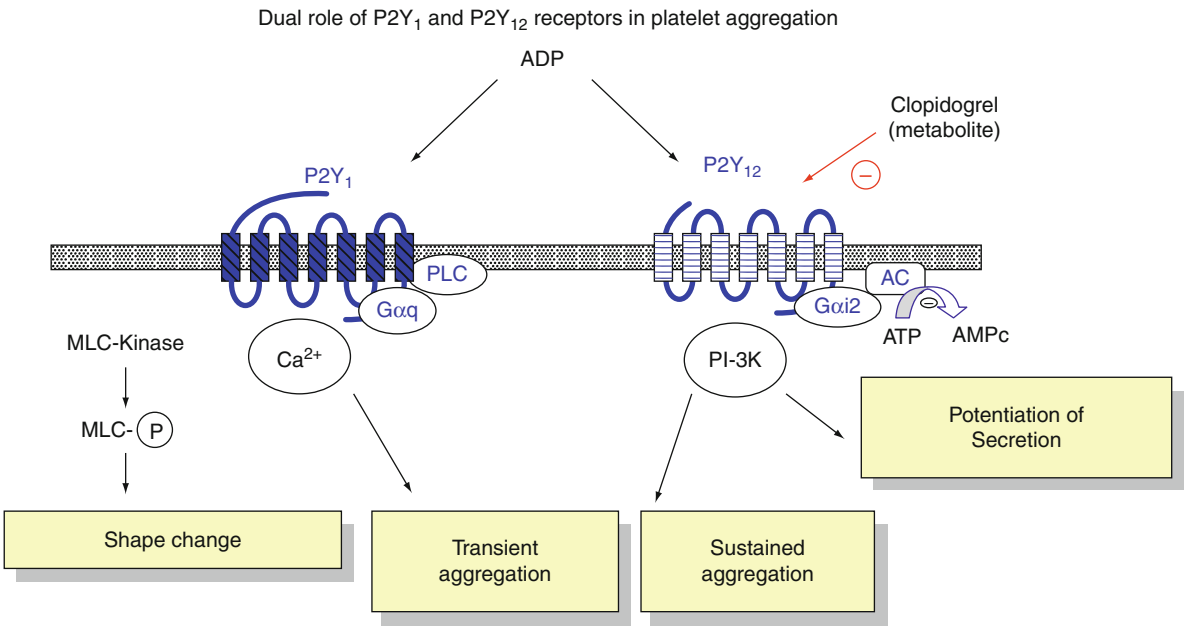
Gene silencing techniques have been instrumental in establishing the function of P2Y receptors (Table 2). ADP released from platelet dense granules amplifies platelet aggregation. This action requires the cooperation between two P2Y receptors: $P2Y_1$ and $P2Y_{12}$ (Fig. 1). $P2Y_1$ is involved in the initial platelet shape change and transient aggregation, while $P2Y_{12}$ is responsible for sustained aggregation and secretion. Both $P2Y_1^{-/-}$ and $P2Y_{12}^{-/-}$ mice show defective platelet aggregation ex vivo, increased bleeding time, and resistance to thrombosis (Leon et al. 1999; André et al. 2003). The only P2Y receptor ligands currently used as medicinal products are the thienopyridine antagonists of the $P2Y_{12}$ receptor, ticlopidine, clopidogrel, and prasugrel, which are used as antithrombotic agents.

ATP and UTP stimulate the secretion of chloride by epithelial cells through a channel distinct from CFTR (Cystic Fibrosis Transmembrane Regulator) (Fig. 2). Studies of knockout mice have demonstrated that this action is mediated by the $P2Y_2$ receptor in the airways (Cressman et al. 1999) and by $P2Y_4$ in the gut (Robaye et al. 2003). The $P2Y_2$ agonist denufosol is currently in phase III clinical development for the treatment of cystic fibrosis via mucus hydration.

Multiple P2Y receptors are expressed in the heart: $P2Y_2$ and $P2Y_6$ receptors on cardiomyocytes and $P2Y_4$ on microvascular endothelial cells. Nucleotides are released from cardiomyocytes in response to mechanical stretch or ischemia. The use of siRNA revealed that the $P2Y_6$ receptor plays a role in cardiac fibrosis resulting from pressure overload (Nishida et al. 2008).

Nucleotide Receptor P2Y, Table 2 Effects of P2Y gene silencing

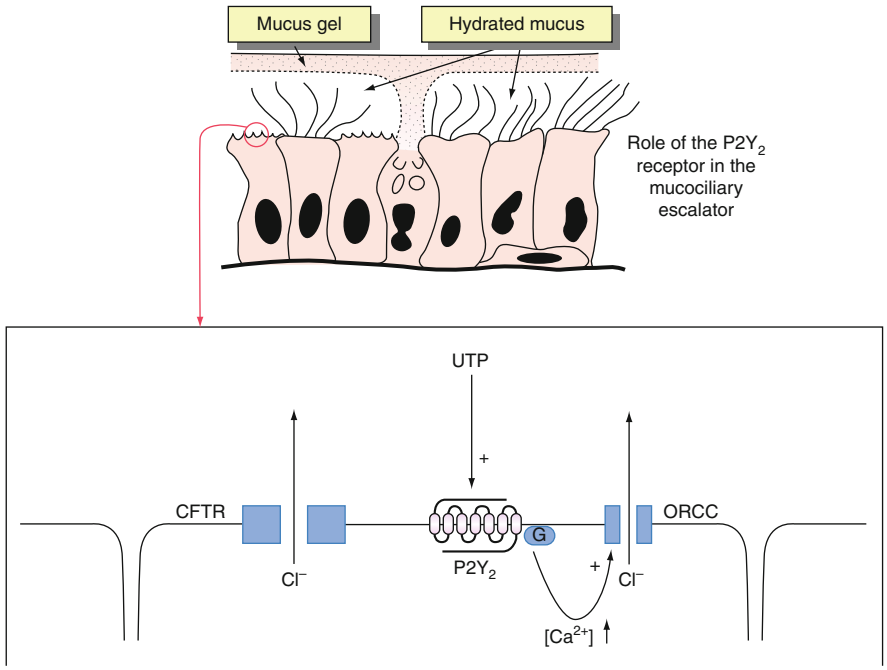
Receptor	Gene silencing method	Consequence of gene silencing
$P2Y_1$	Knockout mice	Inhibition of platelet aggregation and resistance to thromboembolism
		Smaller atherosclerotic lesions
$P2Y_2$	Knockout mice	Decreased neutrophil and monocyte/macrophage chemotaxis
		Decreased infiltration of eosinophils in asthmatic airways
		Abolition of ATP-induced Cl^- secretion in airways
$P2Y_4$	Knockout mice	Abolition of ATP-induced Cl^- secretion in the gut
$P2Y_6$	Antisense	Decreased microglial phagocytosis
	siRNA	Decreased pressure overload-induced cardiac fibrosis
$P2Y_{12}$	Knockout mice	Inhibition of platelet aggregation and resistance to thromboembolism
		Decreased microglial migration
$P2Y_{13}$	siRNA	Decreased HDL endocytosis by hepatocytes



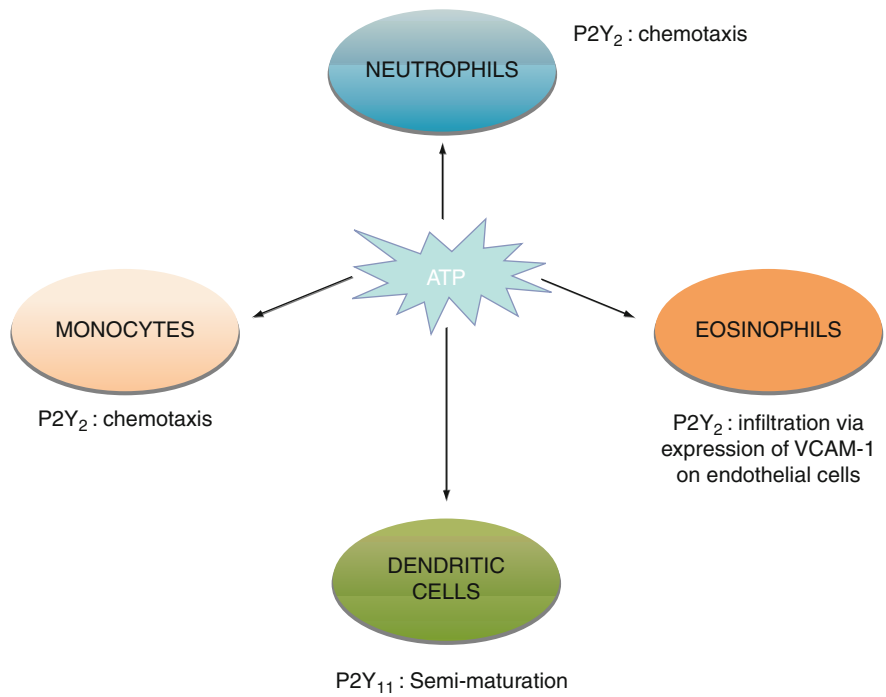
Nucleotide Receptor P2Y, Fig. 1 Cooperation between $P2Y_1$ and $P2Y_{12}$ receptors in platelet aggregationActivation of the $P2Y_1$ receptor by ADP induces a shape change of platelets and their transient aggregation, while its stimulatory effect on $P2Y_{12}$ induces a stable aggregation and potentiates the secretion of dense granules content

Multiple P2Y receptors might play a role in the development of atherosclerotic lesions, independently from their role in platelet activation. Aortic lesions were smaller in double ApoE/$P2Y_1$ knockout mice than in $ApoE^{-/-}$ mice (Hechler et al. 2008). This difference was unrelated to the role of $P2Y_1$ in platelet activation since it was unaffected by bone marrow transplantation from $P2Y_1$ wild-type mice, indicating the role of $P2Y_1$ in non-hematopoietic-derived cells, most likely endothelial cells. On the other hand, the $P2Y_{13}$ receptor plays a role in the reverse cholesterol transport, at the level of hepatocytes. It has indeed been shown that HDL Apo A-I activates an ecto-ATPase that generates ADP from ATP on the surface of hepatocytes. ADP then stimulates the endocytosis of HDL particles via the activation of $P2Y_{13}$ receptors, as demonstrated by the use of siRNA (Jacquet et al. 2005).

P2Y receptors are involved at various steps in the inflammatory process (Fig. 3). ATP released from neutrophils amplifies their attraction by chemotactic signals and its release from apoptotic cells constitutes a "find-me signal" for monocytes/macrophages



Nucleotide Receptor P2Y, Fig. 2 Role of the $P2Y_2$ receptor in the regulation of the airways mucociliary escalatorActivation of the $P2Y_2$ receptor by ATP stimulates the three components of this escalator: mucus secretion, mucus hydration, and mucus mobilization by ciliary activity. Mucus hydration results from Cl^- secretion which is mediated either by CFTR (Cystic Fibrosis Transmembrane Regulator) or ORCC (Outwardly rectifying chloride channels) that are opened by an increase in $[Ca^{2+}]_i$ in response to ATP



Nucleotide Receptor P2Y, Fig. 3 Role of P2Y receptors in various immune cellsThe $P2Y_2$ receptor plays a role in the tissue infiltration of eosinophils and the chemotaxis of neutrophils and monocytes. The $P2Y_{11}$ receptor mediates the semi-maturation of dendritic cells that favors Th2 differentiation or tolerance

(Chen et al. 2006; Elliott et al. 2009). In a murine model of asthma, the infiltration of esosinophils in the airways involves the $P2Y_2$-mediated expression of VCAM-1 (Vascular Cell Adhesion Molecule-1) on lung endothelial cells (Vanderstocken et al. 2010). P2Y receptors are also involved in adaptive immunity. In particular, ATP induces via the $P2Y_{11}$ receptor the semi-maturation of human monocyte-derived

dendritic cells, characterized by the upregulation of co-stimulatory molecules and the inhibition of IL-12 secretion, resulting in an enhanced ability to induce Th2 differentiation of T lymphocytes (Wilkin et al. 2001). Moreover, ATP confers tolerogenic and tumorigenic properties to dendritic cells (Marteau et al. 2005; Bles et al. 2010).

Microglia from $P2Y_{12}^{-/-}$ mice are unable to polarize, migrate, or extend processes toward ADP, and in vivo they showed decreased directional branch extension toward sites of laser-induced cortical damage (Haynes et al. 2006). Independently from this chemotactic action of ADP, UDP stimulates the uptake of microspheres by rat microglia, and this action was blocked by an antisense oligonucleotide targeting the $P2Y_6$ receptor (Koizumi et al. 2007). These complementary actions of ADP, a find-me signal, and UDP, an eat-me signal, involving a cooperation between $P2Y_{12}$ and $P2Y_6$, might be beneficial in neurodegenerative conditions such as Alzheimer's disease, via an increased clearance of amyloid-β deposits.

Summary

Nucleotides are released in the extracellular fluids following cell damage (necrosis or apoptosis), mechanical stimulation, or by exocytosis. They act on G protein–coupled P2Y or ionotropic P2X receptors. There are eight P2Y receptors encoded by distinct genes. They can be divided in two groups according to structural features and coupling to specific G proteins. The $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptors couple mainly to G_q, and the $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$ receptors couple to G_i. They exhibit a selectivity for distinct nucleotides: ATP, ADP, UTP, UDP, and UDP-glucose. The study of knockout mice and other methods of gene silencing have demonstrated their involvement in multiple biological processes: platelet aggregation, epithelial surface lubrication, migration of neutrophils, monocytes and microglia, microglial phagocytosis, etc.

Neural Wiskott–Aldrich Syndrome Protein; Wiskott–Aldrich Syndrome-Like (WASL)

Historical Background

Wiskott–Aldrich syndrome (WAS), a pediatric disorder, was first described in 1937 by Alfred Wiskott as a "hereditary thrombopathy" in males, presenting with thrombocytopenia, eczema, bloody diarrhea, episodes of fever, and recurrent bacterial infections. Robert A. Aldrich would later demonstrate an X-linked mode of inheritance of this disease. Other features of WAS were later recognized, including immunodeficiency involving both humoral and cellular immunity, high rate of autoimmunity and malignancies, abnormal apoptosis, and defective cell motility. The mutated gene giving rise to this disease was identified in 1994 by positional cloning and referred to as *WAS*, and mutations of the WAS protein (WASP) were demonstrated not only in patients with WAS, but also in those with X-linked thrombocytopenia (XLT), a disease showing milder clinical phenotype with a more favorable prognosis (Notarangelo et al. 2008). Northern blot analysis indicated that WASP mRNA is expressed exclusively in hematopoietic cells. Two years later, a novel protein with ~50% amino acid identity to the *WAS* gene product was reported as a binding partner for the Grb2/Ash adapter protein. In contrast to WASP, this protein was expressed ubiquitously, but strongest expression was observed in neuronal cells and was thus named Neural-WASP (▶ N-WASP) (Miki and Takenawa 2003).

▶ N-WASP and WASP are actin-nucleating promoting factors (NPF) and are the founding members of the WASP-family of NPFs that contain tandem V (Verprolin homology, also known as WH2; WASP

homology 2), C (Central or Connecting), and A (Acidic) regions, referred to as the VCA domain. Other members of this family are the WAVE/Scar, WASH, and WHAMM/JMY subfamilies. Evolutionary analyses indicate that these VCA domain-containing proteins are widely expressed among eukaryotes and evolutionarily ancient (Veltman and Insall 2010).

Structure of N-WASP

▶ N-WASP and WASP have a conserved domain organization that allows interaction with multiple distinct binding proteins (Table 1). They have a WASP homology 1 (WH1; also known as EVH1) domain that binds primarily WASP interacting protein (WIP)-family members, a basic sequence that binds phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P_2), a GTPase-binding domain (GBD), containing a Cdc42 and Rac interactive binding (CRIB) motif that binds Cdc42-GTP, and a proline-rich region that binds SH3 proteins. The C-terminus of both proteins contains a VCA domain that binds actin via the V region and the Arp2/3 complex via the CA region but ▶ N-WASP has an additional V region (Takenawa and Suetsugu 2007) (Fig. 1). In vitro data using the purified VVCA domain of ▶ N-WASP showed that this domain alone was sufficient for actin polymerization and its activity was higher than the isolated VCA domain of WASP (Zalevsky et al. 2001).

Regulation of N-WASP

Autoinhibition and Activation by Cdc42

▶ N-WASP is regulated by diverse signals including Rho family GTPases, phospholipids, kinases, many SH3 domain-containing proteins, and both bacterial and viral pathogen proteins (Takenawa and Suetsugu 2007) (Table 1). In the resting state, ▶ N-WASP and WASP are autoinhibited through intramolecular interactions between the C-terminal VCA region and a hydrophobic pocket in the GBD but other regions, such as from the WH1 domain, may also participate in autoinhibition. In addition, it is generally considered that favorable electrostatic interactions between the basic region and the A region further stabilize the GBD–VCA interface. The Rho family GTPase Cdc42 was the first protein shown to bind ▶ N-WASP/WASP and is an important regulator of both proteins. The active, GTP bound form of Cdc42 disrupts the hydrophobic core of the GBD and releases the VCA domain, which can now bind G actin and the Arp2/3 complex. The Arp2/3 complex, which is composed of seven polypeptides, nucleates actin polymerization and contributes to branched filamentous actin (Takenawa and Suetsugu 2007). Another Rho family GTPase, Rac1, can activate ▶ N-WASP in vitro, but is probably not involved in WASP activation (Tomasevic et al. 2007). Evidence also suggests that Cdc42 may require an additional intermediate for the activation of ▶ N-WASP, such as F-BAR proteins of the CIP4 subfamily, which include Toca-1, CIP4, and FBP17. These proteins bind directly to Cdc42 and also contain a SH3 domain that binds to the polyproline region of ▶ N-WASP, and is required for ▶ N-WASP functions, such as endocytosis.

Regulation by Phosphorylation

Although it is generally accepted that the binding of Cdc42-GTP to WASP is important for allosteric release from autoinhibition, other signaling events can also modulate ▶ N-WASP function. One such event is phosphorylation of a conserved tyrosine residue (Y256 in human ▶ N-WASP and Y291 in human WASP) by non-receptor tyrosine kinases, e.g., ▶ Src, and is required for several cellular functions of ▶ N-WASP, such as neurite extension. Remarkably, this residue is located in the C-terminus of the GBD, and its phosphorylation is thought to alter the charge and therefore stability of the autoinhibited form of both proteins shifting the proteins toward the open, active conformation (Thrasher and Burns 2010). Additionally, tyrosine phosphorylation may prime the molecule for activation by proteins that contain SH2 domains contributing to an additional regulatory input. However, tyrosine phosphorylation may also target both WASP and ▶ N-WASP to various protein degradation pathways, thus resulting in signal termination (Dovas and Cox 2010).

PtdIns(4,5)P_2, SH3 Domains, and EspFu

Additional levels of control of ▶ N-WASP activity following allosteric activation also exist, facilitating the integration of multiple signals in the efficient control of ▶ N-WASP activity. These are generally

N-WASP, Table 1 ▶ N-WASP/WASP binding proteins

Binding protein	Binding domain	N-WASP/WASP binding region	Effect on (N)WASP/function
WIP, CR16, WICH/WIRE	Proline-rich	WH1	Stabilization, targeting, inhibition of activity
CIB		WH1	Coupling to integrin $\alpha_{IIb}\beta_3$
Cdc42/Chp		CRIB	Activation
TC10/RhoT		CRIB	Activation
mDab1	PTB	CRIB	
PtdIns(4,5)P_2		Basic	Localization, synergistic activation with Cdc42 and Nck
Hsp90		Basic	Stabilization
FBP11	WW	Proline-rich	
Src-family kinases (Src, Hck, Lck, Lyn, Fyn, Fgr)	SH3 (SH2?)	Proline-rich	Phosphorylation, activation, protein degradation
Grb2	SH3	Proline-rich	Activation, localization
Nck	SH3	Proline-rich	Activation, localization
Crk adaptors (CrkII, CrkL)	SH3	Proline-rich	Activation, localization
Vinexin beta	SH3	Proline-rich	
Cortactin, HS1	SH3	Proline-rich	Targeting, activation, invadopodium/ podosome formation
Abi1	SH3	Proline-rich	Activation, endocytosis
Endophilin	SH3	Proline-rich	Activation, endocytosis
Amphiphysin	SH3	Proline-rich	Endocytosis
Tuba	SH3	Proline-rich	Activation via Cdc42
CIP4, Toca-1, FBP17	SH3	Proline-rich	Cdc42-mediated activation
Tec family kinases (Tec, Btk, Itk)	SH3	Proline-rich	Phosphorylation, activation
WISH/DIP	SH3	Proline-rich	Activation
PSTPIP1	SH3	Proline-rich	Activation, localization
Syndapin	SH3	Proline-rich	Activation, endocytosis
Nostrin	SH3	Proline-rich	Endocytosis
srGAP	SH3	Proline-rich	
Profilin	SH3	Proline-rich	Actin polymerization
IRSp53	SH3	Proline-rich	Activation, localization
PTP-PEST		Proline-rich	Dephosphorylation, inactivation
Sorting nexin (SNX9, SNX18)	SH3	Proline-rich	Activation, endocytosis
Arg	SH3	Proline-rich	Phosphorylation, activation
Intersectin-1, -2	SH3	Proline-rich	Localization, activation
Abp1	SH3	Proline-rich	Activation, endocytosis
VASP		Proline-rich	Localization, actin polymerization
Casein kinase	?	?	VCA phosphorylation
Arp2/3		CA	Actin polymerization

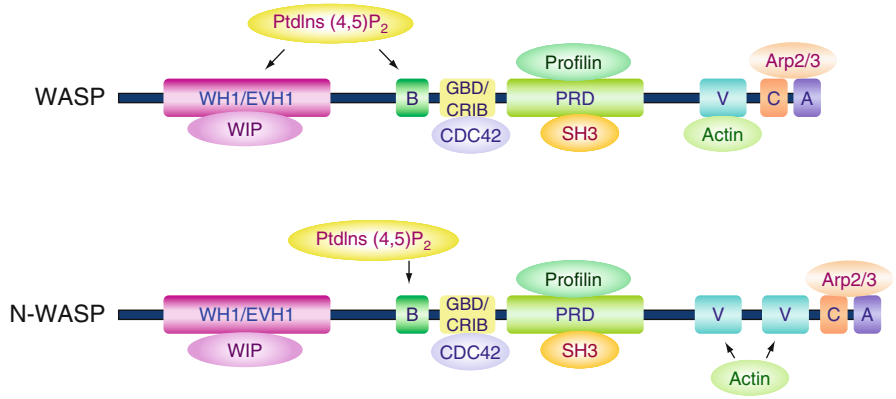
F-actin		Basic	Branching
Merlin, ERM (ezrin/radixin/moesin)	FERM domain	WH1	Inhibition of actin polymerization
CD44			Stabilization, localization
IQGAP1		Basic-CRIB	Activation

? unknown



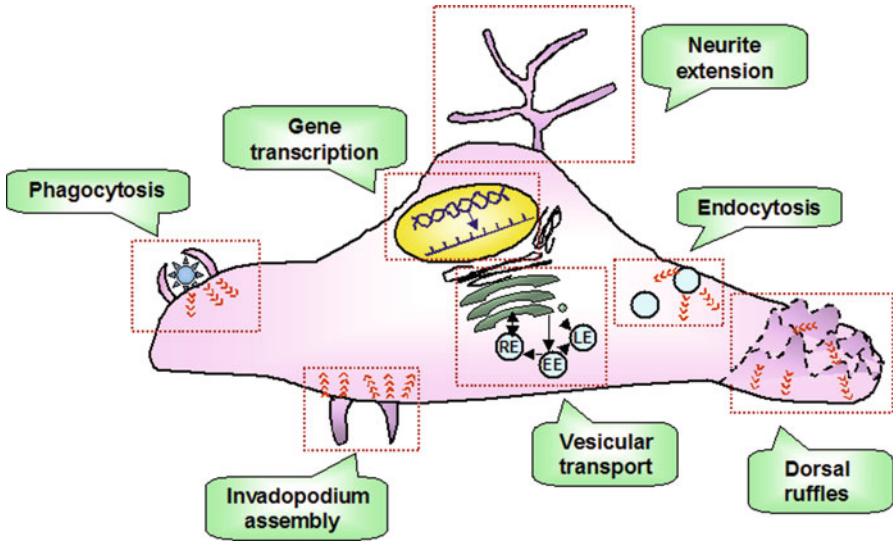
N-WASP, Fig. 1 *Domain organization and molecular interactions of* ▶ *N-WASP and WASP*. ▶ N-WASP and WASP have similar overall domain organization, with an additional V region present in ▶ N-WASP. The WH1 domain interacts with WIP and its related proteins. The basic domain mediates interactions with PtdIns(4,5)P_2 on membranes. The CRIB motif inside the GBD region binds to Cdc42-GTP and is instrumental in ▶ N-WASP activation. The polyproline stretch is a site for docking of SH3 domains, while distinct regions mediate binding to profilin. Finally, the VCA domain binds G-actin and the Arp2/3 complex and nucleates actin polymerization

thought of as influencing the activity of ▶ N-WASP by correctly localizing the molecule and/or by influencing its dimerization status (Padrick and Rosen 2010). The latter is an important means of control of ▶ N-WASP-dependent actin polymerization since VCA domain dimers bind the Arp2/3 complex with higher affinity than monomers, thus contributing to enhanced actin polymerization. PtdIns(4,5)P_2 is an important regulator of actin organization mediated by both ▶ N-WASP and WASP. PtdIns(4,5)P_2 synergizes with Cdc42 in the activation of ▶ N-WASP. Increased PtdIns(4,5)P_2 density hyperactivates ▶ N-WASP in vitro, and is required for actin comet tail formation in vivo, pointing to both membrane targeting and dimerization as means by which PtdIns(4,5)P_2 regulates ▶ N-WASP.

Adaptor proteins that contain multiple SH3 domains participate in an additional level of control of ▶ N-WASP activity via dimerization. One prominent example is Nck1, which contains five SH3 domains and is able to hyperactivate ▶ N-WASP in vitro, while dimeric BAR domain proteins that contain SH3 domains may also act by inducing ▶ N-WASP dimers. Importantly, the enhanced activity of ▶ N-WASP upon dimerization is exploited by enterohemorrhagic *Escherichia coli*, to induce its spread. The bacterial protein EspFu, which is injected into the host cell cytoplasm, contains multiple repeats of a segment that can bind the GBD of ▶ N-WASP. Therefore, EspFu activates ▶ N-WASP allosterically by competing for GBD binding with the VCA domain while at the same time clustering multiple ▶ N-WASP molecules to stimulate Arp2/3-dependent actin polymerization and pedestal formation. Therefore, these data suggest that the proline-rich region may receive activation signals as well as localization signals from proteins containing SH3 domains, and that similar mechanisms are exploited by pathogens to induce their spread.

WIP: A Major Binding Partner

WIP interacts with the WH1 domain of ▶ N-WASP and WASP and performs critical regulatory functions (Ramesh and Geha 2009). Primarily, it is required for the stability of WASP protein levels in vivo. This is highlighted by the fact that the most frequent WAS mutations are clustered at the WH1 domain and affect amino acids important for the interaction with WIP. WIP also targets WASP to sites of activity. For example, WIP targets WASP to sites of T cell receptor clustering and also recruits ▶ N-WASP to vaccinia virus particles. However, WIP also inhibits the ability of ▶ N-WASP to stimulate actin polymerization, at least in vitro. It may be possible that WIP does not dissociate from ▶ N-WASP but may undergo conformational changes that relieve inhibitory interactions and allow ▶ N-WASP activation in vivo (Ramesh and Geha 2009).



N-WASP, Fig. 2 *Cellular functions of* ▶ *N-WASP*. ▶ N-WASP plays important functions inside cells. It mediates endocytosis and vesicle motility; participates in plasma membrane extensions, such as in the outgrowth of neurites, during phagocytosis, dorsal ruffle formation and invadopodium formation, and regulates gene expression by shuttling in and out of the nucleus

The Role of N-WASP

▶ N-WASP exerts its functions primarily via the regulation of Arp2/3-mediated actin polymerization. As such, it participates in a plethora of actin-dependent functions including endocytosis, phagocytosis, invadopodium assembly, neurite extension, vesicular transport, pathogen infection, and dorsal ruffle formation (Fig. 2). ▶ N-WASP is also found in the nucleus where it participates in gene transcription through association with a nuclear complex that contains RNA polymerase II. This role of ▶ N-WASP also relies on its ability to polymerize nuclear actin (Wu et al. 2006). Similar nuclear functions have been described for WASP, where it is important in the transcription of key genes required for the differentiation of $CD4^+$ T_H1 cells (Taylor et al. 2010). ▶ N-WASP also regulates sarcomeric actin assembly in skeletal muscle, though independently of the Arp2/3 complex (Takano et al. 2010).

▶ N-WASP has not been associated with human disease and appears to be essential in mammals as ▶ N-WASP deficiency in mice results in embryonic death at day E12. Tissue-specific ablation of ▶ N-WASP, however, has revealed roles for ▶ N-WASP in T cell development (Cotta-de-Almeida et al. 2007), hair follicle cycling (Lefever et al. 2010), and myelin sheath formation by Schwann cells (Novak et al. 2011). The importance of tight regulation of ▶ N-WASP activity is suggested by the hematopoetic-restricted WASP in which activating mutations have been shown to induce a separate syndrome, X-linked neutropenia (XLN). Therefore, both inactivating and activating mutations in WASP contribute to human disease.

Common and Distinct Functions of N-WASP and WASP

Although there is a high degree of homology in the functional domains of ▶ N-WASP and WASP, they may not be able to completely substitute for one another. WASP and ▶ N-WASP may serve both redundant and nonredundant functions depending on the cellular context. For example, only ▶ N-WASP, and not WASP, can support *Shigella* motility in cells (Snapper et al. 2001). Also, while WASP is expressed exclusively in hematopoietic cells, ▶ N-WASP is also expressed in these cells, albeit at low levels (Isaac et al. 2010). Recently, unique functions for ▶ N-WASP were demonstrated in macrophages. A striking feature of WASP-deficient macrophages is the lack of podosomes. Podosomes mediate adhesion to the extracellular matrix and perform matrix degradation. WASP localizes to the F-actin-rich core along with other actin-regulatory proteins, such as cortactin/HS1 and Arp2/3. Interestingly, certain aggressive cancer

cells and ▶ Src-transformed cells possess podosome-like structures called invadopodia that appear to be directly responsible for extracellular matrix degradation. Invadopodia have similar organization and actin regulatory machinery localization compared to podosomes. However, invadopodia are regulated by ▶ N-WASP given the absence of WASP expression in these cells. When ▶ N-WASP was reduced in macrophage cells, podosomes still formed, but they were unable to perform matrix degradation (Nusblat et al. 2011). This defect was rescued by re-expression of ▶ N-WASP, but not by overexpression of WASP. Additionally, reducing ▶ N-WASP levels mistargets the matrix-degrading enzyme MT1-MMP and it no longer localizes to podosomes. Additionally, ▶ N-WASP only co-localizes with MT1-MMP positive vesicles at podosomes, suggesting that ▶ N-WASP may play a role on the targeting or fusion of MMP-containing vesicles to podosomes in macrophage cells (Nusblat et al. 2011). A unique role for ▶ N-WASP was also found for phagocytosis by macrophages and a study indicated that ▶ N-WASP may play a role in membrane delivery to the growing phagocytic cup while WASP may be required for the actin polymerization during phagocytosis (Park and Cox 2009). ▶ N-WASP and WASP have both overlapping and unique functions when expressed in the same cell.

Summary

Both ▶ N-WASP and WASP proteins play critical roles in rapid reorganization of actin filaments induced in response to diverse extracellular stimuli. Although they have high homology in their functional domains, ▶ N-WASP and WASP also have different requirements for activation and participate in distinct cellular processes. Studies in leukocytes, which express both proteins, may reveal unique functions and distinct aspects of regulation and can contribute to a more profound understanding of their cellular activities and further delineate the immunological abnormalities in WAS. Identification of different binding partners between ▶ N-WASP and WASP will provide important answers to the intriguing questions about the differential activation and unique roles of these proteins. Tissue-specific ablation of ▶ N-WASP will also help reveal its functions in vivo. Novel findings on the nuclear or Arp2/3-independent functions of ▶ N-WASP suggest that many aspects of this molecule remain unknown and promise exciting new avenues for research.

Odorant receptors; Olfrs; ORs

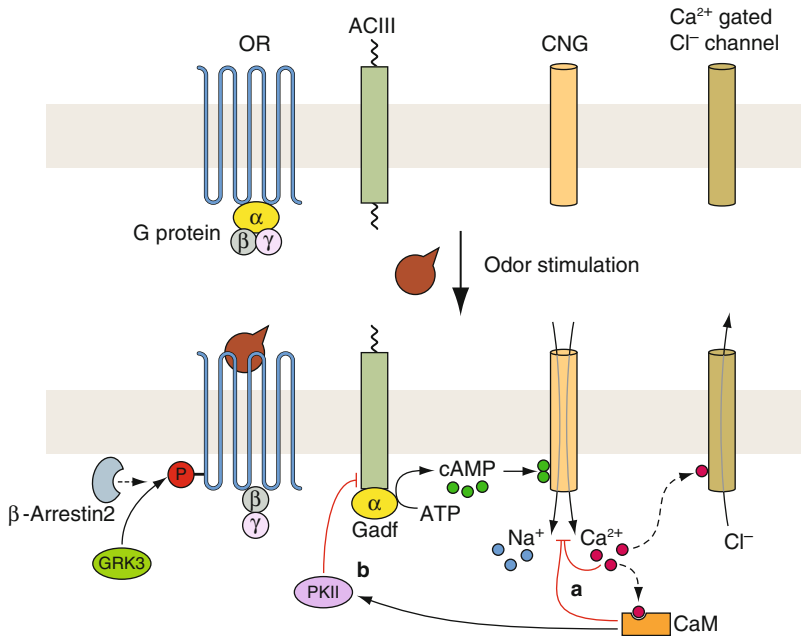
Historical Background

Among the five senses, smell is unique in that it is dedicated to discriminating an enormous diversity of stimulating ligands. Olfactory sensory neurons achieve this detection by the expression of a multigene family of seven-transmembrane G protein–coupled receptors (GPCRs) originally identified by Linda Buck and Richard Axel (Buck and Axel 1991). These receptors, termed olfactory receptors (OR, plural ORs), are expressed in the olfactory tissue of all terrestrial vertebrates examined thus far, and have been shown to respond directly to odorant binding. The identification and subsequent study of ORs has provided great insight into the molecular and neuronal organization of the olfactory system. Indeed, in 2004, Buck and Axel were jointly awarded the Nobel Prize in Physiology for their pioneering work in odorant receptor discovery. Most of the current understanding of ORs results from experiments from the mouse model which is the focus of this review.

General Physiology and Classification of ORs

Olfactory sensory neurons reside in the main olfactory epithelium (MOE) which is located in the distal recess of the nasal cavity. The MOE covers the evaginated nasal terbinates resulting in increased surface capacity to sample ligands. The dendrite of each olfactory neuron projects toward the nasal lumen providing direct sensory contact with the odor environment. The dendrite is tufted with 20–30 sensory cilia and OR proteins localized to these cilia membranes further increase surface exposure to the ligand environment. Active sniffing draws odorant ligands into the nasal cavity enabling binding and subsequent activation of ORs. Each odorant receptor is expressed from a single coding gene. Together, individual odorant receptor genes comprise the largest GPCR family in the mammalian genome (in the human genome they account for approximately 3% of predicted exons). ORs belong to class A GPCRs (Rhodopsin family) and can be broadly divided into classes I and II (Zhang and Firestein 2002). Class I is highly conserved across evolution;

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,



Olfactory Receptors, Fig. 1 Endogenous G protein signaling and desensitization pathway activated by odorant receptors on odor binding. Signaling: On binding an odor molecule, the odorant receptor activates the Gαolf, which stimulates ACIII to generate cyclic AMP. cAMP regulates ion channel CNG to allow influx of sodium and calcium ions. Calcium ions in turn regulate a chloride channel to induce efflux of chloride ions. Influx and efflux of the said ions result in depolarization of the olfactory sensory neuron. Desensitization: Calcium and calcium-binding proteins like calmodulin CaM act as feedback inhibitors of OR-induced signaling by (**a**) binding and blocking CNG or (**b**) inducing PKII to phosphorylate and inhibit ACII. GRK3 may phosphorylate the odorant receptor so it can now bind β arrestin for desensitization and internalization

related to chemosensory receptors in fish. Sequence analysis shows class II to be more divergent, suggesting that this OR class may have evolved to provide specific ecological adaptations.

Evolution of Odorant Receptors

Comparative genomics has revealed that the odorant receptor family shows rapid gene birth and death events across evolution. Tandem gene duplications have resulted in chromosomal clusters of closely related ORs with high sequence homology and similar ligand-binding profiles. In the mouse, there are 43 odorant receptor clusters found on every chromosome. Old world primates, including humans, have a significantly smaller OR repertoire (390 putatively functional genes) compared to other sequenced vertebrates such as mice (1,468 putatively functional genes), rats (1,750 putatively functional genes), and dogs (922 putatively functional genes). The evolutionary loss of functional OR coding regions has been attributed to the correlated evolution of trichromatic vision and an increased utilization of visual stimuli.

OR-Mediated Signal Transduction

Upon ligand stimulation, odorant receptors initiate a signal transduction cascade that results in neuron depolarization and transmission of the signal to the brain (Fig. 1). In most olfactory sensory neurons, detection of a cognate odor ligand alters the confirmation of the OR to activate a specialized heterotrimeric ▶ guanine nucleotide binding protein (Gαolf) (Bakalyar and Reed 1991; Dhallan et al. 1990; Jones and Reed 1989) which converts guanosine tri phosphate (GTP) to guanosine di phosphate (GDP). GTP-bound Gαolf stimulates adenylate cyclase III (ACIII) to produce secondary messenger cyclic adenosine monophosphate (cAMP); and cAMP regulates

a heteromeric calcium channel composed of cyclic nucleotide gated (CNG) channels alpha 2 (CNGA2), alpha 4 (CNGA4), and beta 1b (CNGB1b) to permit entry of calcium ions. Calcium entry subsequently gates a chloride channel resulting in the efflux of chloride ions to depolarize the sensory neuron (Brunet et al. 1996; Song et al. 2008). Neural depolarization transmits the sensory signal to second-order neurons in the olfactory bulb in the brain. In addition to these canonical mechanisms, there are specialized subsets of sensory neurons in the MOE that alternatively signal through the transient receptor potential channel (TrpM5), or utilize cyclic guanidyl mono phosphate (cGMP) produced by the expression and activation of a membrane-receptor guanylyl-cyclase (GC-D). The smell of an odor is rapidly sensitizing. This is due, in part, to signaling events in the sensory neuron as activated olfactory signal transduction molecules are targeted for negative feedback regulation. Calcium and calcium-binding protein, calmodulin (CaM), bind and close the CNG channels. Calcium/Calmodulin (Ca/CaM)-dependent protein kinase II phosphorylates ACIII, reducing cAMP production. Desensitization of the odorant receptors appears to occur through phosphorylation by G protein–coupled receptor kinase 3 (GRK3) interaction with β-arrestin2 (Mashukova et al. 2006).

Olfactory Receptor Choice: The Singularity of OR Gene Expression

A remarkable property of the olfactory system is the ability to detect and distinguish among a seemingly endless variety of odor molecules. To achieve this precise discrimination, each individual olfactory sensory neuron expresses only one of the many OR genes present in the genome. Indeed this has been referred to as the "one neuron-one receptor" rule. Expression of a single OR dedicates each sensory neuron is responsive only to the cognate ligands of the expressed receptor, and sensory neurons that express different receptors display differential response profiles to odor ligands. The mechanisms that enable a neuron to activate the expression of a single receptor, and additionally silence all other OR loci distributed across the genome, are only partially understood. Recent whole genome chromatin immunoprecipitation analysis suggests that MOE neurons initially employ a distinct type of methylation of OR loci to generate heterochromatin silencing of all ORs. In a second step, one receptor reverses this silencing. The choice of which particular OR gene will be expressed in each neuron is thought to be largely a random process. However, each OR is restricted to a stereotypic expression "zone" in the MOE which may be regulated by zone-specific transcription factors. *OR* genes are polyallelic, and analysis of the expression of maternal and paternal genes have revealed that only one allele is expressed per neuron. This allelic exclusion simplifies the mechanistic challenge of coordinating receptor activation between both alleles and further increases the ability of genetic variation to functionally diversify odorant detection. Activation of the chosen receptor requires physical interaction of the OR promoter with a *cis*-acting locus control region (LCR). For one of the OR clusters, containing mouse olfactory receptor28 (MOR28), the LCR known as the "H-region," was identified as a 2.1 kb noncoding sequence that is evolutionary conserved between mouse and human. Deletion of the H-region abolishes the expression of MOR28 *OR* genes. Other LCRs that act in *cis* to regulate the expression of ORs within a cluster, or in *trans* to coordinate receptor choice across the genome, are still largely unknown. Additional experiments with transgenes have shown that if the chosen receptor cannot produce a functional protein (either through a frameshift or a deleltion) a second receptor will be activated. This suggests that the OR protein itself generates a negative feedback signaling to ultimately repress the activation of additional ORs. How functional ORs repress expression of additional ORs in olfactory sensory neurons remains unknown as mutating an ORs ability to activate G-protein mediated signaling has no effect on OR negative feedback regulation. Future experiments will be necessary to uncover the mechanisms that stabilize the expression of one receptor.

Role of ORs in Axon Pathfinding

Olfactory sensory neurons that express the same OR converge in specific neuropil, called glomeruli, in the olfactory bulb in the brain. Sensory neurons use both dorsal/ventral and anterior/posterior coordinates to

direct their axons to the correct glomeruli. While the general process of receptor choice is stochastic, each OR is expressed in a stereotypic "zone" within the olfactory epithelium. The mechanisms that regulate this zonally restricted anatomic organization have not been identified; however, the positional organization of ORs correlates with the expression of complementary gradients of guidance molecules including Robo-2, Neuropilin-2 (Nrp2), and Sema-3f in the sensory neurons. Corresponding gradients of Slit-1 and Slit-3 are present in the olfactory bulb thereby creating a topographic organization of glomeruli along the dorsal/ventral axis that mirrors the general spatial organization of ORs in the MOE (Cho et al. 2007).

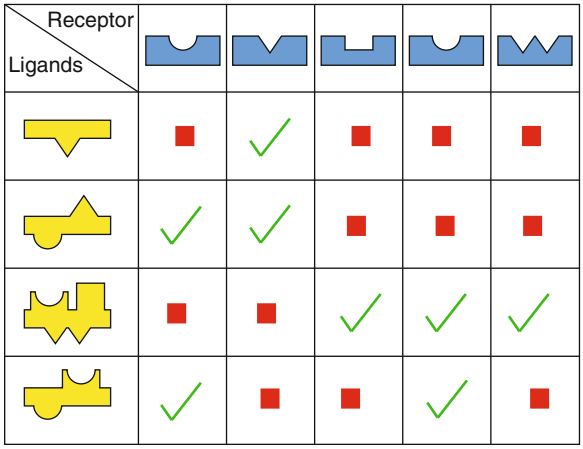
In contrast to these genetically determined mechanisms, an elegant series of experiments has shown involvement of an activity driven mechanism, signaling from the OR itself, to direct anterior/posterior axon guidance. The first indication of this arose from generation of mice in which pairs of genomic OR coding regions were swapped. These mutant mice displayed OR-driven mis-localization of their glomeruli. Moreover, OR protein was found to be localized to the axon terminus; a pivotal position to direct axon guidance. How do ORs guide axons? Key insights came from the observation that ORs mutant in Gs signaling failed to form proper glomeruli. Complementary studies of constitutively active Gs and PKA mutants indicate that high levels of OR-mediated cAMP directs axons to the posterior, while low cAMP levels directs axons to the anterior. cAMP levels directly correspond to the transcription of neuropilin-1 (Nrp1) an axon guidance molecule. Nrp1 and Sema3A expression levels form complementary anterior/posterior gradients in olfactory neurons. Axon–axon interactions are thought to sort and organize neurons as they develop toward their targets (Imai et al. 2009). While these mechanisms account for general axon targeting, it is thought that OR-mediated cAMP signaling additionally further refines glomerular patterning. Levels of neuronal activity regulate additional sets of axon guidance and adhesion molecules including Kirrel2, Kirrel3, EphA5, and ephrin-A. The repulsive and adhesive effects of these molecules are thought to promote homotypic formation of individual glomeruli (Serizawa et al. 2006). The mechanism of how individual ORs generate differential levels of cAMP activity that can distinguish the position of neighboring glomeruli remains to be understood.

The Combinatorial Code of ORs to Encode Odor Identity

How do the repertoire of ORs (390 in humans or 1,468 in mice) discriminate a seemingly endless array of odor ligands? Elegant experiments have shown that ORs can respond to a variety of structurally distinct odor molecules (Fig. 2) (Malnic et al. 1999). Each neuron (and therefore OR) is not tuned to the entire ligand per se, but instead is responsive to molecular features of the given ligand, such as the carbon chain length or functional group components of the odor molecule. Therefore, an individual OR can detect many ligands that differ in overall structure as long as they share a common molecular feature recognized by the OR. Moreover, this principle results in each ligand activating multiple receptors each able to bind different features of the molecule's overall structure. Pure ligands have been shown to activate approximately 10% of the expressed ORs. This distributed activity is referred to as the "combinatorial code" of odor processing. Assuming that the OR repertoire is able to detect a large variety of molecular features, this strategy would enable the detection of potentially unlimited number of odor molecules. The combinatorial coding strategy immediately deconstructs each odorant at the sensory receptor interface and because this information is separated into anatomically distinct glomeruli in the olfactory bulb, each odorant generates multiple lines of distinct activity processed in parallel. How this information is ultimately bound into an odor percept is still unknown.

Other Olfactory Receptors

In addition to the ORs, the main olfactory epithelium also expresses a family of trace amine receptors (TAARs) which have been shown to detect volatile amines (Liberles and Buck 2006). Additionally most vertebrates have an accessory olfactory system, the vomeronasal organ (VNO), which is physiologically and morphologically distinct from the main olfactory epithelium. The VNO has been shown to express at least three classes of chemosensory receptors that are evolutionarily distinct both from the odorant receptors and from each other: vomeronasal receptors class I (V1Rs, Vmn1Rs) (Dulac and Axel 1995), vomeronasal receptors class II (V2Rs, Vmn2Rs) (Herrada and Dulac



Olfactory Receptors, Fig. 2 Combinatorial receptor codes for odors. *Green* tick mark shows receptors (*top panel*) that recognize odorants (*left panel*). The identity of each odor molecule is encoded by a unique combination of receptors. Each receptor can act as one component of the combinatorial code for more than one odor molecule. This model allows for the recognition and discrimination of almost unlimited number and variety of odor molecules

1997; Matsunami and Buck 1997; Ryba and Tirindelli 1997), and formyl peptide receptors (FPRs) (Liberles et al. 2009; Riviere et al. 2009). GPCRs expressed in the VNO are thought to largely detect volatile and peptide pheromonal ligands that mediate social behaviors like courtship, territorial aggression, gender and individual recognition, maternal aggression, and interspecies defense (Bean and Wysocki 1989; Chamero et al. 2007; Del Punta et al. 2002; Haga et al. 2010; Kimoto et al. 2005; Leinders-Zufall et al. 2000; Papes et al. 2010; Wysocki and Lepri 1991).

Summary

Environmental odor cues are detected by hundreds of seven-membrane-spanning odorant receptors, expressed in the olfactory system. These olfactory receptors can be broadly classified into type I and type II, type I being evolutionarily more ancient and conserved. On binding odors, ORs can signal through a canonical pathway involving cAMP second messenger that regulates the activity of the CNG channel, depolarizing the neurons. Additionally there are other noncanonical signal transductions involving TrpM5 or cGMP. Each olfactory neuron expresses a specific receptor and activation of different combinations of receptors by an odor or mixture of odors helps an organism to distinguish an endless repertoire of chemicals.

Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function

Vladana Vukojević, Yu Ming and Lars Terenius
Department of Clinical Neuroscience,
Karolinska Institute, Stockholm, Sweden

Synonyms

Nociceptin opioid receptor; δ-opioid receptor; κ-opioid receptor; μ-opioid receptor

Historical Background

The existence of opioid receptors (OR) was postulated in 1954 (Beckett and Casy 1954), at a time when evidence for specific drug-responsive substances was evasive and the concept of biochemical receptors was still in its infancy. Unequivocal confirmation of specific binding sites for opioids in the brain was first reported in 1973 (Pert and Snyder 1973; Simon et al. 1973; Terenius 1973). This breakthrough was shortly followed by evidence that opioid ligands bind specifically to different anatomical locations and show different pharmacological activity, suggesting that several types of opioid receptors exist (Martin et al. 1976; Lord et al. 1977). Based on extensive pharmacological and animal model studies that followed, opioid receptors were originally classed in four types: mu (μ), kappa (κ), sigma (σ) and delta (δ). They were named after specific ligands used for their characterization: μ after morphine, κ after ketocyclazocine, and σ after SKF-10047, whereas the δ-opioid receptor was

identified in mouse and named after the thick-walled tube in the male reproductive system that transports sperm cells from the epididymis (called *vas deferens*) in which it was characterized (Lord et al. 1977). The ultimate proof for opioid receptor existence and partitioning into different types was provided by the isolation of mouse δ-opioid receptor mRNA, leading to cDNA synthesis and receptor cloning (Kieffer et al. 1992; Evans et al. 1992). Subsequent studies have led to the identification of receptor sequences for the μ and κ opioid receptors, dismissed the σ-opioid receptor from the opioid receptor family, and revealed the existence of an unknown sequence that was similar to opioid receptors but differed in opioid ligand binding. This "opioid receptor-like" (ORL) or nociceptin/orphanin (N/OFQ) protein remained an "orphan" receptor until its corresponding endogenous peptide ligand nociceptin/orphanin FQ was identified in 1995 (Meunier et al. 1995; Reinscheid et al. 1995). It is nowadays commonly regarded that the opioid receptor family contains four types, the classical opioid receptors μ, δ, and κ, and the nonclassical nociceptin opioid receptor. The Committee on Receptor Nomenclature and Drug Classification of the International Union of Basic and Clinical Pharmacology (IUPHAR) has recommended that μ, δ, κ and nociceptin opioid receptors should be denoted as MOP, DOP, KOP, and NOP, respectively.

Opioid Receptor Relevance

Opioid receptors MOP, DOP, KOP, and NOP, and their respective peptide ligands endorphins, enkephalins, dynorphins, and nociceptin/orphanin constitute the endogenous opioid neuromodulatory system. This system plays a critical role in regulating vital physiological, sensory, cognitive and emotional functions (Bodnar 2010). For example, the opioid system modulates the nociceptive pathways and plays a decisive role in substance and behavioral addiction, mental disorders, memory, learning, and response to stress. In addition, the opioid system is implicated in the regulation of the neuroendocrine, cardiovascular, gastrointestinal, renal and hepatic functions, hormonal activity, respiration, thermoregulation, and immunological responses.

Opioid receptors are also very important pharmacological targets – natural alkaloid opiates like morphine, or synthetic opiates like methadone are potent pain-killers but also highly addictive drugs. Opioid antagonists, such as naltrexone are clinically used to reduce craving in substance addiction (heroin, alcohol, and amphetamine), food abuse in obesity, and the hedonic responses in non-substance-related, that is, behavioral addictions (gambling and gaming).

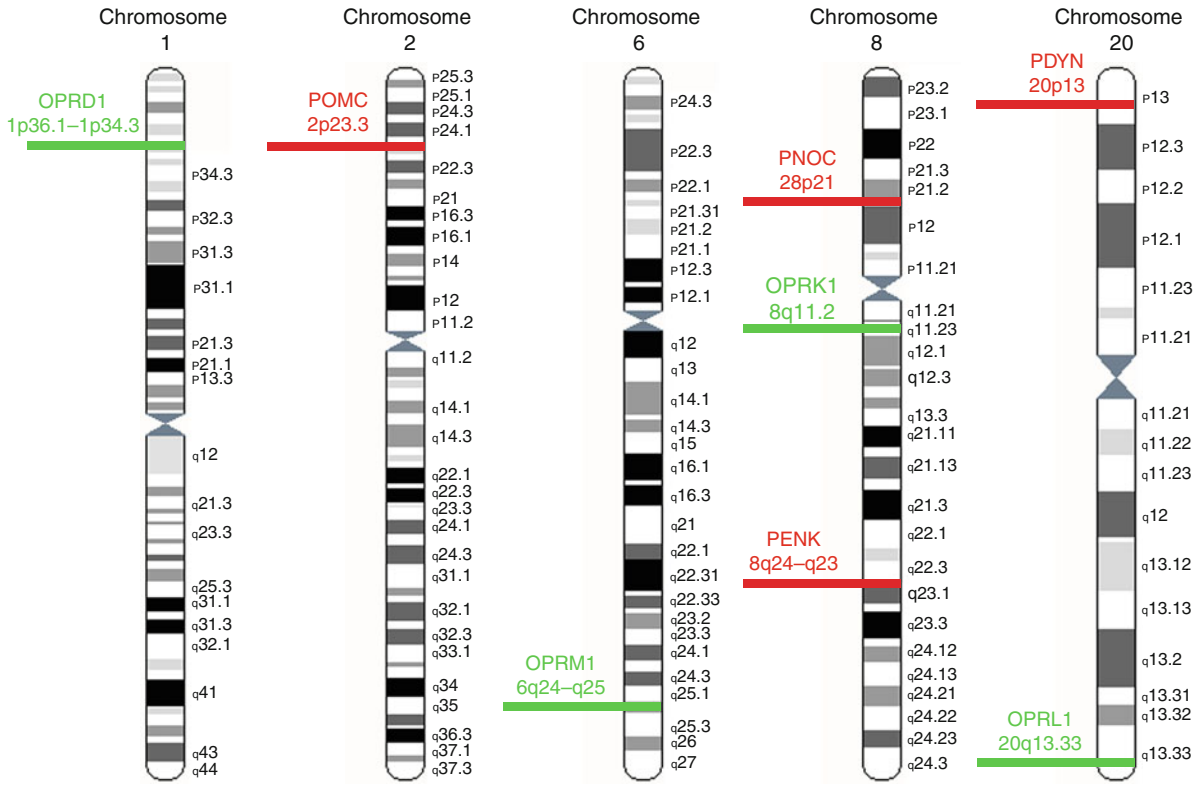
Opioid Receptor Evolution

The opioid system is an ancient neuromodulatory system. Chromosomal phylogeny studies suggest that the opioid system, with four receptor types and four opioid peptide precursors, was already present approximately 450 million years ago (Dreborg et al. 2008). These studies imply that the ancestral opioid peptide precursor and opioid receptor gene were located on the same chromosome and concomitantly duplicated in two whole genome duplication events. The first genome duplication incident yielded two genes DOP/MOP and NOP/KOP and their precursors. A second genome duplication event has led to the development of four opioid receptor types, and three opioid precursor molecules. The fourth opioid peptide precursor gene appeared to be created later on, through local gene duplication (Dreborg et al. 2008).

The opioid system, with four types of receptors and opioid peptide precursors has been identified in all vertebrate organisms, in neuronal and nonneuronal cells. In humans, opioid receptors are encoded by opioid receptor (OPR) genes: OPRM1 encoding MOP, OPRD1 encoding DOP, OPRK1 encoding KOP, and OPRL1 encoding NOP. They are located on four different chromosomes: OPRD1 on chromosome 1, OPRM1 on chromosome 6, OPRK1 on chromosome 8, and OPRL1 on chromosome 20 (Fig. 1). Opioid peptides are derived from four prepropeptide genes: the pro-opiomelanocortin (POMC), proenkephalin (PENK), prodynorphin (PDYN), and prepronociceptin (PNOC), encoding the precursors of endorphins, enkephalins, dynorphins, and nociceptin/orphanin, respectively (Fig. 1).

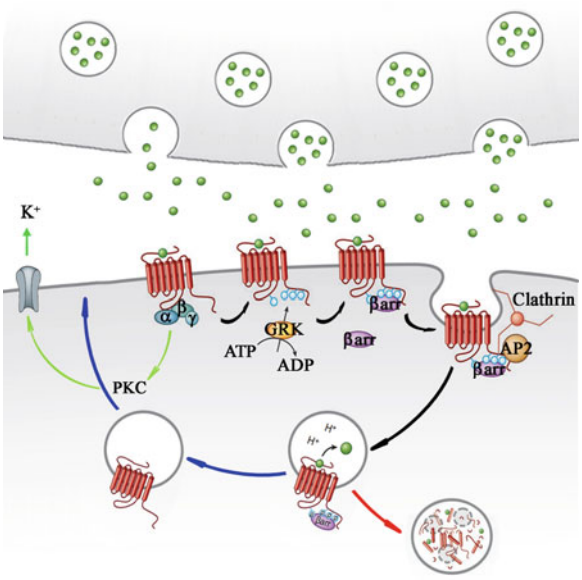
Opioid Receptor Cellular Physiology and Function

The function of opioid receptors is to transmit chemical signals across the cellular plasma membrane.



Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function, Fig. 1 Chromosomal mapping of human opioid system genes. Opioid receptors genes: OPRM1 encoding MOP, OPRD1 encoding DOP, OPRK1 encoding KOP, and OPRL1 encoding NOP sequences are located on four different chromosomes: 6, 1, 8, and 20, respectively. The opioid peptide precursors' genes: pro-opiomelanocortin (POMC), proenkephalin (PENK), prodynorphin (PDYN), and pronociceptin (PNOC) are located on three different chromosomes: 2, 8, 8, and 20, respectively. Chromosomal phylogeny studies suggest that the ancestral opioid peptide precursor and opioid receptor genes were located on the same chromosome and suggest that the current system with four opioid receptor types and four opioid peptide precursors had evolved through two whole genome duplication events, where the ancestral opioid receptor and opioid peptide precursor genes were concomitantly duplicated. Through this process all four opioid receptor genes and three opioid peptide precursor genes were derived, whereas the fourth opioid peptide precursor gene was suggested to evolve through a local duplication event (Dreborg et al. 2008). (The image is adapted using the *Ensembl* genome databases for vertebrates and other eukaryotic species as template http://Jun2011.archive.ensembl.org/Homo_sapiens/Gene/Family/Genes?db=core;family=ENSFM00500000269674;g=ENSFM00500000269674, Flicek et al. 2011)

The complex cellular physiology of opioid receptors is an integral part of opioid receptor function. In brief, the opioid receptors are assembled by ribosomes, transferred to the endoplasmic reticulum (ER), the Golgi complex, and the trans-Golgi network (TGN) and sorted into transporting vesicles. During this process, opioid receptor molecules undergo several posttranslational modifications such as disulfide bond formation, palmitoylation, acetylation, phosphorylation, and glycosylation. At the nerve termini transporting vesicles fuse with the plasma membrane, enabling opioid receptor presentation at the neuronal surface. Opioid peptides secreted by presynaptic neurons bind to opioid receptors on the postsynaptic neurons and activate the secondary messenger system (Fig. 2). Opioid receptors have no direct link with effector proteins. Instead, the message is relayed via the so-called G proteins, heterotrimeric guanine nucleotide-binding proteins –opioid receptors are therefore classed as G protein-coupled receptors (GPCR). It has been demonstrated that activation of opioid receptors may lead to the closing of voltage sensitive calcium channels (VSCC), stimulation of potassium efflux or reduced cyclic adenosine monophosphate (cAMP) production



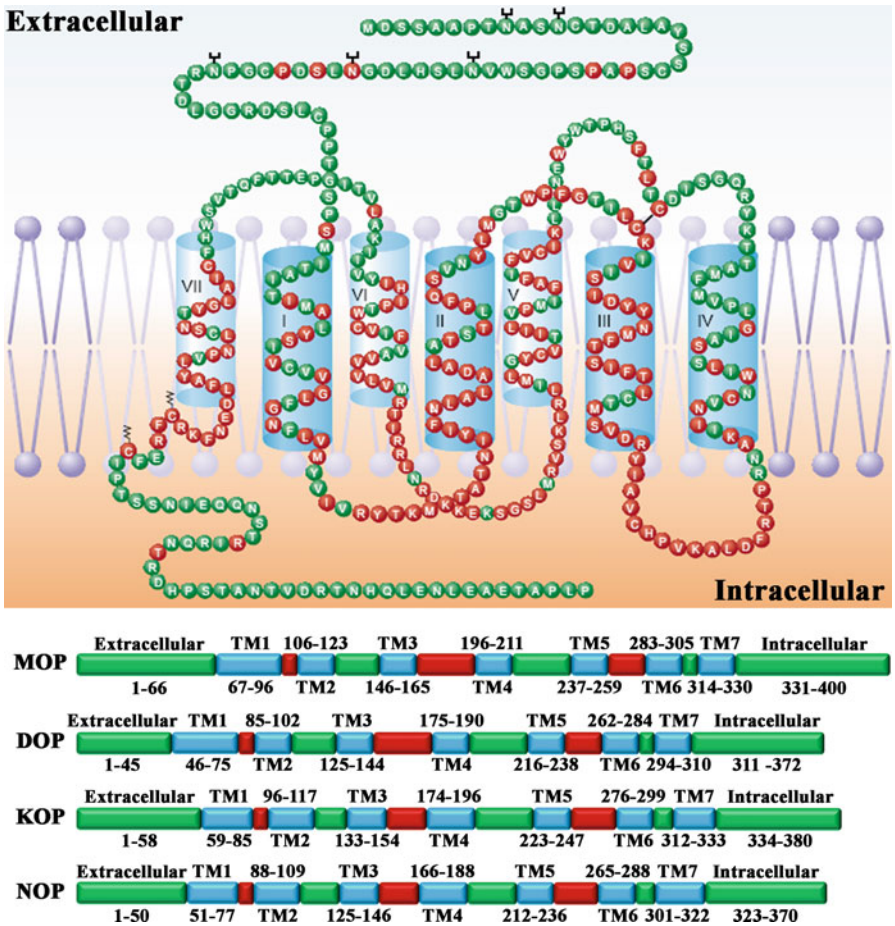
Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function, Fig. 2 Schematic presentation of a synaptic cleft with opioid receptor signaling and intracellular trafficking. Endogenous opioid ligand molecules (*green sphere*) secreted from the presynaptic neuron (on *top*) bind to an opioid receptor (*red*, far *left*) located at the postsynaptic neuron (*down*). The agonist-bound receptor initiates cellular signaling by activating the heterotrimeric G protein and causing its dissociation into α- and βγ-subunits. The subunits can activate a number of cellular responses, such as protein kinase C (PKC)-mediated enhancement of K_{ATP} channel activity (*green arrows*), whereas the agonist-bound opioid receptor devoid of the G protein rapidly undergoes phosphorylation by GPCR kinases (GRK) (*black arrows*). Selective phosphorylation of the activated receptor and subsequent binding of β-arrestin prevents further interactions of the activated receptor with G proteins and enables receptor sorting to clathrin-coated pits for receptor endocytosis, thereby effectively terminating the G protein-mediated signaling. Further sorting of endocytosed opioid receptors between divergent downstream pathways may produce additional distinct effects on cellular signaling. For example, sorting of internalized receptors to lysosomes promotes proteolytic degradation of receptors (*red arrow*), preventing receptors from signaling again and producing a prolonged attenuation of cellular signaling. In contrast, sorting of internalized receptors into a rapid recycling pathway promotes the return of intact receptors to the plasma membrane and effectively resensitizes cells to respond again to the extracellular ligand (*blue arrow*). This mechanism has been inferred from numerous studies; however, quantitative information on the cellular dynamics of opioid receptors and the kinetics of the underlying interactions is still limited (Image adapted and reprinted with permission from Hanyaloglu and von Zastrow 2008)

via inhibition of adenylyl cyclase, etc. In this way, opioid ligands cause a range of physiological and behavioral effects that are lasting several seconds to several days at the organism level (Dean et al. 2009). Selective phosphorylation of the activated receptor and subsequent binding of β-arrestin prevents further interactions of the activated receptor with G proteins and enables receptor sorting to clathrin-coated pits for receptor endocytosis, thereby effectively terminating the G protein-mediated signaling (Fig. 2).

Increasing experimental evidence supports the notion that opioid receptor cellular dynamics – the time-dependent change in receptor properties and localization in the cell, is central to opioid receptor signaling. Cellular dynamics of surface receptors is a critical factor in determining receptor availability, function, and the downstream consequences of receptor activation (Hanyaloglu and von Zastrow 2008). For example, endocytic membrane trafficking is an important regulator of opioid receptor density at the cell surface (Fig. 2). Through this dynamic process the surface density of opioid receptors and their availability for ligand activation can be controlled without modifying the overall number of receptors through receptor synthesis (up- or downregulation). Opioid receptor ligands differ in their ability to induce receptor trafficking. For example, opioid peptides such as DAMGO cause internalization of MOP, whereas the alkaloid morphine produces little MOP internalization.

Opioid Receptor Structure

The crystal structures of opioid receptors are not yet determined. Therefore, opioid receptor's structures and structural requirements for ligand binding and selectivity have to be assessed indirectly, using methods such as site-directed mutagenesis, affinity labeling, and chimeric receptor design. In addition, computational techniques enabling homology modeling are used in order to predict the three-dimensional (3D) receptor structure and the possible binding sites for different ligands (docking studies). Over the years, these methods have been successfully used to build realistic models of the opioid receptors primary, secondary, and tertiary structures in their native environment, the cellular plasma membrane and identify the key contacts in ligand recognition sites (Kane et al. 2006). These studies have shown that opioid receptors are integral, rhodopsin-like proteins



Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function, Fig. 3 Opioid receptor structure. Schematic drawing of human MOP structure. Amino acids conserved between human MOP, DOP, and KOP are indicated in red. Putative asparagine-linked glycosylation sites in the extracellular N-terminus and alleged palmitoylation sites at cysteine residues in the C-terminus are indicated. A potential intramolecular disulfide bond between cysteine residues in extracellular loops 1 and 2 is also shown. The sites for opioid ligand binding are not unequivocally determined, but the role of Asp in the third transmembrane domain (TM3:08) and His in the sixth transmembrane domain (TM6:17) have been repeatedly shown to be relevant for opioid ligand binding. The large intracellular loop between TM5 and TM6 is presumed to be the contact site with the G-protein α-subunit. A schematic representation of the secondary structure all for types of opioid receptors is presented below

that span the plasma membrane by seven helical transmembrane (TM) domains (Fig. 3). Opioid receptor types show a high sequence identity in their transmembrane (TM) domains (about 75%) and the cytoplasmic loops (about 65%), whereas the sequence identity in the N- and C-terminal domains and extracellular loops appears to be rather modest (about 37%). The sites for opioid ligands binding are not unequivocally determined, but the role of Asp in the third transmembrane domain (TM3:08) and His in the sixth transmembrane domain (TM6:17) have been repeatedly shown to be relevant for opioid ligands binding. The large intracellular loop between TM5 and TM6 is presumed to be the contact site with the G-protein α-subunit.

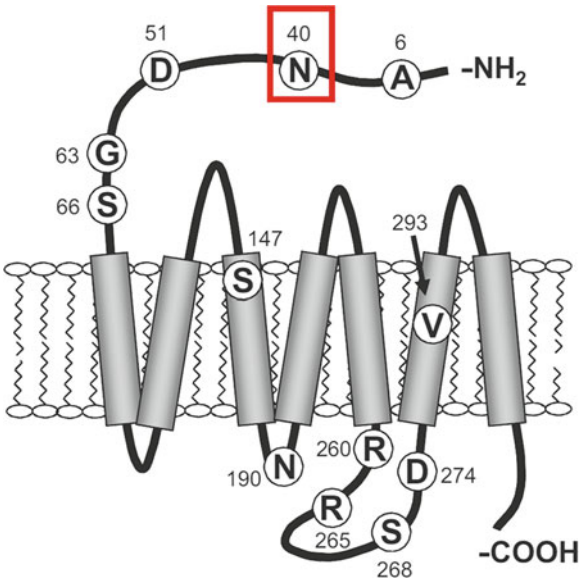
Opioid Receptor Isoforms

Naturally occurring differences in opioid receptor primary structure can alter opioid receptor binding properties and signaling, thereby predisposing for susceptibility to disease and receptiveness to therapy.

Two principle mechanisms through which opioid receptor variants are generated are missense mutations and alternative splicing.

In missense mutations, a single nucleotide is changed yielding a protein molecule with only one amino acid different. To this point, 18 missense mutations have been identified in the human MOP gene OPRM1, with 12 missense mutations occurring naturally at a frequency >1%. Consequences of the most commonly occurring missense mutations in the OPRM1 gene on MOP primary structure are schematically depicted in Fig. 4. For example, the N40D polymorphism (Fig. 4, highlighted in red) is suggested to be related with improved response to naltrexone, an opiate antagonist used clinically for treating addiction to opiate drugs and alcohol (Anton et al. 2008).

Splicing is a regulated modification of the pre-mRNA, generated by gene transcription in which introns are removed and exons are joined. Alternative splicing of pre-mRNA may result in the creation of different mRNAs, which may be translated into opioid receptor isoforms differing in several amino acids. So far, at least 6 alternative splicing variants of hMOP have been described (Pan et al. 2003).



Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function, Fig. 4 MOP variants generated by naturally occurring missense mutations. Schematic drawing of MOP structure with alterations in amino acid sequence due to the 12 most frequently encountered missense mutations. The N40D polymorphism (Fig. 4, highlighted in *red*) is suggested to be related to improved response to naltrexone, an opiate antagonist used clinically for treating addiction to opiate drugs and alcohol 2006; Fortin et al. 2010)

Opioid Receptor Oligomerization

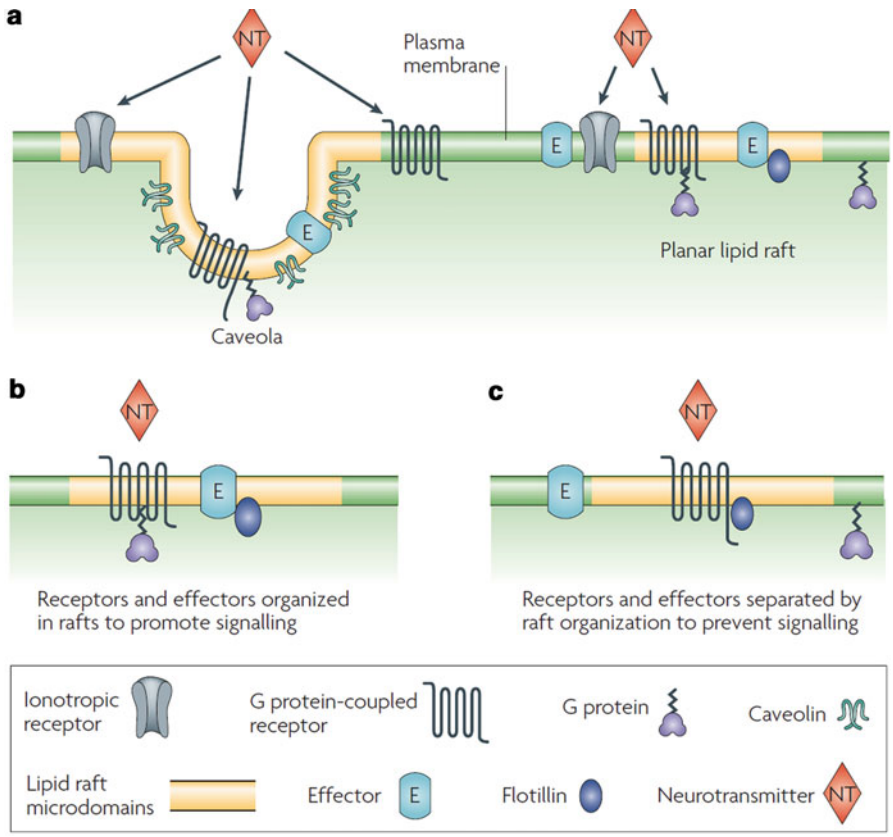
Surface receptor oligomerization is a common way to increase the functional repertoire of the receptor and represents a key regulatory step in the function of several GPCRs (Milligan 2010). In addition, receptor oligomerization may be a critical step for rapid "fine-tuning" of receptor density at the plasma membrane. The dynamic equilibrium between monomers and oligomers can be changed quickly in one direction or the other, rendering the receptor available/not available for the ligand (Vukojević et al. 2008). Opioid receptor homo- and hetero-oligomerization has been inferred from a variety of studies, however quantitative information on the cellular dynamics of opioid receptor dimers is still limited and many molecular details of the oligomerization process have yet to be resolved.

Opioid Receptor Association with Lipid Rafts

The cellular dynamics and function of opioid receptors can be significantly affected by its micro-environment in the cell membrane. The plasma membrane is highly organized into structurally and functionally distinct microdomains. Opioid receptors, G-proteins and signaling effectors, such as second-messenger-generating enzymes appear to be primarily localized to membrane microdomains called lipid rafts (Fig. 5) (Baker et al. 2007). Disruption of lipid rafts may alter the binding properties and signal transduction of opioid receptors localized in rafts. For example, it has been shown that disruption of lipid rafts in rat caudate putamen membranes decreased the E_{max} values of both DAMGO and morphine at MOP without affecting their EC_{50} (Huang et al. 2008).

Summary

The opioid neuromodulatory system is a dynamic, spatiotemporally organized structure comprising signaling circuitries at different levels of organization – the cellular, organ, and organism levels. The opioid



Opioid Receptors: Cellular and Molecular Mechanisms Underlying Opioid Receptor Function, Fig. 5 Schematic representation of lipid raft's role in opioid receptor function. (**a**) Lipid rafts are cholesterol- and sphingolipids-enriched submicroscopic assemblies about 25–100 nm in diameter, which are spontaneously generated in the plasma membrane. In mammalian cells, these dynamic assemblies can be planar or flask-shaped invaginations of the plasma membrane to which signaling and effectors molecules, such as opioid receptors, G proteins, and second-messenger generating enzymes may be located forming functional signaling units. (**b**) The lipid raft signaling hypothesis proposes that signaling molecules are spatially organized to promote kinetically favorable interactions that are necessary for signal transduction. (c) Alternatively, lipid raft microdomains might inhibit interactions by separating the signaling molecules, thereby dampening signaling responses image reprinted permission from Allen et al. 2007)

system is implicated in the regulation of physiological, sensory, cognitive, and emotional functions. The importance of the opioid system for normal physiology is well accepted and drugs addressing this innately complex system have been used for centuries recreationally and for medical purposes. In spite of this vast experience, competence in opiate pharmacotherapy, and intensive research, the opioid system function is not fully understood and it is still not known how to control the potentially deleterious effects of opioids – given the importance of the opioid system it is not surprising that drugs addressing it show numerous unwanted side effects, such as inhibition of gastrointestinal motility, respiratory depression, muscle rigidity, altered thermoregulation, sedation, dependence, and abuse.

This review summarizes current understanding of the cellular and molecular mechanisms underlying opioid system function, with a focus on the opioid receptor role in cellular signaling. In our opinion, the most pertinent information still missing are the 3D structures of opioid receptors at atomic resolution, quantitative information on the kinetics of opioid receptor interactions in living cells, opioid receptors organization in the plasma membrane, and cellular trafficking dynamics.

The necessity of knowing the 3D receptor structure is obvious from the notion that structure determines

selectivity. In addition, the 3D opioid receptor structure is expected to shed more light on an unusual feature of the MOP receptor, its potential to successfully accommodate and elicit a specific response to more than dozens of compounds differing largely in chemical composition and reactivity.

Cellular mechanisms are essential for understanding opioid receptor function because drug-induced signals are converted in long-term alterations in cellular function at this level of organization. Changes in opioid receptor organization in the plasma membrane and altered cellular trafficking may be the first steps in a cascade of events leading to remodeling of opioid cellular signaling circuits, and eventually to altered behavior, drug-seeking, and compulsive use. Such changes at the neuronal level may even underlie long persistence of addiction and risk for relapse. Quantitative studies of opioid receptor function at the molecular and cellular levels are therefore of relevance for understanding the integral opioid system function. Such studies may also deepen our understanding of the opioid system role in development of tolerance and addiction, adaptive transformations specific for MOP-mediated signaling pathways that are largely restricting the useful clinical application of opiates.

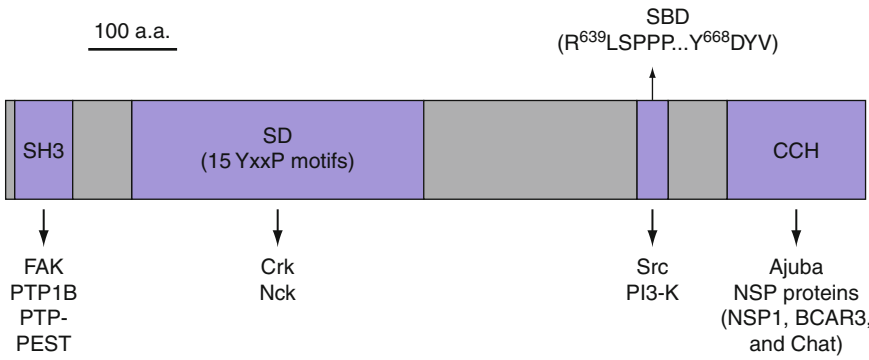
Synonyms

Breast cancer antiestrogen resistance protein 1 (BCAR1); Cas scaffolding protein family member 1 (CASS1); Crk-associated substrate (CAS)

Historical Background

p130Cas is a major substrate of the ► Src tyrosine kinase that functions in integrin signaling to promote cell motility, invasion, proliferation, and survival (reviewed by Defillipi et al. 2006; Tikhmyanova et al. 2010). p130Cas was first recognized in the late 1980s by immunoblot detection with an anti-phosphotyrosine antibody in cells transformed by retroviral oncogenes v-*crk* and v-*src*. The p130 designation indicates the apparent molecular mass of ~130 kDa during SDS polyacrylamide gel electrophoresis (PAGE), and Cas is acronymic for "Crk-associated substrate." Characterization of the direct interactions of p130Cas with the v-Crk and v-Src proteins was significant in the recognition of Src homology 2 (SH2) domains as phosphotyrosine-binding modules in signal transduction. p130Cas was independently identified as

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,



p130Cas, Fig. 1 The primary structure of p130Cas and major interacting proteins. The primary structure is depicted to scale with major domains emphasized. *SH3* Src homology 3, *SD* substrate domain, *SBD* Src-binding domain, *CCH* C-terminal Cas-homology. A nonexclusive list of key binding partners are indicated below the domains with which they associate. For more information on these and other p130Cas binding partners, see also the following reviews: Chodniewicz and Klemke 2004; Defillipi et al. 2006; Tikhmyanova et al. 2010

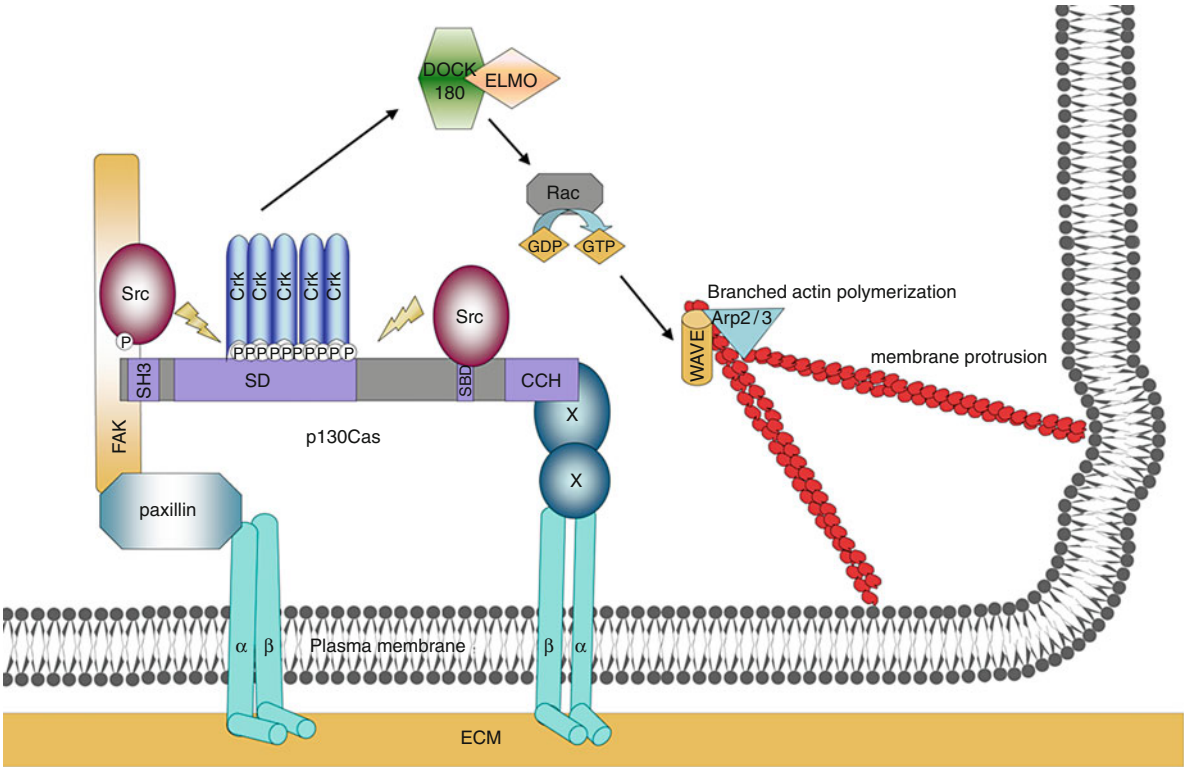
a binding partner of the integrin-associated tyrosine kinase FAK (focal adhesion kinase) (Polte and Hanks 1995). The interaction with FAK occurs by virtue of a Src-homology 3 (SH3) domain at the p130Cas N-terminus. Molecular cloning revealed that the primary structure of p130Cas includes various domains and motifs for mediating protein–protein interactions (Sakai et al. 1994; Polte and Hanks 1995), but lacks domains indicative of intrinsic enzymatic activity (Fig. 1). Hence, p130Cas is considered to be a docking or scaffolding protein in signal transduction. The molecular mass of p130Cas predicted from cDNA clones is only ~94 kDa, far less than the apparent mass by SDS-PAGE. This unusual feature of the protein suggests the presence of an extended structural component that resists full denaturation.

p130Cas is the founding member of the "Cas family" of proteins that, in mammals, also includes HEF-1/Cas-L/NEDD9, Efs/Sin, and HEPL (Tikhmyanova et al. 2010). One Cas family member is present in *Drosophila*, but there are none in yeast or *C. elegans*. All Cas family proteins have the following domain organization: an N-terminal SH3 domain, a central substrate domain (SD), and a C-terminal Cas-family homology (CCH) domain (Fig. 1). However, they appear to be functionally nonredundant due to differences in their tissue distribution and small nuances in primary structure. Of the vertebrate Cas family members, p130Cas is most widely expressed in embryonic and adult tissues. In adult tissues, highest p130Cas expression levels are in the brain, lung, intestine, kidney, and testis (Sakai et al. 1994).

Early studies implicated p130Cas as a signaling component of the focal adhesion protein complex that assembles at sites of integrin-mediated cell adhesion to the extracellular matrix (ECM). Focal adhesions are major cellular sites of tyrosine kinase signaling, in addition to their functions in establishing the transmembrane linkage between the ECM and actin cytoskeleton. Like its binding partner FAK, p130Cas localizes prominently to focal adhesions where it undergoes tyrosine phosphorylation in response to cellular adhesion and contractile force generation. Both the SH3 and CCH domains have important functions in targeting p130Cas to focal adhesions (Donato et al. 2010). FAK aids in the recruitment of p130Cas to focal adhesions via interactions made by the p130Cas SH3 domain (Donato et al. 2010). The CCH region of p130Cas is known to bind NSP family proteins (NSP1, NSP2/AND-34/BCAR3, NSP3/Chat/Shep-1) as well as a zyxin family member Ajuba, but none of these proteins are implicated in p130Cas focal adhesion targeting. They may, however, play a role in targeting p130Cas to plasma membrane ruffles and protrusions.

Regulation of p130Cas Tyrosine Phosphorylation

Despite the direct interaction with FAK, tyrosine phosphorylation of p130Cas has been attributed largely to the kinase activity of Src (Ruest et al. 2001). Nevertheless, FAK has a role in promoting p130Cas tyrosine phosphorylation by serving as a scaffold in the



p130Cas, Fig. 2 Schematic of p130Cas pro-motile signaling through the Crk-Rac pathway. Docking of p130Cas at focal adhesions allows the SD to be efficiently tyrosine phosphorylated by Src and then recruit SH2-adaptor proteins including Crk. Focal adhesion localization of p130Cas is mediated by the SH3 and CCH domains. The CCH-binding partner(s) regulating p130Cas association with focal adhesions is yet unknown. Coupling of p130Cas/Crk is associated with enhanced Rac activity via Crk association with the guanine nucleotide exchange factor complex DOCK180/ELMO. Rac is a member of the Rho family of small GTPases and is known to promote branched actin polymerization through the Arp2/3 complex

recruitment of Src to p130Cas (with the p130Cas SH3 domain bound to FAK proline-rich motifs and the Src SH2 domain bound to the FAK autophosphorylation site). The Src SH3 and/or SH2 domains can also bind directly to motifs near the p130Cas C-terminal region termed the "Src binding domain" (SBD), further contributing to tyrosine phosphorylation of p130Cas in integrin signaling (Fig. 2).

Major sites of p130Cas tyrosine phosphorylation reside in the SD, which is defined by 15 scattered Tyr-x-x-Pro (YxxP) motifs. From phospho-proteomics studies, all but one of the YxxP tyrosines have been detected as in vivo phosphorylation sites. Most notable are nine major sites within Tyr-Asp-x-Pro (YDxP) motifs, where tyrosine phosphorylation generates optimal binding sites for SH2 domains of Crk and Nck adaptor proteins (Shin et al. 2004). Crk and Nck proteins are the best-characterized downstream effectors in p130Cas-mediated signaling pathways.

Cellular stretching enhances tyrosine phosphorylation of the p130Cas SD in focal adhesions, and mechanical extension of the SD increases the accessibility of SD tyrosines for phosphorylation by Src (Sawada et al. 2006). These observations implicate p130Cas SD tyrosine phosphorylation in the process of mechanotransduction whereby cells sense a physical force and initiate a biochemical response. While the tertiary structure of the SD is undetermined, intramolecular interactions within the SD may maintain a conformational state wherein the YDxP tyrosine hydroxyl groups are hidden from Src until exposed by traction forces. The unique structural properties of the SD also appear to account for the retarded SDS-PAGE mobility of p130Cas, since deletion of this domain results in a protein that migrates according to the predicted molecular mass.

In addition to integrin-mediated cell adhesion, many studies have shown that p130Cas tyrosine

phosphorylation occurs in response to ligand stimulation of various receptor tyrosine kinases and G-coupled protein receptors (see Tikhmyanova et al. 2010 for more details). In many of these cases, p130Cas phosphorylation may be a secondary response brought about by increased cellular contractility.

Tyrosine phosphorylation of the p130Cas SD is rapid and greatly enhanced upon inhibition of cellular tyrosine phosphatases, indicating a signaling transience subject to negative regulation by phosphatases. p130Cas has been characterized as a substrate of several tyrosine phosphatases including PTP1B, PTP-PEST, RPTP-α, and SHP-2. PTP1B and PTP-PEST bind the p130Cas SH3 domain.

Critical Roles for p130Cas in Development

As a major signaling component in focal adhesions, it is not surprising that p130Cas is critical for many aspects of development. Heart and brain development are two well-documented examples. *Cas* −/− mice die at embryonic day 12.5 due to severe cardiac abnormalities (Honda et al. 1998). In the myocardium of *cas* −/− embryos, myofibrils and Z-disks show extensive disorganization. In cultured cardiac myocytes, p130Cas is prominently localized in the Z-disks where, via its interaction with FAK, it functions to regulate sarcomeric organization as well as the program of gene expression associated with hypertrophy (Kovacic-Milivojević et al. 2001).

Cas −/− mouse embryos exhibit an overall growth retardation, and have decreased brain size. p130Cas is expressed to particularly high levels in the developing cerebellum, and p130Cas tyrosine phosphorylation is enriched in the growth cones of extending neurites (Huang et al. 2006). Impairment of p130Cas expression or SD tyrosine phosphorylation in cultured cerebellar granule cells results in defects in growth cone elongation (Huang et al. 2006). The *Drosophila* p130Cas homolog was similarly shown to function in integrin-dependent neurite outgrowth and axon guidance during development (Huang et al. 2007), indicating conserved neuronal functions of Cas family proteins.

The above studies indicate a general role for p130Cas in mediating actin cytoskeletal rearrangement in various settings. *Cas* −/− mouse embryo fibroblasts (MEFs) also have defects in actin organization and cell motility (Honda et al. 1998), and these cells have been instrumental to understanding p130Cas-activated signaling events impacting the actin cytoskeleton.

p130Cas Signaling Functions Leading to Enhanced Cell Motility

The requirements for p130Cas functional domains in promoting cell motility have been evaluated through expression of wild-type versus mutational variants in *cas* −/− MEFs (Shin et al. 2004; Donato et al. 2010; Meenderink et al. 2010). These studies demonstrated that p130Cas functions to enhance cell motility, while also showing requirements for all major p130Cas functional domains (SH3, SD, SBD, and CCH). Mutation or deletion of any of the domains has a negative impact on tyrosine phosphorylation of the SD, which is a key signaling function of p130Cas in cell motility. The small adaptor proteins Crk and Nck, which bind to tyrosine phosphorylated motifs in the SD, have been implicated in p130Cas-motility responses. These adaptors consist essentially of SH2 domains (with high binding affinity for phosphorylated YDxP motifs in the SD) and SH3 domains for mediating interactions with downstream effector proteins. Most notably, p130Cas coupling to Crk adaptors (Crk-II and Crk-L) has been implicated in promoting plasma membrane protrusion by activating Rac1 GTPase via a Crk SH3 domain interaction with the guanine nucleotide exchange factor complex DOCK180/ELMO (reviewed in Chodniewicz and Klemke 2004). Activated Rac1 can promote membrane protrusion by activating the Arp2/3 complex to stimulate branched actin polymerization (Fig. 2). The p130Cas-Crk-Rac pathway has been implicated in other actin-mediated cellular processes, including the phagocytosis of the pathogenic bacteria *Yersinia* (reviewed in Tikhmyanova et al. 2010). Nck adaptors (Nck1 and Nck2) can also promote Arp2/3 complex activation via the interaction of their SH3 domains with other proteins including N-WASP and ▶ Pak1. The interaction of p130Cas with Nck adaptors has been linked to cytoskeletal reorganization and chemotaxis stimulated by platelet-derived growth factor (PDGF) (Rivera et al. 2006). It is not clear, however, if p130Cas/Nck coupling in response to PDGF stimulation occurs solely in dorsal membrane ruffles or if this coupling also has a focal adhesion signaling component.

In addition to its role in promoting plasma membrane protrusion via coupling to Crk and/or Nck, p130Cas has another role in cell motility to sustain the disassembly of mature focal adhesions (Meenderink et al. 2010). SD tyrosine phosphorylation was implicated in the focal adhesion disassembly process, while the SBD was also found to have a role in this process distinct from its ability to promote SD phosphorylation (Meenderink et al. 2010). These observations emphasize two distinct signaling functions of p130Cas: (1) SD tyrosine phosphorylation to recruit SH2-containing effectors and (2) SBD-mediated activation of Src (and possibly other signaling proteins that bind to this site) to act on substrates other than p130Cas.

p130Cas and Cancer

While p130Cas is essential to normal developmental processes, elevated p130Cas expression and/or SD tyrosine phosphorylation is seen in various forms of cancer and is likely to contribute to the malignant progression of these diseases (reviewed in Defillipi et al. 2006; Tikhmyanova et al. 2010). A role for p130Cas in invasive and metastasic cell behavior was demonstrated in studies of Src-transformed fibroblasts, where the formation of invasive structures called podosomes, activation of matrix-degrading metalloproteases, and experimental metastasis were all shown to be greatly reduced in the absence of p130Cas SD tyrosine phosphorylation (Brabek et al. 2005). The p130Cas-Crk-Rac1 pathway is implicated in both plasma membrane protrusion and cell survival during invasion (reviewed in Chodniewicz and Klemke 2004).

Much attention has been directed to the role of p130Cas in breast cancer. In breast cancer patients, high p130Cas levels are associated with a poor response to tamoxifen therapy, early disease recurrence, and lower long-term survival (for details, see Dorssers et al. 2001; Tikhmyanova et al. 2010). In mouse transgenic studies, p130Cas overexpression in mammary gland epithelia was associated with hyperplasia and, in combination with overexpression of the HER2/Neu oncogene, with shorter tumor latency (Defillipi et al. 2006). Interestingly, p130Cas was independently identified as the product of the human gene *BCAR1* that confers resistance to antiestrogen drugs (e.g., tamoxifen) in breast cancer cells (Dorssers et al. 2001). Tamoxifen is a common and effective treatment for estrogen-receptor positive (ER+) breast cancer, but patients frequently develop resistance to this treatment. The discovery that p130Cas confers tamoxifen resistance provided new mechanistic insight into antiestrogen resistance. Tamoxifen resistance conferred by p130Cas does not appear to be regulated by activation of ER target genes, but rather has been linked to Src-driven cell proliferation and survival pathways. These pathways appear to be mediated either by p130Cas-Src complexes formed with the ER where MAPK and cell cycle signaling has been implicated (reviewed in Defillipi et al. 2006; Tikhmyanova et al. 2010), or through an ER-independent pathway involving the epidermal growth factor receptor and Stat5b (Riggins et al. 2006). Other studies revealed a role for adhesion-dependent p130Cas signaling in promoting activation of the PI3K-Akt cell survival pathway in response to ER antagonism by antiestrogens (Cowell et al. 2006). Thus, p130Cas may confer antiestrogen resistance through multiple mechanisms.

p130Cas has also been implicated in the more aggressive ER-negative breast cancers. p130Cas SD tyrosine phosphorylation is commonly elevated in ER-negative breast cancer cell lines and linked to enhanced migration, invasion, and survival of ER-negative breast cancer cells (Cunningham-Edmondson and Hanks 2009).

Summary

p130Cas, first recognized as a prominent tyrosine-phosphorylated protein in cells transformed by retroviral oncogenes v-*crk* and v-*src*, is a widely expressed docking/scaffolding protein that functions as a major Src substrate in integrin-mediated signaling and mechanotransduction. p130Cas was independently identified as a FAK-interacting protein and as the product of the *BCAR1* gene that confers antiestrogen resistance in breast cancer cells. Src is recruited to phosphorylate p130Cas by directly binding to the SBD and indirectly by binding to FAK. Src phosphorylates multiple YDxP motifs in the p130Cas SD to create high-affinity binding sites for Crk and Nck adaptor proteins that act as downstream effectors in p130Cas-mediated signaling pathways. p130Cas SD

couplings to Crk and Nck are implicated in promoting leading edge actin polymerization and plasma membrane protrusion in cell motility and invasion processes. SBD-mediated binding and activation of Src is a distinct signaling function of p130Cas that may be involved in maintaining focal adhesion disassembly during cell migration. A general role for p130Cas in mediating actin and adhesion dynamics is further indicated by developmental studies showing that p130Cas deficiency causes functional defects in sarcomere organization of cardiac myocytes and neuronal outgrowth and axon guidance in the central nervous system. p130Cas expression and/or SD tyrosine phosphorylation is commonly elevated in various forms of cancer where it likely contributes to the malignant disease progression. In conferring antiestrogen resistance in breast cancer cells; p130Cas SD signaling has been linked to the activation of Src-driven cell proliferation and survival pathways.

GPR105; KIAA0001

Historical Background

Extracellular purine and pyrimidine nucleotides act as signaling molecules through the activation of P2X ion channels and P2Y G protein-coupled receptors (GPCRs) (Abbracchio et al. 2006). Among the eight members of the P2Y receptor family, four respond to extracellular uracil nucleotides: P2Y$_2$, P2Y$_4$, P2Y$_6$, and P2Y$_{14}$ receptors. None of the P2X ion channels are substantially activated by uracil nucleotides.

P2Y$_2$, P2Y$_4$, and P2Y$_6$ receptors belong to the P2Y$_1$-like subgroup of G$_q$-coupled receptors, and the P2Y$_{14}$ receptor belongs to the P2Y$_{12}$-like subgroup that couples to ▶ G protein αi to inhibit ▶ adenylyl cyclase. The P2Y$_{14}$ receptor is distributed in various tissues, that is, placenta, adipose, stomach, intestine, brain, spleen, thymus, lung, heart, placenta, mast cells, and discrete brain regions (Harden et al. 2010). It is activated by uridine-5′-diphosphoglucose (UDPG, **1**, Fig. 1), other endogenous UDP-sugars, and uridine-5′-diphosphate (UDP, **3**). The P2Y$_{14}$ receptor plays a role in the neuroimmune system, with expression occurring in T cells, dendritic cells, and hematopoietic stem cells. It is of interest in the following therapeutic areas: immune system disorders, inflammation, pain, asthma, glaucoma, and other diseases.

Originally, Chambers et al. (2000) cloned a human GPCR designated GPR105 or KIAA0001 that was found to respond to uracil nucleotide sugars, such as UDPG, but lacked a response to most other nucleotides. Soon thereafter this sequence was designated the P2Y$_{14}$ receptor, because it was recognized to belong structurally and functionally to the P2Y receptor family, which was previously known to be activated by various nucleotides other than UDPG.

Structure and Signaling Pathways

X-ray crystallographic structural information is not yet available for any of the P2Y subtypes, but sequence analysis and modeling studies predict that the general structural and functional features of the family A of GPCRs are conserved for the P2Y receptors: seven hydrophobic transmembrane (TM) domains connected by three extracellular loops (ELs) and three intracellular loops (ILs) with an extracellular N-terminus and an intracellular C-terminus. From the sequence comparison, the P2Y$_{14}$ receptor belongs to the P2Y$_{12}$-like subfamily, with a sequence identity of about 47% to the P2Y$_{12}$ receptor (human subtypes, Communi et al. 2001). There are four cysteine residues in the extracellular region of the P2Y$_{14}$ receptor forming two possible disulfide bridges: One disulfide bridge is highly conserved in the family A of GPCRs and it connects the extracellular part of TM3 with the EL2; the other putative disulfide bridge connects the N-terminus to the EL3. A recent homology model of the P2Y$_{14}$ receptor (Deflorian and Jacobson 2011) concluded that the most applicable structural template was that of the CXCR4 receptor. Residues from the extracellular regions of TM3, TM6, TM7, and the EL2 likely coordinate the ligand(s), and specifically, basic residues of TM6 (Arg253) and TM7 (Lys277), conserved among the P2Y$_{12}$-like family, are predicted to coordinate the phosphate groups of nucleotides agonists.

In model functional studies of the P2Y$_{14}$ receptor activities of nucleotide analogs, it has been convenient to use the recombinant human or rat homologue expressed in cell lines, such as COS, CHO, or HEK-293 cells (Fricks et al. 2008; Carter et al. 2009). Heterologous coexpression of a chimeric G protein that responds to G$_i$-coupled receptors allows the use of phosphoinositide hydrolysis as assay readout, but this also can affect the observed agonist efficacy. Agonist potencies of **1** - **7** were determined at the human $P2Y_{14}$ receptor; Antagonist potencies of **8** - **10** were determined in binding to the chimpanzee $P2Y_{14}$ receptor.

$P2Y_{14}$ Receptor, Fig. 1 Structures of selective $P2Y_{14}$ againsts (1–7) and antagainsts (8–11) and their potencies

lines in which a native $P2Y_{14}$ receptor occurs are: RBL-2H3 mast cells, C6 glioma, and A549 and BEAS-2B epithelial cells (Gao et al. 2010; Muller et al. 2005). Synergistic signaling of the $P2Y_{14}$ receptor has been proposed in combination with the $P2Y_6$ receptor to promote various cell functions including activation of the MAP kinase isozymes ▶ Erk1/Erk2 (Harden et al. 2010).

Physiological Role

Identification of the physiological functions of the $P2Y_{14}$ receptor has been difficult to establish, and isolated reports of the involvement in immune function, chemotaxis, differentiation, and chemokine release have appeared. Extracellular release of **1** upon trafficking of glycoproteins to the plasma membrane has been demonstrated, suggesting its widespread role in signaling (Lazarowski et al. 2003). UDP-sugars are required for glycosylation of proteins in the endoplasmic reticulum (ER) and Golgi apparatus as they are trafficked to the surface and are present there in high concentrations and dependent on specific nucleotide-sugar transporters (Sesma et al. 2009). Thrombin enhanced UDPG release (Kreda et al. 2008), and the $P2Y_{14}$ receptor was detected in platelets, but its role is undetermined. In the rodent stomach, Bassil et al. (2009) used agonists and $P2Y_{14}$ knockout (KO) mice to demonstrate differential effects of the $P2Y_{14}$ receptor in contractility and gastric emptying.

The $P2Y_{14}$ receptor has been studied in epithelial tissues. In cultured mouse uterine cells, UDPG triggered innate immunity through the production of inflammatory cytokines (Arase et al. 2009), but not all of the pharmacological observations were consistent with the $P2Y_{14}$ receptor.

The $P2Y_{14}$ receptor is endogenously expressed in RBL-2H3 mast cells (Gao et al. 2010), where it mediates degranulation, suggesting it as a potential novel therapeutic target for allergic conditions. $P2Y_{14}$ receptor agonists also induced [^{35}S]GTPγS binding to RBL-2H3 cell membranes, and phosphorylation of ▶ MAP kinases: ▶ Erk1/Erk2, P38 and JNK. UDPG **1** and selective agonist MRS2690 **2** concentration-dependently enhanced hexosaminidase release with EC_{50} values of 1,150 and 103 nM, respectively, which was blocked by pertussis toxin and significantly diminished by $P2Y_{14}$ receptor-specific siRNA. UDP was a partial agonist in RBL-2H3 cells. The $P2Y_{14}$ receptor was recently identified to be an early pivotal regulator in mesenchymal stem cell commitment and was shown to be active in adipogenic differentiation (Zippel et al. 2011).

In the central nervous system, $P2Y_{14}$ receptors are associated with astrocytes. mRNA for the receptor is prominently expressed in immune cells including neutrophils, lymphocytes, and megakaryocytic cells. The inflammatory effects of UDPG in N9 microglia are not mediated by $P2Y_{14}$ receptor activation (Brautigam et al. 2008).

UDP also activates the $P2Y_6$ receptor, and the relative degree of involvement of multiple native agonists of the $P2Y_{14}$ receptor, various UDP-sugars that originate in a vesicular compartment and UDP, is still unclear. Nevertheless, this observation led to the synthesis of a variety of UDP analogues as selective agonists.

Structure-Activity Relationship (SAR)

Depending on the model examined, UDP has been reported to either be a full agonist, a partial agonist, or a competitive antagonist at the human $P2Y_{14}$ receptor and a potent agonist at the rat $P2Y_{14}$ receptor (Carter et al. 2009). In cellular assay systems utilizing a native G protein rather than a chimeric one, UDPG (pIC50 6.5) and UDP (pIC50 6.5) are both potent agonists of the human $P2Y_{14}$ receptor.

The SAR of synthetic analogues of both UDP and UDPG has been probed at the $P2Y_{14}$ receptor. The $P2Y_{14}$ receptor appears to be one of the least permissive among P2Y receptors (Das et al. 2010). Most modifications of the nucleobase or ribose moieties abolished activity, but the glucose moiety was amenable to substitution with other sugars (e.g., UDP-galactose **4**, pIC50 6.2). Stereochemistry of this moiety influenced potency, for example, the β-glucoside was only twofold less potent than the native α-isomer. One of the few modifications of the uracil ring possible was 2-thiol, which in the analogue of UDPG (MRS2690, **2**, pIC50 7.3) increased potency by sevenfold and prevented activation of the $P2Y_2$ receptor. Stabilizing phosphonate groups have been introduced in analogues of UDP. For example, α,β-difluoromethylene-UDP, MRS2802 **5** (pIC50 7.2) is inactive at the $P2Y_6$ receptor and fully activates the human $P2Y_{14}$ receptor. MRS2905 **6** (pIC50 8.7) is of

>2,000 selective for the $P2Y_{14}$ in comparison to the $P2Y_6$ receptor.

The carboxylate group of uridine-5′-diphosphoglucuronic acid proved to be suitable for flexible substitution by chain extension through an amide linkage. This led to the design of multivalent, polymeric conjugates having greatly increased potency as $P2Y_{14}$ receptor agonists (Das et al. 2009). For this purpose, G4 (fourth-generation) through G6 polyamidoamine (PAMAM) dendrimers containing amino groups for conjugation of ligands were amide-linked to uridine-5′-diphosphoglucuronic acid moieties. High potencies in $P2Y_{14}$ receptor activation were observed in conjugates such as **7**, in which an average of 147 out of 256 amino groups were conjugated to the nucleotide.

Two classes of nonnucleotide antagonists of the $P2Y_{14}$ receptor were recently identified in high throughput screening using a FLIPR-based calcium flux assay in HEK cells overexpressing the mouse or chimpanzee $P2Y_{14}$ receptor. The dihydropyridopyrimidine derivative **8** is a $P2Y_{14}$ antagonist with good oral bioavailability and potency (pIC50 8.0), but noncompetitive with UDP (Guay et al. 2011). The 4,7-disubstituted naphthoic acid antagonists **9** and **10** (binding K_i values at the chimpanzee $P2Y_{14}$ receptor of 4 and 1.9 nM, respectively) are competitive with UDP (Gauthier et al. 2011). **10** was also derivatized through its carboxylic acid as a prodrug **11** to greatly improve bioavailability in this hydrophobic series (Robichaud et al. 2011).

Summary

The $P2Y_{14}$ receptor is a cell-surface signaling protein (G protein coupled) that is activated by extracellular uracil nucleotides and couples to inhibition of ▶ adenylyl cyclase. It occurs in the immune system, including T cells, dendritic cells, and mast cells, and in various tissues, that is, placenta, adipose, stomach, intestine, brain, spleen, lung, heart, and brain. In mast cells, this receptor promotes the release of inflammatory mediators, suggesting that it is a possible target for allergic diseases. Chemical modification of the native agonist uridine-5′-diphosphoglucose has led to novel, selective nucleotide agonists, and nonnucleotide antagonists have been derived by optimization of screening hits. UDP, which also activates the $P2Y_6$ receptor, appears to be an endogenous agonist. Multivalent, polymeric conjugates of $P2Y_{14}$ receptor agonists, based on covalent tethering through the structurally permissive glucose moiety, have been shown to greatly increase the potency in receptor activation.

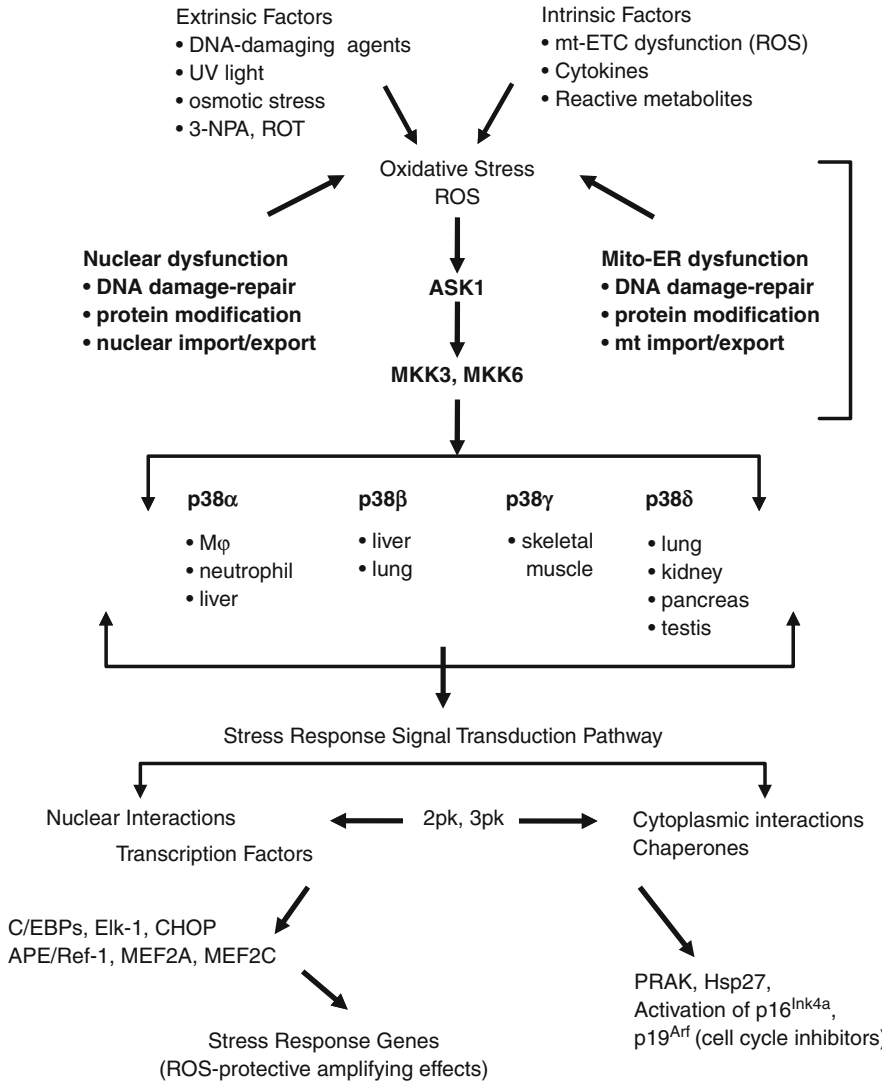
Synonyms

2-, 3pk (MAPKAPK-2, -3); CREB (cyclic AMP-responsive element-binding protein); Hsp 27 (heat shock protein 27); MAPK (mitogen activating protein kinase); MAPKAPK (MAP kinase-activated kinase); MKK (MAP kinase kinase); MKKEE (activated form of MKK6); MKKK (MAP kinase kinase kinase); MKP (MAPK phosphatase); Mnk (MAP kinase-interacting kinase); mtDNA (mitochondrial DNA); NES (nuclear export sequence); NLS (nuclear localization sequence); P-38α (phospho p38α); PRAK; ROS (reactive oxygen species); TNFα (tumor necrosis factor α)

Historical Background: The p38 MAPK Family of Stress Response Signaling

The biological transduction of physiological and environmental signals involves highly specific protein–protein interactions and posttranslational modifications that regulate both genetic and epigenetic processes in response to intrinsic and extrinsic challenges. The overall biochemical phenotype of tissues at all stages of the life cycle, i.e., growth and development, maturation, and aging are therefore consequences of those biological signaling systems that respond to intrinsic and extrinsic challenges. In mammals, the ▶ p38 mitogen activating protein kinase(p38 MAPK) family consists of α, β, γ, and δ isoforms. These isoforms are ubiquitously expressed at significantly different levels and are important factors in tissue-specific responses to growth factors, hormones, intermediates of metabolism, and environmental factors. In particular, members of the p38 MAPK family are activated by a wide variety of intracellular and extracellular signals (Fig. 1) which include such extracellular stresses as UV irradiation, oxidative stress (ROS), osmotic stress, and inflammatory cytokines. Activation of MAPK signaling leads to the regulation of gene clusters that mediate such complex biological responses as inflammation, cell proliferation, differentiation, apoptosis, senescence, and aging (Ono and Han 2000; Zer et al. 2007; Cuadrado and Nebreda 2010).

The proteins of the p38 MAPK family comprise a cascade of multiple upstream tyrosine and downstream serine/threonine kinases and phosphatases; the signals are transduced by phosphorylation events that enhance specific serine/threonine kinase activities and dephosphorylation of their catalytic sites that attenuate the signaling activities. There are numerous reviews on the structure and function of the p38 MAPK family of signaling proteins (Ono and Han 2000; Zer et al. 2007;



p38 MAPK Family of Signal Transduction Proteins, Fig. 1 A summary of the signaling pathways of the p38 MAPK isoforms. Members of the p38 family of signaling proteins are activated by a variety of intracellular (intrinsic) and extracellular (extrinsic) factors. The intrinsic and extrinsic factors are sources of oxidative stress (ROS) which activate the pathway, i.e., ASK1 – MKK3/MKK6 – p38. Activation of the p38 MAPK isoforms targets multiple physiological processes involved in the cellular response to stress. (For a more detailed presentation of proteins targeted by p38 MAPK isoforms see Cuadrado and Nebreda (2010)). The upstream tyrosine kinases that transduce signals to the ASK1 are not included in this map. (**a**) Environmental factors (UV, osmotic shock, anisomycin, rotenone, 3-nitropropionic acid, and antimycin A) activate stress response physiological processes via the p38 MAPK signaling pathway. The p38 MAPK isoforms are depicted as central components of the pathway because of their role in the translocation of signals to nuclear and cytoplasmic stress response processes. (**b**) The upstream activators of the p38 MAPK pathway are MAP kinase kinase kinases (ASK1, and MKKKs) and the MAP kinase kinases (MKKs 3 and 6). (**c**) A nuclear complex of p38 pk2/pk3-MAPK-phosphatase represents a potential mechanism for the activation of transcription factors by p38 MAPK and 2pk/3pk

Cuadrado and Nebreda 2010). In this review, we focus on the serine/threonine kinase components of the p38 MAPK stress response signaling pathway, its regulation, and its relevance to tissue responses to extrinsic and intrinsic stress factors.

The p38 MAPK Family of Stress Signaling Pathways: Tissue Specificities

The p38 MAPK family of signaling proteins are serine/threonine kinases that regulate stress response genes

(nuclear) or chaperones (cytoplasmic) via upstream cytoplasmic activator proteins (tyrosine kinases; Fig. 1). The p38 MAPK isoforms are, therefore, major nucleocytoplasmic trafficking proteins and are a major crossroads for the delivery of biological responses to environmental challenges (Fig. 1). The protein–protein interactions of the MAPK pathways are, therefore, major mechanisms that control the activation of transcription factors and their targeted genes in response to intrinsic (biological) and extrinsic (environmental) factors.

The p38α and p38β MAPK are 60% identical to p38γ and p38δ, indicating that they represent related but distinct MAPK subgroups (Ono and Han 2000; Zer et al. 2007; Cuadrado and Nebreda 2010). The four isoforms are ubiquitously expressed but at significantly different levels in each tissue. Both p38α and p38β are the predominant isoforms in the liver whereas p38γ is predominant in skeletal muscle (Lechner et al. 1996; Li et al. 1996) and δ is enriched in lung, kidney, testis, pancreas, and small intestine (Jiang et al. 1997). The isoforms have distinct biological functions due, in part, to their ability to selectively phosphorylate and activate specific transcription factors, by extracellular stimuli via the upstream tyrosine kinases. Importantly, the p38 MAPK kinases serve as a distribution center for the receipt and dissemination of biological signals within the cytoplasm as well as to their nuclear gene targets. The pathway consists, therefore, of a cascade of three serine/threonine kinase families, i.e., MAP kinase kinase kinases (MKKK), ▶ MAP kinase kinases (MKK), and ▶ MAP kinases i.e., the p38 MAPK proteins (Fig. 1). These proteins are activated in series such that the MKKKs phosphorylate the MKK activation loop serines, which then activate the p38 MAPKs by phosphorylation of threonine-180 (Thr^{180}) and tyrosine-182 (Tyr^{182}).

Tissue-Specific Distribution, Substrate Specificity, and Mechanism of Transduction of Stress Signals by p38 MAPK Isoforms

The importance of the tissue-specific expression of the p38 MAPK isoforms is indicated by the observation that sustained p38α activity is associated with ischemia-induced lethality in cultured rat neonatal cardiomyocytes (Saurin et al. 2000). Specific inhibition of p38α activity is protective against inflammatory insults. There is also evidence that activation of p38β correlates with cell viability. Thus, inhibition of the lethal effects of p38α and maintenance of the protective effects of p38β result in increased cell viability (Conrad et al. 1999). This is consistent with the differences in targets of p38α and p38β in cardiomyocyte ischemia, and is further evidence for specific biological consequences of differential isoform activation.

The specificities of p38 MAPK isoform activities, i.e., lethality, apoptosis, survival, etc., indicate the importance of the balance of p38 MAPK isoforms in a particular tissue, e.g., lung tissues and their response to external challenges. For example, the lung epithelial cells express p38β and p38δ where the pool levels of p38β $>>$ p38δ. However, the numbers of macrophages and neutrophils are elevated in inflamed, injured lungs and the pool level of p38α is threefold higher than that of p38δ in macrophages; and ninefold higher than p38δ in neutrophils. In view of the differential levels of p38 MAPK isoforms in various cell types of the diseased/inflamed lung tissues, the higher levels of p38α in the inflammatory cell lineages may overpower those of the lung tissue epithelium and favor pathological consequences such as inflammation, apoptosis, and ultimately lethality which may then enhance fibrosis.

The specificity of p38 biological functions are also supported by the observation that activation of p38α (phosphorylation of its catalytic site) by overexpression of MKK6EE, a constitutively active version of ▶ MKK6 in 3T3 fibroblasts, enhances their entry into replicative senescence (Haq et al. 2002). Thus, the over production of P-p38α in the p38β and p38δ dominant lung tissue may play a role in the development of senescence and aging characteristics in response to environmental factors. This also applies to other respiratory tissues such as vascular cells and/or inflammatory cells that may exhibit accelerated senescence and overall respiratory disease of the lung.

Substrate Specificity of p38 MAPK Isoforms

Formation of p38 MAPK to transcription factor complexes is a critical determinant of kinase specificity. For example, p38α and p38β phosphorylate and activate the muscle-specific transcription factors, MEF2A and MEF2C (Yang et al. 1999). These p38 isoforms target transcription factors by a docking

domain distinct from the phosphoacceptor motifs that confer responsiveness for p38α and p38β but not p38γ or p38δ (Engel et al. 1995; Jiang et al. 1997).

The diverse functions of the four MAPK isoforms are seen in their role in the Fas-mediated apoptosis of endothelial cells of the murine liver sinusoids (Cardier and Erickson-Miller 2002) versus their role as the MAPK required for pathogen defense against *Pseudomonas* infection in *C. elegans* (Kim et al. 2002). Furthermore, it has been shown that the *B. anthracis* lethal factor selectively induces apoptosis by cleaving the amino-terminal domain of map kinases kinases (MKKs) thereby eliminating the docking domain that is required for the activation of p38 MAPK (Park et al. 2002). This dismantling of the p38 MAPK–MKK interaction is the mechanism by which *B. anthracis* paralyzes the host inmate immunity. Similarly, in HeLa cells, p38α induces apoptosis while p38β promotes cell survival suggesting both overlapping and distinct physiological roles of the p38 isoforms, but clearly demonstrating their roles in establishing a biochemical phenotype. The p38 MAPKs also exhibit differential responses to specific drugs and inflammatory agents (Lee et al. 1999; Peifer et al. 2009). One subgroup (p38α and p38β) is inhibited by pyridinyl imidazole derivatives, drugs which inhibit the production of proinflammatory cytokines, while the others (p38γ and p38δ) are insensitive to these drugs (Lee et al. 1999). Thus, the four p38 MAPK isoforms can target genes in response to specific drugs and inflammatory agents (Lee et al. 1999; Peifer et al. 2009; Cuadrqado and Nebreda 2010).

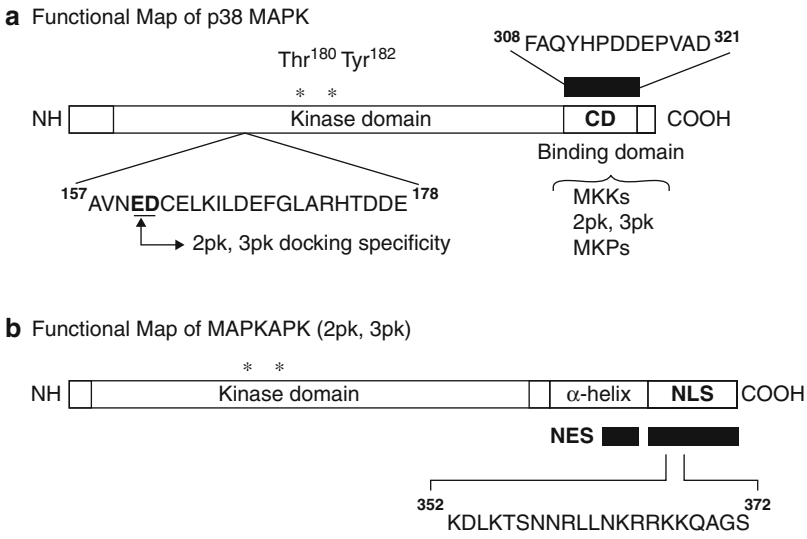
p38 MAPK signaling is mediated by interaction with upstream serine/threonine MAPK kinases, ▶ MKK3 and MKK6 (Fig. 1). While MKK6 is a common activator of p38α, β, γ, and δ, MKK3 activates only p38α, γ, and δ (Yang et al. 1998). This exclusive activation of p38β by MKK6 contributes to this pathway's signaling specificity. Targeted disruption of the *mkk3* and *mkk6* genes has shown their non-redundant functions (Enslen et al. 1998; Lee et al. 1999). For example co-expression of MKK3 with p38β enhances hypertrophy, whereas co-expression with p38α enhances apoptosis (Enslen et al. 1998; Wang et al. 1998). This signaling specificity exemplifies the importance of how specific complexing of pathway proteins target and affect specific biological processes.

Factors that contribute to the specificity of p38 MAPK activation are (Jiang et al. 1997; Enslen et al. 1998): (a) the selective formation of functional complexes between MKKs and the p38 MAPK isoforms, which requires the presence of a p38 MAPK docking site at the N-terminus of the MKKs (Fig. 2); (b) selective recognition of the activation loop (T-loop) or catalytic domain of p38 MAPK isoforms; (c) the T-loop contains the Thr^{180}-Tyr^{182} residues involved in kinase activation. Together, these provide a mechanism for the selective activation of p38 MAPKs in response to activated MKKs (Fig. 2).

The activation (phosphorylation) of all four p38 MAPK isoforms requires the interaction of the MKKs with a p38 docking domain which is located in the N-terminal region of the MKKs (Fig. 2; Enslen et al. 1998). Synthetic peptides of the MKK6 docking sites inhibit activation of p38β indicating that MKK binding is necessary for the activation. On the other hand, MKK3, which lacks this docking site, can activate p38α, p38γ, and p38δ, but not p38β; this accounts for the selective activation of p38α but not p38β by MKK3. Differences in the primary sequences of the T-loop of the p38 MAPK isoforms also contribute to signaling specificity (discussed below). Thus, the specificity of p38 MAPK activation by MKKs requires multiple intramolecular domains present in both kinases, i.e., p38 MAPK and MKKs.

Other important p38 MAPK protein–protein interactions involve the nuclear localization of the MAP kinase-activated protein kinases (▶ MAPKAPKs; 2pk, 3pk; Fig.2b). The formation of 2pk- or 3pk-p38 MAPK functional signaling complexes occurs at a conserved docking motif localized to the C-terminal region. This domain is used for binding to MKKs, nuclear localized 2pk, 3pk and ▶ MAPK phosphatases (MPKs; Fig. 2). The p38α CD domain is located outside of the active center (Fig. 2). Conceptually, therefore, recognition between p38 MAPKs and interacting proteins involves both the docking interaction domains and the transient enzyme–substrate interaction at the T-loop (Thr^{180}-Tyr^{182}), both of which regulate the efficiency and specificity of the enzymatic (kinase) reactions (Jiang et al. 1997; Muda et al. 1998; Wang et al. 1998; Yang et al. 1998; Gavin and Nebreda 1999).

The ED site, shown by a 3D molecular model of MAPK, determines docking specificity toward 2pk and 3pk, which are the nuclear enzymes that associate with p38 MAPK and transcription factors (Fig. 2a, b ; Gavin and Nebreda 1999). This structure would explain their ability to serve as a common docking groove



p38 MAPK Family of Signal Transduction Proteins, Fig. 2 Maps showing the functional domains of the p38 MAPK isoforms and the pk2/3pk docking sites. (**a**) The p38α docking sites for upstream activators (MKKs) and downstream substrates (2pk/3pk). (**b**) A map of the pk2/pk3 domains. The nuclear localization signal (NLS), nuclear export signal (NES), and p38 docking domains are at the C-terminal of pk2/pk3

(Tanoue et al. 2001). In p38 this site is located at Glu^{160} and Asp^{161}. This 3D molecular model of MAPK shows the proximity of the CD and the ED domains. Thus, every MAPK-interacting molecule may bind to this docking groove and each residue therein is differentially involved in each docking interaction (Ben-Levy et al. 1998). Since a major function of the p38 MAPKs involves the activation of transcription factors, the mechanism of this function involves the interaction of p38 MAPK isoforms with 2pk or 3pk to form a complex that activates transcription factors (Figs. 3 and 4). This complex also contains a map kinase phosphatase (MKP) which terminates the transcription activation (Fig. 3). Thus, the 2pk and 3pk proteins contain trafficking domains that mediate the import as well as the export of a p38 MAPK-2pk/3pk complex from the nucleus to the cytoplasm (Figs. 3 and 4; Ben-Levy et al. 1998).

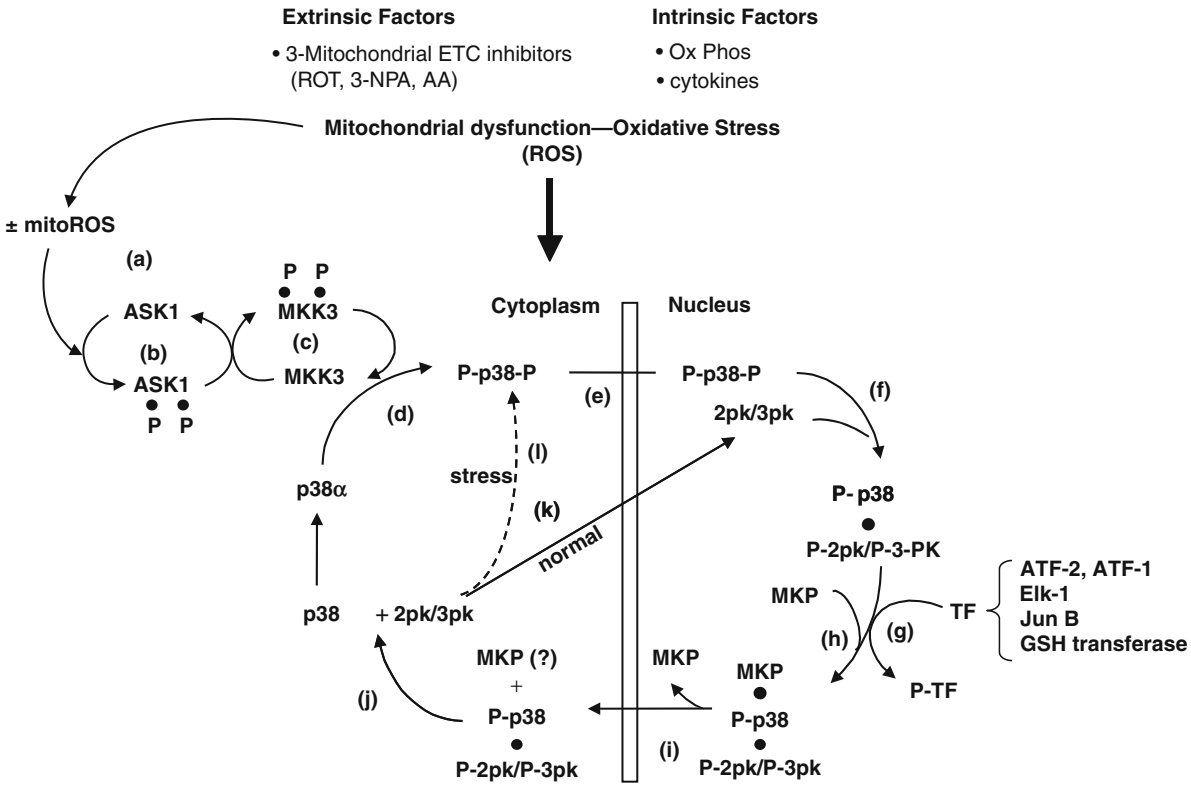
Activation of the p38 Catalytic Site

Activation of the p38 MAPKs occurs by phosphorylation of Thr^{180} and Tyr^{182} in the T-loop (Fig. 2). While p38α is phosphorylated preferentially on Tyr^{182} by MKK3 due to its lack of a MAPK docking site those with a MAPK docking site (MKK6) phosphorylate both Thr^{180} and Tyr^{182} residues of p38α MAPK. Thus, this differential phosphorylation by MKK3 versus MKK6 participates in the specificity of signaling of these upstream activators.

Subcellular Localization and Nucleocytoplasmic Transport of the p38 MAPK Signal

Subcellular localization is an integral part of the diverse functions of the p38 MAPK signaling pathway (Figs. 3 and 4). The mechanism of complex formation involves the nucleocytoplasmic trafficking of 2pk, 3pk which are p38 MAPK nuclear substrates. Both 2pk, 3pk contain nuclear localization sequences (NLS) and nuclear export sequences (NES) as an integral part of their structure. These proteins are localized in the nucleus in unstimulated cells. Upon stimulation, they dock with and are phosphorylated by p38 MAPK (Gavin and Nebreda 1999). Although this complex phosphorylates (activates) specific transcription factors, it is also exported to the cytoplasm. Furthermore, phosphorylation of 2pk and 3pk by p38 MAPK not only activates the kinase so that it can phosphorylate its transcription factor substrates, but it has also been postulated to expose the nuclear export sequence (NES) that results in cytoplasmic localization of both proteins (Fig. 4; Engel et al. 1995; Ben-Levy et al. 1998; Enslen et al. 1998).

The NES and nuclear localization sequence (NLS) of 2pk and 3pk are located at their C-terminal ends (Fig. 2; Engel et al. 1995; Gavin and Nebreda 1999). In addition, 3pk is localized in the nucleus before osmotic stress, and in the cytoplasm upon recovery. The docking of p38 with 2pk or 3pk is essential for their phosphorylation and nucleocytoplasmic export of the



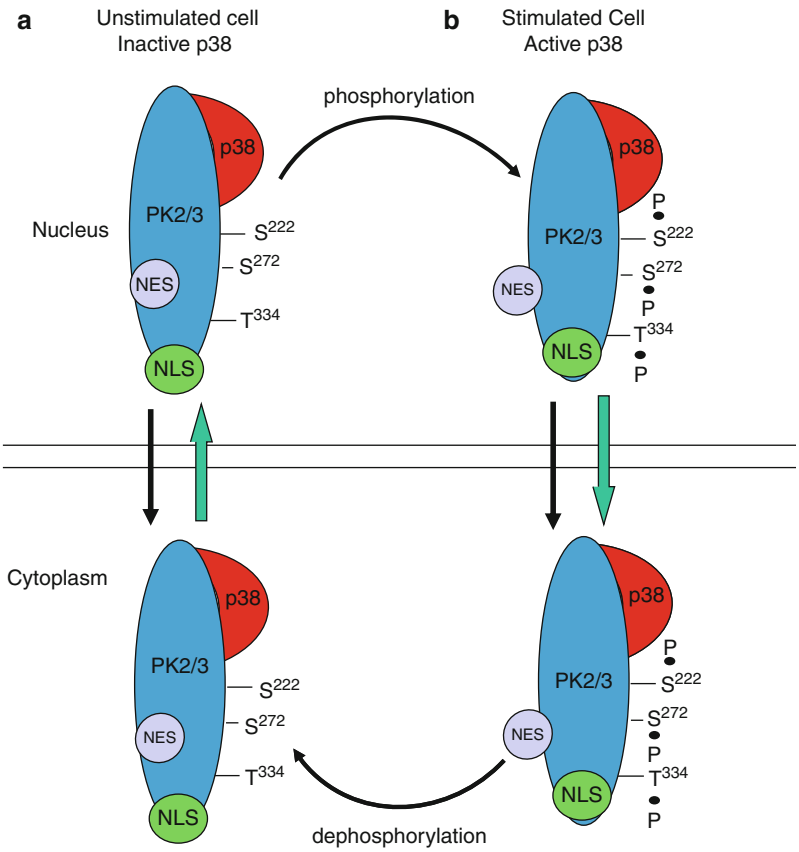
p38 MAPK Family of Signal Transduction Proteins, Fig. 3 A proposed pathway for the nucleocytoplasmic trafficking of p38 signaling proteins, their upstream activators (MKKs), and downstream substrates (pk2/pk3 and transcription factors). (**a**) Activation of p38 (P-p38-P) occurs in the cytoplasm in response to a challenge such as oxidative stress (ROS); (**b**, **c**) the activated ASK1 transduces its signal to MKK3; (**d**, **e**) MKK3 activates p38 which is translocated to the nucleus where, (**f**) it complexes with and activates (by phosphorylation) 2pk/3pk; (**g**) this complex associates and activates transcription factors (TFs); (**h**) interaction of MAPK-phosphatase (MKP) with the complex inactivates the signaling processes by dephosphorylation and, (**i**) translocation of the complex to the cytoplasm; (**j**) the p38-2pk/3pk-MKP complex dissociates; (**k**) the dephosphorylated 2pk/3pk are translocated to the nucleus where they reenter the TF activation cycle. The p38 is reactivated in the cytoplasm in response to a new stress

complex. Thus, the docking interaction between p38 and 3pk is achieved via direct interaction of the CD domain and the ED site of p38 with the C-terminal portion of 3pk (Figs. 2 and 4). The model in Fig. 4 suggests, therefore, that a p38-2pk/3pk complex may be formed in the cytoplasm of unstimulated cells and translocated to the nucleus where it may be activated.

The fact that there are cytoplasmic substrates, e.g., PRAK and Heat shock protein 27 (Hsp27), that are phosphorylated by p38 MAPK in the cytoplasm points to the diversity of its activity for downstream targets. Interestingly, the activation of p38 MAPK by DNA-damaging agents supports the idea that the p38 cascade might be initiated in the nucleus (Suh 2001). Activation of p38 MAPK in the nucleus, on the other hand, would indicate that MKK3 and MKK6 must be localized there. Ben-Levy et al. (1998) found that both MKK3 and MKK6 are localized in both the cytoplasm and nucleus. Thus, 2pk and 3pk may serve a dual function, both as effectors of p38 MAPK by phosphorylating substrates such as Hsp27 (cytoplasmic) and the nuclear cAMP responsive element binding protein (CREB), and as determinants of p38 MAPK localization (Figs. 3 and 4).

Feedback Control of MAPK-Regulated Transcription

Inactivation of the MAPKs is achieved by the dual-specificity MAP kinase phosphatases (MKPs) which target the two regulatory phosphorylation sites of the catalytic domain (Keyse 2000). There are ~9 mammalian MKPs, divided into two groups according to their



p38 MAPK Family of Signal Transduction Proteins, Fig. 4 A model of the regulation of nuclear and cytoplasmic localization of a MAPKAPK-2/3-p38 MAPK complex as a mechanism for the activation of p38 MAPK in the nucleus. (**a**) In the unstimulated cell a MAPKAPK-2/3-p38 MAPK complex is formed in the cytoplasm. The nuclear localization signal (NLS) of MAPKAPK is exposed and mediates the translocation of the complex to the nucleus. (**b**) In the stimulated cell, the active complex mediates its transcription factor activation. The nuclear export signal (NES) is exposed and the complex is translocated to the cytoplasm. In the cytoplasm of the recovered cell, MAPKAPK-2/3 is dephosphorylated and the NLS is exposed. This results in the translocation of the complex to the nucleus. In the model the p38 MAPK may be phosphorylated in either the cytoplasm or nucleus

patterns of transcriptional regulation and subcellular localization (Keyse 2000). The nuclear MKPs are rapidly and highly inducible by many of the stimuli that activate the MAPKs. It is postulated, therefore, that these MKPs play an important role in the feedback control of MAPK signaling in the nucleus. Hutter et al. (2000) showed that activation of MKP-1 involves its interaction with the C-terminal end of nuclear p38 MAPK to activate MKP-1 catalytically. This raises the question of whether a 2pk/3pk-p38-MKP complex forms in the nucleus and is exported into the cytoplasm (Fig. 3) and whether this complex is targeted in the process of inactivation of p38 MAPK.

Several cytosolic MKPs can be triggered by direct interaction with MAPKs. MKP-3 interacts specifically with ERK; binding of ERK2 to MKP-3 dramatically enhances the latter's catalytic activity (Tanoue et al. 2001). On the other hand, MKP-4 interacts with all members of the three major MAPK subfamilies to become catalytically activated (Keyse 2000). These novel mechanisms ensure the tight feedback control of MAPK signaling in the cytosol.

Role of p38 MAPK Signaling in Response to Stress Challenges and Aging

Elevated and sustained expression of p38 MAPK signaling activity is a major physiological characteristic of aging (Papaconstantinou and Hsieh 2010). This

age-associated state of chronic stress is attributed to mitochondrial ETC dysfunction and is a key factor that promotes stress-induced aging characteristics. Thus, endogenous reactive oxygen species (ROS) are important factors that regulate signaling pathways that control the development of senescence and aging phenotypes. It has been proposed that mitochondrial generated ROS may activate p38 MAPK through the ASK1-signalosome → p38 MAPK pathway (Papaconstantinou and Hsieh 2010). Activation of ASK1 initiates the activation of MKK3/6 and p38 MAPK. Thus, the mechanism of regulation of p38 MAPK in response to ROS involves activation of the ASK1-signalosome. Through this mechanism mitochondrial generated ROS activates p38 MAPK and links the activation of senescence pathways ($p16^{Ink4a}$ and $p19^{Arf}$) via p38 MAPK. Based on this hypothesis, it might be expected that (a) the increased and persistent level of oxidative stress may affect the activity of the p38 MAPK stress signaling pathways; (b) as aging progresses, the constitutive activity of stress-activated signal pathways, would increase; and (c) this new level of activity is stabilized – becoming a basic factor in the development of chronic stress in aged tissues.

Summary

Biological signaling is a highly specific process that enables cells and tissues to regulate their responses to their environment, both intrinsic and extrinsic. This review focused on the p38 MAPK family of signaling proteins that respond to mitogenic and stress-activating signaling molecules. Although the p38 MAPK stress response pathway was first discovered in response to an inflammatory challenge by bacterial endotoxin (LPS), its diverse functions have been rapidly identified thus making it a major and critical pathway that regulates numerous biological processes. This is seen in its regulation of differentiation, apoptosis, senescence, and aging. The demonstration that the mechanism of cellular destruction by anthrax lethal factor involves blocking the p38 pathway adds to the significance of the diversity of this pathway. Most certainly, there are other equally important signaling pathways that play a key role in the response to stress factors, mitogens, hormones, etc., such as the ERK and SAPK/JNK pathways, and the hormone-activated pathways such as insulin/IGF-1 and GH pathways. All of these pathways share several mechanisms of signal transduction, e.g., protein–protein interactions (docking), protein modifications (phosphorylation), and intracellular trafficking (nucleocytoplasmic, mitochondrial). Thus, in our discussion of the mechanisms of p38 MAPK pathways, our purpose was to familiarize the reader with these mechanisms which occur in most signaling processes. Furthermore, our focus on how aging affects the function of the p38 MAP kinase pathway is meant to demonstrate that in addition to environmental and intrinsic factors, signaling pathways also play a key regulating role in biological processes during the entire life cycle, i.e., spanning the embryonic young adult and aging phases of life.

Historical Background

As the major tumor suppressor in multicellular organisms, p53 arguably is one of the most intensively studied human proteins (over 54,000 publications including nearly 7,000 reviews) because it is critical for maintaining genomic stability and cellular homeostatic processes in response to multiple stresses. The p53 protein is a tetrameric, sequence-specific, DNA-binding transcription factor, stabilized and activated in response to genotoxic and non-genotoxic stresses; estimates are that the activation of p53 directly or indirectly induces or represses the expression of about 1,500 genes. These genes coordinate the cellular response to protect cells and/or the organism from damage by arresting the cell cycle and inducing repair, by initiating apoptosis, a program of cell death, or by triggering senescence, a permanent arrest of the cell cycle (Vousden and Prives 2009). Discovered almost simultaneously just over 30 years ago (Table 1) by several groups as an antigen associated with the large tumor antigen of the small DNA tumor virus SV40, p53 initially was considered an oncogene (Levine and Oren 2009), partly because the initial, mutant cDNA clones derived from tumors cooperated with several oncogenes, notably *HRAS*, to transform primary cell cultures. On its own, mutant p53 facilitated cell immortalization. Only after cloning of the wild-type cDNA from normal mouse cells and comparing its sequence with earlier mutant clones was p53 firmly established to be a tumor suppressor that became known as the "guardian of the genome" (Lane 1992). Several groups then demonstrated that the p53 gene (*TP53*) is mutated in approximately half of all human cancers, and now it is known that a variety of mechanisms inactivate the p53 pathway in virtually all other cancers (Olivier et al. 2010; Vousden and Prives 2009). Indeed, *TP53* knockout mice rapidly develop tumors, confirming the importance of p53 in tumor suppression (Donehower and Lozano 2009).

p53, Table 1 p53: A short timeline

Date	Event
1979	p53 discovered
1983	p53 cDNA cloned
1984	"p53" demonstrated to be oncogenic
1984	p53 shown to be induced by DNA damage
1986	First p53 phosphorylation sites identified
1988	Wild-type p53 cDNA cloned
1989	p53 determined to be a tumor suppressor and mutated in human cancers
1990–1992	p53 identified as a transcription factor
1991	p53 discovered to induce cell cycle arrest and apoptosis
1992	MDM2 proven to negatively regulate p53
1992	*TP53* knockout mice revealed as cancer prone
1994	p53 DNA-binding-domain and tetramerization-domain structures revealed
1997	MDM2 shown to ubiquitinate p53; p53 shown to be acetylated
1997	p63 and p73 described
1998	ATM demonstrated to phosphorylate p53 Ser15
2000	First mouse p53 phosphorylation site knock-in mutant made
2003	p53 shown to induce transcription-independent apoptosis via mitochondria
2004	Methylation shown to regulate p53 activity
2005	p53 established as regulating metabolism and having an antioxidant function
2007	p53 demonstrated to be required for embryo implantation
2009	Structure of full p53 tetramer described
2010	Processing of miRNAs and regulation of lincRNAs modulated by p53

But how does p53 prevent tumors? The mechanistic answer to this question began to emerge in the early 1990s with the discoveries that p53 possessed a potent transactivation domain and was a site-specific, DNA-binding protein that could induce the expression of genes controlling the progression of the cell cycle (e.g., *CDKN1A* ($p21^{Waf1}$)) and apoptosis (e.g., *BAX*) (Lane 1992; Levine and Oren 2009). Subsequently, the induction of p53 was shown to promote cellular senescence, although the underlying mechanism(s) are just emerging. Thus, p53 was established as

a transcription factor that regulates the expression of genes which control and implement the major cellular mechanisms for preventing cancer by arresting the cell cycle so to allow time to repair DNA damage or by inducing senescence or apoptosis. Subsequently, transcription-independent functions of p53 were uncovered. Among these is the ability of p53 to induce apoptosis through an interaction with the mitochondrial membrane causing the subsequent release of pro-apoptotic factors such as cytochrome C (Vaseva and Moll 2009).

The early history of p53 research is coupled intimately with that of the small DNA tumor viruses, SV40, polyomavirus, adenovirus, and papillomavirus (Levine 2009). Each virus produces a protein, respectively, the SV40- and polyoma-T-antigens, the adenovirus E1b-55kd protein, and the papillomavirus E6 protein, that during the early phase of a productive infection inactivates p53 (and suppresses apoptosis) as part of the viral strategy for maximizing virus yields. The expression of these proteins from integrated viral sequences also is required to initiate and maintain cell transformation; remarkably, except for a few papillomavirus serotypes, these viruses seemingly do not produce tumors in humans. During the past 20 years, much research on p53 focused on cellular responses to DNA damage. In normal unstressed cells, p53 has a low basal concentration of about 17,000 molecules per cell; however, after exposing cells to UV light or ionizing radiation, both of which damage DNA and are carcinogenic, p53 is "induced" and accumulates to higher levels. These seminal findings, which subsequently have been strengthened and enhanced, provide the rationale for p53 functioning as a multifaceted tumor suppressor in multicellular organisms (Zilfou and Lowe 2010; Vousden and Prives 2009).

The complex mechanisms that regulate p53 activity are far from being completely understood. Earlier, p53 was shown to be a phosphoprotein, and, as detailed below, it is now known that p53 is posttranslationally modified in multiple ways on more than 10% of its 393 (human protein) amino acid residues (Anderson and Appella 2009; Meek and Anderson 2010). An allosteric model for p53 activation as a DNA-binding protein was proposed which suggested that phosphorylation of residues in p53's carboxyl-terminal regulatory domain relieved an inhibition of DNA binding and promoted activation as a transcription factor. The oncoprotein, MDM2 (mouse double minute 2) binds to the N-terminal transactivation domain of p53 and blocks its activity as a transcription activator; subsequently, MDM2 was identified as an E3 ligase that ubiquitylates p53 at multiple sites, marking it for degradation by the 26S proteasome and thus maintaining its low cellular concentration in normal, unstressed cells. Several groups demonstrated that the ATM kinase, which is mutated in the disease ataxia telangiectasia and is activated in response to DNA damage, phosphorylates serine 15 (Ser15) in the transactivation domain of p53. Subsequently, phosphorylation of Ser15 was suggested to induce the dissociation of MDM2 from p53, thereby stabilizing it. While it is now known that the mechanisms regulating p53 are more complex, these early findings undoubtedly stimulated interest in clarifying the signaling mechanisms regulating p53 function. These studies were aided substantially by mouse models that use site-specific knock-in technology to explore p53 biology in a living animal (Broz and Attardi 2010).

Origin of the p53 Family

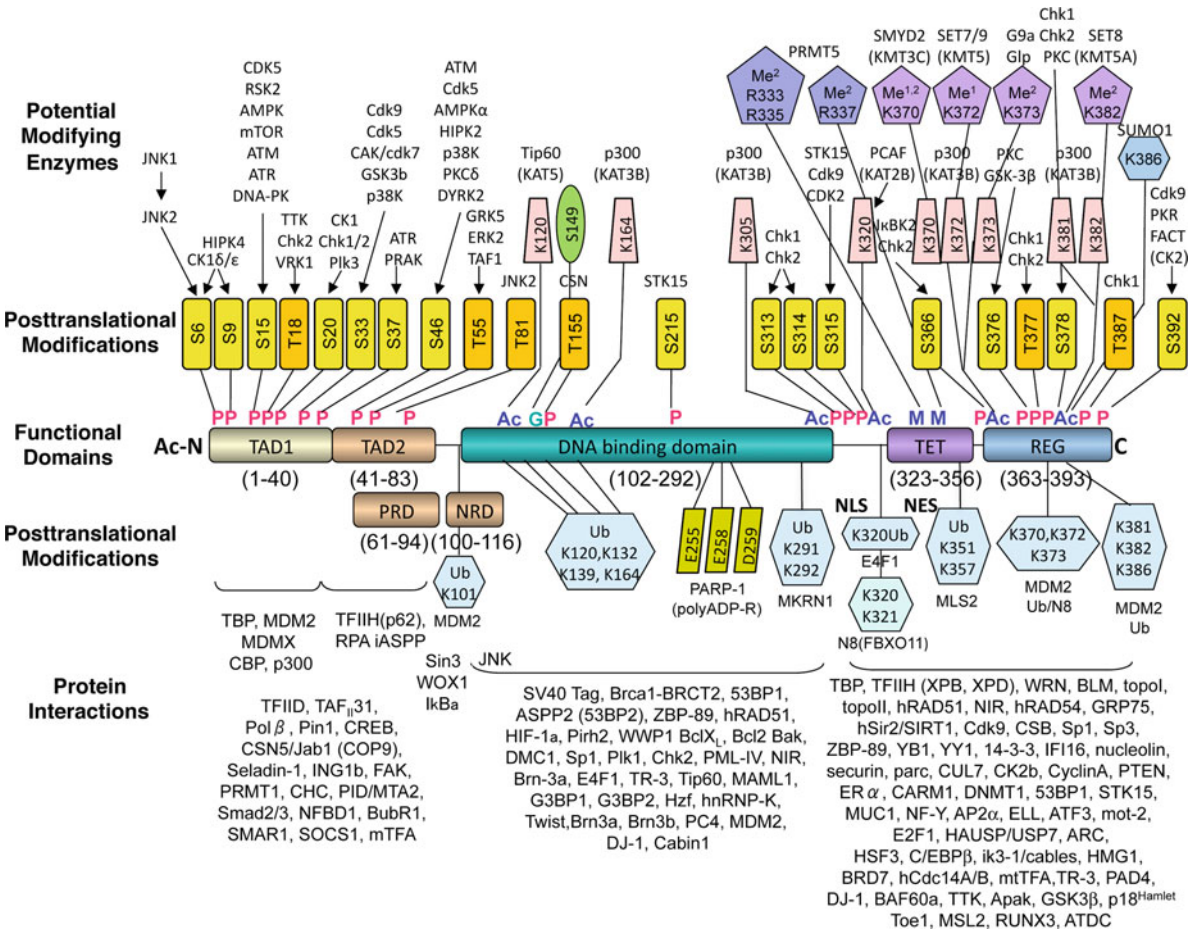
Knowledge of the primordial p53 and its signaling pathways might well offer insights to elucidate more p53 functions and potential cancer therapies (Lu et al. 2009). In addition to *TP53*, the genomes of most vertebrates, including that of humans, contain genes for two closely related homologues, namely, *TP63* and *TP73* (Dötsch et al. 2010). The domain structures of these three proteins are similar (see below), but p63 and p73 also contain an additional carboxy-terminal sterile alpha motif (SAM) that probably facilitates additional protein–protein interactions. All three proteins in this p53 family bind similar DNA sequences and activate several common target genes, but their cellular functions have diverged significantly. Although p63 and p73 have tumor-suppressor functions in mouse models, neither is mutated often in human cancers. The development of squamous epithelia requires p63, as does maintaining a pool of proliferating epithelia stem cells; p73 is indispensable for development of the central nervous system and the olfactory and immune systems. All three genes generate a plethora of isoforms due to alternative modes of initiating transcription and splicing; up to nine different isoforms have been reported for the

TP53 gene. Transactivation (TA) competent isoforms of p63 and p73 are important for maintaining genome stability in human oocytes; however, of particular importance for development are the so-called Δ isoforms of p63 and p73 that lack the N-terminal transactivation domain and function as inhibitors of the three full-length proteins. Interestingly, mice that lack a functional p53 gene develop normally but are highly cancer prone, while those without either p63 or p73 suffer from developmental defects and die soon after birth. Rare germ-line mutations in p63 are associated with developmental defects in humans. While signaling by the p53 family should be considered collectively, readers should consult recent reviews for further information on the functions of p63 and p73.

p53 and its family members do not occur in prokaryotes, fungi, or plants, but extensive genome sequencing revealed p53- and p63/73-like genes in many invertebrate species, including clams, mollusks, insects, and worms, as well as in unicellular choanoflagellates and amoeba (Lu et al. 2009). p53 from non-vertebrates is most extensively characterized in the fruit fly *Drosophila melanogaster* and the nematode *Caenorhabdites elegans* (*CEP-1*). However, instead of a vertebrate-like p53, both species express p63/73-like proteins with carboxy-terminal SAM domains that function in germ-line cells; interestingly, neither species has an MDM2-like negative regulatory gene. The discovery of p63 and p73 in the late 1990s suggested that p53 was derived from an ancestral p63/p73-like gene through gene duplication and loss of the SAM domain. However, the more recent detection of p53- and p63/73-like genes in unicellular and simple multicellular eukaryotes challenges this view, indicating that the primordial function of p53 was not tumor suppression; apparently, this property evolved much more recently. Notably, D. Lane's group recently identified both *MDM2*- and *TP53*-like genes that are well conserved in placozoans, which are simple eukaryotes with only four cell types and with genomes only 10 times the size of that of *Escherichia coli*. Remarkably, not only is the basic structure of the placozoan p53 conserved, but so also are key amino acid residues involved in DNA binding and posttranslational modification. Studying the functions of p53 in more primitive species may uncover new roles for p53 and additional modes of signaling.

Structure and Posttranslational Modifications

The p53 polypeptide, with the classical features of a sequence-specific transcriptional factor, is functionally divided into three major domains (Fig. 1): an amino- (N) terminal transactivation segment (TA, Met1-Lys101, numbering for human p53) that interacts with regulatory proteins and components of the transcription machinery; a central, sequence-specific, DNA-binding domain (Thr102-Lys292); and, a carboxyl- (C) terminal tetramerization and regulatory domain (Gly293-Asp393) (Anderson and Appella 2009; Joerger and Fersht 2008). The unstructured N-terminal region contains two independent transcription activation domains, TAD1 (Met1-Met40) and TAD2 (Asp41-Pro83). The former is highly conserved and is required for most transactivation activity; it interacts with several coactivators and corepressor proteins (e.g., histone acetyltransferases (HATs) and histone deacetylases (HDACs)), and also with p53's major negative regulator, the E3-ubiquitin ligase, MDM2. Residues Glu11-Leu26 may function as a secondary nuclear export signal. TAD2 largely overlaps a proline-rich domain (PRD, Asp61-Leu94) that is important for assuring p53 stability, transactivation ability, and the induction of transcription-independent apoptosis. It also contains binding sites for the corepressor Sin3a and the proline isomerase Pin1. While TAD1 and the C-terminal region of TAD2 are highly conserved among mammals, the length and sequence of residues Asp41-Ala79 of human p53 are not well conserved. Except for Lys101, which can be ubiquitylated by the E3 ligase MDM2, the N-terminal TA region of p53 is covalently modified exclusively by phosphorylation at 10 serines/threonines, namely, Ser6, 9, 15, 20, 33, 37, and 46, and Thr18, 55, and 81. Phosphorylation of p53 at Ser33, Ser46, and Thr81 (and at Ser315) generates binding sites for the proline isomerase, Pin1. Pin1-catalyzed proline isomerization generates or removes binding sites for several p53 binding partners that regulate p53 acetylation and ubiquitylation, and consequently ensures the efficient loading of p53 on to target promoters. p53 TA has the most significant polymorphism in p53, a C or G in codon 72 that changes the amino acid from proline (CCC) to arginine (CGC) and affects its activity as a transcription factor (Whibley et al. 2009).



p53, Fig. 1 p53 domains, posttranslational modifications, and binding partners (Updated from Anderson and Appella (2009) and Meek and Anderson (2010))

In contrast to the unstructured N- and C-terminal regions, the central core of p53 consists of an immunoglobulin-like β-sandwich offering a scaffold for the DNA-binding surface (Fig. 1). This surface is formed by two large loops, L2 (Lys164-Leu194) and L3 (Met237-Pro250), stabilized by a zinc ion (Joerger and Fersht 2008; also see http://proteopedia.org/wiki/index.php/P53). p53 is the most frequently mutated tumor suppressor in humans, and most such tumor-derived mutations are missense mutations in the central domain that block or alter sequence-specific DNA binding or induce conformational changes in the domain structure. Six so-called hot-spot mutations (R175H, R248Q, R248W, R273H, R273C, and R282W) account for about 20% of the somatic mutations in human cancers (Olivier et al. 2010). X-ray crystallography and NMR revealed the three-dimensional structures of the DNA-binding domain, free or bound to DNA, and the structures for several mutant p53s in their DNA-free state. Recent high-resolution crystal structures of complexes between the p53 core domain tetramers and DNA targets point to mechanisms by which p53 may recognize specific REs in mammalian genomes and how such recognition may be modulated through post-translational modification or interactions with partner proteins. The DNA-binding domain can be posttranslationally modified by phosphorylation at Thr155 and Ser215, O-glycosylated at Ser149, acetylated at Lys120 and Lys164, ubiquitylated at Lys120, 132, 139, 164, 291, and 292, and ADP-rybosylated at Glu255, 258, and Asp259. In particular, the acetylation of Lys120, which is a DNA-contact residue, by the Tip60/hMOF histone acetylases in response to DNA damage might be important for p53-mediated transcriptional activation and for inducing apoptosis.

The carboxyl-terminal region contains a nuclear localization signal (Thr312-Asp324), a tetramerization domain (Leu323-Gly356), and a basic 30 amino acid segment that binds RNA and certain DNA structures, including short single strands, four-way junctions, and insertions/deletions in a sequence-independent manner, as well as numerous partner proteins (Fig. 1). The unmodified C-terminal domain initially was thought to negatively regulate sequence-specific binding by the core DNA-binding domain; subsequently it was shown to be necessary for efficiently activating transcription, possibly by facilitating the identification of response elements by promoting diffusion along the DNA. The C-terminal domain can be posttranslationally modified at multiple sites in many ways. Ser313, 314, 315, 366, 376, 378, and 392 may be phosphorylated along with Thr377 and 387; Lys305, 320, 370, 372, 373, 381, and 382 can be acetylated; K370, 372, 373, and 382 also can be mono- or dimethylated; Arg333, 335, and 337 can be dimethylated; K351 and K357 can be ubiquitylated; K320, 321, 370, 372, 373, 381, 382, and 386 can be ubiquitylated or neddylated; and, K386 can be sumoylated. Arg333, 335, and 337, as well as Lys351 are in the core tetramerization domain, and, though untested, their modification might directly affect p53 oligomerization. Regulation of the formation of p53 tetramers is an underappreciated aspect of p53 signaling. The dissociation constant for its formation apparently is tuned so that p53 is largely in a monomeric (or dimeric) state in unstressed cells; however, the modest approximately threefold increase in p53 concentration after stress is sufficient to push p53 toward the formation of tetramers, and only tetrameric p53 is active as a transcription factor. Thus, the effect of p53 stabilization on transcription is much greater than would be expected from the relatively small increase in its concentration. Tetramer formation also hides the p53 nuclear export signal in the tetramerization domain (Fig. 1). p53 acetylation and ubiquitylation reportedly inhibit p53 tetramer formation, while the binding of several proteins, including c-Abl, ARC, and 14-3-3, are reported to negatively or positively affect tetramer formation, respectively. Finally, some p53 posttranslational modifications only occur on tetrameric p53.

Structural studies of full-length human p53 have been impeded because ~40% of the molecule is intrinsically unstructured and because p53 has a low thermal stability. Nevertheless, A. Fersht's group determined the low-resolution structure of a stabilized variant of full-length human p53 with and without DNA using small-angle X-ray scattering (SAXS), NMR, and electron microscopy (Joerger and Fersht 2008); this structure has been confirmed and further enhanced by applying biophysical and computational techniques. The free protein in solution forms an elongated cross-shaped tetramer with loosely coupled core domain dimers and extended N- and C-termini. Upon DNA binding, p53 wraps around the DNA, and the structure becomes more rigid. All four N-termini point away from one face of the core domain/DNA complex, consistent with the fact that they become heavily posttranslationally modified and serve as an interaction scaffold for numerous interacting proteins, including MDM2, the histone acetyltransferases p300/CBP, the single-stranded binding protein RPA, and several components of the transcriptional apparatus (Fig. 1). Interestingly, a cryo-electron microscopy structure of full-length murine p53 is inconsistent with this structure. While elucidating the quaternary structure of p53 with DNA is an important achievement, the fact is that cell DNA is mostly packaged in nucleosomes, and, while some promoter regions may be nucleosome-free, this is an unlikely scenario for many p53 binding sites. To resolve this issue, A. Nagaich and colleagues have begun to examine how p53 interacts with nucleosomal response elements. Ostensibly, the bending of DNA enhances p53 binding when the response element is positioned near the nucleosomal dyad, but the response element is inaccessible if the orientation of the core nucleosome changes by ~180°. Sequestering by the nucleosome of the many potential p53 recognition sites in mammalian cells may partly explain how the relatively few p53 molecules find their important target sequences, and why different cells, with different chromatin organizations, may respond differently to the activation of p53.

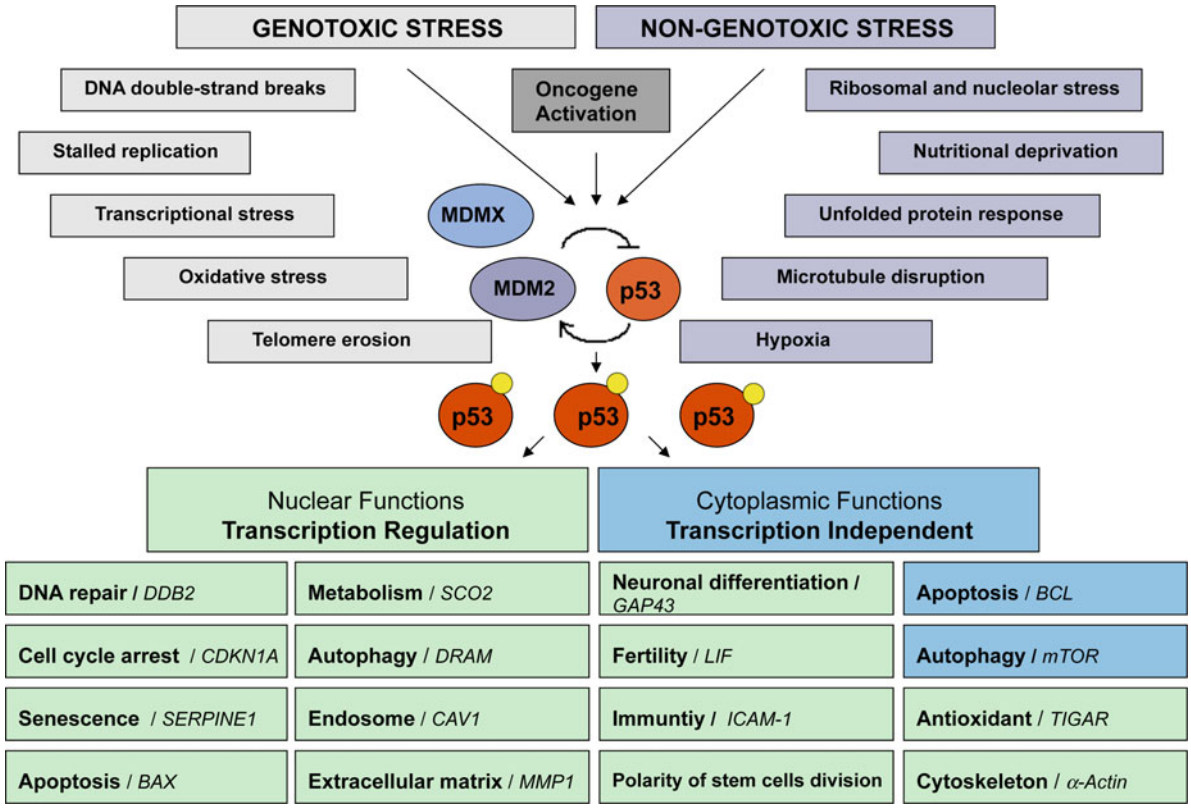
Signaling to p53

p53 activity is regulated not only through control of its cellular location and concentration, but also through posttranslational modifications that affect its structure or alter its interaction with protein-binding partners. In unstressed cells, the half-life of p53 is short (~20 min), and low levels of p53 are maintained primarily by the E3 ubiquitin ligase MDM2 (Perry 2010) that transfers ubiquitin to multiple p53 lysines (Fig. 1); however,

several additional E3 ubiquitin ligases, including Pirh2, COP1, CHIP, ARF-BP1, E6-AP, TOPORS, and TRIM24, may contribute to p53 ubiquitylation in specific cells or under specific circumstances. Polyubiquitylation of p53 targets it for degradation through the 26S proteasome, while monoubiquitylation (or oligo-, less than ~4) marks p53 for nuclear export to the cytoplasm and non-transcriptional functions (see below) or affects its binding specificity. The complex switch between inhibition of ubiquitylation, mono- or polyubiquitylation, probably is cell-type dependent and is regulated by posttranslational modifications to both p53 and MDM2, and by interactions with several binding factors, including the histone acetyltransferases p300/CBP and the proline isomerase, Pin1 (above). The switch is modulated in response to various genotoxic and non-genotoxic stresses through several signaling networks. Furthermore, MDM2 interacts with its homolog MDMX (or MDM4), which does not have ubiquitin ligase activity, but affects MDM2 activity and autoubiquitylation, and therefore, p53 levels. Deleting or inactivating either MDM2 or MDMX in mice results in a lethal embryonic phenotype, but the simultaneous deletion of p53 recovers viability in both cases. Both MDM2 and MDMX also bind the N-terminal transactivation domain of p53, preventing it from interacting with the transcriptional apparatus and activating transcription. p53 also induces the expression of MDM2 (but not MDMX) to create a negative feedback loop. Indeed, the p53 circuit communicates with several other transcriptional targets, including Wnt-β-catenin, IGF-1-AKT, Rb-E2F, p38MAP kinase, cyclin-cdk, p14/19 ARF pathways, and cyclin G-PP2A, as well as the ubiquitin ligases Cop-1 and Pirh-2 creating several negative- and positive-feedback loops that modify its activity or concentration (Harris and Levine 2005).

Although early studies suggested that p53 binding to DNA was regulated allosterically through posttranslational modifications to its C-terminus, experiments with the small-molecule inhibitor, nutlin-3a, suggested that increases in p53 concentration alone can activate many p53 target genes, although the transcriptional response may be somewhat different than those induced by DNA-damaging agents. Nutlin binds MDM2 and inhibits MDM2 binding to p53, thereby blocking p53 degradation without obviously activating stress signaling pathways that posttranslationally modify p53. Likewise, the induction of integrated, recombinant p53 under the control of exogenous regulatory elements similarly can activate p53 transcriptional responses. While unmodified p53 may be transcriptionally competent, it is widely accepted that in normal cells posttranslational modifications to p53 and its partner binding proteins in response to the many cellular stresses to which it responds (Fig. 2) not only stabilizes p53 but "activates" it, fine tuning the transcriptional responses in a stress- and cell-type-specific manner. Figure 1 shows the known sites at which human p53 can be posttranslationally modified and some of the enzymes that accomplish these modifications, at least in vitro. Also listed are many of the proteins that reportedly interact with p53 with the p53 interaction domain indicated. Not all enzymes that have been reported to modify p53 in vitro will do so in vivo; likewise, the list of interacting proteins, though certainly incomplete, may contain false positives. Nevertheless, the potential complexity is daunting ($>10^{12}$ possible posttranslational combinations), even though only a minute fraction of the possible combinations can exist at one time in any one cell.

The best characterized signaling pathways that modify and modulate p53 are those that are activated in response to DNA damage – primarily DNA double-stranded breaks (DSBs) and stalled or collapsed replication forks (Anderson and Appella 2009; Meek and Anderson 2010). The induction of DSBs triggers a complex signaling network characterized by the rapid activation of the ataxia telangiectasia–mutated (ATM) protein kinase. ATM is a member of the family of phosphatidylinositol-3 kinase-related kinases (PIKKs) that includes ATR (ATM-related), DNA-PK (double-stranded DNA-activated protein kinase), ▶ mTOR (mammalian target for the immunosuppressant drug, rapamycin), and SMG1 (homology to *C. elegans* SMG-1). Activated ATM directly phosphorylates p53 on Ser15, while also activating several effector kinases, including ▶ CHK2, that can phosphorylate p53 on several different sites in the N-terminal transactivation domain (e.g., Thr18, Ser20) as well as multiple sites in the C-terminal domain, including Ser313, 314, 366, 378, and Thr377. Under some circumstances, ATM may phosphorylate additional sites, such as Ser46, whose phosphorylation is important for p53-induced apoptosis in response to severe DNA damage. Stalled or collapsed replication



p53, Fig. 2 p53 signaling in response to genotoxic and non-genotoxic stress

forks (caused, e.g., by exposure to UV light) preferentially activate the ATR kinase, which, like ATM, phosphorylates p53 at Ser15 and also actuates effector kinases including Chk1; similarly to Chk2, Chk1 phosphorylates multiple p53 residues. Ultimately, most of the known 21 p53 phosphorylation sites may be phosphorylated in response to DNA damage, with different DNA damage-inducing agents engendering different phosphorylation profiles, thus partly accounting for different outcomes. For example, exposing fibroblasts to moderate levels of ionizing radiation primarily arrests the cell cycle, while exposure to UV light strongly induces apoptosis. Within the N-terminal transactivation domain, a complex interdependency between phosphorylation sites exists. For example, phosphorylation of Thr18, Ser20, and Ser46 may depend upon prior phosphorylation of Ser15. The molecular basis for this interdependency is unknown, but it may represent one way in which p53 integrates signals from different stress pathways, and/or insures that activation requires sustained signaling from several sources.

Phosphorylation of N-terminal sites, especially phosphorylation of Thr18, weakens binding by MDM2 and, in part, accounts for p53 stabilization in response to DNA damage. Equally important is the modification of MDM2 in response to DNA damage. Like p53, MDM2 and MDMX are highly modified proteins (Meek and Hupp 2010). Briefly, ATM directly phosphorylates MDM2 Ser395, which impairs nuclear export and p53 degradation; it also activates the cAbl kinase, which phosphorylates MDM2 Tyr394 and inhibits MDM2-mediated p53 ubiquitylation. Exposure to ionizing radiation also results in hypophosphorylation of several residues in the central, acidic domain of MDM2, thereby weakening the interaction with p53 and contributing to p53 stabilization. Similarly, DNA damage changes the phosphorylation of MDMX (Meek and Hupp 2010).

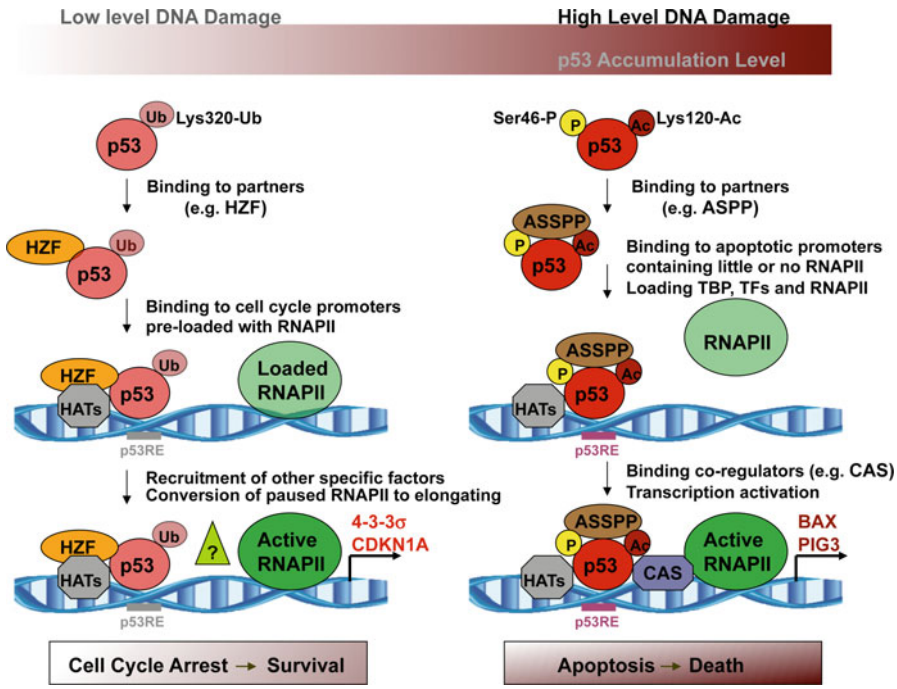
In addition to inhibiting binding to MDM2, the phosphorylation of multiple sites in the N-terminal transactivation domain of p53 also enhances p53's interaction with the HATs p300/CBP, so generating a posttranslational modification cascade that causes the

acetylation of multiple lysines in the DNA-binding and C-terminal domains of p53, including Lys164, 305, 370, 372, 381, and 382. Lysine 320 can be acetylated by the HAT ▶ pCAF. Acetylation of p53 may augment its stability by preventing ubiquitylation; acetylation has both positive and negative effects on tetramer formation and DNA binding. While no single acetylation site appears to be critical for p53 activity, when its eight C-terminal lysines were changed to arginine, it became transcriptionally "dead," suggesting that acetylation is an important p53 modification. Upon severe DNA damage, the MYST family of acetyl transferases, hMOF and TIP60, target Lys120 in the central DNA-binding domain, and the Lys120 acetylated p53 preferentially binds and activates promoters of pro-apoptotic genes (Meek and Anderson 2010). Three lysines, Lys370, 372, and 382, at the C-terminus of p53 are methylated in response to DNA damage. Mono-methylation at Lys372 and dimethylation at Lys370 activate p53, while mono-methylation at Lys370 and at 382 inhibit its activity. p53 Lys372 is targeted by the Set7/9 methyltransferase, a necessary modification for recruiting the TIP60 HAT complex. Lys372 methylation prevents mono-methylation at Lys370, which is a "repressive mark." The enzymes that acetylate and methylate p53 in response to DNA damage also may modify histones near the p53 binding site, supporting crosstalk between the p53 signaling pathway and epigenetic regulation of chromatin.

Enzymes that reverse posttranslational modifications and restore homeostasis upon recovery from stress also are important components of the cellular signaling networks regulating p53 activity. At least four phosphatases, PP1, PPM1D (Wip1), PP2A, and Cdc14A, reportedly dephosphorylate specific p53 residues (Anderson and Appella 2009; Meek and Anderson 2010). PPM1D, acting as an oncogene, is overexpressed in approximately 15% of primary breast cancers; in model rodent systems, its inhibition or elimination delays or prevents tumor formation. Several deacetylases, including HDAC1 and SIR2, the demethylase KDM1A (LSD1), and the de-ubiquitylation enzyme HAUSP, directly target p53 to remove modification marks. The lifetimes of such modifications on free and chromatin-bound p53 largely are unknown (Anderson and Appella 2009).

In addition to DNA damage, a variety of non-genotoxic physiological processes and stresses, including nutrient deprivation, microtubule distribution, hypoxia, and hyperoxia, may activate p53 through interconnected, and, as yet incompletely characterized signaling pathways that involve kinases such as AMPK and mTOR, both of which are involved in energy metabolism and can induce phosphorylation of p53 at Ser15, the ▶ Aurora kinase A (STK15) which phosphorylates Ser215 and Ser315, and the p38MAP kinase which phosphorylates Ser33 and Ser46 (Anderson and Appella 2009). An unfolded protein response (ER stress) may result from glucose starvation, aberrant protein glycosylation, expression of mutant proteins, extreme environmental conditions, and release of Ca_2+ from the lumen, thereby compromising ER homeostasis. If homeostasis cannot be restored, cells are induced to undergo apoptosis through p53-independent pathways. ER stress is the only one yet identified that leads to p53 protein destabilization, thereby preventing p53-mediated apoptosis. Hypoxia, a common form of non-genotoxic stress, triggers a p53 response resulting from abnormal development of vasculature during the growth of solid tumors or in ischemic disorders. Ser15 of p53 becomes phosphorylated and p53 accumulates under severe hypoxia (<0.2% oxygen). Unlike other types of stress, this hypoxia-triggered response predominantly leads to transcriptional repression, not activation. Nutritional deprivation activates the AMP kinase (AMPK), which senses the intracellular AMP:ATP ratio. Glucose limitation induces cell cycle arrest and causes an accumulation of p53 phosphorylated at Ser15, while glucose starvation causes p53 phosphorylation at Ser46 (a site phosphorylated after severe DNA damage) and triggers p53-mediated apoptosis. The disruption of nucleolar and ribosomal functions by normal physiological processes or various stresses release excess ribosomal proteins L5, L11, and L23 that bind and inhibit MDM2, thereby stabilizing p53 and promoting cell cycle arrest without inducing p53 phosphorylation. Deregulation of cell adhesion, and disruption of the microtubular architecture and dynamics each can engender p53 stabilization and activation. While less well defined, the non-genotoxic stress pathways activating p53 are distinct from those induced by genotoxic stress.

The activation or overexpression of oncogenes such as Ras, c▶ Myc, or E1A, as occurs during the initiation of cancer, stabilizes and activates p53 by inducing ARF, the product of the alternative reading frame of the cell cycle regulatory gene, INK4a (*CDKN2A*).



p53, Fig. 3 Models for p53-dependent transcriptional activation

ARF, in turn, binds MDM2 and inhibits p53 ubiquitylation. The activation of p53 by oncogenes undoubtedly is a driving force underlying the mutation of p53 in cancers.

Transcription-Dependent p53 Functions

The transcriptional activity of p53 crucially supports its function as a tumor suppressor. Once stabilized, modified, and accumulated in the nucleus, p53 recognizes and binds DNA as a tetramer, via its core domain, to a consensus sequence known as a response element (RE). The canonical p53 RE comprises two decamer palindromic half-sites (5′-RRRCWWGYYY-3′ wherein R is A or G, W is A or T, and Y is C or T), separated by a spacer 0–13 bp long. The core domains of two p53 monomers bind to a half-site to form a symmetrical dimer, and two such dimers assemble on a full site to form a p53 tetramer. Both the sequence and the spacer's length have important roles in the outcome of p53 binding to a RE. The C and G of the core CWWG motif are strongly conserved, while the WW motif and the flanking RRR and YYY segments exhibit considerable variation, an ambiguity that generates thousands of putative binding sites across the human genome. Once bound, p53 either drives transcriptional activation or represses large networks of target genes. Different computing algorithms predict hundreds of thousands of putative p53REs in the human genome, but based on the amount of p53 protein accumulated after stress activation in the normal cell nucleus ($\sim 2 \times 10^4$ monomers/nucleus), a given cell probably can bind no more than 1,500–2,000 p53 targets at one time. By binding and transcriptionally regulating different sets of target genes, after mild DNA damage p53 typically arrests the cell cycle, allowing time for DNA repair and cell survival; however, after severe DNA damage p53 triggers either senescence or apoptosis in a cell-type dependent manner (Fig. 3). The induction of p53-dependent cell cycle arrest in the G_1 phase is mediated through the transcriptional activation of targets, such as the cyclin-dependent kinase inhibitor gene *CDKN1A* (p21), one of the best-studied p53 targets, while the induction of 14-3-3σ contributes to inhibiting the G_2/M transition. Triggering p53-dependent apoptosis involves the transcription activation of genes in the mitochondrial apoptotic pathway, such as *PUMA*, *APAF1*, and *BAX*, and in the death receptor pathway, such as *FAS* and *TNFRSF10B*. However, as noted below, p53 also can induce apoptosis independent of transcription.

Since 1992, when El-Deiry and colleagues first identified the p53 RE (Table 1), considerable effort

has been directed toward understanding its role in p53 stress-specific responses. p53 displays well-documented different binding affinities for different REs and, depending on the level of p53 accumulation after stress, may bind different sets of REs, with the highest affinity sites being occupied first. This pattern fits well with the observation that overall cell cycle promoters have stronger binding sites than do pro-apoptotic genes. At low stress levels, p53 binds and regulates cell cycle genes, while severe stress entails higher levels of stabilized p53 (or more highly modified p53) that enable binding to weaker REs and the activation of pro-apoptotic genes. The difference between "cell cycle" and "apoptotic" p53 REs is supported by their divergent evolution and the relatively poor conservation of apoptotic REs compared to cell cycle regulating REs as determined from comparative genomic studies of mice and humans. Recently, p53 was found to utilize partial REs (half- and three-quarter-sites), in conjunction with other transcription factors such as the estrogen receptor, a feature which greatly expands the number of genes that p53 potentially regulates (Menendez et al. 2009). p53 also may bind some simple sequences (e.g., $(5'\text{-TGYCC-}3')_{n>10}$) and non-B-form DNA structures, either to regulate transcription, or, perhaps, DNA repair and chromatin structure.

According to the classical "selective binding" model (see below for "selective context" model), p53-specific posttranslational modifications and specific binding partners assure that p53 discriminates among the variety of REs available for binding, based on their sequence characteristics. Once bound to an RE, p53 loads transcriptional coactivators, such as HATs and chromatin-remodeling factors, resulting in the acetylation of histones and the opening of chromatin for binding the components of the basal transcriptional machinery, such as TBP, TFs, and RNAP II. A few lines of evidence support this model. First, p53 REs are diverse, with different affinities for p53 that specifically impact the mode of regulation; second, certain p53 partners can "direct" p53 binding to cell cycle or to pro-apoptotic promoters; and, third, at these two groups of promoters, specific p53 posttranslational modifications are enriched. Lastly, p53 loads coactivators, such as p300/CBP and PCAF, at many of its target promoters, with the consequent opening of chromatin and subsequent activation of transcription.

Specific p53 posttranslational modifications directly influence the selection of p53REs. For example, as C. Sardet's group showed, p53 ubiquitylated at Lys320 specifically activates cell cycle arrest genes without affecting pro-apoptotic targets, while, in response to severe DNA damage, Ser46 phosphorylation specifically promotes p53 binding to pro-apoptotic genes (Anderson and Appella 2009; Meek and Anderson 2010). Furthermore, as shown by Y. Xu's group, in a mouse knock-in mutant, wherein Lys319 (the equivalent of human Lys320) is changed to the non-modifiable residue Ala, the p53-dependent apoptotic response is impaired, but cell cycle arrest is unaffected. Interestingly, some of the p53 tumor-derived mutations also selectively compromise the ability to regulate transcription; for example, the R175P mutant p53 arrests the cell cycle but cannot induce apoptosis. p53 binding partners (Fig. 1) also influence target selectivity, and their interaction with p53 may be affected by posttranslational modifications. A classical example is that of the ASPP protein family, consisting of the three members ASPP1, ASPP2, and iASPP. While binding of ASPP1 and ASPP2 to p53 directs it to pro-apoptotic genes and stimulates apoptosis, iASPP inhibits these interactions. 53BP1 is a binding partner involved in both regulating cell cycle arrest and repairing DNA damage; therefore, it could contribute to coordinating these processes. Another binding partner, HZF, was described by Lee's group to selectively load p53 on cell cycle regulating promoters without affecting the regulation of pro-apoptotic genes (Anderson and Appella 2009). Although these data support the selective binding model, since clearly certain posttranslational modifications and particular binding partners provide a signal for p53's selective occupation of a target, the model recently was challenged because of findings pointing to the regulation of transcription at the p53 post-binding stage.

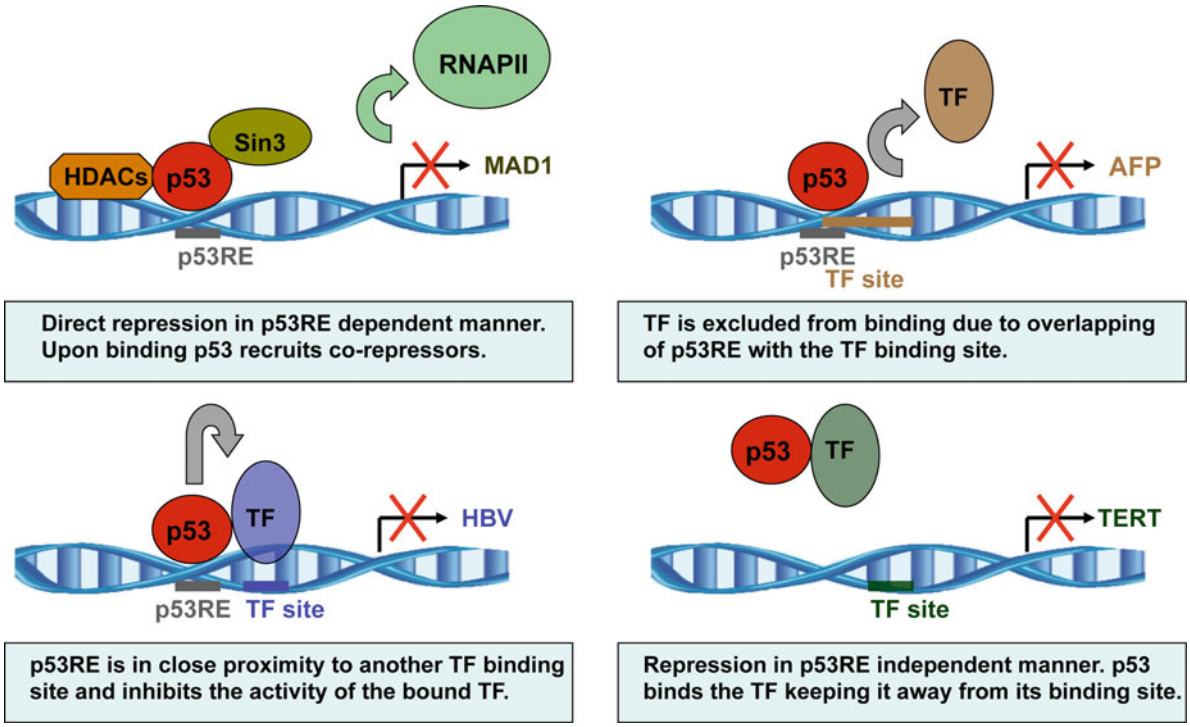
According to the "selective context" hypothesis recently proposed by Gomes and Espinosa (2010), the outcome of p53 binding to its targets might depend on additional factors that are required due to the promoter's state before binding. For example, promoters for cell cycle genes contain bound but inactive RNAP II prior to their activation by stress; in contrast, pro-apoptotic genes contain little or no pre-bound RNAP II. Accordingly, additional factors would be needed by cell cycle–regulating promoters to convert

the paused RNAP II into an elongating one, while, for pro-apoptotic promoters, basal transcription factors and RNAP II first must be loaded (Fig. 3). The "selective binding" and "selective context" models are not mutually exclusive, and it is noteworthy that different p53-regulated core promoters (the minimal DNA sequence containing promoter elements that direct initiation of transcription by RNAP II) vary in their promoter element compositions and, therefore, may require different co-regulators. Although TATA element-containing "focused" core promoters are more ancient, in vertebrates, most core promoters are of the "dispersed" type that do not contain the TATA element and commonly are found in CpG islands. Therefore, the classical model in which p53 helps to load TBP and the rest of the basic transcriptional machinery is applicable to only a fraction of regulated, focused promoters, and the need for specific co-regulator loading may depend on the particular elements of the core promoter at a given target. The epigenetic state of the targets before binding of p53 also may impose specific requirements before transcription is activated. In support of the selective context model, co-regulators recently were described as co-occupying specific sets of p53-regulated target promoters. For example, hCAS was reported by C. Prives' group to associate with a subset of pro-apoptotic p53 targets and to enhance their transcription by reversing H3 Lys27 methylation (a modification blocking transcription). In contrast, Bach1, a transcription factor that binds at a subset of oxidative stress-inducible p53 target genes and promotes histone deacetylation, as shown by K. Igarashi's group, inhibits transcription from these genes, thus suppressing p53-mediated cellular senescence. Likewise, the calcineurin-binding protein, Cabin1, physically interacts with p53 (Fig. 1) on certain promoters and, by regulating histone modifications, represses p53-dependent transcription in the absence of genotoxic stress. Finally, Gomes and Espinosa recently reported that expression of *PUMA* (*BBC3*), a pro-apoptotic p53 target gene, is regulated through a newly discovered "noncanonical" mechanism involving the insulator protein CTCF (the CCCTC-binding factor) and the cohesion complex that occupy intragenic chromatin boundaries and inhibit transcriptional elongation in the absence of stress. These findings demonstrate the role of the chromatin landscape in regulating p53-mediated transcriptional responses.

Although much is known about p53's activation of transcription, it is well-documented that p53 also can repress it. Following particular types of stress, for example, hypoxia, p53 predominantly represses transcription at many of its targets. Different mechanisms of p53-dependent repression have been reported (Fig. 4). Direct repression in a p53RE-dependent manner involves recruiting co-repressors, such as Sin3 and chromatin-modifying HDACs, which promote the formation of repressive chromatin structures and prevent the binding of transcriptional activators at target promoters. Several studies have examined the role of the p53RE structure in directing transcription repression. An early study of the survivin (*BIRC5*) promoter suggested that p53REs with a spacer length of 3 bp directed repression, while a zero-length spacer between half-sites caused activation. Subsequently, it was found that a spacer length of 3 bp which, compared to the same RE with no spacer (as is found in most activating p53REs), significantly weakened p53 binding and was insufficient to direct repression (Riley et al. 2008). More recently, E. C. Ren's group showed that when the WW in the core p53RE sequence CWWG was AT, AA, or TT, the RE activated transcription, while other dinucleotides, including CG, GG, and TG, directed transcriptional repression. Large-scale studies in vivo are needed to address the extent to which the REs at repressed p53 targets conform to that rule. Another way p53 can repress transcription is by interfering with the binding of transcription activators at neighboring binding sites, or by directly competing for binding when a p53RE overlaps with other activator binding sites. p53 may indirectly cause repression in an RE-independent manner by binding to, and sequestering other transcriptional activators (Fig. 4). A recent report from J. Rinn's lab demonstrated that p53 directs the expression of a set of large, intergenic, noncoding (linc) RNAs that are responsible for repression of some p53 responsive genes by an unknown mechanism.

Transcription-Independent p53 Functions

Several studies showed that p53 can induce apoptosis in the presence of transcriptional or translational inhibitors, strongly suggesting a transcription-independent role for p53 in the apoptotic process (Vaseva and Moll 2009). Subsequently, mutants deficient for transcriptional activation were shown to retain the ability to activate apoptosis. While initially controversial,



p53, Fig. 4 Models for p53-dependent transcriptional repression

transcription-independent p53 functions now are well recognized and characterized, particularly in regulating apoptosis and autophagy (Fig. 2). DNA damage, hypoxia, or oncogene activation promote p53 translocation to the cytoplasm where it inhibits the anti-apoptotic proteins Bcl-2 and Bcl-xL, causing permeabilization of the outer mitochondrial membrane, the release of cytochrome C, and the activation of caspases, followed by chromatin condensation, targeted proteolysis, and cell death. Since the p53 protein lacks a classical mitochondrial translocation motif, the signaling mechanisms that promote cytoplasmic and mitochondrial localization were investigated. Key studies from U. Moll's lab led to the current model for mitochondrial p53 targeting, in which MDM2 mono-ubiquitylates p53, thereby promoting its translocation to the cytoplasm and mitochondria, whereupon it rapidly is de-ubiquitylated by mitochondrial HAUSP, generating an apoptotically active p53. Autophagy is subjected to dual p53 regulation, activation, or inhibition, both transcription dependently and transcription independently (Vousden and Prives 2009). Upon genotoxic stress or oncogene activation, induced p53 activates autophagy as does p53 loss in the absence of stress, implying an inhibitory effect of basal p53 activity on autophagy in nonstressed cells. Transcription-independent p53 activation of autophagy depends on activation of the nutrient sensor AMPK, followed by mTOR repression. Besides its essential role in cellular housekeeping by regulating protein turnover, autophagy serves as another tumor-suppressor mechanism, since loss of autophagy increased DNA damage and genetic instability.

Summary

In the 30 years since its discovery (Table 1), p53 has become perhaps the best characterized mammalian transcription factor. While its roles as the central hub in cellular stress responses and as a tumor suppressor have been detailed, many questions remain and new ones are emerging. Thus, surprisingly little is understood about the biochemical mechanisms by which the many p53 posttranslational modifications regulate its function. G. Lahav's lab demonstrated oscillations in p53 abundance in stressed and unstressed cells, but transcription is activated only in the former,

presumably due to specific posttranslational modifications. This raises a plethora of questions: Where and when are these modifications accomplished, in the cytoplasm, nucleoplasm, or on chromatin? How do they differ among different cell types? What fraction of p53 is modified and which modifications coexist on the same p53 molecule and on the same p53 tetramer? What is the functional interplay among p53 family members? Furthermore, while p63 and p73 carry out different functions, they bind the same or similar REs. How do the more than a hundred p53 binding partners influence p53 activity, and how are these interactions regulated? Like p63 and p73, p53 is expressed as several different isoforms, some lacking the transactivation domain or having different carboxyl termini. How do these influence p53 "activity"? How does p53 discriminate between the thousands of potential REs available for binding in mammalian genomes? Does p53 activity and function vary among individuals? Are polymorphisms in p53REs important in human health? How does the chromatin landscape, including epigenetic modifications such as DNA methylation, modulate p53 binding and regulate transcription. Is it all about transcription? Or are there other functions for p53 sequence-specific DNA binding? Besides its major role as a cellular tumor suppressor, recent studies illuminated many stress-independent p53 functions, including the regulation of cellular metabolism and autophagy, the composition of the extracellular matrix and cell cytoskeleton, immunity and fertility in mammals, stem cell renewal, and neuronal differentiation. Unsurprisingly, p53 has been implicated in the development of a broad spectrum of pathologies other than cancer, including ischemia after stroke, myocardial infarction, and Parkinson's and Alzheimer's disease. Also, other work suggests that too much p53 activity promotes aging. The mechanisms responsible for balancing p53 activity for suppressing tumors and extending longevity remain to be defined. There is little doubt that research on p53 as a signaling molecule has a long, bright future.

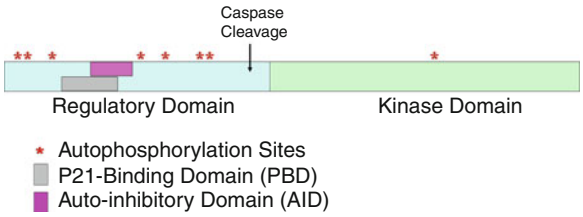
Historical Background

Pak2 (p21-activated protein kinase 2) is the serine/threonine protein kinase PAK I, which was first detected as a protease activated form in Dr. Traugh's laboratory in early 1980s (Tahara and Traugh 1981, 1982). Pak2 was further cloned and sequenced in the same lab in 1996 (Jakobi et al. 1996). Pak2 belongs to the PAK (p21-activated protein kinase) family, which can be activated by Rac and Cdc42 (Manser et al. 1994). The PAK family consists of group I protein kinases, including the highly homologous Pak1 (α-PAK), Pak2 (γ-PAK), and Pak3 (β-PAK), and the recently identified group II, including Pak4, Pak5, and Pak6 (Jaffer and Chernoff 2002). The 60-kDa Pak1 is expressed in brain and is also detected in muscle and spleen. The 60-kDa Pak3 is expressed mainly in brain. Pak2 is 58 kDa and expressed ubiquitously in mammalian cells (Roig and Traugh 2001) (http://www.genecards.org/cgi-bin/carddisp.pl?gene=PAK2).

Pak2 Structural Information

Pak2 is a serine/threonine protein kinase. This 58-kDa protein contains 524 residues. The residues 1–228 is defined as the regulatory domain and the residues 229–524 is the catalytic domain (Fig. 1) (http://www.uniprot.org/uniprot/Q13177). The catalytic domain has a typical bilobol kinase structure, which is composed of a β-sheet-formed small lob and a α-helix-formed large



Pak2, Fig. 1 Pak2 schematic presentation. The p21-binding domain (PBD), autoinhibitory domain (AID), autophosphorylation sites (*), and caspase 3 cleavage site are marked. The regulatory domain is *blue*; the protein kinase domain is *green*

lob (Lei et al. 2000). The ATP binding sites are located in the active site cleft between the two lobs. The conserved catalytic loop, Mg binding loop, and activation loop also reside in the active site cleft. The regulatory domain contains seven autophosphorylation serines, 19, 20, 55, 141, 165, 192, and 197, and the catalytic domain contains one autophosphorylation threonine 402 (Walter et al. 1998).

Pak2 Inhibition and Activation

Pak2 formed a transinhibited dimer before autophosphorylation and activation. The autoinhibitory domain is located in the region 92–133 in the regulatory domain. In the inactive state, the AID interacts with the catalytic domain to inhibit its kinase activity. PAK activation is through disruption of autoinhibition, followed by autophosphorylation. The two main activation mechanisms of Pak2 are caspase-mediated activation and small G protein-mediated activation.

The small GTPases Rac and Cdc42 can activate Pak2 (Fig. 2). GTP-bound Cdc42 can disrupt autoinhibition, which, in turn, leads to autophosphorylation and activation of PAK (Tu and Wigler 1999). The basal autophosphorylation activity of Pak2 is observed, and Pak2 is autophosphorylated at five sites, serines. Additional three phosphorylation sites (serines 141 and 165 and threonine 402) are autophosphorylated in the presence of Cdc42(GTP) and ATP (Gatti et al. 1999). Autophosphorylation of Thr402 in the activation loop is required for the kinase activity of Pak2.

Pak2 can be activated in response to a lot of stresses. Moderate stresses, like hyperosmolarity, ionizing radiation, DNA-damaging agents, and serum-deprivation, induce Pak2 activation in cells and lead to cell cycle arrest at G2/M (Roig and Traugh 2001). Activated Pak2 inhibits translation by phosphorylation of various substrates. Pak2 has specific protein substrates, e.g., histone 4, myosin light chain, prolactin, c-Abl, eukaryote translation initiation factor 3 (eIF3), eIF4B, eIF4G, and Mnk1. Pak2 recognizes the consensus sequence (K/RRXS).

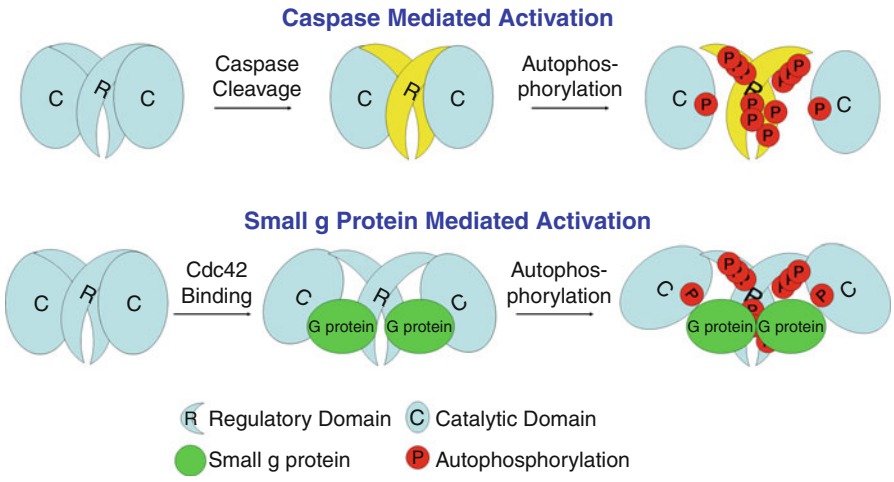
Pak2 is the only member of the PAK family that is directly activated by caspase 3. When Pak2 is cleaved and activated by caspase 3, Pak2 promotes the morphological and biochemical changes of apoptosis. The proapoptosis protease, caspase 3, cleaves Pak2 after Asp 212 and thus produces a p27 fragment containing primarily the regulatory domain and a p34 fragment containing a small piece of the regulatory domain and the entire catalytic domain (Fig. 2). This event loosens the autoinhibitory dimer structure and leads to a complete autophosphorylation, which then results in a constitutively active p34 kinase domain (Hsu et al. 2008). The nuclear import signal (245–251) is required for nuclear localization (Jakobi et al. 2003). Disruption of the region (197–246), containing nuclear export signal, results in the nuclear localization of the Pak2 p34 fragment.

Pak2 and Apoptosis

Pak2 is activated in response to various biological stress, such as hyperosmolarity, ionizing radiation, DNA-damaging agents, and serum deprivation (Roig and Traugh 2001). Among them, the heat shock, H2O2, and UV radiation have been shown to stimulate apoptosis.

Pak2 is proteolytically cleaved during apoptosis. This cleavage event generates two Pak2 fragments and leads to the autophosphorylation and activation of Pak2. The p34 fragment containing the kinase domain is the active fragment. It can localize to nuclear and plays an important role in regulation of the apoptotic cell. The caspase-cleaved Pak2 (p34) has also been reported posttranslationally myristoylated (Vilas et al. 2006). Myristoylation of p34 can induce the relocation from cytosol to membranes and induce cell death without mitochondria damage. Nef protein of HIV has been shown to bind to and activate Pak2 and activates Pak2 and induces apoptosis in Jurkat T cell (Krautkramer et al. 2004).

Proteolytic kinase activation and protein kinase phosphorylation have become an important method



Pak2, Fig. 2 Pak2 activation mechanisms

of regulation in apoptosis (Bokoch 1998). These protein kinases include Pak2, MEKK1, FAK, DNA-PK, PITSLRE, PAKCaKII, Akt and Raf-1.

Pak2 and Cancer

Pak2 can be activated by Ras-related small GTPases, which can regulate the structure, mobility, and migration of the cytoskeleton in cancer cells, indicating the role of Pak2 in tumorigenesis and metastasis of the cancer cells (Kumar et al. 2006; Dummler et al. 2009). Pak2 can react with some key substrates related to cancer development, such as PIX and MLCK in cytoskeleton remodeling, ▶ c-Myc, MNK1, prolactin, and c-Raf1 in cell growth, and BAD in cell survival.

Pak2 is a negative regulator of Myc and suggested Pak2 may be the product of a tumor suppressor gene (Huang et al. 2004). Pak2 mediates tumor invasion in breast carcinoma cells (Coniglio et al. 2008). Inhibition of RhoA in Pak2-depleted cells decreases MLC phosphorylation and restores cell invasion. Also, the NF2 tumor suppressor Merlin is a substrate of Pak2 (Kissil et al. 2002). Wilkes MC (2009) showed that Erbin regulates the function of Merlin through Pak2 binding to Merlin.

Summary

Pak2 is a highly regulated enzyme. It can stimulate both cell growth through small GTPase binding and cell death through caspase cleavage. This characteristic makes this enzyme important for the future researches in apoptosis and cancer.

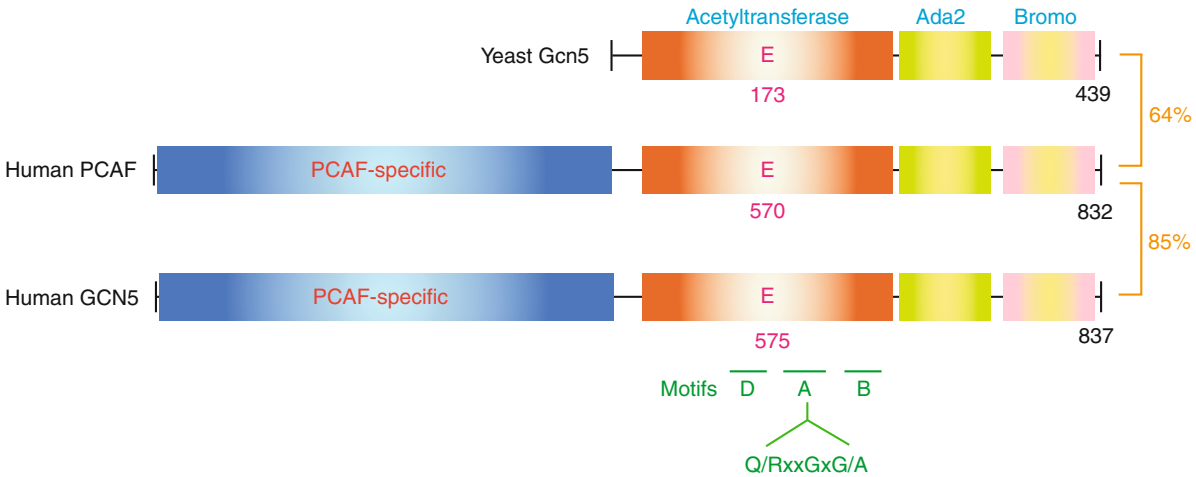
Historical Background: Identification of PCAF as an Acetyltransferase

Human PCAF was identified in the mid-1990s based on an analogy between yeast and mammalian transcriptional control systems (Yang et al. 1996). In the budding yeast *Saccharomyces cerevisiae*, amino acid starvation results in derepression of expression of enzymes for different biosynthetic pathways. This phenomenon suggests co-regulation of different pathways and is thus referred to as "general control of amino acid biosynthesis" (Hinnebusch and Fink 1983; Thireos et al. 1984). Genetic screens in the late 1970s and early 1980s uncovered various mutant strains with defects in the gene control response (Hinnebusch and Fink 1983). Responsible genes of two such mutant strains were named *Gcn4* (*g*eneral *c*ontrol *n*on-derepressible 4, also referred to as *a*mino acid *a*nalog-*s*ensitive 3, *Aas3* or *Aas101*) and *Gcn5* (also called *Aas104*) (Hinnebusch 1984; Thireos et al. 1984). The former was cloned and found to encode a DNA-binding transcription factor (Thireos et al. 1984), whereas analysis of the latter mutant strain suggested that *Gcn5* encodes a transcriptional coactivator (Georgakopoulos and Thireos 1992). Consistent with this conclusion, subsequent cloning revealed that Gcn5 possesses a structural domain with sequence similarity to several other transcriptional regulators without obvious DNA-binding activity (Georgakopoulos and Thireos 1992). This structural domain was initially discovered in *Drosophila* Brahma and was thus named "bromodomain" (Haynes et al. 1992; Tamkun et al. 1992). Along with *Ada2* (*a*lteration/*d*eficiency in *a*ctivation 2) and *Ada3*, *Gcn5* was also uncovered in yeast genetic screens, which were carried out in the early 1990s and aimed at identifying transcriptional adaptors (Marcus et al. 1994). Biochemical data indicated that the three proteins form a transcriptional coactivator complex (Marcus et al. 1994).

In mammalian cells, studies of cAMP-dependent transcriptional responses led to the identification of CBP (*C*REB-*b*inding *p*rotein) as a coactivator able to bind CREB (*c*AMP-*r*esponsive *e*lement *b*inding protein) that was specifically phosphorylated by the cAMP-dependent protein kinase PKA (*p*rotein *k*inase *A*) (Arany et al. 1994). CBP was found to be homologous to p300, a 300 kDa cellular protein associated with adenoviral oncoportein E1A (Arany et al. 1994). Both were shown to coactivate c-Jun, a leucine-zipper transcription factor with sequence and functional similarity to yeast Gcn4. Moreover, both p300 and CBP contain bromodomains homologous to yeast Gcn5 and display sequence similarity to a small domain of yeast Ada2 (Arany et al. 1994). Together with the conclusion that Gcn5 and Ada2 are components of a coactivator complex, these similarities suggested a potential role of mammalian homologs of yeast Gcn5 and Ada2 as transcriptional coactivators. With these considerations, PCAF was cloned in the mid-1990s as an 832-residue human protein with its C-terminal half homologous to yeast Gcn5 (Fig. 1) (Yang et al. 1996). A highly relevant development was that p55, a 55 kDa *Tetrahymena* protein with significant sequence homology to yeast Gcn5, was identified as a histone acetyltransferase (Brownell et al. 1996), thereby leading to the demonstration of intrinsic histone acetyltransferase activity in PCAF (Yang et al. 1996). This activity was also shown with human GCN5 (KAT2A) (Yang et al. 1996; Wang et al. 1997), which is paralogous to PCAF (Fig. 1). These studies established that from yeast to humans, Gcn5 and its homologs form an evolutionarily conserved family of histone acetyltransferases with important roles in transcriptional regulation. This notion has been subsequently validated in numerous studies with various transcription factors.



PCAF Lysine Acetyltransferase, Fig. 1 Domain organization of yeast Gcn5 and human PCAF and GCN5. Yeast Gcn5 possesses three domains: an acetyltransferase core, an Ada2-intercation module (*Ada2*), and a bromodomain (*bromo*). Human PCAF and GCN5 are paralogous to each other. Their C-terminal parts are highly homologous to yeast Gcn5, but they possess long N-terminal extensions. The amino acid sequence similarity between yeast Gcn5 and the corresponding region of PCAF is 64% (shown at *right*), whereas the overall similarity between human PCAF and GCN5 is 85%. The *red* and *dark* numbers below each protein denote positions of the catalytic glutamate (E) residue and the C-terminal end. Rough positions of motifs A, B, and D conserved with other members of the Gcn5-related N-acetyltransferase (GNAT) family are indicated at the bottom of the acetyltransferase domains, along with the motif A signature sequence Q/RxxGxG, which is also found in the MYST family of acetyltransferases

Domain Organization and 3D Structure of PCAF

Compared to yeast Gcn5, PCAF has a long N-terminal extension (Fig. 1). Similar to yeast Gcn5, the C-terminal half of PCAF contains three domains: an acetyltransferase core, an Ada2-interacting module, and a bromodomain (Fig. 1). PCAF is paralogous to human GCN5 because they share high sequence similarity in the entire sequence, i.e., both the N-terminal extension and the Gcn5-like C-terminal half. The N-terminal extension is conserved in *Drosophila* Gcn5 and mediates the association with p300 and CBP. One report indicated that the N-terminal extension of PCAF also contains an E3 ubiquitin ligase activity. Additional studies are needed for the N-terminal extension, but lots of knowledge has been gained about the C-terminal half.

The acetyltransferase core possesses three conserved motifs, A, B, and D (Fig. 1), which are shared by members of the GNAT (*G*cn5-related *N*-*a*cetyl*t*ransferease) family (Roth et al. 2001). The peptide QVKGYG within motif A of PCAF matches nicely to the Q/RxxGxG/A signature sequence present in members of the GNAT as well as MYST families of histone acetyltransferases. Crystal structure of the PCAF acetyltransferase core has been determined and is similar to that of yeast Gcn5, with motifs A and B forming the acetyl coenzyme A-binding pocket. A key catalytic residue is E-570, which is located at the N-terminal part of motif A and serves a base to extract a proton from the amino group of an acetylatable lysine residue during catalysis. Structural comparison with other Gcn5 family members suggests how this family of acetyltransferases can accommodate various substrates with divergent sequence. Two correlations have been reported: (1) the acetylatable lysine residue itself and its C-terminal region, especially residues at positions +2 and +4, play a particularly important role in substrate selectivity, and the backbone of the substrate in this region in positions +1 and +3 also contributes to substrate binding; and (2) the substrate region N-terminal to the lysine residue modulates substrate affinity. This flexibility of substrate recognition explains that PCAF has been shown to acetylate numerous proteins substrates.

At the C-terminal end of PCAF is a bromodomain (Fig. 1). This domain was initially discovered as a structural motif that *Drosophila* Brahma and yeast Snf2 share with other proteins. NMR structural determination and peptide interaction assays revealed an acetyl-lysine binding pocket within the bromodomain of PCAF (Dhalluin et al. 1999). This property has been demonstrated in other bromodomains and plays a role in acetylation-dependent chromatin remodeling (de la Cruz et al. 2005). The PCAF bromodomain prefers acetyl-K binding site a hydrophobic residue at position +2 and an aromatic or positively charged residue at position +3.

Between the acetyltransferase core and bromodomain of PCAF is a small ADA2-interaction module (Fig. 1). As with yeast Gcn5, Ada2 interaction is required for activation of PCAF. Further studies are needed to map the details of the interaction, e.g., which residues are crucial. As detailed in the next section, there are two paralogous ADA2 proteins in humans and dependent on which one PCAF associates with, different multisubunit complexes are formed (see the next section).

Multisubunit PCAF Complexes

Yeast Gcn5 is part of high-molecular-weight multisubunit ADA and SAGA (*S*pt-*A*da-*G*cn5-*a*cetytransferase) complexes (Grant et al. 1997). As yeast genetic screens suggested, both complexes contain Ada2 and Ada3. Compared to Gcn5 alone, these complexes are more active in acetylating nucleosomes (Baker and Grant 2007). A SAGA-like PCAF complex consists of more than 20 distinct polypeptides (Nagy and Tora 2007). Interestingly, the N-terminal extension is not required for the complex formation (Ogryzko et al. 1998). Among the subunits are several TBP-associated factors (TAFs) that form a histone-octamer subcomplex. Another prominent subunit is TRRAP (TRansactivation/tRansformation domain Associated Protein), a 400 kDa protein originally isolated from a Myc-associated transcription coactivator (McMahon et al. 1998). Electron microscopy revealed that the complex forms an slightly twisted L-shape structure consisting of five modular domains, with PCAF or GCN5 occupying domain III in the middle region (Nagy and Tora 2007). As in *Drosophila*, there are two Ada2-like proteins in mammals, Ada2a and Ada2b (Barlev et al. 2003; Pankotai et al. 2005). The SAGA-like complex contains Ada2b, whereas Ada2a is present in a different complex, known as ATAC (Ada two A containing), that also contains another acetyltransferase ATAC2 and additional subunits that are absent in the SAGA complexes (Suganuma et al. 2008). Some of these additional subunits are components of the JNK pathway and confer the ability of the ATAC complex to regulate JNK signaling (Suganuma et al. 2010). Therefore, different from the SAGA complex, the ATAC complex possesses two acetyltransferases. Both GCN5 and PCAF are present in the two types of complexes.

PCAF Function in Various Cellular Processes

Consistent with its acetyltransferase activity toward numerous substrates, PCAF and its orthologs regulate different cellular processes in diverse organisms from the fly to humans. Many transcription activators and cell-cycle regulatory proteins such as nuclear receptor, c-Myc, KLF, and E2F family contact directly and recruit PCAF-containing complexes to specific promoters. The PCAF coactivators can be recruited to a target gene promoter by a transcription activator. At the gene promoter, the coactivators catalyze lysine acetylation on either histone tails, the transcription activator, and/or the basal transcription machinery components. These reactions help unmask the promoter DNA from the nucleosomes, stabilize the transcription factor, enhance its interaction with DNA or protein partners, and/or promote transcription initiation and elongation. As a result, the transcription of the target gene is activated.

PCAF Function in Development

Human PCAF is ubiquitously expressed in adult tissues, but more abundant in heart and skeletal muscle. The expression of mouse *Pcaf* is low during embryonic development but increases in adult heart and skeletal muscle. By contrast, mouse *Gcn5* expression is high during early development and decreases after birth, suggesting distinct roles of *Pcaf* and *Gcn5* during mouse development (Lin and Dent 2006). Indeed, gene disruption of mouse *Pcaf* did not yield any obvious phenotypes except some defects in short-term

memory and stress responses (Maurice et al. 2008), whereas inactivation of *Gcn5* is embryonic lethal at E8.5. Moreover, knock-in mouse embryos expressing an inactive acetyltransferase mutant (E568A/D609; mouse E568 is a key catalytic residue and is equivalent to E575 of human GCN5, Fig. 1) of Gcn5 exhibited severe cranial neural tube closure defects and exencephaly, indicating that the acetyltransferase activity is required for cranial neural tube closure. Thus, even though they are highly homologous at the amino acid sequence level and display similarity at the biochemical level, mouse Pcaf and Gcn5 have different roles in different tissues and developmental stages due to their different patterns of expression. On the other hand, although *pcaf* expression is low during early development, deletion of both *Pcaf* and *Gcn5* led to a more severe phenotype, indicating that they also have overlapping functions during early development.

Summary

PCAF was initially identified in 1996 and contains an N-terminal extension and a C-terminal Gcn5-like half that comprises an acetyltransferase core, an Ada2-interaction module, and a bromodomain. The three-dimensional structures of the acetyltransferase core and bromodomain have been solved and provide structural and mechanistic details as to how these two domains carry out lysine acetylation and recognize an acetyl-lysine peptide, respectively. Although it is absent in yeast Gcn5, the N-terminal extension of PCAF is conserved from orthologs from flies to humans. In mammals, GCN5 shares high sequence similarity with PCAF in the entire sequence. Like GCN5, PCAF exists at least two different multisubunit complexes, SAGA and ATAC. While the SAGA complex is conserved in yeast, the ATAC complex is metazoan-specific. At the functional level, PCAF is well known to serve as a transcriptional coactivator. Through acetylating histones and numerous non-histone substrates, PCAF also regulates diverse cellular programs. While little difference has been reported for them at the biochemical level, roles of PCAF and GCN5 in mouse – and perhaps also human – development are quite different owing to rather distinct spatiotemporal expression patterns.

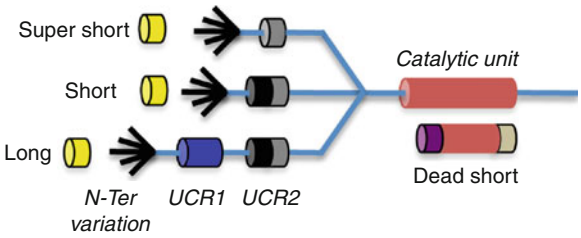
Historical Background

Cyclic 3’5’ adenosine monophosphate (cAMP) is a key second messenger that is responsible for

regulating many pivotal signaling processes in all mammalian cell types (Tasken and Aandahl 2004). It influences cell growth, differentiation, shape, and movement as well as processes such a cardiac contraction, metabolism, water retention, learning, and memory. Most intriguingly, however, cAMP can selectively regulate a variety of very different processes in any one particular cell type. Indeed, uncovering the molecular mechanisms that allow cAMP to selectively regulate disparate processes within a single cell has provided a major challenge. Only very recently has the means whereby cAMP signaling is compartmentalized in cells begun to be understood (Tasken and Aandahl 2004; Baillie et al. 2005; Willoughby and Cooper 2007). One key requirement is for spatially discrete signaling complexes to be assembled in cells that have the machinery for detecting cAMP and translating this into an appropriate action. Critically, however, is a need for machinery able to dynamically regulate the access of cAMP to the detections system(s) and this is achieved by controlling the rate of cAMP degradation in the immediate vicinity of the signaling complex by targeted phosphodiesterases (Houslay 2010). Spatially constrained cAMP degradation has the functional consequence of adjusting the threshold for activation of cAMP sensors, in particular signaling complexes, in the face of a prevailing level of cAMP formation by ▶ adenylyl cyclase activity. Carrying out this process are forms of cAMP degrading phosphodiesterases (PDEs) that have specific 'zip codes' allowing them to be targeted to particular signaling complexes (Houslay 2010). These PDEs convert cAMP to 5'-adenosine monophosphate (AMP) and so play a pivotal role in not only degrading the cAMP signal but, critically, in forming and shaping cAMP gradients in cells so as to regulate the activity of distinct signaling complexes. Indeed, recent technological advances have allowed cAMP gradients formed by PDEs to be dynamically visualized in living cells (Zaccolo 2009). These are FRET-based genetically encoded sensors that are based upon the cAMP effectors, either protein kinase A (PKA), which phosphorylates specific target proteins, or Exchange Protein Activated by cAMP (EPAC), which activates the mini G-proteins, Rap1/2.

Our understanding of how targeted cAMP degradation underpins cAMP signaling has been revolutionized by studies on members of the multigene PDE4 subfamily.



PDE4, Fig. 1 Schematic of PDE4 isoform classification. These four classes are defined by their complement of UCR1 and UCR2 domains with individual isoforms defined by distinct N-terminal domains

What Is PDE4?

Eleven PDE families describe enzymes that hydrolyse either or both cAMP and cGMP (Conti and Beavo 2007; Lugnier 2006). Four genes (*PDE4A*/*B*/*C*/*D*) encode the PDE4 family of enzymes (Houslay 2010; Conti and Beavo 2007). Through the use of distinct promoters and alternative nRNA splicing these genes encode a series of splice variants that are classified as long, short, super-short, and dead-short isoforms. Each isoform is characterized by a unique N-terminal region with the sole known exceptions being PDE4B5 and PDE4D6, which have identical N-terminal regions, albeit encoded by distinct exons (Fig. 1).

Long PDE4 isoforms possess dual regulatory domains that are unique to PDE4, namely, Upstream Conserved Region 1 (UCR1) and Upstream Conserved Region 2 (UCR2). These are located between the isoform-specific N-terminal region and the highly conserved catalytic unit (Fig. 1). UCR1 is tethered to UCR2 by the heterogeneous linker region LR1, with UCR2 tethered to the catalytic unit by the heterogeneous linker region, LR2. The PDE4 C-terminal regions from different subfamilies show no similarity but are identical for all active isoforms within any particular subfamily.

The presence or absence of UCR1/2 underpins classification; long forms have both, short forms lack UCR1, super-short forms lack UCR1 and have a truncated UCR2 while catalytically inactive dead-short forms lack both UCR1 and UCR2 and, through a unique 3' splicing event, have a truncated catalytic unit and novel C-terminal region.

Regulation by Phosphorylation

The rate of cAMP degradation by PDE4 can be dynamically regulated by phosphorylation. Pivotal to this are the UCR1 and UCR2 regulatory domains, which direct the functional outcome on the catalytic unit in response to phosphorylation (Houslay and Adams 2003).

UCR1 contains a classical site for PKA phosphorylation, which confers activation on long isoforms. Thus long isoforms play a prime role in the desensitization of cAMP signaling by facilitating cAMP degradation when cAMP levels rise sufficiently to activate PKA.

The catalytic unit of all PDE4 isoforms, save those from the PDE4A subfamily, contains a classical site for ERK phosphorylation. However, the UCR modules direct the functional outcome of such ERK phosphorylation, with long forms being inhibited by ERK phosphorylation, while short forms are activated and super-short isoforms show no activity change.

The inhibitory effect of ERK phosphorylation of PDE4 long isoforms can be overcome by PKA phosphorylation. This provides a potential feedback regulatory unit where ERK-mediated inhibition of a long PDE4 can cause local cAMP levels to rise, activating local PKA, which then phosphorylates the long PDE4 to disinhibit it, causing cAMP levels to fall. Thus, through this route, ligands activating ERK can lead to a programmed transient rise in cAMP through effects on PDE4 long forms.

Additionally, an unidentified kinase activated by reactive oxygen species can phosphorylate PDE4. Although this does not alter PDE4 activity, it reprograms the effect of inhibitory ERK phosphorylation of long isoforms to one of activation.

UCR1 is also the site of phosphorylation by the stress-activated kinase, MK2 (MAPKAPK2). This does not alter PDE4 activity, but attenuates the ability of PKA to activate long forms.

Certain PDE4 forms are also modified by ubiquitination and SUMOylation. While neither alters PDE4 activity, SUMOylation of PDE4D5 enhances its activation by PKA while reducing its inhibition by ERK phosphorylation. Very recently it has been demonstrated that GSK3 can phosphorylate PDE4D isoforms, causing their ubiquitination and targeting for degradation.

Multisite phosphorylation confers dynamic regulation upon PDE4 activity and certain targeting events. In this, the UCR1 and UCR2 domains perform critical roles in defining the effect of phosphorylation on PDE4 catalytic activity. Unfortunately there are no determined structures for full-length PDE4 isoforms due to the propensity of PDE4 enzymes to multimerize upon purification. However, biochemical studies have shown that UCR1 and UCR2 interact with each other, as does UCR2 with the catalytic unit. Indeed, recent structural studies demonstrate that UCR2 docks to the catalytic unit alongside the catalytic pocket. In fact, in certain conformational states a portion of UCR2 may even bind across the catalytic pocket, obscuring access to cAMP and engendering inhibition. This process may be regulated by phosphorylation, dimerization, and interaction with binding partner proteins.

The core PDE4 catalytic unit is a compact structure of 17 α-helices folded into three sub-domains. At the junction of the three sub-domains is a deep cAMP substrate-binding pocket that contains two essential Me^{2+} binding sites, considered natively to be Zn^{2+} at the deeper site and Mg^{2+} at the more surface exposed site. The Zn^{2+} is tightly bound by four direct ligand interactions, with the fifth position being provided by water that bridges to the loosely held Mg^{2+} and plays the key role of nucleophilic attack in hydrolysis of the cyclophosphodiester bond. Structural changes arising from post-translational modification, UCR1/2 domain interaction, and partner protein sequestration may be relayed into the catalytic center through helices 10 and 11.

Targeting of PDE4

Each PDE4 isoform has a signature N-terminal (N-Ter) domain whose major function is to confer intracellular targeting to specific signaling complexes and intracellular locations (Houslay 2010; Keravis and Lugnier 2010). The paradigm for this concept is the super-short PDE4A1 isoform that has a unique 25 amino acid N-Ter region. PDE4A1 is entirely membrane associated, being found in Golgi and vesicles that traffic from it. However, the engineered removal of its unique N-Ter region generates a soluble, cytosolic species that is clearly correctly folded as it remains fully catalytically active. This observation led to the notion that the PDE4 N-Ter region determined intracellular targeting, thus providing a functional reason for the diversity of PDE4 isoforms.

Such targeting is invariably driven by protein–protein interactions although, as in the case of PDE4A1, it may also involve protein–lipid interactions.

All of the information required for membrane association and targeting is encompassed within the unique N-Ter region of PDE4A1 as when it is fused to various soluble proteins the distribution of such chimeric species parallels that of full-length PDE4A1. NMR analysis of the PDE4A1 N-Ter region revealed two α-helical domains separated by a flexible hinge. The binding of Ca^{2+} to Asp21 in helix-2 elicits a conformational change that allows insertion of a core Trp19:Trp20 unit into the bilayer. However, PDE4A1 membrane targeting also requires helix-1, which increases the efficiency of helix-2 membrane association as well as conferring targeting to the trans-Golgi stack, probably by interacting with a Golgi-localized protein subsequent to membrane insertion of helix-1. Additionally, helix-1 allows PDE4A1 to undergo a dynamic intracellular redistribution to phosphatidic acid-rich regions upon Ca^{2+}-binding to Asp6. Thus PDE4A1 provides a paradigm for the targeting of PDE4 isoforms to specific complexes and for such interactions to be functionally, and dynamically, regulated.

Subsequently, specific PDE4 isoforms have been found to associate with signaling scaffold proteins (RACK1, myomegalin, β-arrestin, AKAPs, Ndel1, spectrin, Shank2, Lis1), receptors (p75 neurotropin receptor, ryanodine receptor, β_1-adrenoceptor), enzymes (ERK, DNA-PKc), certain SH3 domain-containing proteins (e.g., ▶ Src family tyrosyl kinases), and transcription factors (AIP/XAP2). The mapping of interaction surfaces between many of these partnerships has been greatly facilitated by peptide array approaches. These have driven mutagenesis strategies to define interaction surfaces and in developing cell-permeable peptides for use in disrupting specific PDE4 partnerships in cells and so allowing functional assessment.

Dominant negative, siRNA, and gene-targeted knockout approaches have unequivocally shown that individual PDE4 isoforms can have specific functional roles and that there is no redundancy in the system. It is now appreciated that the diversity of PDE4 isoforms allows for targeting of particular species to specific, spatially defined signaling complexes in cells in order to allow for their exquisite control by gradients of cAMP sculpted by tethered PDE4 isoforms. A paradigm for this is the sequestration of the PDE4D5 isoform with the signaling scaffold β-arrestin. This complex is recruited to the β_2-adrenergic receptor when cells are challenged with β-adrenergic receptor agonists, thus delivering an active cAMP degrading system to the site of cAMP synthesis. This complex has a dual desensitization role. Thus β-arrestin uncouples the β_2-adrenoceptor from the guanine nucleotide binding protein, Gs, and so negates activation of adenylyl cyclase, while PDE4D5 lowers local cAMP levels and switches off the activity of plasma membrane and β_2-adrenergic receptor-tethered PKA. The importance of β-arrestin-delivered PDE4D5 in the control of these PKA subpopulations was gathered by a dominant negative approach. This involved making a single point mutation deep within the cAMP-binding pocket of PDE4D5 so as to destroy catalytic activity while leaving the ability of PDE4D5 to bind β-arrestin unaltered. Overexpressing this inactive species in cells displaces active wild-type PDE4D5 from β-arrestin and allows plasma membrane PKA activity to rise unhindered in the face of challenge with β-adrenergic receptor agonists. However, no such action was seen if different catalytically inactive PDE4 isoforms were used or if a catalytically inactive PDE4D5 construct was engineered so as to disrupt its β-arrestin binding site.

Various of these PDE4 partnerships can be dynamically altered by external cues so as to reprogram cAMP gradients within cells. This can take the form of either changes in the expression of scaffolds, allowing new or competing partnerships to occur, or posttranslational modification that can alter specific partnerships. Thus the Mdm2-mediated ubiquitination of PDE4D5 enhances its interaction with β-arrestin while the PKA-mediated phosphorylation of PDE4D3 serves to enhance its interaction with the mAKAP scaffold while decreasing its interaction with the Ndel1 scaffold.

PDE4 and Disease

The first indication that PDE4 might provide an effective therapeutic target came from observations that rolipram, the first reported PDE4 selective inhibitor, exerted antidepressant properties. However, such therapeutic potential was negated by side effects, primarily severe emesis and nausea. Indeed, these issues have characterized, to a greater or lesser extent, all

active-site-directed PDE4 inhibitors to date and provided a major challenge to the pharmaceutical industry in developing selective inhibitors with effective therapeutic windows (Houslay et al. 2005). PDE4 selective inhibitors also exert potent anti-inflammatory actions and have been developed for treating inflammatory lung diseases such as asthma and COPD. Promisingly, in this regard, Roflumilast® has been approved for use in treating COPD in Europe and the USA.

The central problem with therapeutic exploitation of active-site-directed inhibitors is that they inhibit all PDE4 isoforms rather than just those that govern the target therapeutic process. As PDE4 catalytic units are identical in all isoforms from a particular subfamily and near identical between subfamilies, the chance of obtaining isoform-specific inhibitors through this route is nigh on impossible. Indeed generating subfamily selective inhibitors poses a severe challenge that has, to date, only shown scant possibilities for PDE4D and PDE4B. Further obfuscation arises from the fact that interacting proteins and posttranslational modification can alter the conformation of PDE4 isoforms. This, as shown in various instances, can translate into alterations in their susceptibility to active-site-directed inhibitors. Indeed, recent structural studies have given insight into how UCR2 interaction with the catalytic unit may drive some of these (Houslay and Adams 2010).

One possibility for the future is to determine whether the inhibition of a specific PDE4 isoform that was anchored could provide a route to treating defined diseases. If so, a novel therapeutic approach might be employed based upon developing either small molecules, peptides, or peptidomimetics that disrupt such a key partnership. This would have the effect of displacing a specific PDE4 isoform from the site where it is needed to function in the cell, thereby raising only local cAMP levels, thus eliciting a highly targeted and specific action for therapeutic advantage while minimizing/negating side effects.

PDE4 diversity has been highly conserved in evolution. Interestingly, mutations in the PDE4 gene in *Drosophila melanogaster* have been described that lead to learning defects. This correlates with studies on mammals showing that cAMP is intimately linked with learning processes and a panoply of studies showing that PDE4 inhibitors can act as cognitive enhancers, which may offer future promise for the utility of PDE4 inhibitors in Alzheimer disease. More recently, the *PDE4B* gene has been linked to schizophrenia in certain families. Indeed, in an example of converging genetic and biochemical approaches, the scaffold protein DISC1, mutations in whose gene can provide strong association with schizophrenia, can interact with PDE4 isoforms, including PDE4B.

Mutations in the *PDE4D* gene have also been linked to stroke susceptibility. However, the linkage appears likely to depend on both the type of stroke and ethnic background. The basis of the linkage is obscure to date but mutations appear to locate in noncoding regions upstream of the PDE4D7 isoform, which may indicate effects on the specific promoter for this isoform.

PDE4 inhibitors have also been suggested to have therapeutic possibilities for treating certain cancers. They, seemingly, can promote B-cell apoptosis in chronic lymphocytic leukemia and can inhibit the growth and migration of colon cancer cells, for example.

Summary

PDE4 isoforms provide a major route for underpinning compartmentalized cAMP signaling in all mammalian cells. The plethora of isoforms provides a library of species that can be targeted to specific intracellular locales/signaling complexes. This enables them to sculpt local cAMP gradients, thereby gating the activation of tethered cAMP effectors to cAMP. The selective expression of PDE4 isoforms with different regulatory regions (UCR1/2) allows them to perform distinct roles in both the cellular processes for desensitizing cAMP signaling and for cross-talk with other critical signaling systems so as to integrate cellular responses in cell-type specific fashions.

Members of the diverse PDE4 family are invariably located at nodes that link multiple signaling pathways and, as such, are set to play key roles in regulating pivotal cellular responses. Our understanding of the range of PDE4 partner proteins and multiple sites for phosphorylation, ubiquitination, and SUMOylation is only just beginning to be appreciated. Furthermore there is also the exciting possibility that the function of the PDE4 enzymes is not just to carry out targeted cAMP degradation but also to provide a signaling role for themselves (Murdoch et al. 2011).

Current studies have served to set the scene for a more detailed appreciation of the importance and pervasiveness of PDE4 isoforms, their key roles in biology, health and disease, and future therapeutic exploitation.

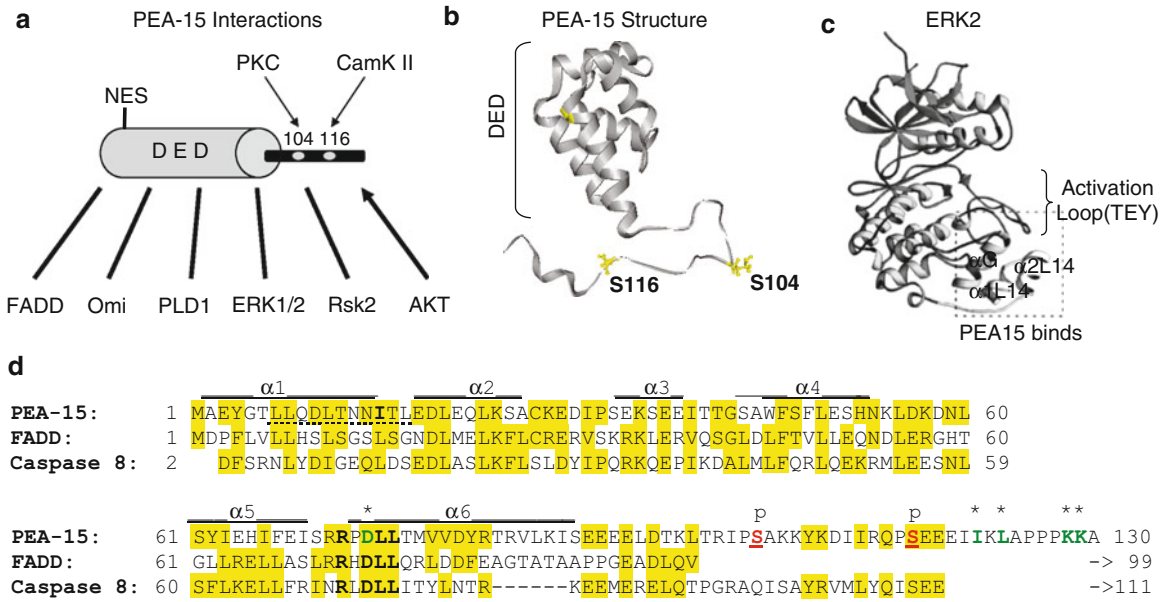
Historical Background

Phosphoprotein Enriched in Astrocytes 15 kDa (PEA-15), also known as PED-15, is a 15 kDa protein that is highly expressed in the nervous system with particularly high levels in astrocytes and neurons of the hippocampus. Chneiweiss and colleagues first characterized PEA-15 as a major substrate for Protein Kinase C (PKC) in astrocytes and later cloned the cDNA encoding the protein (Araujo et al. 1993; Estelles et al. 1996). Subsequently, a portion of the 3′ UTR of the PEA-15 mRNA, called MAT1, was identified as a mammary transforming gene associated with mouse mammary carcinogenesis (Bera et al. 1994). It remains unclear how this relates to the function of the full-length PEA-15 protein. The initial functional significance of PEA-15 was identified when it was shown to be a phosphoprotein overexpressed in skeletal muscle in patients with type 2 diabetes (Condorelli et al. 1998). In this context, PEA-15 was shown to inhibit insulin-stimulated glucose transport indicating it may be involved in development of type 2 diabetes. PEA-15 was further found by expression cloning to inhibit H-Ras signaling to integrins (Ramos et al. 1998). This work provided an additional potential connection to cancer and the first suggestion that PEA-15 may modulate cell adhesion. This was quickly followed by the first two reports showing that PEA-15 can act as an anti-apoptotic protein that blocks cell death by preventing Fas-Associated via Death Dominion protein (FADD) recruitment and activation of Caspase 8 in response to Fas or Tumor Necrosis Factor Receptor (TNFR) activation (Condorelli et al. 1999; Kitsberg et al. 1999). Thus from the initial handful of papers it was clear that PEA-15 is a multifunctional protein affecting many distinct cell signaling pathways.

PEA-15 Structure and Binding Partners

PEA-15 is encoded by two highly conserved mRNAs that are alternatively spliced in the large 3′ UTR. The mRNA is expressed in most tissues while the protein expression is more limited. The message encodes a nonenzymatic 15 kDa cytoplasmic protein consisting of 130 amino acids (Estelles et al. 1996). The N-terminal 80 amino acids encode a canonical death effector domain (DED), while the remaining 50 amino acid C-terminal tail lacks structure, but contains two



Pea15, Fig. 1 PEA-15 Structure and Binding Partners. (**a**) PEA-15 is 130 amino acids in length and consists of a death effector domain (DED) that constitutes amino acids 1–80. PEA-15 is phosphorylated at serine 104 by protein kinase C (PKC) and at serine 116 by either Calcium calmodulin kinase II (CamK II) or AKT. *Arrows* depict these phosphorylations and PEA-15 binding partners are indicated by *connecting lines*. (**b**) The NMR-derived structure of PEA-15. The C-terminal tail lacks structure and has an extended and flexible conformation in the unphosphorylated state. (**c**) The structure of ERK2 is shown. PEA-15 binds the MAP kinase insert that is located just below the activation loop that contains the phosphorylated TEY sequence. (**d**) The full amino acid sequence of PEA-15 is indicated aligned with the DEDs of two other DED family members, FADD and Caspase 8. Conserved amino acids are highlighted in *yellow*. The six predicted alpha helices are indicated above the sequence by the over-lined α regions. The phosphorylated serines are *underlined* and in *red* and point mutants that abrogate ERK binding are indicated by a *star (*)* and are in *green*. The consensus nuclear export sequence (NES) is underlined by a *dashed line* (aa 7–17)

serines that are phosphorylated by PKC (Ser104) or AKT and (Calcium Calmodulin Kinase II) CamKII (Ser116) (Ramos 2005). Proteins containing DEDs are known to regulate apoptosis, the process of programmed cell death and have more recently been found to also affect proliferation (Valmiki and Ramos 2009). PEA-15 is a member of this DED family of proteins (Fig. 1). PEA-15 also has a functional nuclear export sequence (NES) which, when mutated, leads to the accumulation of PEA-15 in the cell nucleus (Formstecher et al. 2001). In addition PEA-15 protein stability is regulated by ubiquitination, which is blocked by phosphorylation of Ser116 by CamKII downstream of PKCζ or phorbol esters (Fiory et al. 2009).

PEA-15 binds several proteins known to regulate apoptosis, transcription, and proliferation and thereby affects these processes (Ramos 2005). Among identified interacting partners some of the most extensively characterized are extracellular signal-regulated kinase 1 and 2 (ERK1/2) MAP Kinase, FADD, (Phospholipase D) PLD, ribosomal protein S6 kinase 2 (RSK2), and AKT. PEA-15 binding to ERK and FADD is regulated by phosphorylation at the two serines. This indicates that phosphorylation is one mechanism by which PEA-15 binding to its partners is determined. PEA-15 can also simultaneously bind ERK and the ERK substrate RSK2 and thereby act as a scaffold to target ERK to RSK2. Thus far this remains the only identified instance of PEA-15 acting as a scaffold. PEA-15 binding to FADD acts predominantly to block FADD binding to and activation of Caspase 8 while binding to PLD appears to serve to activate that lipase (Fig. 1) (Fiory et al. 2009; Ramos 2005). In this way, the function of PEA-15 is determined by its binding partners.

PEA-15 in Glucose Transport

PEA-15 was identified by differential display to be overexpressed in the adipose and skeletal muscle tissues, as well as in skin fibroblasts of type 2 diabetic

patients and their first-degree relatives. Moreover PEA-15 expression in skeletal muscle impairs glucose transporter type 4 (GLUT4) translocation and thereby inhibits insulin-stimulated glucose transport. This established early on that PEA-15 likely plays a significant role in type 2 diabetes (Condorelli et al. 1998). Subsequently, transgenic mice overexpressing PEA-15 were found to have some of the hallmarks of type 2 diabetes. These transgenic mice had impaired glucose tolerance, resistance to insulin action on glucose disposal, reduced insulin-stimulated glucose transport in fat and skeletal muscles, and impaired insulin effects on GLUT4 membrane translocation (Fiory et al. 2009). These effects may be caused in part by the ability of PEA-15 to directly bind and stabilize ▶ phospholipase D (PLD) thereby inducing PKC activity (Fiory et al. 2009). This hypothesis is further supported by the observation that inhibition of PEA-15 binding to PLD restores insulin-stimulated glucose uptake. Thus targeting the PEA-15/PLD1 interaction may provide a new approach to improving sensitivity to insulin action in diabetics (Fiory et al. 2009).

PEA-15 in Apoptosis

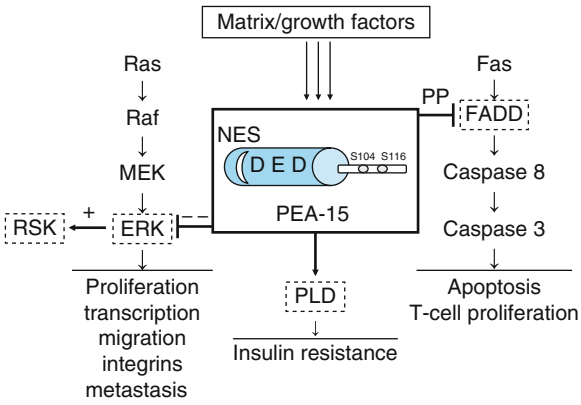
PEA-15 regulates apoptosis by inhibiting the death receptor–activated extrinsic cascade. PEA-15 is expressed at particularly high levels in astrocytes and its N-terminal DED supports its interaction with other DED-containing proteins including FADD and possibly Caspase 8. This was an early indicator that PEA-15 may play an anti-apoptotic role in these cells. Indeed, sensitivity to TNF-dependent apoptosis is significantly increased in astrocytes from PEA-15-null mice (Kitsberg et al. 1999). Moreover, this unusual sensitivity to TNF can be repaired by exogenous expression of PEA-15 in the knockout astrocytes. In separate experiments, PEA-15 was also reported to block the extrinsic apoptotic pathway in human mammary carcinoma cells (MCF-7). The likely mechanism is that by binding to both FADD and Caspase 8, PEA-15 inhibits their interaction and thereby prevents the formation of the death-inducing signaling complex (DISC). Thus Caspase 8 and downstream caspases are not activated. This is the same mechanism suggested for the anti-apoptotic effects of another DED family protein called cFLIP. The anti-apoptotic effect of PEA-15 appears to extend to other cancer cell types as well. Human malignant glioma cells are often highly resistant to TNF-related apoptosis-inducing ligand (TRAIL)-induced apoptosis. Because of this, these gliomas cannot be treated with chemotherapies based on TRAIL activation. However, knockdown of PEA-15 in these cells restores their sensitivity to TRAIL (Fiory et al. 2009; Valmiki and Ramos 2009). These results suggest that reducing PEA-15 levels in some cancer cells may improve their response to death receptor–based therapies.

Phosphorylation at Ser116 stabilizes PEA-15 levels and promotes its interaction with FADD, while phosphorylation at Ser-104 abrogates PEA-15 binding to ERK. Moreover, only the dually phosphorylated PEA-15 is found in the death-inducing signaling complex (DISC) in TRAIL-resistant glioma cells, suggesting that dual phosphorylation is necessary for its protective role (Fiory et al. 2009). Indeed, treatment with inhibitors of PKC (known to phosphorylate PEA-15 at Ser104) abrogated the anti-apoptotic function. Similarly, inhibitors of AKT/PKB block phosphorylation of PEA-15 at Ser116 and increase PEA-15 degradation leading to elevated TRAIL-mediated apoptosis. Thus dual phosphorylation of PEA-15 is essential for it to block extrinsic apoptosis initiated by Fas, TNFR, or TRAIL (Fiory et al. 2009). PEA-15 levels are also regulated in apoptosis by the serine protease Omi/HtrA2. This pro-apoptotic mitochondrial protease is released in response to different cellular stresses and exerts pro-apoptotic function by promoting Caspase 3 activation through its protease activity. Omi/HtrA2 also promotes apoptosis by degrading PEA-15 and thus preventing PEA-15 anti-apoptotic activity (Fiory et al. 2009). Hence PEA-15 anti-apoptotic function is regulated by phosphorylation, ubiquitination, and proteolytic degradation of the protein.

In addition to regulating extrinsic apoptotic cascades, PEA-15 also inhibits stress-induced apoptotic responses to oxidative agents, serum deprivation, and anisomycin treatment. In human kidney embryonic cells (HEK293), overexpression of PEA-15 decreased anisomycin- and H_2O_2-induced apoptosis and inhibited the phosphorylation of JNK1/2 and p38. Impaired activity of these stress kinases by PEA-15 correlated with inhibition of stress-induced Cdc-42, MKK4, and ▶ MKK6 activation (Fiory et al. 2009). PEA-15 is therefore well established as an important anti-apoptotic protein that functions by multiple mechanisms to promote cell survival.

PEA-15 in the ERK Mitogen-Activated Protein Kinase (MAPK) Pathway

Expression of the oncogenic small GTPase H-Ras can decrease binding of integrins to their extracellular ligands such as fibronectin. This causes reduced cell adhesion and prevents assembly of the extracellular matrix. The H-Ras signal is mediated by the Raf/ERK MAP kinase signaling cascade. PEA-15 can inhibit this H-Ras suppression of integrins when it is co-expressed. Furthermore the effect of PEA-15 is at the level of ERK but PEA-15 does not alter ERK activity (Fiory et al. 2009; Ramos et al. 1998). In subsequent studies it was found that PEA-15 binds directly to ERK and prevents translocation of active ERK into the nucleus. The cytoplasmic sequestration of ERK blocks ERK-dependent transcription and proliferation (Ramos 2008; Valmiki and Ramos 2009). PEA-15 not only restricts ERK to the cytoplasm, it can target cytoplasmic ERK to its substrate kinase RSK2. In this way, PEA-15 acts as a scaffold for ERK activation of RSK2. Moreover like most scaffold proteins, PEA-15 effects on RSK2 activation depend on the expression level of PEA-15. For example at optimum molar ratios of PEA-15, ERK, and RSK2, PEA-15 enhances RSK2 activation. Whereas expression at high molar excess of PEA-15 in comparison to ERK or RSK2 can inhibit RSK2 activation (Ramos 2008; Vaidyanathan et al. 2007; Valmiki and Ramos 2009). RSK2 is itself a serine/threonine kinase that has a number of downstream targets and can regulate transcription, proliferation, survival, and migration. Thus it is likely that some of the effects of PEA-15 on these functions are due to its effects on RSK2 activity. The mechanisms of PEA-15 regulation of cell signaling are depicted in Fig. 2.



Pea15, Fig. 2 PEA-15 regulates both apoptotic and ERK-pathways. The phosphorylation status of PEA-15 determines if it binds to ERK MAP kinase or FADD. If serine 104 is not phosphorylated, PEA-15 can bind to ERK and regulate its function by altering its location and interaction with RSK2. If PEA-15 is phosphorylated at serines 104 and 116, it binds to FADD and can regulate FADD-mediated signaling by blocking FADD binding to and activation of caspases. Phosphorylation of PEA-15 is regulated by growth factors. Finally, PEA-15 can bind and activate PLD

PEA-15 in Cancer Development and Progression

PEA-15 is reported to play diverse roles in many types of cancer including mammary, ovarian, skin, and glioma (Fiory et al. 2009; Ramos 2005). However, the effects of PEA-15 expression are not the same in each cancer and indeed PEA-15 is reported to act in the manner of both a tumor promoter and a tumor suppressor. The functions of PEA-15 that make it particularly interesting in cancer research are its effects on apoptosis, chemoresistance, senescence, adhesion, and migration.

Cancer cells frequently become resistant to apoptosis-mediated cell death. PEA-15 can effectively block apoptosis induced by death receptors in many cellular contexts. In glioma, B cell carcinoma, as well as breast and small cell lung cancer, increased PEA-15 expression levels correlate with resistance to death receptor–induced apoptosis (Fiory et al. 2009). Similarly, PEA-15 inhibits apoptosis in a skin carcinoma mouse model by abrogating TPA-dependent Caspase 3 activation (Fiory et al. 2009). The ability of PEA-15 to prevent apoptosis suggests it could be a valuable target for development of drugs to be used in combinatorial therapy to make cancer cells more prone to elimination (Ramos 2005). Thus, the ability of PEA-15 to block apoptosis may partly explain cancer resistance to radiation- and chemotherapy-induced cell death.

Cancers also typically develop the ability to undergo increased, uncontrolled cell proliferation in the absence of apoptosis or senescence. PEA-15 binds to ERK, prevents ERK translocation into the nucleus, and thereby impairs ERK-dependent transcription and proliferation. This function of PEA-15 appears to be key in the ability of PEA-15 to limit

proliferation of ovarian and breast cancers (Bartholomeusz et al. 2010; Bartholomeusz et al. 2006). PEA-15 may also prevent proliferation of some cancers by inducing cellular senescence as described in fibroblasts. In both instances, PEA-15 levels may be controlled by the adenovirus E1A. In ovarian cancer E1A upregulates PEA-15, which prevents ERK nuclear signaling and thereby decreases cell proliferation (Bartholomeusz et al. 2006). Conversely, in mouse embryo fibroblasts, E1A downregulates PEA-15, promoting ERK nuclear localization and thereby preventing Ras-induced senescence. Thus PEA-15 restriction of ERK to the cytoplasm is necessary in these cells for Ras to induce senescence. This provides an alternative method by which PEA-15 can prevent tumor cell proliferation even in the presence of an oncogene by promoting senescence (Fiory et al. 2009; Ramos 2005).

The initial discovery of PEA-15 as an inhibitor of Ras/MAPK signaling to integrins was the first indication of its potential role in cell adhesion, migration, and invasion. Since then PEA-15 has been reported to inhibit mammary tumor invasion (Glading et al. 2007) and astrocytoma migration and invasion (Renault-Mihara et al. 2006) by differing mechanisms. Immunohistochemical microarray analysis shows that PEA-15 expression is correlated with decreased invasive behavior of breast carcinoma and this effect seems to relate to the nuclear localization of activated ERK1/2. In these tumors, PEA-15 inhibits invasion by preventing ERK translocation to the nucleus. Indeed PEA-15 mutants that cannot bind or sequester ERK are unable to inhibit invasion. Additionally, membrane-localized ERK1 that is unable to translocate to the nucleus also decreases invasion. These results reveal the significance of nuclear entry of ERK1/2 in tumor behavior and indicate that the PEA-15 inhibitory effect on cell invasion depends on its ability to bind ERK (Glading et al. 2007). Additionally, the use of organotypic culture analysis of highly invasive primary astrocytomas revealed that only tumor cells expressing low levels of PEA-15 migrated away from the originating explants. Similarly, PEA-15-null astrocytes demonstrated significantly elevated motility compared to wild-type control cells and this was reversed by transfection of PEA-15. Moreover, mouse embryo fibroblasts transfected with PEA-15 displayed reduced migration (Renault-Mihara et al. 2006). Pharmacological treatments in these experiments excluded participation of ERK1/2, PI3K/AKT, CamK II in this effect of PEA-15. Rather inhibition of astrocyte migration is dependent on PEA-15 downregulation of PKCδ (Fiory et al. 2009; Renault-Mihara et al. 2006). Independently of the mechanism, the loss of cell invasiveness strongly suggests a role for PEA-15 as a potential metastasis suppressor.

High PEA-15 expression correlates to better prognosis for several cancer types. Women with high PEA-15-expressing ovarian tumors survive longer than those with low PEA-15-expressing tumors. PEA-15 was thus proposed to be a potentially important prognostic marker in ovarian cancer (Fiory et al. 2009). Similarly, PEA-15 expression correlates with World Health Organization (WHO) grading criteria for astrocytic tumors. High PEA-15 levels correlate with lower grade tumors. Hence here too PEA-15 may prove to be a useful prognostic marker (Watanabe et al. 2010). Finally, PEA-15 expression levels inversely correlate with cell motility and invasiveness in astrocytomas and mammary carcinomas (Glading et al. 2007; Renault-Mihara et al. 2006). Thus, PEA-15 expressions tend to reduce proliferation and invasion in some cancers and can thereby act as a tumor suppressor in these tumors. Whether PEA-15 acts to increase or decrease tumorigenesis therefore likely depends upon its phosphorylation status and the affected signaling pathways and microenvironment of the tumor.

PEA-15 in the Immune Response and Spatial Learning

Normal PEA-15 function has been investigated using PEA-15 null mice (Kitsberg et al. 1999). The PEA-15 null mice are born at Mendelian ratios, appear grossly normal, and did not evidence any abnormal brain size, neuron number, or structural defects. PEA-15 is highly expressed throughout the brain and regulates ERK, RSK2, and CREB function. As these proteins are important in cognitive function, the PEA-15 null mice were examined for nervous system function and cognitive defects. In these studies the effects of loss of PEA-15 was investigated in a series of experiments designed to measure stress activity, as well as learning and sensory functions. PEA-15 knockout mice exhibit impaired spatial learning, while their fear conditioning, passive avoidance, egocentric navigation, and

odor discrimination are normal. Additionally, PEA-15 knockout mice exhibit impaired forepaw strength. The knockout mice also were of normal weight, pain sensitivity, and coordination and have normal visual, auditory, and olfactory abilities (Ramos et al. 2009). It is attractive to suggest that these cognitive defects may be the result of abnormal ERK- and RSK2-dependent ▶ CREB transcription.

PEA-15 null mice were noted by Dr. Chneiweiss to suffer enlarged spleens and lymph nodes when kept in uncontrolled antigen-rich environments. This largely went away when the mice were kept in controlled Hepa-filtered cages. Thus a potential role for PEA-15 in the immune response was investigated. Pastorino and colleagues found that PEA-15 null mice have no significant defects in thymic or splenic lymphocyte cellularity or differentiation. However, activation of PEA-15 null T cells results in hyperproliferation in comparison to wild-type littermates. This increased proliferation results at least in part from increased ERK translocation into the nucleus and the resultant elevated activation of IL-2 transcription and secretion (Pastorino et al. 2010). In vitro studies conducted in Jurkat T cells confirm that PEA-15 negatively regulates T-cell receptor signaling restricting cell proliferation, ERK nuclear translocation, and IL-2 transcription (Pastorino et al. 2010). Interestingly, there is no indication that apoptosis is altered in the PEA-15 null immune cells. Hence, PEA-15 is a novel player in T-cell homeostasis and thereby contributes to the regulation of the immune responses. Significantly, the effects of PEA-15 deletion on both cognitive function and immune response can be explained by changes in ERK MAP kinase signaling.

Summary

PEA-15 modulates signaling in extrinsic apoptosis, ERK MAP kinase, and PLD pathways. This leads to changes in cell death, proliferation, and motility among others. As a result of these effects, PEA-15 plays an important role in normal glucose metabolism, the immune response and learning while its abnormal expression is associated with type 2 diabetes and cancer. Therefore, it will be important to determine if manipulation of PEA-15 is a valid therapeutic approach in diabetes and cancer. However, the fact that PEA-15 expression can both enhance and impair cancer progression provides a note of caution that the context of any PEA-15 directed therapy must be well understood before progressing. To this end, much work is still needed.

Historical Background

PHLDA1 (pleckstrin homology-like domain, family A, member) gene encodes for a member of an evolutionarily conserved pleckstrin homology-related domain protein family and was first identified as a potential transcription factor required for Fas expression and activation-induced apoptosis in mouse T cell hybridomes (Park et al. 1996). Further, PHLDA1 homologues were identified and isolated in rat (Gomes et al. 1999) and human (Kuske and Johnson 2000), and sequencing comparison showed that mouse, human, and rat PHLDA1 cDNAs exhibit high level of identity. The genes encoding for the members of the pleckstrin homology-related domain protein family are located in different chromosomes, PHLDA1 (also named PHRIP/TDAG51/DT1P1B11/MGC131738; 12q21.2), PHLDA2 (also named IPL/BRWR1C/HLDA2/TSSC3; 11p15.4), and PHLDA3 (also named TIH1; 1q32.1), but have a similar simple gene structure with two exons (one coding exon) and a small intron (Frank et al. 1999).

Protein Structure and Biochemical Function

The human PHLDA1 gene encodes a 401 amino acid protein containing plackstrin homologue (PHL) domain spanning amino acids from 150 to 283 interrupted by a small proline/glutamine rich sequence (QQ) and protein–protein interaction domains in its carboxy-terminal region, as proline-glutamine (PQ) and proline-histidine-rich (PH) tracts (Fig. 1). The PHL domains are evolutionary conserved and found in a wide range of eukariotic proteins (Lemmon et al. 2002). The PHL domains are composed of about 100–120 aa residues with properties to bind phosphatidylinositol lipids (Lemmon et al. 2002). Many proteins containing PHL domains (such as IRS proteins) are found to Interact with membrane components and participate in cell signaling transduction, vesicular trafficking, and cytoskeletal rearrangement (Lemmon and Furgson 2000). Poly-glutamine (QQ), proline-histidine (PH), and proline-glutamine (PO) tracts are well-conserved motifs in eukariotic proteins and were reported to be involved in transcriptional regulation and protein-protein interaction in the development of neurodegenerative diseases (Williamson 1994; Butland et al. 2007). In addition, number variations of QQ repeats are associated with the development of neurodegenerative diseases (Butland et al. 2007). Although the function of the members of the plackstrin homologue (PHL) domain protein family (PHLDA1, PHLDA2, and PHLDA3) in different types of human cells remain to be elucidate, PHLDA1 has been shown to be regulated by different stimuli and associated with cell proliferation, cell survival, and tumorigenesis.

Expression Regulation

PHLDA1 is expressed in several mammalian tissues displaying subcellular localization predominantly in the cytoplasm and nucleoli (Gomes et al. 1999; Hinz et al. 2001; Neef et al. 2002; Oberg et al. 2004; Xi et al. 2007; Nagai et al. 2007). PHLDA1 mRNA and protein expression is induced by different stimuli such as growth factors, differentiation agents, and ER-stress agents (Fig. 2). In T cell hybridome, PHLDA1 is rapidly induced upon TCR activation (Park et al. 1996). In rat neuronal cells, PHLDA1 is induced by fibroblast growth factor (FGF) and differentiation agent (Gomes et al. 1999). Phorbol ester (TPA)/ionomycin induce PHLDA1 expression in different transformed T cell lines (Hinz et al. 2001). PHLDA1 was found to be induced by both PDGFβ and AKT activation in MERAKT cells (Kuhn et al. 2001). IGF-1 induces PHLDA1 mRNA and protein in NIH-3 T3 (NWTb3) cells through IGF-1R via p38MAPK pathway and in normal skin fibroblasts via PI3K pathway (Toyoshima

PHL (plackstrin homologue domain spanning amino acids from 150 to 283; *QQ* proline/glutamine rich sequence; *PQ* proline-glutamine tracts; and *PH* proline-histidine-rich tracts

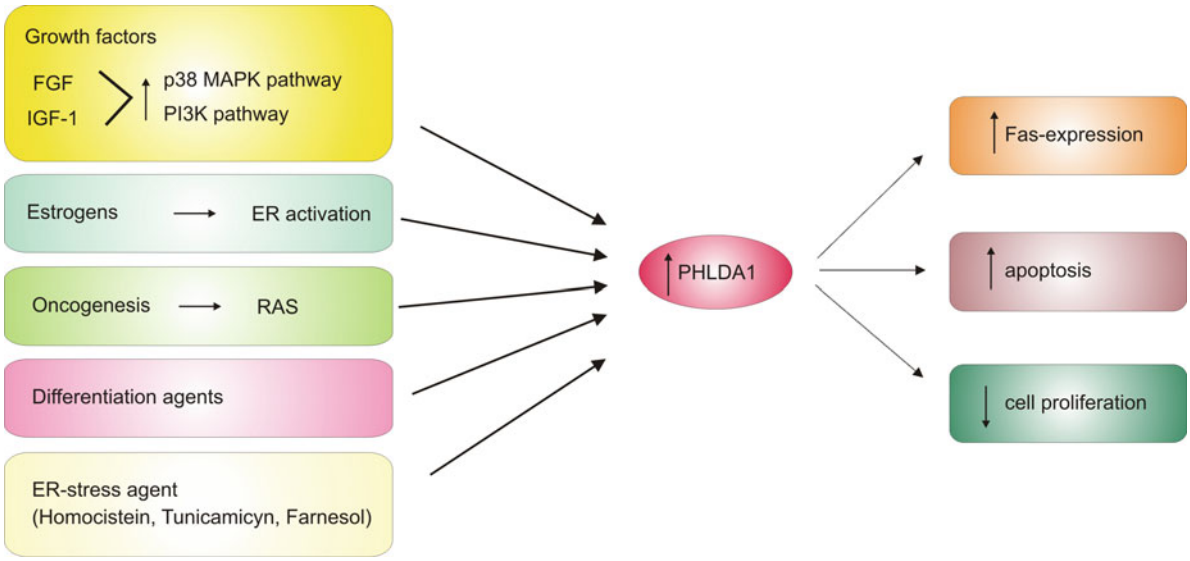
et al. 2004; Wu et al. 2010). In MCF-7 breast cancer cells PHLDA1 is upregulated by estrogen via estrogen receptor (ER) (Marchiori et al. 2008). PHLDA1 expression is also induced by ER stress-inducing agents, such as homocysteine, tunicamycin, and farnesol in different cell types (Hossain et al. 2003; Joo et al. 2007).

Role in Cell Death

Several experimental evidences consistently indicate that PHLDA1 is involved in cell death induction. The pro-apoptotic activity of PHLDA1 was first demonstrated in mouse T cell hybridome where PHLDA1 is required for Fas(CD95)-expression, which plays an important role in TCR-induced apoptosis (Park et al. 1996). PHLDA1 expression was found to be dependent upon the activity of PKC, and PKC activation only induces Fas-expression in cells expressing wild type PHLDA1 (Wang et al. 1998). However, Rho et al. (2001) demonstrated that PHLDA1−/− mice express normal levels of Fas and had normal T-cell apoptosis, indicating that PHLDA1 is not essential for Fas-expression. Microinjection of differentiating H19-7 cells with a neutralizing antibody anti-PHLDA1 increases cell survival, and transient PHLDA1 expression decreases cell survival in both differentiating and non-differentiating H19-7 cells, indicating that PHLDA1 acts as a mediator of differentiation-associated apoptosis in H19-7 hippocampal cells (Gomes et al. 1999). In 293 T cells, PHLDA1 was found to interact with two mRNA-binding proteins, eIF3-p66 and PABP, and PHLDA1 co-transfection with the luciferase gene leads to protein biosynthesis inhibition, a process important in the execution of apoptosis (Hinz et al. 2001). Overexpression of PHLDA1 in endothelial cells leads to changes in cell morphology, decreases cell adhesion, and promotes detachment-mediated cell death (Hossain et al. 2003). Knockdown of PHLDA1 abolish the ability of IGF-1 to prevent NIH-3 T3 (NWTb3) cells from undergoing apoptosis in response to serum starvation (Toyoshima et al. 2004). Constitutive PHLDA1 expression in different melanoma-derived cell lines leads to reduced cell growth, reduced colony formation, and increased basal apoptosis (Neef et al. 2002). Stress-induced heat shock proteins (Hsp70, Hsp110, and Hsp40) directly bind to the pleckstrin domain of PHLDA1 and suppress its pro-apoptotic function in MEF cells (Hayashida et al. 2006). The promoter region of the PHLDA1 has HSE-binding sites where the heat shock transcription factor 1 (HSF1) binds and modulates PHLDA1 expression; in addition, HSF1 is able to directly bind to and activate PHLDA1 in response to heat shock in male germ cells (Hayashida et al. 2006). Moreover, during the time-course induction of cryptorchidism rat testis, Hsf1 and Phlda1 are strongly expressed, suggesting that the Hsf1/Phlda1 pathways play an important role in the apoptosis of primary spermatocytes in criptorchid testis (Liu et al. 2011).

Role in Cancer

Evasion from apoptosis or programmed cell death, which is an active, energy-dependent process involving biochemical and molecular events regulated by a series of distinct genes, is a hallmark of cancer (Hanahan and Weinberg 2000, 2011). Several experimental studies provided evidences that PHLDA1 plays a role in apoptosis induction and cell proliferation, cell adhesion, and migration. Alterations in the PHLDA1 mRNA and/or protein expression were observed in different types of tumors, such as melanomas, breast



PHLDA1 (Pleckstrin Homology-like Domain, Family A, Member): Alias: PHRIP; TDAG51; DT1P1B11; MGC131738, Fig. 2 Schematic illustration for PHLDA1 in cell signaling and function. PHLDA1 can be up-regulate by several stimuli, such as growth factor cell signaling pathways, estrogen receptor activation, ras activation, and ER-stress agents. In addition, PHLDA1 up-regulation leads to an increase in Fas-expression, enhanced apoptosis and decreased cell proliferation

tumors, and intestinal tumors. Decreased PHLDA1 protein levels were demonstrated in melanomas (Neef et al. 2002) and breast carcinomas (Nagai et al. 2007; Johnson et al. 2011). On the other hand, PHLDA1 was found to be strongly expressed in human intestinal adenomas and the majority of intestinal carcinomas and PHLDA1 knockdown in colon cancer cells inhibits anchorage-independent cell growth and reduces cell migration (Sakthianandeswaren et al. 2011).

PHLDA1 reduced expression was found in metastatic as compared with primary melanoma cells, suggesting that PHLDA1 downregulation may contribute to the progression of malignant melanomas (Neef et al. 2002). Constitutive PHLDA1 in different melanoma-derived cell lines leads to reduced cell growth, colony formation, increased basal apoptosis, and increased sensitivity to apoptosis induced by chemotherapeutic agents, doxorubicin and camptothecin (Neef et al. 2002). Expression profiling analysis identified the PHLDA1 transcripts to be overexpressed in hair follicular stem cells (Ohyama et al. 2006). A recent study identified consistent positive immunoreactivity for PHLDA1 in trichoepitheliomas and negative immunoreactivity in basal cell carcinomas, indicating that PHLDA protein expression may allow differential diagnosis between trichoepitheliomas and basal cell carcinomas (Sellheyer and Nelson 2011). PHLDA1 protein downregulation was a strong predictor of poor prognosis for breast cancer patients and patients with tumors showing reduced PHLDA1 expression and paucity for ER has the worse outcome (Nagai et al. 2007). Reduction of PHLDA1 expression in HME16C mammary epithelial cells during ras-mediated cellular transformation induces proliferation under anchorage-independent conditions and results in increase in ERK activation, suggesting that PHLDA1 opposes ERK-mediated proliferation in breast cancer cells (Oberst et al. 2008). Recently, a regulatory loop between Aurora-A and PHLDA1 was observed in breast cancer cells (Johnson et al. 2011). In MDA-MB-231 breast cancer cells, Aurora-A predominantly phosphorylates PHLDA1 at serine residue 98 (Ser98) leading to its degradation and PHLDA1 overexpression results in decreased levels of Aurora-A, suggesting that PHLDA1 acts as a negative regulator of Aurora-A-mediated breast oncogenesis (Johnson et al. 2011).

Summary

In summary, several reports provide evidence that PHLDA1 plays an important role in apoptosis

induction and cell proliferation inhibition leading to reduced cell survival; however, little is known about the mechanisms or cell signaling pathways involved in the pro-apoptotic functions of PHLDA1 in different cell types. PHLDA1 is induced by different stimuli, including ER-stress agents, cell differentiation agents, and mitogenic agents, such as growth factors and estrogens, suggesting that PHLDA1 may play diverse roles in addition to apoptosis. Downregulation of PHLDA1 has been shown in skin cancer and breast cancer biopsies, indicating a tumor-suppressive function for PHLDA1; however, new clinical studies are required to evaluate if this suppressive effect is restricted to certain types of tumors or is common to the majority of human tumors. In melanoma cells, PHLDA1 expression increases chemosensitivity to doxorubicin and camptothecin; it will be interesting to see if and how PHLDA1 improves efficacy to chemotherapeutic drugs in different cell types. Further experimental studies in vitro and in informative and testable animal models are required to *improve the understanding* of PHLDA1 mechanisms of action both in normal and cancer cells and its role as a prognostic and predictive factor in cancer.

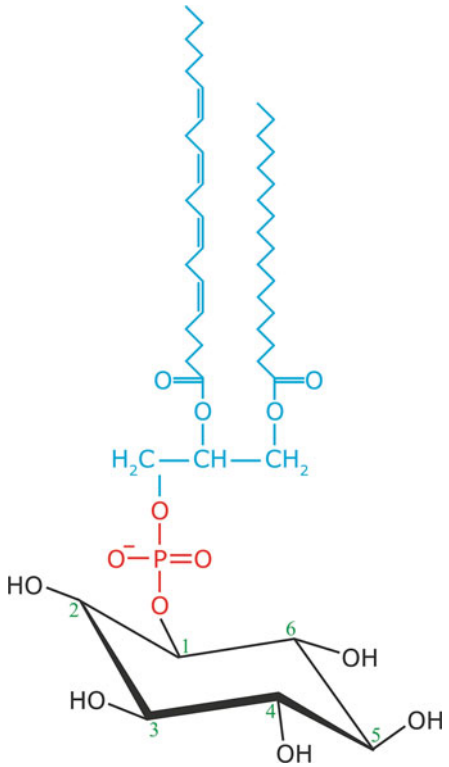
Historical Background

Phosphatidylinositol 5-phosphate 4-kinase (PIP4K) is an enzyme activity capable of converting a mono-phosphorylated lipid substrate into a bis-phosphorylated product, a reaction that is fundamental in the maintenance of the cellular phosphoinositide (PI) cycle. PIP4K catalyzes the addition of a phosphate group to position D-4 of the inositol head-group of PtdIns5*P* (Figs. 1 and 2). Downstream effects of signaling molecules generated by the PI cycle are diverse and include vesicle trafficking, ion channel activity, cytoskeletal dynamics, cell differentiation, proliferation, and apoptosis (Toker 2002; Irvine 2003; Di Paolo and De Camilli 2006; Gonzales and Anderson 2006).

Pioneering work in the early 1950s led to the elucidation of the roles of multiple kinases and phosphatases required to generate the diverse array of inositol lipid species in the PI cycle and in the numerous regulatory, signaling, and metabolic pathways that they are involved in (Hinchliffe et al. 1998; Anderson et al. 1999). The first activities, isolated from human erythrocytes, to convert PtdIns4*P* to PtdIns(4,5)P_2 were classified as Type I and Type II enzymes (Bazenet et al. 1990). Subsequent studies revealed that these two enzymes had distinct substrate



Phosphatidylinositol 5-phosphate 4-kinase, Fig. 1 Molecular structure of PtdIns (1[stearoyl], 2[arachidonoyl]-diacyl-*sn*-glycero-3-phospho-[1-D-*myo*-inositol]). Stearoyl (C18:0) and arachidonyl (C20:6) fatty acid chains on the diacylglycerol moiety are the commonest substitutions found in cellular phosphoinositides. The hydrophilic diacylglycerol "tail" sits within the membrane while positions D-3, D-4, and D-5 of the inositol head-group are available for phosphorylation

specificities, and that the Type II enzyme was in fact solely utilizing PtdIns5*P*, a contaminant of the commercial PtdIns4*P* substrate in the assay (Rameh et al. 1997). Although the preferred substrate of PIP4K is PtdIns5*P* it has also been shown to phosphorylate PtdIns3*P* in vitro (Fig. 2), producing PtdIns(3,4)P_2 (Hinchliffe et al. 1998; Clarke et al. 2007). Both of these substrates are minor components of the typical cellular phosphoinositide content, PtdIns5*P* and PtdIns3*P* constituting 2% and 5% of total PtdIns*P*, respectively, the majority being PtdIns4*P* (Toker 2002). As a consequence, the contribution of PIP4K activity to cellular PtdIns(4,5)P_2 synthesis is thought to be restricted to specific isolated compartments, or the role of the enzyme is to attenuate the putative signaling function of PtdIns5*P* itself. Three mammalian PIP4K isoforms have so far been discovered (α, β, and γ), with no known splice variants to date, and each has been shown to have a specific distribution and subcellular localization (Clarke et al. 2010).

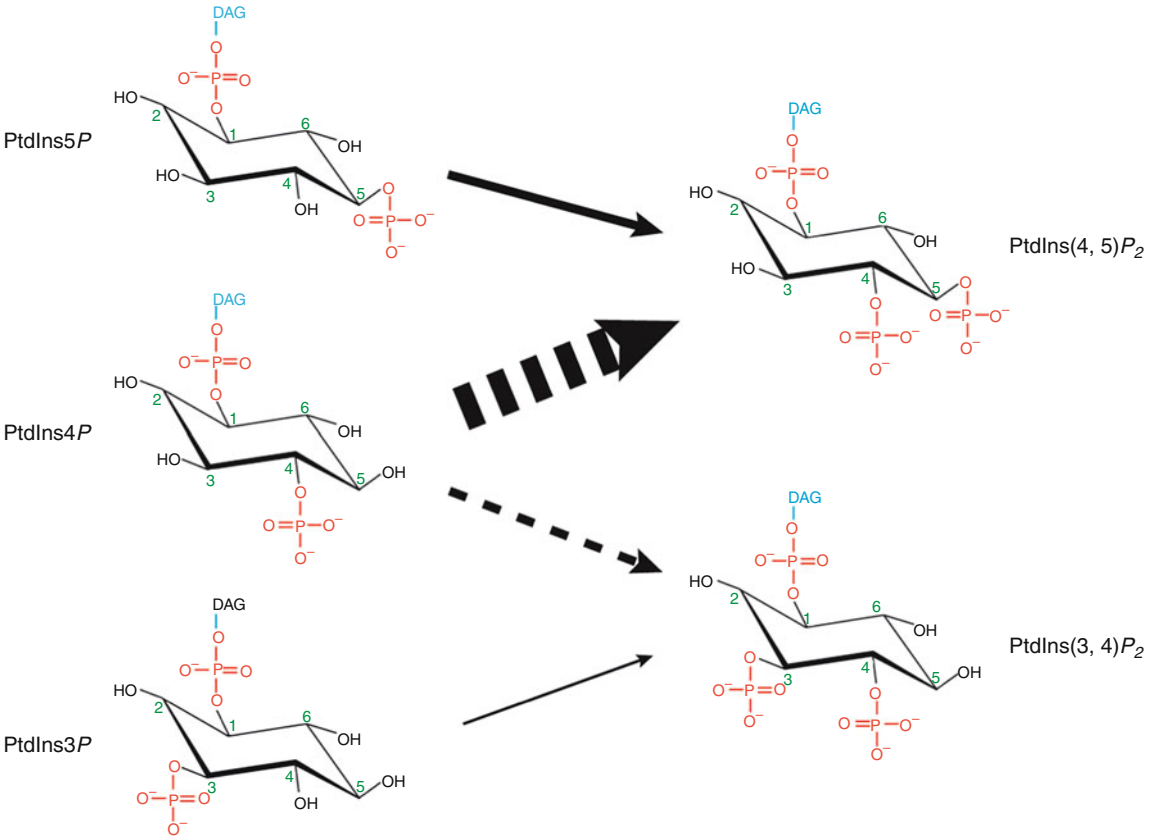
PIP4K Molecular Evolution

Homologs to genes encoding PIP4K proteins have been discovered in over 50 species with completed genomic sequences. Early divergence of the PIP4K and phosphatidylinositol 4-phosphate 5-kinase (PIP5K) enzymes (Fig. 3), which share significant identity over the conserved kinase-core domain (discussed below), presumably occurred by gene duplication, as did the later emergence of PIP5KL1, an inactive scaffolding protein for PIPKs (Chang et al. 2004). Lower eukaryotes, such as the yeast *Saccharomyces cerevisiae*, do not have an identified PIP4K activity, and within the plant kingdom, 11 of the *Arabidopsis thaliana* atPIPK proteins have sequence similarity to both PIP4K and PIP5Ks although the examples studied so far use PtdIns4*P* as substrate (Mueller-Roeber and Pical 2002). A single PIP4K activity is present in nematodes such as *Caenorhabditis elegans* (PPK-2), arthropods such as *Drosophila melanogaster* (dPIP4K), and urochordates such as *Ciona intestinalis*. The later divergences produce first PIP4Kγ, then PIP4Kα and PIP4Kβ (Fig. 3). PIP4Kα is present in all vertebrates, with a few organisms missing either PIP4Kβ or PIP4Kγ; the exception of the latter isoform from any of the bird genomes completed to date is particularly notable. Within the human genome each isoform is present as a single-copy gene, with *PIP4K2A* (coding for PIP4Kα) located on chromosome 10 (p12.2), *PIP4K2B* (coding for PIP4Kβ) on chromosome 17 (q21.2), and *PIP4K2C* (coding for PIP4Kγ) on chromosome 12 (q13.2).

PIP4K Structure

Although the PIP4K isoforms have a significant level of identity at the amino acid level, they share only 30% identity with the phosphatidylinositol 4-phosphate 5-kinases (PIP5Ks) and constitute a novel family with no significant identity to any other lipid or protein kinases (Anderson et al. 1999).

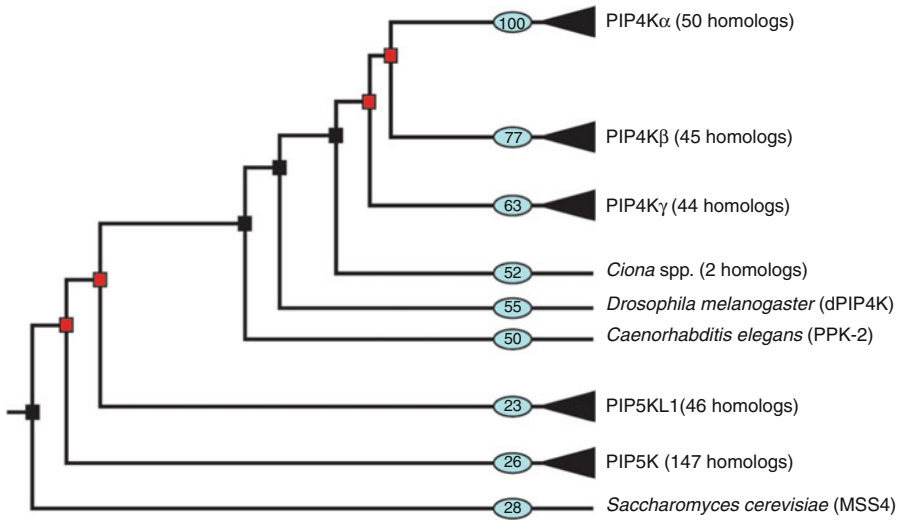
Homology between the PIPKs is mostly limited to the large kinase core domain (Fig. 4) as defined in



Phosphatidylinositol 5-phosphate 4-kinase, Fig. 2 Production of PtdInsP_2 from PtdIns$P$. PIP4K is able to use two of the three possible PtdIns$P$ species as substrates (in vitro), producing PtdIns(4,5)P_2 from PtdIns5P and PtdIns(3,4)P_2 from PtdIns3P (*filled arrows*, relative substrate preference indicated by width). Alternative routes of production (from PtdIns4P) by PI3K (PtdIns(3,4)P_2) and PIP5K (PtdIns(4,5)P_2) are also shown (*dashed arrows*, relative contribution indicated by width), although other phosphoinositides are omitted

deletion studies by Ishihara et al. and structural similarity alignment by Rao et al. (reviewed in Hinchliffe et al. 1998; Anderson et al. 1999). Regions of low similarity outside of the kinase core define the functional differences between the PIP4K and PIP5Ks. Three-dimensional structure by X-ray crystallography has been elucidated for both the PIP4Kβ (3.0 Å resolution, PDB i.d. 1BO1, Rao et al. 1998) and the PIP4Kγ (2.8 Å resolution, PDB i.d. 2GK9, Thorsell, Protein Data Bank online submission) isoforms, which share 79% similarity by structural comparison. These data show the PIP4K structure to be two domains arranged across a central cleft, which has catalytic and ATP-binding residues conserved with a protein kinase, PKA. Four conserved catalytic residues are identified, and the mutation of at least one (aspartate 273 in PIP4Kα, or aspartate 278 in PIP4Kβ) results in biochemical inactivity. This active site is open on one side, such that the proposed binding of ATP and a phospholipid head-group would accommodate PtdIns5P or PtdIns3P (Rao et al. 1998).

The N-terminal domain has seven β-sheets and four α-helices, and the crystal structure shows that the protein homodimerizes along the interface of two adjacent β1 strands (Fig. 4) to form a broad, flat face that is able to contact cell membranes by means of electrostatic interaction with lipid head-groups (Rao et al. 1998). Recent data has also shown the potential of the PIP4K isoforms to heterodimerize, suggesting a possible means of inter-isoform regulation based on protein expression levels in different tissues (Bultsma et al. 2010; Wang et al. 2010). This domain also contains a putative ATP-stabilizing G-loop motif (Rao et al. 1998).



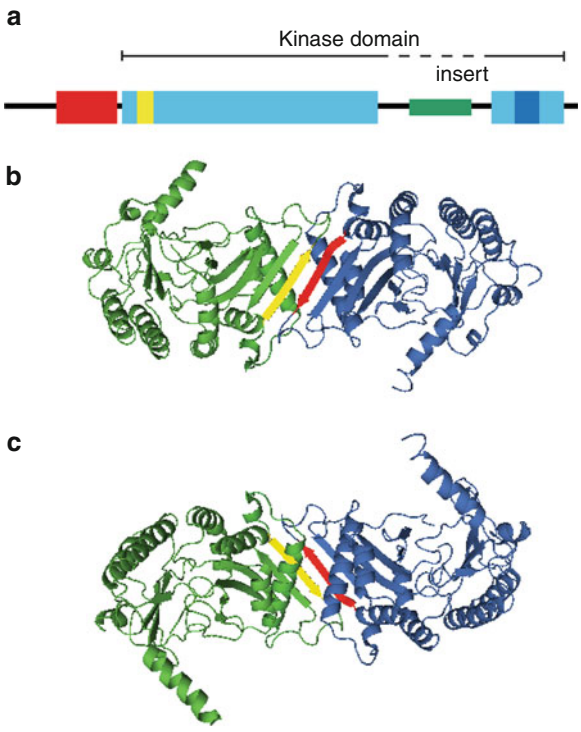
Phosphatidylinositol 5-phosphate 4-kinase, Fig. 3 Phylogenetic plot of PIP4K gene evolution with all currently annotated genes in the Ensembl database (EMBL-EBI). *Branch points* indicate divergence, *black nodes* represent speciation, and *red nodes* represent a potential gene duplication event. Species with single genes with similarity to human PIP4K are listed by name (gene name in brackets). Separate PIPK gene branches indicate number of total homologs (orthologs of PIP4Ks and PIP5KL1, orthologs plus paralogs of PIP5K) in vertebrates (48 species with PIP4Kα, 44 species with PIP4Kβ, and 38 species with PIP4Kγ). *Boxed numbers* represent percentage similarity of human homologs (or individual *D. melanogaster*, *C. elegans*, *S. cerevisiae*, and *Ciona* genes) to human PIP4Kα protein sequence (average similarity for *Ciona* species and PIP5K isoforms)

The C-terminal domain consists of five β-sheets and four α-helices and contains the "activation loop" and "variable insert" (Fig. 4). The activation loop region (amino acids 373–391) confers substrate specificity as demonstrated by domain swapping between PIP4K and PIP5K enzymes (Kunz et al. 2000). The variable insert region interrupts the catalytic kinase core and represents the region of least similarity between the PIP4K isoforms. In PIP4Kβ the α7 helix in this insert serves as a specific nuclear localization motif (Ciruela et al. 2000), and other inter-isoform differences could be accounted for in this region.

Mammalian PIP4K Isoforms

PIP4Kα

The PIP4Kα isoform was the first to be cloned independently by two groups in 1995, from human circulating-leukocyte and bone marrow cDNA libraries (Boronenkov and Anderson 1995; Divecha et al. 1995). It is the most catalytically active of the three isoforms (Table 1). Northern blotting suggests that the enzyme has a ubiquitous but low expression in tissues compared to the other isoforms, with slightly elevated levels in brain and hematocytes (reviewed in Clarke et al. 2010), which is confirmed in subsequent quantitative PCR experiments (Fig. 5). Overexpression studies in DT40 and HeLa cells suggest that PIP4Kα is predominantly cytosolic (Clarke et al. 2007; Richardson et al. 2007) and has been observed to translocate to the cytoskeleton upon integrin-mediated signaling, potentially via interaction with a PIP5K activity (Hinchliffe et al. 2002). Translocation of a PIP4K enzyme was also seen in agonist-induced platelet α-granule secretion, and this activity was regulated by PKC activation and attenuated by calpain cleavage (Rozenvayn and Flaumenhaft 2003; O'Connell et al. 2005). Recent studies, using genomically tagged PIP4Kα and high-resolution mass spectrometry, were able to assess endogenous protein in DT40 cells and show that significant amounts of this enzyme are also found in the nucleus. This distribution is thought to occur via association with the PIP4Kβ isoform (Bultsma et al. 2010; Wang et al. 2010) as discussed above. The PIP4Kα isoform activity is regulated by phosphorylation on different serine and threonine residues. Cell stimulation results in both removal of inhibitory phosphorylation, such as at threonine 376 by protein kinase D, and further activating



Phosphatidylinositol 5-phosphate 4-kinase, Fig. 4 PIP4K structure. (**a**) The PIP4K domain structure shows that the kinase catalytic core domain (*light blue*) is interrupted by the "variable insert," a region with the least sequence similarity between the three isoforms (*green*). The C-terminal kinase domain contains the "activation loop" (*dark blue*) and the N-terminal domain contains the "G-loop" motif (*yellow*). The dimerization region is shown in *red*. (**b**, **c**) Ribbon diagrams of the crystallographic structure of PIP4Kβ as a homodimer (Rao et al. 1998) with the dimerization region highlighted (*green* monomer with *yellow* region, *blue* monomer with *red* region). Views are from the membrane contact surface (**b**), showing the flattened face, and from the cytosolic side (**c**), showing the stabilization of the dimerization interface by α-helices

Phosphatidylinositol 5-phosphate 4-kinase, Table 1 Comparison of activities of the PIP4K isoforms. Experiments were carried out as in (Wang et al. 2010). Specific activity is defined as nmoles of ATP incorporated into lipid per minute per mg of protein under the same assay conditions. Turnover number (k_{cat}) is defined as the number of ATP (hence PtdIns5*P* to PtdIns(4,5)P_2) reactions per second

PIP4K isoform	Specific activity	K_M for ATP (μM)	k_{cat} (s^{-1})
PIP4Kα	3.7×10^{-2} (± 0.12)	03.9	2105.1
PIP4Kβ	1.6×10^{-5} (± 0.08)	67.1	0019.1
PIP4Kγ	3.7×10^{-7} (± 0.12)	94.2	0001.1

phosphorylation (Hinchliffe and Irvine 2006). Protein kinase CK2 also specifically phosphorylates serine 304, although this has not been shown to affect enzyme activity (Hinchliffe et al. 1999). Upregulation of PIP4Kα activity has also been observed on tyrosine phosphorylation in bovine photoreceptor rod outer segments, although this is thought to be an indirect response (Huang et al. 2001).

PIP4Kβ

Yeast two-hybrid screening of a murine cerebellar cDNA library, using a cytoplasmic domain of the human p55 TNF-α receptor as bait, resulted in the cloning of the PIP4Kβ isoform (Castellino et al. 1997). Although this isoform has 77% amino acid similarity to PIP4Kα, it has 100-fold less in vitro activity by catalytic turnover (Table 1). PIP4Kβ mRNA was detected in all tissues tested, and was found to be specifically enriched in skeletal muscle and brain (Fig. 5 and Castellino et al. 1997). At a subcellular level, although PIP4Kβ has been shown to associate with the TNF-α, EGF, and ErbB2 (HER2) receptors (Castellino et al. 1997; Castellino and Chao 1999), and undoubtedly has a cytoplasmic role, it is also the only isoform to specifically localize to the cell nucleus. The targeting of PIP4Kβ to the nucleus is affected by a nuclear localization sequence unique to this isoform (Ciruela et al. 2000), and genomic tagging indicates that the majority of endogenous PIP4Kβ is transported across the nuclear membrane in DT40 cells (Richardson et al. 2007). Activation of PIP4Kβ has been shown to be mediated by TNF-α in specific cytokine-responsive cells (Castellino et al. 1997). Within the nucleus, PIP4Kβ activity is inhibited by p38 mitogen activated protein kinase (MAPK) phosphorylation of serine 326 after ultraviolet irradiation, leading to increases in nuclear PtdIns5*P*, which is sensed by the cell stress–responsive nuclear adapter protein ING2 (Jones et al. 2006); note that this residue is also present in PIP4Kα, so it is possible that nuclear PIP4Kα (see above) is similarly regulated. PIP4Kβ that is co-localized to nuclear speckles (pre-mRNA processing sites) with the Cul3-SPOP ubiquitin ligase complex is itself targeted for degradation by ubiquitylation (Bunce et al. 2008). Intriguingly, PtdIns5*P* activation of p38 MAPK stimulates the activity of the Cul3-SPOP complex, suggesting that a feed-forward mechanism of regulation exists, which could in part be explained by the interaction between PIP4Kβ and PIP4Kα in the nucleus (Bultsma et al. 2010). There is also evidence that

	BRAIN	LIVER	KIDNEY	LUNG	MUSCLE	HEART	SPLEEN	TESTIS
PIP5K2A	18.67	1.36	2.83	1.11	5.34	6.64	8.62	1.00
PIP5K2B	39.78	10.11	6.71	1.80	58.24	22.26	2.31	3.38
PIP5K2C	11.16	3.45	43.19	1.54	4.14	11.93	1.72	6.87

Phosphatidylinositol 5-phosphate 4-kinase, Fig. 5 Expression of PIP4K mRNA in mouse tissues. Expression of *PIP4K2A*, *PIP4K2B*, and *PIP4K2C* was determined by quantitative PCR using the comparative threshold cycle (CT) method (As described in Clarke et al. 2008)

PIP4Kβ is able to regulate insulin-induced signaling in cells by an indirect mechanism. Carricaburu et al. showed that PIP4Kβ regulated PtdIns5*P* levels were responsible for activation of a PtdIns(3,4,5)P_3-specific 5-phosphatase, which removed this PI 3-kinase (PI3K) signaling product, resulting in reduced Akt/PKB protein kinase phosphorylation (Carricaburu et al. 2003).

PIP4Kγ

The PIP4Kγ isoform is the most recent to be discovered, and was isolated from a rat brain cDNA library by Itoh et al. in 1998. PIP4Kγ shares approximately 63% similarity with PIP4Kα and PIP4Kβ at the protein level, but has a 2,000-fold lower in vitro catalytic turnover of PtdIns5*P* than the PIP4Kα isoform (Table 1), and no detectable activity against any other phosphoinositide substrates. Highest levels of PIP4Kγ expression are observed in the kidney and brain (Fig. 5), with significant levels also in the heart, ovary, and testis (Itoh et al. 1998; Clarke et al. 2008, 2009). Within the kidney, the expression is limited to the distal nephron and restricted to the epithelial cells of the thick ascending limb of the loop of Henle and to intercalated cells of the collecting duct (Clarke et al. 2008). Expression of PIP4Kγ is also seen at early developmental stages in the zebra fish embryo, localized to the pronephric duct and brain. In the mouse brain PIP4Kγ has a restricted expression, found only in specific neuronal subpopulations, such as cerebellar Purkinje cells, hippocampal pyramidal cells, and mitral cells in the olfactory bulb, and is excluded from granule cells (Clarke et al. 2009). At a subcellular level, endogenous PIP4Kγ is partially associated with the *cis*-Golgi matrix and predominantly with an unidentified vesicular compartment, which in kidney epithelial cells is concentrated at the apical secretory membrane (Clarke et al. 2008). PIP4Kγ undergoes protein phosphorylation on serine residues in vivo, and at least two phosphorylated forms are differentially expressed in mouse brain regions (Itoh et al. 1998; Clarke et al. 2009). In a β-pancreatic cell line, the mTORC1 complex is thought to be responsible for phosphorylation of PIP4Kγ at two specific sites (L. Rameh, personal communication 2011), although it is not known whether these modifications lead to in vivo activation of the enzyme. Phosphorylation may be regulated by mitogenic cell stimulation with EGF or PDGF, and to a lesser extent with lysophosphatidic acid or bradykinin (Itoh et al. 1998). Enzyme expression may also be regulated in thyrocytes by thyroid-stimulating hormone (Park et al. 2001).

PIP4Ks and Disease

Aberrant regulation of cellular phosphoinositides has been implicated in a number of diseases including cancer and diabetes. Interference with PtdIns(3,4,5)P_3 regulation of Akt signaling via enzymes such as PI3K and the phosphatases PTEN and SHIP1, are linked to many forms of cancer (McCrea and De Camilli 2009). PtdIns(4,5)P_2 can also regulate ion channels, the dysfunction of which can lead to epilepsy and rare forms of congenital channelopathies (Halstead et al. 2005). In these cases any involvement of the PIP4Ks would be indirect, via the downstream production of lipid substrates and second messengers themselves. However, some direct effects of the PIP4Ks in disease have been reported.

PIP4Kβ, as discussed above, has been implicated in the regulation of Akt/PKB activation during insulin signaling by reducing PtdIns5*P* levels that inhibit the enzymatic removal of PtdIns(3,4,5)P_3 (Carricaburu et al. 2003). In agreement, PIP4Kβ-/- knockout mice are viable but hypersensitive to insulin, suggesting that the presence of the PIP4Kβ substrate, PtdIns5*P*, is directly required for maintenance of PtdIns(3,4,5)P_3 levels for enhanced Akt/PKB phosphorylation. Removal of PtdIns5*P* by PIP4Kβ reduces the effectiveness of insulin signaling, which may have consequences in type 2 diabetes (Lamia et al. 2004).

Early reports suggest that PIPK activity was upregulated in malignant tumors (Singhal et al. 1994). More recent studies have shown that as well as PIP4Kβ interacting with the HER2b receptor (see above), the *PIP4K2B* gene is located close to the *HER2* locus on chromosome 17. Gene amplification of *HER2* occurs in 25% of breast cancer cases, and increased levels of PIP4Kβ have also been detected in these tumors (Luoh et al. 2004). *PIP4K2B* has also been linked to neuroblastoma development, as this gene is one of three to be disrupted by a translocation breakpoint characteristic of this tumor type (Schleiermacher et al. 2005).

Treatment of bipolar disorder with lithium is thought to be involved with phosphoinositide metabolism. Subsequent linkage studies have implicated PIP4Kα as a candidate gene for susceptibility to schizophrenia, either through a common single nucleotide polymorphism or transcriptional repression (Stopkova et al. 2003).

Summary

PIP4K enzymes phosphorylate their preferred phospholipid substrate, PtdIns5*P*, to produce PtdIns(4,5)P_2. The relative scarcity of PtdIns5*P* in cells suggests that the PIP4Ks function to remove a lipid signal provided by this phosphoinositide, or to produce a small pool of PtdIns(4,5)P_2 that is required in an isolated cellular compartment. PIP4K exists as three distinct isoforms (α, β, and γ) with PIP4Kα being significantly more active than PIP4Kβ or PIP4Kγ. Each isoform has a different tissue distribution and subcellular localization, and this is mediated in part by differences in highly variable regions within the more conserved common catalytic core domain. The isoforms form dimers by interaction between β1-sheets, and the possibility of forming heterodimers suggests a mechanism by which the more active isoform is targeted to different cellular locations by other isoforms in a tissue and possibly cell-type-dependent manner. PIP4Ks may have direct links to diabetes and psychological disorders, and PIP4Kβ has recently been shown to be upregulated in human cancers, suggesting that this family of enzymes may be potential targets for disease treatments.

Historical Background

The STAT (Signal Transducers and Activators of Transcription) proteins were first identified as signaling proteins that function as second messengers and transcription factors in response to cytokines and growth factors (Santos and Costa-Pereira 2011; Li 2008). Mammals have seven STAT genes, namely, *STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B*, and *STAT6* (Santos and Costa-Pereira 2011). All the STAT proteins are highly conserved and contain six domains including the SH2, linker, coiled-coil, and DNA binding domain (Bromberg and Darnell 2000). Traditionally, unphosphorylated STAT is believed to reside in the cytoplasm in an inactive form; upon phosphorylation by JAK or another tyrosine kinase, the phosphorylated (active) STAT translocates into the nucleus to induce transcription of target genes (Bromberg and Darnell 2000). However, recent studies have prompted revisions to this paradigm. In addition to the canonical signaling pathway, there is increasing evidence that unphosphorylated STAT shuttles back and forth between the nucleus and cytoplasm (Santos and Costa-Pereira 2011). In this noncanonical mode of signaling, unphospho-STAT seems to carry additional functions, such as chromatin remodeling and heterochromatin dynamics (Li 2008).

STAT's Protein Structure and Isoforms

STAT proteins are 750–850 amino acids long and possess six functionally conserved domains (Fig. 1). The crystal structures of both phospho- and unphospho-STAT dimers have been solved for STAT1; both of them adopt a nutcracker-like structure (Lim and Cao 2006). The six conserved domains have been extensively studied and can have overlapping functions. Although most of the domains are functionally conserved across species, the differences within the conserved domains among the different STAT proteins allow specificity in their responses in signaling. There are also multiple isoforms and posttranslational modifications that can determine the specificity of STAT regulation.

The N-terminal domain (NTD) is required for dimerization of unphosphorylated STATs and tetramerization between STAT1, STAT3, and STAT5. In addition, the NTD can also recruit transcriptional co-activators, such as CREB binding protein (CBP)/p300 by promoting protein-protein interaction, and is also involved in tyrosine phosphorylation and dephosphorylation of STATs. The coiled-coil domain (CCD) is important for the interaction of STATs with other proteins to mediate transcription. For example, STAT3 interacts with c-Jun to induce transcription of target genes in response to IL-6 induction and binds to epidermal growth factor (EGF) receptors via its CCD domain. Besides, a leucine-rich segment is located within the CCD domain, which also regulates nuclear translocation of STAT proteins. Even though the DNA-binding domain (DBD) is highly conserved across the protein family, the small differences in the amino acid sequences of DBD across different STATs are responsible for their different DNA-binding specificities. Upon cytokine stimulation, the heterodimers formed by phosphorylated STAT1 and STAT3 require the DBD for nuclear translocation as well. Next to the DBD is the α-helical linker domain

Phospho- and Unphospho-STATs in Signal Transduction and Gene Regulation (STAT), Fig. 1 The structural organization of STAT proteins. All the STATs have six main domains, namely, the NTD at the N-terminal end of the peptide, coiled-coil domain (CCD), DNA binding domain (DBD), linker domain (LD), the Src-homology 2 domain (SH2D), and transactivation domain (TAD) at the very carboxyl-terminal end. Phosphorylated sites are as indicated

(LD). It links two crucial domains in STAT, namely, DBD and the ▶ Src-homology 2 (SH2) domain (Santos and Costa-Pereira 2011). Additionally, LD is also crucial for the transcriptional activation of STAT1 following ▶ IFN-γ stimulation and has been implicated in the constitutive nucleocytoplasmic shuttling of unphophorylated STATs in resting cells (Yang et al. 1999; Marg et al. 2004). The 100 amino acid long SH2 domain, located at the C-terminal end of the peptide, is probably the most well-conserved domain in STAT; it plays a crucial role in protein-protein interactions between STATs and other proteins (Santos and Costa-Pereira 2011). SH2 domain recognizes phosphorylated tyrosine residue and binds to phosphorylated Janus kinase (JAK) or STAT (Huang et al. 2008; Watanabe and Arai 1996). Moreover, a number of residues within this domain are important for STAT to mediate cellular functions. In particular, the phosphorylation of STAT1 on tyrosine 701 and its subsequent homodimerization are dependent on the arginine 602 residue within the SH2 domain (Li 2008); when proline 630 is mutated, tyrosine phosphorylation of STAT2 is impaired and it no longer dimerizes with STAT1 (Santos and Costa-Pereira 2011). The last domain on the C-terminal end is the transactivation domain (TAD). In addition to its function in activating transcription, TAD is used to interact with other proteins as well. For instance, TAD is required for the interaction of STAT1 with breast cancer 1 (BRCA1) and CBP/p300 (Santos and Costa-Pereira 2011).

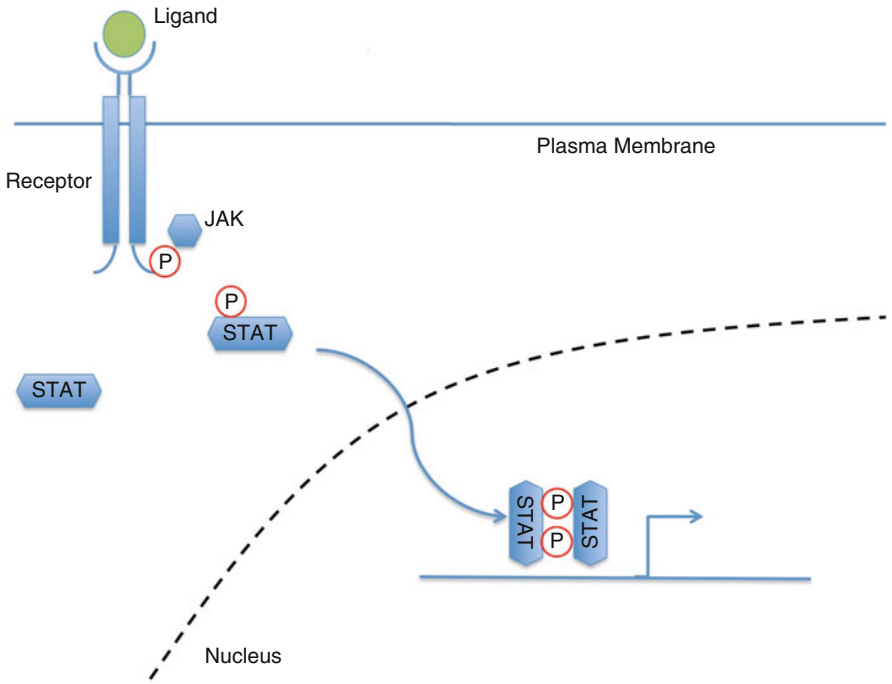
STAT in the Canonical JAK-STAT Pathway

In the canonical pathway, when a ligand (e.g. a cytokine or growth factor) binds to its transmembrane receptor, conformational changes lead to receptor dimerization and cross-activation of the receptor-associated tyrosine kinase, Janus kinase (JAK). As a result, multiple phosphorylation events occur and the phospho-tyrosines on the cytoplasmic tail of the receptor serve as docking sites for the binding of latent STATs residing in the cytoplasm (Fig. 2). Once bound, JAK can then phorphorylate associated STATs and result in dimerization of the STAT proteins via phosphorylated tyrosine residue located in the SH2 domain. These activated STAT dimers then translocate into the nucleus to regulate transcription of STAT target genes in response to cytokine or growth factor stimulation (Li 2008).

STAT is involved in regulating many cellular processes such as cell proliferation, apoptosis, growth, hematopoiesis, antiviral responses, and immune systems (O'Shea et al. 2004). Typically, STAT binds to well-defined DNA consensus sequences and initiates transcription of interferon (IFN)-stimulated genes (ISGs). It is also known to regulate the transcription of many genes including the B-cell lymphoma 2 (Bcl-2) family proteins, cyclin D1, ▶ Myc, and many genes implicated in angiogenesis or metastasis (Li 2008). In addition to the consensus sequence, STAT tetramer complexes can also recognize and bind weakly to non-consensus regions via the NTD domain for added specificity in its regulation . Besides inducing transcription, STAT can also act as a negative regulator of transcription in some instances (Boucheron et al. 1998). As an example, STAT3β, a naturally occurring splice variant of STAT3, inhibits transcription of STAT3's target genes (Caldenhoven et al. 1996).

Unphosphorylated STATs in Gene Regulation

The canonical JAK/STAT pathway had to be revised when much evidence has suggested that at least a fraction of the unphosphorylated STATs may have biological functions and shuttle continuously into the nucleus, instead of maintaining its latency in the cytoplasm (Li 2008). Work done in *Drosophila* has shown that loss of *STAT* strongly suppresses position effect variegation (PEV), a heterochromatin-dependent gene



Phospho- and Unphospho-STATs in Signal Transduction and Gene Regulation (STAT), Fig. 2 The canonical JAK/STAT signaling pathway. Canonically, unphosphorylated STATs maintain their latency and reside in the cytoplasm. When ligand binds to the transmembrane receptors, they homo-dimerize and are phosphorylated by JAK, a tyrosine kinase. Following that, a series of phosphorylation events result in conformational changes on the receptor that open up binding sites for recruiting STATs. Consequently, JAK can then phosphorylate STATs. Phospho-STATs then dimerize and translocate into the nucleus to mediate transcription of target genes

silencing process (Li 2008). Further investigation has shown that unphospho-STAT associates with heterochromatin protein 1 (HP1) in the nucleus to maintain heterochromatin stability (Li 2008; Shi et al. 2008a). However, upon phosphorylation, STAT disperses from heterochromatin, causing HP1 displacement and heterochromatin destabilization (Shi et al. 2008b). Consistent with the observation in *Drosophila*, mammalian unphospho-STATs, STAT3 and STAT5A in particular, have also been shown to localize at the nucleus as well (Liu et al. 2005). Even though it is still unclear if mammalian STATs also associate with HP1 and localize at heterochromatin, unphospho-STATs in mammals clearly regulate gene transcription by a mechanism distinct from the canonical JAK-STAT signaling pathway (Yang and Stark 2008). Due to their effects on chromatin structure, it is not surprising that STATs are crucial for gene regulation in stem cells and during organisms' development (Boyer et al. 2006; Hochedlinger and Jaenisch 2006). Therefore, as opposed to the traditional view of STAT, unphospho-STATs are not completely dormant and play important roles in the regulation of gene transcription.

The Role of STATs in Cancer

STAT1, STAT3, and STAT5 are often misregulated in many cancer cells, especially STAT3, which is a known oncogene (Silva 2004). STAT3 is believed to contribute to cancer cell transformation via its inflammatory response (Yu and Jove 2004). However, no STAT mutations have been identified in association with cancer incidents. In most cases, the abnormal activities of the upstream kinases are the cause of STAT signaling misregulation in cancer cells. In fact, a well-established tumor model in *Drosophila* involves a hyperactive JAK kinase called $hop^{Tumorous\text{-}L}$ ($hop^{Tum\text{-}L}$) that causes STAT over-activation and over-proliferation of blood cells, analogous to human leukemia (Li 2008). The role of STAT activation in these pathological conditions has so far been attributed mostly to over-activation of the canonical

JAK-STAT pathway that upregulates STAT target genes. In addition to the canonical pathway, disruption of STAT's function in stabilizing heterochromatin may also contribute to tumorigenesis since heterochromatin has been implicated in tumor suppression. Therefore, respective contributions of canonical and noncanonical JAK-STAT signaling in cancer development are currently under investigation.

Summary

In conclusion, STAT is a crucial signaling molecule in animal cells that translates extracellular signals into changes in gene transcription. In the canonical JAK-STAT pathway, only phosphorylated STATs translocate into the nucleus and act as transcription factors, whereas unphosphorylated STATs are assumed to remain latent in the cytoplasm. In the noncanonical mode of JAK-STAT signaling, unphosphorylated STATs are also found, at least in fruit flies, to localize in the nucleus and play important roles in regulating gene expression by modulating heterochromatin formation. It has recently been shown that mammalian JAK2 plays a role in regulating heterochromatin formation (Dawson et al. 2009). Whether STAT's function in heterochromatin is conserved in mammals is yet to be determined. Proper function of STAT is essential for different stages of development and maintaining the health of individual organisms and misregulation of STAT has been implicated in multiple human diseases. STAT thus poses as an attractive potential therapeutic target, because it mediates a rather straightforward signaling pathway and the phospho-tyrosine residue can conceivably be targeted. However, since STAT has proven to be versatile and involved in multiple functions via distinct mechanisms, targeting STAT may cause unexpected cellular responses. Therefore, the biological functions and cellular effects of STAT proteins must be thoroughly investigated even though STAT remains a potential therapeutic target.

Synonyms

Calmodulin-dependent cyclic nucleotide phosphodiesterase; PDE 1

Historical Background

Cyclic nucleotide phosphodiesterase (PDE) was demonstrated after the discovery of cAMP (Sutherland and Rall 1958). In most tissues, PDE exists in multiple forms which differ in subcellular localization, relative substrate specificity toward cAMP and cGMP, regulatory and immunological properties (Beavo 1995; Kakkar et al. 1999; Goraya and Cooper 2005). Most tissues examined have been shown to contain Ca^{2+} and calmodulin (CaM)-dependent cyclic nucleotide phosphodiesterase 1 (PDE1) and this enzyme has been intensively studied (Beavo 1995; Kakkar et al. 1999). Earlier, it was suggested that PDE1 consists of a single species (Wells and Hardman 1977), but later found to exist as a tissue-specific and immunological distinct enzyme (Sharma et al. 1984). With the rapidly expanding list of PDE1 isozymes, a new nomenclature was developed based on the primary structure of different PDEs (Beavo et al. 1994). It is now known that at least three different genes encode the PDE1 family; they are named PDE1A, PDE1B, and PDE1C. The complementary DNAs (cDNAs) encoding the brain 63 kDa PDE1 isozyme (PDE1B1), brain 60 kDa PDE1 isozyme (PDE1A2), heart PDE1 (PDE1A1), and 70 kDa PDE1 (PDE1C) were suggested to represent subfamily members. In addition, new splice variants of mouse and human PDEs (PDE1C1, PDE1C2, PDE1C3, PDE1C4, PDE1C5, PDE1A3, and PDE1B1) have been reported. They have been characterized in terms of their regulation by Ca^{2+}, sensitivity to inhibitors, and tissue/cell-specific expression. The genes for different PDEs undergo tissue-specific alternative splicing that generates structurally and functionally diverse gene products.

Differential Stimulation of PDE1 by CaM and Ca^{2+}

PDE1 can be distinguished from other forms of PDE by the stimulation with CaM in the presence of Ca^{2+}. Although brain PDE1A2 and heart PDE1A1 isozymes are almost identical immunologically and kinetically in their properties (Sharma et al. 1984; Sharma and Kalra 1994), they are differentially activated by CaM (Sharma and Kalra 1994). It may be possible that differential affinity for CaM may reflect subtle differences in Ca^{2+} activation of these PDE1 isozymes. The differences in CaM affinity exhibited by these isozymes may be related to the relative concentration of CaM in these tissues. It has been suggested that the differential of CaM affinity is an important mechanism by which the regulatory action of CaM may be fine-tuned (Klee 1988). However, the physiological significance of differential CaM affinity requires further research in this area. It is noteworthy that CaM concentration in mammalian brain is approximately 10 times higher than in mammalian heart (Klee and Vanaman 1982). The PDE1A1 isozyme have a higher affinity for CaM than brain PDE 1A2 (Hansen and Beavo 1986; Sharma 1991). Similarly, the pig brain PDE1 has been shown to have a lower affinity for CaM than the isozymes from pig artery (Keravis et al. 1986). In addition, Ca^{2+} and CaM interact synergistically in activation of PDE1 isozymes (Huang et al. 1981). When the CaM concentration is increased, the Ca^{2+} concentration required for half-maximal activation is decreased. Such synergistic interactions have been repeatedly shown for various CaM-dependent enzymes. Although the physiological significance of the observed differential Ca^{2+} sensitivity of the PDE1 isozymes is not known, these studies suggest that the differential Ca^{2+} affinity of the tissue-specific isozymes may be a mechanism by which CaM regulatory reactions are adapted in the respective tissues. The lung PDE1 isozyme has the highest apparent affinity for CaM, since it contains CaM as a subunit (Sharma and Wang 1986a). A change in CaM concentration had no effect on the Ca^{2+} concentration of the lung enzyme, suggesting that this isozyme does not undergo a Ca^{2+}-dependent reversible association with CaM. At present, the significance of CaM as a subunit is not known.

Kinetic Properties of PDE1 and Its Inhibitors

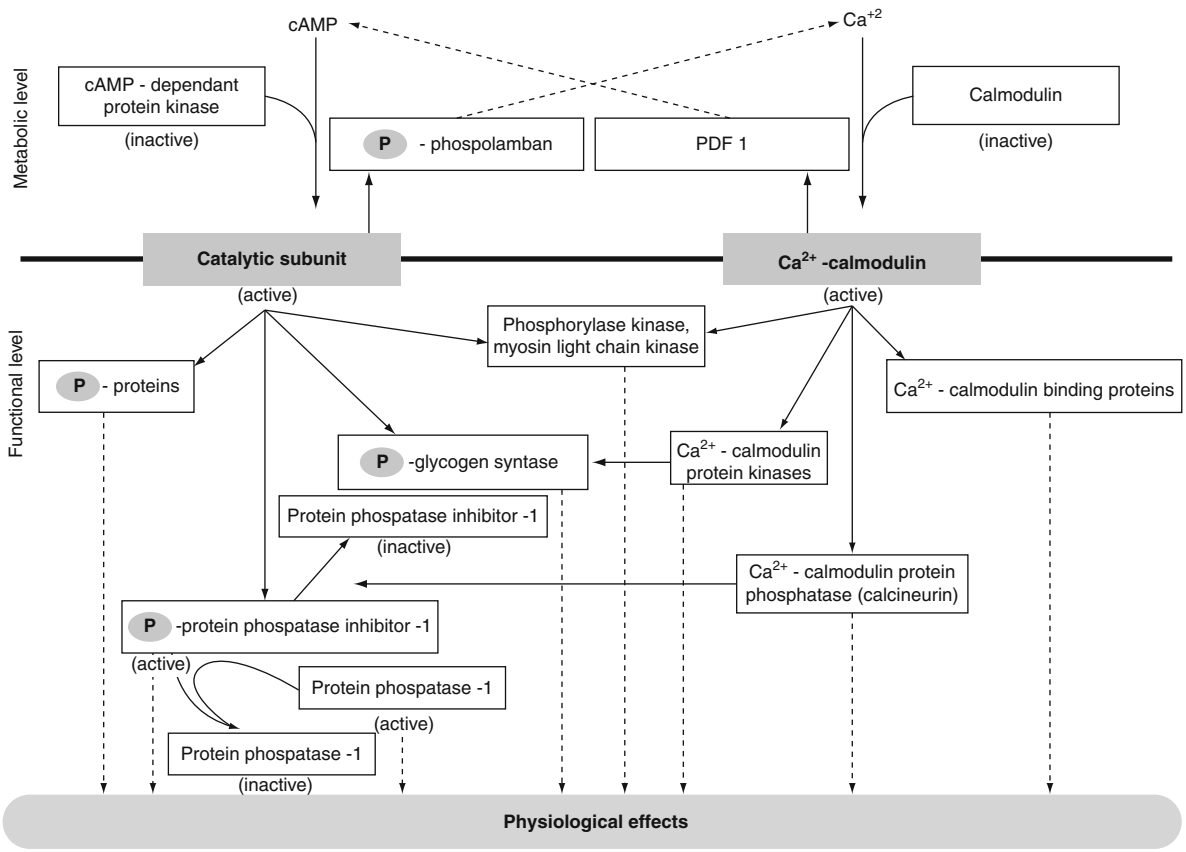
Originally, it was reported that PDE1 displays a much higher affinity for cGMP than for cAMP (Beavo 1995; Kakkar et al. 1999). The earlier studies from various laboratories reported marked differences in kinetic parameters; the discrepancy may be due to the purity of enzyme, as well as varying assay conditions. To understand the physiological role of PDE1 isozymes, purified PDE1 isozymes were used to determine kinetic parameters. PDE1 isozymes have a higher affinity toward cGMP than cAMP (Kakkar et al. 1999). However, PDE1B1 isozyme exhibits two- to threefold higher affinity for both the substrates, cAMP and cGMP, compared to PDE1A2 and PDE1A1 and a higher V_{max} for cGMP and cAMP (Kakkar et al. 1999). It is interesting to note that PDE1A2 and PDE1A1 isozymes have very similar kinetic properties, whereas PDE1B1 isozyme is kinetically distinct from other PDE1 isozymes (Kakkar et al. 1999). However, PDE1C1 has approximately similar K_m and V_{max} for cAMP and cGMP (Vandeput et al. 2007).

Early studies on inhibitors were carried out by using purified or partially purified PDE1. Therefore, it was not clear from previous studies which of the purified or partially purified PDE1 isozymes were used. Ginsenosides were found to be potent inhibitors of heart PDE1A1 and brain PDE1A2 but not of brain PDE1B1 (Kakkar et al. 1999). However, deprenyl (selegiline hydrochloride), an antiparkinsonian agent also inhibits brain PDE1A2 but is a poor inhibitor of brain PDE1B1 (Kakkar et al. 1999). In addition, amantadine only inhibits brain PDE1A2 isozyme but not brain PDE1B1, heart PDE1A1, and lung PDE1 isozymes (Kakkar et al. 1999). Since the inhibition of these isozymes is overcome by increasing the concentration of CaM, this suggests that these compounds act specifically and reversibly against the action of CaM. Therefore, these compounds may be valuable tools to investigate the diverse physiological roles of distinct PDE1 isozymes. Unlike other CaM-dependent enzymes, PDE1 has been suggested to be inhibited by dihydropyridine calcium antagonists, which act as direct vasodilator drugs rather than indirectly through their actions on CaM. In previous studies, it was not clear which of the specific PDE1 isozymes were used (Kakkar et al. 1999). The effect of dihydropyridine Ca^{2+} channel blockers felodipine and nicardipine on purified brain PDE1 isozymes has been examined. The results indicate that both brain isozymes are inhibited by felodipine and nicardipine by partial competitive inhibition, and these two Ca^{2+} antagonists appear to counteract each other (Sharma et al. 1997). The K_i values for felodipine (1.8 and 2.8 μM) and nicarpidine (2.3 and 5.8 μM) for PDE1A2 and PDE1B1, respectively, suggest that the two brain PDE1 isozymes have similar affinities for the Ca^{2+} antagonists, and both the isozymes bind felodipine slightly tighter than they bind nicarpidine. This study further demonstrated the existence of a specific site, distinct from the active site on PDE1 isozyme, which exhibits high-affinity binding of these drugs.

Interaction of the Ca^{2+} and cAMP Second Messenger Systems

All cells have the ability to identify and respond to changes in their environment. They recognize extracellular signals through specific cell membrane receptors. The stereospecific binding of the signal molecules to the receptors results in a series of rapid events which translate the external signal into specific cellular responses. Most of these intracellular reactions depend on second messenger systems, which are composed of second messenger molecules such as cAMP and Ca^{2+} and a host of enzymes, protein factors, and cell organelles which regulate the metabolism of and mediate the regulatory actions of the messenger molecules. In most cases, different second messenger systems undergo complex yet precise interactions, on one hand to achieve integrated regulation of cellular activities and on the other hand to terminate cell activities in an orderly manner. The interaction between the Ca^{2+} and cAMP second messenger system is among the most extensively studied. The two systems appear to interact at multiple levels and in either a synergistic or an antagonistic manner depending on the cellular process and/or the cell type.

The Ca^{2+} regulatory cascade (calcium signaling) is mediated by a Ca^{2+} binding protein, CaM, and involves a Ca^{2+}-dependent, reversible association of CaM with its target protein(s) (Klee 1988). This results in changes in targeted protein activity. In the case of the cAMP second messenger system, cAMP-dependent protein kinase(s) is considered to be the essential molecule which regulates wide-ranging physiological effects. Upon binding of cAMP to a regulatory subunit, the subunits dissociate and two catalytically active subunits are released which



Phosphodiesterase 1, Fig. 1 Schematic interactions between the cAMP and Ca^{2+} second messenger systems. The second messenger molecules cAMP and Ca^{2+} interact in several important fashions to integrate a physiological response. Some of these interactions are involved in the regulation of PDE1 (Adapted from Kakkar et al. 1999)

catalyze phosphorylation of specific proteins. In addition, numerous cyclic nucleotide-binding proteins have been characterized. Firstly, the high-affinity allosteric binding sites on cGMP-stimulated phosphodiesterase constitute a family of homologous cAMP-binding sites on several proteins. Secondly, the cGMP and cAMP-binding sites on cyclic nucleotide-gated channels include the potassium channel on cardiac pacemaker cells (Fesenko et al. 1985). Initially, such channels were thought to be present only in the retina and cardiac pacemaker cells. However, these channels have since been identified in many other cell types as well. Recently, Epac (Eoac1, Epac2, exchange protein directly activated by cAMP) has been recognized as a genomic sequence with homology to cAMP-binding sites and GEFs (guanine nucleotide exchange factors) for Ras-like proteins. Originally, Epac1 and Epac2 were also identified as a cAMP-GEF1 and cAMP-GEF2, respectively (Kowasski et al. 1998).

In many biological systems, the two second messengers, Ca^{2+} and cAMP, act in a concerted fashion to control regulatory processes. Several regulatory pathways for the interactions between Ca^{2+} and cAMP second messenger systems have been observed (Fig. 1). At the metabolic level, one second messenger regulates the metabolism of the other second messenger. For example, PDE1 controls cAMP concentration, and the phospholamban/Ca^{2+}-ATPase system regulates cytoplasmic Ca^{2+} concentration.

On a functional level, there are at least three mechanisms by which the two messenger systems exert their mutual effects (Fig. 1). Firstly, CaM-stimulated enzymes are substrates of cAMP-dependent protein kinase, such as phosphorylase kinase and smooth muscle ▶ myosin light chain kinase. A second mechanism

of Ca^{2+}-CaM and cAMP interaction involves phosphorylation of common protein substrates by Ca^{2+}-CaM and cAMP-dependent protein kinases. For example, glycogen synthase can be phosphorylated by cAMP-dependent protein kinase, by the CaM-dependent glycogen synthase kinase and phosphorylase kinase, as well as by at least four other kinases. These phosphorylations inactivate both muscle and liver glycogen synthases with the expectation that phosphorylation of the liver enzyme by CaM-dependent glycogen synthase kinase has no effect on enzyme activity. A third mode of interaction between the Ca^{2+} and cAMP signal systems involves the dephosphorylation of protein phosphatase inhibitor-1. Upon phosphorylation, protein phosphatase inhibitor-1 is active and inhibits the activity of protein phosphatase-1. When it is dephosphorylated by CaM-dependent protein phosphatase (calcineurin, CaN), protein phosphatase inhibitor-1 is inactivated, allowing protein phosphatase-1 to be active.

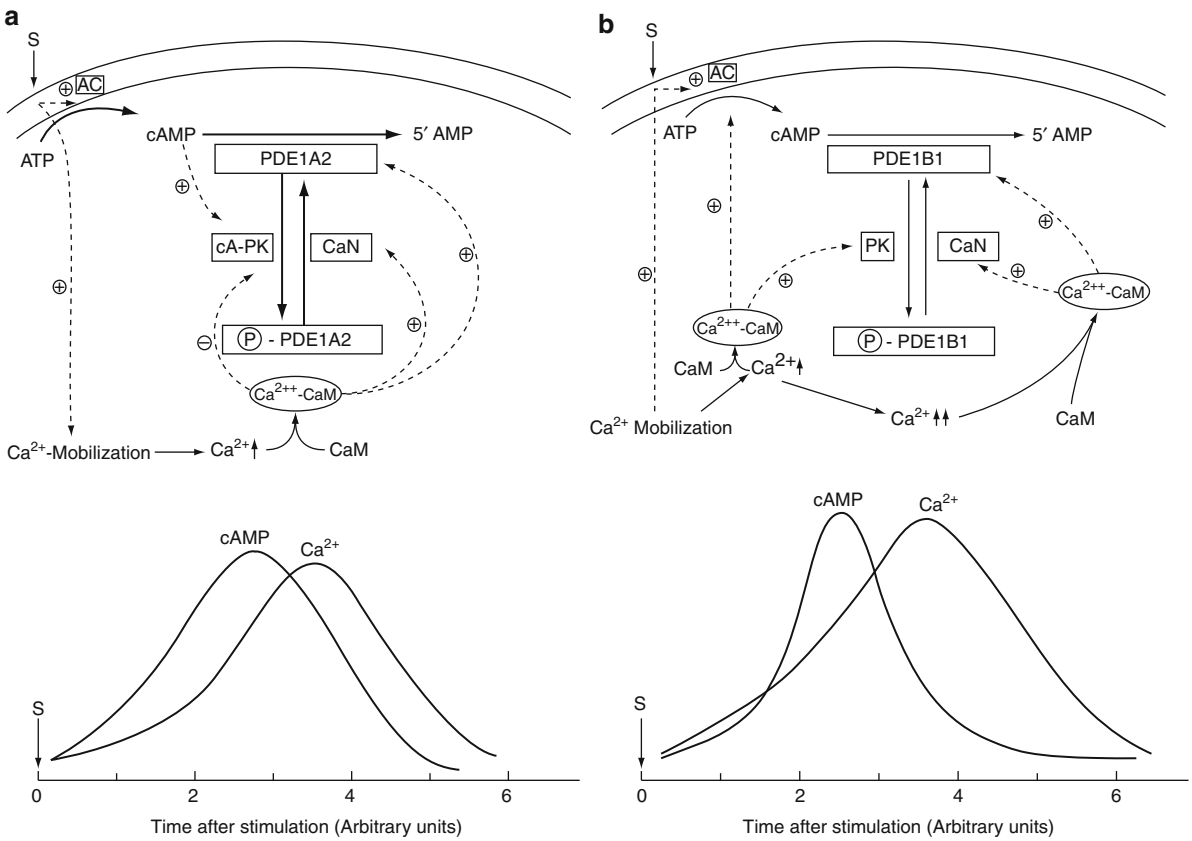
Regulation of PDE1 Isozymes by Phosphorylation

The main difference is that the brain PDE1A2 and heart PDE1A1 are substrates of cAMP-dependent protein kinase (Sharma and Wang 1985; Sharma 1991; Florio et al. 1994), and phosphorylation is inhibited by Ca^{2+} and CaM whereas brain PDE1B1 is phosphorylated by CaM-dependent protein kinase II in a Ca^{2+}/CaM-dependent manner (Sharma and Wang 1986b). The phosphorylation of PDE1A2 and PDE1A1 is accompanied by a decrease in the isozymes affinity toward CaM and an accompanying increase in the Ca^{2+} concentrations required for the isozyme activation by CaM. PDE1A2 and PDE1B1 are phosphorylated by different protein kinases; however, both can be dephosphorylated by CaM-dependent protein phospatase. This dephosphorylation is accompanied by an increase in the affinity of the isozymes for CaM as well as decrease in the Ca^{2+} concentration for the activation of isozyme by CaM. It is interesting to note that PDE1C is phosphorylated by cAMP-dependent protein kinase and upon phosphorylation of PDE1C activity is inhibited with increased EC_{50} for CaM (Ang and Antoni 2002).

Role of PDE1A2 and PDE1B1 in the Regulation of cAMP Concentration

A working hypothesis describing the role of PDE1A2 in the coupling between the two messenger fluxes is presented in Fig. 2a. In most cases, cell activation involves transitory increase in both cAMP and cell Ca^{2+}. The operation of the different regulatory mechanisms on PDE1 may be temporally separated during the signal fluxes. The temporal separation of the regulatory reactions is a result of the Ca^{2+} and cAMP signal fluxes on the one hand and contributes to determining the intensity and duration of the fluxes on the other hand. Thus, and initial increase in cAMP concentration during cell activation may bring about phosphorylation of PDE1A2 and thereby prevent the enzyme from being activated by the low concentrations of Ca^{2+} existing at the early stages of cell activation. The hydrolysis of cAMP, therefore, would be inhibited coordinately with the stimulation of ▶ adenylate cyclase by external signals. This would ensure a rapid and sharp rise in intracellular cAMP. At later stages of cell activation, when intracellular fee Ca^{2+} concentration is increased, the phosphatase reaction may be activated to reverse phosphorylation of the PDE1A2. The PDE1A2 then becomes fully activated by Ca^{2+} and CaM. Since Ca^{2+}-CaM can block PDE1A2 phosphorylation, the dephosphorylated state of the enzyme will be maintained even though the cAMP concentration may still be high in the cell. The concerted actions of these regulatory mechanisms on PDE1A2, namely, the phosphatase reaction, Ca^{2+}-CaM stimulation of PDE1A2, and Ca^{2+}-CaM inhibition of phosphorylation, may bring about a rapid decline in cAMP concentration. A similar hypothesis has been proposed for heart PDE1A1.

The multiple regulatory actions of the PDE1B1 isozyme are dependent on Ca^{2+} and CaM (Fig. 2b), whereas phosphorylation of PDE1A2 by cAMP-dependent protein kinase is inhibited by Ca^{2+} and CaM. Regulation of PDE1B1 by Ca^{2+} and CaM can occur by at least three mechanisms: (1) the PDE1B1 isozyme depends on Ca^{2+} and CaM for full activity, (2) it requires higher concentrations of Ca^{2+} for activation upon phosphorylation by Ca^{2+} and CaM-dependent protein kinase(s), and (3) the phosphorylation of PDE1B1 is reversed by the CaM-dependent protein phosphatase. Therefore, these three distinct CaM-dependent reactions can regulate PDE1B1 and can produce opposite effects on PDE1B1. Based on the findings from studies (Sharma and Wang 1985, 1986b), a working hypothesis has been proposed to indicate how these regulatory actions, separated temporally, could bring about meaningful interactions



Phosphodiesterase 1, Fig. 2 Hypotheses of the temporally separated regulation of PDE1A2 (**a**) and PDE1B1 (**b**) by Ca^{2+} and cAMP. between the Ca^{2+} and cAMP signal systems during cell activation (Fig. 2b). It is postulated that adenylate cyclase and the CaM-dependent protein kinase(s) can be turned on at lower concentration of Ca^{2+} during cell activation, whereas the activation of the PDE1B1 and CaM-dependent protein phosphatase require higher concentration of Ca^{2+}. The first two reactions which act in concert to increase cAMP concentration predominate at the early stage of surge in cytosolic Ca^{2+}, whereas the other two reactions will reduce cAMP concentrations at the higher concentrations of the Ca^{2+} flux. For this proposed hypothesis, it is necessary that adenylate cyclase and the CaM-dependent protein kinase(s) be activated by lower concentrations of Ca^{2+} than the CaM-dependent protein phosphatase and PDE1B1 (Fig. 2b). It has been reported that brain adenylate cyclase is indeed activated by much lower concentration of Ca^{2+} than the PDE1. The validity of the working hypothesis depicted in Fig. 1b has been tested by purification and characterization of CaM-dependent protein kinase from bovine brain. Bovine brain contains two CaM-dependent protein kinases which were separated on a Sephacryl S-300 column (Zhang et al. 1993a). The high molecular weight 500 kDa protein kinase has been purified close to homogeneity. On the basis of its molecular mass, subunit size, and protein substrate specificity, the purified bovine brain CaM-dependent protein kinase is considered to belong to the CaM-dependent protein kinase II family. The phosphorylation of PDE1B1 by the CaM-dependent protein kinase II is dependent on the presence of Ca^{2+} and CaM, and after phosphorylation a further increase in Ca^{2+} concentrations is required for enzyme activation.

Phosphodiesterase 1, Fig. 3 Schematic representation of the regulation of PDE1B1 by Ca^{2+} and cAMP as mediated by the autophosphorylation mechanism of CaM-dependent protein kinase II. The scheme depicts the complex interactions among *cA-PK* cAMP-dependent protein kinase, *PP-1* protein phosphatase-1, *I-1* protein inhibitor-1, *P-* phosphorylated, *CaN* Ca^{2+}-CaM dependent protein phosphatase (calcineurin), ⊕ activation, Θ inhibition, *light arrow* early events, *dark arrow* late events (Adapted from Kakkar et al. 1999)

Earlier, it was postulated (Fig. 2b) that the CaM-dependent protein kinase is activated by CaM at much lower concentrations of Ca^{2+} than the CaM-dependent protein phosphatase and PDE1B1. However, this suggestion was not supported when the dose-dependent activation of PDE1B1 by Ca^{2+} was compared with the purified CaM-dependent protein kinase II at identical concentrations of CaM. The results suggest that CaM-dependent protein kinase II and the PDE1B1 have similar Ca^{2+} concentration dependence at identical concentrations of CaM (Zhang et al. 1993a). However, the observation that the CaM-dependent protein kinase II becomes Ca^{2+}-independent and fully activated upon autophosphorylation suggests an alternative mechanism (Zhang et al. 1993b). Therefore, the CaM-dependent protein kinase may use the autophosphorylation reaction to override its requirements for higher concentrations of Ca^{2+}.

Bovine brain CaM-dependent protein kinase II is autophosphorylated rapidly in the presence of Ca^{2+} and CaM; however, it is converted into a Ca^{2+}-independent protein kinase, that is, the phosphorylation of PDE1B1 isozyme by autophosphorylated CaM-dependent protein kinase II becomes Ca^{2+}-independent. It is postulated that the autophosphorylation reaction can be used to achieve the required temporal separation of the activation of protein kinase from that of phosphatase and/or PDE1B1. Therefore, upon very brief exposure to high concentrations of Ca^{2+}, the CaM-dependent protein kinase II becomes active and insensitive to subsequent increases in Ca^{2+} concentrations, whereas the activation of PDE1B1 requires the continued presence of high concentrations of Ca^{2+}.

There are a number of possible ways by which such a brief exposure of CaM-dependent protein kinase II to high concentrations of Ca^{2+} can occur at onset of Ca^{2+} flux. Studies of agonist-induced Ca^{2+} flux in single cells have suggested that overall Ca^{2+} surge may be composed of a series of rapid Ca^{2+} transients. Such Ca^{2+} transients may, therefore, be used to trigger autophosphorylation of protein kinases at onset of Ca^{2+} surge. Alternatively, it is possible that CaM-dependent protein kinase II may be localized proximal to the sites of Ca^{2+} entry and, therefore, may be autophosphorylated rapidly at onset of Ca^{2+} flux. Immunocytochemical studies have shown that CaM-dependent protein kinase II is localized at inner surface of plasma membranes, as well as at outer surface of mitochondria and at synaptic vesicles and microtubules. Therefore, autophosphorylation of CaM-dependent protein kinase II may provide an additional mechanism that can be incorporated into a revised hypothesis for regulation of PDE1B1 isozyme, which is presented schematically in Fig. 3. In addition to temporal separation, a hypothesis is required to include a number of other regulation possibilities. For

example, autophosphorylation of CaM-dependent protein kinase II can be reversed by protein phosphatase-I and this protein phosphatase-I is regulated by protein inhibitor-I. When cAMP levels rise in the cell, cAMP-dependent protein kinase phosphorylates protein inhibitor-I to activate it. Phosphorylated protein inhibitor-I can then inhibit protein phosphatase-I. When protein inhibitor-I is dephosphorylated and inactivated by CaM-stimulated protein phosphatase, protein phosphatase-I is reactivated. As a result, cAMP may exert an inhibitory effect on PDE1B1 isozyme through a regulatory cascade involving protein phosphatase inhibitor-I, protein phosphatase-I, and CaM-dependent protein kinase II. This complex regulatory interaction is in agreement with the previously suggested role for PDE1B1 isozyme in the dynamic coupling of cAMP and Ca^{2+} fluxes in the cell.

In summary, during the early stage of cell activation, initial increase in cAMP and Ca^{2+} causes a temporary suppression of PDE1B1 isozyme activity to maintain the rise in cAMP concentration. As Ca^{2+} concentration in the cell is subsequently elevated, CaM-dependent protein phosphatase is activated to reverse the phosphorylation of PDE1B1 isozyme and reactivate PDE1B1. Since CaM-dependent protein phosphatase also dephosphorylates protein phosphatase inhibitor-I to cause reactivation of protein phosphatase-I, autophosphorylation of CaM-dependent protein kinase II is also reversed. Therefore, rephosphorylation of PDE1B1 isozyme will no longer occur as Ca^{2+} concentration subsides in the cell.

The main feature of the working hypothesis for the regulation of PDE1 isozymes is that the multiple regulatory actions exerted by second messengers on a single PDE1 isozyme are temporally separated. This is possible because the concentrations of both cAMP and Ca^{2+} undergo continuous change during cell activation. When the cell Ca^{2+} flux changes, cAMP flux will change accordingly. The transitory elevations of two messengers during cell activation are, therefore, coupled to each other with PDE1 isozymes playing key roles in this signal coupling phenomenon.

Summary

One of the most intensively studied cyclic nucleotide phosphodiesterase enzymes is the calmodulin-dependent cyclic nucleotide phosphodiesterase (PDE1) which is stimulated by the binding of Ca^{2+} and calmodulin. The earlier notion that PDE1 consists of a single species has been surpassed and it is clear that PDE1 exists as different isozymes, namely, PDE1A, PDE1B, PDE1C, and their various splice variants. These isozymes are regulated by multiple second messenger–dependent regulatory systems. One of the main features of the findings is that during cell activation, the various regulatory activities are temporally separated. Therefore, a temporal separation of second messenger–dependent reactions can be considered as natural consequences of dynamic fluxes of the messengers. These studies indicate that the activity of PDE1 is precisely regulated by cross talk between the Ca^{2+} and cAMP-signaling pathways.

Despite substantial progress, it is important to acknowledge that the understanding of the functions of PDE1 in disease states is far from complete. In the future, it is important to identify adaptive responses where PDE1 isozyme's activity and expression are changed and the change in levels of proteins which regulate and target PDE1 isozymes.

Phosphodiesterase 10A

Takashi Sasaki, Jun Kotera and Kenji Omori
Advanced Medical Research Laboratories, Mitsubishi Tanabe Pharma Corporation, Yokohama, Kanagawa, Japan

Synonyms

PDE10; PDE10A

Historical Background

Identification of phosphodiesterase 10A (PDE10A) was first reported in mice and humans at the same period from three laboratories (Soderling et al. 1999; Fujishige et al. 1999a; Loughney et al. 1999). Primary sequence of PDE10A possesses a catalytic domain (HD domain) conserved within the 3, 5′-cyclic nucleotide phosphodiesterase family. PDE10A shows substrate specificity for both cyclic AMP (cAMP) and cyclic GMP (cGMP), and hydrolyzes these molecules to 5′-AMP and 5′-GMP, respectively. PDE10A mRNA and protein are highly expressed in the brain, particularly, in the striatal medium spiny neurons (Fujishige et al. 1999b; Seeger et al. 2003). Genetic deletion of PDE10A gene in mice as well as PDE10A inhibition by papaverine, a first reported PDE10 inhibitor, showed altered behavioral responses to several schizophrenia models (Siuciak et al. 2006; Siuciak et al. 2008); therefore, therapeutic implications of PDE10A inhibitor for psychiatric diseases have been received with considerable attention. To date, several potent and selective inhibitors for PDE10A have been reported to be efficacious in rodent models for positive, cognitive, and negative symptoms of schizophrenia (Schmidt et al. 2008; Grauer et al. 2009), while it remains to be demonstrated that whether these inhibitors provide a therapeutic benefit for schizophrenia patients or not.

Enzymatic Property

Kinetic analyses of human, mouse, and rat PDE10A indicated that PDE10A has higher affinity for cAMP

(K_m value of 0.05–0.158 μM) than cGMP (K_m value of 0.26–9.3 μM) (Soderling et al. 1999; Fujishige et al. 1999a; Loughney et al. 1999). On the other hand, V_{max} values for cAMP is twofold lower than that for cGMP. As expected from this observation, the catalytic activity for cAMP is significantly inhibited by the presence of cGMP (Fujishige et al. 1999a). Two major N-terminal splice variants have been reported in humans: PDE10A1 and PDE10A2 (Kotera et al. 1999). PDE10A2 is the most predominant splice form in the brain. Fujishige et al. reported various N-terminal splice variants in rats (PDE10A2-PDE10A6), but enzymatic properties and biological functions of minor splice variants have not determined yet (Fujishige et al. 1999b). Another feature in the primary structure of PDE10A is the two GAF domains (stands for cGMP binding and stimulated phosphodiesterases, Anabaena ▶ adenylyl cyclases, and *Escherichia coli* FhlA) that are situated in the N-terminus of the catalytic domain. Initial study using chimeric constructs with PDE10A GAF domain and bacterial adenylyl cyclase indicated that the cyclase activity was activated by cAMP binding to the GAF domain (Gross-Langenhoff et al. 2006). Subsequent study conducted by Matthiesen et al. has demonstrated that binding of cAMP does not stimulate hydrolytic activity of full-length human PDE10A2 (Matthiesen and Nielsen 2009). Crystal structure of PDE10A GAF-B domain with cAMP has been reported (Handa et al. 2008). This study has demonstrated that a cNMP-binding pocket tightly binds cAMP, and the β1 and β2 strand in the pocket contribute to the recognition of adenine base. At present, implication of the nucleotide binding to GAF domain for the biological pathway in vivo remains to be determined.

Tissue Expression and Subcellular Localization

PDE10A transcripts are highly expressed in basal ganglia, particularly in striatum and caudate nucleus in the central nervous system (Fujishige et al. 1999a, b). In the peripheral tissues in humans, moderate expression was detected in the thyroid, testis, heart, and kidney (Fujishige et al. 1999a; Loughney et al. 1999). Immunohistochemical analysis has revealed that PDE10A protein is expressed exclusively in the cell body of the striatal GABArgic medium spiny neurons and their projecting axons in substantia nigra (Seeger et al. 2003). Striatal expression of PDE10A transcripts and proteins is conserved among humans and rodents, but there are slight species differences in other region in the brain. For example, in rats, marked expression was observed in hippocampus and cerebellum, whereas only minimum expression was detected in these tissues in mice (Coskran et al. 2006). PDE10A proteins are clearly detectable in cerebral cortex in humans. On the other hand, the expression in this area is relatively low in mice and rats. Growing evidence has suggested the idea that subcellular localization of PDEs contributes to the compartmentation of cyclic nucleotide signals. Human and rat PDE10A2 proteins were demonstrated to be localized in membrane fraction in PC12 cells, while human PDE10A1, and rat PDE10A3 were mainly expressed in cytosolic fraction (Kotera et al. 2004). Rat PDE10A2, a major splice variant in the striatum, has been mainly detected in the membrane fraction prepared from striatum by using specific antibody for PDE10A2 (Kotera et al. 2004). Xie et al. reported detailed subcellular localization of PDE10A in striatum by immunoelectron microscopy study (Xie et al. 2006). The report has indicated that the PDE10A protein was confined in vesicle-filled presynaptic terminals of striatal neurons in rats. Two modes of posttranscriptional regulation are known to alter subcellular localization of PDE10A. Kotera et al. has reported that phosphorylation at Thr-16 of PDE10A2 by PKA-mediated pathway causes alteration of subcellular localization from membrane to cytosol in PC12 cells (Kotera et al. 2004). Charych et al. has demonstrated that palmitoylation of Cys-11 of PDE10A2 is required for membrane association in vivo and distal dendritic trafficking of the protein in cultured striatal neurons (Charych et al. 2010). Phosphorylation of PDE10A2 at Thr-16 interfered with palmitoylation at Cys-11, resulting in the retention of PDE10A2 in cytosolic fraction. Zinc finger domain-containing DHHC domain-containing protein (ZDHHC)-7 and -19 were identified as candidates for the enzyme-mediating palmitoylation of PDE10A2.

Implication for Cellular Signaling

Striatal medium spiny neurons can be categorized into two distinct neurons: dopamine D1 receptor-containing (direct pathway) neurons and dopamine

D2 receptor-containing (indirect pathway) neurons, which are involved in the regulation of cortico-striatal-thalamic loop. Involvement of PDE10A on corticostriatal signaling was investigated by Threlfell et al. using electrophysiological technique in vivo (Threlfell et al. 2009). Single-cell recording from direct or indirect pathway neurons, which were identified based on the response to antidromic stimulation, has revealed that administration of PDE10A inhibitors, papaverine and TP-10, increase the responsiveness of striatal neurons to cortical stimulation in vivo. Moreover, robust increase of the activity in response to cortical input was observed in striatopallidal neurons but not striatonigral neurons. As well as PDE10A, ▶ PDE4 is expressed in stiratum. Nishi et al. have reported distinct role of PDE4 and PDE10A in striatum (Nishi et al. 2008). Expression of PDE10A was detected in all ▶ DARPP-32 positive neurons, while PDE4B was mainly expressed in striatopallidal neurons rather than striatonigral neurons. PDE10A inhibition by papaverine, but not PDE4 inhibition by rolipram, caused DARPP-32 and GluR1 phosphorylation in stiatum. On the other hand, phosphorylation of tyrosine hydroxylase was increased by rolipram at presynaptic dopaminergic terminals. In striatonigral neurons, PDE10A inhibition activated cAMP-pathway (measured by DARPP-32 phosphorylation) resulting in the potentiation of dopamine D1 receptor pathway. In striatopallidal neurons, papaverine activated cAMP-pathway by potentiating adenosine A2a receptor pathway and inhibiting dopamine D2 receptor pathway simultaneously.

Knockout (KO) Mouse Phenotype

Behavioral characteristics of PDE10A KO mice (C57BL/6 background) have been reported by Siuciak et al. (2008). PDE10A KO mice showed slight decrease in spontaneous locomotor activity and delayed acquisition in conditioned avoidance response (CAR). MK-801-induced increase of locomotor activity was blunted in KO mice compared with wild-type mice, while there was no difference in PCP-induced locomotor response. Unexpectedly, basal cyclic nucleotide concentration and ▶ CREB phosphorylation were unchanged in striatum from KO mice, whereas dopamine turnover was increased in KO mouse striatum. KO mice demonstrated increased response to amphetamine and methamphetamine administration. These observations suggested the hypothesis that PDE10A may influence cortical glutamatergic neuronal activity via both D1 receptor-mediated direct pathway and D2 receptor-mediated indirect pathway. Sano et al. has reported increased social interaction behavior in KO mice of PDE10A2, a major splice form in the brain (Sano et al. 2008). Although elevation of cAMP and CREB phosphorylation in striatum was observed, PDE10A2 KO mice did not exhibit abnormalities in spontaneous locomotor activity. Behavioral test battery has revealed that responses in elevated plus maze, rotor rod, conditioned fear, and forced-swim were unchanged between PDE10A2 KO and wild-type mice.

Inhibitors

Papaverine, an opium alkaloid used for the treatment of visceral spasm and smooth muscle relaxation, was a first-identified inhibitor for PDE10A (IC_{50} value = 36 nM) (Siuciak et al. 2006). Papaverine has shown to increase cGMP and CREB phosphorylation in mouse striatum; in addition, these observations were completely abolished in PDE10A KO mice. In 2008, a research group from Pfizer has reported the discovery of a novel class of inhibitor, TP-10 (Schmidt et al. 2008). TP-10 potently inhibited rat PDE10A (K_i value = 0.3 nM) and showed great selectivity (> 3,000-fold) against other PDEs. TP-10 caused dose-dependent increase of cAMP, cGMP, and phosphorylated CREB levels in mouse striatum in vivo. Administration of TP-10 inhibited CAR and reversed amphetamine-induced auditory gating deficits in rodents. Clinically used D2-antagonists and atypical antipsychotics have been known to induce catalepsy. Although TP-10 induced weak catalepsy, the response was not increased by the dose elevation in contrast to the D2-antagonists and atypical antipsychotics. In 2009, detailed evaluation of MP-10, a novel compound that is closely related analogue of TP-10, in several animal models for schizophrenia was reported (Grauer et al. 2009). MP-10 demonstrated IC_{50} value of 1.3 nM for human PDE10A and at least 1,300-fold selectivity for other PDEs. As expected from the results in TP-10 treatment, MP-10 caused significant increase of cAMP and cGMP in vivo. In addition, phosphorylation of CREB, DARPP-32, and GluR1 was increased by MP-10 treatment. MP-10 administration demonstrated

weak catalepsy and disruption of CAR in rodents. Increased phosphorylation of GluR1 at Ser-845 and upregulation of enkephalin and substance-P mRNA accompanying with MP-10 treatment further supports the idea that PDE10A modulate dopaminergic and glutamatergic neurotransmission. The fact that MP-10 improved social odor memory, and increased time spent in social side in social approach/social avoidance model in mice suggest that MP-10 has a potential for the improvement of cognitive function and negative symptoms in schizophrenia patients. To date, many structurally different classes of PDE10A inhibitors have been reported from various laboratories. Comprehensive review of these inhibitors was published by Kehler and Kilburn (2009). Currently, phase 1 clinical trial using MP-10 has been conducted.

Summary

PDE10A is a dual-specific and cGMP-inhibited phosphodiesterase that is highly expressed in the striatal medium spiny neurons. This unique expression property has suggested association of this enzyme for basal ganglia function. Recent advances in the research of PDE10A using genetic deletion and selective inhibitors have suggested that PDE10A is involved in the control of dopaminergic circuit as well as the modulation of gultamatergic neuronal transmission. D2 antagonist and atypical antipsychotic drugs are widely used for the treatment of schizophrenia, while these medications exhibit several side effects such as extrapyramidal disorder and obesity, and ineffectiveness for negative symptom in schizophrenia. Distinct roles of PDE10A in the regulation of neuronal circuit may provide novel hypothesis in the regulation of brain function by PDE10A and therapeutic opportunity for schizophrenia by PDE10A inhibitor.

Phosphoinositide 3-Kinase

Lomon So and David A. Fruman
Department of Molecular Biology & Biochemistry, University of California, Irvine, CA, USA

Synonyms

Phosphatidylinositol 3-kinase; Phosphatidylinositol 3-OH kinase; PI 3-K; PI 3-kinase; PI3K; PI(3)K

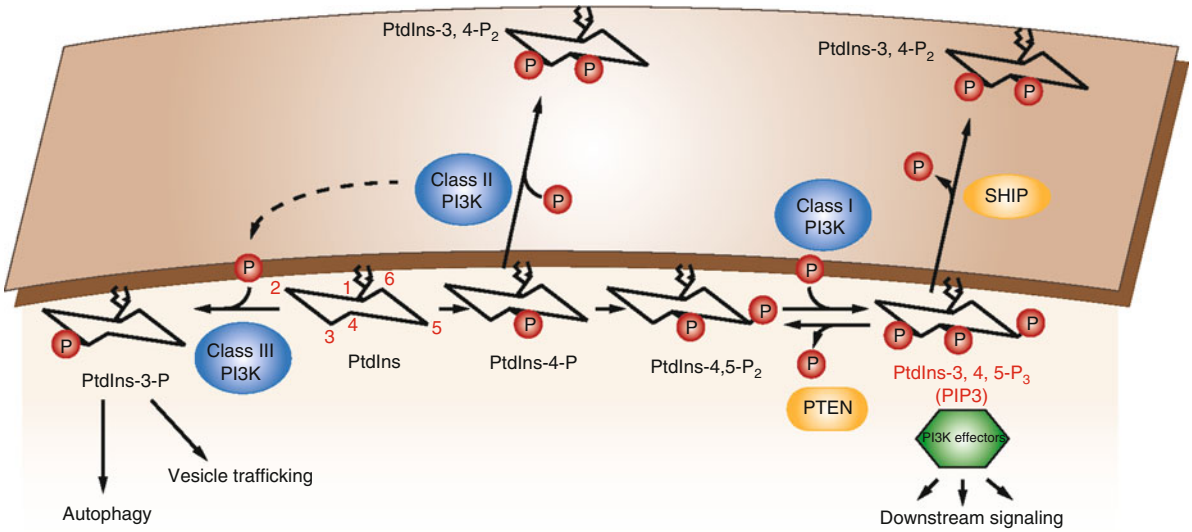
Historical Background

Phosphoinositide 3-kinase, commonly abbreviated PI3K, is one of the most well-studied enzymes in the field of signal transduction (Fruman et al. 1998; Vanhaesebroeck et al. 2010). PI3K actually refers to a family of enzymes encoded by eight genes in mammals. Orthologs of one or more PI3K genes exist in all animals as well as in yeast. These enzymes share the ability to phosphorylate the 3′-hydroxyl of the inositol head group of phosphatidylinositol (PtdIns), generating the lipid PtdIns-3-P (Fig. 1). Some members of the PI3K family can act on phosphoinositides, which are phosphorylated derivatives of PtdIns (such as PtdIns-4,5-P_2). Therefore, the family is properly referred to as phosphoinositide 3-kinases rather than simply phosphatidylinositol 3-kinases. The products of PI3Ks, generally termed 3-phosphorylated inositides (3-PIs), serve as membrane recruitment signals for cytoplasmic proteins with selective 3-PI-binding domains. Since the production of 3-PIs is transient and reversed by lipid phosphatases, PI3K activation provides a means to dynamically control assembly of signaling complexes at cellular membranes.

PI3K was first discovered in the mid-1980s as an enzymatic activity that co-precipitated with activated growth factor receptors and oncoproteins (Cantley et al. 1991). Although controversial at first, it was soon appreciated that activation of PI3K and production of 3-PIs is a signaling response common to a great variety of receptor systems. The genes encoding PI3Ks were cloned starting in the early 1990s. Identification of PI3K inhibitors began at this time and continues to the present day, with pharmaceutical companies and academic laboratories around the world racing to develop the most potent and selective compounds (Marone et al. 2008; Yap et al. 2008; Engelman 2009; Liu et al. 2009; Workman et al. 2010). The reason for this intense activity is that hyperactive PI3K signaling is now recognized as a driving force in human cancer, inflammatory diseases, metabolic disorders, and in many other clinical conditions (Engelman et al. 2006; Fruman and Bismuth 2009). PI3K genes are *bona fide* oncogenes in that gain-of-function mutations are found in a large fraction of human cancers (Samuels and Ericson 2006; Denley et al. 2008). Some of the most common tumor suppressor genes act by opposing PI3K signaling (Salmena et al. 2008). Gene targeting studies have confirmed the central role of PI3K enzymes and regulatory subunits in cell proliferation and in a diverse set of physiological functions (Deane and Fruman 2004; Fruman and Bismuth 2009; Vanhaesebroeck et al. 2010). *Note to reader: The review articles cited in this section are definitive resources that provide references to primary literature. The main text cites additional reviews relevant to specific topics not covered in the above references.*

PI3K Enzymes and Products

The eight PI3K catalytic subunits in mammals are grouped into three classes according to structure and

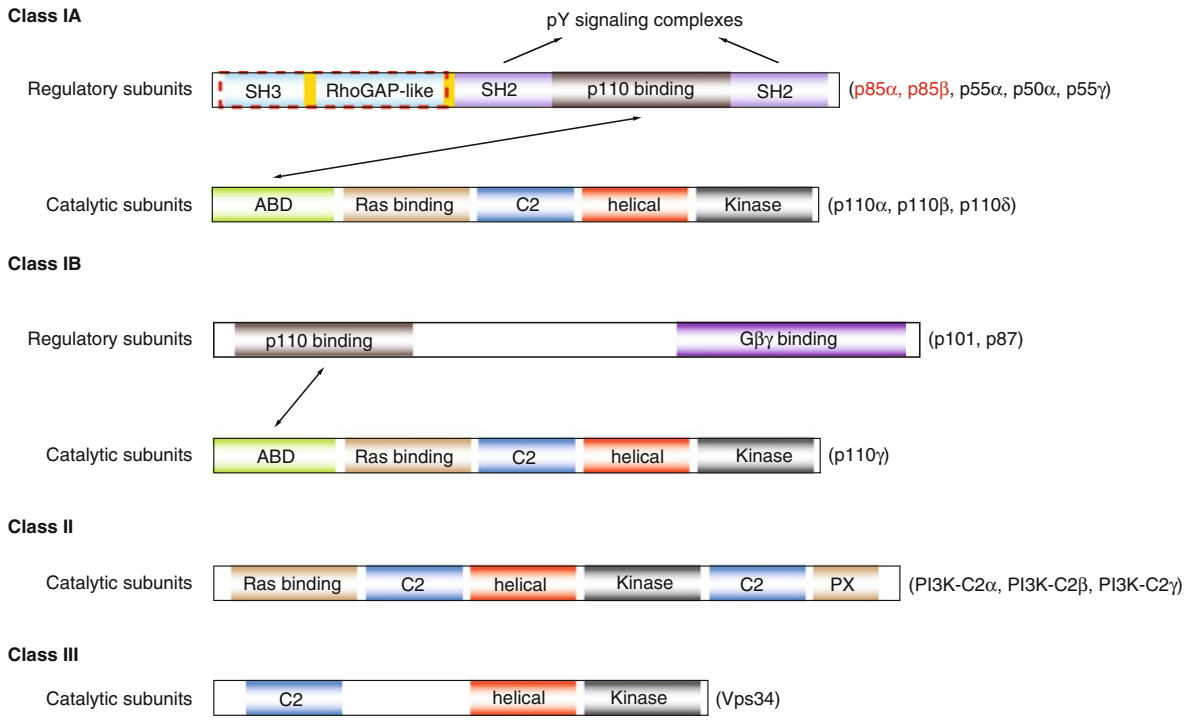


Phosphoinositide 3-Kinase, Fig. 1 Pathways of synthesis and degradation of 3-phosphorylated phosphoinositides (3-PIs). The *brown* area represents the inner leaflet of the membrane bilayer, viewed en face. The three classes of PI3K are indicated in *blue*; major phosphatases are in *orange*. Effectors of class I PI3K (*green*) bind selectively to PIP_3 and/or PtdIns-3,4-P_2. The colors designated in this figure legend and others refer to the electronic versions of the figures

substrate preference (Fig. 2). Class I PI3Ks can utilize various substrates, but it is thought that the primary activity of these enzymes is to convert PtdIns-4,5-P_2 to PtdIns-3,4,5-P_3 (PIP_3) (Fig. 1). PIP_3 is nearly undetectable in unstimulated cells but is rapidly produced following engagement of receptors that activate class I PI3K – which include most receptor tyrosine kinases, tyrosine kinase-coupled receptors, and G-protein-coupled receptors (GPCRs). PIP_3 can be converted back to PtdIns-4,5-P_2 by the phosphatase and tensin homolog (► PTEN), or dephosphorylated on the 5′-phosphate by SH2-containing inositol phosphatases (SHIP1 or SHIP2) to produce PtdIns-3,4-P_2. The four class I enzymes are customarily subdivided into class IA (p110α, β, δ) and class IB (p110γ), based on their distinct regulatory subunits and upstream activators (Fig. 2). Class IA enzymes form obligate heterodimers with one of five regulatory isoforms (p85α, p55α, p50α, p85β, or p55γ) whereas the class IB PI3K associates with distinct regulatory isoforms (p87 or p101). Each class IA regulatory isoform contains Src homology-2 (SH2) domains that mediate binding to tyrosine-phosphorylated signaling complexes. The class IB regulatory subunits link class IB PI3K to GPCR signaling via heterotrimeric G proteins. However, there is increasing evidence that class IA enzymes can be activated downstream of GPCRs, indicating that the class IA-IB distinction is not absolute. Furthermore, both class IA and class IB isoforms possess domains for binding to Ras, a GTPase activated downstream of tyrosine kinases.

Structural studies have provided considerable insight into the domain topology of class I PI3Ks, their mode of regulation by regulatory subunits and Ras, and their interaction with inhibitor compounds (Williams et al. 2009). The p110γ isoform was the first to be crystallized, followed more recently by p110α, p110β and p110δ. The studies of p110α have provided insight into the mechanisms by which oncogenic mutations in the genes encoding p110α (*PIK3CA*) and p85α (*PIK3R1*) cause elevated activity of p85α/p110α dimers.

There are three class II enzymes, each containing a C2 domain and termed PI3K-C2α, PI3K-C2β, and PI3K-C2γ. There is a single class III PI3K that is homologous to the yeast PI3K enzyme Vps34. Class III enzymes associate with the protein Vps15. Class II and III enzymes act on PtdIns to produce PtdIns-3-P, though the class II PI3Ks might also convert PtdIns-4-P to PtdIns-3,4-P_2. It is clear that regulated production of PtdIns-3-P is essential for vesicle trafficking and for the initiation of autophagy. However, compared to the class I PI3Ks, less is known about the function of class II and class III PI3Ks. A recent review article provided



Phosphoinositide 3-Kinase, Fig. 2 Domain structure of PI3K catalytic and regulatory subunits. Among the class IA regulatory subunits, only p85α and p85β possess the domains denoted by the *red* dashed box

a comprehensive review of the available literature on class II and III PI3Ks (Vanhaesebroeck et al. 2010).

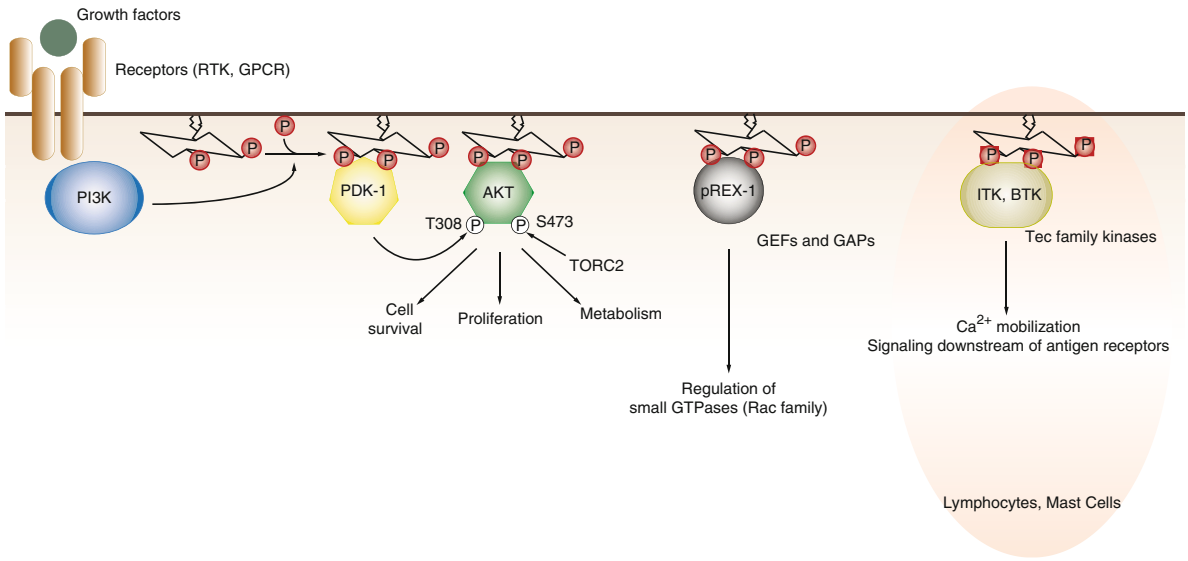
PI3K Effectors

The term "PI3K effector" is applied to any protein that contains a domain with selective affinity for 3-PIs, allowing the protein to be recruited to membranes where a PI3K enzyme is active (Fig. 3). There are several types of 3-PI-binding domain, of which the most common are the pleckstrin homology (PH), phox homology (PX), and FYVE domains (Lemmon 2008). PH domains have diverse lipid preferences, with only a subset binding selectively to 3-PIs and, within this group, differing preference for PIP_3, PtdIns-3,4-P_2, etc. Most PX domains are selective for PtdIns-3-P or PtdIns-3,4-P_2, and FYVE domains mostly bind to PtdIns-3-P.

PH domains selective for PIP_3 or PtdIns-3,4-P_2 are present in a number of important signaling enzymes and small G protein modifiers (Fig. 3). PDK-1 (phosphoinositide-dependent kinase-1) is a constitutively active serine/threonine kinase whose PH domain allows the enzyme to interact with membrane-associated substrates. Most notable of these are the AKT family of serine/threonine kinases (also known as protein kinase B). The three AKT proteins (AKT1, 2, 3) possess PH domains and are phosphorylated by PDK-1-on a threonine residue in the activation loop (T308 in AKT1). Further AKT activation is achieved by phosphorylation of a C-terminal hydrophobic motif (S473 in AKT1). In many cellular contexts, the target of rapamycin (TOR) complex-2 (TORC2) is responsible for AKT-S473 phosphorylation. Active AKT phosphorylates numerous substrates that regulate cell survival, proliferation, nutrient uptake, and metabolism (Manning and Cantley 2007).

PIP_3-selective PH domains are also present in most tyrosine kinases of the Tec family, including ITK and BTK that control Ca^{2+} mobilization and other crucial signaling events downstream of antigen receptors in lymphocytes and mast cells. PH domains in guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) link PI3K activation to regulation of some small GTPases. One well-known example is ▶ pREX-1, a GEF for Rac family GTPases that acts downstream of p110γ in neutrophils.

Many important signaling components and transcription factors are activated (or inactivated)

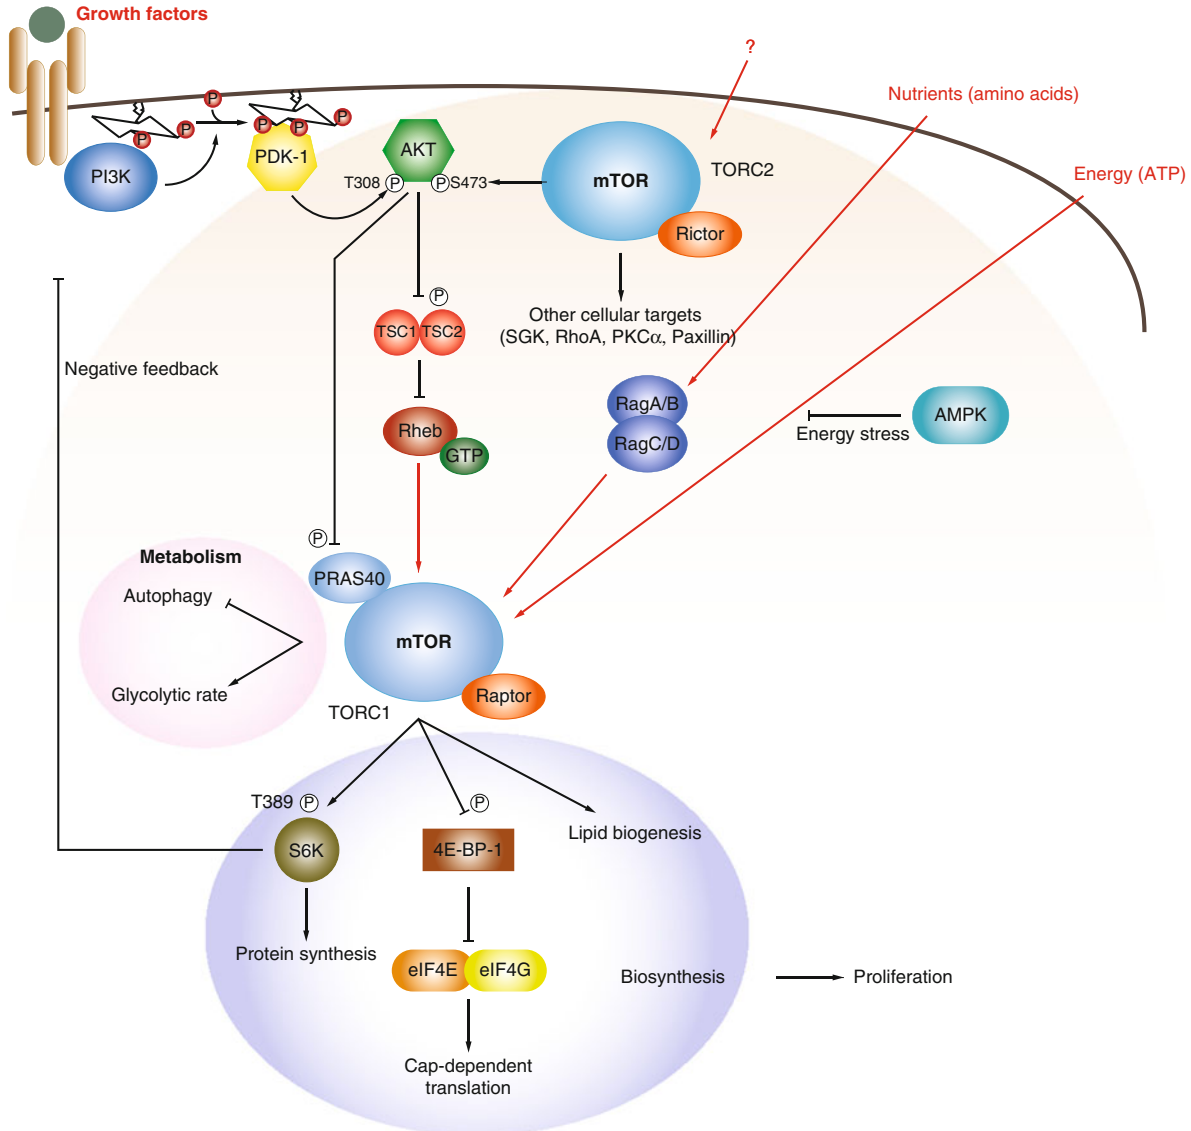


Phosphoinositide 3-Kinase, Fig. 3 Examples of PH domain-containing effectors of class I PI3K. Each of the proteins shown (PDK-1, AKT, pREX-1, Tec family kinases) bind selectively to PIP_3. Key downstream events controlled by these PI3K effectors are shown

indirectly by PI3K signaling, via the direct effectors described in the preceding paragraphs. Space constraints do not allow a comprehensive summary of PI3K-regulated cellular components. The discussion here will focus on one crucial downstream network controlled by TOR complex-1 (TORC1) (Fig. 4). The enzyme TOR (also known as ▶ mTOR) is a serine/threonine kinase that exists in two complexes with distinct components, TORC1 and TORC2 (Foster and Fingar 2010; Sparks and Guertin 2010). While TORC2 acts upstream on AKT as mentioned above, TORC1 acts downstream of AKT. When fully active, TORC1 promotes biosynthetic events that drive cell proliferation, including protein and lipid synthesis; TORC1 also regulates metabolism by increasing glycolytic rates and inhibiting autophagy. TORC1 actually integrates signals from many sources: growth factor signaling pathways (AKT and others), nutrient availability, and stress response pathways. AKT promotes TORC1 activity by phosphorylating and inhibiting two negative regulators of TORC1. One AKT substrate, TSC2, is part of the tuberous sclerosis complex (TSC) that has GAP activity toward the Rheb GTPase upstream of TORC1. Proline-rich AKT substrate of 40kDa (PRAS40) is part of the TORC1 complex and its phosphorylation by AKT relieves PRAS40-mediated suppression of TORC1 activity. Active TORC1 phosphorylates ribosomal S6 kinases (S6K1 and S6K2) and eIF4E-binding proteins (4EBPs) to promote mRNA translation, and other cellular substrates to regulate autophagy and other processes. It has become increasingly clear, however, that compensatory pathways can maintain TORC1 activity in the absence of detectable PI3K/AKT signaling, particularly in cancer cells. The implications of this will be discussed in the section "PI3K Pharmacology."

PI3K Genetics

Gene targeting and transgenesis experiments have greatly added to the understanding of PI3K gene function in model organisms. The discussion that follows will focus on studies of class I PI3K genes in mice. For each of the catalytic subunits, null "knockout" (KO) alleles as well as kinase-dead "knock-in" (KI) alleles have been reported. p110α (*Pik3ca*) KO or KI results in an embryonic lethal phenotype in homozygotes. Mice heterozygous for p110αKI are viable but display severe defects in organismal metabolism, including insulin resistance, hyperglycemia and adiposity. At the molecular level, p110α-deficient cells show reduced signaling downstream of receptors that couple to insulin receptor substrate (IRS) proteins. Together with pharmacological studies, this finding illustrates that p110α has a nonredundant function in cellular



Phosphoinositide 3-Kinase, Fig. 4 Simplified diagram of the TOR signaling network. The target of rapamycin (denoted "mTOR" in this figure, in keeping with previous literature in which the protein is called "mammalian" or "mechanistic" target of rapamycin) is a single kinase that exists in two cellular complexes, TORC1 and TORC2. The subunit composition differs among these complexes, as do the activation mechanisms and downstream functions as indicated. Key points are that TORC2 functions upstream of AKT, TORC1 functions downstream of AKT, and TORC1 also feeds back through S6 kinases to dampen PI3K and AKT activity

responses to insulin and insulin-like growth factor. Other studies of p110αKI mice have revealed a role for this isoform in angiogenesis. A distinct knock-in strain carrying a mutation in the Ras-binding domain of p110α provided evidence that p110α is a Ras effector important for lymphangiogenesis and cellular transformation.

Mice with germline deletion of p110β (*Pik3cb*) die early in embryogenesis, but p110βKI mice are viable. Together with other results this finding establishes kinase-independent functions of the p110β isoform. Kinase-dependent functions of p110β have also been identified through analysis of p110βKI mice as well as strains with conditional p110βKO in specific tissues.

Key observations include the following: (1) p110β plays an important role in the malignant phenotype of cancer cells with loss of PTEN, suggesting that p110β mediates growth factor-independent "basal" production of PIP_3 that is normally hydrolyzed by PTEN. (2) p110β has a key function downstream of GPCRs including receptors for lysophosphatidic acid and chemokines, a finding supported by pharmacological approaches. It remains unclear how p110β activity or localization is modulated by GPCR signaling.

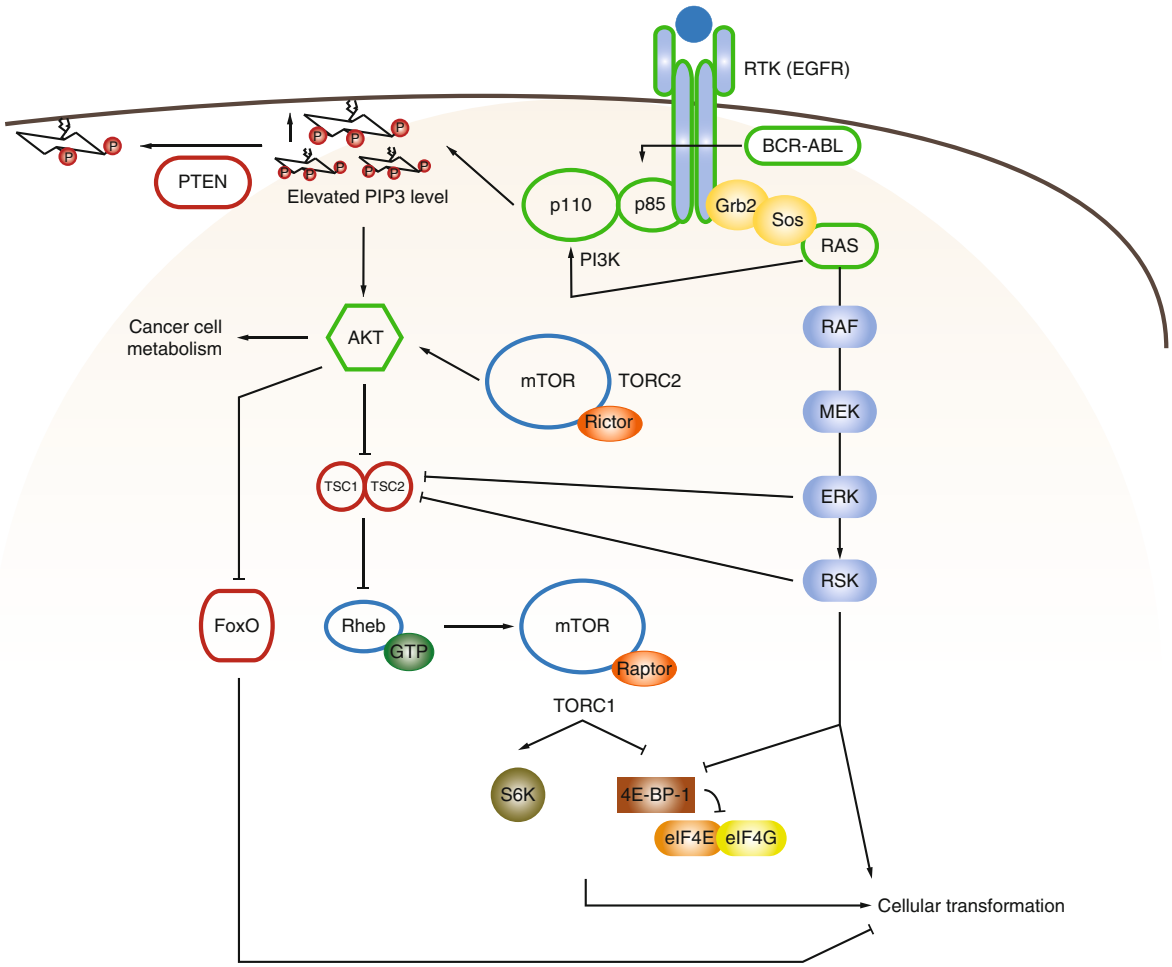
Unlike p110α and p110β, p110δ and p110γ are not ubiquitously expressed, and germline KO mice are viable. The most dramatic phenotypes of p110δ (*Pik3cd*) and p110γ (*Pik3cg*) KO mice are in the immune system. Notable examples include, for p110δKO and KI, impaired B cell development and function, and defective T cell differentiation and trafficking. In p110γKO and KI mice, there are major defects in migration and function of innate immune cells (i.e., macrophages and dendritic cells). Combined inactivation of p110δ and p110γ produces an early block in T cell development and affects natural killer (NK) cell function. Mast cell function and allergic responses are impaired in the absence of either p110δ or p110γ.

There are three genes encoding class IA regulatory subunits: *Pik3r1* encodes p85α, p55α, and p50α; *Pik3r2* encodes p85β; and *Pik3r3* encodes p55γ. Although inactivation of the *Pik3r3* gene has not been reported, the *Pik3r1* and *Pik3r2* genes have been targeted in various ways and in combination. These investigations have shown complex biology of the class IA regulatory subunits. There are unique functions of individual isoforms in some contexts and redundant functions in others. The functions of class IA regulatory subunits in insulin signaling are particularly complex, in that individual deletion of p85α and p85β enhances insulin sensitivity whereas combined deletion reduces insulin sensitivity. p85α and p85β each have diverse functions in immune cells. Studies of insulin-responsive cells and lymphocytes have also provided evidence for "scaffolding" functions of p85α and p85β, independent of the associated catalytic subunit. There are two genes encoding class IB regulatory subunits (*Pik3r5* encodes p101, *Pik3r6* encodes p87). Knockout of *Pik3r5* has shown a nonredundant role for p101 in neutrophil signaling and functional responses to inflammatory stimuli.

Gain-of-function alleles of class I catalytic subunits have been tested in transgenic models and in tissue culture. Increased p110 activity can be accomplished by overexpression of wild-type or oncogenic mutants, including naturally occurring p110α alleles (see below) and engineered mutations that target p110 proteins constitutively to the membrane. Cell culture experiments were the first to demonstrate transforming activity of p110 proteins, and have shown that any of the four class I enzymes can transform fibroblasts when mutated and/or overexpressed. In vivo, activated alleles of p110α and p110β are oncogenic in mice. Analyses of mice with targeted deletion of PTEN have confirmed the tumor suppressor function of this lipid phosphatase and have shown gene dosage-dependent tumor penetrance. In addition, PTEN heterozygous mice develop lymphoproliferative disease. Similarly, mice expressing constitutively active AKT in T cells develop lymphoproliferation and thymic lymphomas. A truncation mutant of p85α (p65) that causes elevated PI3K signaling also disrupts T cell homeostasis and has oncogenic potential.

PI3K in Disease

Many human diseases have been associated with aberrant control of PI3K signaling. The most prominent correlation is between elevated cellular PI3K/AKT activity and cancer. It is now accepted that a large majority of human cancers possess mutations that drive elevated PIP_3 production. This can occur through activated tyrosine kinases (e.g., EGFR, BCR-ABL) or oncogenic Ras upstream of PI3K, loss or inactivation of PTEN, or mutations in PI3K genes themselves (Fig. 5). In epithelial cancers, gain-of-function mutations in *PIK3CA* (p110α) are common. Mutations in *PIK3R1* (p85α, p55α, and p50α) that derepress the associated catalytic subunit are found in glioblastoma at a frequency similar to *PIK3CA* mutations. Elevated p110δ activity has been associated with certain hematologic malignancies. Gene targeting studies support the model that class I PI3K activity is essential for efficient transformation by BCR-ABL or Ras. It is thought that AKT is the major PI3K effector responsible for enhanced proliferation, survival, and altered metabolism in cancer cells. Indeed, some tumor samples display mutation or overexpression of *AKT* genes. The activity of both TOR complexes, TORC1 and TORC2, also appears to be important for the establishment and maintenance of cellular transformation. Notably, some cancer cells can maintain TORC1 signaling in the absence of PI3K/AKT activity through



Phosphoinositide 3-Kinase, Fig. 5 Various mechanisms identified in cancer cells that result in elevated cellular PIP_3 levels. Components in *green* represent protein products of oncogenes that display gain-of-function in cancer. Components in *red* represent tumor suppressors that display loss-of-function in cancer. FOXO proteins are transcription factors that promote cell cycle arrest and apoptosis

inputs from the Ras-ERK pathway and other mechanisms. Also, humans with heterozygous mutations in TSC1 or TSC2 develop benign tumors whose growth is driven by elevated TORC1 activity.

Inflammatory conditions and autoimmune diseases are associated with increased PI3K/AKT/TOR signaling in immune cells. This phenomenon is generally secondary to other environmental or genetic conditions that maintain a heightened state of activation in specific immune cells. Nevertheless, the correlation between immune cell activation and PI3K/AKT/TOR signaling has placed this pathway at the center of worldwide drug discovery efforts for inflammatory diseases.

Insulin-resistance syndromes are a growing health epidemic. By definition, insulin resistance is associated with reduced signaling responses to insulin – including dampened PI3K/AKT activation. Agents that increase PI3K activity or block hydrolysis of PIP_3 could be useful therapies for insulin resistance.

PI3K Pharmacology

As summarized in the previous section, altered PI3K output is involved in the pathogenesis of many human diseases. Consequently, there has been intense and sustained research and development of compounds that modulate PI3K/AKT/TOR signaling for therapeutic benefit. The section that follows will briefly discuss five general strategies (summarized in Table 1) and their potential applicability to human cancer and inflammatory diseases.

Phosphoinositide 3-Kinase, Table 1 Strategies to target PI3K/AKT/TOR activity for human disease therapy

Strategy		Notes	Examples
Pan-class I PI3K inhibition		Has advantage over pan-PI3K inhibitors such as Wortmannin and LY294002 in terms of toxicity. However, may still have toxicity due to inhibition of all class I PI3Ks.	GDC-0941
Isoform-selective PI3K inhibition		Less toxic compared to pan-class I inhibition and may provide better efficacy in diseases driven by a specific isoform of PI3K. On the other hand, the spectrum of applications would be limited.	TGX-221 (p110β), CAL-101 (p110δ)
AKT inhibition		May provide efficacy in cancers driven by elevated AKT activity. Therapeutic window is questionable due to central role of AKT in whole-body glucose homeostasis.	GSK690693
Allosteric TOR inhibition		Currently approved for immunosuppression (rapamycin) and renal cell carcinoma (rapalogs). However, rapalogs have shown overall disappointing efficacy in cancer, correlating with inhibition of negative feedback loop.	Rapamycin, rapalogs (RAD001, CCI-779)
ATP-competitive mTOR inhibition	Nonselective	Have strong anticancer efficacy compared to rapalogs. However, inhibition of PI3K can have toxicity issues such as in the immune system.	BEZ235, XL675
	Selective (asTORi)	Evidence so far shows equivalent anticancer efficacy and less immunosuppression compared to pan PI3K/mTOR inhibitors.	PP242, Torin-1, AZD8055, WYE-354, INK128, OSI-027

One approach is to develop inhibitors of all class I PI3Ks. Until recently, the available PI3K inhibitors were nonselective and suppressed activity of all PI3K classes as well as other cellular enzymes. Now, compounds are available for both preclinical and clinical studies that are highly selective for class I enzymes ("pan-class I inhibitors"). A well-studied example is GDC-0941, a compound developed by Genentech that is in phase I trials for cancer. Other companies and academic laboratories have synthesized compounds with a comparable target profile. A second approach is to develop isoform-selective PI3K inhibitors. An inhibitor of p110δ, CAL-101, has entered trials for blood cancers, and other p110δ or dual p110δ/p110γ inhibitors are under consideration for inflammatory diseases. The relative benefits of pan-class I inhibitors versus isoform-selective inhibitors in cancer have not yet been established, and might vary among tumor subtypes. Inhibitors selective for p110α might be particularly effective against cancers with *PIK3CA* mutations, while avoiding toxicities associated with pan-PI3K inhibition. Likewise, inhibitors of p110β might find utility in cancers with loss of PTEN.

A third approach is to inhibit AKT. Various compounds have been developed that are either ATP-competitive or act through allosteric inhibition of enzyme activity or membrane localization. Considering that AKT inactivation has more profound effects on cellular and organismal metabolism than does PI3K inactivation, there is some concern about the therapeutic window for AKT inhibitors. Another concern about both PI3K and AKT inhibitors in general is that they will not prevent TORC1 activation through other mechanisms.

A fourth approach is to use allosteric inhibitors of TOR, exemplified by rapamycin and its analogs RAD001 and CCI-779. Rapamycin (sirolimus) has been a clinically approved immunosuppressant since 1997. RAD001 (everolimus) and CCI-779 (temsirolimus) are approved for the treatment of advanced renal cell carcinoma. However, the results of oncology trials with rapalogs have been disappointing overall. Rapamycin and rapalogs have mechanistic drawbacks. They do not completely inhibit TORC1 activity and do not bind to TORC2 or inhibit TORC2 activity acutely in cells. Furthermore, rapamycin disables a negative feedback loop by which S6K1 dampens upstream PI3K/AKT and Ras signaling. Therefore, cancer cells treated with rapalogs generally display elevated PI3K/AKT and Ras activity, enhancing survival even when proliferation is suppressed.

A fifth approach is to use ATP-competitive TOR inhibitors. These bind in the active site of the TOR enzyme in both complexes, and fully inhibit phosphorylation of all known TORC1 and TORC2 substrates. There are two classes of competitive TOR inhibitors. One class is not TOR-selective and inhibits

PI3K enzymes (which are structurally related to TOR) at equivalent concentrations. These are termed panPI3K/TOR inhibitors, exemplified by the compounds BEZ235 and XL675. The other class, which was developed only recently, is highly selective active-site TOR inhibitors (asTORi) that do not directly inhibit PI3K. Examples of asTORi are PP242, Torin-1, AZD8055, WYE-354, and INK128. The evidence thus far indicates that asTORi provide anticancer efficacy that is equivalent to panPI3K/TOR inhibitors, and better than rapamycin and rapalogs. asTORi are also less immunosuppressive than panPI3K/TOR inhibitors or rapamycin. Further preclinical and clinical studies are needed to identify the optimal target profile that balances efficacy and tolerability in different cancer patient populations.

Although some genetic events that activate PI3K/AKT are sufficient to transform cells in vitro and promote tumorigenesis in animal models, patient-derived human cancers generally carry multiple additional genetic lesions. Thus, it is likely that inhibitors of this pathway will be most effective when combined with other targeted therapies directed to upstream or parallel pathways. Combined targeting of PI3K/AKT/TOR with Ras/RAF/► MEK/ERK is emerging as a useful strategy in some settings.

Summary

PI3K enzymes generate 3-phosphorylated inositol lipids that coordinate many aspects of cellular physiology. In response to extracellular signals, class I PI3K produces the second messenger PIP_3 that recruits numerous cytoplasmic proteins to the plasma membrane to propagate key signaling pathways. In general, PIP_3 production promotes cell proliferation and survival, and also plays a key role in cellular and organismal metabolism. Most cancer cells carry mutations that trigger constitutive elevation of PIP_3 levels, and activated immune cells depend on PI3K signaling to carry out specialized functions. Gene targeting in mice has revealed unique and complex functions of individual PI3K catalytic and regulatory isoforms. Based on the role of aberrant PI3K activation in human disease, PI3K drug discovery has been a priority and will continue to produce inhibitor molecules of interest to basic and translational researchers.

Phospholipase A_2

Makoto Murakami
Lipid Metabolism Project, The Tokyo Metropolitan Institute of Medical Science, Setagaya-ku, Tokyo, Japan

Synonyms

Arachidonic acid; cPLA2; iPLA2; Leukotriene; Phospholipid; Prostaglandin; sPLA2

Historical Background

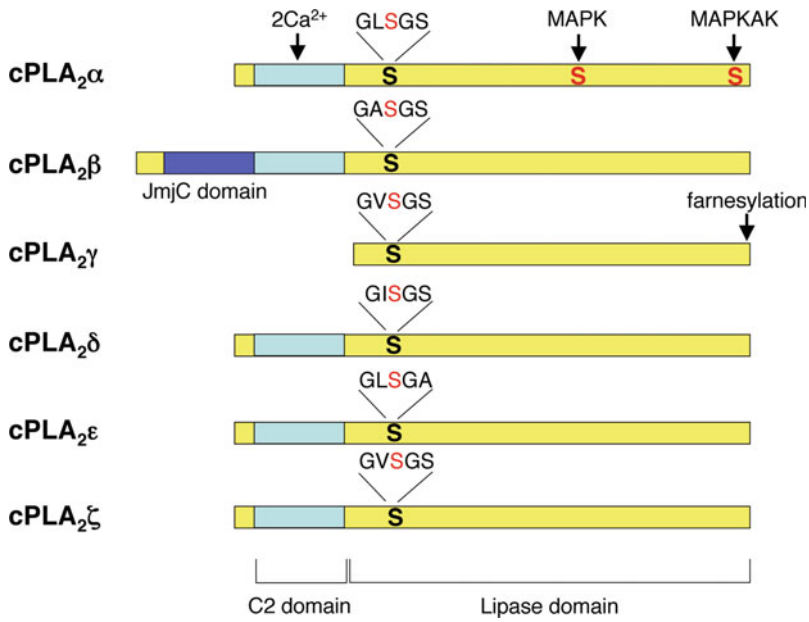
Phospholipase A_2 (PLA_2) hydrolyzes the *sn*-2 position of glycerophospholipids to yield fatty acids and lysophospholipids. In the view of signal transduction, the PLA_2 reaction has been considered to be of particular importance since *arachidonic acid*, one of the polyunsaturated fatty acids released by PLA_2, is metabolized by cyclooxygenases and *lipoxygenases* to the potent lipid mediators *prostaglandins* and ▶ leukotrienes, which are often referred to as *eicosanoids*. In addition, lysophospholipids or its metabolites, such as *lysophosphatidic acid (LPA)* and *platelet-activating factor (PAF)*, also represent another class of lipid mediators. These lipid mediators exert numerous biological actions through their cognate G protein-coupled receptors on target cells. PLA_2 has also been implicated in membrane glycerophospholipid remodeling, thereby contributing to cellular homeostasis.

The PLA_2 enzymatic activity was originally identified more than a century ago in snake venom that potently hydrolyzed egg phosphatidylcholine (PC). By the 1980s, many secreted PLA_2s ($sPLA_2$s) were purified from various venomous animal species including snakes and insects as well as from pancreatic juices in various animals. Pancreatic $sPLA_2$, the first $sPLA_2$ subtype identified in mammals, is now called group IB $sPLA_2$. In the late 1980s, several groups purified and cloned the second mammalian $sPLA_2$ that was markedly induced in inflammatory fluids in human and various animal species. This second type of $sPLA_2$, now called group IIA $sPLA_2$ (also known as an inflammatory $sPLA_2$), was thus supposed to play a key role in the production of *arachidonic acid*-derived lipid mediators in various inflammatory diseases. In the early 1990s, however, the situation became more complex with the identification of the first intracellular PLA_2, i.e., cytosolic PLA_2 group IVA ($cPLA_2\alpha$). Because of its specificity for phospholipids with *arachidonic acid* and its unique properties to undergo stimulus-coupled membrane translocation and phosphorylation, much of the interest was shifted to this enzyme as a central regulator of *arachidonic acid* metabolism. Meanwhile, the late 1990s saw a rapid increase in the discovery of multiple $sPLA_2$s as well as many other intracellular PLA_2s including Ca^{2+}-independent PLA_2s ($iPLA_2$s), PAF acetylhydrolases, lysosomal PLA_2s, and so on, by means of in silico database searches. So far, it is now known that human and mouse genomes encode genes for more than 30 PLA_2 or related enzymes, among which the $cPLA_2$ (6 isoforms), $iPLA_2$ (9 isoforms), and $sPLA_2$ (11 isoforms) families represent three major groups.

$cPLA_2\alpha$-deficient mice, which were first reported in 1997 (Uozumi et al. 1997; Bonventre et al. 1997), have provided unequivocal evidence for the central role of this enzyme in *arachidonic acid* metabolism in many, if not all, biological events. Since the beginning of the twenty-first century, mice with transgenic overexpression and/or targeted disruption of many PLA_2 subtypes have been generated. The phenotypes displayed in individual PLA_2 gene-manipulated mice might not be simply the reflection of changes in lipid mediator signaling or more particularly *eicosanoid* signaling, but could be due to the hydrolysis of one or a combination of various target membranes. In addition, several PLA_2s have been shown to link with human diseases. Here, the properties and functions of PLA_2s in the three major groups ($cPLA_2$, $iPLA_2$ and $sPLA_2$) are overviewed.

Cytosolic PLA_2s ($cPLA_2$s)

Intracellular PLA_2s comprises the $cPLA_2$ (often called group IV PLA_2) and $iPLA_2$ (group VI PLA_2) families, in which six and nine isoforms have been, respectively, identified in mammals. There is structural similarity between $cPLA_2$s and $iPLA_2$s in that the catalytic domain is characterized by a three-layer $\alpha/\beta/\alpha$ architecture employing a conserved Ser/Asp catalytic dyad instead of the classical catalytic triad. A characteristic of all these serine acylhydrolases is their ability to catalyze



Phospholipase A_2, Fig. 1 *The cPLA$_2$ family*. The enzymes belonging to this family typically possess a C2 domain, which binds to two Ca^{2+} ions, near the N-terminus followed by a catalytic domain with the lipase consensus motif GXSXG/A. cPLA$_2$α (group VIA) is a prototypic enzyme in this family, displays arachidonic acid selectivity, and plays a central role in eicosanoid biosynthesis. Phosphorylation at two sites by mitogen-activated protein kinases (MAPK) and MAPK-activated protein kinases (MAPKAPK) is essential for the activation of cPLA$_2$α in cells. cPLA$_2$β (group IVB) has a JmjC domain prior to the C2 domain. Genes for cPLA2β, δ (group IVD), ε (group IVE), and ζ (group IVF) are clustered in the same chromosomal locus, suggesting their latest evolutional relationship. cPLA$_2$γ (group IVC) is unique in that it lacks the C2 domain and that human but not mouse enzyme undergoes farnesylation at the C-terminus. The functions of cPLA$_2$β – ζ in vivo are entirely unknown

multiple reactions (PLA$_2$, PLA$_1$, lysophospholipase, transacylase, or lipase activity) in varying degrees. Therefore, in a general view, these two families seem to be evolved from a common ancestral gene. The cPLA$_2$ family has emerged at the branching point of vertebrates, in correlation with the development of the *eicosanoid* signaling cascades. Enzymes belonging to the cPLA$_2$ family (α, β, γ, δ, ε, and ζ) are characterized by the presence of a C2 domain at their N-terminal region, with an exception of cPLA$_2$γ in which this domain is absent (Fig. 1) (Ohto et al. 2005). cPLA$_2$α, the most extensively studied isoform in the cPLA$_2$ family, is widely expressed in mammalian cells and is the only PLA$_2$ subtype that has specificity for phospholipids containing *arachidonic acid*. Because of its role in initiating agonist-induced release of *arachidonic acid* for the production of *eicosanoids*, cPLA$_2$α activation is important for regulating various pathophysiological processes in a variety of cells and tissues. The biological roles of cPLA$_2$ isoforms other than cPLA$_2$α remain largely obscure.

The overall topology of the C2 domain, which is essential for membrane translocation of cPLA$_2$α in response to calcium signaling, consists of eight antiparallel β-strands interconnected by six loops. Two Ca^{2+} ions bind at one end of the C2 domain. The membrane-binding of cPLA$_2$α is driven by hydrophobic interactions that are achieved by the penetration of hydrophobic residues in the C2 domain into the PC-rich membrane core. The catalytic domain of cPLA$_2$α is composed of 14 β-strands and 13 α-helices. During the nucleophilic Ser^{228} attacks at the *sn*-2 ester bond of glycerophospholipids, Asp^{549} contributes to the activation of this catalytic center. Within the active-site channel, which penetrates one-third of the way into the catalytic domain, the catalytic dyad (Ser^{228} and Asp^{549}) is placed at the bottom of a deep and narrow cleft. The funnel is lined with hydrophobic residues and forms a cradle, to which fatty acyl moieties of phospholipids may bind. Ser^{505}, which represents a phosphorylation site by ▶ MAP kinases, is located near the interdomain linker region (Dessen et al. 1999).

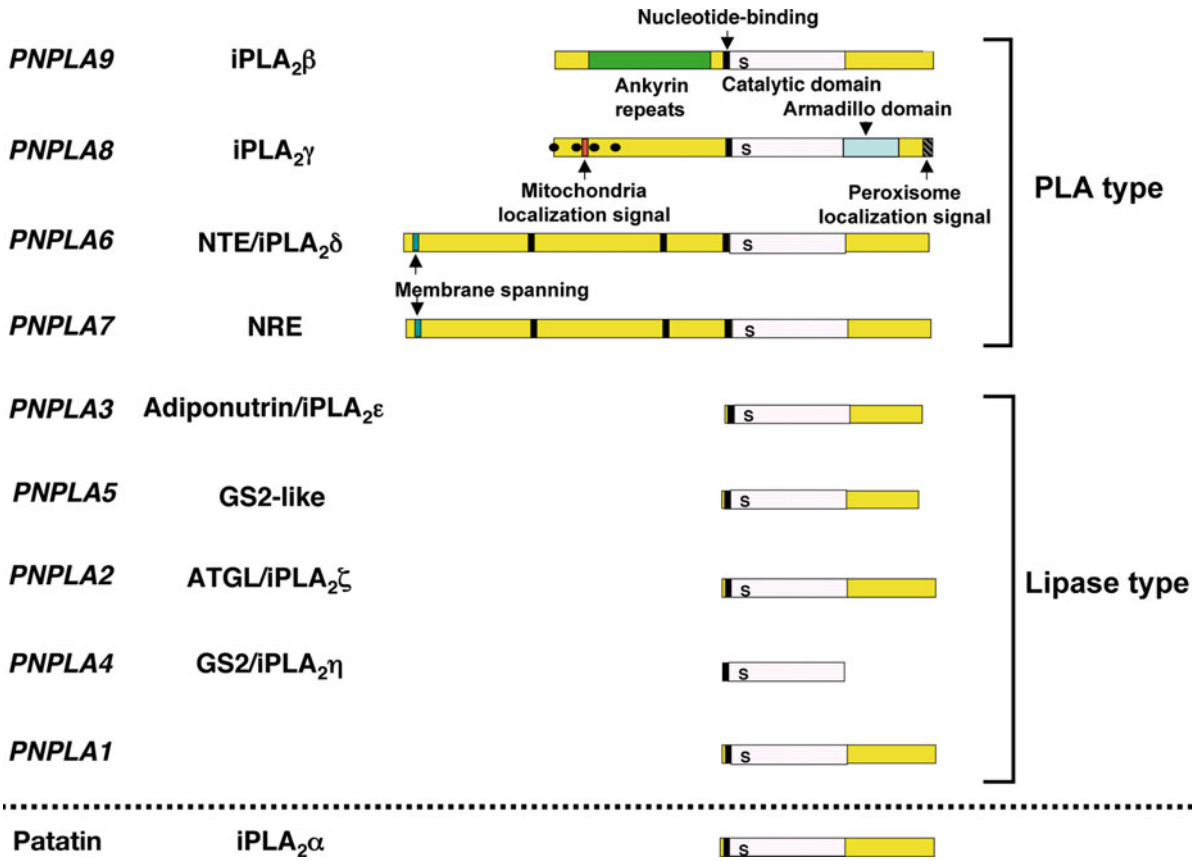
The C2 domain-directed, Ca^{2+}-dependent translocation of cPLA$_2\alpha$ from the cytosol to the Golgi and perinuclear membrane has been thought to be essential for the initiation of *arachidonic acid* release and subsequent *eicosanoid* production in agonist-stimulated cells (Clark et al. 1991). In addition to the C2 domain, the catalytic domain contributes to membrane residence of cPLA$_2\alpha$. Beyond the regulatory role of calcium signaling, the maximal activation of cPLA$_2\alpha$ in cells requires sustained phosphorylation of Ser^{505} by MAP kinases (Lin et al. 1993). The main role of Ser^{505} phosphorylation is to promote membrane penetration of hydrophobic residues in the active-site rim by inducing a conformational change of the protein, and these enhanced hydrophobic interactions allow the sustained membrane interaction of cPLA$_2\alpha$ in response to transient Ca^{2+} increase at a submicromolar level. The full activation of cPLA$_2\alpha$ is achieved by additional phosphorylation at Ser^{727} by MAP kinase-activated protein kinases that disrupts the inhibitory interaction of annexin A2 with cPLA$_2\alpha$. Phosphatidylinositol 4,5-bisphosphate (PIP_2) binds with high affinity and specificity to cPLA$_2\alpha$. Mutations in a PIP_2 binding site (Lys^{488}/Lys^{543}/Lys^{544}) reduce *arachidonic acid* release from cells without alteration in Ca^{2+}-dependent translocation or interfacial binding to membranes, indicating that PIP_2 binding in the catalytic domain principally acts to regulate cPLA$_2\alpha$ hydrolytic activity (Tucker et al. 2009). In addition, ceramide-1-phosphate (C1P) interacts directly with the cationic β-groove of the C2 domain and may contribute to translocation of cPLA$_2\alpha$ to Golgi membranes in response to stimuli.

cPLA$_2\alpha$-deficient mice display a number of phenotypes, most of which can be explained by the reduction of lipid mediators including *eicosanoids* and *PAF* (Uozumi et al. 1997; Bonventre et al. 1997; Nagase et al. 2000). Production of these lipid mediators are markedly if not solely reduced in inflammatory cells such as macrophages, neutrophils, and mast cells in cPLA$_2\alpha$-deficient mice. The null mice are protected from airway disease models such as asthma, acute respiratory distress syndrome and pulmonary fibrosis, brain injury models such as ischemia and amyloid β-induced deficits in learning and memory, autoimmune disease models such as experimental autoimmune encephalomyelitis and collagen-induced arthritis, intestinal cancer, and atherosclerosis. Beyond these roles in pathology, the cPLA$_2\alpha$-dependent *eicosanoid* pathway is also important for tissue homeostasis, as ablation of cPLA$_2\alpha$ perturbs female reproduction, renal function, platelet function, and long-term depression in cerebellar Purkinje cells.

Ca^{2+}-Independent PLA_2s (iPLA$_2$s)

Multiple iPLA$_2$-related genes are encoded in the genomes of yeast, ameba, plants, worms, insects, and vertebrates suggesting that this group of enzymes play fundamental roles in cellular lipid metabolism conserved in the eukaryote kingdom. The human genome encodes 9 iPLA$_2$ enzymes, which are also called patatin-like phospholipase domain-containing lipases (PNPLA1-9) that share a protein domain discovered initially in patatin (iPLA$_2\alpha$), the most abundant protein of the potato tuber. The designation "PNPLA" appears to be more appropriate than "iPLA$_2$," since more than half of these enzymes function mainly as lipases rather than as phospholipases. Briefly, enzymes bearing a large and unique N-terminal region act mainly on phospholipids (phospholipase-type), whereas those lacking the N-terminal domain act on neutral lipids such as triglyceride (lipase-type) (Fig. 2). Herein, the two representative phospholipase-type of iPLA$_2$/PNPLA enzymes, iPLA$_2\beta$ and iPLA$_2\gamma$, are overviewed.

iPLA$_2\beta$ (PNPLA9) is a prototypic iPLA$_2$ enzyme that is ubiquitously expressed in various cells and occurs as several splice variants. iPLA$_2\beta$ shows no strict specificity with respect to *sn*-2 fatty acid and head group of the substrate phospholipids, is fully active in the absence of Ca^{2+}, and also exhibits *sn*-1 lysophospholipase activity and transacylase activity. Like other PNPLA enzymes, iPLA$_2\beta$ has a conserved nucleotide-binding motif proximal to the catalytic site. The N-terminal domain of iPLA$_2\beta$ has eight to nine ankyrin repeats, which contribute to a tetramer formation and give a negative effect on the enzymatic catalysis. Because of its Ca^{2+}-independent property, iPLA$_2\beta$ has long been thought to be involved in homeostatic phospholipid remodeling through deacylation of phospholipids in the land's cycle. However, accumulating evidence suggests that iPLA$_2\beta$ plays fundamental roles in cellular signaling leading to cell activation, proliferation, migration, or apoptosis. Genetic screening of *Drosophila* points Orai1 and STIM1 (components of store-operated Ca^{2+} entry (SOCE) channels) as well as an ortholog of iPLA$_2\beta$



Phospholipase A_2, Fig. 2 *The iPLA$_2$/PNPLA family*. The structures and alternative names of PNPLA1 ~ 9 are illustrated. This family is subdivided into two classes; enzymes acting on phospholipids (PLA type) and on neutral lipids (lipase type). The catalytic center (S) is located in a conserved catalytic domain that shows hology with patatin/iPLA$_2$α from potato. Adjacent to the catalytic center, there is a conserved nucleotide-binding motif. The PLA-type enzymes typically possess a long N-terminal domain, which may be involved in protein-protein interaction, distinct translation, and membrane spanning. The lipase-type enzymes lack the N-terminal domains and are thought to act primarily on triglycerides in lipid droplets. In humans, gene mutations of iPLA$_2$β or iPLA$_2$δ (NTE/PNPLA6) are linked with neurodegeneration, iPLA$_2$ζ (ATGL/PNPLA2) with neutral lipid storage disease, and iPLA$_2$ε (adiponutrin/PNPLA3) with hepatic steatosis

(CG6718) as gene products giving a great impact on SOCE (Vig et al. 2006). iPLA$_2$β has a binding site for calmodulin near the C-terminus, and the association with calmodulin leads to inactivation of iPLA$_2$β. Activation of SOCE channels and capacitative Ca^{2+} influx, which are triggered by depletion of intracellular Ca^{2+} stores, displaces inhibitory calmodulin from iPLA$_2$β, resulting in activation of iPLA$_2$β and generation of lysophospholipids that ultimately activate capacitative Ca^{2+} influx (Bolotina 2008). Given this theory, the SOCE-mediated activation of iPLA$_2$β lies upstream of Ca^{2+}-dependent activation of cPLA$_2$α. In apoptotic cells, iPLA$_2$β is cleaved at one or multiple sites by caspase-3, an event that activates iPLA$_2$β. Inhibition of iPLA$_2$β suppresses phosphatidylserine externalization at an early phase of apoptosis, suggesting that the caspase-truncated form of iPLA$_2$β accelerates apoptotic membranous changes. Strikingly, lysophosphatidylcholine (LPC) produced by the caspase-3-cleaved iPLA$_2$β is released from apoptotic cells and acts as an attracting ("find-me") signal for phagocytes (Lauber et al. 2003). Thus, during the process of inflammation, in which extravasation of neutrophils to the site of inflammation precedes a second wave of emigrating monocytes, the emigrated neutrophils undergo apoptosis leading to iPLA$_2$β-promoted generation of LPC, which in turn attracts monocytes.

Analyses of iPLA$_2$β-deficient and -transgenic mice have revealed broad roles of this enzyme in stimulus-induced *arachidonic acid* release, sperm motility,

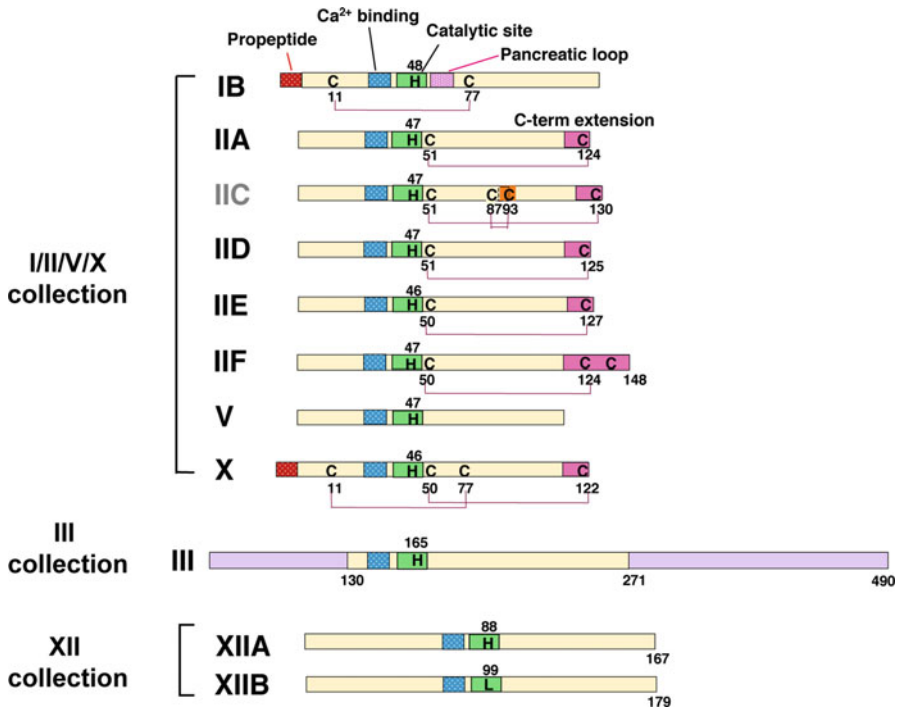
vascular contractility and relaxation, apoptosis induced by endoplasmic reticulum stress, antiviral response, age-related bone loss, glucose-stimulated insulin secretion by pancreatic β-cells, tumorigenesis, and neurodegeneration, among others (Bao et al. 2006; Shinzawa et al. 2008). Because of impaired islet secretory reserve, a high-fat diet induces severe glucose intolerance in $iPLA_2\beta$-null mice, whereas the glucose tolerance is improved in β-cell-specific $iPLA_2\beta$-transgenic mice (Bao et al. 2006). Tumorigenesis and ascites formation are ameliorated in $iPLA_2\beta$-null mice, and the $iPLA_2\beta$ gene haplotypes in humans are strongly associated with a higher risk of colorectal cancer (Hoeft et al. 2010). A locus for the neuroaxonal dystrophies such as infantile neuroaxonal dystrophy (INAD), neurodegeneration with brain iron accumulation (NBIA), and parkinsonism, which harbor the distinctive pathologic feature of axonal degeneration with distended axons (spheroid bodies) throughout the central nervous system, is mapped to the human $iPLA_2\beta$ gene (Morgan et al. 2006). Likewise, mice with $iPLA_2\beta$ deficiency or point mutation display severe motor dysfunction due to widespread degeneration of axons and synapses, accompanied by formation of numerous spheroids and vacuoles (Shinzawa et al. 2008).

$iPLA_2\gamma$ (PNPLA8) has four potential translation initiation sites, which produce distinct sizes of the protein. $iPLA_2\gamma$ catalyzes the cleavage of fatty acids from the *sn*-1 or *sn*-2 position of phospholipids depending upon the substrates. Remarkably, $iPLA_2\gamma$ has a mitochondrial and a peroxisomal localization signal in the N- and C-terminal regions, respectively, and are preferentially distributed in these organelles. Mice null for $iPLA_2\gamma$ display multiple bioenergetic dysfunctional phenotypes, including growth retardation, cold intolerance, reduced exercise endurance, increased mortality from cardiac stress after transverse aortic constriction, skeletal muscle atrophy, abnormal mitochondrial function with a dramatic decrease in oxygen consumption, and hippocampal neurodegeneration with massive autophagy and cognitive dysfunction (Mancuso et al. 2009). $iPLA_2\gamma$-deficient mice are also resistant to diet-induced obesity, hyperlipidemia, and insulin intolerance (Song et al. 2010). Importantly, the reduction in tissue cardiolipin content, accompanied by an altered cardiolipin molecular composition, in $iPLA_2\gamma$-deficient mice indicates that this $iPLA_2$ isoform is involved in mitochondrial cardiolipin remodeling. The phenotypes of $iPLA_2\gamma$-deficient mice are reminiscent of Barth syndrome, an X-linked cardioskeletal myopathy accompanied by exercise intolerance and neutropenia, which is caused by mutations in the gene encoding tafazzin, a mitochondrial phospholipid-lysophospholipid transacylase.

Secreted PLA_2s ($sPLA_2$s)

The $sPLA_2$ family represents structurally related, disulfide-rich, low molecular weight, lipolytic enzymes with a His-Asp catalytic dyad. $sPLA_2$s occur in a wide variety of vertebrate and invertebrate animals, plants, bacteria, and viruses; in mammals, there are 11 $sPLA_2$ isozymes (IB, IIA, IIC, IID, IIE, IIF, III, V, X, XIIA, and XIIB) (Fig. 3). Of these, $sPLA_2$s belonging to the group I/II/V/X collection are closely related, 14–19-kDa secreted enzymes with a highly conserved Ca^{2+}-binding loop (XCGXGG) and a catalytic site (DXCCXXHD). In addition to these elements, there are six absolutely conserved disulfide bonds and up to two additional unique disulfide bonds, which contribute to the high degree of stability of these enzymes. Group III and group XII $sPLA_2$s share homology with the I/II/V/X collection of $sPLA_2$s only in the Ca^{2+}-binding loop and catalytic site, thereby representing the group III and XII collections, respectively. $sPLA_2$s hydrolyze the ester bond at the *sn*-2 position of glycerophospholipids in the presence of millimolar concentrations of Ca^{2+} without showing strict fatty acid selectivity. Since individual $sPLA_2$s display distinct cellular/tissue distributions and substrate head group specificities, they may play nonredundant, isoform-specific roles in vivo. The latest biochemistry and biology of the $sPLA_2$ family have been detailed in recent reviews (Murakami et al. 2010; Lambeau and Gelb 2008).

Group IB $sPLA_2$ has a unique five amino acid extension termed the pancreatic loop in the middle part of the molecule and a group I-specific disulfide between Cys^{11} and Cys^{77}. It is synthesized in the pancreatic acinar cells, and after secretion into the pancreatic juice, an N-terminal heptapeptide of the inactive zymogen is cleaved by trypsin to yield an active enzyme in the duodenum. The main role of this pancreatic $sPLA_2$ is digestion of dietary and biliary phospholipids. Perturbation of this process by gene disruption or pharmacological inhibition of group IB



Phospholipase A_2, Fig. 3 *The sPLA$_2$ family*. Mammalian sPLA$_2$s contain 11 isoforms, which are subdivided into three collections, namely, group I/II/V/X (classical sPLA$_2$s), group III, and group XII. All enzymes have a conserved catalytic center with a His-Asp dyad and a Ca^{2+}-binding loop. sPLA$_2$-IB, a pancreatic sPLA$_2$, is characterized by an N-terminal propeptide whose proteolytic removal gives rise to a functional enzyme, the presence of a Cys11-Cys77 disulfide bond (group I-specific disulfide), and a unique pancreatic loop. The group II subfamily (IIA, IIC, IID, IIE, and IIF) is characterized by the absence of the propeptide and the presence of Cys49-Cys within the C-terminal extension (group II-specific disulfide). sPLA$_2$-IIC is absent in humans (pseudogene). sPLA$_2$-IIF has a longer C-terminal extension, which is Pro-rich. sPLA$_2$-V is evolutionally close to the group II subfamily, but is devoid of the group II-specific disulfide. sPLA$_2$-X possesses an N-terminal propeptide and both group I- and II-specific disulfides, thus having both group I and II properties. sPLA$_2$-III is unique in that the central sPLA$_2$ domain, which is more similar to bee venom PLA$_2$ than to group I/II/V/X sPLA$_2$s, is flanked by unique and highly cationic N- and C-terminal domains. The group XII collection contains two isoforms, XIIA and XIIB, whose overall structures (except for the catalytic domain and Ca^{2+}-binding site) do not show any homology with other sPLA$_2$s. The catalytic center His is replaced by Leu in sPLA$_2$-XIIB, indicating that this enzyme is catalytically inactive

sPLA$_2$ leads to protection from diet-induced obesity and insulin resistance due to decreased lipid digestion and absorption in the gut.

Group IIA sPLA$_2$ has a group II-specific disulfide linking Cys^{50} to the C-terminal Cys and a C-terminal extension of seven amino acids in length. The levels of group IIA sPLA$_2$ in sera or exudative fluids are well correlated with the severity of inflammatory disease: this is the reason why this isozyme is often called inflammatory sPLA$_2$. When overexpressed, group IIA sPLA$_2$ is capable of augmenting *arachidonic acid* release in cytokine-stimulated cells. Despite these facts, the contribution of group IIA sPLA$_2$ to inflammation has remained a subject to debate until recently, since a natural mutation of its gene in C57BL/6 and 129 Sv mice prevents the proper assessment of its functions by a classical gene targeting strategy. A recent study using group IIA sPLA$_2$-deficient BALB/c mice as well as its transgenic mice have provided evidence that the enzyme does play an exacerbating role in inflammatory arthritis. The best-recognized physiologic function of group IIA sPLA$_2$ is the degradation of bacterial membranes, thereby providing the first line of antimicrobial defense of the host. The serum level of group IIA sPLA$_2$ also shows good correlation with the risk of cardiovascular diseases, and group IIA sPLA$_2$-transgenic mice develop atherosclerosis when fed an atherogenic diet. This effect is most likely because sPLA$_2$-mediated hydrolysis of low-density lipoprotein (LDL) phospholipids

leads to generation of small-dense, pro-atherogenic LDL particles that facilitate macrophage foam cell formation.

Group IIC $sPLA_2$ has an additional disulfide bond between Cys^{87} and Cys^{93} in an extended loop region and is expressed in rodent testis. In the human genome, the absence of a portion of one exon indicates that it is a pseudogene and not expressed as a functional protein. Group IID $sPLA_2$ is structurally most similar to group IIA $sPLA_2$, and its transcript is constitutively detected in the lymphoid organs. Group IIE $sPLA_2$, which is another group IIA-related enzyme that is expressed constitutively in several tissues at low levels, has much lower catalytic activity than other group II $sPLA_2$s at least under the standard PLA_2 assay conditions. Group IIF $sPLA_2$ possesses a unique 30-amino acid C-terminal extension that contains an additional cysteine residue, which might contribute to the formation of a homodimer or a heterodimer with a second protein. Group IIF $sPLA_2$ is expressed most abundantly in the skin and seems to play a role in the regulation of skin permeability barrier.

Group V $sPLA_2$ does not possess the group I- and group II-specific disulfides and the group II-specific C-terminal extension. This enzyme potently releases *arachidonic acid* and LPC from cultured cells when overexpressed or added exogenously. Gene ablation of group V $sPLA_2$ in mice results in partial reduction of *eicosanoid* production in zymosan-stimulated macrophages. Group V $sPLA_2$-null mice are protected from fungal infection, since macrophages in the null mice show reduced phagocytosis of fungal particules. Contrary to mice lacking group IIA $sPLA_2$ (see above), those lacking group V $sPLA_2$ are more sensitive to inflammatory arthritis, likely because macrophage phagocytosis of the immune complex, a process that depends on cysteinyl leukotrienes, is hampered in the arthritic joints. The action of group V $sPLA_2$ on LDL phospholipids is rather strong, and LDL receptor-deficient mice transplanted with group V $sPLA_2$-null bone marrow cells are protected from atherosclerosis development. A recent tagging single nucleotide polymorphism analysis has revealed an association of the human group V $sPLA_2$ gene haplotype with LDL levels in patients with type 2 diabetes. Group V $sPLA_2$ is expressed in bronchial epithelium and alveolar macrophages, and its gene ablation in mice leads to protection from airway disorders such as asthma and respiratory distress syndrome. Pulmonary surfactant, a lipid-protein complex that lowers surface tension along the alveolar epithelium and thereby promotes alveolar stability, is one of the best targets of group V $sPLA_2$. Accordingly, transgenic overexpression of this enzyme in mice causes aberrant hydrolysis of surfactant PC, leading to neonatal death.

Group X $sPLA_2$ has both the group I- and II-specific disulfides, the group II-specific C-terminal extension, and the group I-specific propeptide. Like group IB $sPLA_2$, group X $sPLA_2$ is synthesized as a zymogen, and removal of the N-terminal propeptide produces an active mature enzyme. Among mammalian $sPLA_2$s, group X $sPLA_2$ shows the highest binding affinity for PC and thus exhibits the most potent activity to release *arachidonic acid* and LPC from the plasma membrane of target cells. Group X $sPLA_2$ is constitutively expressed in the digestive, respiratory, and genital organs, and is also expressed at trace levels in hematopoietic cells such as neutrophils and eosinophils. Group X $sPLA_2$-null mice are refractory to antigen-induced asthma, with markedly reduced eosinophil and lymphocyte infiltration and reduced cytokine and eicosanoid levels. The null mice are also protected from neutrophil-induced myocardial damage following ischemia-reperfusion. Group X $sPLA_2$ is abundantly stored in acrosomes in the sperm head, and its absence hampers acrosome reaction and fertility of spermatozoa in mice. Although group X $sPLA_2$ is potently active on LDL phospholipids in vitro, its role in atherosclerosis in vivo still remains obscure.

Group III $sPLA_2$ is an unusually large protein (55 kDa) among the $sPLA_2$ family and consists of three domains, in which the central $sPLA_2$ domain that displays all of the features of bee venom $sPLA_2$s, including ten cysteines and the key residues of the Ca^{2+} loop and catalytic site, is flanked by large and unique N- and C-terminal regions. The enzyme is processed to the $sPLA_2$ domain-only form that retains full enzymatic activity in vivo. Transgenic overexpression of group III $sPLA_2$ in mice results in increased atherosclerosis due to accelerated LDL hydrolysis and in increased inflammation due to elevated *eicosanoid* formation. A recent knockout study has revealed an unexplored role of this atypical $sPLA_2$ in epididymal sperm maturation through regulating sperm membrane remodeling.

Group XIIA $sPLA_2$ is a 19-kDa enzyme containing the central catalytic domain with a His-Asp catalytic dyad, yet the locations of cysteines outside the

catalytic domain are far distinct from those of other $sPLA_2$s. Furthermore, in the consensus segment of the Ca^{2+}-binding loop ($X_1CG_1X_2G_2$), the G_2 (glycine) is replaced by proline in group XIIA $sPLA_2$. High expression of this enzyme is found in many tissues, yet its enzymatic activity is very weak compared with others. A study using *Xenopus* suggests the role of this enzyme in early neuronal development. In the ectoderm, gain-of-function of $sPLA_2$-XIIA in embryos leads to ectopic neurogenesis and to the specification of ectopic olfactory sensory structures including olfactory bulb and sensory epithelia. These data identify group XIIA $sPLA_2$ as the factor sufficient to induce anterior sensory neural structures during vertebrate development. However, the roles of $sPLA_2$-XIIA and its catalytically inactive homolog group XIIB $sPLA_2$, in which the catalytic center His is replaced with Leu, in mammals are entirely unknown.

Summary

The understanding of the biological functions of all PLA_2s is now a challenging area of research and will be clarified hopefully in the next decade. The control of particular PLA_2 activities should have advantages over the inhibition of selective lipid mediator pathways and of some other biological events in the treatment of pathological states. Since more than one PLA_2 are likely to be involved in the pathology of various diseases in either a positive or negative way, the understanding of the expression, function, and regulation of each PLA_2 in specific tissues and disease states would be of particular importance. In certain situations, it would be favorable to control the activity of a particular PLA_2 subtype for the treatment of particular disorders. This is indeed true, if we see a particular case where groups IIA and V $sPLA_2$s play opposite (offensive and defensive) roles in inflammatory arthritis. This is probably the main reason why the current application of pan-$sPLA_2$ inhibitors, which broadly inhibits $sPLA_2$s in the group I/II/V/X branch, to rheumatoid arthritis was unsuccessful. Nevertheless, the pan-$sPLA_2$ inhibitor A-002 (valespladib) can decrease the atherosclerotic lesion area by approximately 75% in high-fat diet-fed $apoE^{-/-}$ mice (Rosenson et al. 2009). A-002 is more efficacious when combined with pravastatin. Furthermore, a phase II double-blind, randomized, placebo-controlled trial to assess the effects of A-002 in human patients with stable coronary heart disease demonstrates that the serum concentration of group IIA $sPLA_2$ as well as the levels of vascular (oxidized LDL) and general (C-reactive protein) inflammation markers is progressively decreased to nearly an order of magnitude less than baseline, with no excess of adverse events. A-002 also reduces LDL cholesterol concentrations and particle numbers, mainly by reducing small-dense LDL. These animal and early phase clinical studies highlight that $sPLA_2$s are potential therapeutic targets for atherosclerosis. Likewise, efipladib, an indole inhibitor of $cPLA_2\alpha$ that displays oral efficacy in rat inflammation models, is currently undergoing clinical trials for treatment of inflammatory diseases.

Synonyms

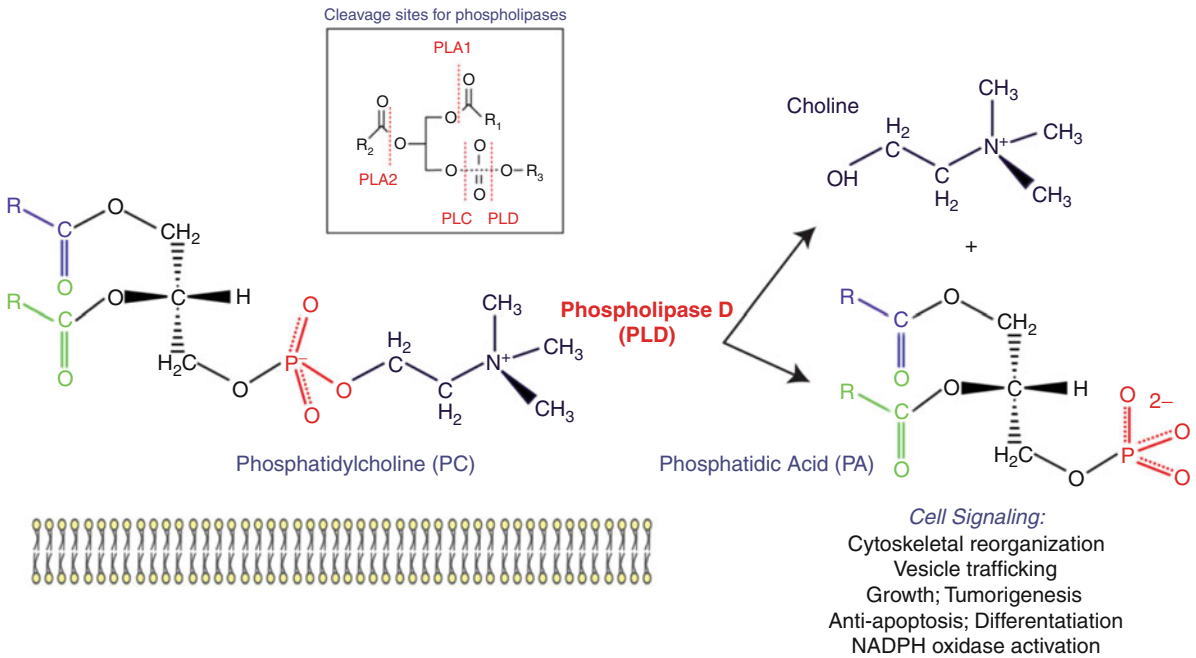
Phospholipase D1; Phospholipase D2; PLD1; PLD2

Historical Background

PLD was first characterized in vegetables by Hanahan and Chaikoff (1947) and changes in its lipase activity have been reported in relation to lipid metabolism in seed germination and lipid turnover and lipid composition during plant development and in membrane deterioration as a result of stress injuries. PLD was first cloned from cabbage (*Brassica oleracea)*, castor bean (*Ricinus communis* L.), rice (*Oryza sativa* L.), corn (*Zea mays* L.), and rockcress (*Arabidopsis*), which code for an 808-amino acid cytosolic protein of ~90 kDa MW, as mentioned in the review by (Cockcroft 1996). Plant PLD is linked to membrane deterioration during plant senescence as a result of decreased membrane phospholipid content. Additionally, PLD is present in large quantities in bacteria (*Streptomyces*), yeast (*Saccharomyces cerevisiae*), and mammalian cells.

Within mammalian sources, PLD has been found in a variety of cell types including neutrophils, promyelocytic leukemia, hepatocytes, platelets, endothelial cells, and spermatozoa, and is predominant in three organs, placenta, brain, and lung. A majority of the primary literature on PLD or PLD activity has been centered on in vivo and in vitro studies referring to changes in cellular distribution, intrinsic molecular alterations, association with other proteins or regulators, and availability of substrate as pertaining to phospholipid turnover in cellular membranes or wherever the substrate might be localized in the cell. PLD is expressed in a wide variety of tissues and cell lines and its activity has been reported predominantly in the plasma membrane, as well as in cytoplasmic locations, the mitochondrial membrane, the Golgi endoplasmic reticulum (ER), the nucleus, the nuclear membrane, and subcellular compartments. Additionally, PLD is palmitoylated on conserved cysteine residues and contributes to localization to membranous environments (Foster and Xu 2003).

As PLD is a protein that breaks down phospholipids, its main mission is directly related to phospholipid turnover and maintenance of the structural integrity of cellular or intracellular membranes (Frohman et al. 1999). In a two-step process, the enzyme PLD first hydrolyzes ester or phosphodiester bonds of lipids in cell membranes such as phosphatidylcholine (PC) that yields two lipid second messengers, phosphatidic acid (PA) and lyso-phosphatidic



Phospholipase D, Fig. 1 The substrate and products generated by the enzymatic action of PLD. The lipase usually utilizes phosphatidylcholine that is hydrolyzed into choline and PA, which is a *bona fide* second messenger involved in many cellular functions (some of which are denoted within this figure). The *inset panel* depicts the cleavage sites of PLD and related other phospholipases in the glycerol backbone of the phospholipid substrate. Copyrighted from Gomez-Cambronero (2010). DOI:10.1100/tsw.2010.116. Reproduced with permission from The Scientific World/Corpus Alienum Oy

acid (lyso-PA), and free choline (the precursor to the common neurotransmitter acetylcholine) and results in the subsequent production of diacylglycerol (DAG) (Gomez-Cambronero 2010) (Fig. 1). PLD degrades the phospholipid substrate to form a phosphohistidine-PLD intermediate and the second step involves the transfer of the phosphatidyl moiety to either H_2O or a primary alcohol, as detailed in the review by Exton (2000). The conversion of PC to PA by PLD in general is dependent on the presence of the cofactor phosphatidylinositol 4,5-bisphosphate (PIP_2) (a lesser anionic lipid localized primarily to the plasma membrane) because (1) neomycin appropriates PIP_2, which inadvertently negatively regulated both GTPγS- and Arf-mediated PLD activity and (2) Mg.ATP increased GTPγS-dependent PLD activity (Cockcroft 1996). PIP_2 plays a role in both Arf-regulated PLD activity, as well as Rho-regulated PLD activity via potential docking of PLD to the plasma membrane (Hammond et al. 1997). As mentioned in the review by Exton (2000), the potential exists for PLD to be directly involved in vesicle trafficking to and through the Golgi via PA generation, which results in membrane budding. Additional evidence of PLD's diverse role in vesicle trafficking is evidenced by its involvement in GLUT4 glucose transporter translocation, EGF-R and FcγRI-R internalization, hepatic very low density lipoprotein assembly, and the release of nascent secretory vesicles from the trans-Golgi network, as described by Powner and Wakelam (2002). Additionally, when endogenous PLD substrates are utilized to measure PLD lipase activity, the fatty acids myristate or palmitate can be used, as well as lyso-PC or choline to label PC (Cockcroft 1996). When the lipase is studied in vitro, short-chain aliphatic alcohols are included in the assay media. PLD can also generate rare phospholipids in the form of phosphatidylalcohols (such as phosphatidylethanol (PEt) and phosphatidylbutanol (PBut)) in the presence of a primary alcohol, such as ethanol or butanol via the transphosphatidylation reaction, which is a unique characteristic marker of PLD and thus is the accepted index of distinguishing PLD activity from that of phospholipase C (PLC). Additionally, incubation of mast cells with a primary alcohol could suppress the antigen-stimulated activation of the lipase without

interfering with translocation of PLD1, which actually facilitated the translocation of PLD1 from vesicles to the plasma membrane (Powner et al. 2002; Powner and Wakelam 2002).

Development of potent isoform-specific small-molecule PLD inhibitors would be integral to the advancement of the PLD field. Until recently, many PLD inhibitors lacked isoform specificity and did not act directly on the lipase. Halopemide and its subsequent derivative 5-fluoro-2-indoyl des-chlorohalopemide (FIPI) have been found to be very effective inhibitors of PLD-mediated F-actin cytoskeleton reorganization, cell spreading, and chemotaxis (Su et al. 2009). Use of iterative analog library synthesis approaches coupled with biochemicals assays and mass spectrometric lipid profiling of cellular responses has given rise to the next generation halopemide derivatives, which have yielded the development of dual PLD1/2, PLD1 selective and PLD2 selective inhibitors (Lewis et al. 2009). Small molecules that either indirectly or directly inhibit PLD1 or PLD2 could represent novel approaches for the treatment of metastatic cancer and inflammatory diseases.

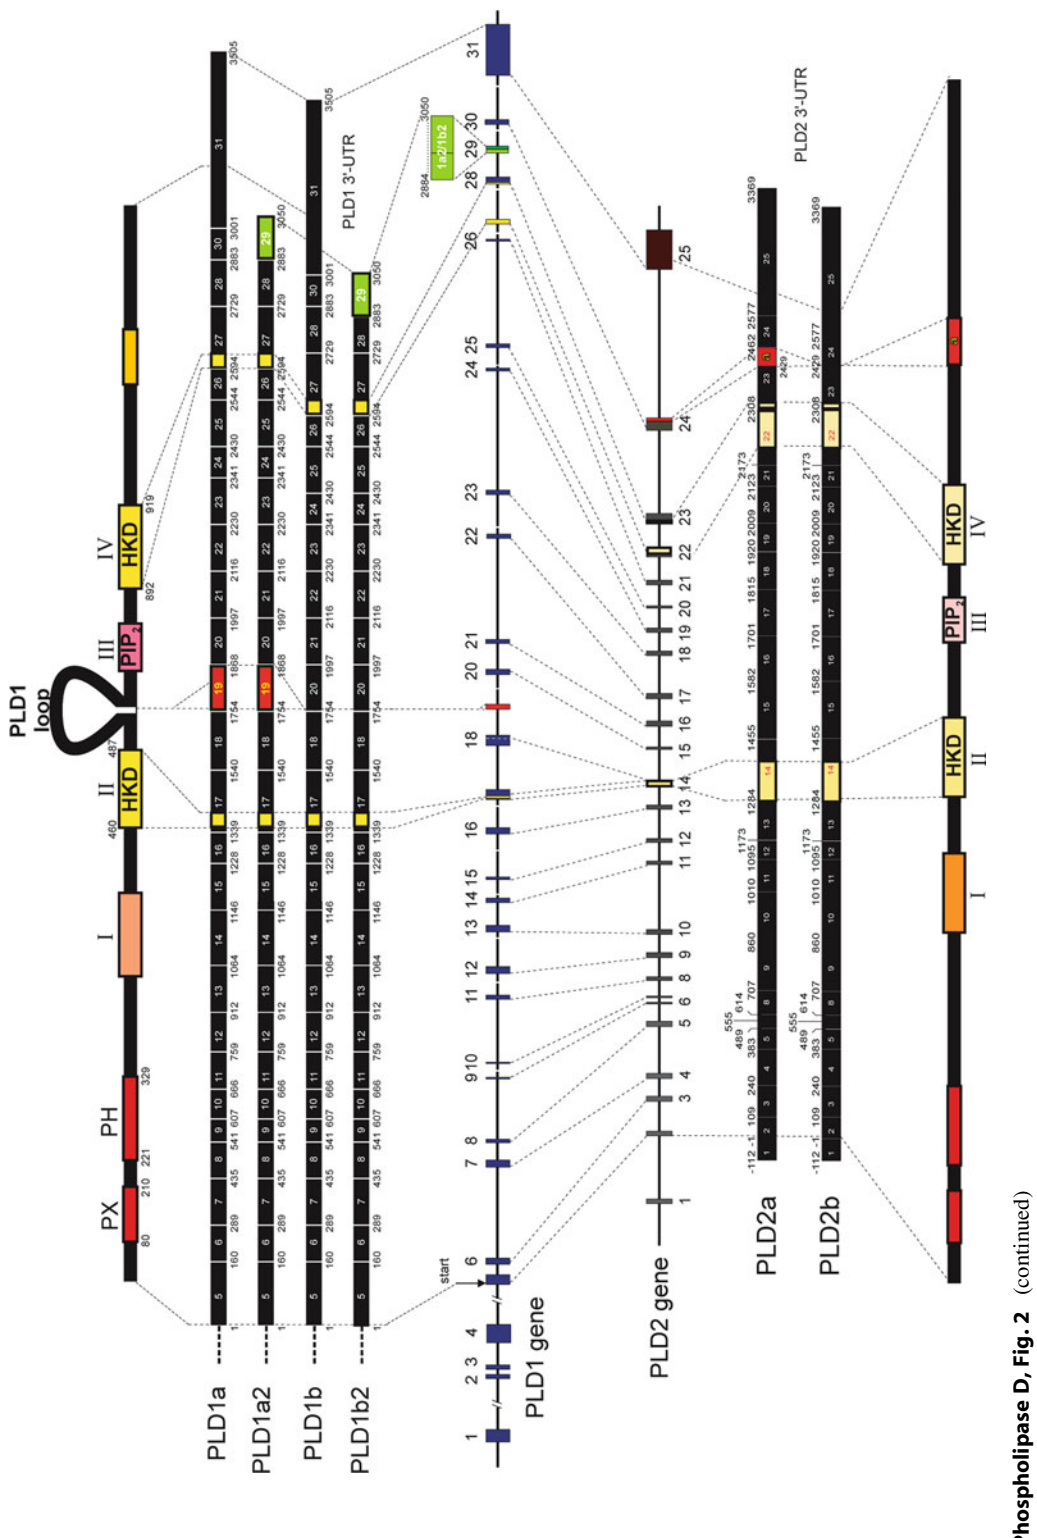
Characterization of PLD

In addition to cloned bacterial PC-specific PLDs from *Corynebacterium pseudotuberculosis*, yeast (SPO14gene), and plant (castor beans, etc.), there are currently two mammalian isoforms of the gene that have been cloned from human and murine sources, *PLD1* and *PLD2*, which yield the PLD1 and PLD2 proteins and four slightly shorter splice variants (Fig. 2). *PLD* genes undergo qualitative/quantitative changes in transcriptional upregulation during granulocytic differentiation of HL-60 cells.

The *PLD1* gene has been localized to the long arm (q) of chromosome 3 (3q26) (Park et al. 1998a), covers 210 kb of genomic DNA that is defined by 31 exons, whereby 27 exons result in the expression of four splice variants (PLD1a, PLD1a2, PLD1b, and PLD1b2) (Hammond et al. 1997; Katayama et al. 1998). PLD1a and PLD1a2 mRNAs express exon 19 (113 bp) and 29 (166 bp), respectively, while PLD1b and PLD1b2 do not express exon 19. PLD1a is the longest PLD1 splice variant at 1,072 amino acids in length and yields a 120 kDa MW protein. PLD1 is for the most part associated with perinuclear, Golgi and heavy membrane fractions, as reiterated in the review by Foster and Xu (2003). PLD1 is PC specific, Mg^{2+} dependent, and Ca^{2+} insensitive (Hammond et al. 1997), inhibited by oleate and has a basal level that is virtually undetectable. Human PLD1 is regulated by the cytosolic GTP binding protein Arf (Arf 1 and Arf3) and by small GTPases (Rac, Cdc42 and RhoA) via GTPγS, while it is also regulated by PKC (α and β isoforms) via Ca^{2+} and DAG/PMA (Cockcroft 1996; Hammond et al. 1997). Evidence of synergy between Arf, Rho, and PKC as related to regulation/activation of PLD1 activity has been reported first in human HL-60 leukemic cells and then in human neutrophils and rat brain, as reiterated by Cockcroft (1996). These facts implicate a widespread and ubiquitous nature to Arf-dependent PLD activity and specifically implicates only one PLD isoform in this process of lipase activation instead of activation by multiple other PLD forms.

The mammalian *PLD2* gene is found on the short arm (p) of chromosome 17 (17p13) (Park et al. 1998b), is defined by 25 known exons of a genomic region spanning 16.3 kb, and encodes for two splice variants (PLD2a and PLD2b) of 933 amino acids in length each (Steed et al. 1998), which yields functionally indistinguishable proteins of 106 kDa MW. PLD2 is for the most part localized on the plasma membrane in light membrane lipid rafts that also associate with caveolin, as restated in the subject review by Foster and Xu (2003). The first PLD2 gene exon (112 bp) encodes for the 5′-untranslated region, the initiation codon ($A^{1}TG$) is located on the second bp of exon 2, whereas the stop codon (TAG^{2803}) is located 568 bp downstream in exon 25. The PLD2b variant is the result of 33 bp being alternatively spliced from exon 23 of the originally described PLD2a. PLD2 requires PIP_2 and is largely insensitive to PKCα, Arf, or Rho (unlike PLD1 which is dependent upon these three cofactors).

Although the DNA sequences of both PLD1 and PLD2 share about 50% homology, all members of the PLD superfamily possess two highly conserved phosphatidyltransferase HKD catalytic domains (HKD1 and HKD2) that are defined by the consensus peptide sequence $HxK(x)4D(x)_6GSxN$, which are vital to the lipase activity, as well as the phox homology (PX) and pleckstrin homology (PH) domains and the phosphatidylinositol 4,5-bisphosphate [PIP_2] binding site (Frohman et al. 1999). As stated in the review by Exton (2000), PLD HKD motifs are requisite for



Phospholipase D, Fig. 2 (continued)

catalytic activity and possibly dimerize to form an active center and are also present in biologically diverse proteins represented by bacterial phospholipid synthases and endonucleases, a pox envelope protein and a Yersinia toxin. Lysine to arginine point mutations of the HKD2 domain of PLD1 at K^{860} or of either the HKD1 or HKD2 domains of PLD2 at K^{444} or K^{758}, respectively, result in lipase-dead enzymes because these K→R mutations yield lipases catalytically incapable of synthesizing PA or PBut as the readout for PLD activity. It has been theorized that the histidine in one of the HKD domains of PLD acts as a nucleophile to degrade the phosphodiester bond and the histidine in the other HKD domain protonates the oxygen of the leaving group, as reiterated by Exton (2000). The PX domain has been heavily implicated in binding to certain regulatory factors (PIP) and proteins (growth factor receptor-bound protein 2 (Grb2) and epidermal growth factor receptor (EGF-R)), while the PH domains of PLD1 and PLD2 have been demonstrated to function as strong modulators of the membrane recycling machinery that results in regulated growth factor receptor endocytosis and also linked to binding to SH2/SH3-containing tyrosine kinases. Deletion of either the PX or the PH domains results in a gross relocalization of PLD from the plasma membrane back to endosomes and in vivo renders the lipase unable to be activated, which ultimately negatively affects the catalytic activity of these isoenzymes.

PLD has been associated with a variety of physiological cellular functions, such as cancer cell progression, intracellular protein trafficking, cytoskeletal dynamics, membrane remodeling and cell proliferation in mammalian cells and meiotic division and sporulation in yeast. PLD regulation in mammalian cells falls into two major signaling categories: growth factors/mitogens that implicate tyrosine kinases (Frohman et al. 1999; Min et al. 1998) and small GTPases (Cockcroft 1996; Hammond et al. 1997; Powner and Wakelam 2002).

Role of Tyrosine Kinases and Phosphatases in PLD Signaling

Although PLD2 can be phosphorylated by the serine/threonine kinase AKT at residue T^{175} which serves to upregulate DNA synthesis, more typically PLD is known as a substrate for many receptor (EGF-R and PDGF-R) and non-receptor tyrosine kinases (Src and JAK3). Reagents like hydrogen peroxide when in the presence of vanadate can activate PLD in many different cells via tyrosine phosphorylation (Exton 2000; Min et al. 1998). Use of phorbol esters (PMA or TPA) or the PKC inhibitor Ro31-8220 to deplete PKC in the cell resulted in a significant loss of PLD activation (Cockcroft 1996). Additionally, evidence of considerable synergy between GTPγS and tyrosine kinase–based mechanisms has been reported using permeabilized cells as mentioned in the review by Cockcroft (1996). The PLD1 isoform is phosphorylated on tyrosine residues, which does not lead to changes in lipase activity (Min et al. 1998). The PLD2 isoform is expressed as a constitutively active enzyme in many different cell types that is detected as a phosphotyrosine protein in vivo and in vitro. These two scenarios heavily implicate a role for phosphorylation/dephosphorylation of PLD by protein tyrosine kinases and phosphatases in the control of PLD activity in response to such signaling mechanisms as osmotic

Phospholipase D, Fig. 2 A genomic and protein map of PLD isoforms. Schematic drawings of the PLD1 (*upper half* of the figure) and PLD2 (*lower half* of the figure) cDNA homologies as related to the specific genomic organization of each PLD gene. Data used to generate the figure were deduced from analysis of the human genome (www.ncbi.nlm.nih.gov). The specific PLD1- or PLD2-spliced exons are depicted in *red* boxes. Exon numerals are indicated beneath the exon boxes (*blue* for PLD1 and *gray* for PLD2 genes); nucleotide positions are in *black* and on *top* of each cDNA representation. Human *PLD1* and *PLD2* genes share ~50% identity and are located on the long arm of chromosome 3 (reverse stand locus 3q26) and on the short arm of chromosome 17 (locus 1p13.1), respectively. The human *PLD1* gene spans ~20.8 kb genomic DNA and is defined by 31 exons, which directs the expression of at least four alternatively spliced variants: PLD1a, PLD1b, PLD1a2, and PLD1b2. PLD1b and the evolutionarily conserved splice variant of PLD1a arise from splicing of a 38-amino acid, codified by the alternate exon 19 (*yellow box*), whereas PLD1a2 is the result of exon 29 splicing (*green box*). In the case of PLD2, ~16.3 kb genomic DNA, located in 25 exons, defines the gene. The *PLD2* gene is responsible for the generation of at least two alternatively spliced transcripts: PLD2a and PLD2b. PX, phox consensus sequence; PH, pleckstrin homology; HKD, HxxxxKxD; PIP2, phosphatidylinositol phosphate; 3′UTR, 3′-untranslated region. Copyrighted from Gomez-Cambronero et al. (2007). Phospholipase D, Fig. 3 Schematic representation highlighting the biological significance of phosphorylation/dephosphorylation of PLD2. (**a**) Effect of kinases on PLD2. EGF-R, JAK3, and Src are capable of phosphorylating PLD2 in vitro, and the targets are Y^{296} for EGF-R, Y^{415} for JAK3, and Y^{511} for Src. EGF-R, JAK3, and Src phosphorylate an "inhibitory site," an "activator site," and an "ambivalent site" (one that can yield either effect), respectively. The degree that each site is activated or inhibited depends on the cell type considered. In COS-7 cells, which possess the highest level of PLD2 activity, the Y^{415} is a prominent site that, when phosphorylated by JAK3, compensates for the negative effect by EGF-R on Y^{296}. In MCF-7 cells, which possess the lowest level of PLD2 activity, the opposite is valid, the Y^{296} cannot compensate for the positive effect by Y^{415}. MTLn3 cells, which possess medium or low levels of lipase activity, exhibit an intermediate level of regulation, which is closer to that of MCF-7 cells than to that of COS-7 cells. (**b**) Effect of phosphatases on PLD2. Low concentrations of phosphatases or phosphatases targeting Y^{511} or Y^{296} are positively regulated by the "activator" sites and result in high levels of lipase activity. On the other hand, higher concentrations of phosphatases or phosphatases that specifically target Y^{415} (the activator site) result in the loss of lipase activity to varying extents based on to what degree the cell relies on activator or inhibitory sites. It is proposed that Y^{296}, an inhibitory site in MCF-7 cells, is the reason for the observed low lipase activity in this breast cancer cell line and further emphasizes the importance of this site during PLD2 regulation. stress, de novo DNA synthesis, cell proliferation, differentiation, transformation, and degranulation of mast cells.

Choi et al. (2004) have found that PLD2 is specifically phosphorylated on residues Y^{11}, Y^{14}, Y^{165}, and Y^{470}. Mutation of Y^{470} resulted in a 50% decrease in PLD2 activation and suggests some partial loss of catalytic activity. Additionally, mutation of only Y^{14} and not the other three tyrosine residues yielded mislocalization of PLD2 when using immunofluorescence microscopy. Recently, phosphorylation targets within the PLD2 molecule have been mapped that are vital to its regulation as a lipase and thus correlated in vitro to at least three different tyrosine kinases: EGF-R, Src, and Janus Kinase 3 (JAK3) (Gomez-Cambronero 2010). Using LC-MS analyses to prove the presence of phospho-PLD2-peptides, the specific PLD2 tyrosine residues phosphorylated by these kinases are Y^{296}, Y^{511}, and Y^{415}, respectively, that yield either positive or negative effects on the lipase (Fig. 3a). PLD2 but not PLD1 physically complexes with and interacts with the intracellular part of the EGF-R in a ligand-independent manner following receptor activation. Elevation of either PLD1 or PLD2 has the potential to transform rat fibroblasts and contribute to cancer progression of the malignant phenotype in cells that also have elevated levels of EGF-R or Src tyrosine kinases (Foster and Xu 2003). The potential exists for stimulation of PLD activity to directly contribute to cell proliferation, which further compounds the formation of a fully malignant phenotype (Foster and Xu 2003). Contrarily, it has been hypothesized that PLD2 activity in certain breast cancer cell lines is low compared to non-cancerous cells or other breast cancer cell lines because it is downregulated by tyrosyl phosphorylation at Y^{296} via

EGF-R (Gomez-Cambronero 2010), which can also be correlated to a negative impact on the relative levels of cell invasiveness of these breast cancer cells (Foster and Xu 2003). This low level of PLD activity can be increased by in vitro treatment with either JAK3 or Src. Src participates in the activation of PLD through the Ras pathway and the kinases Fyn and Fgr but not Lyn (Choi et al. 2004). Phosphorylation of PLD2-Y296F at residues Y^{415} or Y^{511} positively affected PLD2 lipase activity in certain breast cancer cell lines, which suggests that when Y^{296} can no longer be utilized by EGF-R, other kinases (possibly JAK3 or Src) are able to use PLD2 more efficiently as a phosphorylation substrate and ultimately yields greater PLD activity.

Phosphorylation/dephosphorylation of PLD2 at certain tyrosine residues dictates whether or not PLD2 is activated or suppressed by certain signaling molecules at other subsequent tyrosine residues. This dichotomy is achieved in part through a complex process of phosphorylation by tyrosine kinases and dephosphorylation by phosphatases, such as CD45 and protein tyrosine phosphatase 1b (PTP1b) (Fig. 3b). PTP1b is already known to dephosphorylate EGF-R substrates and regulate the kinase in vivo. Experiments with phosphatases indicate that both activator and inhibitory sites exist on the PLD2 molecule (Gomez-Cambronero 2010). Low concentrations of phosphatases or phosphatases that target inhibitory or ambivalent sites specifically result in positive regulation of PLD2 and high lipase activity. Contrarily, high concentrations of phosphatases or phosphatases that specifically target activator sites result in loss of lipase activity based on the degree of cellular dependence on activator or inhibitory sites.

Additionally, phosphorylated PLD2 forms a ternary complex with both PTP1b and Grb2 (Gomez-Cambronero 2010), a critical signal transducer of EGF-R, via two SH2 recognition sites (Y^{169} and Y^{179}) expressed within the context of the consensus YXNX in the PX domain of PLD2, which occurs independent of the lipase activity. A recent report indicates that increased cell transformation in PLD2-overexpressing cells occurs as a result of increased de novo DNA synthesis induced by PLD2 with the specific tyrosine residues involved in these functions being Y^{179} and Y^{511} (Gomez-Cambronero 2010). PLD2 residue Y^{169} modulates lipase activity, while PLD2 residue Y^{179} regulates total tyrosine phosphorylation of PLD2 (Gomez-Cambronero 2010). Complete simultaneous removal or phenylalanine replacement of these two sites on PLD2 completely abrogates or reduces binding to Grb2, respectively. Although the kinase that phosphorylates these two PLD2 residues is still unknown, interaction occurs through the C-terminal proline-rich domain of the Ras guanine-nucleotide exchange factor, Sos, and links PLD2 via residue Y^{169} to cellular proliferation and the MAPK and Ras/Erk pathways.

Role of Small GTPases in PLD Signaling

A role for PLD and its product PA has been presumed in the regulation of actin (Porcelli 2002) and leukoctye cell migration (Gomez-Cambronero 2010) because the formation of lamellipodia structures and membrane ruffles can be abolished if PLD is inhibited. It has also been surmised that Rho GTPase stimulation of PLD activity is key to actin stress fiber formation and the ultimate regulation of cell movement because PLD activity has already been shown to aid the formation of stress fibers, as restated by Foster and Xu (2003). These findings indicate a potential signaling feedback mechanism does in fact exist between the activation loop (Switch 1) of the Rho family of small GTPases (RhoA, RhoB, RhoC, Rac1, Rac2, Cdc42, and TC10) and PLD and potentially protein kinase C (PKC) (Cockcroft 1996). These GTPases must be in the active (GTP- or GTPγS-liganded) form to yield PLD stimulation/activation (Exton 2000). Preincubation of plasma membranes from liver cells with RhoGDI (a protein that extracts membrane-associated Rho) led to the removal of both RhoA and Cdc42 concomitant with a decrease in PLD activity, which was reversed in part with the addition of recombinant RhoA and Rac1 (Cockcroft 1996). Rho and Rac activate the synthesis of PIP_2 via the PI4-P5 kinase (PI4-P5K), and PIP_2 controls PLD activity in vivo and in vitro via mediation of nucleotide-binding interactions, such as GTPγS regulation and Mg.ATP. As reported in a mini review elsewhere (Powner et al. 2002), members of the Rho family of small GTPases physically bind to PLD1 between amino acid 984 and 1000. Therefore, taking into consideration these sets of facts, it is likely that Rac, PIP_2, and PLD are involved in the same signaling pathways and collectively regulate a variety of cellular functions.

In neutrophils, Rac1 plays an important role during gradient detections and actin assembly via PI-3K and AKT and has been reported to directly activate PLD1 (Powner and Wakelam 2002). Rho GTPases indirectly regulate PLD1 lipase activity via stimulation of PI(4,5)P_2 kinase, Rho kinase and intracellular translocation of PLD (Powner et al. 2002). RhoA, Rac1, Arf, and Cdc42 also directly interact with and stimulate PLD1 activity in the presence of GTPγS (Cockcroft 1996), because mutation of the Rho-binding site on PLD1 abrogates PLD1–Arf interaction (Du et al. 2000). PLD1 is a downstream target of the Ras/RalA small GTPase cascade that has been associated with mitogenic and oncogenic signaling (Foster and Xu 2003).

PLD2 can be activated in intact cells by agonists and possibly by PLD1 (Foster and Xu 2003) and can be regulated by small GTPases and certain PKC family members (Du et al. 2000). PLD2 and Rac2 physically interact and heterodimerize in vitro, and recently, the biphasic effect of a monomeric GTPase acting as a master switch has been shown to both promote and inhibit phospholipase activity as related to the timeline of chemotaxis (Peng et al. 2011). Macrophages that overexpressed both Rac2 and PLD2 experienced a strong initial response toward the chemoattractant that was significantly decreased at later time points. This initial positive response was attributed to the presence of a PLD2-Rac2 positive feedback loop, while the subsequent negative response of Rac2 on PLD2 was confirmed using cells from $Rac2^{-/-}$ mice that exhibited increased PLD2 enzymatic activity, which was reversed by PIP_2. It has been hypothesized that this Rac2-mediated inhibition of PLD2 function occurs because of Rac2 sterical interference with the PH domain membrane-binding site of PLD2 and ensuing PIP_2 deprivation. Rac2 localized in vivo to the leading edge of leukocyte pseudopodia with PLD2 being physically posterior to this wave of Rac2. Both PLD2 and PA signal to DOCK2, which mediates Rac activation and actin modeling (Nishikimi et al. 2009).

Role of PLD in Leukocyte Cell Adhesion and Migration

Leukocyte adhesion and migration are steps crucial to the antimicrobial and cytotoxic functions of leukocytes. PLD is expressed in monocytes, macrophages, basophils, eosinophils, dendritic cells, lymphocytes and NK cells and a variety of leukemic cells (U937, THP-1, HL-60, and PLD-985) and has been associated with tumor invasion, chemotaxis, adhesion, phagocytosis, degranulation, microbial killing, and leukocyte maturation. PLD is activated in human and murine myeloid-macrophage cell lines following adhesion to various extracellular matrix (ECM) proteins and plastic (Iyer et al. 2006). PLD concentrates at forming phagosomes, which occurs as a result of PA being concomitantly produced (Rossi et al. 1990) and demonstrates that PLD is in fact catalytically active during this process. PLD activation is an early event in neutrophil signal transduction following exposure of adherent cells to GM-CSF and is regulated by tyrosine phosphorylation, which can in turn be inhibited by tyrosine kinase inhibitors.

PLD1 activity is rapidly enhanced following cell adhesion, which serves to regulate the initial stages of neutrophil and macrophage adhesion. If PLD activity is inhibited, then a likewise inhibition in cell adhesion is evidenced. PLD activation plays a vital role in actin cytoskeleton formation, which stimulates the formation of actin stress fibers in cells, and use of lipase-dead mutants suggests this to be a PLD1-mediated process (Powner and Wakelam 2002). Immunofluorescence microscopy of human neutrophils has shown that both PLD isoforms were associated with cell polarity and directionality concomitant with adhesion and F-actin polymerization in response to IL-8 (Gomez-Cambronero 2010). It has been reported elsewhere (Powner and Wakelam 2002) that actin directly binds PLD2 with a concomitant decrease in lipase activity, which can be reversed by Arf1.

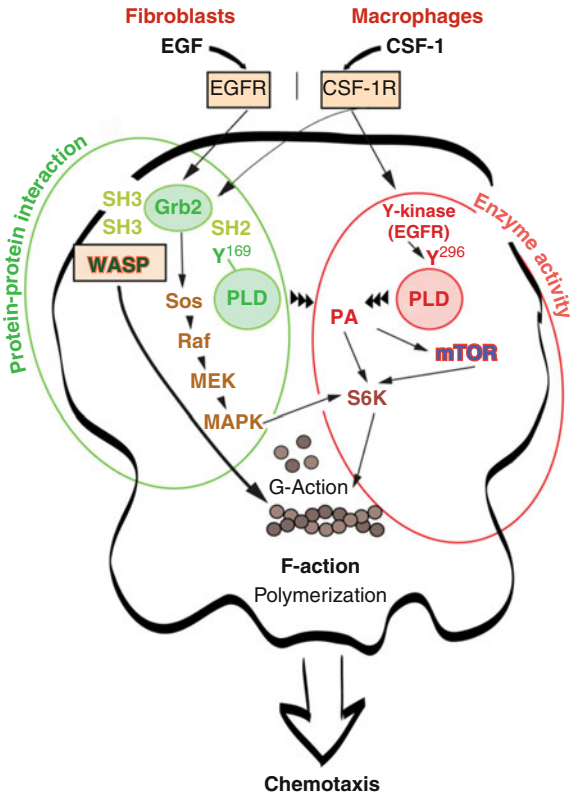
Chemokine receptors differentially regulate PLD, and while PLD1 has been implicated in other migration processes besides chemotaxis (rolling, adhesion, and diapedesis), PLD2 is more directly specialized for chemotactic processes (Gomez-Cambronero et al. 2007). PA is a second messenger in neutrophils that transduces signals to the cell interior upon agonist stimulation and results in development of polarized neutrophil morphology with focused distribution of F-actin, which is also partially dependent on basal PI3K activity and interaction with the C-terminal region of DOCK2 (Nishikimi et al. 2009). PLD-produced PA was able to sequester DOCK2 at the leading egde of migrating neutrophils from the cytocol via interaction with a DOCK2 polybasic amino acid cluster (Ser-Lys-Lys-Arg) that contributed to an

increase in actin polymerization, which was also dependent on an intact lipase activity (Nishikimi et al. 2009). PIP_3 was another cofactor manufactured during this process besides PA, which implicates both phospholipids in chemotactic translocation and stabilization.

Recently, PLD has been implicated as being needed to leukocyte, macrophage, and fibroblast movements. This was demonstrated through use of RNA interference–mediated depletion of PLD1 and PLD2, which resulted in impaired leukocyte adhesion and reduced chemokinesis and chemotaxis toward the chemokine gradient (Gomez-Cambronero 2010; Knapek et al. 2010). Overexpression of either active PLD1 or active PLD2 yielded cell migration capabilities that were elevated well beyond that of chemoattractant only negative controls. The mechanism for this enhancement in lipase activity is complex and involves two different pathways: one pathway is dependent on the lipase activity and signals directly through the product of this reaction, PA, and the other pathway involves protein–protein interactions.

First, PLD-mediated chemotaxis is mediated through extracellular PA, the pleiotropic lipid second messenger derived from PLD hydrolysis, which has been documented to act as a chemoattractant in human neutrophils and dHL-60 cells as membrane-soluble dioleoyl-PA (DOPA) elicited actin polymerization, cell spreading, pseudopodia formation, and chemotaxis (Frondorf et al. 2010). PLD's involvement is directly implicated in these cell migration processes (1) as PC on the outer leaflet of the plasma membrane can be cleaved by PLD action that is secreted by microorganisms following interaction with a phagocyte and (2) via intracellular PLD-derived PA generated by PLD2. It has previously been shown that extracellular PA stimulates PLD and results in the generation of intracellular PA and ultimately amplifies the original signal. Exogenous PA or PA generated in situ by bacterial PLD (*Streptomyces chromofuscus*) enters the cell and results in S6K accumulation in vesicle-like cytoplasmic structures (Frondorf et al. 2010).

Second, PLD-mediated chemotaxis is mediated through specific protein–protein interactions, such as Grb2, which serves as a docking or intermediary protein for PLD2 as detected using co-immunoprecipitation experiments and immunofluorescence microscopy where the PLD2-Grb2 protein complex localizes to actin-rich membrane ruffles during stimulation of murine macrophages via the Y^{169} residue of PLD2, which was dependent on the SH2 domain of Grb2 because use of the SH2-domain-deficient Grb2-R86K mutant impeded chemotaxis (Knapek et al. 2010). Additionally, PLD2/Grb2-mediated chemotaxis of LR5/RAW264.7 macrophages is dependent upon Grb2 interacting with other proteins, especially the ▶ Wiscott-Aldrich syndrome protein (WASP) (Fig. 4).



Phospholipase D, Fig. 4 Model of the role of PLD in the physiological process of chemotaxis. Based on our results and from others, it is proposed that PLD and Grb2 participate in cell chemotaxis, which involves three major pathways: (1) PA, the by-product of PLD2, binds to target proteins mTOR, S6K, or Sos. S6K then stimulates actin polymerization. Data in the present study indicate that Y^{169} is involved in lipase activity (PA production), leading to chemotaxis. (2) PLD can bind to either Grb2 or Sos, whereby residue Y^{179} is required for a PLD2-Grb2 protein–protein interaction that results in the downstream activation of MAPK. MAPK can crosstalk to S6K and provide positive feedback to enhance migration. S6K is heavily implicated in RAW/LR5 macrophage migration via the Y^{296} residue, which is phosphorylated by EGF-R kinase. (3) PLD and PA interact directly via interaction with actin or indirectly via interaction with WASP. Copyrighted from Knapek et al. (2010). DOI 10.1128/MCB.00229-10. Reproduced with permission from American Society for Microbiology

Simultaneous cell transfection of PLD2, Grb2, and WASP has the greatest effect on chemoattractant-mediated chemotaxis than any other limited variation of the three proteins combined.

Additionally, another protein–protein interaction that positively affects PLD-mediated chemotaxis occurs with S6K via the p70 subunit of the ribosomal S6 kinase (p70S6K), which correlates well with immunofluorescent staining of S6K that translocates from perinuclear regions and colocalizes with PLD2 in the cytosol following chemokine stimulation (Gomez-Cambronero 2010). LR5/RAW264.7 macrophages also use a PLD2/S6K-dependent chemotactic pathway that signals through PLD2-Y^{296}, which is already known to be phosphorylated by EGF-R (Knapek et al. 2010) (Fig. 4). Mutation of this tyrosine residue to phenylalanine completely abrogates chemotaxis to basal levels. Overexpression of PLD2 in dHL-60 leukemic cells results in an elevation of S6K activity, phosphorylation of p70S6K and chemokinesis, while both lipase-dead PLD mutants and si-RNA specific for PLD were inhibitory to this type of cell movement. A similar negative effect of the lipase-dead PLD2-K758R mutant on chemotaxis is also evidenced in LR5/RAW264.7 macrophages and through *n*-butanol treatment of cells.

Summary

PLD regulation in cells occurs via two different signaling pathways. One is via growth factors/mitogens, such as EGF, PDGF, insulin, and serum, and implicates tyrosine kinases. This pathway involves interactions with Grb2; Sos; and the kinases EGF-R, JAK3, and Src. The other pathway is via the small GTPases, such as Arf and Rho, and is directly related to chemotaxis, a process in which PLD plays a vital role. Even though the end results of PLD action as related to downstream signaling mechanisms are still currently being elucidated, adhesion and chemotaxis, which are both requisite for the inflammatory actions of leukocytes, are modulated directly by PLD. The functional consequences of receptor activation are not limited to leukocyte movement but also include degranulation, gene transcription, and mitogenic and apoptotic effects and are seen in angiogenesis, organogenesis, inflammation, and tumor development, growth, and metastasis.

Provirus insertion site of Moloney murine leukemia virus 1 Pim-1

Historical Background

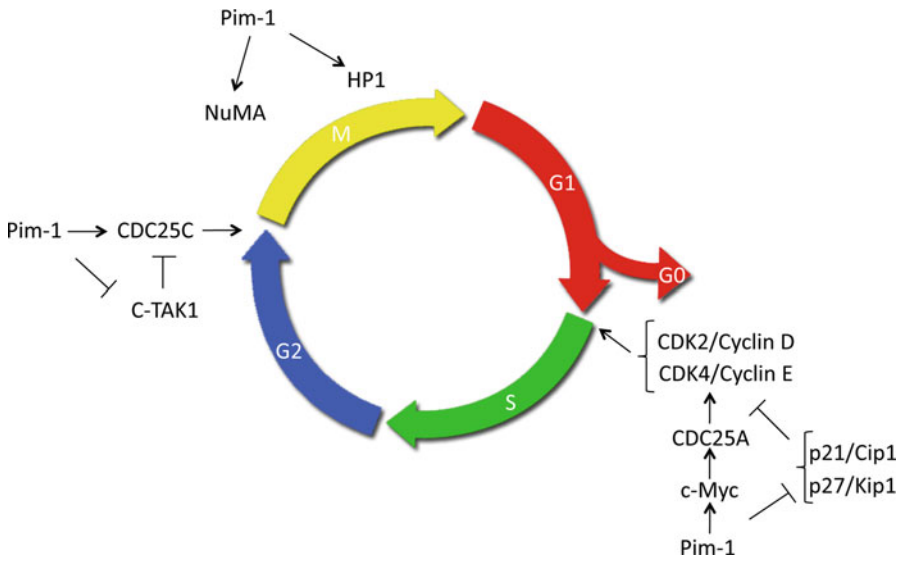
The serine-threonine kinase Pim-1 belongs to the Calmodulin-dependent protein kinase family together with two other highly conserved family members (Pim-2 and Pim-3). Pim-1 is the preferential site of integration for the Moloney murine leukemia virus (*P*roviral *I*ntegration for *M*oloney Virus) discovered over 25 years ago (Selten et al. 1985). Pim-1 plays pivotal roles in cellular proliferation, differentiation, metabolism, and survival by phosphorylating and interacting with many targets. A literature search reveals the dynamic expression and activity of Pim-1 depends upon cell type and response to stimuli, either pathologic or homeostatic. Specifically, Pim-1 is expressed in various hematopoietic sites including thymus, spleen, bone marrow, and fetal liver, but can also be found in the heart, oral epithelia, prostate, hippocampus, vascular smooth muscle, and many tumorigenic cell types (reviewed in Nawijn et al. (2011)). Expression of Pim-1 is preferentially elevated in the hematopoietic system and during fetal development coinciding with periods of increased cell cycling. Upon maturation, Pim-1 is downregulated in most organs until induced by pathologic stimuli to promote survival (Muraski et al. 2007). Presence of Pim-1 in neoplastic cell types can result in a poor prognosis depending on the type of malignancy. For example, the presence of Pim-1 together with a synergistic partner named c-Myc support a good prognosis in prostate adenocarcinoma, yet the opposite is true in the case of mantle cell lymphomas (reviewed in Nawijn et al. (2011)). Ironically, Pim-1 promotes survival and regeneration in heart tissue considered to be resistant to neoplastic transformation (Muraski et al. 2007). Therefore, the same molecular mechanisms that produce relatively bleak outcomes in cancer patients have the potential to produce therapeutic interventions in patients with cardiomyopathy.

Structure and Function

Genomic mapping identified Pim-1 on chromosome 17 in mice and chromosome 6 in humans. Six exons make up the 313 amino acid protein which has two isoforms stemming from alternative start sites; the larger 44 kD and smaller 34 kD isoforms contain a kinase domain, a proton acceptor site, a glycine loop motif, and a phosphate-binding site (Bachmann and Moroy 2005). Both isoforms of Pim-1 are short-lived (~5 min–6 h depending on cell type) and constitutively active. Paradoxically, Pim-1 is known to phosphorylate itself despite the fact that it does not contain the consensus sequence needed for phosphorylation. Selective peptide mapping identified the Pim-1 consensus sequence as either $(K/R)_3$-X-**S**/**T**-X or R/K-R/K-R-R/K-X-**S**/**T**-X where X is an amino acid with a small side chain but neither basic nor acidic (Bachmann et al. 2006). Pim-1 has numerous targets in various cellular compartments, giving rise to speculation that subcellular localization defines effect, with nuclear Pim-1 stimulating proliferation and mitochondrial/cytoplasmic localization promoting survival.

Controlling Pim-1

Regulation of Pim-1 occurs primarily at transcriptional and translational levels. *Pim-1* gene expression is induced by a large array of cytokines: most interleukins, granulocyte macrophage colony-stimulating factor (GM-CSF), epidermal growth factor (EGF), leukemia inhibitory factor (LIF), and interferon-alpha. Cytokine stimulation results in the activation of multiple pathways such as the Janus kinase-signal transducer and activation of transcription (Jak-STAT) and nuclear factor kB (NFKB)–growth factor signaling pathways. Interleukins 5 and 7 (IL-5 and IL-7) activate

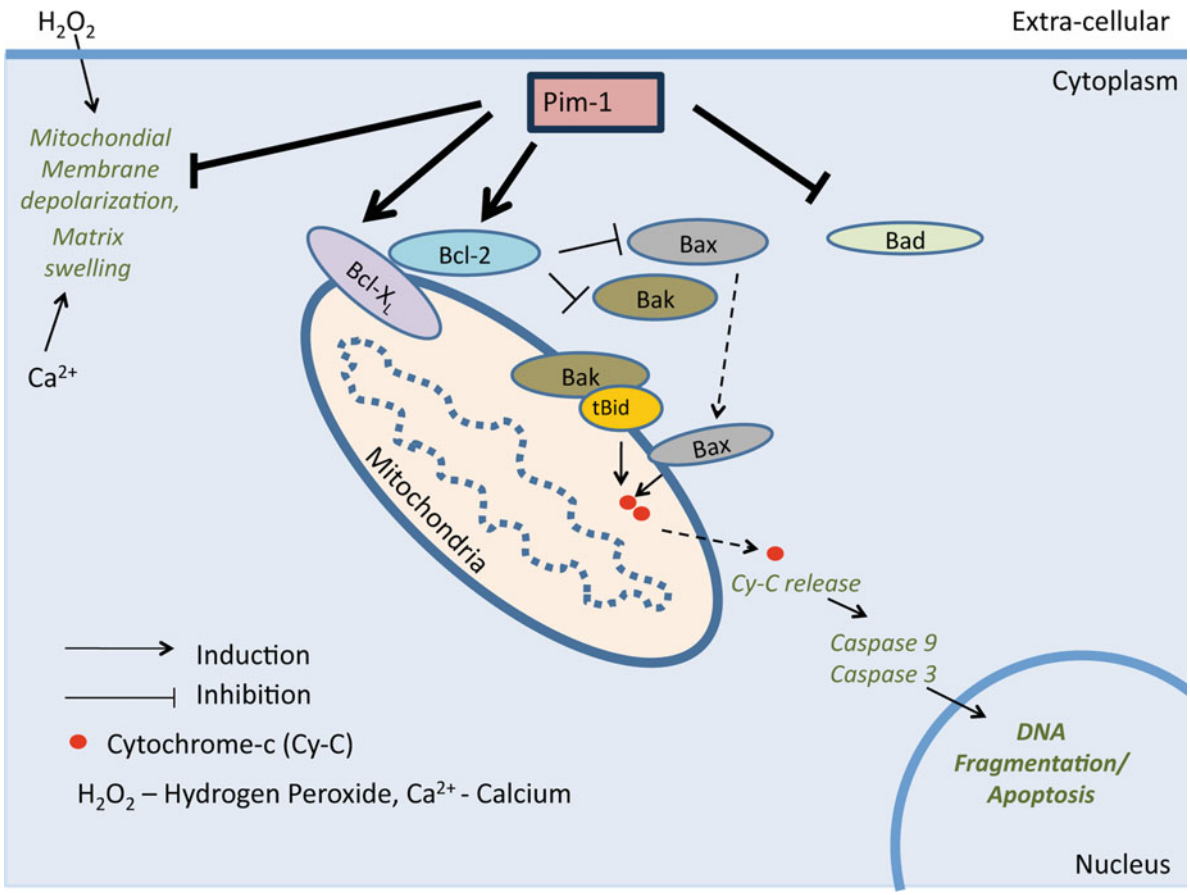


Pim-1, Fig. 1 Cell cycle regulation by Pim-1. Pim-1, together with c-Myc, works synergistically to drive G1/S transition by stabilizing CDK2/Cyclin D and CDK/Cyclin E complexes by phosphorylating CDC25A and cell cycle inhibitors p21/Cip1 and p27/Kip1. Pim-1 phosphorylates c-Tak1, inhibiting c-Tak1 kinase activity, promoting CDC25C driving G2/M transition. During mitosis, Pim-1 interacts with NuMa at the spindle poles, which is thought to promote the segregation of chromosomes. The exact role of Pim-1 during mitosis is currently under investigation but it is known that Pim-1 interacts with and phosphorylates HP-1

STAT5, whereas GM-CSF and EGF activate STAT 3. STAT3/STAT5 are both able to bind to the *Pim-1* promoter and induce transcription (Bachmann and Moroy 2005). Platelet-derived growth factor (PDGF) also increases *Pim-1* transcription in vascular smooth muscle cells resulting in enhanced proliferation that can be blunted with Jak-STAT pathway inhibitors (Willert et al. 2010). The hormone prolactin stimulates *Pim-1* transcription independent of STAT transcription factors. Alternatively, transcription is induced through the PI3K/AKT signaling pathway establishing Akt as an upstream regulator of Pim-1 activity (Krishnan et al. 2003). In addition, pathological stimuli such as DNA damaging agents including peroxide or 5-fluorouracil stimulate *Pim-1* through kruppel-like factor 5 binding to the *Pim-1* promoter activating transcription and subsequently preventing apoptosis (Zhao et al. 2008). Hypoxia elevates levels of Pim-1 mRNA and protein by inhibiting ubiquitin-mediated proteasomal degradation and causes Pim-1 translocation from the cytoplasm to the nucleus (Chen et al. 2009).

Pim1 mRNA has a short half-life due to five copies of the AUUU(A) destabilization motif in the 3' untranslated region (UTR) (Selten et al. 1985). The 5' UTR of Pim-1 contains multiple secondary structures due to repetitive GC rich regions, necessitating a 7-methylguanosine cap. By capping the 5' end of the message, ribosomal assembly is supported resulting in an abundant increase in Pim-1 protein (reviewed in Nawijn et al. (2011).

In addition to transcriptional control, Pim-1 is regulated posttranslationally through protein stabilization. Interactions with several molecules and complexes inhibit ubiquitination and dephosphorylation resulting in accumulation and persistence. Several facets of Pim-1 activity rely on synergistic partners that enhance and sustain kinase activity by preventing degradation. One such partner is heat shock binding partner 90 (Hsp90), association of Pim-1 and Hsp90 prevent ubiquitin-mediated destruction, whereas inhibition or silencing of Hsp90 promote rapid Pim-1 proteolysis (Shay et al. 2005). Conversely, Hsp70 binds ubiquitinated Pim-1 and directs Pim-1 to the proteosome for degradation (Shay et al. 2005). Similar to Akt, Pim-1 is inactivated by protein phosphatases including protein phosphatase 2A (PP2A). Once dephosphorylated, Pim-1 is quickly ubiquitinated and shuttled to the proteosome for degradation (reviewed in Bachmann and Moroy (2005)).



Pim-1, Fig. 2 Mechanisms by which Pim-1 inhibits apoptosis and maintains mitochondrial integrity. Pim-1 inhibits apoptosis by multiple means, involving upregulation of anti-apoptotic proteins, Bcl-2 and Bcl-X_L (in the cytosol and mitochondria respectively), while directly phosphorylating and inhibiting pro-apoptotic protein, Bad. Bcl-2 in turn is known to inhibit pro-apoptotic proteins, Bax and Bak, which translocate into the mitochondria upon stress and induce the release of cytochrome c, triggering apoptotic cell death (in a pathway involving caspase proteins). Pim-1 inhibits tBid-induced cytochrome c release in hearts, thereby inhibiting apoptosis. Pim-1 also maintains mitochondrial integrity by protecting against oxidative stress-induced mitochondrial inner membrane depolarization and calcium-induced matrix swelling

Pim-1 and Cell Cycle

Studies utilizing transgenic mice to overexpress Pim-1 and knockdown techniques to eliminate expression concluded that Pim-1 contributes to cell cycle progression in hematopoietic, cardiovascular, and embryonic stem cells. Subsequent studies revealed that cellular proliferation is achieved by modulating mitotic signals throughout the progression of the cell cycle. Downstream substrates and cell cycle regulators that allow Pim-1 to influence proliferation are depicted in Fig. 1. During G1-S progression, Pim-1 binds and phosphorylates cell division cycle 25 homolog A (CDC25A) increasing its phosphatase activity which in turn activates cyclin-dependent kinase 2 (CDK2) and cyclin-dependent kinase 4 (CDK4) (Mochizuki et al. 1999). In addition, Pim-1 increases CDK2 activity by phosphorylating cell cycle inhibitors p21/Cip1 (Zhang et al. 2007) and p27/Kip1 (Morishita et al. 2008) resulting in nuclear export and degradation. In a similar fashion Pim-1 enhances progression through G2/M by phosphorylating the N-terminus of Cdc25C enhancing phosphatase activity (Bachmann et al. 2006). To further stimulate transition into M phase, Pim-1 phosphorylates Cdc25C-associated kinase 1 (C-TAK-1), an inhibitor of Cdc25C at multiple sites reducing its kinase activity allowing Cdc25C to promote G2/M transition (Bachmann et al. 2006).

During mitosis Pim-1 is enriched in the nucleus facilitating cell division (Bhattacharya et al. 2002). Pim-1 stabilizes spindle poles by interacting with Nuclear Mitotic Apparatus protein (NuMA) during mitosis, most likely phosphorylating NuMA as cells with kinase dead forms of Pim-1 do not co-localize with NuMA and have a higher frequency of apoptosis (Bhattacharya et al. 2002). Pim-1 phosphorylates NuMA to promote complex formation at the microtubule (−) end and provide a docking site for dynein and dynactin to promote proper chromosome segregation (Bhattacharya et al. 2002). In addition to NuMA, Pim-1 also phosphorylates heterochromatin protein-1 (HP-1) to further contribute to spindle fiber assembly during mitosis.

The transcription factor ▶ c-Myc is a well-characterized partner for Pim-1 known to promote cellular proliferation and differentiation when the two are co-expressed. Pim-1 binds, phosphorylates, and stabilizes ▶ c-Myc, facilitating cell cycle progression by promoting ▶ c-Myc-dependent transcription of target genes (Zhang et al. 2008). Pim-1 contributes to the regulation of around 20% of ▶ c-Myc target genes by promoting heterodimerization between c-Myc and Max that bind to E-box promoter elements present in approximately 15% of all human genes, (Zippo et al. 2007). During mitosis, ▶ c-Myc activates CDC25A, CDK2, and CDK4 driving entry and progression through the cell cycle. Overexpression of Pim-1 in cardiac progenitor cells results in increased cell cycling and elevated ▶ c-Myc expression (Cottage et al. 2010). Pim-1 regulates ▶ c-Myc-dependent transcription by phosphorylating Histone 3 on serine 10, unraveling chromatin providing E box-binding sites for ▶ c-Myc to bind and promote transcription (Zippo et al. 2007).

Pim-1 and Cell Survival

Mitochondrial membrane integrity regulates the release of pro-apoptotic cytochrome C and subsequent caspase cleavage eventually ending in DNA fragmentation and cell death. Multiple Pim-1-dependent cellular survival mechanisms are depicted in Fig. 2. Pim-1 effects cell death at the mitochondria via pro- and anti-apoptotic ▶ Bcl-2 family members. During normal homeostatic conditions ▶ Bcl-2 family members ▶ Bcl-2 and Bcl-XL reside in the outer membrane regulating mitochondrial outer membrane permeabilization. Upon apoptotic stimuli, pro-apoptotic family members, Bax and Bad, associate with ▶ Bcl-2 and Bcl-XL permeabilizing the outer membrane permitting cytochrome C release. Pim-1 phosphorylates BAD on serine 112 resulting in translocation from the mitochondria to the cytoplasm and binding to 14-3-3 scaffold proteins (Zhao et al. 2008). Overexpression of Pim-1 increases levels of both ▶ Bcl-2 and Bcl-XL in mitochondrial fractions protecting cardiomyocytes from hydrogen peroxide-induced stress (Borillo et al. 2010). In addition to forming heterodimers with Bcl-XL, ▶ Bcl-2 interacts with pro-apoptotic family members Bax and Bak to prevent membrane permeabilization and cytochrome C release (Fig. 2). Other non-mitochondrial-associated cell survival–related targets have been proposed using bioinformatic software; however, these are a topic of future research geared at elucidating the role of Pim-1 upon cellular survival.

Conclusions

In summary, Pim-1 is capable of manipulating protective signaling by promoting proliferative and survival signaling in a variety of ways and in a variety of cell types. Oncologists view Pim-1 as an enzyme capable of driving tumorigenesis with transformation promoting partners like ▶ c-Myc. In most hematopoietic malignancies, Pim-1 propels cell proliferation while simultaneously promoting survival creating a "recipe for disaster" and poor prognosis. To slow metastasis, pharmacologists are actively synthesizing new Pim-1 inhibitors in the hope of reversing mitogenic signaling. In contrast, cardiovascular biologists view increased proliferation as a breakthrough capable of resuscitating cardiac cells during times of myocardial damage. Pim-1-engineered cardiac stem cells (CSCs) have been adoptively transferred into damaged myocardium in order to promote repair. Several weeks after transplantation, hearts receiving Pim-1-engineered stem cells contain regenerated cardiomyocytes and possess increased functional output (Fischer et al. 2009). In addition to enhancing stem cell therapy, cardiotropic adenoviruses (AAV-9) overexpressing Pim-1 promote cellular proliferation and survival in cardiac cells. Tail vein injections of Pim-1 overexpressing AAV-9 reversed the effects of diabetic cardiomyopathy without surgery (Katare et al. 2011). In summary,

inhibiting Pim-1 may serve as a powerful therapeutic to halt cancer progression whereas overexpressing Pim-1 empowers stem cells and reverses the deleterious effects of cardiovascular disease.

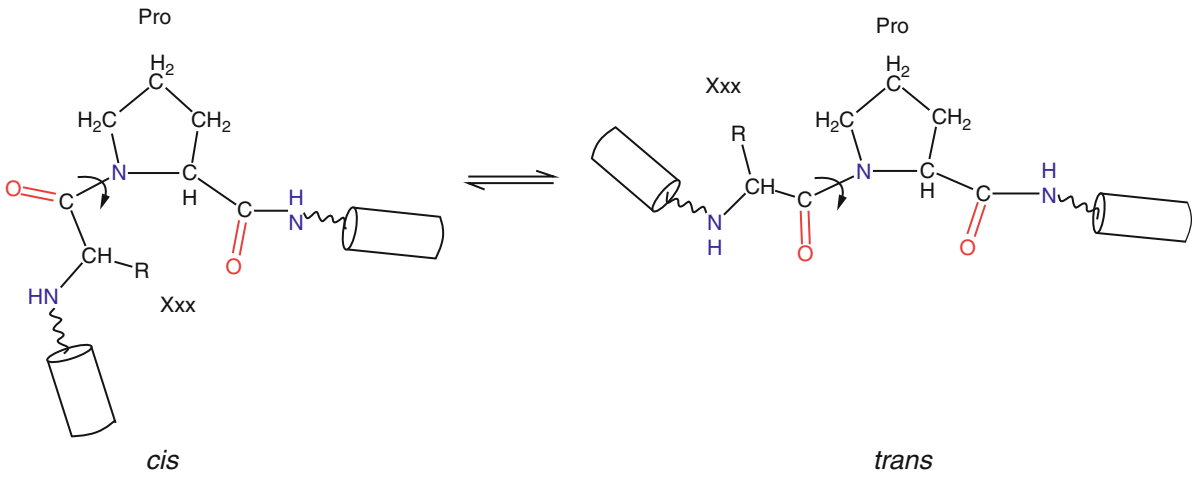
Historical Background

Pin1 is a phosphorylation-dependent peptidyl-prolyl isomerase that was first isolated by a yeast two-hybrid screen designed to identify human proteins which interact with the "Never in Mitosis" gene A (NIMA) (Lu et al. 1996). Sequence analysis revealed that human Pin1 exhibits approximately 45% sequence similarity with the product of the ESS1 gene which was previously identified as essential for growth in the budding yeast *Saccharomyces cerevisiae* (Hanes et al. 1989). It has subsequently been found that Pin1-like proteins are highly conserved, found in both eukaryotes and prokaryotes (Maruyama et al. 2004). While it was initially implicated as a regulator of mitosis, it is evident that Pin1 has roles in a number of biological processes.

Pin1 is classified as a peptidyl-prolyl isomerase (PPIase), catalyzing the cis-trans conversion of the peptide bond between a proline and the preceding amino acid (Fig. 1). It is part of a large superfamily of PPIases,



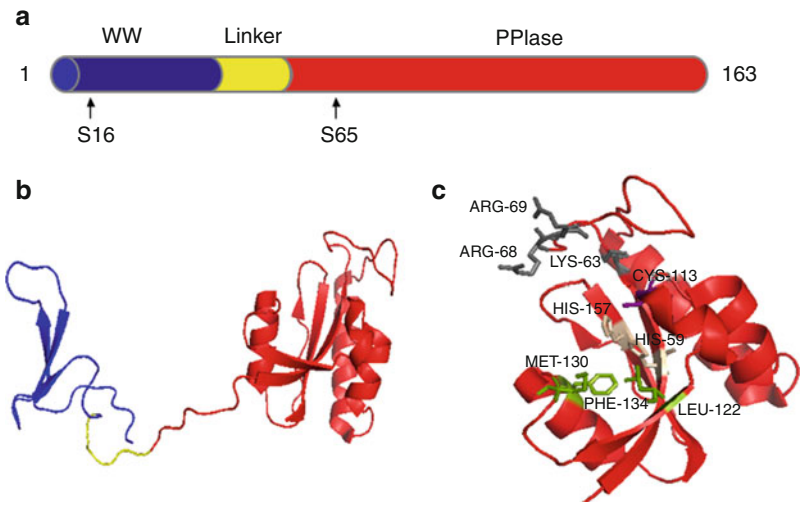
Pin1, Fig. 1 Peptidyl-prolyl isomerization. Cis-trans isomerization of the peptide bond (*arrow*) preceding the proline. Xxx represents any amino acid

which is divided into three families: the cyclophilins, the FK506 binding proteins (FKBPs), and the parvulins (Gothel and Marahiel 1999). One distinguishing characteristic among the three families of PPIases is their substrate specificities, particularly concerning the residue directly preceding the proline. Like all members of the parvulin family, Pin1 has a preference for hydrophobic residues. However, unique to Pin1 is its phosphorylation dependence, requiring that the preceding residue be a phosphorylated serine or phosphorylated threonine (Yaffe et al. 1997). With phosphorylation playing a pivotal role in cell signaling, one can infer that an isomerase with phosphorylated residues in its specificity determinants would add an additional layer of complexity to signaling pathways. This has been shown in multiple cellular processes where Pin1-catalyzed isomerization regulates the conformation of key cellular proteins (Lu and Zhou 2007).

Structural and Enzymatic Features of Pin1

High-resolution structures of Pin1 determined by x-ray crystallography revealed that it consists of two structural domains connected by a relatively short linker, which had originally been predicted from its primary sequence (Fig. 2). The N-terminal WW domain is named for two conserved tryptophan residues and comprises residues 1–39. It consists of a triple-stranded antiparallel β-sheet, with a hydrophobic patch on the surface (Zhou et al. 1999). Generally described as a protein-protein interaction domain, the WW domain of Pin1 binds pSer/Thr-Pro motifs, thus facilitating interactions between Pin1 and its substrates (Lu et al. 1999). The 118 amino acid catalytic PPIase domain (residues 45–163) is found on the C-terminal end of the protein, and consists of four antiparallel β-sheets, and four α-helices. Within this domain are two relatively well-described regions, the proline binding pocket and the phosphate binding loop, which lie on opposite sides of the active site. The hydrophobic proline binding pocket contains three highly conserved residues, Leu122, Met130, and Phe134, which are thought to be responsible for holding the proline in place during catalysis (Ranganathan et al. 1997). The phosphate binding loop contains two positively charged arginine residues at positions 68 and 69, as well as another positively charged amino acid, lysine at position 63, conferring upon Pin1 its preference for phosphorylated residues preceding the proline (Zhou et al. 1999). A short linker connects the WW and PPIase domains, whose flexibility may contribute to the broad substrate specificity of Pin1 (Li et al. 2005). Interestingly, although both domains of Pin1 bind the pSer/Thr-Pro motif, it appears that they may bind differently since the WW domain typically has a higher binding affinity for peptides than the PPIase domain (Lu et al. 1999).

In spite of the evidence confirming the ability of Pin1 to catalyze cis-trans isomerization, there are still questions concerning its precise catalytic mechanism. On the basis of a crystal structure of Pin1, Ranganathan et al. (1997), initially proposed a mechanism that



Pin1, Fig. 2 (**a**) Linear representation of Pin1. Phosphorylation sites are indicated. (**b**) and (**c**) High-resolution structure of Pin1 determined by x-ray crystallography (PDB: 1NMV). (**b**) The WW domain is shown in *blue*, the linker region is *yellow*, and the PPIase domain is shown in *red*. (**c**) Key residues of the PPIase domain are highlighted. See text for more details

involved the formation of a covalent enzyme-substrate intermediate with Cys113, His59, and His157 being key residues involved in catalysis. Since then, however, additional evidence has argued instead for a non-covalent mechanism. In this respect, Lippens et al. (2007) proposed that the role of Cys113 is to destabilize the peptide prolyl bond to allow for its rotation. This hypothesis is supported by data from Behrsin et al. (2007) showing that the Cys113/Asp substitution did not abolish Pin1 function. Additionally, with regard to the histidine residues, it has been shown that they do not directly participate in catalysis, suggesting they instead act structurally to support the integrity of the active site (Bailey et al. 2008).

Physiological Regulation of Pin1

It appears that Pin1 is subject to regulation at a number of levels (Lu and Zhou 2007). For example, its expression is upregulated in response to growth factors through E2F-mediated transcription, an observation consistent with its role in the cell cycle (Lu et al. 2002). Pin1 is also regulated through posttranslational modifications, including phosphorylation and possibly oxidation. Phosphorylation on Ser16 and Ser65 has opposing effects: the former prevents interactions with substrates, while the latter reduces ubiquitylation, thus increasing stability of Pin1. Oxidation of Pin1 may have a relationship to pathologies such as Alzheimer's disease, rather than as a part of normal cell regulation (Sultana et al. 2006).

Cellular Functions of Pin1

Pin1 is primarily localized in the nucleus; however, it can also be detected in the cytoplasm. This pervasive distribution of Pin1 is consistent with its extensive list of target proteins that are localized throughout the cell (Lu et al. 2002). As previously noted, Pin1 was first identified due to its interaction with NIMA, a protein kinase involved in mitotic regulation. This relationship was the first of many which suggested that Pin1 plays an integral role in regulation of the cell cycle and growth. Since then, Pin1 has been shown to be involved in a variety of additional cellular processes, emphasizing its diversity and importance (Fig. 3). Loss of function mutations or deletions of Pin1 in yeast and mammalian cells provides striking evidence for its role in the cell cycle, as these cells undergo mitotic arrest and apoptosis (Lu et al. 2002). Furthermore, Pin1 has a lengthy list of substrates which are known to be involved in the cell cycle, including a number of mitotic regulatory proteins (e.g., ▶ CDC25 and WEE1) which are targets of proline-directed protein kinases, such as CDKs and MAPKs (Lu and Zhou 2007). Pin1-catalyzed isomerization of these phosphorylated sites may be responsible for coordinating the activity of mitotic proteins, thus allowing for progression through the cell cycle (Lu and Zhou 2007). Pin1 has also been shown to coordinate duplication of centrosomes, DNA synthesis (Suizu et al. 2006), and to assist in chromosome condensation (Xu and Manley 2007) further emphasizing its role in the cell cycle.

	SUBSTRATE	CONSEQUENCE OF PIN1 INTERACTION
Cell Cycle Regulation	CDC25	Dephosphorylation
	WEE1	Inhibition of activity
	Cyclin D1	Stabilization
Apoptosis	p53	Stabilization
Neuro-degeneration	Tau	Dephosphorylation
	APP	APP processing

Pin1, Fig. 3 Selected Pin1 substrates and consequences of interaction

Similar to its actions in the cell cycle, Pin1 has been shown to interact with proteins involved in cell signaling events and pathways involving proline-directed protein kinases. One such example is the MAPK pathway, where, following proline-directed phosphorylation by MAPK, the proteins c-Jun and c-Fos are acted upon by Pin1 (Lu et al. 2007).

Briefly adding to the growing list of functions, Pin1 has also been shown to regulate expression of some genes through regulation of their transcription factors (Lu et al. 2007), to assist in the maintenance of telomeres through interactions with TRF1 (Lee et al. 2009), to facilitate DNA repair through interactions with p53 (Takahashi et al. 2008), and finally, to support breast development (Wulf et al. 2003).

Additionally, Pin1 has been shown to have specific roles in the immune and nervous systems. These additional functions provide links to the implication of Pin1 in various pathogenic conditions, which will be discussed in the following section. In short, however, it has been shown that Pin1 is important for regulating transcription of cytokines in T cells, as well as for survival of eosinophils (Lu et al. 2007). The importance of Pin1 in the brain is evident in Pin1 knockout mice, which have progressive and age-related neurodegeneration. This is directly related to the ability of Pin1 to promote normal neuronal cell functioning and survival through the interaction with proteins such as Tau and amyloid precursor protein (APP) (Lu and Zhou 2007).

Pin1 in Pathogenesis

Considering the diversity of its roles and importance as a key regulator of many cellular and biological processes, it is not unexpected that Pin1 appears to be involved in various pathological conditions, including cancer, Alzheimer's disease, and asthma.

In this respect, Pin1 has been implicated in a variety of cancers, including breast, lung, colon, and prostate cancer (Lu and Zhou 2007). This is not surprising given its role as a regulator of the cell cycle. However, the precise role Pin1 plays in cancer is controversial, as levels of Pin1 have been shown to be either positively or negatively related to cancer (Yeh and Means 2007). One of the better understood pathways in which overexpression of Pin1 appears to participate in cancer involves cyclin D1. Not only can Pin1 increase expression of cyclin D1, Pin1 can also directly bind and stabilize cyclin D1 to enhance cyclin D1/CDK activity (Lu et al. 2006). Conversely, loss of Pin1 can suppress transformation by Neu or Ras (Ryo et al. 2002). Additionally, Pin1 has been shown to stabilize ▶ p53, an important tumor suppressor which promotes apoptosis in response to genotoxic stresses (Yeh and Means 2007).

With regard to Alzheimer's disease, the precise role of Pin1 in pathogenesis remains uncertain, although evidence suggests that various mechanisms in Alzheimer's disease downregulate and/or inactivate Pin1 (e.g., through oxidation), suggesting it has a neuroprotective role (Lu and Zhou 2007). The loss of Pin1 function has impacts on two proteins, namely, APP and Tau, both found in senile plaques and neurofibrillary tangles. A current model suggests that without Pin1, the pThr668-Pro motif of APP remains in the cis form and accumulates in plaques. Similarly, the Tau pThr231-Pro motif is also found mostly in the cis form, leading to its hyperphosphorylation and subsequent accumulation (Lu and Zhou 2007).

The association between Pin1 and asthma can be traced back to the role Pin1 plays in immune cell function. By regulating the release of cytokines from eosinophils, and participating in the apoptotic decision of both T-cells and eosinophils, activated Pin1 modulates the allergic inflammatory response in the lungs associated with asthma (Esnault et al. 2008).

Emergence of Pin1 as a Candidate for Molecular-Targeted Therapy

The prevalence of Pin1 in various human diseases, cancer in particular, makes it an obvious candidate for therapies. Additionally, the fact that other PPIase proteins, specifically cyclophilin and FKBP, have been shown to be good therapeutic targets lends support to attempts to achieve the same success with Pin1. The first general inhibitor of parvulins was juglone, and although it has the ability to irreversibly inhibit Pin1, its use as an anticancer therapy is limited by its non-specificity (Wang and Etzkorn 2006). More recently, work has been focused on structure-based design of Pin1 inhibitors. Features that have been targeted by these rationally designed Pin1 inhibitors include its hydrophobic binding pocket, the phosphate binding loop (Potter et al. 2010), and Cys113 within its active site (Dong et al. 2010). Thus far, these Pin1 inhibitors have had varying degrees of specificity, as well as issues with potency, degradation, and cell permeability. In addition to these inhibitors, there have also been efforts to isolate inhibitors in the form of cyclic peptides which are less likely to be subject to proteolysis and may bind Pin1 with a higher affinity due to their reduced flexibility (Liu et al. 2010; Duncan et al. 2011). Although some inhibitors are able to inhibit Pin1 at nanomolar concentrations, their usage currently appears to be more appropriate for further investigations regarding the cellular functions of Pin1, rather than as therapeutic agents. However, this does not preclude the notion of using them as models to guide the design of novel, potentially therapeutic inhibitors of Pin1.

Summary

Since its discovery in 1996, much has been learned regarding the structure, function, and regulation of Pin1. In comparison to other PPIases, one particularly intriguing feature of Pin1 is its phosphorylation dependence which enables Pin1 to introduce an additional level of control in pathways involving proline-directed protein kinases such as CDKs that are central drivers of cell-cycle progression. While Pin1 was initially implicated as a key regulator of mitosis, it has subsequently been shown to be important in a diverse array of cellular processes. In concert with its participation in a broad spectrum of biological events, it is noteworthy that Pin1 has been implicated in a variety of diseases including cancer, neurological disorders such as Alzheimer's disease and asthma. Pin1 has thus emerged as a potential candidate for molecular-targeted therapy. Consequently, it can be anticipated that ongoing efforts to understand its regulation and functions and to elucidate its precise catalytic mechanism will foster efforts to develop new approaches that will harness its promise as a therapeutic target.

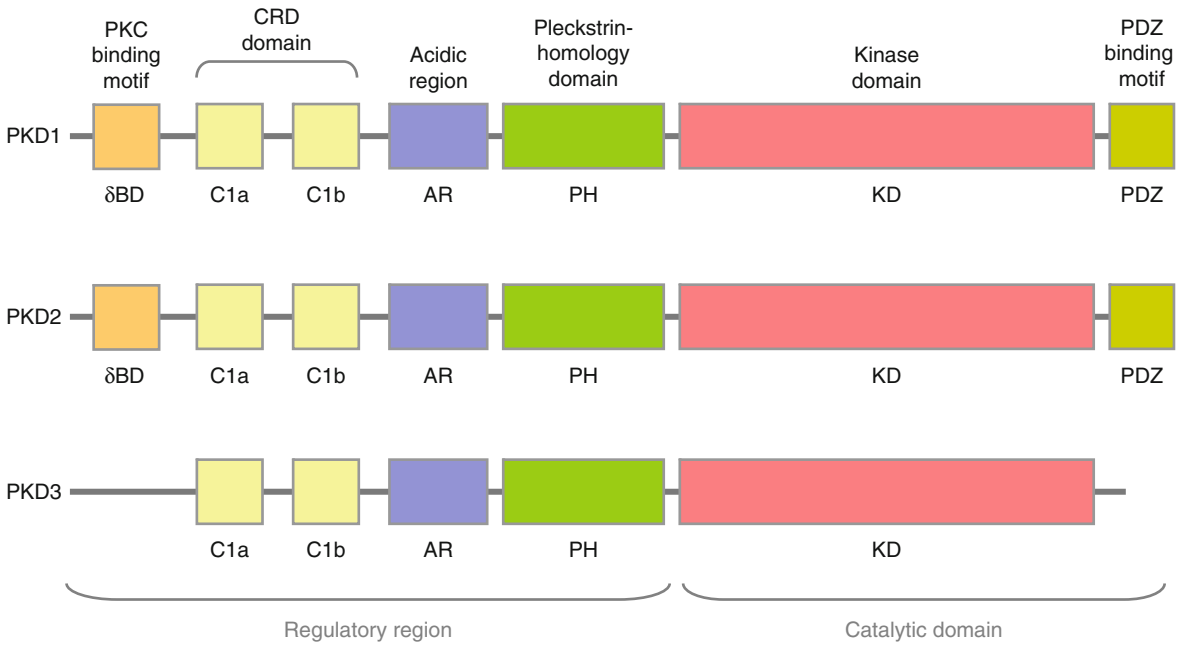
PKD (isoforms: PKD1/PKCμ, PKD2, PKD3/PKCν)

Historical Background

The serine/threonine kinase protein kinase D (PKD) was first described in 1994. Due to some homology in its kinase domain, its ability to bind the lipid diacylglycerol (DAG), and its responsiveness to phorbol ester, PKD was originally classified as a member of the protein kinase C (PKC) family (Johannes et al. 1994). Later it became evident that PKD represents an own group of kinases more closely related to the calcium/calmodulin-regulated (Cam) kinases (Manning et al. 2002). Initially, the PKD field focused on determining the functions of the structural elements and domains of PKD1 as well as the activation mechanisms for this kinase. With the identification of the PKD phosphorylation motif (Hutti et al. 2004) and the subsequent generation of a substrate-specific antibody (Döppler et al. 2005), optimal conditions were provided for the discovery of PKD substrates. This led to an increasing wealth of information on PKD downstream signaling, its role in various cellular processes, as well as its potential roles in health and disease. For example, it was shown that PKD has multiple functions within cells ranging from regulating golgi organization and vesicle transport, cell proliferation, cell survival, to mitochondrial signaling to the nucleus (reviewed in Wang 2006). To date, three highly conserved isoenzymes, PKD1/PKCμ, PKD2, and PKD3/PKCν, have been described. Dependent on the cellular context the three PKD family members may have redundant or unique functions. This is currently under intense investigation using shRNA strategies in cellular settings or knock-out and knock-in animal models.

Structure of PKD Enzymes

PKD enzymes consist of a C-terminal kinase domain and a N-terminal regulatory region (Fig. 1). The regulatory region comprises a binding motif for PKCδ, two cystein-rich C1 domains (also named C1a and C1b or CRD domain), an acidic region (AR), and a pleckstrin homology (PH) domain. The deletion of either of these domains or regions leads to increased PKD activity, suggesting that the N-terminal region acts negative-regulatory for the kinase domain (reviewed in Van Lint et al. 2002). C1 domains are required for binding to the lipid diacylglycerol (DAG), which targets PKD to different intracellular membranes including the plasma membrane, the golgi, or mitochondria (Cowell et al. 2009; Baron and Malhotra 2002). Both C1 domains have distinct roles in targeting and maintaining PKD at the plasma membrane. C1a achieves fast maximal and reversible translocation, while C1b translocates the enzyme more persistent. Persistent localization also requires the binding of a G-protein $G\alpha_q$ subunit to the C1b domain. The C1b domain also includes a nuclear targeting sequence. A role for the acidic region is not known. The PH domain does not bind any particular phosphoinositide with high specificity, but serves as a protein–protein interface. For example, it recruits upstream kinases such as PKCη or binds the G-protein βγ subunit. The PH domain further is required for nuclear export (Rozengurt et al. 2005). Additionally, several phosphorylation sites within this domain control PKD intracellular localization and activity. The C-terminal kinase domain includes an ATP-binding motif, an activation loop motif that requires phosphorylation at two serine residues and an autophosphorylation site within a PDZ-binding motif (Van Lint et al. 2002; Sanchez-Ruiloba et al. 2006).



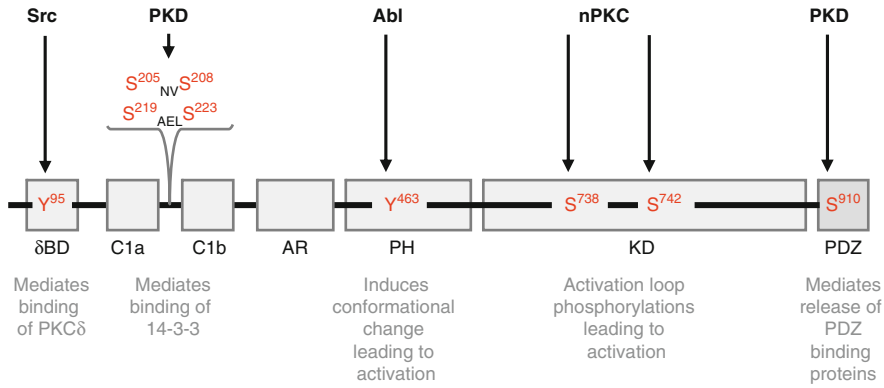
PKD, Fig. 1 Structural organization of PKD enzymes. Structures of the PKD family members PKD1/PKCμ, PKD2, and PKD3/PKCν. PKD enzymes consist of a regulatory region and a kinase domain (KD). The regulatory regions comprise a PKCδ binding motif (δBD; only in PKD1 and PKD2), the CRD region with the two C1 domains C1a and C1b, the acidic region (*AR*), and the pleckstrin homology domain (*PH*). The kinase domain includes a PDZ-binding motif (PDZ; only in PKD1 and PKD2)

Regulation of PKD Activity

Regulation of PKD activity occurs through lipid binding and phosphorylation events (Fig. 2). An initial step leading to PKD activation is its binding to diacylglycerol (DAG) which targets PKD to intracellular membranes. DAG is formed by phospholipases. For example, in response to growth factor receptor signaling PKD1 is activated at the plasma membrane through DAG generated by PLCγ or PLCβ, and in response to mitochondrial oxidative stress PKD1 is activated through binding to mitochondrial DAG that is indirectly (via phosphatidic acid) generated by ▶ PLD1 (Cowell et al. 2009). Membrane targeting as an initial step of PKD activation is followed by phosphorylation events to gain full enzymatic activity (Rozengurt et al. 2005). Dependent on the stimulus and the cellular localization of PKD activating phosphorylations are mediated by members of the novel PKC (nPKC) group and tyrosine kinases such as ▶ Src and Abl.

The canonical activation pathway for PKD is binding to DAG or phorbol ester, which leads to the release of the inhibition through the regulatory domain and subsequent phosphorylation of PKD by nPKC enzymes including PKCε, PKCδ, PKCη, and PKCθ. For example, in response to growth factor signaling, after translocation to the plasma membrane via binding to DAG, PKD is activated through nPKC. PKC enzymes phosphorylate PKD in the activation loop of the kinase domain at serine residues Ser738 and Ser742 (for human PKD1). These phosphorylation steps are required for PKD to gain full activity (Rozengurt et al. 2005). Active PKD can be released from the plasma membrane after this phosphorylation or can stay attached to intracellular membranes through binding to adapter proteins (i.e., golgi localization through binding of G-protein βγ subunits to the PH domain).

Activation of PKD1 and PKD2 in response to oxidative stress requires additional phosphorylation events. For example, at the mitochondria the activation of PKD1 by reactive oxygen species (ROS) also is initiated through binding to DAG. However, PKD1 activation then requires further phosphorylations at several tyrosine residues through the kinases Src and Abl. For example, Abl phosphorylates PKD1 in its PH domain at tyrosine residue Y463 (for human PKD1) and this leads to a release of the inhibitory regulatory domain. Subsequently, Src phosphorylates PKD1 at tyrosine



PKD, Fig. 2 Regulation of PKD1 activity. PKD1 activity is regulated by sequential activation steps. An initial step is the binding of diacylglycerol (DAG). Dependent on the activation mechanism of PKD1 this can be followed by Src- and Abl-mediated tyrosine phosphorylations. Eventually, PKD1 gains full kinase activity through nPKC-mediated phosphorylation of the activation loop serines (S738 and S742 in human PKD1). Other regulatory phosphorylation sites are the serine residues S203, S208, S219, and S223, whose phosphorylation lead to 14-3-3 binding and reduced kinase activity. Moreover, autophosphorylation at S910 regulates the association of a PDZ motif binding protein. The phosphorylation sites shown are for human PKD1

residue Y95, generating a binding motif for PKCδ, which then phosphorylates the two activation loop serines in the kinase domain (Döppler and Storz 2007).

Activation of PKD was also linked to autophosphorylation at serine residue S910 (in human PKD1) (Matthews et al. 1999). However, there is increasing evidence that this site gets phosphorylated independently or prior to PKD1 activation loop phosphorylation, suggesting that in vivo also other kinases may be involved in the phosphorylation of this residue. S910 is localized within a PDZ (Postsynaptic Density-95/Discs Large/Zonula occludens-1-binding motif) motif and its phosphorylation leads to a release of a PDZ-binding protein. This process was functionally linked to the release of vesicles from the TGN (Sanchez-Ruiloba et al. 2006).

Additional in vivo phosphorylation sites in PKD include residues S203, S208, S219, and S223 (for human PKD1), whose phosphorylation regulates binding of PKD1 to 14-3-3, a mechanism that negatively regulates the activity of the kinase (Hausser et al. 1999). The phosphorylation of these sites is most likely mediated through auto- or transphosphorylation.

Cellular Localization and Functions

Shuttling of PKD within cells – Canonical activation of PKD occurs at the plasma membrane. Upon generation of DAG PKD shuttles from the cytosol to the plasma membrane where it obtains activating phosphorylations. Dependent on the stimulus active PKD is then released into the cytosol or shuttled to the nucleus. Cytosolic PKD, for example, mediates activation of the ▶ MAP Kinase cascade. Nuclear targets for PKD are histone deacetylases (HDACs), whose phosphorylation by PKD leads to nuclear export (reviewed in Wang 2006).

PKD at the mitochondria – PKD can be localized to the mitochondria in response to either exogenously or endogenously induced oxidative stress. The mechanism of how PKD1 localizes to the mitochondria is not fully understood, but requires tyrosine phosphorylations and binding to DAG. Substrates for PKD1 at the mitochondria have not been described so far. PKD requires mitochondrial activation to gain the ability to activate anti-apoptotic and anti-oxidant signaling through the transcription factor ▶ NF-κB (Cowell et al. 2009; Storz and Toker 2003). The functions for mitochondrially activated PKD are stress resistance and cell survival.

PKD at the golgi compartment – A subcellular pool of PKD is localized to the *trans*-golgi network (TGN) and regulates the fission of transport carriers specifically destined to the cell surface (reviewed in Ghanekar and Lowe 2005). For example, PKD1 and PKD2 regulate neurotensin secretion in pancreatic cancer cells. A kinase-dead version of PKD1 blocks the detachment of tubes with cargo for the plasma membrane from the TGN. Binding of PKD to the

TGN requires DAG and recruitment to the TGN occurs via the C1a domain (Baron and Malhotra 2002). Further, PKD activation is mediated by PKCη and G-protein βγ subunits. Only few PKD substrates at the golgi were described so far. Phosphatidylinositol 4-phosphate (PI4-P) generated from phosphatidylinositol by PI4 kinases (PI4K) is an important lipid mediator in vesicular trafficking. Phosphorylation of the PI4 kinase PI4KIIIβ by PKD at the golgi complex facilitates its stabilization and increases its kinase activity through binding of 14-3-3 proteins (Hausser et al. 2005). Another PKD substrate is CERT (ceramide transport), which is also somehow involved in PKD activation at the golgi (Fugmann et al. 2007).

PKD at the actin cytoskeleton – Recently it was shown that a subcellular pool of PKD interacts with actin and once active inhibits actin reorganization at the lamellipodium (Eiseler et al. 2009). PKD isoenzymes can be activated by small Rho GTPases including RhoA, Rac, and Cdc42 (Rozengurt et al. 2005). All these Rho GTPases have major roles in regulating responses that lead to cytoskeletal reorganization involved in the regulation of actin stress fibers, focal adhesions, or cell motility, and it was shown that PKD1 regulates some of the RhoA-mediated cytoskeletal changes through phosphorylation of SSH1L and regulation of cofilin activity (Eiseler et al. 2009).

PKD in Human Disease

The in vivo functions for PKD enzymes are not well understood. So far, best studied are the roles in cardiac failure, immune cell function and cancer, although the exact contributions of the three PKD isoforms are still ill-defined.

Role of PKD in coronary heart disease – coronary heart disease is associated with cardiac hypertrophy, which precedes cardiac failure. Cardiac hypertrophy can be mediated by altered expression of genes regulating myocyte contraction, cell metabolism or calcium homeostasis. The transcription of such genes is regulated by histone acetylation processes. PKD1 was shown to negatively regulate the function of histone deacetylase (HDAC) enzymes resulting in increased transcriptional activity of genes that have been linked to mediating hypertrophy in mycocytes (Vega et al. 2004).

Role of PKD in immune cells – PKD is activated after immune cell receptor stimulation. This includes the activation of mast cell receptors and B-cell and T-cell receptors and suggests potential roles for PKD enzymes in mediating diverse immune responses. However, the roles of PKD isoforms in regulating immune functions in vivo are not well defined. Recently, the analysis of knock-in and knock-out animal models demonstrated that PKD2 has a major role in regulating antigen receptor induced cytokine production and T-cell dependent antigen responses in vivo.

Role of PKD in cancer – The functions of PKD enzymes in cancer range from tumor initiating events including increased DNA synthesis, proliferation and survival signaling to events regulating tumor cell progression such as angiogenesis (Wang 2006). Moreover, PKD is activated by tumor-promoting phorbol esters and activating phosphorylations are mediated by PKCs, Src, and Abl, all kinases that previously have been implicated in various functions in cancer. Therefore, on first view PKD represents a *bona fide* oncogene. However, the role of PKD in processes regulating tumor cell migration and invasion are not well understood. Accumulating reports suggest that PKD1/2 activation suppresses and PKD3 increases directed cell migration and tumor cell invasion (Sanchez-Ruiloba et al. 2006; Eiseler et al. 2009). Moreover, converse results were obtained regarding the function of PKD1 in regulating cell migration in epithelial or endothelial cells and it is possible that the effect of PKD1 on cell motility is cell type and cancer type dependent. Additionally, epigenetic silencing of PKD1 occurs in invasive breast or gastric cancers at the transcriptional levels through methylation of a CpG island in its promoter (Kim et al. 2008). This suggests that PKD1 expression may be needed for early tumorigenic events, but is down-regulated during metastatic progression.

Summary

Although intensively investigated since over 15 years, the in vivo roles of PKD enzymes are still unclear. Most of the knowledge on PKD signaling bases on cell culture experiments performed on PKD1. Because of their potential role in human cancer PKD signaling molecules gained increasing interest as chemotherapeutic targets. However, it remains obscure if these strategies will be effective for invasive cancers since PKD enzymes in some cancers may inhibit the

migration and invasion of cancer cells at multiple levels, in other cells may have a promoting function for these processes. In animals adult tissues often show co-expression of the different PKD isoforms and functional redundancy between the family members has been described, but is not always the case. PKD1 and PKD2 are the most closely related mammalian PKD isoforms with an approximately 86% overall identity at the amino-acid level. Within recent years it became apparent that both share common regulatory mechanisms and have redundant functions to some stimuli and unique or even converse functions in response to others. In cancer this becomes most apparent. For example, PKD1 contributes to early events leading to epithelial tumor cell proliferation and survival, but is also a negative-regulator of cell invasion. On the other hand PKD3 seems to facilitate metastatic progression. In other diseases such as cardiac hypertrophy, where all three PKD isoforms seem to have overlapping functions, the use of PKD-specific inhibitors may be more effective.

PKR

Anthony John Sadler
Centre for Cancer Research, Monash Institute of Medical Research, Monash University, Clayton, VIC, Australia

Synonyms

Double-stranded RNA-activated protein kinase; EIF2A protein kinase 2; Interferon-inducible eIF2α kinase; Interferon-inducible RNA-dependent protein kinase; P1/eIF2A protein kinase; p68 kinase, dsRNA-activated inhibitor (DAI); Protein kinase interferon-induced double-stranded RNA-activated (PRKR); Protein kinase RNA-activated (PKR)

Historical Background

Control of protein translation is a universal checkpoint that enables eukaryotic cells to respond to environmental challenge. Accordingly, it had been noted that virus infection halted host protein synthesis, and it was established that viral double-stranded (ds) RNA provoked this effect. A protein kinase, now designated PKR, was identified which phosphorylated the translation initiation factor 2α that accounted for this effect. It was subsequently demonstrated that this kinase was induced by interferon (IFN), establishing this enzyme as an effector molecule for the central antiviral response. It was subsequently shown that stimuli besides dsRNA activate, and conversely, inhibit PKR. The transcript cDNA was cloned and the genetic locus was identified (on human chromosome 2p21 and mouse chromosome 17, band E2), and its regulatory promoter elements described. It was shown that the gene (EIF2AK2) was induced by responses other than IFN. Generation of transgenic mice mutated for the enzyme cemented the function of PKR as an antiviral protein. Moreover, analysis of cells from these transgenic mice identified that PKR acts as a cell-signaling molecule that regulates inflammatory responses. Additional protein substrates, besides eIF2α, have subsequently been identified. The precise mechanisms by which PKR affect cell signaling and the biological consequences of this function are still emerging.

PKR, Table 1 Proteins that interact with PKR as regulators of the kinase's activity, as substrates, or that are not directly phosphorylated but participate in cell-signaling associations are listed. Each protein and their abbreviations are described in the text

Regulators	Substrates	Cell-signaling integrators
PACT	eIF2α	TRAF2
Caspase-3	RHA	TRAF3
Caspase-7	ILR3	TRAF5
Caspase-8	B56α	TRAF6
TARBP2	IRS1	STAT1
MRPL18	MAP2K6	STAT3
METAP2	NPM1	TIRAP
DNAJC3	SPNR	IKK-α/β
PKRKIR		MAP3K5
PPP1C		MAP3K7
HSP70		TAB2
HSP90		FANNC
PKRKIP1		PTEN

The PKR Protein Network

Cellular proteins that have been reported to interact with PKR to convey cell signals are listed in Table 1. These interactions fall into three functional categories in which the interacting proteins modify the activity of PKR, are substrates for the kinase, or are regulated by PKR without being directly phosphorylated. These relationships are not mutually exclusive, as some proteins that modify the activity of PKR are also substrates for the kinase.

PKR Regulators

Three nonprotein ligands for PKR have been identified. Relief of steric hindrance between the N-terminal RNA-binding and C-terminal kinase domains activates

PKR. Accordingly, dsRNA, single-stranded RNA with secondary structures and specific features, such as 5'triphosphate moities, bind to the N-terminal RNA-binding motifs (RBMs) to activate PKR. RNA with these features is characteristic of virus replication. In addition, some endogenous mRNAs are also competent to activate PKR by virtue of specific structural motifs. A second activating ligand is heparin oligosaccharide. Heparin with eight or more sugar residues associates with residues within the protein's kinase domain to relieve autoinhibition. The third PKR non-protein ligand is the nucleotide adenosine triphosphate (ATP). As for other protein kinases, ATP binds PKR within the protein's kinase-fold that is formed between sub-domains (designated the N- and C-lobes) within the kinase domain. PKR has been demonstrated to respond to other nonprotein ligands, for instance lipid molecules such as ceramide, but the mechanisms of these interactions are not well characterized and appear to be indirect. The remaining regulators of PKR are proteins.

PKR is cleaved at the asparagine residue number 251 between the two structured domains of PKR by caspases (caspase-3, -7, and -8) (Saelens et al. 2001). This cleavage relieves autoinhibition by separating the N- and C-termini of the kinase. Caspase cleavage has been demonstrated to generate a constitutively active truncated kinase, as well as advancing activation of the full-length protein.

The PKR protein activator (PACT) binds directly to activate PKR (Patel et al. 1998). Extensive biochemical analysis of this protein interaction has identified residues within the C-terminal RBM as being crucial to disrupt RBM-mediated autoinhibition of PKR. Although not phosphorylated by PKR, PACT must first be phosphorylated by another kinase before activating PKR. Other stress signals lead to activation of PACT that subsequently activates PKR. The activation residue in PACT (serine 18) constitutes a putative phosphorylation motif for mitogen-activated kinases. Accordingly, PKR's response to stress stimuli, such as hydrogen peroxide and the sphingolipid ceramide, appears to be mediated by PACT-dependent activation.

In keeping with the mechanism of RBM-mediated autoinhibition, a number of other proteins containing RBMs interact to inhibit PKR. The transactivation response RNA-binding protein-2 (TRBP2), which encodes three RBMs, inhibits PKR (Park et al. 1994). The adenosine deaminase acting on RNA-1 (ADAR1), which encodes two RBMs, interacts with and inhibits PKR (Toth et al. 2006). Furthermore, the dihydrouridine synthase 2-like (DUS2L) protein, which catalyzes the reduction of uridine residues on the displacement loop of transfer RNA, interacts with PKR to repress its activity (Mittelstadt et al. 2007). Additional proteins that encode RBM have been demonstrated to bind to PKR, such as the protein-coded DRBP120, but the role of these proteins and so the consequence of this interaction is unknown.

Formation of the active dimeric PKR enzyme proceeds by autophosphorylation, and so, the enzyme can be repressed through dephosphorylation. Accordingly, the protein phosphatase-1 (PPP1C) has been demonstrated to inhibit PKR (Tan et al. 2002). Other PKR inhibitors are: the PKR-interacting protein-1 (PKRIP1) (Yin et al. 2003); the mitochondrial ribosomal protein L18 (MRPL18) which sequesters the kinase to the ribosome (Kumar et al. 1999); and in a somewhat similar mechanism, the methionine aminopeptidase-2 (METAP2) also inhibits PKR to prevent translational inhibition (Gil et al. 2000). In addition, two cytosolic chaperones, the heat-shock proteins (HSP) 70 and 90, regulate PKR (Donze et al. 2001). The association with HSP70 mediates an observed interaction between PKR and mutant Fanconi anemia proteins (directly with the complementation group C protein, FANCC). A co-chaperone of HSP70, DNAJC3 (or P58(IPK)), also acts as a PKR inhibitor (Polyak et al. 1996). Interestingly, DNAJC3 is itself regulated by a repressor, PKRIR (or p52(rIPK)) that competes with PKR for binding to DNAJC3 (Gale et al. 1998).

PKR Substrates

PKR is a serine, threonine and, less accepted, a tyrosine protein kinase. The best-described PKR substrate is the α subunit of the eukaryotic initiation factor (eIF2α). Phosphoryation of the serine residue 51 on eIF2α arrests translation of cap-dependent transcripts (Farrell et al. 1977). Importantly, this translational block is not complete, and a number of transcripts escape repression by virtue of specific structures in the 5'untranslated region of their mRNA. Prominent among these escape transcripts are the activating

transcription factors (ATFs), with the best example being the induction of ATF4. Biological processes regulated by ATF4 include redox processes, mitochondrial function, and secretory pathways regulated by protein chaperones and lipid synthesis machinery. In this way, eIF2α phosphorylation, with subsequent ATF4 induction, elicits a manifold response to mitigate stress. Hence, eIF2α phosphorylation is generally considered a protective response. This contradicts many of the proposed functions determined in vitro that supposes a mainly pro-inflammatory role for PKR.

The consequence of PKR's regulation of other substrates is less well established as the functions of the protein substrates themselves, or the consequences of specific modified residues involved are poorly characterized. The various substrates are discussed below.

Nucleoplasmin family member-1 (NPM1) is a PKR substrate (Pang et al. 2003). The specific residues phosphorylated by PKR have not been identified. NPM1 is a highly phosphorylated protein, with at least two other kinases demonstrated to modify the protein. NPM1 has been ascribed a broad range of functions. Relevant to translational control, NPM1 has been demonstrated to mediate ribosomal protein assembly. Aberrant expression of NPM1 has been observed in numerous human malignancies. Although PKR-dependent effects on NPM1 function have not been identified, NPM1 has been shown to inhibit PKR.

Phosphorylation of B56α by PKR has been demonstrated to inhibit this substrate (Xu et al. 2000). As a consequence, PKR promotes the activity of the protein phosphatase 2 catalytic subunit (PP2A) that is controlled by B56α. As PP2A is a significant modulator of global phosphorylation, PKR-dependent control of its regulatory subunit is undoubtedly of biological significance. However, control of PP2A activity is complex with multiple regulatory factors involved besides B56α. Moreover, there are three other cytosolic serine/threonine phosphatases, in addition to PP2A, that have a degree of overlapping substrate specificity. Hence, it is difficult to discern the specific effects of PKR's regulation of B56α.

The mitogen-activated kinase MAP2K6 is reportedly phosphorylated by PKR (Silva et al. 2004). Regulation of MAP2K6 was proposed as the mechanism by which PKR affects the downstream mitogen-activated kinase MAPK14. However, the consequence of PKR-dependent control of MAP2K6 is unclear as the residues phosphorylated did not encompass conserved residues that regulate kinase activity.

PKR has also been reported to phosphorylate the tumor suppressor ▶ p53 at the serine residue 392 (Cuddihy et al. 1999). This is potentially very interesting because of the manifold responses regulated by p53. Phosphorylation of the 392 residue is dispensable for activation of p53 target genes. Consequently, PKR-dependent phosphorylation can only affect transactivation-independent p53 pathways. Modification of this residue has been shown to affect the stability of p53 by enhancing protein oligomerization. This appears to only be of consequence for the mis-folded mutant p53 as modification of the 392 site has not been shown to alter the stability of the wild-type protein. Hence, PKR could regulate nonspecific binding of mutant p53 to DNA structures associated with DNA repair and recombination. Phosphorylation at serine 392 has been correlated with tumor development, and so, PKR-dependent control of p53 may contribute to tumor progression.

It has recently been asserted that the insulin receptor substrate-1 (IRS1) is a substrate of PKR (Nakamura et al. 2010). The IRS1 serine residue 307 is modified by PKR, though this appears at odds with the role of PKR proposed in the study that identified IRS1 as a substrate. It was contended that PKR induces insulin resistance. However, analysis of transgenic mice with a point mutation of the 307 residue of IRS1 demonstrated that phosphorylation control of this site maintains insulin sensitivity. Interestingly, in light of PKR's regulation of PP2A, the okadaic acid inhibitor of PP2A stimulated the mammalian target of rapamycin (▶ mTOR)-dependent phosphorylation of the serine 307 residue on IRS1. Consistent with this, the rapamycin inhibitor of mTOR reduced 307 phosphorylation on IRS1. PKR has been demonstrated to influence the downstream effects of a second phosphatase that influences insulin signaling, the phosphatase, and tensin homolog deleted from chromosome 10 (▶ PTEN). Translational control in response to PTEN is diminished in PKR-null cells. Hence, it appears as if PKR is activated in PTEN-dependent signaling. These effects were independent of PTEN's effects on phosphoinositide 3'-kinase (PI3K). Coincidentally, PTEN has also been shown to dephosphorylate IRS1.

Hence, two other potential mechanisms exist, in addition to the proposed direct phosphorylation, by which PKR might regulate insulin signaling.

Activation of PKR is mediated by autophosphorylation at some 15 residues. Among the autophosphorylation sites identified are residues within the N-terminal RBMs of PKR. This establishes the RBM as a protein substrate. Fittingly, a number of other proteins that share the RBM have been identified as substrates. PKR phosphorylates the RNA helicase A (RHA) within the RBM (Sadler et al. 2009). This phosphorylation inhibits the helicase's association with its nucleic substrates. The interleukin factor-3 (ILF3) is similarly phosphorylated within its RBMs (Langland et al. 1999). The consequence of this phosphorylation has not been identified. In addition, PKR associates with the spermatid perinuclear RNA-binding protein (STRBP). Although not reported as a substrate of PKR, STRBP was identified as being phosphorylated, at serine residues within the two RBMs, in cell culture. All three of these RBM-containing proteins (RHA, ILF3, and STRBP) have been demonstrated to inhibit PKR activity.

Non-substrate Protein Interactions with PKR

Investigation of PKR-dependent cell signaling in vitro has principally been proposed to promote inflammation. PKR participates in cell signals initiated from a variety of receptors that include toll-like, interleukin-1, platelet-derived growth factor (PDGF), IFNγ, and the tumor necrosis factor-α (▶ TNFα) receptors. Through these receptors, PKR modulates the activity of a number of transcription factors. The mechanism(s) by which PKR is integrated into these diverse signaling pathways has not been categorically established. The currently favored mechanism involves association with the TNF receptor-associated factors (TRAFs). PKR encodes two TRAF-binding motifs within each of its structured domains. TRAF factors act as adaptor proteins and ubiquitin ligases. Through this activity, these proteins shape signaling complexes and regulate the stability of the protein components. Dependence upon TRAFs for PKR-dependent control correlates with the transcription factors activated: nuclear factor-κB (▶ NF-κB), c-jun, the signal transducers and activators of transcription (STAT) 1 and 3, and IFN-regulated factor-1 (IRF1). Furthermore, the association with TRAFs could account for other reported associations between PKR and signaling proteins: the I-κB kinases (IKKα and β), mitogen-activated protein kinase kinase kinase-7 (MAP3K7, or TAK1), TAK1-binding protein-2 (TAB2), the toll/interleukin-1 (TIR) domain containing adaptor protein (TIRAP), and the mitogen-activated protein kinase kinase kinase-5 (MAP3K5, or ASK1). Through the association with TRAFs, it is asserted that PKR modifies other components of the signaling complex. Two alternatives have been proposed, by which PKR either modifies signaling components by phosphorylation, or alternatively, may act merely as a scaffold protein independent of its kinase activity. This latter point has support from experiments that have shown that a kinase-dead PKR mutant is competent to activate the NF-κB transcription factor.

Mediation of PKR-dependent cell signaling by TRAFs is attractive as it offers a common explanation for diverse activities of PKR. However, it remains possible that PKR mediates these effects through direct interaction with the separate components, through as yet unidentified interactions, or that alternative adaptors regulate some or all of these effects. As an instance of the latter case, the interaction with HSP90 presents a potential mechanism that could account for many PKR-dependent cell-signaling events. Like TRAFs, HSP90 interconnects with many of the pathways PKR is reported to regulate. HSP90 interacts with the NF-κB regulatory complex, STATs, and p53. As HSP90 has been demonstrated to inhibit PKR, this interaction may support the contention that kinase activity is irrelevant in some PKR-dependent cell-signaling processes. HSP90 has been demonstrated to associate with a large number of other kinases, and so, has been suggested as a general regulator of the kinome.

Summary

In this entry, the endogenous protein interactions and the cell-signaling functions of PKR have been catalogued. The first recognized function of PKR, to combat viral infection, has not been discussed here. It is frequently written that the significance of PKR in the antiviral response is evident by the numerous viral inhibitors that target PKR. It is evident from this discussion that a number of endogenous proteins exist to regulate PKR activity. Hence, this might also be taken

to indicate the significance of PKR-mediated cell signaling. Accordingly, PKR has been shown to respond to stress signals other than dsRNA, and has been shown to phosphorylate additional protein substrates besides eIF2α. Moreover, PKR may modulate cell-signaling pathways independent of its kinase activity. Combined, these observations suggest a more complex regulation and a broader function for PKR than merely in the innate immune response to viral infection that remains to be clarified.

Synonyms

Plasma membrane Ca^{2+} ATPase; Plasma membrane Ca^{2+} pump; PMCA

Historical Background

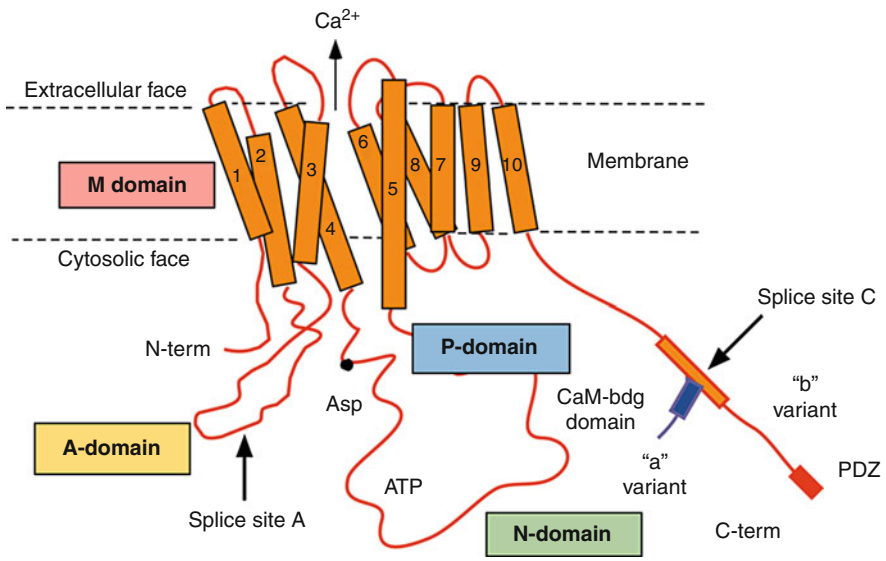
The existence of a plasma membrane calcium-transporting ATPase (PMCA) that actively pumps Ca^{2+} ions out of the cell was first demonstrated in erythrocyte (red blood cell) membranes by Schatzmann (1966). Because of its generally low abundance and difficult biochemical properties, it took over a decade until the PMCA was first isolated in purified form. Crucial for the successful purification was the discovery that the PMCA binds with high affinity, and in a Ca^{2+}-dependent manner, to the Ca^{2+} sensor protein calmodulin (Niggli et al. 1979). Subsequent work showed that at least one type of plasma membrane Ca^{2+} ATPase is found in all eukaryotic cells including those from fungi, animals, and plants (Axelsen and Palmgren 1998; Thever and Saier 2009). It is now well established that active Ca^{2+} expulsion by the PMCAs is an essential component of eukaryotic cellular Ca^{2+} handling. Although PMCAs were originally thought to be required mainly for the "housekeeping" function of maintaining and resetting the low intracellular free $[Ca^{2+}]$ levels, recent studies have shown that these pumps are also active participants in global and local Ca^{2+} signaling.

General Structure and Isoforms

PMCAs belong to the large superfamily of P-type ion-transporting ATPases, where they are classified as IIB subfamily (Axelsen and Palmgren 1998) or family 2 in the IUBMB transporter classification system (Thever and Saier 2009; see www.tcdb.org). The characteristic feature of P-type ATPases is the formation of an obligatory phosphorylated intermediate during the reaction cycle (Pedersen and Carafoli 1987). The PMCA consists of a single polypeptide, which in vertebrates contains about 1,200 amino acids and has a molecular mass of about 140 kDa. The protein has 10 membrane-spanning segments, and both the N- and the C-terminal ends are facing the cytosol. Most of the protein mass is on the cytosolic side of the membrane, only short loops connecting pairs of transmembrane segments are facing the extracellular side. Figure 1 schematically illustrates the domain arrangement of the PMCA in a 2-dimensional model.

The cytosolic loops between transmembrane segments 2 and 3 and between transmembrane segments 4 and 5 are large and contribute the bulk of the mass to the so-called A (actuator) and N/P (nucleotide-binding/catalytic phosphorylation) domains, respectively. In animal PMCAs, the C-terminal tail following the last membrane-spanning segment is about 150 residues long and contains the auto-inhibitory regulatory sequences and the high-affinity calmodulin-binding domain. In contrast, in several plant PMCAs, the calmodulin-binding and auto-inhibitory regulatory domain are instead found in the extended N-terminal tail. The three-dimensional structure of the PMCA has not yet been solved in atomic detail, but based on the high conservation of secondary structure elements (including the 10 transmembrane helices and the functionally important A, N, and P domains), the general structure of the PMCA is thought to be very similar to that of the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA), for which several high-resolution x-ray structures are available (Toyoshima 2009).

Mammalian PMCAs are encoded by four separate genes, which give rise to PMCA isoforms 1–4. The human genes (gene symbols ATP2B1-ATP2B4) are located on chromosomes 12q21.3, 3p25.3, Xq28, and 1q32.1, respectively, whereas the orthologous mouse genes (Atp2b1-Atp2b4) are on chromosomes 10C3, 6E3, XA7.3, and 1E4. The RNA transcripts of all genes are subject to complex alternative splicing, resulting in over 30 possible PMCA splice variants. The two major sites (sites A and C) where alternative splicing affects the PMCA protein structure are indicated in Fig. 1. Figure 2 shows a scheme of the resulting splice variants found in mammalian PMCAs. The two major splice variants generated at



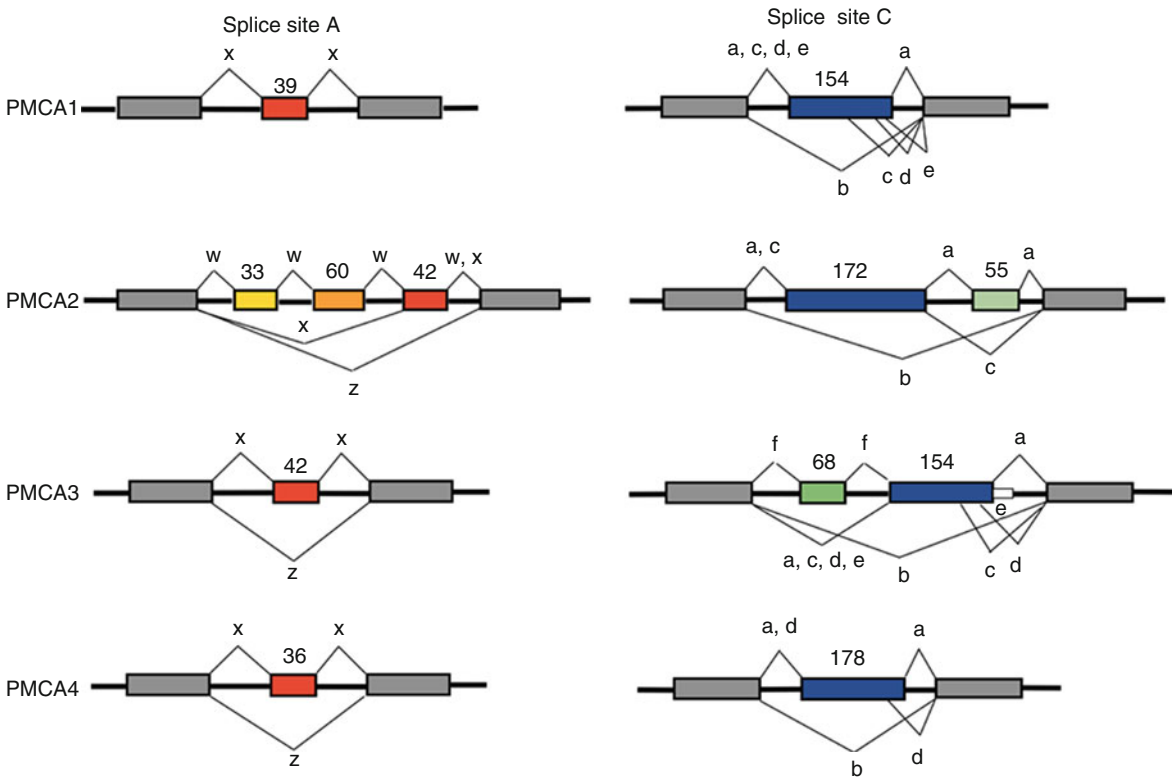
Plasma Membrane Calcium-Transporting ATPase, Fig. 1 Scheme of the plasma membrane Ca^{2+}-transporting ATPase, showing major domains and sites affected by alternative splicing. The 10 membrane-spanning regions are numbered and shown as cylinders forming the M domain. The amino- (N-term) and carboxy-terminal ends (C-term), the conserved aspartate (Asp) residue undergoing phosphorylation during the reaction cycle, and the ATP binding site (ATP) are labeled. The direction of Ca^{2+} transport is indicated by an arrow. The three main cytosolic domains are labeled A (actuator), P (phosphorylation), and N (nucleotide-binding). Splice sites A and C are indicated by *arrows*. Splicing at site C affects the calmodulin-binding (CaM-bdg) domain and results in major splice variants "a" and "b," which differ in their C-terminal amino acid sequence. The "b" splice variants contain a C-terminal PDZ-binding motif, which is missing in the "a" variants

site C are "a" and "b"; they differ significantly in their C-terminal tails because of a change in the open reading frame introduced by the splice. In contrast, splice variants generated at site A ("w," "x," "y," "z") contain different peptide insertions in the first cytosolic loop, but otherwise retain the same reading frame. Alternative splicing affects the cellular targeting and the regulatory and functional properties of the different PMCA isoforms, and thus plays an essential role in the dynamic regulation of Ca^{2+} signaling in cell physiology (Strehler and Zacharias 2001).

Regulation and Functional Properties

The basic function of the PMCA is to catalyze the "uphill" transport of Ca^{2+} ions across the membrane. PMCAs couple the hydrolysis of one molecule of ATP to the transport of 1 Ca^{2+} ion across the membrane. They are high-affinity, but low capacity, Ca^{2+} transporters with a maximal turnover number of ~100/s (Brini and Carafoli 2009). Their general reaction mechanism is conveniently described by the E1–E2 scheme (Fig. 3), in which the pump toggles between two major conformational states E1 and E2. Thus, transport of a Ca^{2+} ion from the intracellular (cytosolic) side to the extracellular side of the membrane is accompanied by large conformational changes in the PMCA. These are a result of the reactions taking place at the intracellular ATP binding and phosphorylation site (where the γ-phosphate of ATP is transferred to an invariant Asp residue), which are coupled to rearrangement of the membrane-spanning domain of the PMCA. The positive charge transfer resulting from the transport of Ca^{2+} across the membrane is at least partially compensated by countertransport of protons (H^+). Accordingly, the PMCA is sensitive to pH, with alkaline pH in the extracellular milieu having an inhibitory effect.

At low intracellular [Ca^{2+}] (<50–100 nM), the PMCA is inactive and present in an auto-inhibited conformation in which the C-terminal tail makes intramolecular contacts with the A- and N-domains. Upon a rise in [Ca^{2+}] the PMCA is activated, and this activation is accelerated and enhanced by Ca^{2+}-calmodulin, which binds to the auto-inhibitory tail and releases

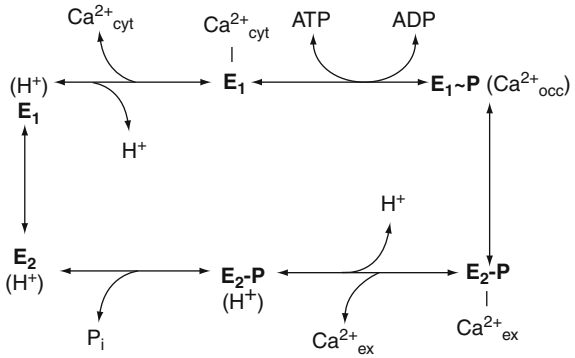


Plasma Membrane Calcium-Transporting ATPase, Fig. 2 *Alternative splicing options of human PMCA isoforms 1–4 at splice sites A and C*. The exon structure of the region involved in alternative splicing is shown for each of the four PMCA genes. Constitutively spliced exons are shown as *gray boxes*. The sizes of alternatively spliced exons (different shades of *gray*) are given in nucleotides, the splice options are indicated by connecting lines, and the resulting splice products are labeled by their lowercase symbol. Note that in PMCA1, only splice option "x" has been detected, and that in PMCA3, splice variant "e" results from a read-through of the 154-nt exon into the adjoining intron (indicated as *thin white box*). Combinatorial use of the splice options at sites A and C results in over 30 possible PMCA splice variants

the inhibition. The effect of calmodulin thus is to shift the apparent Km(Ca^{2+}) for activation of the PMCA to lower [Ca^{2+}] (0.2–0.5 μM). Different isoforms and splice variants of the PMCA vary significantly in their calmodulin affinity and the speed with which they are activated. This is of physiological significance as "fast" PMCAs (such as PMCA2b and PMCA3f) are generally found in "fast" cells (muscle, nerves) requiring rapid Ca^{2+} clearance after a spike. PMCAs are also regulated by acidic phospholipids such as phosphatidylserine and phosphatidylinositol, dimerization (oligomerization), phosphorylation on Ser/Thr residues in the regulatory tail, partial proteolysis of the auto-inhibitory tail by ▶ calpain, as well as by specific protein interactions with regulatory proteins and the cytoskeleton (Strehler et al. 2007; Brini and Carafoli 2009). Multiple other regulatory interactions have also been demonstrated for various PMCA isoforms with proteins such as 14-3-3ε, calcineurin A, RASSF1, α-1 syntrophin and an increasing list of signaling, trafficking, and anchoring proteins containing PDZ (PSD95/Dlg/ZO-1) domains. A summary scheme listing currently known PMCA-interacting proteins is shown in Fig. 4. It should be noted that several of these proteins interact specifically with some, but not all PMCA isoforms and splice variants. For example, the a-splice variants of the PMCA lack a canonical PDZ-binding sequence motif at their C-terminus and are therefore unable to engage in PDZ domain-mediated interactions with other proteins.

Tissue and Subcellular Expression

All tissues and cells express at least one isoform of the PMCA; however, multiple PMCA isoforms and splice variants are often found in the same cell. During



Plasma Membrane Calcium-Transporting ATPase, Fig. 3 *Reaction scheme for the plasma membrane Ca^{2+}-transporting ATPase*. The PMCA assumes two major states E1 and E2. E1 has high affinity for Ca^{2+} on the cytosolic side (Ca^{2+} cyt). Ca^{2+} binding stimulates the ATPase activity of the pump, resulting in the phosphorylation of a conserved Asp residue and formation of the phosphorylated intermediate (E1∼P), as well as occlusion (occ) of the bound transport Ca^{2+} ion. The Ca^{2+} ion is translocated across the membrane and the stored energy is released during the conformational transition from the E1∼P to the E2-P state. The Ca^{2+} affinity of the E2-P state is low and Ca^{2+} dissociates on the extracellular side of the membrane (Ca^{2+} ex). Hydrolysis of the phosphoenzyme E2-P and conformational rearrangement of the E2 to the E1 state complete the cycle. The positive charge movement during Ca^{2+} transport is at least partially compensated by countertransport of protons (H^+)

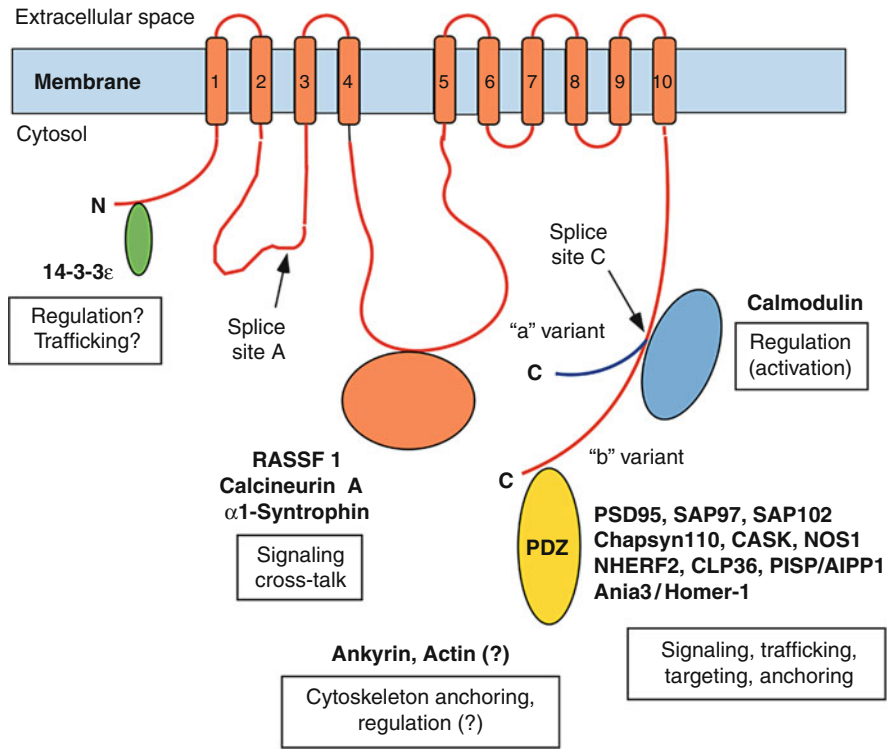
(mouse) embryonic development, PMCA1 (splice variant 1x/b) is detected from the earliest time points studied and is expressed in most tissues throughout life. PMCA1 is thus considered a "housekeeping" PMCA isoform, although this only applies to splice variant 1x/b. PMCA1x/a and 1x/c are much more restricted in their expression and are mainly found in differentiated neurons and skeletal muscle cells. PMCA4x/b is also fairly ubiquitous, although there are large differences in PMCA4b expression among different tissues and cell types. By contrast, PMCAs 2 and 3 are almost exclusively found in excitable tissues including brain and muscle, as well as in secretory cells such as insulin-secreting pancreatic β-cells and lactating mammary epithelial cells (Strehler and Zacharias 2001). Some splice variants are highly specific for particular cells: PMCA2w/a, for example, is specifically and abundantly expressed in auditory and vestibular hair cells of the inner ear (Hill et al. 2006). Different PMCAs are often co-expressed in the same cell, where they are specifically targeted to distinct membrane compartments. This suggests that different PMCA isoforms fulfill distinct roles in global and local Ca^{2+} handling. In cochlear hair cells, for example, PMCA1x/b is expressed in the basolateral membrane where it is involved in maintaining the low resting level of Ca^{2+} in the cell soma. In the same cells, PMCA2w/a is highly concentrated in the apical stereocilia where it plays an important role in regulating $[Ca^{2+}]$ in the endolymph and modulating the function of the mechanotransduction channels.

Functions in Health and Disease

In cells such as human erythrocytes, where the PMCA is the sole Ca^{2+} export system, the pump is obviously essential for normal Ca^{2+} homeostasis and cell physiology. However, because of its low abundance in most plasma membranes and its low capacity (maximal turnover of about 100 Ca^{2+} ions per second), the PMCA is generally not well suited for handling high global Ca^{2+} loads such as those occurring with each heart beat in a cardiac muscle cell. Conversely, due to its very high Ca^{2+} affinity (Kd < 0.2–0.5 μM) in the activated state, the PMCA is the only Ca^{2+} export system capable of lowering intracellular $[Ca^{2+}]$ to the very low resting levels (∼100 nM) normally found in most cells. In terms of global cellular Ca^{2+} homeostasis, the expression of different PMCA isoforms and splice variants allows cells to finely tune and maintain the specific Ca^{2+} set point optimal for their physiological function.

In tissues involved in transcellular Ca^{2+} transport, the PMCA plays an essential role in normal physiology. In kidney and intestinal epithelial cells, PMCA localized in the basolateral membrane is important for the vectorial transport of Ca^{2+} from the apical (lumenal) to the basal (blood) compartment, and thus for Ca^{2+} reabsorption. As may be expected, in these tissues the expression and localization of the PMCA are under hormonal control by vitamin D3. Similarly, in the lactating mammary gland, the PMCA (isoform PMCA2w/b) is concentrated in the apical membrane of secretory epithelial cells and is essential for the export of Ca^{2+} into the (milk) lumen. Accordingly, female mice lacking PMCA2 produce Ca^{2+} deficient milk and their offspring are underweight (Reinhardt et al. 2004).

In addition to their roles in bulk vectorial Ca^{2+} transport, PMCAs are involved in the spatiotemporal control of Ca^{2+} signaling. Specific PMCA isoforms and



Plasma Membrane Calcium-Transporting ATPase, Fig. 4 *Proteins interacting with the PMCA, and their possible roles in PMCA regulation and function.* PMCA-binding proteins are schematically shown as gray ovals near the domain of the PMCA with which they interact. Known or suspected roles of these proteins in PMCA function, regulation, and signaling are indicated in boxes beneath the listed proteins. The PMCA is schematically shown on the top, with the membrane-spanning segments numbered 1–10, and the N- and C-terminal ends labeled N and C, respectively. The two major sites of alternative splicing are also indicated, and the two main splice variants "a" and "b" are shown with separate C-terminal tails to indicate their sequence divergence. Note that PDZ domain-containing proteins (PDZ) can only bind to "b-splice" variants of the PMCA, and that not all PMCA isoforms interact with all of the listed proteins. Ankyrin and actin may also interact directly with the PMCA, although the site of interaction has not yet been established

splice variants are targeted to plasma membrane subcompartments where they form multiprotein signaling complexes that control local Ca^{2+} signals ("Ca^{2+} signalosomes"). By influencing the amplitude and the time to recovery of locally evoked Ca^{2+} spikes, the PMCAs contribute to the decoding of Ca^{2+} signals and affect the frequency of Ca^{2+} oscillations. By reducing the spread of a local increase in Ca^{2+}, they help suppress signaling "noise," thereby increasing the fidelity and spatial resolution of Ca^{2+} signaling. Because of the pronounced differences in their kinetic and regulatory properties, different PMCA isoforms are adapted to handle very different Ca^{2+} signals ranging from slow, solitary Ca^{2+} waves to highly localized, high-frequency Ca^{2+} spikes such as those elicited at neuronal synapses. For example, specific PMCA2 splice variants play important roles in pre- and postsynaptic function such as in the regulation of excitatory synaptic transmission at hippocampal CA3 synapses or in short-term plasticity in cerebellar parallel fiber to Purkinje neuron connections. Deficiency of the corresponding PMCA leads to functional deficits such as impaired motor coordination (Huang et al. 2010). In general, other PMCA isoforms are unable to compensate for the deficiency in a specific isoform, supporting the notion of the highly defined functions that specific PMCAs assume in Ca^{2+} signaling.

Given its early expression during development and ubiquitous presence in all tissues, it is not surprising that PMCA1 ablation is embryonic lethal (Prasad et al. 2007). Heterozygous mice lacking one copy of the PMCA1 gene are phenotypically normal, although they do show physiological differences from the wild type such as an increased stimulated peak tension of

bladder smooth muscles. Deletion of PMCA2 leads to profound deafness, ataxia, and various other deficiencies such as a decrease of milk calcium (as already mentioned above), reduced visual responses from retinal bipolar cells, and spinal cord pathology (Prasad et al. 2007). Even single point mutations affecting the function of PMCA2 can cause significant hearing impairment, underscoring the importance of the unique concentration of PMCA2w/a in auditory hair cell function. Mutations in the PMCA2 (ATP2B2) gene are the only human PMCA mutations linked so far to inherited disease (hearing loss), although polymorphisms or mutations acting as modifiers of other inherited diseases are likely to be discovered in different PMCA genes in the near future (Brini and Carafoli 2009). In mice, knockout of the PMCA4 (Atp2b4) gene results in viable animals without gross abnormalities. However, males are infertile due to a defect in sperm hyperactivated motility, which is apparently dependent on PMCA4 normally concentrated in the sperm tail (Prasad et al. 2007). Lack or altered expression of PMCA4 also leads to changes in cardiac physiology, such as altered response to beta adrenergic stimulation and change in blood pressure, reinforcing the notion of the PMCA4 as an important signaling molecule rather than as general "sump pump" to remove global Ca^{2+} (Holton et al. 2010).

Considering the universal importance of Ca^{2+} signaling, it is no surprise that numerous diseases are characterized by altered expression of specific PMCAs. Major diseases that show distinct changes in PMCA isoform expression and activity (normally a decrease, but in some cases an overexpression) include diverse cancers, neurodegenerative disorders such as Alzheimer's and Huntington's disease, and diabetes (Lehotsky et al. 2002; Brini and Carafoli 2009). However, in most cases it is not clear whether aberrant PMCA expression is causative or reflects a secondary reaction to a different primary insult. Regardless, these findings suggest that targeting specific PMCAs may offer promising new strategies for intervention.

Summary

Plasma membrane Ca^{2+}-transporting ATPases (PMCAs) are essential components of the calcium signaling toolkit of eukaryotic cells. These membrane-embedded transporters couple the expulsion of 1 Ca^{2+} ion to the hydrolysis of 1 ATP, and attain maximal rates of about 100 Ca^{2+} transported per second. PMCAs are the major high-affinity Ca^{2+} export system dedicated exclusively to the export of Ca^{2+} from cells, and are essential for the maintenance of the steep $[Ca^{2+}]$ concentration gradient that is a prerequisite for the high specificity and fidelity of Ca^{2+} signaling. In mammals, four genes encode PMCAs 1–4; alternative RNA splicing augments the number of distinct isoforms to over 30. The PMCAs are highly regulated by multiple mechanisms including Ca^{2+}-calmodulin, acidic phospholipids, phosphorylation, oligomerization, and interactions with numerous signaling, targeting, and anchoring proteins. PMCA isoforms and splice variants show developmental, tissue- and cell type-specific expression, and are targeted to specific cell membrane compartments where they contribute to local Ca^{2+} handling. PMCA isoforms show characteristic differences in kinetic and regulatory properties, providing cells with many options to deploy specific PMCAs to distinct plasma membrane compartments with different Ca^{2+} signaling needs. Consistent with a role in local Ca^{2+} handling, deletion or mutation of specific PMCAs causes characteristic cellular defects. Deletion of the ubiquitously expressed PMCA1 results in embryonic lethality. In contrast, mice lacking PMCA4 are superficially normal but show altered cardiac stress responses and are male-infertile due to impaired sperm hyperactivated motility. Deletion or mutation of PMCA2 results in hearing loss, balance and vision defects, ataxia, spinal cord pathology, as well as reduced milk calcium, with the degree of severity depending on the level of remaining normal PMCA2. PMCAs are rapidly being recognized as major players in spatiotemporal Ca^{2+} signaling with specific involvement in diverse cell functions, and are potential targets for intervention in the treatment of various diseases linked to abnormal Ca^{2+} handling.

Historical Background

The *pkd2* gene encodes the protein polycystin-2, a member of the ▶ transient receptor potential (TRP) protein family. The genetic locus for *pkd2* was elucidated in 1993 by the Kumar and Spruit groups during the search for genes involved in autosomal dominant polycystic kidney disease (ADPKD) (Kimberling et al. 1993;

Peters et al. 1993). Mutations in *pkd2* account for approximately 15% of the ADPKD patients, with the remainder of ADPKD patients having mutations in *pkd1* or *pkhd1* (Koulen and McClung 2006).

Functionally, polycystin-2 has been implicated in Ca^{2+} release from intracellular stores (Koulen et al. 2002, 2005; Kaja et al. 2011). In conjunction with polycystin-1, polycystin-2 forms a receptor-calcium channel complex that is formed in the cilium of renal epithelial cells (Xia et al. 2010). In *C. elegans* both polycystin-1 and -2 are expressed in the primary cilia of sensory neurons (Barr and Sternberg 1999). These receptor-channel complexes respond to inputs such as mechano-sensation, receptor tyrosine kinases, and G-coupled-protein receptor complexes; and function to regulate diverse cellular processes such as differentiation and morphogenesis (Koulen and McClung 2006; Spirli et al. 2010; Zhou 2009; Montalbetti et al. 2007). Polycystin-2 localizes either to the endoplasmic reticulum (ER) or to the plasma membrane of primary cilia. This localization is dependent on cell type and the subcellular compartment in which polycystin-2 is expressed (Koulen and McClung 2006). However, expression of polycystin-2 has also been detected in the cytoplasm, and the apical and basolateral membranes in the kidney (Zhou 2009). Although mutations in polycystins 1/2 are most commonly associated with ADPKD, recent papers have shown functional genes are required for bone development, cardiac development, and left–right axis patterning (Tsiokas 2009; Xiao and Quarles 2010). Polycystin-2 functions in conjunction with other intracellular Ca^{2+} release channels as part of a positive feedback system during calcium-mediated signaling events (Kaja et al. 2011; Koulen et al. 2002, 2005; Koulen and McClung 2006). In adult mammals polycystin-2 is expressed in kidney, liver, spleen, lung, pancreas, ovary, testicular germ cells, Sertoli cells, corneal epithelium, retinal pigment epithelium, uterus, salivary glands, brain, adrenal cortex, epithelial cells of the GI tract, muscles (cardiac, vascular smooth, and skeletal), and bone (Koulen and McClung 2006; Xiao and Quarles 2010). Polycystins 1/2 function in cilia to sense mechanical shear stress, with bending of the cilia causing increased Ca^{2+} entry into the cell. Additionally, it has been shown that the actin cytoskeleton directly modulates polycystin-2 activity (Tsiokas 2009). Sharif-Naeini et al. showed the dosage dependence of polycystins 1/2 in cilia-mediated pressure sensing, further implicating the polycystin complex as a sensor of pressure and mechanical stress (Sharif-Naeini et al. 2009). In polycystin-2 knockout mice, endothelial cells could not sense fluid sheer stress, and were deficient in the production of nitrous oxide in response to increased blood flow (AbouAlaiwi et al. 2009).

Structure

Polycystin-2 is a membrane spanning protein with six transmembrane domains with both the N and C termini present in the cytoplasm (Tsiokas 2009). The polycystin-2 protein forms a voltage-dependent, calcium-dependent, large conductance calcium permeable nonselective cation channel (Koulen et al. 2002, 2005; Koulen and McClung 2006; Kaja et al. 2011). Polycystin-2 must interact with polycystin-1 to form a functional Ca2+ pore complex. The *Homo sapiens* pkd2 gene consists of 15 exons, that encode the polycystin-2 protein containing 968 amino acid residues (Miyagi et al. 2009). Residues 828–895 of the *H. sapiens* polycystin-2 protein form a coiled coil domain located at the C-terminus, and are required for this protein–protein interaction (Tsiokas 2009; Petri et al. 2010). Additionally the C-terminal tail of polycystin-2 contains an EF-hand domain (residues 720–797), with a linker (residues 798–827) between the coiled coil and EF-hand domains, and the EF-hand domain responsible for the calcium dependence of the pore complex (Koulen and McClung 2006; Petri et al. 2010). The N-terminal tail of polycystin-2 contains an RVxP motif that is responsible for localization of the protein to cilia (Geng et al. 2006).

Interactions with Ligands and Other Proteins

For review of ligand and protein interactions described before 2006, see Koulen and McClung, UCSD Nature Molecule Pages (2006). Polycystin-2 forms complexes with members of other transient receptor potential (TRP) channel families forming heteromultimeric channels with unique properties. The polycystin-2/TRPC1 is a G-protein-coupled activated channel that displays a conductance, ion permeability, and amiloride sensitivity different from channel properties of either protein alone in single channel experiments. The interaction of polycystin-2/TRPV4 in cilium

forms a thermo/mechano-sensitive sensor that effects flow induced Ca^{2+} transients in renal epithelium cells. α-actinin and polycystin-2 colocalize in Madin-Darby canine kidney (MDCK) epithelium cells, medullary collecting duct cells, NIH 3T3 fibroblasts, and human syncytiotrophoblast (hST) vesicles. In vitro electrophysiological recordings show that this interaction stimulates polycystin-2 channel activity (Zhou 2009). Polycystin-2 interacts with the inositol 1,4,5-trisphosphate receptor (IP_3R) through the acidic C-terminal domain of polycystin-2 and the N-terminal ligand domain of the ▶ IP_3R. The consequence of this interaction is increased Ca^{2+} release via IP_3 and other Ca^{2+} agonists (Sammels et al. 2010). Filamin A and polycystin-2 interaction is necessary for polycystin-2's inhibition of stretch activated channels (SACs) which have been implicated in mechano-sensation in kidney epithelium (Sharif-Naeini et al. 2009). Polycystin-2 acts to regulate the cell cycle by interactions between eIF2α, pancreatic ER-resident eIF2α kinase (PERK), and itself. Formation of the complex is necessary for PERK-mediated phosphorylation of eIF2α. Polycystin-2 also interacts with Id2, a member of the helix–loop–helix (HLH) protein family, whose expression suppresses p21 (Zhou 2009; Li et al. 2005). Trafficking of polycystin-2 from Golgi, ER, and the plasma membrane is achieved through phosphorylation of polycystin-2 by casein kinase 2, which regulates the interaction of phosphofurin acidic cluster sorting protein (PACS)-1 and PACS-2 with phosphorylated polycystin-2 protein. Phosphorylation of the N-terminus of polycystin-2 by glycogen synthase kinase 3 (GSK3) has been found to regulate the amount of polycystin-2 resident on the plasma membrane of MDCK cells. Finally degradation of polycystin-2 is regulated through its interaction with ATPase p97, HERP, and glucosidase subunit beta PRKCSH (Gao et al. 2010).

Function

Polycystin-2 is a member of the ▶ TRP channel family and along with polycystin-1(PC1) is linked to cyst formation in polycystic kidney disease. Polycystin-2 is located on the plasma membrane, endoplasmic reticulum membrane, and in cilia (Tsiokas et al. 2007). When located on the plasma membrane, polycystin-2 functions as a nonselective cation channel. Localization of polycystin-2 to the plasma membrane is tightly regulated by ER retention signaling and several chaperone proteins, including PC1. Epidermal growth factor has been shown to activate polycystin-2 in kidney epithelial cell lines, with increases in cytosolic calcium from extracellular, not intracellular, calcium sources (Zhou 2009; Tsiokas 2009). When localized to the ER, polycystin-2 acts as a calcium-induced calcium release channel (Koulen et al. 2002, 2005; Kaja et al. 2011). In addition, it modifies the function of other the ER calcium release channels, ▶ ryanodine receptor (RyR), and inositol trisphosphate receptor (IP_3R) (Zhou 2009; Tsiokas et al. 2007). The C-terminus of polycystin-2 associates with RyR2 and inhibits calcium release in cardiomyocytes and mouse renal epithelial cells. The C-terminus of polycystin-2 associates with the IP_3Rs and enhances the duration of calcium signaling (Sammels et al. 2010; Anyatonwu et al. 2007). Association with several actin and microtubule-associated proteins within the cell changes functional release by polycystin-2 channels, suggesting a role in cytoskeletal remodeling in response to both mechanical and osmotic pressure changes (Zhou 2009; Montalbetti et al. 2007). Cell cycle regulation is also implicated as another possible function of polycystin-2. Association with the Id family directly controls cell cycle regulation, and expression on mitotic spindles has been shown to affect calcium signaling during mitosis. Whether this effect is due directly to polycystin-2 or its interaction with mammalian Diaphanous 1 (mDia1) is not known (Zhou 2009; Tsiokas et al. 2007). In the cilium, association with TRPV4 allows cations to enter the cell in response to mechanical stimulation; and removal of either subunit abolishes this response (Zhou 2009; Tsiokas et al. 2007).

Summary

Mutations of pkd2 are responsible for 15% of APKD cases. However, due to the localization of polycystin complexes to cilia, and the broad expression of these proteins in various tissues, we should not overlook the role that mutations within these complexes may play in other disease processes such as Alzheimer's disease, glaucoma, and hypertension. The polycystin proteins act to integrate multiple inputs such as mechano-stress, G-protein coupled receptors, perturbation of the

cytoskeleton, and kinase cascades into calcium-mediated signaling events. Activation of the polycystin protein complex leads to a positive calcium feedback loop that affects the function and characteristics of other intracellular Ca^{2+} channels. Future research should be directed toward an examination of the regulatory elements that control induction and expression of the pkd2 gene as well as the regulatory posttranslational modifications that control the function, localization, and half-life of the polycystin protein. Researchers should also continue to identify ligands, cofactors, scaffolds, and other regulatory mechanisms in order to elucidate potential pharmacological targets for controlling diseases caused by mutated or mis-regulated polycystin-2 proteins.

Synonyms

Metal-dependent protein phosphatase; PPM; Protein serine/threonine-phosphatase 2C

Historical Background

Protein phosphatase 2C (PP2C) was first defined as magnesium (or manganese)-dependent Ser/Thr-specific dephosphorylation activity in mammalian tissue extract (Cohen 1989). This activity was also found to be resistant to okadaic acid, a potent inhibitor of Ser/Thr-phosphatases. Because of its cation dependency, PP2C is sometimes referred as PPM (protein phosphatase, magnesium or manganese dependent). Genes encoding PP2C were subsequently isolated from yeast to humans, revealing a conserved protein phosphatase family with no apparent sequence similarity to the other Ser/Thr-phosphatases such as PP1, PP2A, and PP2B. It is also notable that eukaryotic species have more genes encoding for PP2C than those for the other Ser/Thr-phosphatase families. For example, the budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*, have seven and six PP2C or PP2C-related phosphatase genes, respectively. The human genome contains at least 16 PP2C genes that express at least 22 isoforms by alternative splicing (Lammers and Lavi 2007). Genome projects in different organisms are rapidly identifying more PP2C genes, ten gens in the fruit fly *Drosophila melanogaster* and eight genes in the nematode *Caenorhabditis elegans*. A record-breaking number, 80, of PP2C-family genes have been identified in the popular plant model system *Arabidopsis thaliana* (Xue et al. 2008).

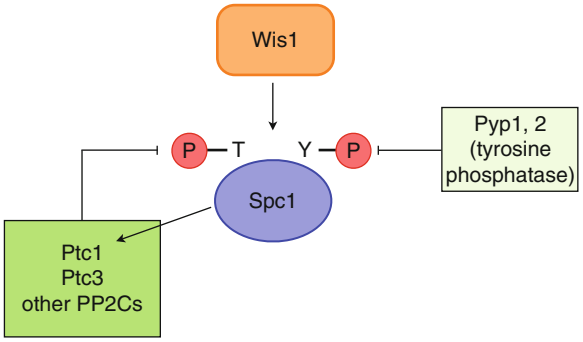
Despite the lack of apparent sequence similarity between PP2C and the PP1, PP2A, and PP2B families, the determined crystal structures of their catalytic cores share significant resemblance (Barford et al. 1998), suggesting a common catalytic mechanism. On the other hand, most PP2C enzymes are found to be monomeric, while PP1, PP2A, and PP2B usually require regulatory subunits for their activity/function. PP2C and PP2C-like enzymes are involved in many different biological processes in diverse organisms; in addition to eukaryotic PP2Cs, several metal ion-dependent phosphatases in bacteria also exhibit sequence similarities to PP2C enzymes (Hecker et al. 2007; Hilbert and Piggot 2004). Some of the well-characterized PP2C functions in eukaryotic signal transduction systems will be reviewed here.

PP2C Negatively Regulating the Stress-Activated MAPK

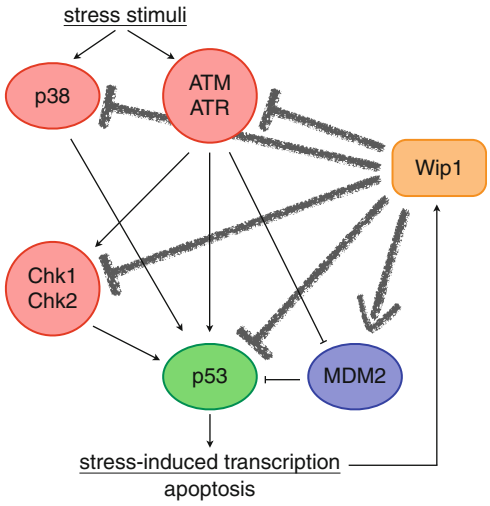
Because of the relatively broad substrate specificity of PP2C enzymes, it is not easy to search cellular substrates of PP2C through biochemical approaches. Genetic screens were instrumental to uncover important roles of PP2C in the negative regulation of the stress-activated MAP kinase (MAPK) cascades.

Two PP2C isoforms in budding yeast, Ptc1 and Ptc3, were identified in a screen for genes whose overexpression suppresses the lethality caused by hyperactivation of Hog1, a MAPK responsive to high osmolarity stress (Hohmann 2002). Studies in the fission yeast *S. pombe* found that loss of Ptc1 and Ptc3 brings about a defective phenotype which can be suppressed by inactivation of a Hog1-like Spc1 MAPK, implying hyperactivation of Spc1 in the absence of PP2C (Hohmann 2002). Indeed, the following biochemical studies in *S. pombe* showed that Ptc1 and Ptc3 inhibit Spc1 MAPK by dephosphorylating its Thr-171, one of the activating phosphorylation sites conserved in the T-loop of all MAPKs (Fig. 1). Furthermore, activation of Spc1 MAPK induces expression of Ptc1, indicating that Ptc1 is part of the negative feedback loop to suppress Spc1 activity. In budding yeast, Thr-174 of Hog1 MAPK, the equivalent of Spc1 Thr-171, is known to be the target of three PP2C enzymes, Ptc1, Ptc2, and Ptc3; Ptc1 dephosphorylates Thr-174 to maintain the low basal activity of Hog1 as well as to inactivate Hog1 during cellular adaptation to osmostress. Ptc2 and Ptc3 appear to limit the maximum activation level of Hog1 during the stress (Martín et al. 2005).

Also in mammals, PP2C enzymes are implicated in the negative regulation of the stress-activated MAPKs called p38 and JNK, through dephosphorylation of



PP2C, Fig. 1 Negative regulation of the stress MAPK by PP2Cs in fission yeast. In response to environmental stress, Wis1 MAP kinase kinase (MAPKK) phosphorylates Thr-171 and Tyr-173 in the T-loop of Spc1 MAPK. Activated Spc1 in turn phosphorylates the downstream transcription factor to induce stress-resistance genes as well as the PP2C gene encoding Ptc1. Dephosphorylation of Spc1 Thr-171 by Ptc1 or by constitutively expressed Ptc3 inactivates Spc1 MAPK. The other activating phosphorylation of Spc1 at Tyr-171 is removed by the Pyp1 and Pyp2 tyrosine-specific phosphatases



PP2C, Fig. 2 Negative regulation of the p53 pathway by Wip1 PP2C. Wip1 negatively regulates the p53 tumor suppressor pathway by dephosphorylating p53 and the protein kinases (*red*) that phosphorylate p53 in response to DNA-damaging stress. In addition, Wip1-dependent dephosphorylation of MDM2 promotes degradation of p53. Expression of Wip1 is induced by active p53, thus forming a negative feedback loop

their T-loop (Lu and Wang 2008). For example, Thr-180 in the T-loop of p38 is dephosphorylated by PP2Cα and PP2Cδ/Wip1 isoforms. Interestingly, p38 MAPK activated by UV stress phosphorylates the tumor suppressor ▶ p53, which induces transcription of Wip1. Thus, as seen with the regulation of the Ptc1 phosphatase in fission yeast, the p38-regulated transcription of Wip1 forms a negative feedback loop (Fig. 2). Moreover, not only MAPKs, but also MAPKKs (MKK3, 4, 6, 7) and MAPKKKs (ASK1, TAK1) that function upstream of p38 and JNK MAPKs are under the negative regulation by PP2Cα, β, and ε isoforms.

In *Arabidopsis*, two PP2C enzymes, AP2C1 and PP2C5, have been identified as negative regulators of the stress-activated MAPKs (Brock et al. 2010; Schweighofer et al. 2007). Environmental stress stimuli activate multiple *Arabidopsis* MAPKs such as MPK3, MPK4, and MPK6, to which AP2C1 and PP2C5 physically bind. Deletion of the *AP2C1* gene in the genome leads to higher activation of MPK4 and MPK6 upon wound stress. Simultaneous deletion of both *AP2C1* and *PP2C5* phosphatase genes induces extremely high activity of MPK3, 4, and 6 in response to the plant hormone abscisic acid (ABA). On the other hand, overexpression of either AP2C1 or PP2C5 represses the stress-activated MAPKs. Expression of AP2C and PP2C5 is significantly induced by wounding and ABA, respectively, implying a negative feedback mechanism. It has not been determined, however, whether the induction is dependent on the stress-activated MAPKs.

Wip1 (PP2Cδ) Negatively Regulating the p53 Tumor Suppressor

Amplification of the PP2Cδ/Wip1 gene is frequently detected in human breast tumors. In addition, PP2Cδ/Wip1 knockout mice are less prone to tumor formation, and fibroblasts derived from the mice are resistant to the transformation activity of oncogenes. Consistent with these observations, recent studies are unveiling the oncogenic activity of the PP2Cδ/Wip1 phosphatase, through inhibition of the p53 tumor suppressor by multiple means (Lu et al. 2008) (Fig. 2). As discussed in the last section, Wip1 dephosphorylates and inactivates p38 MAPK, an activator of p53. p53 is also a direct substrate of the Wip1 phosphatase; ionizing radiation and UV stress activate the ATM and ATR kinases that phosphorylate Ser-15 of p53 to induce apoptosis, while dephosphorylation of this residue by Wip1 suppresses apoptosis. The Ser-15 phosphorylation is also inhibitory to the interaction of p53 with MDM2, the E3 ubiquitin ligase involved in p53 degradation, and therefore, dephosphorylation of Ser-15 by Wip1 can destabilize p53. Moreover, Wip1 indirectly affects the stability and activity of p53

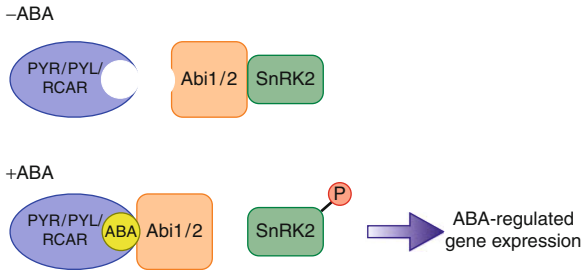
PP2C, Fig. 3 A schematic representation of the PHLPP domain structure

through dephosphorylation of MDM2 as well as inhibition of the ATM kinase that phosphorylates MDM2 (Fig. 2). The ATM-dependent phosphorylation of MDM2 at Ser-395 is removed by Wip1 to stabilize MDM2 and promote its interaction with p53 for increased ubiquitination and degradation of p53.

In the regulation of the p53 pathway discussed above, the Wip1 phosphatase counteracts the ATM and ATR kinases on two different substrates, p53 and MDM2 (Fig. 2). It has also been reported that Wip1 dephosphorylates the protein kinases Chk1 and Chk2 that are phosphorylated by ATR (Fig. 2). Consistent with these observations, Wip1 preferentially dephosphorylates Ser and Thr residues followed by Gln, the consensus sequence motif phosphorylated by the ATM and ATR kinases.

PHLPP, Atypical PP2C with Multiple Regulatory Domains

PHLPP (pleckstrin homology (PH) domain *l*eucine-rich repeat *p*rotein *p*hosphatase) was discovered by genome database search for human PP2C carrying the PH domain (Brognard and Newton 2008). While other PP2C proteins in humans are composed mostly of a catalytic domain, the PHLPP family members possess multiple regulatory domains, an N-terminal PH domain followed by approximately 20 leucine-rich repeats as well as a C-terminal PDZ-binding motif (Fig. 3). PHLPP exhibits PP2C-like protein phosphatase activity, but its catalytic domain lacks the two Asp residues crucial for placing the essential metal ions in the catalytic center of PP2C enzymes. PHLPP dephosphorylates the hydrophobic motif of the protein kinases Akt/PKB and PKC for catalytic inactivation and protein degradation, respectively. Dephosphorylation of Akt by PHLPP promotes apoptosis and suppresses tumor growth. PHLPP also removes the inhibitory phosphorylation of another kinase called Mst1 (*m*ammalian *st*e20-like kinase 1) to induce apoptosis (Qiao et al. 2010). A member of the PHLPP family, called PHLPP1β/SCOP, interacts with K-Ras through the leucine-rich repeats and down-regulates the Ras-Raf-► MEK-ERK pathway (Shimizu et al. 2010). However, it remains to be determined whether the phosphatase activity of PHLPP1β is required for the down-regulation.



PP2C, Fig. 4 Abscisic acid (ABA) signaling through the Abi1/2 PP2C. In the absence of ABA (-ABA), the Abi1/2 PP2C represses SnRK2 by removing the activating phosphorylation on SnRK2. In the presence of ABA (+ABA), the PYR/PYL/RCAR protein bound to ABA forms a complex with the Abi1/2 PP2C to repress its phosphatase activity, resulting in phosphorylation and activation of SnRK2. Active SnRK2 then induces gene expression through activation of the downstream transcription factors

Abi1/2 PP2Cs in Abscisic Acid Signaling in Plants

The *Arabidopsis thaliana* genome contains 80 PP2C genes, which can be classified into 13 subgroups based on the encoded amino acid sequences (Xue et al. 2008). The *Abi1/2* subgroup that functions in the abscisic acid (ABA) signaling (Cutler et al. 2010; Hubbard et al. 2010) has been most extensively characterized. ABA is a plant hormone that has multiple roles in the regulation of plant physiology, including seed dormancy, growth inhibition, and stomatal closure. PP2Cs in the Abi1/2 subgroup negatively regulate the ABA signaling, and mutations to the genes encoding Abi1, Abi2, and some other subgroup members result in ABA-hypersensitive phenotypes.

Recent attempts to discover the ABA hormone receptor successfully identified PYR/PYL/RCAR (*py*rabactin *r*esistance 1/*py*rabactin resistance 1-*l*ike/ *r*egulatory *c*omponent of *A*BA *r*eceptor) family proteins that directly recognize and bind ABA. The PYR/PYL/RCAR proteins belong to the START-domain superfamily, members of which are soluble proteins with a hydrophobic ligand-binding pocket flanked by two loop structures called the "gate" and the "latch." ABA binding to the open pocket closes the gate and locks the latch, creating a new interaction surface for

the Abi1/2 family PP2C (Fig. 4). When the PP2C binds to the ABA-PYR/PYL/RCAR complex, a Trp residue conserved among the Abi1/2 family PP2Cs is pulled to form a contact with ABA via a water molecule, stabilizing the ternary complex of ABA, the ABA receptor, and the Abi1/2 PP2C. The phosphatase activity of Abi1/2 is inhibited in this ternary complex. In the absence of ABA, however, the Abi1/2 PP2C released from the complex can dephosphorylate and inactivate the SNF1-related protein kinases SnRK2s (Fig. 4). Activated SnRK2s in turn phosphorylate and activate downstream transcription factors to induce ABA-regulated genes.

Summary

In eukaryotic species, protein kinases outnumber protein phosphatases. Therefore, PP2C and other protein phosphatases are likely to catalyze dephosphorylation of multiple protein substrates, but our knowledge is still very limited as to the in vivo substrates for each PP2C enzyme. Identification of a complete set of substrates for each PP2C is necessary for a comprehensive understanding of the contribution of the PP2C family enzymes to the cellular signaling network.

Most PP2C enzymes appear to be constitutively active and function as monomer. This is a stark difference from other protein phosphatase families such as PP1 and PP2A, which form multiple different complexes with non-catalytic subunits that determine their substrate specificities (Shi 2009). The PYR/PYL/RCAR family in plants is the first example of regulator proteins for PP2C and may represent a breakthrough in the PP2C field. It will be of great interest to test if other members of the START superfamily also function as regulators of PP2Cs.

PKNOX

Historical Background

PREP1 (named PKNOX1, Pbx/KNOX 1) was identified by Chen et al. (1997) in their effort to characterize genes mapping in the human chromosome 21. At the same time, PREP1 was identified as one of the components of the human transcription factor complex UEF3, urokinase enhancer factor 3. Prep1 was found to be a homeodomain-containing DNA-binding protein belonging to the TALE (Three Aminoacid Loop Extension) superclass, most closely related to TGIF (TGF β–induced factor homeobox) and Meis1 (Meis homeobox 1) and recognizing the TGACAG motif. Furthermore, it has been demonstrated that Prep1 heterodimerizes with Pbx, enhancing its affinity and DNA-binding specificity to include both the TGACAG and the TGATNNAT motifs (hence the acronym, for Pbx regulating protein 1) (Berthelsen et al. 1998).

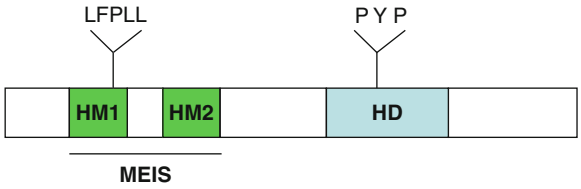
PREP2 was identified by Imoto et al. (2001) as a TALE homeodomain-encoding gene, located at 11q24 in the human genome.

Gene and Protein Structure

The human PREP1 gene maps on chromosome 21 (21q22.3) and covers 102.25 kb, from 43,225,370 to 43,327,616, on the direct strand. The cDNA coding for Prep1 contains a 126 -bp-long 5′-UTR (untranslated region), a 1308 -bp-long ORF (open reading frame), and a 3′-UTR region of more than 1,000 bp. The coding region, when using the canonical ATG translation start, encodes for a protein of 436 amino acids, for a total of 64 kDa (Berthelsen et al. 1998). Murine PREP1 maps on chromosome 17 and covers 42.94 kb, from 31,701,703 to 31,744,640, on the direct strand. The mRNA coding for the murine Prep1 is 4,093 nucleotides long. The protein has the same length and the same characteristics as human Prep1 with only 21 aminoacidic substitutions, 10 of which are conservatives (Ferretti et al. 1999).

Human PREP2 gene maps on chromosome 11 (11q24) and covers 268.73 kb, from 124,539,770 to 124,808,495, on the direct strand. A 4 kb transcript was observed in most tissues, while a longer (7–8 kb long) mRNA is testis-specific. The full length protein is 461 amino acids long (Fognani et al. 2002). Murine PREP2 maps on chromosome 9. Three transcripts (3.8 kb, 1.6 kb, and 0.8 kb long) were identified; the relative accumulation of the longer ones differs among organs, whereas the 0.8 kb form was detected only in testis. Murine Prep2 protein is 462 residues long (Haller et al. 2002). Alternative splicing gives rise to multiple isoforms, including a 25-kDa variant due to retention of intron 4 that lacks the C-terminal half of the protein and the homeodomain (Haller et al. 2004).

The PREP family of proteins (including Prep1 and Prep2 in vertebrates) belongs to the MEIS class of TALE superclass of DNA-binding proteins. Homeoproteins belonging to this superclass contain a divergent homeodomain (HD) with a 3 amino-acid loop extension (TALE, P-Y-P) between the first and



Prep, Fig. 1 Prep-protein structure. The structure of Prep proteins is shown. The homeodomain (HD) contains the TALE motif (Proline-Tyrosine-Proline), which is responsible for contacting the hexapeptide motif of Hox proteins. The bipartite MEIS domain (HM1 and HM2) contains the LFPLL motif, which is essential for Pbx binding

second α-helix. The TALE motif contacts the hexapeptide motif of Hox proteins (Moens and Selleri 2006).

Further, members of the MEIS class (which includes Homothorax in flies and Meis and Prep proteins in vertebrates) encode a bipartite 130-amino-acid-long MEIS domain (also called HM1 and HM2 domains) upstream of the HD (Fig. 1). The PREP family proteins do not contain any well-conserved specific motifs, besides a region downstream the homeodomain that may be the last remnant of a specific motif (Mukherjee and Bürglin 2007). Structure-function analyses demonstrated that a LFPLL motif in the MEIS domain of Prep1 is essential for Pbx1 binding (Díaz et al. 2007).

Sites of Expression

Prep1 is expressed ubiquitously with expression levels modulated in different organs and tissues. Prep1 is expressed in all organs in early zebrafish and mouse embryos. In the adult mouse, highest levels of expression were observed in testis, brain, and thymus (Ferretti et al. 2006). In the hematopoietic system, Prep1 is highly expressed in the stem cell compartment with levels decreasing upon cell differentiation (Di Rosa et al. 2007). Interestingly, Prep1 levels are usually lower in human tumor samples if compared to the normal tissue (Longobardi et al. 2010).

Human Prep2 is highly expressed in heart, brain, skeletal muscle, and ovary (Fognani et al. 2002). Testis-specific transcripts have been detected in both human (7–8 kb) and mouse (0.8 kb) tissues (Fognani et al. 2002; Haller et al. 2002).

Cellular Functions

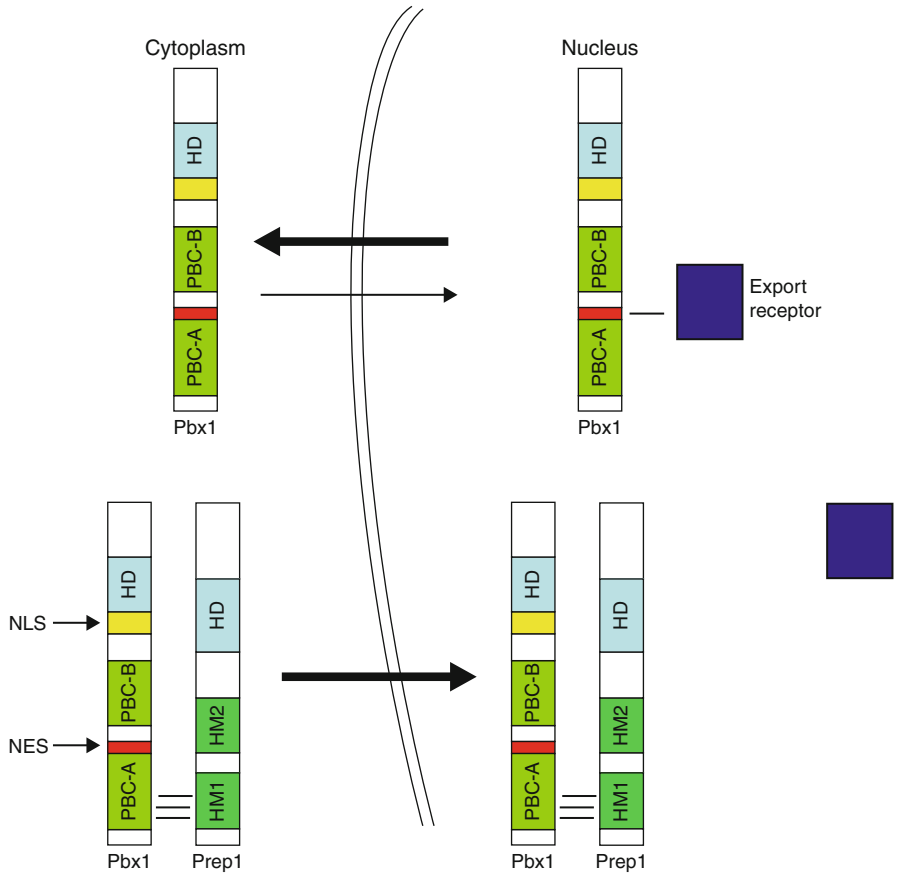
Prep proteins are able to bind the conserved sequence TGACAG. They can bind this sequence on their own, but with low affinity; the interaction with Pbx1a, Pbx1b, or Pbx2 increases the affinity to DNA and allows binding to a TGATNNAT motif (Berthelsen et al. 1998; Fognani et al. 2002). Several targets of the complexes have been identified, including somatostatin (Goudet et al. 1999), HoxB2 (Ferretti et al. 2000), Pax6 (Mikkola et al. 2001), and FSH β-subunit (Bailey et al. 2004).

The interaction between Pbx and Prep proteins is important for their translocation to the nucleus. In its homeodomain, Pbx proteins contain two Nuclear Localization Signals (NLS) that are not present in Prep proteins. Therefore, the interaction with Pbx1 allows nuclear translocation of Prep1 (Berthelsen et al. 1999). Pbx also has a Nuclear Export Signal (NES) in the PBC-A domain that favors its exit from the nucleus. The interaction with Prep (or Meis) masks this signal, allowing nuclear retention of the dimeric complex (Berthelsen et al. 1999) (Fig. 2). Cytoplasmic Prep2 localization is dependent on Crm-1-mediated nuclear export and association with the actin and microtubule cytoskeleton (Haller et al. 2004).

The interaction between Pbx and Hox is compatible with the interaction of Pbx with Prep. Indeed, Prep and Pbx interact through regions in the N-terminal (PBC-A in Pbx and HM1-HM2 in Prep), while the interaction of Hox proteins with Pbx involves the homeodomain. Therefore, ternary complexes between Pbx, Hox and Prep can be formed and are able to bind DNA (Berthelsen et al. 1998). This increases the specificity to the DNA consensus sequences of Hox genes to include both TGACAG and TGATNNAT separated by few bases. As an example, Fig. 3 shows the ternary complex formed between HoxB1, Pbx1, and Prep1 in the rhomobomere 4 enhancer of the *HoxB2* gene (Ferretti et al. 2000).

Prep1-Pbx1 complexes interact also with non-Hox proteins, cooperating in the activation of different promoters. For example, Pbx1 and Prep1 activate the somatostatin promoter when co-expressed with the pancreatic homeodomain factor Pdx1. Also in this context, the cooperative binding of two regulatory elements (UE-A by the Pbx1/Prep1 dimer and TSEI by Pdx1) of the promoter is necessary for the full activation (Goudet et al. 1999).

Prep1 and Pbx1 form trimeric complexes also with non-homeodomain proteins. Indeed, Pbx1 and Prep1 have been identified as Smad partners in a trimeric complex involved in the regulation of FSH β gene by activin (Bailey et al. 2004).

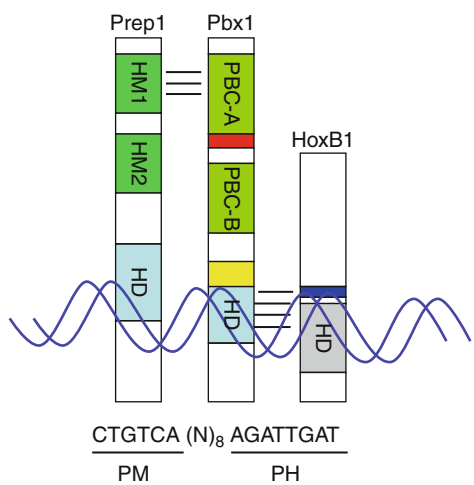


Prep, Fig. 2 Model of Pbx–Prep traslocation to the nucleus. In specific cell contexts, in the absence of Prep/Meis proteins, Pbx1 is actively exported from the nucleus, a process requiring the NES, located within its PBC-A domain, which is recognized by a nuclear export receptor. Pbx1 forms a stable complex with Prep1, when co-expressed, through an interaction surface that coincides with the region required for nuclear export, thereby shielding it. The newly formed complex translocates into the nucleus due to the NLS located within the homeodomain of Pbx1

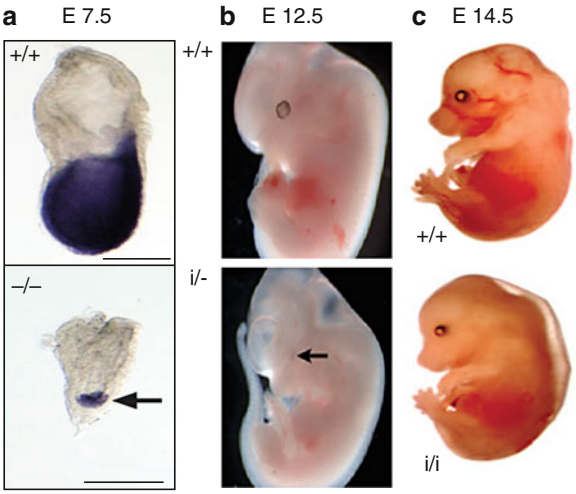
Besides Hox and TALE factors, other Prep1 interactors have been discovered such as Mybbp1A (p160), which may function as an inhibitor of its transcriptional activity (Díaz et al. 2007).

Loss of Function–Associated Phenotypes

Prep1-null embryos die before gastrulation because epiblast cells undergo ▶ p53-dependent apoptosis (Fernandez-Diaz et al. 2010). Mouse embryos carrying a hypomorphic *Prep1i/i* mutation (expressing 2% mRNA, 3–7% protein) show general organ hypoplasia and, in 75% of cases, die at about E17 with major alterations in hematopoiesis, angiogenesis, and eye development (Ferretti et al. 2006; Di Rosa et al. 2007). Interestingly, a further decrease of the Prep1 mRNA level to about 1% (double heterozygous *Prep1i/-* embryos) shows an intermediate phenotype with embryonic lethality around E12.5 (Rowan et al. 2010). A gene dosage effect of Prep1 on embryonic development is evident from these studies (Fig. 4).



Prep, Fig. 3 HoxB1-Pbx1-Prep1 ternary complex in the rhombomere-4 enhancer of HoxB2. In the case of the PM-PH sites of the Hoxb2 enhancer, Hoxb1 forms a dimeric complex with Pbx1 on the PH site (AGATTGAT), while Prep1 binds the PM site (CTGTCA). In this way, three homeodomains are bound to DNA



Prep, Fig. 4 Prep1 loss-of-function phenotypes during embryonic development. (**a**) Whole mount in situ hybridization against Oct4 at E7.5 in *Prep1*+/+ and *Prep1*−/− embryos (Fernandez-Diaz et al. 2010). (**b**) *Prep1*+/+ and *Prep1i*/- embryos at E12.5 (Rowan et al. 2010). (**c**) *Prep1*+/+ and *Prep1i*/*i* embryos at E14.5 (Ferretti et al. 2006)

Remarkably, homozygous *Prep1i*/*i* hypomorphic mice surviving embryonic lethality are prone to develop tumors within 20 months of age, and Prep1 heterozygosity accelerates ▶ Myc-dependent lymphomagenesis (Longobardi et al. 2010).

A loss-of-function mutation for Prep2 has not been described.

Summary

Prep proteins have been extensively studied as critical mediators of the activity of other homeodomain transcription factors (in particular Hox and Pbx proteins). Nevertheless, at least for Prep1, a loss-of-function model has recently demonstrated that this is the only protein of the family which is essential at very early stages of embryonic development (Fernandez-Diaz et al. 2010). This strongly suggests that this protein has other, not yet identified, cellular functions.

Prep1 loss-of-function phenotypes have two other remarkable features:

– Pleiotropy: Prep1 has a pivotal role in several embryonically unrelated cell types, consistently with its ubiquitous expression, suggesting a role in the biology of stem cells of different tissues.
– Gene-dosage dependence: small differences in its expression have great impact on cellular and tissue homeostasis, suggesting that Prep1 levels must be tightly regulated.

Furthermore, recent data demonstrate that (unlike the other TALE factors) Prep1 functions as a tumor suppressor, further prompting for a deep investigation of its mechanisms of action.

Prep2 has not been extensively studied, so far. In particular, a loss-of-function genetic model would be extremely important in order to exploit its functions which, given also its narrower tissue distribution, might be different from Prep1.

Synonyms

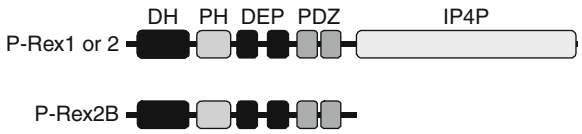
P-Rex1 (BC067047; G630042G04; KIAA1415; mKIAA1415; P-Rex1; Phosphatidylinositol (3,4,5)-trisphosphate-dependent Rac exchanger; PREX1), P-Rex2 (DEP domain containing 2; DEP.2; Depdc2; P-Rex2; phosphatidylinositol 3,4,5-trisphosphate-dependent RAC exchanger 2; PREX2; PtdIns(3,4,5)-dependent Rac exchanger 2)

Historical Background

A phosphatidylinositol 3,4,5-trisphosphate-dependent Rac exchanger (P-Rex) is an intracellular signaling molecule that regulates leukocyte function and neuronal development by activating a small guanine nucleotide-binding protein, Rac. The *Homo sapiens* genome encodes two P-Rex genes, P-Rex1 and P-Pex2. In 2002, Welch et al. purified a PIP_3-dependent Rac activator from pig neutrophil lysates, identified a 196 kDa Dbl-like GEF (guanine nucleotide exchange factor) protein for Rac, and designated it as P-Rex1 (Welch et al. 2002). They characterized its synergistic activation by Gβγ subunits of heterotrimeric G proteins and PIP_3, and its physiological function in reactive oxygen species (ROS) production in neutrophils (Welch et al. 2002). P-Rex2 and the spliced variant, P-Rex2B, were identified in a search for P-Rex1-homologous genes (Donald et al. 2004; Rosenfeldt et al. 2004). Using P-Rex knockout mice, Welch et al. and the other group clarified physiological roles of P-Rex genes in peripheral white blood cells and in neuronal development (Donald et al. 2008; Dong et al. 2005; Welch et al. 2005). Recently, several studies indicated the involvement of P-Rex genes in proliferation and metastasis of human tumors. Especially, Fine et al. demonstrated that P-Rex2 activates the PI3K (▶ phosphoinositide 3-kinase) pathway by a direct inhibition of ▶ PTEN (phosphatase and tensin homolog) (Fine et al. 2009).

Molecular Structure and Regulation

In vitro, P-Rex catalyzes guanine nucleotide exchange on Rac and Cdc42, but not Rho (Welch et al. 2002). However, P-Rex specifically activates Rac in vivo (Welch et al. 2002). P-Rex activity is positively and negatively regulated by heterotrimeric G protein signals (Mayeenuddin and Garrison 2006; Welch et al. 2002). P-Rex is directly and synergistically activated by Gβγ and PIP_3, which is produced by PI3K in vivo, and is inhibited by direct phosphorylation by cAMP-dependent kinase (Protein kinase A; PKA) (Mayeenuddin and Garrison 2006; Urano et al. 2008).



P-Rex, Fig. 1 Domain structure of P-Rex1, P-Rex2, and P-Rex2B

The human P-Rex1 and P-Rex2 are highly related 1659 and 1606 amino acid proteins containing an amino-terminal DH (Dbl-homology), a PH (Pleckstrin homology), two DEP (Dishevelled, Egl-10, and Pleckstrin), two PDZ (PSD-95, Dlg, and ZO-1), and a carboxyl-terminal IP4P (inositol polyphosphate 4-phosphatase) like domains (Fig. 1). The tandem DH/PH domains are minimal and constitutively active elements that catalyze the exchange of guanine nucleotide on Rac. The DH domain possesses the catalytic core and is thought to be directly stimulated by Gβγ (Hill et al. 2005). The PH domain mediates PIP_3-dependent activation (Hill et al. 2005), promotes translocation of P-Rex from cytosol to plasma membrane (Barber et al. 2007), and confers its substrate specificity (Joseph and Norris 2005). Functions of tandem DEP and PDZ domains have been unclear, but these domains keep the basal GEF activity low (Hill et al. 2005) and mediate Gβγ-dependent activation through their interaction with IP4P-like domain (Urano et al. 2008). The IP4P-like domain shows a significant similarity to inositol polyphosphate 4-phosphatase (Donald et al. 2004; Rosenfeldt et al. 2004; Welch et al. 2002), but its phosphatase activity has not been characterized. Truncation mutants of P-Rex1 indicated that the DH/PH domains act as a constitutively active form and the other domains contribute to keep low basal activity (Hill et al. 2005).

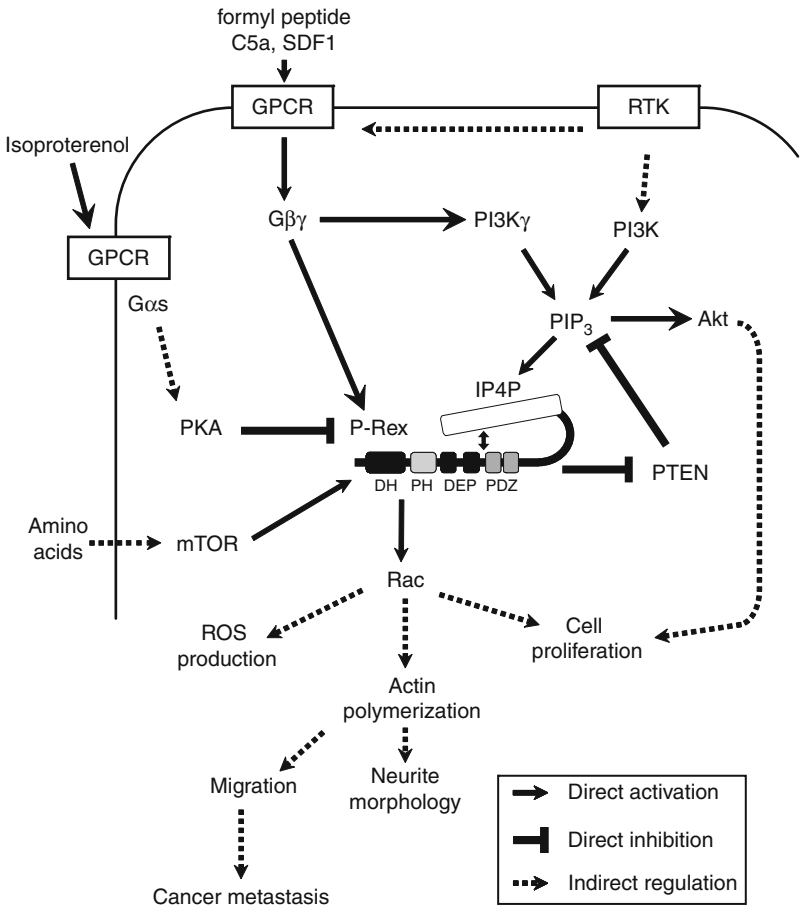
In addition to heterotrimeric G proteins, several receptor tyrosine kinases (RTK) indirectly activate P-Rex1 in a PI3K-dependent manner. The P-Rex activation regulates cell morphology and migration in neuronal cells and human tumor cells (Montero et al. 2011; Qin et al. 2009; Sosa et al. 2010; Yoshizawa et al. 2005) (Fig. 2). In breast cancer cells, heregulins/neuregulins and their receptors, the ErbB subfamily of RTKs, activate P-Rex1 through the transactivation of CXCR (CXC chemokine receptor) and PI3K (Sosa et al. 2010). Neuregulin also regulates P-Rex activity through dephosphorylation of inhibitory residues and phosphorylation of activating residues of P-Rex1 (Montero et al. 2011), although kinases and phosphatases which regulate the phosphorylations have not been clarified yet. Moreover, P-Rex mediates Rac activation and cell migration with ▶ mTOR (mammalian target of rapamycin) (Hernandez-Negrete et al. 2007; Kim et al. 2011), which is a serine-threonine kinase activated by growth factors and nutrient stress. P-Rex1, P-Rex2, and P-Rex2B directly interact with mTOR through the tandem DEP domains (Hernandez-Negrete et al. 2007), but the mechanism of how mTOR modulates P-Rex activity remains unclear.

Physiological Roles

P-Rex plays important roles in Rac-mediated actin polymerization that leads to lamellipodia formation, ROS production, and transcriptional regulation. P-Rex1 is highly expressed in peripheral blood leukocytes and the brain (Donald et al. 2008; Welch et al. 2002; Yoshizawa et al. 2005), and P-Rex2 is abundant in the lung and brain (Donald et al. 2008). In contrast to P-Rex1, expressed widely throughout the whole brain (Donald et al. 2008; Yoshizawa et al. 2005), P-Rex2 expression is more restricted to the cerebellum (Donald et al. 2008). P-Rex2B expression was shown, by northern blots, to be only in the heart (Donald et al. 2004). Knockout mice of P-Rex1 (Donald et al. 2008; Dong et al. 2005; Hill et al. 2005) and P-Rex2 (Donald et al. 2008) revealed their physiological and developmental roles. In peripheral blood leukocytes, P-Rex1 is involved in GPCR (G protein–coupled receptor)-dependent Rac activation, ROS production, cell migration, and cell adhesion (Dong et al. 2005; Lawson et al. 2011; Welch et al. 2002, 2005). P-Rex1 knockout mice also exhibit defects of Rac1 activation, cell migration, and superoxide production in macrophages (Wang et al. 2008). P-Rex2 regulates dendrite structure in mouse cerebellar Purkinje cells (Donald et al. 2008). P-Rex1/P-Rex2 double knockout mice grow up healthy and are fertile, but show morphological defects in cerebellar Purkinje cells and a strong motor coordination defect (Donald et al. 2008).

Roles in Cancer

Overexpression of Rho-family GTPases and GEFs participates in cancer progression and metastasis in



P-Rex, Fig. 2 Signaling pathways mediated through P-Rex1 and P-Rex2. Direct regulation was indicated as *solid lines*. Indirect activation was shown as *dashed line*

various types of tumors. Recently, several studies indicated the involvement of P-Rex genes in proliferation and metastasis in breast and prostate tumors (Fine et al. 2009; Kim et al. 2011; Montero et al. 2011; Qin et al. 2009; Sosa et al. 2010). The human P-Rex1 gene is located on the chromosome 20q13, which is a region frequently amplified in breast cancer, and P-Rex2 gene is on the chromosome 8q13, a region of high amplification in breast, prostate, ovarian, and colorectal cancers. Indeed, it has been recently reported that P-Rex1 mediates Erb2-dependent migration and tumorigenesis in breast cancer cells (Montero et al. 2011; Sosa et al. 2010) and promotes spontaneous metastasis in prostate cancer cells (Qin et al. 2009). P-Rex2 is also highly expressed in several human cancers, and directly inhibits phosphatase activity of PTEN (Fine et al. 2009), which is a tumor suppressor frequently mutated in human cancers and an enzyme that dephosphorylates $PI(3,4,5)P_3$ into $PI(4,5)P_2$. P-Rex2-mediated inhibition of PTEN accumulates PIP_3, and consequently promotes cell proliferation with activation of Akt in breast cancer cells (Fine et al. 2009).

Summary and Perspective

P-Rex proteins function as Rac activators and are involved in ROS production, cell morphology, migration, proliferation, and gene expression in various cells and tissues. P-Rex is activated by heterotrimeric G proteins, RTK and PI3K-pathways, and inhibited by cAMP/PKA signals, allowing it to potentially integrate various hormonal stimuli into a Rac signaling. It is unclear how P-Rex keeps basal activity low and is activated by Gβγ and the molecules. X-ray crystal structure analysis of P-Rex should provide insights into understanding them. Higher expression level of P-Rex1 is linked to malignancy in human breast and prostate tumors, and potentiates RTK signals. However, the mechanisms of how RTK signals activate

P-Rex/Rac pathway have not been clarified. Two potential mechanisms for activation of P-Rex pathways indirectly through transactivation of G proteins or by phosphorylation and dephosphorylation control of P-Rex by RTK signaling have been described, but a more detailed analysis should yield better understanding of multiple P-Rex1 regulations.

Historical Background

Transmissible spongiform encephalopathies (TSEs) are neurodegenerative diseases characterized by neuron loss, glial reactions, and tissue spongiosis, which course with motor and/or cognitive symptoms (Knight and Will 2004). The TSEs are associated with conformational conversion of the prion protein (PrP^{C}, the product of the *Prnp* gene), wherein the predominantly α-helical secondary structure of PrP^{C} changes into an aggregation-prone, β-sheet richer structure known as PrP^{Sc}. The latter is believed to coerce PrP^{C} molecules into conformational conversion, thus behaving as a *proteinaceous infectious particle*, or *prion* (Prusiner 1998), which gave TSEs the epithet *prion diseases*.

The much needed development of effective treatment for these still incurable diseases depends on the understanding of functional properties of the prion protein (Soto and Satani 2010). Most studies of physiological functions of PrP^{C} have been directed at its major cell-surface GPI-anchored form, whereas minor transmembrane and cytosolic forms have usually been studied in the context of pathogenesis of prion diseases. The current account, therefore, focuses upon the physiological functions of the GPI-anchored PrP^{C}.

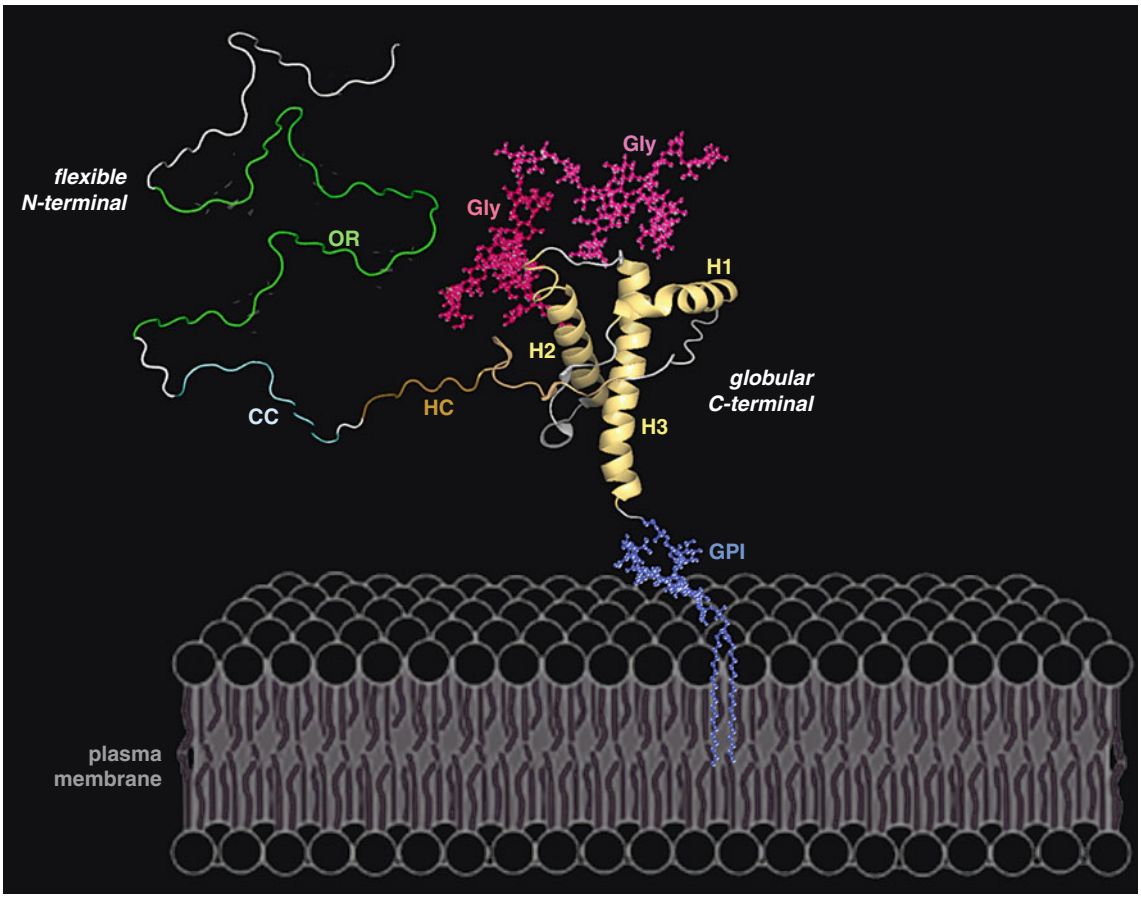
Several dozen distinct molecules have been shown to bind PrP^{C}, albeit on the basis of somewhat variable evidence. The expression and the engagement of PrP^{C} with a variety of ligands activate numerous signal transduction pathways, thus leading to modulation of proliferation, differentiation, and cell death in the nervous and immune systems, as well as in many other organs and cell types. In addition, PrP^{C}-mediated signaling is affected by trafficking of the protein both laterally between distinct plasma membrane domains and along endocytic pathways, as well as by its continuous and rapid recycling. A recent review of these functional properties suggests that the prion protein has a general function analogous to intracellular scaffolding proteins, as a dynamic cell surface platform for the assembly of signaling modules (Linden et al. 2008).

Structure, Expression, and Regulation of the Prion Protein

PrP^{C} is an *N*-glycosylated, glycosyl-phosphatidylinositol (GPI)-anchored protein of 208–209 amino acids, containing an amino (N)-terminal flexible, random coil sequence and a carboxy (C)-terminal globular domain, the major structural features of which are preserved among both mammalian and non-mammalian species (Fig. 1). The globular domain of human PrP^{C} contains 3 α-helices interspersed with an antiparallel β-pleated sheet formed by β-strands at two short stretches, and contains a single disulfide bond. The N-terminal flexible tail spans approximately half of the mature protein, and a short flexible C-terminal domain attaches to the GPI anchor (Wuthrich and Riek 2001).

Full length PrP^{C} is found in non-, mono-, or diglycosylated forms, corresponding to the variable occupancy of two asparagine residues (Rudd et al. 2001). A rather large variety of N-glycans were found attached to both full-length and truncated PrP^{C}, which may be differentially distributed in various areas of the central nervous system (CNS).

A single exon within the *Prnp* gene codes for PrP^{C}. Control of *Prnp* gene expression has been attributed to sequences within the 5′-flanking region, within the first intron, and to 3′-untranslated sequences, as well as to



Prion Protein (*PRNP*), Fig. 1 The structure of the prion protein is drawn at a roughly approximate scale, in a montage of elements taken from various sources: The globular C-terminal domain is a Pymol representation of mouse PrP121-231; the flexible N-terminal domain was freely drawn to scale from segments of unstructured sequences of amino acids in the same Pymol representation, maintaining the number of amino acids ascribed to each individually defined domain (see below); the GPI anchor and the structure of N-linked sugars were taken from (Rudd et al. 2001); the depiction of the plasma membrane is just a rough sketch modified from a drawing in Wikipedia (Abbreviations: *CC* charged cluster, *Gly* N-linked sugars, *GPI* GPI anchor, *H1*, *H2*, *H3* α-helix domains, *HC* hydrophobic core, *OR* octapeptide repeat domain)

interactions between promoter and intronic regions. Differing from the *Prnp* open reading frame, the degree of homology of potential promoter sequences among various mammalian species is quite variable (Mastrangelo and Westaway 2001).

Prnp is often labeled as a housekeeping gene, but evidence that transcription of *Prnp* is modulated by chromatin structure, as well as the identification of potential binding sites for many transcription factors, indicate that expression of *Prnp* likely depends on a variety of cellular factors. Notwithstanding some variation between species, the following elements were reported both in the 5′-flanking region and within the first intron: Sp1, AP1, AP2, MZF-1, MEF2, MyT1, Oct-1, ▶ NFAT, POZ (BCL6); RP58 (ZNF238); NEUROG1; EGR4, Oct-1/Oct-2, NF-IL6, MyoD, ▶ p53, HSE, MRE, MLS (Linden et al. 2008 for review).

Expression of both *Prnp* messenger RNA (mRNA) and prion protein are developmentally regulated, and subject to modulation by growth factors such as NGF, PDGF, and various cytokines. Expression can also be modulated by stressful conditions, inclusive of heat shock, hypoglycemia, oxidative stress and inflammation, as well as copper overload.

The prion protein is highly expressed within the nervous system, although its content varies among distinct brain regions, among differing cell types and

among neurochemically distinct neurons. In addition, substantial amounts of PrP^C are expressed in various cellular components of the immune system, the bone marrow, blood, and peripheral tissues. Other organs and tissues also express PrP^C (Table 1).

Many reports are available on putative ligands of the prion protein, and candidate physiological ligands are listed in Table 2. It can be appreciated that binding domains identified for a number of ligands extend along the entire PrP^C molecule (Fig. 2). It should, however, be noted that the techniques used for those studies were quite variable, and many interactions detected by screening methods have yet to be confirmed by biochemical and cell biological approaches. In particular, some putative ligands appear not to be accessible from the usual topology of PrP^C, which constitutes a critical question to be addressed by future studies (Rutishauser et al. 2009).

Trafficking, Endocytosis, and Recycling of the Prion Protein

An N-terminus peptide (aa. 1–22) is used to drive nascent PrP^C into the endoplasmic reticulum, where its GPI-anchor is added at the C-terminus. Distinct topologies of PrP^C have been described, some of which are of pathological interest. PrP^C follows the classical pathway for its insertion at the plasma membrane, passing through the Golgi and following a Brefeldin A-sensitive pathway to reach the cell surface (Prado et al. 2004 for review).

At the cell surface, PrP^C molecules are found predominantly anchored to low density, detergent insoluble membrane domains, rich in cholesterol and sphingolipids (*lipid rafts*). GPI-anchored proteins located in rafts are thought to recycle between the plasma membrane and intracellular organelles, in particularly to the Golgi. In neurons, endogenous PrP^C appears to internalize as fast as classical membrane receptors, such as the transferrin receptor, with a $T_{1/2}$ of approximately 3–5 min.

Initial data pointed to the possibility that PrP^C, similar to other GPI-anchored proteins, is internalized by a raft-mediated mechanism that is independent from clathrin. Although caveolae anf flotilin-derived vesicles may participate in the internalization of PrP^C in non-neuronal cells and in astrocytes, mounting evidence suggests that, in neurons, clathrin-mediated endocytosis plays an important role on PrP^C internalization. Cell surface biotinylation, live cell microscopy, GFP-tagged PrPs, and electron microscopy support the view that clathrin-coated vesicles and classical endosomal organelles are involved in endocytosis of PrP^C (reviewed by Linden et al. 2008). Dominant negative approaches indicated a role for the activities of dynamin and clathrin in the internalization of PrP^C in distinct cell lines. It was proposed that an N-terminal, positively charged domain of PrP^C (KKRPKP) is responsible for the constitutive endocytosis of PrP^C by clathrin-coated vesicles. Remarkably, a number of reports indicated a role for the N-terminal region of PrP^C upon endocytosis and cellular trafficking, and this basic region of the protein has been previously implicated in the binding of negatively charged proteoglycans, which are thought to modulate PrP^C sequestration (Prado et al. 2004) (Fig. 3).

The hypothesis that GPI-anchored PrP^C may "piggy-back" on an integral membrane protein had long been raised, and recent studies indicated that the low-density lipoprotein receptor-related protein 1 (LRP1) may participate in clathrin-mediated endocytosis of PrP^C, because knock-down of LRP1, but not LRP1b, reduced internalization of PrP^C. LRP1 has also been implicated in PrP fibril entry in cells (Parkyn et al. 2008; Taylor and Hooper 2007).

High extracellular levels of Cu^{2+} induce the endocytosis of PrP^C to intracellular organelles and the Golgi. It was reported that Cu^{2+}-induced endocytosis of PrP^C expressed in neuroblastoma cells caused its movement from raft to non-raft membrane regions. Although the KKRP motif was shown to be important for endocytosis, this motif is not essential for the lateral displacement of PrP^C to non-raft membrane, indicating that this movement occurs prior to PrP^C endocytosis. It was also suggested that Cu^{2+} may destabilize a putative PrP^C interaction within rafts, rather than inducing PrP^C to interact with a non-raft protein. It is not clear yet if the KKRP domain is required for binding to LRP1 or to other membrane proteins that may be accessory in this process. Interestingly, amyloid β peptide 1–42, a major culprit in Alzheimer's disease was recently shown to bind PrP^C. A binding site was identified at aa. 90–110 and, more recently, the endocytic motif 23–27 was also shown to mediate binding to amyloid β peptide. This suggests that amyloid β may be able to regulate PrP^C trafficking. Moreover, one of the ligands of PrP^C, hop/STI1, which

Prion Protein (*PRNP*), Table 1 Expression and distribution of prion protein

Species	Organ/tissue	Cell type/subcellular distribution	Technique	Detection level and regulation
Hamster	Brain	Neuron cell bodies	IHC, WB	
Mouse, hamster	Brain	Neurons, intracellular	IHC	
Hamster, macaque, human	Brain	Pre-synaptic, *not* in cell bodies	WB, IHC (mAb 3F4), EM	
Hamster	Developing brain	Mainly along axon tracts	IHC (mAb 3F4)	Developmentally regulated, remains high in adult olfactory bulb and hippocampus
Mouse	Embryonic brain, spinal cord, PNS	Neurons, non-neuronal cells	ISH	Developmentally regulated.
Mouse	Brain	Neurons, neuronal processes, *not in* glia	IHC (pAbs GAx), ISH	Varied both among and within brain regions, depending on cell type and neurochemical phenotype. Protein often *not* correlated with mRNA.
Hamster, human	Hippocampus	Pre-synaptic	IHC, EM	
Hamster	Cerebellum	Pre- *and* post-synaptic	IHC, EM	
Human	Cerebellum	Neurons	IHC (mAb 3F4)	Low level in cerebellar granule cells of normal brain
Rat	Cerebellum	Neuron and glial cell bodies and processes	IHC (mAb 8H4), EM	
Rat	Neonatal retina	Retinal precursors and differentiating neurons	WB, IHC (mAb 6H4, pAb N10, pAbMo)	
Hamster	Brain (hippocampus, septum, caudate nucleus, thalamus), DRG, blood, heart, skeletal muscle, lung, gut, spleen, testis, ovary, and others	Both in neuronal cell bodies and neuropil	WB, IHC (mAb 3F4 + 2 distinct pAbs), EM	Highest in hippocampus
Mouse	Olfactory bulb, PNS, bone marrow, lymphoreticular system, gut, lung, kidney, testis, skin, *not* liver	Peripheral axons, neuron cell bodies, *not* glia; haemopoietic progenitors, megakaryocytes, monocytes, *not* granulocytes in bone marrow; dendritic cells, pericytes, intraepithelial lymphocytes in various tissues	IHC (pAbs GAx, mAb SAF61), ISH	Varied both among and within distinct organs and tissues. Scattered cells with high expression. Protein correlated with mRNA.

(*continued*)

Table 1 (continued)

Species	Organ/tissue	Cell type/subcellular distribution	Technique	Detection level and regulation
Mouse	Intestine	Submucosa, muscularis mucosa	ISH	
Hamster	Stomach, intestine, lung, kidney	Secretory globules	IHC (pAbs Br-1, R073, P38, mAb 3F4), EM	
Human	Stomach, kidney, spleen	Secretory globules	IHC (pAbs Br-1, R073, P38, mAb 3F4), EM	
Bovine	Ovary	Ovarian follicles	Microarray, real time PCR, WB (mAb HumP)	Up regulated in theca cells of dominant, as compared with subordinate follicles
Sheep	Spleen, lymph node, lung, heart, kidney, skeletal muscle, uterus, adrenal gland, parotid gland, intestine, mammary gland, *not* liver, *not* pancreas.		WB (home-made pAbs and mAbs), NB	
Mouse, hamster, human	Muscle	Subsynaptic sarcoplasm, *not* postsynaptic plasma membrane	IHC (pAb R254, R073), EM	
Mouse	Muscle	Myoblast cell lines	WB (pAb Ra5)	Up regulated with differentiation of myotubes from myoblasts
Human	Blood	Lymphocytes and lymphoid cell lines, monocytes, *not* erythrocytes, *not* mature granulocytes	FC (mAb 3F4), NB	Downregulated with differentiation in granulocytes
Human	Blood	Monocytes, T cells, NK cells, B cells	FC (mAbs 3F4, 3F5)	Up regulated in activated T cells and monocytes, not uniform among NK cells, low in B cells

Human	Blood	Monocytes, T cells, B cells, DC	FC (4 distinct mAbs)	Upregulated in activated T cells
Human	Blood	$CD34^+$ cells, megakaryocytes, platelets	WB, FC, IHC (mAb 6H4), EM (pAb P3), RT-PCR	Surface PrP^C increases upon platelet activation
Mouse	Bone marrow, thymus, fetal liver, *not* spleen, *not* peritoneum	Haemopoietic stem cells, immature thymocytes, *not* peripheral blood leukocytes, *not* gut intraepithelial lymphocytes	FC (mAb 6H4)	
Mouse	Skin, thymus, spleen, lymph nodes	DC	FC (mAb SAF83)	Heterogeneous distribution among DC subtypes; absent in B220+ DCs; up regulated with DC maturation
Bovine	Spleen, lymph nodes, blood	Follicular DC, B cells, lymphocytes, monocytes, PMN	IHC, FC (mAb 6H4)	Monocytes and PMN immunoreactivity low, B cells high
Sheep	Blood	B cells, T cells, monocytes, *not* granulocytes, *not* erythrocytes	FC (mAbs 8H4, 5B2, 7A12), RT-PCR	Platelet fraction contained PrP mRNA, *not* surface PrP^C
Sheep	Blood	PBMC, platelets, *not* granulocytes	WB, FC (mAbs FH11, 4F2. 8G8, 6H4)	PrP^C in platelets intracellular only; Level of PrP^C expression in B cells higher in scrapie-susceptible than in scrapie-resistant genotype

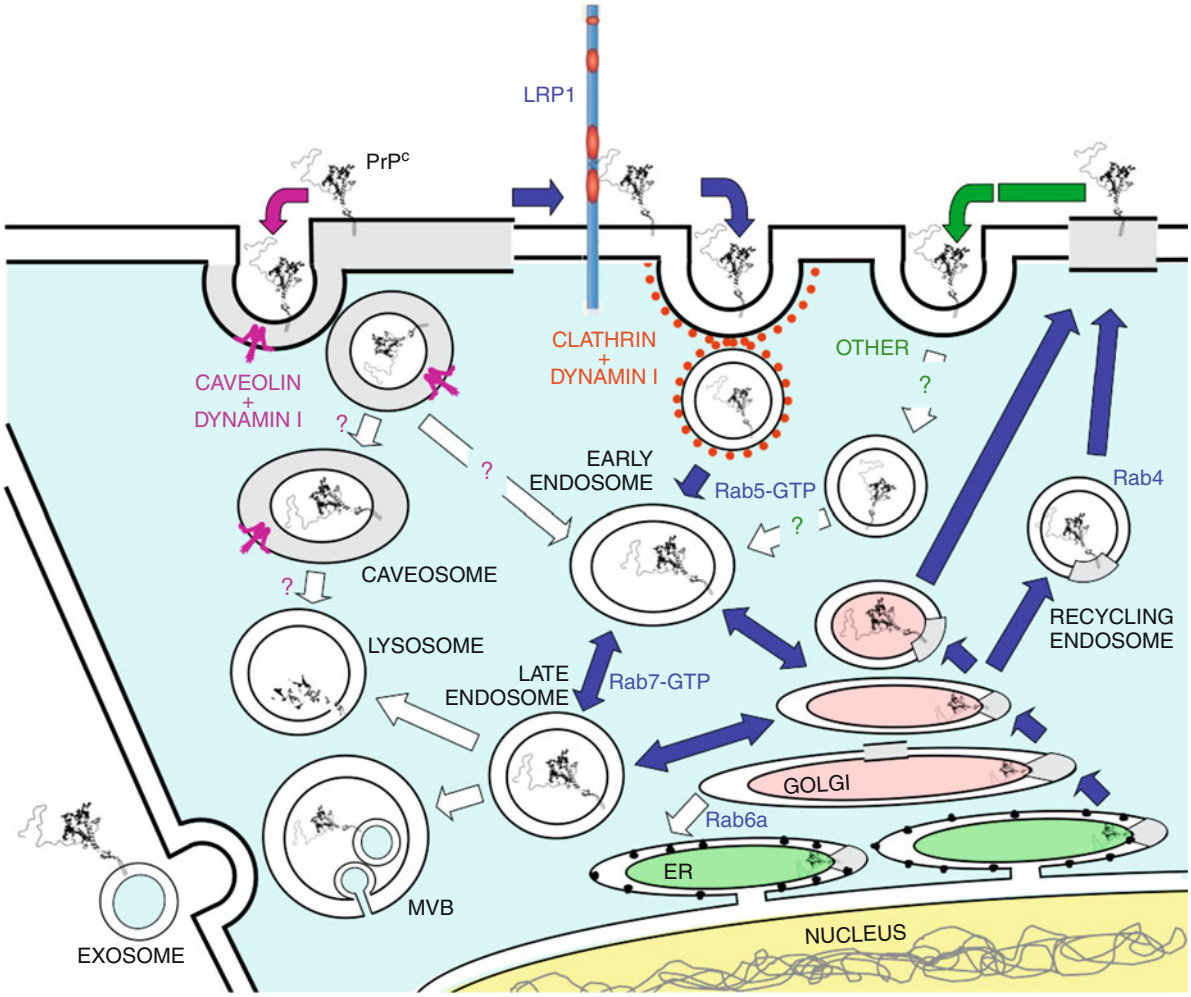
Prion Protein (*PRNP*), Fig. 2 The translated sequence of the mouse prion protein is depicted as a rod-like shape, with major domains shown in color such as in Fig. 1. Each binding partner is indicated together with the stretch of aa. residues that contain their binding domain in mouse PrP^C. *Pink stars* indicate the position of the glycosylation residues. The *double arrow* straddling the whole mature molecule represents undetermined binding site for the partners listed at the bottom of the figure. Abbreviations as in Fig. 1, and Table 2, plus: *SP* signal peptide, *GPIp* PI anchor-signaling peptide (Modified from Fig. 3 in Linden et al. 2008)

signals in cells by coupling PrP^C to the alpha7 nicotinic acetylcholine receptor, triggers the internalization of PrP^C, which regulates the extent of PrP^C modulated neuronal signaling.

Systemic Functions of the Prion Protein

The systemic functions of the prion protein have been addressed in PrP-null mice, in transgenic mice overexpressing PrP^C, or in transgenic mice expressing deletion mutants of PrP^C (Linden et al. 2008; Weissmann et al. 1998; Wadsworth and Asante 2010; Martins et al. 2010 for reviews). Although no overt phenotypic changes were described in the first generated PrP-null animals, later studies showed altered patterns of sleep, enhanced locomotor activity, and increased anxiety, possibly because of changes in the glutamatergic system. Impairment of both short- and long-term memory is found in old PrP-null mice. On the other hand, spatial memory is impaired in young PrP-null mice, which can be rescued upon PrP^C expression in neurons. Impairment of memory formation and retention in rats also followed the blockade of PrP^C interaction with its ligands, by direct hippocampal infusion of anti-PrP^C antibodies or competitor peptides.

At the synaptic level, impairment in long-term potentiation (LTP) was found in the CA1 area of the hippocampus of PrP^C-null mice when experiments were done at physiological temperature. These results were, however, not reproduced when LTP was examined at room temperature. LTP in hippocampal CA1 is at the root of memory formation of one-trial inhibitory (passive) avoidance in the rat. Thus, changes in LTP in PrP-null mice may explain at least in part their memory impairment, as may be the case following PrP^C blockade by specific antibodies. Changes in the afterhyperpolarization potential (AHP) were also detected both in constitutive PrP^C-null mice, and in conditional



Prion Protein (*PRNP*), Fig. 3 Subcellular trafficking of PrP^C. The plasma membrane is represented by *thick lines*, intracellular membranes by *thinner lines*, and lipid rafts by a *gray*-shaded wider bilayer. The cytoplasm is colored *light blue*. PrP^C is depicted similar to Fig. 1, including a loose representation of the N-terminal flexible domain. The major vesicular systems involved in both the synthesis (*bottom right*), the endocytic cycle of PrP^C, and release of PrP^C-containing exosomes (*bottom left*) are indicated with *black* lettering, and the major pathways of trafficking are indicated in *colored* letters. Molecules involved in the clathrin-dependent pathway are indicated in *dark blue* lettering. *Arrows* indicate trafficking, the most likely pathways based on current experimental evidence are shown with *dark blue arrows*. Clathrin is represented by *red circles*, caveolin is depicted in *purple*. Note that PrP^C is associated with rafts early in the secretory pathway and that cell surface PrP^C leaves the rafts and associated with LRP1 on its way to internalization via clathrin. Abbreviations: *MVB* multivesicular bodies, *ER* endoplasmic reticulum, *LRP1* Low density lipoprotein receptor like protein-1 (Modified from Linden et al. 2008)

knockouts in which the expression of PrP^C is abolished at 12 weeks of age. This indicates that this phenotype was caused by neural dysfunction, rather than by a developmental deficit.

Although the changes in the central nervous system are subtle, and do not compromise the life of the PrP-null mice, the expression of some deletion mutants such as PrPΔ32-121, PrPΔ32-134, PrPΔ94-134 in knockout mice causes neurodegeneration. In particular, the deletion of amino acids 105–125 causes cerebellar atrophy, loss of cerebellar granule cells, gliosis, and astrocytic hypertrophy, with decreased body size, immobility, myoclonus, and death within one month after birth. This suggests that compensatory

mechanisms effective in PrP-null mice do not function upon expression of specific deletion mutants. Remarkably, these deleted domains contain sites for binding of ligands that promote specific responses at the cellular level (Linden et al. 2008; Martins et al. 2010 for reviews).

PrP^C has also been implicated in protection against brain insults. In PrP-null mice the threshold for seizures is lower than in wild-type. In addition, PrP-null mice suffered more extensive damage in the brain than wild-type following either hypoxic-ischemic insult or administration of ethanol. Remarkably, overexpression of PrP^C reduced infarct volume and improved neurobehavioral signals after cerebral ischemia in rats.

In transgenic mouse models of amyotrophic lateral sclerosis, the expression of human mutated superoxide dismutase 1 (SOD1) in the absence of PrP^C causes significantly reduced life span, an earlier onset, and accelerated progression of disease when compared with control transgenic mice expressing PrP^C. In this case, PrP^C has a pivotal function in the control of neuronal and/or glial factors associated with antioxidant defenses (Steinacker et al. 2010). Recently, it was also shown that the expression of the prion protein in axons is required for maintenance of peripheral myelin (Bremer et al. 2010).

The absence of PrP^C is associated with altered sensitivity to injury not only in the central nervous system, but also in other tissues. PrP-null mice showed impairment of locomotor activity under extreme exercise conditions. PrP^C is also a relevant regeneration factor in acutely damaged muscle (Stella et al. 2010). Moreover, a uniform pattern of increased PrP^C expression was described in a series of muscular disorders, as well as in an experimental model of chloroquine-induced myopathy, which suggests a role for PrP^C in muscle physiology (Linden et al. 2008 for review).

The expression of PrP^C is variable both across species and among subsets and states of maturation of immune cells. Although PrP-null mice do not present gross defects in the immune system, PrP^C modulates the ability of long-term hematopoietic stem cells (HSC) to sustain self-renewal under stress. PrP-null mice also showed altered inflammatory responses, and it has been shown that PrP^C in dendritic cells is a positive regulator of the immunological synapse (Linden et al. 2008; Nitta et al. 2009; Isaacs et al. 2006 for reviews).

Cellular Functions of the Prion Protein

Studies of the expression of PrP^C during development, and also its cellular distribution in neuronal cell body, dendrites, and axons provided conflicting results, highlighting the difficulties in attributing function to PrP^C on the basis of its distribution. Nonetheless, a large number of studies have identified roles of PrP^C in cell proliferation, differentiation, and cell death in both neural precursors and central neurons. In addition, functions were also attributed to PrP^C in peripheral neurons, lymphoid cells, and some tumor cells (Linden et al. 2008; Martins et al. 2010; Mehrpour and Codogno 2010) (Table 3).

PrP^C in a cell can modulate cellular functions of either the same (in *cis*) or of a distinct cell (in *trans*). The *trans* effects were demonstrated in experiments with recombinant, Fc-bound soluble PrP^C or its fragments, GPI-anchorless recombinant forms, or using a feeder layer of PrP^C expressing cells. The evidence that PrP^C can be secreted by exosomes from various cell types extends the possibilities of *trans* effects at both the tissue and system levels (Porto-Carreiro et al. 2005).

The rate of proliferation of neuronal precursors correlated with PrP^C content in both the subventricular zone and dentate gyrus of the hippocampus of adult mouse brain, but PrP^C expression in proliferating zones was restricted to postmitotic neurons. Thus, the effect of PrP^C upon proliferation of neuronal precursors are probably indirect, a possibility that must be considered when dealing with complex tissues. One hypothesis, not yet explored, is the potential effect of exosomes containing PrP^C from postmitotic neurons. PrP^C can also affect the proliferation of splenic lymphocytes, splenocytes, and enterocytes.

The role of PrP^C in neurite and axon outgrowth has been demonstrated both in human and mouse neurons from hippocampus, cerebellum, cortex, dorsal root ganglia, as well as in neuronal derived cell lines. These effects are mediated by PrP^C acting in *cis* upon binding to specific ligands, such as hop/STI1, laminin, and NCAM, and in *trans* together with either NCAM or other unidentified ligands at the cell surface. PrP^C also modulates astrocyte differentiation, secretion of neurotrophic factors, and metabolism. These results are consistent with PrP^C functions at system levels (see Sect. Systemic functions of the prion protein).

Prion Protein (*PRNP*), Table 3 Cellular functions of PrP^C

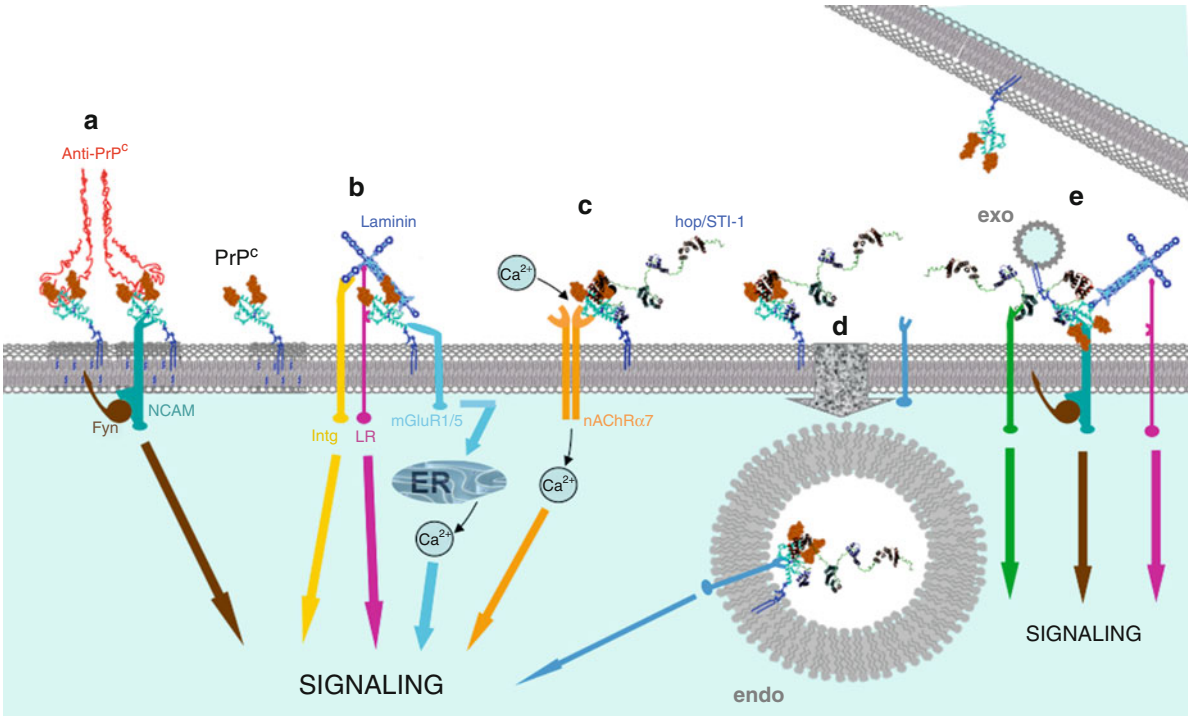
Cell type/organism	Function	Type of interaction/ligand
Neuronal precursors; subventricular zone; dentate gyrus from PrP-null; and wt mice	↑Proliferation	*Cis*-acting PrP
Splenic lymphocytes from PrP-null and wt mice	↑ Mitogen-induced proliferation	*Cis*-acting PrP
Splenocytes from PrP-null and wt mice	↑ or ↓ Mitogen-induced proliferation	*Cis*-acting PrP
Human glioblastoma cell line	↑Proliferation	*Cis*-acting/PrP-hop/STI1 binding
Cultured human enterocytes	Balance between proliferation and polarization – differentiation	*Cis*-acting/interacts with cytoskeleton and desmosome-associated proteins
Multipotent neuronal precursors from PrP-null, wt and PrP overexpressor mice	↑Differentiation	*Cis*-acting PrP
Neurons from hamster developing brain	↑Expression and localization suggest involvement in axon growth, guidance, and synaptogenesis	*Cis*-acting PrP
Hippocampal neurons from PrP-null and wt mice	↑ Neurite outgrowth	*Cis*-acting PrP
Cerebellum granule cells and hippocampal mouse neurons from PrP-null, wt mice, and PrP overexpressor mice	↑Neurite outgrowth	*Trans*-acting: PrP-Fc or PrP expressed by monolayers of CHO cells
Embryonic rat hippocampal neurons	↑Neurite outgrowth, dendrite like and single axon like process, enhanced synaptogenesis	*Trans*-acting recombinant PrP
Embryonic hippocampal mouse neurons from PrP-null and wt mice	Adhesion and neuritogenesis	PrP-laminin
Dorsal root ganglia neurons from PrP-null and wt mice	Axonal growth	PrP-vitronectin
PC-12	↑Neurite outgrowth	PrP-laminin
PC-12	↑Neurite outgrowth	PrP-NCAM
Bone marrow derived granulocytes and HL60 leukemia cells	↓Expression	*Cis*-acting PrP
	↑Differentiation	
Murine peritoneal macrophages from wt and PrP-null mice	↓Phagocytosis	*Cis*-acting PrP
Bone marrow-derived macrophage cell line	↑Phagocytosis	*Cis*-acting PrP
Murine erythroleukemia, neuroectodermal and myeloid cell lines	↑Expression	*Cis*-acting PrP
	↑Differentiation	
myc and *ras* transformed fibroblasts from wt and PrP-null mice	↑Aggregation, embolization, and metastasis	*Cis*-acting
Tissue samples from gastric adenocarcinoma	↑Expression	*Cis*-acting PrP
	↑Histopathological	
	Differentiation and tumor progression	

Embryonic hippocampal neurons from PrP-null and wt mice	↑Differentiation and survival	*Cis*-acting binding to hop/STI1
Embryonic astrocytes from PrP-null and wt mice	↑Differentiation and survival	*Cis*-acting binding to hop/STI1 or laminin
Embryonic astrocytes from PrP-null and wt mice	Regulation of glutamate-dependent lactate transport	*Cis*-acting PrP, complex of GluR2, α2/β2-ATPase, basigin, and MCT1
Immortalized hippocampal neurons from PrP-null and wt mice	Higher sensitivity to apoptosis upon serum deprivation	*Cis*-acting PrP
Fetal human neurons	Protection against bax- induced apoptosis	*Cis* and *Trans*-acting: GPI-anchored, cytosolic and anchorless PrP
Retinal explants from PrP-null and wt mice	↑Survival of undifferentiated postmitotic cells subject to inhibition of protein synthesis	*Cis*-acting
Human neurons, mouse neuronal cell lines	↑Survival, delays conformational change of Bax	*Cis*-acting
Cerebellar granule neurons from PrP-null and wt mice	↑Survival	*Trans*-acting soluble PrP
Undifferentiated post mitotic retinal neurons from PrP-null and wt mice	↑Survival	*Cis*-acting binding to Hop/STI1
Retinal ganglion cells	↑Survival in hypoxia-induced apoptosis	*Trans*-acting, soluble, alpha-secretase-derived N-terminal PrP
Embryonic primary hippocampal neurons or immortalized neuronal cell lines from PrP-null and wt mice	↑Survival	*Cis*-acting PrP:hop/STI1 binding
Cell line derived from neocortical neuronal precursors expressing SV40 large-T antigen v-Src and v-Myc or HEK293	Pro-apoptotic, ↑ sensitivity to staurosporine-induced cell death	Ectopic overexpression of PrP
1 C11 Neuroectodermal cell line	Survival, proliferation, and neuronal plasticity	*Cis*-acting
HEK293 and rabbit kidney epithelial cell line	Pro-apoptotic, ↑ sensitivity to staurosporine-induced cell death	Ectopic overexpression of PrP
Gastric cancer cells	↑Protection against apoptosis	Overexpression of PrP
Human breast cancer cell lines	↑Resistance to TNF-α induce cell death	Overexpression of PrP in resistant cells
Human breast cancer cell line	No effect upon staurosporine-induced cell death	Overexpression of PrP
Pancreatic tumors and melanona	↑Expression of unprocessed signal peptide PrP^{C} ($Pro\text{-}PrP^{C}$) associated with tumorigenesis	Pro-PrP binding to filamin A
Yeast	Survival against Bax-induced cell death	Ectopic expression of mammalian PrP

Abbreviations: *wt* wild-type, *Fc* Fc chain of IgG, *N-CAM* neural cell adhesion molecule, *GluR2* glutamate receptor 2, *MCT1* monocarboxylate transporter 1

Prion Protein (*PRNP*), Table 4 Examples of signaling mediated by the prion protein

Signaling pathway	Cell type	Method	Intracellular messenger	Transmembrane signal transfer
Tyrosine phosphorylation	Embryonic carcinoma 1C11 transformed cell line	Antibody cross-linking	Fyn tyrosine kinase	Caveolin, N-CAM?
Tyrosine phosphorylation	Central nervous system neurons	Overexpression, antibody cross-linking, ligand binding assays, co-IP	Fyn	N-CAM, receptor type protein phosphatase α
Protein kinase A	Central nervous system neurons	Peptide or hop/STI1 binding to PrP^C, PKA antagonist	cAMP	Unknown
Erk MAP kinase	Central nervous system neurons	Peptide or hop/STI1 binding to PrP^C, ► MEK inhibitor	Unknown	Unknown
Erk MAP kinase	Embryonic carcinoma 1C11, neurohypothalamic GTI-7, lymphoid BW5147, and Jurkat T cell lines	Antibody cross-linking	Fyn? ROS?	NADPH oxidase, EGFR?
Erk MAP kinase	Macrophage-like P388D-1 cell line	Soluble PrP^C-Fc fusion protein, Src and PI3-K antagonists	► Src family soluble tyrosine kinases Syk and Pyk2	PI3-kinase
Calcium influx	Central nervous system neurons	Comparison PrP-null vs. wild type; recombinant soluble PrP^C.		Voltage-gated calcium channels
Calcium influx	CEM-T and Jurkat cell lines	Antibody cross-linking		Unknown
Calcium influx	Hippocampal neurons; transfected HEK293 cells	Ligand binding		Alpha-7 nicotinic cholinergic receptor
Calcium homeostasis	Hippocampal neurons; transfected HEK293 cells	Ligand binding		Group I metabotropic ► glutamate receptors
Calcium homeostasis	Chinese hamster ovary cells; neuron-derived cell lines	Overexpression	ER release and mitochondrial uptake	store-operated calcium channels?
Protein kinase C	Splenocytes	Comparison PrP-null vs. wild type;	Calcium-dependent PKC forms	Unknown
► PI 3-kinase	Brain; neural cell lines; hippocampal neurons	Comparison PrP-null vs. wild type; transfection of cell lines; recombinant soluble PrP^C		Unknown
PI3-kinase	P388D-1 macrophage-like cell line	Recombinant soluble PrP^C; PI3-K inhibitor	Erk (reciprocal effect with Akt)	Unknown
PI3-kinase	Hippocampal neurons	Ligand binding	Akt; ► mTOR; p70S6 kinase; 4E-BP1	Unknown



Prion Protein (*PRNP*), Fig. 4 Schematic representation of cell surface signaling modules scaffolded by the prion protein. (**a**–**d**) represent *cis*-acting PrP^C. (**a**) NCAM-Fyn interaction induced by cross-linking of the prion protein; (**b**) laminin receptors, including integrin, the laminin receptor and PrP^C itself may interact in various combinations, and binding of the laminin γ-chain to PrP^C induces calcium release from intracellular stores, transduced by PrP^C-interacting, group 1 metabotropic glutamate receptors, via phospholipase C; (**c**) interaction of hop/STI1 with PrP^C leads to calcium influx mediated by the α7 nicotinic acetylcholine receptor; (**d**) certain signals induced by the interaction of hop/STI1 with PrP^C require endocytosis, and are probably mediated by a hitherto unidentified transmembrane protein; (**e**) *Trans*-acting PrP^C may be located in either neighboring cells or exosomes, and may scaffold various signaling modules. Molecular structures are used only for illustration purposes, and are not to scale. The N-terminal flexible domain of PrP^C was omitted for clarity. Abbreviations as in Table 2, plus: *exo* exosome, *endo* signaling endosome, *ER* endoplasmic reticulum. Lipid rafts are represented by a slightly thicker membrane depiction containing *blue* cholesterol molecules, only where there is evidence for the location therein of assembled complexes at the cell surface (Modified from Linden et al. 2008)

One of the clearest roles of PrP^C is upon cell survival. This is particularly relevant, since PrP^C is associated with TSEs, and, more recently was suggested to play a role in Alzheimer's disease. Although the importance of PrP^C loss-of function in neurodegeneration is still debatable, most studies using primary neuronal brain and retina cultures, immortalized neuronal cells, tumor cell lines, and even yeast support a cytoprotective function for PrP^C. Nonetheless, the expression of PrP^C may also be associated with increased cell death in certain circumstances. Remarkably, in recent years PrP^C has been implicated in tumor proliferation, progression, invasiveness, and resistance to drug treatment (Mehrpour and Codogno 2010 for review).

Together these results suggest that PrP^C may be a therapeutic target to increase neuronal survival in either acute or chronic neurodegenerative diseases. In addition, this ubiquitously expressed molecule may also represent both a new biomarker and a therapeutic target in cancer.

To explain all these possible functions of PrP^C we have raised the possibility that this molecule acts in a much more fundamental level coordinating signaling pathways at the cell surface. Proteins with unstructured domains can bind multiple partners, and are critical as intracellular scaffolds to regulate intracellular signaling. The unstructured N-terminal region of PrP^C may play a similar role and position the protein to organize signaling with multiple partners.

Mechanisms of Prp^{C}-Mediated Signal Transduction

Roles for the prion protein in signal transduction have been unraveled by various approaches. The main procedures involve the use of antibodies, modulation of protein content via either the knockout or overexpression of the *Prnp* gene, the use of anchorless, soluble recombinant forms of PrP^{C}, and engagement of PrP^{C} with one of its ligands.

In certain cases, modulation of signaling was shown by direct measurements, whereas in others, the effect of either pharmacological or molecular inhibitors was used to infer a role of PrP^{C} upon cellular responses. Both approaches may, in fact, unravel downstream responses networked to signaling pathways, instead of direct activation by the PrP^{C}. Also, when antibodies were used, some caution is necessary to interpret the results, since antibodies may have either a blocking or agonist effect, as well as either cross-linking or non-cross-linking activity. Nonetheless, a variety of signaling pathways have been shown to be modulated by the prion protein (Table 4).

Thus, current data strongly support the hypothesis that the prion protein may be physiologically engaged by a variety of extracellular and cell surface ligands, and mediates signal transduction through interaction with various transmembrane partners. The PrP^{C}-dependent signaling complexes are likely to vary among distinct cell types, depending on: the level of expression and distribution of PrP^{C}, as indicated in Table 1; the availability of ligands amongst, at least, those indicated in Table 2; structural rearrangements caused by multiple ligands; and kinetics of endocytosis/recycling. Indeed, the resulting signals likely depend on a complex interplay of allosteric effects caused by the binding to PrP^{C} of multiple partners with varying kinetics. Interactions are likely to be of significance both *in cis* and *in trans*. The latter are inferred mostly from results unraveled with the use of the soluble recombinant forms of PrP^{C}, which may correspond to PrP^{C} located at the surface of either neighboring cells, exosomes, or other exocytic particles (Linden et al. 2008).

Further analysis of signaling mediated by the prion protein is likely to unravel the mechanisms by which modulation of expression, engagement, or exposure to soluble PrP^{C} trigger proliferative, differentiating, or death/survival responses, as well as other effects upon cell metabolism, such as modulation of responses to oxidative stress, synaptic modulation, and immunomodulation. These, in turn, will likely explain the systems-level functions of PrP^{C}. An integrated systems approach may help defining signaling patterns generated by multiple pathways.

Summary and Future Directions

The currently available data suggest that the prion protein plays a significant role in signal transduction. PrP^{C} likely works as a cell surface scaffold protein, with the ability to organize multi-component complexes at the cell surface, which include other proteins, glycosaminoglycans, and free ions (Fig. 4). This role of PrP^{C} probably involves dynamic changes along its path of trafficking among distinct plasma membrane domains and endosomes. The resulting signals contribute to biological responses such as cell proliferation, differentiation, and modulation of cell death and responses to oxidative stress, synaptic modulation, and immunomodulation.

The relative lack of a spontaneous phenotype reported after deletion of the *Prnp* gene, which, for many years, has driven research interest off the physiological roles of the prion protein, may indeed invite one or more among several explanations, such as: a compensatory role of other members of the prion family; complex regulatory changes among networked signaling pathways; or a more subtle role of PrP^{C} as a modulator of signal transduction, particularly in the processing of either systemic or cellular stress and danger signals. Further investigation of these hypotheses, as well as of the proposed role of PrP^{C} as a cell surface scaffold protein, may contribute to a better understanding of its physiological functions, as well as to the establishment of effective therapeutic options for the still incurable transmissible spongiform encephalopathies.

Historical Background

Protein prenylation is a posttranslational modification of proteins involving the addition of isoprenyl lipids (Tamanoi and Sigman 2001). It is a post-translational modification that occurs in the cytosol and is essential for the proper localization and functions of many proteins. There are three kinds of prenyltransferases: protein farnesyltransferase (FTase), protein geranylgeranyltransferase-I (GGTase-I), and Rab geranylgeranyltransferase (RabGGTase). No additional prenyltransferases have been described to date. Farnesyltransferase (FTase) catalyzes the addition of a 15-carbon farnesyl group to proteins such as Ras proteins, Rheb proteins, nuclear lamins, and Hdj2 that end with the Cys-A_1-A_2-X (CA_1A_2X) motif, where A is an aliphatic amino acid and X is usually serine, methionine, glutamine or alanine. The lipid is covalently attached to the Cys via a thioether linkage between C1 of the farnesyl group and the sulfur of Cys. Some CA_1A_2X-ending proteins such as K-Ras and N-Ras undergo geranylgeranylation catalyzed by GGTase-I when farnesylation is inhibited, in a process known as alternative prenylation (Whyte et al. 1997). Interestingly, RhoB protein can be either farnesylated or geranylgeranylated (Lebowitz et al. 1997). See chapters on Ras and Rho for the function of these proteins. A recent study identified novel peptide substrates for FTase (Hougland et al. 2009). In their study, Hougland J.L. et al. selected and screened a library of small peptides representing the C-termini of more than 200 human proteins for reactivity with FTase. They identified two peptide substrate classes with distinct sequence selectivities – one class that exhibits multiple-turnover (MTO) reactivity, and another class that exhibits single-turnover (STO) reactivity, presumably due to slow dissociation of the prenylated peptide substrate under steady-state reaction conditions. In addition, they examined the amino acid composition of the two peptide substrate classes. While the STO peptides vary significantly at both the A_2 and X residues, the MTO peptides are enriched in a non-polar amino acid at the A_2 position and a Phe, Met, or Gln at the terminal X residues (Hougland et al. 2009). Some of the STO peptide substrates identified include CVLL (R-Ras), CAKS (Rab 38), CYSN (Ubiquitin-conjugating enzyme E2 variant 1), and CPLG (Ras association domain family 1) (Hougland et al. 2009).

Protein Farnesyltransferase

Enzyme Structure

FTase is a heterodimeric, zinc metalloenzyme that consists of the α-subunit (48 kDa) and the β-subunit (46 kDa). The α-subunit is composed of fewer amino acids than the β-subunit (377 vs 437 residues)

(Tamanoi and Sigman 2001; Zhang and Casey 1996). FTase and GGTase-I share the same α-subunit; the cDNA cloning of FTase and GGTase-I confirmed that the α-subunits of both prenyltransferases are encoded by the same gene. The β-subunit of FTase is distinct from that of GGTase-I, but they share an overall amino acid similarity of about 30%. Crystal structures have revealed that both α and β subunits are composed primarily of α helices (Park et al. 1997). They are arranged in a crescent-shaped superhelix (α-subunit) that wraps around an α-α barrel (β-subunit) which has a deep central cleft that forms the active site of FTase (Park et al. 1997). Although the majority of the active site residues are derived from the β-subunit, both subunits are important for substrate binding and catalysis.

Crystal structures of FTase indicate the presence of a single Zn^{2+} ion bound to the β subunit near the α/β subunit interface (Taylor et al. 2003). The Zn^{2+} ion is required for catalytic activity and coordinates the Cys thiol of the CA_1A_2X substrate. Mg^{2+} ions have also been found to bind to the active site of FTase and can accelerate the protein farnesylation reaction by up to 700-fold (Pickett et al. 2003). Recently, Yang Y. et al. reported a computational study regarding the Mg^{2+} binding site in FTase. Their calculations support the idea that D352β plays a critical role in Mg^{2+} binding and Mg^{2+} is important for the conformational transition step of the reaction (Yang et al. 2010).

In an earlier study, crystallographic analysis of FTase and GGTase-I complexed with substrate peptides, including those that were derived from the C termini of K-Ras, H-Ras, and TC21, was performed to define rules of protein substrate selectivity for both prenyltransferases (Reid et al. 2004). They showed that residues Trp102β, Trp106β, and Tyr361β of FTase bind to the A_2 residue of the CA_1A_2X. Interestingly, their findings suggested that the X residue of the CA_1A_2X of FTase substrates can bind in one of two different sites, one found by residues Tyr131α, Ala98β, Ser99β, Trp102β, His149β, Ala151β, and Pro152β of FTase, the other formed by residues Leu96β, Ser99β, Trp102β, Trp106β, and Ala151β of FTase (Reid et al. 2004).

Mutagenesis studies and crystal structures have provided an insight into the structure of FTase in complex with the isoprenoid of farnesyl diphosphate (FPP), the prenyl donor (Reid et al. 2004; Bowers and Fierke 2004). FPP reaches to the bottom of the hydrophobic, deep central cleft of the β-subunit. The diphosphate moiety of FPP interacts with residues Lys164α, Arg291β, His248β, Lys294β, and Tyr300β at the top of the α-α barrel. Residues Lys164α, Arg291β, His248β, Lys294β, and Tyr300β form the diphosphate binding pocket. Crystal structures of inactive FTase•FPP•peptide complexes illustrate that Lys164α interacts with the α-phosphate of FPP, while His248β and Tyr300β form hydrogen bonds with the β-phosphate of FPP. Consistent with previous reports, molecular dynamic simulations of the ternary structure of FTase•FPP•acetyl-capped tetrapeptide (acetyl-CVIM) showed that residues Arg291β, Lys164α, Lys294β, and His248β contributed to the binding of the diphosphate group (Cui et al. 2005). In addition, the first isoprene unit (C1-C5) of FPP binds in an aromatic pocket consisting of residues Tyr251β, Tyr166α, Tyr200α, His248β, and His201α.

Regulation of Farnesyltransferase Activity

In one line of investigation, it was shown that insulin stimulates phosphorylation of the α-subunit by four-fold and enhances FTase activity in 3T3-L1 fibroblasts and adipocytes. In another study, phosphorylation of the α-subunit was shown to affect FTase activity. This conclusion was supported by experiments showing that insulin-stimulated vascular smooth muscle cells (VSMC) expressing a non-phosphorylatable mutant FTase-α (S60A, S62A) exhibited reduced phosphorylation and decreased FTase activity (Solomon and Goalstone 2001). Furthermore, expression of the non-phosphorylatable mutant FTase-α (S60A, S62A) in MCF-7 cells blocked IGF-1 and insulin-stimulated BrdU incorporation and cell count. Interestingly, phosphorylation of the α- and β-subunits of FTase was detected in rat adrenal medulla pheochromocytoma (PC12) cells (Kumar and Mehta 1997).

The potential regulation of prenyltransferase activity by glucose, which regulates insulin secretion in the pancreatic β-cell, was investigated (Goalstone et al. 2010). They showed that an insulinotropic concentration of glucose [20 mM] stimulated the expression of the α-subunit of FTase/GGTase-I by about threefold in insulin-secreting INS 832/13 cells and by about fourfold in isolated rate pancreatic islets, but not the β-subunit of FTase or GGTase-I. Moreover, an insulinotropic concentration of glucose stimulated FTase activity in INS 832/13 cells and rat islets by about 2.75- and 3.5-fold, respectively. Likewise,

GGTase-I activity was increased by about 3.5 fold in INS 832/13 cells and by about fourfold in rat islets following exposure to high glucose [20 mM] (Goalstone et al. 2010).

In addition, cleavage of the α-subunit of FTase by caspase-3 during apoptosis was reported (Kim et al. 2001). Serial N-terminal deletions and site-directed mutagenesis showed that residue Asp59 of the α-subunit was cleaved by caspase-3. The cleavage resulted in the inactivation of FTase and GGTase-I. In another line of investigation, it was reported that JNK is involved in the C-terminal processing of Ras proteins (Mouri et al. 2008). Inhibition of JNK was shown to prevent C-terminal processing of H-Ras and its subsequent plasma membrane localization. Interestingly, the C-terminal processing of H- and N-Ras but not K-Ras was sensitive to JNK inhibition. Further study is needed to elucidate the biological significance of the involvement of JNK in C-terminal processing of Ras proteins.

In a recent study, Zhou J. et al. (2009) have shown that FTase forms a protein complex with microtubules and a histone deacetylase HDAC6 in vitro and in cells. FTase was shown to bind microtubules via its α-subunit, and that microtubules are required for the interaction between FTase-HDAC6 (Zhou et al. 2009). Furthermore, treatment with an FTI removes FTase from the protein complex and abrogates the deacetylase activity of HDAC6, suggesting that FTase regulates the function of HDAC6 in a microtubule-dependent manner (Zhou et al. 2009).

Biological Significance of FTase in Tumor Development

Mijimolle et al. (2005) addressed the biological significance of FTase by generating mice with knockout alleles for the gene encoding the β-subunit of FTase. They showed that FTase is essential for embryonic development, but dispensable for adult homeostasis. They reported that mouse embryonic fibroblasts (MEFs) deficient in FTase-β displayed a flat morphology, and reduced motility and proliferation rates. Surprisingly, H-Ras remained associated with the membrane fraction of FTase-β knockout cells, and the development of K-Ras induced tumors was not affected by FTase-β deficiency (Mijimolle et al. 2005). In a more recent study, it was shown that the FTase-β knockout allele generated by Mijimolle et al. yielded a transcript with an in-frame deletion, raising the possibility that this mutant transcript still yielded a protein with some residual FTase activity (Yang et al. 2009).

Conditional knockout of the β-subunit of GGTase-I has been shown to reduce tumor formation and increase survival in mice expressing K-Ras-induced lung cancer (Sjogren et al. 2007). Knockout of GGTase-I-β resulted in disrupted actin cytoskeleton, reduced cell migration and proliferation in fibroblasts expressing oncogenic K-Ras (Sjogren et al. 2007). More recently, Liu et al. (2010) created a conditional knockout allele for FTase-β and reevaluated the effects of FTase-β deficiency on protein prenylation, cell proliferation, and growth of K-Ras induced tumors. Furthermore, they assessed the effect of simultaneous inactivation of both FTase and GGTase-I on the development of K-Ras-induced lung cancer by breeding mice homozygous for conditional knockout alleles in both FTase-β and GGTase-I-β. They showed that FTase-β deficiency blocked proliferation of primary and oncogenic K-Ras-expressing fibroblasts, and that inactivation of FTase-β in mice inhibited K-Ras-induced lung cancer growth and improved survival (Liu et al. 2010). Moreover, simultaneous inactivation of both FTase-β and GGTase-I-β was shown to markedly reduce tumors and improve survival without apparent pulmonary toxicity (Liu et al. 2010). These findings suggested that targeting both prenyltransferases could be useful in cancer therapeutics.

Inhibitors of Farnesyltransferase (FTIs)

There has been considerable clinical interest in developing inhibitors of farnesyltransferase (FTIs) as anticancer agents because FTase catalyzes the processing of the Ras family members. In previous preclinical studies, FTIs were shown to block the growth of numerous tumors, including H-, K-, and N-Ras transgenic mouse models (Kohl et al. 1995). However, K- and N-Ras both undergo alternative prenylation when farnesylation is inhibited (Whyte et al. 1997), suggesting that the effects of FTIs on tumor growth might be due to FTI targets other than Ras. Clinical studies of FTI have been reported. For example, a phase I study to evaluate the tolerance and benefice of a combination of FTI tipifarnib (R115777/Zarnestra®, Janssen Research Foundation) and sorafenib (a multi-kinase inhibitor) in patients with advanced cancer has been reported (Chintala et al. 2008).

Recently, a nonpeptidic FTI, LB42708, has been shown to suppress vascular endothelial growth factor-induced angiogenesis by inhibiting Ras-dependent MAPK and PI3K/Akt signaling pathways (Kim et al. 2010). FTIs have also been shown to inhibit mammalian target of rapamycin complex 1 (mTORC1) signaling (Gau et al. 2005). See chapters on MAP kinases, Akt(PKB) and mTOR for signaling pathways. Moreover, it has been shown that FTIs preferentially inhibit mTORC1 signaling in non-small cell lung cancer cells (Zheng et al. 2010).

In addition, FTIs were evaluated for the treatment of Hutchinson Gilford Progeria Syndrome (HGPS), a rare condition that arises from accumulation of farnesylated prelamin A (Fong et al. 2006). Costello syndrome (CS) is a congenital disorder that is characterized by mental retardation, distinctive facial appearance, cardiovascular abnormalities, tumor predisposition, and skin and musculoskeletal abnormalities (Lin et al. 2005). Interestingly, about 80% of CS patients have *H-Ras* mutations, primarily $H\text{-}Ras^{G12S}$ (34G → A), suggesting that the development of FTIs as therapeutics for the treatment of CS could be promising as H-Ras is a farnesylated protein.

To elucidate the mechanism of FTI selectivity, Reid T.S. and Beese L.S. examined the crystal structures of FTIs, R115777 (tipifarnib/Zarnestra®) and BMS-214662 (Bristol-Myers Squibb), complexed with mammalian FTase (Reid and Beese 2004). Both FTIs are selective toward FTase, with almost no activity against GGTase-I. It was shown that both FTIs bind to the active site of FTase, and that drug binding does not induce a change in the structure of the active site of the enzyme. Furthermore, they showed that both FTIs bind as a ternary complex with farnesyl diphosphate (FPP) and coordinate the catalytic zinc ion (Reid and Beese 2004).

Summary

Protein farnesyltransferase is a heterodimeric enzyme catalyzing farnesylation of proteins ending with the CA_1A_2X motif found at the C-termini of proteins such as Ras, Rheb, nuclear lamins and the γ-subunit of some heterotrimeric G-proteins. The enzyme consists of the α- and β-subunits and its crystal structure has been determined. Regulation of the enzyme activities has been reported. Finally, a variety of small molecule inhibitors have been developed against the enzyme with the intention to inhibit membrane association of signaling proteins such as Ras.
