Historical Background

The intracellular protein tyrosine kinase, PTK6 (also known as the breast tumor kinase, Brk), has been implicated in the development and progression of a number of different tumor types. First identified in three separate studies in the early 1990s, it was initially found in a study to determine which tyrosine kinases were expressed in human melanocytes and then the full-length sequence was subsequently cloned from metastatic breast cancer using a screen to identify novel kinases that were expressed in tumors, but not normal breast tissue. Identification of the murine orthologue, Sik, in mouse intestinal cells was achieved by the generation of a library of kinase catalytic domains.

PTK6 is related to the Src family of protein kinases and belongs to a distinct class of enzymes which includes Frk and SRMS (reviewed in Brauer and Tyner 2010). Under normal physiological conditions, PTK6 expression is highly controlled and is usually limited to differentiating cells of epithelial origin. Several studies have reported that, pathologically (i.e., in disease tissue), PTK6 expression is increased in a number of different cancers compared to normal cells of the same tissue type (reviewed in Brauer and Tyner 2010; Ostrander et al. 2010). The apparent disparity in PTK6 expression and the difference in proliferation status between cellular differentiation in normal tissues, where cells tend not to be dividing; and the fact that tumors are highly proliferative (and cells are dividing rapidly) makes PTK6 an intriguing molecule for study, as there are likely to be both context- and function-specific differences that could be exploited in the development of antitumor therapies conferring benefit to patients.

Cellular Localization

PTK6 has been reported to have different functions in different tissue types; for example, in normal tissues PTK6's role appears to be related to regulating the differentiation process, whereas in tumors PTK6 promotes proliferation and cell survival. Variations in cellular localization are thought to be associated with PTK6's opposing roles in both differentiation and proliferation. Altered cellular localization will no doubt affect the variety of substrates and binding partners that are available for PTK6, thereby contributing to the different functions/effects that have been ascribed to PTK6 expression.

Myristoylation is a post- or co-translational protein modification, whereby a fatty acid-derived group is attached to an N-terminal amino acid. Such modifications allow proteins to associate with membrane structures. Although PTK6 is structurally related to Src, it lacks the amino-terminal myristoylation site (Mitchell et al. 1994). Without a myristoylation site, PTK6 is not able to associate directly with the plasma membrane, and therefore cellular localization is not tightly regulated. Originally PTK6 was thought to be solely a cytoplasmic kinase, however, it is now known to be in different cellular compartments, including at the membrane via association with its binding partners as well as in the nucleus (reviewed in Brauer and Tyner 2010). Association of a protein to the plasma membrane can be mimicked by experimental inclusion of a myristoylation site. Adding a myristoylation site to the N-terminus, enhanced PTK6's oncogenic role by promoting cell proliferation, survival, and migration of human embryonic kidney cells. Trapping PTK6 in the nucleus with synthetic nuclear localization signal abrogated these effects (Kim and Lee 2009); these in vitro experimental effects are supported by evidence from human tumors demonstrating that normal prostate epithelial cells and well-differentiated prostate carcinomas

had nuclear PTK6, whereas as poorly differentiated prostate cancers were found to have cytoplasmic PTK6 (Derry et al. 2003). These studies suggest that PTK6's oncogenic role may be dependent on its cellular localization.

As discussed, PTK6 contains neither myristoylation sites nor nuclear localization signals so it is unclear how PTK6 delocalizes from one subcellular compartment to another and which cellular signals are controlling this transition. It is possible that PTK6 is held in the cytoplasm by an as yet unidentified protein (Brauer and Tyner 2010).

PTK6 Substrates and Binding Partners

As a tyrosine kinase with amino acid sequence homology to Src, PTK6 also has a similar domain structure consisting of SH2 and SH3 domains (which typically interact with phosphorylated tyrosines and proline-rich sequences, respectively) as well as a kinase domain (which phosphorylates its target substrates on tyrosine). It is therefore capable of phosphorylating a number of target molecules and there is a rapidly expanding list of known interacting proteins (summarized in Table 1). To date, 29 PTK6-associated interactions have been identified (Irie et al. 2010; reviewed in Brauer and Tyner 2010), but whether all of these interactions result in phosphorylation has not yet been determined. PTK6 is proposed to have some kinase independent function (Harvey and Crompton 2003), suggesting that a functional kinase domain is not required for all of PTK6's activities. It has been suggested that it may function as an adaptor molecule, and therefore it is highly likely that not all the interacting proteins will be substrates of PTK6's kinase activity. Therefore it is possible that one of PTK6's functions is to stabilize signaling complexes to allow phosphorylation of some of its interacting proteins and/or additional molecules within the complex by other kinases. This association in a large signaling complex, as an adaptor or scaffolding molecule, may also contribute to PTK6's cellular localization.

PTK6 and Signaling Pathways

From the variety of interacting proteins that have already been identified (Table 1), it is clear that PTK6 plays a role in a number of different cellular processes and signaling pathways (Fig. 1). This is also apparent from the range of signaling molecules that activate PTK6, which include epidermal growth factor (EGF), Heregulin (HRG), insulin-like growth factor (IGF), Hepatocyte growth factor (HGF), osteopontin (OPN), and calcium ions.

Although still incomplete, the PTK6-ErbB receptor signaling "picture" is the most comprehensive in term of our current knowledge relating to PTK6's role in tumor cells. PTK6 has been shown to associate with all members of the ErbB receptor family (reviewed in Ostrander et al. 2010) and potentiates the proliferative effects of EGF by activating the phosphoinositide 3-kinase (PI3-K)/Akt signaling pathway (Kamalati et al. 2000). PTK6 is known to play a role in cell migration through the phosphorylation of paxillin, which is a "molecular scaffold" that interacts with signaling molecules and a number of proteins that are involved in cell motility. In response to EGF, activated PTK6 phosphorylates paxillin resulting in the activation of Rac1 and an increase in cell migration

Protein Tyrosine Kinase-6 (PTK6), Table 1 Summary of the localization of the major identified PTK6-interacting proteins

Membrane Proteins	Intracellular Cytoplasmic Proteins	Nuclear-Protein
EGFR	ARAP-1	β-Catenin*
HER2	IRS-1	Sam68
ErbB3	IRS-4	SLM-1
ErbB4	Erk5	SLM-2
IGF-1R	β-Catenin*	PSF
ADAM-15A	Akt	KAP3A*

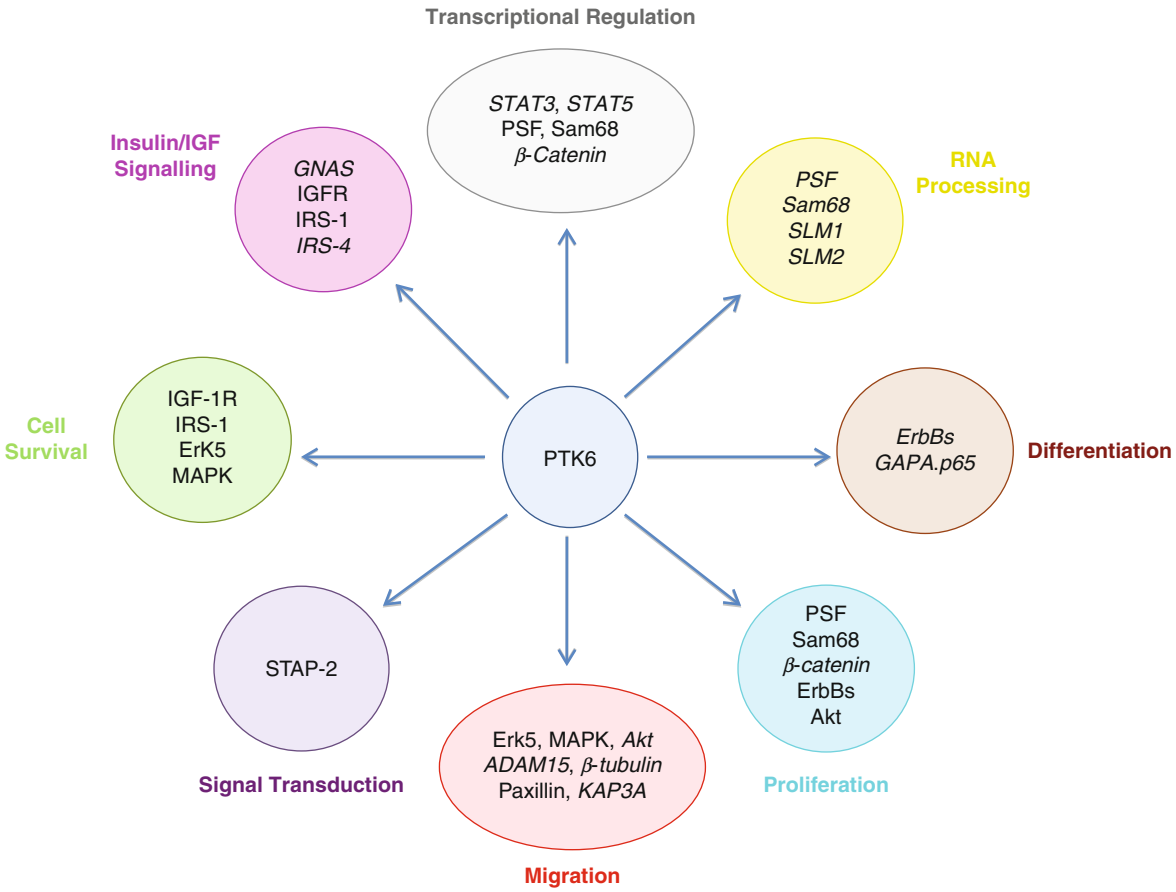
	GapA-p65	

*These proteins are reported to have functions in different cellular compartments; however, it has not yet been determined whether PTK6 affects the function of these proteins in all their localizations. A further two interactions have been reported; however, the proteins involved (which are 23 and 100 kDa in size) have yet to be identified.



Protein Tyrosine Kinase-6 (PTK6), Fig. 1 Potential biological effects of PTK6-mediated interactions. PTK6-substrate interactions result in a number of known biological effects. Known effects of the interactions are represented by normal text font, whereas italic text represents effects based on current knowledge of the PTK6-binding protein

(Chen et al. 2004). Treatment of breast cancer cells with the ErbB ligand HRG also increased cell migration, via activation of both Erk5 and an Erb-PTK6-Rac-p38 MAPK signaling pathway (Ostrander et al. 2007).

PTK6's interactions with the nuclear STAR (Signal Transduction and Activation of RNA) proteins (Sam68 and SLMs) and polypyrimidine tract-binding protein-associated splicing factor (PSF) are induced in response to EGF treatment. Phosphorylation of PSF and Sam68 (as well as the Sam68-like mammalian proteins, SLM1 and SLM2) by PTK6, results in inhibition of their RNA-binding activities. Reducing their RNA binding capability is one mechanism of reducing the function of proteins that bind RNA. As these proteins regulate a number of RNA processing events, including alternative splicing, PTK6 activation could result in the posttranscriptional regulation of gene expression. In addition EGF-mediated activation of PTK6 induced phosphorylation of Sam68 which increased cell proliferation. This presumably occurred through suppressing the antiproliferative properties of Sam68 (Lukong et al. 2005; reviewed in Ostrander et al. 2010).

PTK6 expression has also been linked to the potential regulation of IGF signaling. PTK6 interacts with the IGF-1R/IRS-1 complex resulting in increased activation of IGF-1R as well as Akt. An increase in IGF-1-mediated, anchorage-independent cell survival was also observed in both breast and ovarian cancer cells (Irie et al. 2010). Similar effects on cell survival have also been shown in serum stimulated breast cancer cells, where PTK6 again protected against cell death in suspension culture (Harvey et al. 2009). Interestingly, in IGF-1 stimulated cells PTK6 protected cells from classical apoptosis/anoikis

(Irie et al. 2010), whereas the Harvey study showed that PTK6 protected breast cancer cells from cell death via autophagy. Taken together, these studies indicate that PTK6 can protect cells from different types of programmed cell death, and that this protection could feasibly be through different mechanisms.

Furthermore, treatment of breast cancer cells with the Met receptor ligand, HGF, induced both activation of Erk5 and cell migration (Castro and Lange 2010). The PTK6/Erk5 interaction and the increased migration that was induced in response to HGF was not dependent on the kinase activity of PTK6, providing further evidence that some aspects of PTK6 function are not reliant on its kinase domain. This implies that PTK6 could coordinate the large signaling complexes that are required for cell migration, without directly phosphorylating components of the complex.

Most of the PTK6-mediated interactions and activation events result in altered cell behaviors, such as increased proliferation, cell survival, migration, and the secretion of angiogenic factors, all of which are traits that are characteristic of tumor cells and are required for tumor development (Reviewed in Hanahan and Weinberg 2000). It would appear from the majority of studies carried out in tumor cell lines, that PTK6 could play a central role in tumor progression, especially in breast cancer. In support of this hypothesis Chakraborty and colleagues showed that treating cells with OPN resulted in PTK6 activation and an increase in vascular endothelial growth factor (VEGF) production. Combined with in vivo models, they were able to demonstrate that OPN triggers VEGF-dependent angiogenesis (formation of new blood vessels) and tumor growth as a result of PTK6 activation (Chakraborty et al. 2008).

In cells where PTK6 is physiologically expressed, i.e., normal differentiating cells, the effects of PTK6 activation are distinct to those seen in tumor cells. When keratinocytes (skin cells) are treated with calcium, PTK6 is transiently activated and cell differentiation is induced, in contrast to the proliferation or migration seen in tumor cells (Wang et al. 2005; reviewed in Brauer and Tyner 2010). Recent evidence suggests that PTK6, the EGF receptor (EGFR) and a marker of differentiation, may be co-regulated during differentiation, and that the differentiation of normal primary human keratinocytes could be influenced by altered PTK6 expression (Tupper et al. 2011).

It is clear that PTK6 signaling is diverse (Fig. 1), and that PTK6's function with respect to signaling is different in normal differentiating cells to that in tumor progression. PTK6 has also been shown to associate directly with Akt (Zhang et al. 2005) and, in conjunction with results from several other studies, has lead to the hypothesis that one of PTK6's roles in normal cells could be to constrain Akt activation, possibly to allow differentiation to occur. In tumor cells, the constraint is lost and the PI3-K/Akt pathway subsequently becomes activated (Ostrander et al. 2010), thereby upregulating the processes that are known to be involved in tumor growth.

PTK6 Expression Profile

PTK6 expression is increased in many tumors compared to normal epithelial cells (reviewed in Ostrander et al. 2010; Brauer and Tyner 2010) and this is most notable and most well characterized in breast tissue. The murine homologue of PTK6, Sik, is absent in normal adult mammary gland and during the various developmental stages. PTK6 is not found to be present in normal human mammary cells or in benign lesions (reviewed in Harvey and Crompton 2004), however, separate studies have now demonstrated that up to 86% of breast cancers have elevated PTK6 expression and that the increase in expression correlated with an increase in tumor grade (Ostrander et al. 2007; Harvey et al. 2009). PTK6 expression has also been shown to correlate with HER2 overexpression (Aubele et al. 2007) and, the PTK6 gene is known to be co-amplified with HER2 in some tumors (Xiang et al. 2008). This is important from a tumor development stand-point, as interaction of PTK6 protein with HER2 induces and prolongs the activation of the MAPK pathway which would result in increased cell cycle progression and tumor cell proliferation. In addition, PTK6 is proposed to contribute to resistance to the new more specifically targeted anticancer therapy such as the EGFR/HER2 inhibitor lapatinib (Xiang et al. 2008).

These findings, taken together alongside the current knowledge of PTK6's multiple signaling roles in tumor cells, suggest that PTK6 is strongly implicated in tumor development. It could therefore be expected that PTK6 expression would have a negative impact on breast cancer patient survival. Aubele and colleagues,

however, suggest that PTK6 is a positive prognostic marker of metastasis-free survival (Aubele et al. 2007). One explanation for this arises from previous reports that PTK6 expression may also be correlated with expression of the estrogen receptor, a known positive prognostic indicator (discussed in Harvey et al. 2009). In addition, it is possible that driving tumor cells to proliferate may make them more susceptible to the effects of conventional chemotherapy agents. These are known to target actively dividing rather than "resting" cells, so increasing susceptibility to these agents could enhance the benefits of such therapy thereby aiding patient survival.

Summary

There is little doubt that the role of PTK6 is complex. It depends on a number of factors including cellular localization, accessibility of binding partners, availability of extracellular signaling molecules and potentially, at least in tumor cells, the extent to which PTK6 expression is elevated. There is the possibility that there are tumor specific modifications beyond changes in gene expression, and that there are tumor type and stage specific mechanisms of PTK6 function that need to be considered (Ostrander et al. 2010; Harvey and Crompton 2004). Both Brauer and Tyner, and Ostrander and colleagues (reviewed in Brauer and Tyner 2010; reviewed in Ostrander et al. 2010) suggested that further studies are fundamental to unraveling the complex and distinct roles that PTK6 plays in both normal differentiating cells and in tumor development. Understanding the distinctions between a pro-differentiation role in normal cells, and a potentially oncogenic role in tumor progression, is key to the development of novel therapeutic agents that could target either context-specific or cell-specific molecular functions and/or interactions with minimal effects in other tissues.

Historical Background

The G-protein-coupled receptor (GPCR), PSGR, was first identified by three distinct laboratories using different experimental approaches (Xu et al. 2000; Xia et al. 2001; Yuan et al. 2001). GPCRs constitute the largest gene family in the genome capable of influencing multiple signal transduction pathways; at the same time, they are the target of over half of the medications currently available in the pharmaceutical industry, demonstrating the importance of these receptors in maintaining tissue homeostasis. Research on this molecule has focused on its expression pattern and probable role as a potential biomarker for prostate cancer as well as in the possibility of a role in influencing prostate cancer initiation and progression, and the mechanisms through which this is done.

PSGR as a Molecule: Structural Analysis

Protein sequence analysis of PSGR predicted the presence of seven transmembrane domains with high homology to the olfactory subfamily of GPCRs (Xia et al. 2001). The full-length cDNA of PSGR contains an open reading frame of 320 amino acids (estimated cDNA size of 1.4 kb). Chromosomal analysis showed PSGR to be located at the GPCR cluster region in chromosome 11p15 (Xu et al. 2000). PSGR is also highly conserved among different species. The rat homolog to PSGR, RA1c, was found to have a high level of homology (~93%) with this gene even within the 5′and 3′untranslated regions. Cloning of the mouse PSGR using degenerate PCR amplification showed it is also highly homologous with 93% sequence similarity to the human gene, and 99% sequence similarity to the rat gene.

PSGR expression analysis was performed through multiple methods. First, the distribution of PSGR mRNA in 23 different normal human tissues was analyzed through Northern blot experiments. Results showed that human PSGR mRNA-specific transcripts could be detected only in the prostate (Xu et al. 2000). This data was confirmed by the other two laboratories also working on PSGR (Xia et al. 2001 and Yuan et al. 2001), with the notion of very faint signals for human PSGR in spleen and liver (Yuan et al. 2001). This expression pattern, however, does not remain true for other organisms. Northern blot analysis of mouse RNA showed expression in both brain and colon but no expression in prostate tissues. Rat tissue analysis showed PSGR expression in the brain and liver but none in prostate. These results were further confirmed by RT-PCR.

In an effort to understand the role of PSGR in prostate tissue and disease, PSGR expression levels were analyzed in prostate tumor samples through PCR and Southern blot analysis. Results show that PSGR expression is significantly increased in prostate tumor samples when compared to normal prostate tissue (Xia et al. 2001). Comparison between normal and tumor tissues showed overexpression in approximately 62% of tumor specimens. In situ RNA hybridization showed a significantly higher PSGR expression level in transformed prostate epithelial cells when compared to normal adjacent cells (Xu et al. 2000). Subsequently, a large cohort of human normal and tumor tissue samples were analyzed for PSGR expression levels. The results showed a significant overexpression of PSGR in both prostate intraepithelial neoplasia (PIN) and prostate carcinoma (~76%) when compared to normal tissues and samples with benign prostatic hyperplasia. This study suggested the possibility of a biomarker function for PSGR due to its specificity of expression and overexpression (Weng et al. 2005a).

In an in vitro setting, different prostate cancer cell lines were analyzed for PSGR expression where a weak signal was found only in LNCaP cells, leading researchers to believe that PSGR expression might be tissue context specific or that its expression in cell lines may be lost through continuous cell culture (Xu et al. 2000).

PSGR as a Biomarker for Prostate Cancer

To study the potential function of PSGR as a biomarker, pure target cells, either from normal prostate epithelium or tumor samples, were microdissected using laser capture microdissection (LCM) technology, and then amplified and analyzed. Expression levels for PSGR were graded as fold change between normal and tumor cells. PSGR overexpression was found in 67.2% of tumor samples. Also, Pearson correlation coefficients analysis showed a correlation between PSGR and PSA levels ($P = 0.03$), suggesting a role for PSGR in prostate cancer progression (Xu et al. 2006).

The possibility of a biomarker function for PSGR was further analyzed in conjunction with the already known diagnostic marker AMACR and PSGR2. AMACR or a-methylacyl-CoA racemase is also highly overexpressed in prostate cancer when compared to normal tissue. When used in conjunction with immunohistochemistry (IHC) for basal cell specific markers, this marker is very useful in solving diagnostic problems during a biopsy. Quantitative real-time PCR analysis showed that AMACR expression was related to a Gleason score of 7 but was lower in poorly differentiated tumors than in moderately differentiated tumors. Of all the three markers analyzed, however, AMACR was overexpressed in 78% of the samples, with a 30-fold increase in expression, PSGR was overexpressed in 64% of the samples, with a 10-fold increase, and PSGR2 was overexpressed in 60% of the tissues, with a 20-fold increase. PSGR was not a stronger biomarker than AMACR, according to statistical analysis, nor was there any correlation between overexpression of all three genes. There were, however, some cases where PSGR overexpression was

significantly higher than AMACR, suggesting PSGR may be useful as a biomarker for disease only in specific clinical cases (Wang et al. 2006).

PSGR was also studied as a biomarker for urine analysis diagnosis of prostate cancer. Prostate cancer gene 3 (PCA3) is the current gold standard of prostate cancer diagnosis in urine. It was found that the specificity of each biomarker alone, while fixing the sensitivity at 95%, is somewhat low (15% and 17% respectively). However, measuring both biomarkers increased the specificity to 34%, improving the probability of adequate decision making in a clinical scenario. So overall, PSGR detection in urine was able to aid PCA3 detection and decrease the possibility of false-negative diagnosis of prostate cancer patients.

Regulation of PSGR Gene Expression

In an effort to understand the mechanisms that regulate the specific expression for PSGR in prostate tissues and tumors, Weng and colleagues (Weng et al. 2005b) characterized the PSGR promoter and analyzed its expression. They found that PSGR had two distinct regulating promoters. The first promoter, located within exon 1 and its upstream region, with a TATA box at −31 bp, and the second promoter, located upstream of exon 2, with no TATA box or GC-rich sequences. First, they verified the presence of PSGR in human prostate cancer cell lines, finding the highest expression levels in LNCaP cells. As mentioned before, PSGR has two exons, separated by a 14.9-kb intron. Exon 1 is non-coding; the entire protein coding from exon 2. Bioinformatics analysis showed that aside from the TATA box, exon 1 contains multiple DNA *cis*-element binding sites, including ▶ STAT3, NFkB, CACCC-binding factor, and AP1. For the upstream region of exon 1, a 40-bp sequence previously described (Yuan et al. 2001) was found to be the transcription start site for PSGR. For exon 2, another 40-bp sequence was found upstream of the exon. This sequence lacks a TATA box and is non-GC rich but has *cis*-element binding sites including GATA factors, Lom2 and a forkhead recognition sequence, Freac-6. Luciferase assays characterizing different regions of the potential promoters show that transcriptional activity from sequences outside of exon 1 is not as strong as sequences containing the exon, suggesting that exon 1 has transcription factor–binding sites with a positive transcriptional activity. The activity was also much higher in LNCaP cells, suggesting tissue specificity for these factors. It was concluded that the basic promoter for PSGR is within the first −123 bp before exon 1, including the TATA box at −31 bp. For the second region found before exon 2, a luciferase assay analyzing promoter activity from different orientations showed that its activity is in fact orientation dependent, suggesting it acts as a promoter and not as an enhancer for PSGR transcription. Serial deletion constructs showed that the highest promoter activity was at −331 bp. The transcription start site for this second promoter was determined by RPA protection assay, finding a very strong start site at −311 bp with two other weak ones at −175 bp and −118 bp upstream from the ATG in exon 2. Because of the presence of two transcription initiation sites, the authors propose the presence of two different sizes of PSGR transcripts in prostate tissues, the longer variant being the most commonly expressed one. Finally, both promoter regions were stimulated with a variety of growth factors and cytokines to analyze for PSGR expression regulation. Out of all the factors, including R1881, PSGR promoter activity was mostly increased by stimulation with IL-6. IL-6 has been found to be increased in patients with hormone refractory prostate cancer, and the specific relationship between IL-6 and PSGR remains to be found.

Mechanisms of Action

As mentioned before, PSGR is a member of the olfactory family of GPCRs. Recent research on PSGR has focused on the discovery of a potential ligand capable of activating the PSGR signaling pathway. In order to find a ligand for PSGR, Neuhaus and colleagues (Neuhaus et al. 2009) transiently expressed PSGR in HEK293 cells, which do not normally express the receptor, and stimulated the cells with a mixture of 100 steroid hormones from different structural classes and measured the cell responses with ratiofluorometric Ca^{2+} imaging. Using this technique, this research group identified androgen-related compounds as the active ligands for PSGR; the presence of an aldehyde group at position 3 together with at least two double bonds at positions 4 and 6 (Neuhaus et al. 2009) was the key determinant for compounds being

effective PSGR ligands. Testing another mixture which includes 100 aromatic and short chain aliphatic hydrocarbon compounds, b-ionone was found to be a potential ligand for PSGR. To prove that the effect of b-ionone was specific for PSGR, LNCaP cells were transfected with siRNA for PSGR linked to a GFP marker. Cells were then stimulated with b-ionone and within the same cell culture, siRNA-transfected cell calcium response was compared to non-siRNA-transfected adjacent cells still expressing PSGR. The calcium response in cells still expressing PSGR compared to cells with siRNA for PSGR was significantly higher. No effect was seen with transfection of a scrambled control siRNA as well. They also tested for the functional effect of b-ionone activation on LNCaP and PC3 cells, showing that the suggested PSGR ligand has antiproliferative effects on cell proliferation, possible through activation of the SAPK/JNK signaling pathway.

Recently, a study on the mechanisms behind the induction of a Ca^{2+} cytosolic increase related to PSGR was also published. It was found that PSGR activation by b-ionone in LNCaP cells is able to open Ca^{2+} conducting channels in the plasma membrane and that the behavior of these channels is highly Ca^{2+} concentration dependent, behaving in a time course previously described for TRPV6 channels. To prove activation of the PSGR by b-ionone functions through TPRV6 channels, siRNA linked to a GFP protein was used to knock down TPRV6 channels and were then stimulated with b-ionone. None of the cells showed the typical response described previously, suggesting that the b-ionone-induced Ca2+ response in LNCaP cells is dependent on TRPV6 cells. G protein signaling, however, does not seem to be involved in the b-ionone-induced calcium response, since locking G proteins in their active or inactive states does not change the b-ionone-induced current nor does it seem to be linked to the olfactory receptor canonical pathway. The G_{olf}-mediated activation of adenylyl cyclase, which ultimately leads to a Ca^{2+} influx through cAMP-gated ion channels suggests that PSGR is capable of activating an alternate signaling pathway. The possible mechanism for this alternate pathway is through direct interaction between PSGR and Src kinases, without the involvement of G proteins. The b-ionone-induced current was abolished with the introduction of Src family inhibitors, confirming the involvement of Src kinase family in this pathway.

Summary

PSGR is a G-protein-coupled receptor member of the olfactory subfamily of GPCRs that is specifically expressed in prostate and overexpressed in prostate cancer. Because of this behavior, it was proposed to have possible potential as a prostate cancer biomarker. Several studies performed on prostate and prostate cancer tissues, however, did not find a very strong correlation between PSGR expression and prostate cancer progression. It did increase the specificity of other biomarkers such as *AMACR* and *PCA3*, when analyzed in conjunction with them. It was suggested, however, that PSGR may work as a good biomarker for certain specific clinical scenarios, though which scenarios remains to be found. PSGR expression regulation analysis found two promoter sequences active in the PSGR gene. The first is located upstream of exon 1, with a TATA box as the transcription starting site, while the second is located 311 bp upstream of the ATG site in exon 2, suggesting the existence of two PSGR transcripts. It was also found that PSGR expression is induced by stimulation with IL-6, not R1881 or other growth factors or cytokines. PSGR was also found to respond to b-ionone, an aromatic compound that induces a Ca^{2+} response that inhibits proliferation of prostate cancer LNCaP cells. Furthermore, the b-ionone response seems to be related to the calcium-conducting channels TPRV6, which seem to interact directly through Src kinase family members, independently of G proteins. What does future research on this molecule look like? Current research is focused on elucidating the potential signaling pathway through G proteins that is activated by this receptor, thereby describing its canonical pathway and finding what potential ligands are capable of activating this pathway. Also, there are several mouse models currently in development and characterization that will help understand the mechanisms through which PSGR functions and the role it plays in prostate cancer progression.

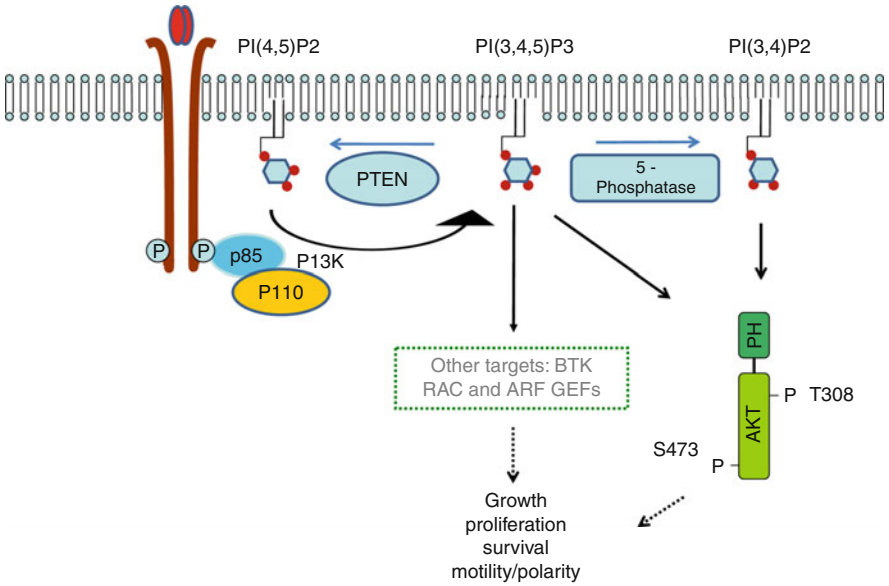
Historical Background

Widespread interest was generated in 1997 when PTEN was identified almost simultaneously by three research groups as a candidate tumor suppressor in cancers of the brain, prostate, and breast (Li and Sun 1997; Li et al. 1997; Steck et al. 1997). As a member of the large and diverse protein tyrosine phosphatase superfamily, it was expected that PTEN would act to oppose oncogenic tyrosine kinase signaling pathways by dephosphorylating specific tyrosine phosphorylated substrates. However, it soon emerged that PTEN is primarily a lipid phosphatase and that by dephosphorylating the lipid second messenger PtdIns $(3,4,5)P_3$, it acts to suppress signaling through the PI3K signaling pathway (Maehama and Dixon 1998) (Fig. 1). Here the substantial insight that has been provided in the last 13 years by the intensive study of this important tumor suppressor will be discussed.



PTEN, Fig. 1 *PTEN and the PI3K signaling pathway*. A schematic diagram of PI3K-dependent signaling pathway is shown. Upon receptor-driven activation of Class I PI3K enzymes, these lipid kinases phosphorylate PtdIns(4,5)P_2 to form the lipid second messenger PtdIns(3,4,5)P_3. This lipid in turn activates downstream responses, generally including cellular growth, proliferation, survival, and motility through direct effector proteins including the AKT and BTK groups of protein kinases and activating exchange factors (GEFs) for the RAC and ARF families of small GTPases. PtdIns(3,4,5)P_3 is in turn metabolized either by the 3-phosphatase PTEN or by members of a family of phopshoinositide 5-phosphatases

PI3K Signaling

The class I ▶ phosphoinositide 3-kinases (PI3K) are a family of lipid kinases that play a central role in an evolutionarily conserved signal transduction pathway/network of which PTEN is part (Hawkins et al. 2006). Their tightly controlled activity phosphorylates the relatively abundant phosphoinositide PtdIns(4,5)P_2 on the D3 position of the inositol ring, to form the lipid second messenger PtdIns(3,4,5)P_3 (Fig. 1). Class II and Class III PI3K enzymes also exist in mammalian cells, but although these phosphoinositide kinases also phosphorylate the D3 position of the inositol ring, they act upon different substrates and will not be further considered here.

The class I PI3Ks exist in cells as heterodimers, comprising a catalytic subunit of 110 kD in size and a regulatory subunit, which ranges in size from approximately 55 kD to 100 kD. The human and mouse genomes each encode four different catalytic p110 subunits, which display some differences in their expression patterns, regulatory partners, and signaling inputs (Hawkins et al. 2006). The p110 α, β, and δ enzymes bind with regulatory subunits, most commonly of 85 kD in size, that contain paired SH2 domains, and result in activation of PI3K activity through tyrosine kinase–based signaling mechanisms, in particular via receptor tyrosine kinase (RTK) signaling. In contrast, the p110 γ PI3K catalytic subunit binds to one of two unrelated regulatory subunits, p84 or p101, that allow regulation of kinase activity through G-protein coupled receptor (GPCR)-based signaling. It has been shown more recently that the p110 β isoform is also activated by many GPCRs, although the mechanism of this activation is currently unclear. Although these differences exist in the inputs into the PI3Ks via their regulatory subunits, each of the four catalytic subunits has a binding site for the activated form of the RAS small GTPases. Thus, PI3K activity appears to be tightly controlled, with low activity in the absence of stimulation that can be provided through mechanisms that include RTK, GPCR, and RAS signaling (Vanhaesebroeck et al. 2010).

The direct PI3K lipid product PtdIns(3,4,5)P_3 propagates the effects of PI3K activation through a large and diverse group of effector proteins that are able to bind directly to this lipid with high selectivity (Fig. 1). The best studied downstream targets for PI3K/PIP_3 activation

are the AKT family of serine/threonine kinases that have an N-terminal PIP_3 binding Pleckstrin Homology (PH) domain and a C-terminal kinase domain. Experiments in flies and worms have shown that the AKT kinases are evolutionarily conserved and key functional mediators of PI3K signaling. The three human AKT kinases have many substrates and are important regulators of cell growth, proliferation, survival, and metabolism (Manning and Cantley 2007). However, estimates are that there are between 25 and 50 selective PIP_3 binding proteins encoded in the human genome and in many cases the relative contributions of these proteins to the PI3K signaling network is unclear (Hawkins et al. 2006).

Once synthesized by PI3K, the PIP_3 signal can be removed either by one of two routes of metabolism. A family of phosphoinositide 5-phosphatases, the best characterized being the ▶ SHIP and SHIP-2 enzymes, dephosphorylate the 5-position of PIP3 to form the alternate phosphoinositide signal PtdIns(3,4)P_2, which shares some selective binding partners with PIP3, including the AKT kinases, and is believed to contribute directly to the outcomes of PI3K activation (Fig. 1). PtdIns(3,4)P_2 in turn appears to be removed at least in part, by the action of the INPP4 phosphoinositide 4-phosphatase enzymes.

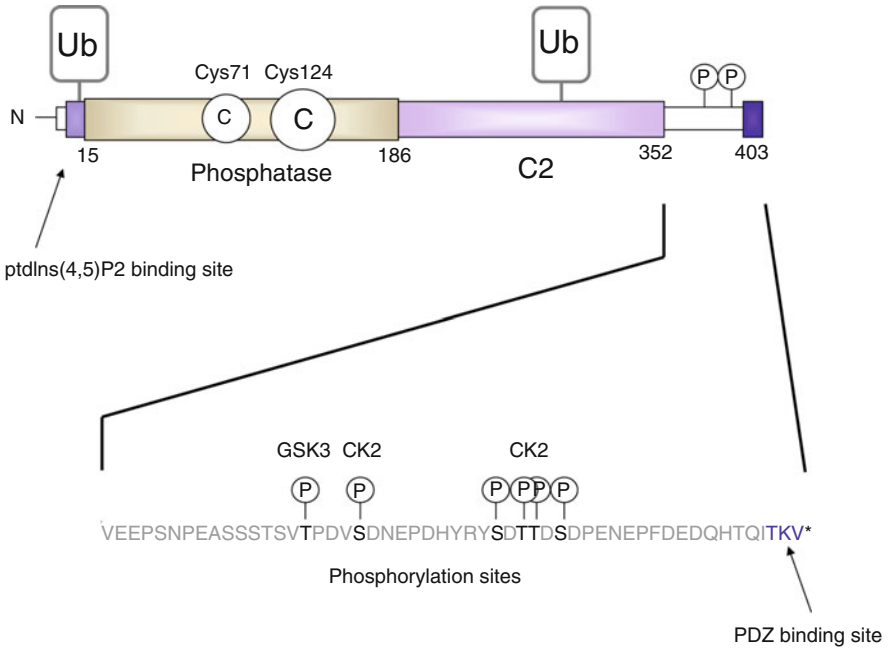
The other main route of metabolism of PIP_3 is by removal of its 3-phosphate, acting to terminate PI3K signaling by reproducing PtdIns(4,5)P_2. It is this reaction that is performed by PTEN and which forms the basis for its tumor suppressor activity.

The PTEN Protein

The human *PTEN* gene appears to encode a single 403 amino acid protein, with an N-terminal phosphatase domain, a more C-terminal C2 domain, and a 50 amino acid regulatory C-terminal tail (Fig. 2). One crystallographic 3D structure has been determined for the minimal phosphatase/C2 core of PTEN, which along with the phosphatase domain amino acid sequence, identifies PTEN as a member of the protein tyrosine phosphatase (PTP) superfamily (Lee et al. 1999). This structure also revealed a broader active site pocket than most other PTP family members, capable of accommodating the inositol lipid headgroup, and containing the conserved PTP family catalytic residues, including the nucleophilic cysteine, Cys124. This would seem to fit with PTEN's substrate selectivity for PtdIns(3,4,5)P_3, over the other 3-phosphorylated phosphoinositides such as PtdIns(3,4)P_2 and the ability of the phosphatase to dephosphorylate peptide substrates, certainly in vitro, with a preference for phospho-tyrosine substrates over phosphorylated serine or threonine substrates (Myers et al. 1997). Although several substrates have been proposed for PTEN's protein phosphatase activity, such as FAK, SHC, and ▶ beta-catenin, further supporting data confirming any protein substrate is currently lacking. Detailed interfacial kinetic analysis also shows that PTEN strongly prefers PtdIns(3,4,5)P_3 (and other phosphoinositide lipid substrates) presented within acidic lipid surfaces over the same phosphorylated inositol headgroup (Ins(1,3,4,5,)P_4) presented as a soluble molecule. This enhanced interfacial activity appears to be mediated by the correct positioning of the active site on lipid surfaces in part by the C2 domain and to be accompanied by conformational activation on such surfaces (Leslie et al. 2008).

In almost all cell types investigated, PTEN is found located throughout the cytosol, and in many cells also in the nucleus. The nuclear localization of PTEN, which appears to be regulated in part by monoubiquitination, will be discussed with more detail below. In a very few tissues, strong subcellular enrichment of PTEN has been demonstrated, most notably localization to apical junctions in the polarized epithelia of the chick epiblast and murine retinal pigment epithelium. However, the reported clear subcellular localization of PTEN with strong validating controls is very rare.

To access its membrane substrate, PTEN associates transiently with the plasma membrane, with an estimated average residence time of a few hundred milliseconds, but any membrane enrichment is not normally evident using normal epifluorescence microscopy. Basic surfaces on the phosphatase domain and the calcium-independent C2 domain appear to be involved in mediating interactions with acidic non-substrate membrane lipids and correctly positioning the active site relative to membrane surfaces. There also appears to be a specific PtdIns(4,5)P_2 interacting motif at the N-terminus of PTEN that mediates a conformational change within the phosphatase and leads to activation. With emerging evidence for rapid regulated changes in the electrostatic surface charge of cellular membranes and PtdIns(4,5)P_2 levels, it will be interesting to see whether such changes play an important role in PTEN regulation.



PTEN, Fig. 2 *The PTEN protein*. The PTEN protein is represented, including an expansion of its regulatory C-terminal tail. As discussed in the text, PTEN can be regulated through phosphorylation of its C-terminal tail, ubiquitination of lysine residues at positions 13 and 289, and oxidation of its active site Cysteine 124, which can form a disulfide bridge to Cysteine 71

PTEN Regulation

Several mechanisms of PTEN regulation have been identified, but it seems worth noting in advance that most of the mechanisms of PTEN regulation are through inhibition of the enzyme. Accordingly, unphosphorylated bacterially expressed PTEN has robust lipid phosphatase activity in vitro that can be inhibited by such mechanisms as phosphorylation, oxidation, and ubiquitination.

PTEN has two well-documented groups of phosphorylation sites: a cluster of serines and threonines surrounded by acidic residues between amino acids 380 and 385 that appear to be phosphorylated by the protein kinase, ▶ CK2, and also threonine 366, which seems to be phosphorylated by Glycogen Synthase Kinase 3 (GSK3) after priming phosphorylation of serine 370 by CK2 (Fig. 2).

It has been shown by many studies that phosphorylation of the 380–385 cluster sites stabilizes a "closed" conformation of PTEN due to a strengthened interaction between the flexible C-terminal tail of PTEN and the phosphatase and C2 domains (Ross and Gericke 2009). This closed conformation interferes with membrane binding, so reduces lipid phosphatase activity, but also enhances PTEN stability, it seems as an indirect consequence of this reduced membrane localization (Maccario et al. 2010). It should be noted that although a small fraction of cellular PTEN has been identified in an unphosphorylated state (at these 380–385 sites) and incorporated in high molecular weight complexes, most cellular PTEN appears to be found in the phosphorylated "closed" state correlating with its cytosolic localization. A similar picture emerges in studies of the 366/370 phosphorylation sites, which have been shown capable of affecting PTEN stability in some, but not all, cells, and also controlling the phosphospecific binding of a nucleolar protein, MSP58 to PTEN. However, as with the 380–385 sites, although at least a little is known about the consequences of phosphorylation, there is no clear picture of how regulated changes in phosphorylation fit into any system of controlling PTEN function.

The catalytic mechanism of PTEN, shared with the rest of the PTP family, makes it potentially sensitive to regulation by oxidation of the reactive catalytic cysteine. The oxidation of a fraction of cellular PTEN occurs in several circumstances in which cells

stimulated by growth factors and other receptor ligands are driven to produce endogenous reactive oxygen (ROS) species and is accompanied by a ROS-dependent activation of downstream signaling (Leslie et al. 2008). Although studies in both cardiac and skeletal muscle have found a correlation between PTEN oxidation and Akt activation in vivo, as with many areas of redox signaling, compelling evidence for the functional significance of any observed oxidation is currently lacking (Leslie et al. 2008).

PTEN, like many proteins, has its degradation controlled in large part through ubiquitination and subsequent proteolysis by the proteasome. Two lysine residues have been proposed to be sites for ubiquitination, Lys13 and Lys289, located within the N-terminal PtdIns(4,5)P_2 binding site and within the C2 domain, respectively (Fig. 2), and two different E3 ubiquitin ligases have been proposed to act on PTEN, the HECT domain ligase NEDD4.1, and the RING domain protein XIAP. PTEN ubiquitination, and in particular, monoubiquitination of Lys289, appears to enhance nuclear localization (Salmena et al. 2008). Significantly, ubiquitination of PTEN in vitro leads to a substantial loss of phosphatase activity, indicating that ubiquitination may act to directly inhibit catalytic activity, in addition to other effects on PTEN function (Maccario et al. 2010). Given the current data, it seems appealing to speculate that there may be significant complexity in the area of PTEN ubiquitination and that individual ubiquitination events on multiple sites, mediated by different regulated ubiquitin ligases, may have distinct functional consequences, with ubiquitination differentially controlling activity, stability, and nuclear localization. The functional consequences of nuclear localization are currently rather unclear, with several PtdInsP_3-independent nuclear functions having been proposed, along with a simple model that nuclear PTEN may be a stable protein pool that cannot access its membrane substrate.

PTEN Functions in Health and Disease: The Significance of PTEN as a Tumor Suppressor

As discussed above, PTEN is a core component and critical regulator of a signaling pathway that controls many diverse cellular processes. As such, PTEN plays a role in a vast array of physiological processes such as neuronal development and function, central control of adiposity, and cardiac hypertrophy and contractility (Chang et al. 2007; Oudit and Penninger 2009; Plum et al. 2006). However, by far the best recognized role for PTEN in human disease is as an important tumor suppressor in many forms of cancer. Analyses of the PTEN coding regions in tumor samples indicate that it is the second most frequently mutated tumor suppressor across all cancers after ▶ p53 (Salmena et al. 2008; Keniry and Parsons 2008). It is also very common that tumors carry deletions of one, or less frequently, both copies of the *PTEN* gene. The pathological significance of loss of the *PTEN* gene in different tumor types, including the loss of just one allele, has been supported by the generation of many different lines of transgenic mice lacking PTEN, throughout the body or in selected tissues, most of which have greatly increased risks of tumor formation (Salmena et al. 2008; Suzuki et al. 2008). It is outside the scope of this entry to describe the wealth of research over the last decade or more that has provided increasing evidence for the significance and mechanisms of PTEN functional loss in cancer, a deeper understanding of the downstream pathways through which PTEN loss affects tumor development and has described the development of therapies aimed at treating the many tumors lacking PTEN. However, these topics have been recently reviewed by others (Keniry and Parsons 2008; Chalhoub and Baker 2009; Garcia-Echeverria and Sellers 2008).

Summary/Future Directions

PTEN's status as one of the most important tumor suppressors in human cancer has driven a great deal of research into its function. In particular, the discovery that PTEN appears to act in a dose-dependent, haploinsufficient manner as a tumor suppressor has broad implications for the potential importance in cancer of pathways that regulate PTEN activity and expression. Also, great efforts are going into understanding what can be learned from a tumor's PTEN status in terms of predicting outcome and response to treatments. It is to be hoped that our developing understanding of PTEN function and the increasing number of drugs targeting the PI3K pathway will lead to an improvement in the outcome for this patient group.

Historical Background

The discovery of PTEN-induced kinase 1 (PINK1) was first described in 2001 by Valente et al. as a novel locus for autosomal recessive Parkinson's Disease (PD). Termed PARK6, the new locus was identified in a genome-wide homozygosity screen performed in a Sicilian family with multiple PD-affected members (Valente et al. 2001, 2004). Localized to the mitochondria, PINK1 was the first nuclear-encoded mitochondrial protein to be implicated in PD pathogenesis and strongly suggests the role of mitochondrial pathomechanisms in PD (Valente et al. 2004). The precise mechanism by which PINK1 contributes to mitochondrial dysfunction, however, remains unclear as there remains a significant gap in knowledge in our understanding of the role of PINK1 in human disease.

First identified as a serine/threonine kinase with reported homology to the Ca2+/calmodulin family, PINK1 does not fall within any of the previously identified kinase families as determined by sequence similarity of their kinase domains (Manning et al. 2002), indicating the PINK1 substrates may be unique. Studies examining the cellular role of PINK1 have shown that the serine-threonine kinase protects cells from oxidative stress and, thus, is proposed to serve an important role in protecting the cell from mitochondrial crisis

(Jendrach et al. 2009). Recent publications have suggested several intriguing hypothesis addressing the cellular functions of PINK1. This review will highlight the role of PINK1 in mitochondrial fission and fusion, in clearance of damaged mitochondria through mitophagy, and in mitochondrial trafficking. Additionally, insight gained from studying PINK1 in model organism or through the identification of PINK1 specific substrates will also be discussed.

Localization and Structure

Located on chromosome 1p35–p36, PINK1 is composed of three main domains: an *N*-terminal mitochondrial targeting sequence (MTS), a small transmembrane domain (TM), and a highly conserved serine/threonine kinase domain that has been reported to exhibit autophosphorylation activity in vitro (Zhou et al. 2008; Thomas and Cookson 2009). Analysis of PINK1's kinase domain led to the recognition of highly conserved subdomains involved in either anchoring and orienting the ATP molecule (subdomains I–IV) or binding of the peptide substrate (subdomains VIa–XI) (Silvestri et al. 2005). PINK1 is made up of eight exons spanning 1.8 kB, corresponding to an ubiquitously expressed 581 amino acid protein. The highest expression levels are observed in the heart, skeletal muscle, and testis (Silvestri et al. 2005), all mitochondrial dense tissue. In the brain, PINK1 expression is primarily neuronal and localized to the hippocampus, *Substantia nigra*, and the cerebellar Purkinje cells (Thomas and Cookson 2009). The 581 amino acids (63 kDa protein) of PINK1 are further processed upon mitochondrial import to generate two mature isoforms, 54 and 45 kDa, respectively (Deas et al. 2009).

It is well established that PINK1 localizes to the mitochondria as the N-terminal mitochondrial target sequence is sufficient for mitochondrial import of PINK1 (Valente et al. 2001; Silvestri et al. 2005). Specific subcellular localization of PINK1, however, remains somewhat controversial as it has been reported to be located on the outer mitochondrial membrane (OMM), the mitochondrial intermembrane space (IMS), the inner mitochondrial membrane (IMM), and even the cytoplasm (Thomas and Cookson 2009). Recent work on the topology of PINK1 has concluded that PINK1 localization depends on the transmembrane domain, which embeds itself into the outer mitochondrial membrane leaving the kinase domain exposed to the cytosol (Zhou et al. 2008). This would imply that PINK1 specific substrates are located in the cytosol or localized to the outer mitochondrial membrane. Interestingly, two of the most widely reported interactors or substrates of PINK1, TRAP1, and Omi/HtrA2 reside within the mitochondria. Therefore, PINK1 interactors (TRAP1 and Omi/HtrA2) and PINK1 localization need to be rectified through additional mechanistic studies.

Substrates and Interactors of PINK1

Identified as a serine/threonine kinase, PINK1 has been shown to exhibit autophosphorylation activity in vitro. However, despite robust phosphorylation activity, the in vivo substrates remain unknown making it difficult to ascertain the biochemical function and physiological substrates of PINK1 (Geisler et al. 2010). One of the first specific PINK1 substrates to be identified was the mitochondrial chaperone tumor necrosis factor type 1 receptor associated protein 1 (TRAP1). Through a combination of both in vitro and in vivo assays, Pridgeon et al. showed that the phosphorylation of TRAP1 by PINK1 played a critical role in protecting cells from oxidative-stress-induced cell death (Pridgeon et al. 2007). The protective action of PINK1 through suppression of cytochrome c release was impaired by PD-linked mutations including G309D, L347D, and W437X, which resulted in a reduced capability for PINK1 to phosphorylate TRAP1. Reported to be a direct substrate for PINK1, this work by Pridgeon et al. provided some of the first insight into the mechanism by which loss of PINK1 leads to neurodegeneration.

Further confirmation that the kinase activity of PINK1 is required for its in vivo function came with the identification of the PD relevant substrate, Parkin. Parkin, also known as PARK2, is one of the most commonly affected PD genes and encodes for an E3 ubiquitin ligase that is also associated with autosomal recessive forms of PD. Shown to mediate both classical and nonclassical ubiquitin linkages, Parkin has been implicated in both protein degradation and inclusion-body formation (Kim et al. 2008). The first indication that Parkin and PINK1 may be linked in a common pathway came from initial work in *Drosophila*, where it was determined that Parkin and

PINK1 function in a linear pathway with PINK1 upstream of Parkin (described below). However, the mechanism by which the two proteins interacted together remained unknown until Kim et al. elegantly performed studies in both mammalian and *Drosophila* systems, that they clearly demonstrated that PINK1's kinase activity regulates the translocation of Parkin to the mitochondria (Kim et al. 2008). Given the role of Parkin in protein degradation and PINK1's proposed role in mitochondrial dynamics, the identification of Parkin as a PINK1 specific substrate has important implications into PD-related mechanisms in which PINK1 and Parkin work together to provide a mitochondrial quality control system. This was further confirmed by Geisler et al., demonstrating that PINK1 kinase activity and its mitochondrial localization sequence are required for the recruitment of Parkin to depolarized mitochondria. Parkin localization results in selective degradation of the damaged mitochondria through selective autophagy of the mitochondria, a process termed mitophagy (Geisler et al. 2010).

Supporting a role of PINK1 in protecting cells from mitochondrial dysfunction, Plun-Favreau et al. reported that the serine protease Omi/HtrA2 is an interactor of PINK1 (Plun-Favreau et al. 2007). Loss of function of Omi/HtrA2 has been reported in the literature to result in a neurodegenerative disorder with a similar phenotype to PD. Classically, Omi/HtrA2 is thought to be released from mitochondria during apoptosis upon permeabilization of the outer mitochondrial membrane. Once in the cytosol, the serine protease binds to inhibitor of apoptosis (IAP) proteins and thus contributes to induction of apoptosis (Plun-Favreau et al. 2007). While proposed to be a proapoptotic protein, the parkinsonian neurodegenerative phenotype observed in Omi/HtrA2 knockout mice has lead to the hypothesis that the serine protease may also serve to protect mitochondrial homeostasis. Further work indicated that PINK1 and Omi/HtrA2 are both components of the same regulatory pathway involved in the maintenance of mitochondria homeostasis. They provided evidence that p38-mediated phosphorylation of Omi/HtrA2 occurs in a PINK1-dependent manner (Plun-Favreau et al. 2007). The authors concluded that PINK1-dependent phosphorylation of HtrA2 may modulate the protease's proteolytic activity and thereby serve to provide a mechanism by which PINK1 phosphorylation of HtrA2 results in increased resistance of cells to mitochondrial stress. It remains unclear, however, whether Omi/HtrA2 is a direct substrate of PINK1 and whether differences in cell viability due to PINK1 inactivation are indirectly affecting other kinases that are responsible for direct phosphorylation of Omi/HtrA2 activity.

Investigating PINK1 Function Using Model Organisms

Several model organisms have been used to help researchers elucidate the roles of PINK1. Specifically, given the role of PINK1 in PD, many of the studies in model organisms have been focused toward determining the mechanism by which loss of PINK1 contributes to the pathogenesis of PD. Using *C. elegans* as a model organism, loss of function PINK1 mutations result in mutant worms demonstrating reduced mitochondrial cristae lengths (Samann et al. 2009). Additionally, worms harboring the mutant form of PINK1 also display an increased sensitivity to the reactive oxygen species catalyst, paraquat, which could be rescued upon expression of transgenic PINK1. The reported mitochondrial phenotype coinciding with an observable sensitivity to oxidative stress supports findings in other model organisms and the hypothesis that PINK1 functions to preserve mitochondrial homeostasis in the cell (Samann et al. 2009).

A second model organism that has been used extensively to gain insight into the function of PINK1 in the cell has been *Drosophila*. Interestingly, these fruit fly models for PD resemble many of the characteristics of the human form of PD including the loss of dopaminergic (DA) neurons along with the presentation of various locomotive defects (Park et al. 2009). In 2006, three papers came out reporting that loss of PINK1, either by loss of function mutations or through the removal of the *Drosophila PINK1* homologue results in male sterility, indirect flight muscle, and DA neuronal degeneration accompanied by locomotive defects. Additionally, loss of PINK1 resulted in defects in mitochondrial morphology (increased mitochondrial cristae fragmentation and mitochondrial swelling observed in tissues with high energy demands) and demonstrated an increased sensitivity to multiple stressors including oxidative stress (Park et al. 2009).

Interestingly, *Drosophila* PINK1 fly mutants phenocopy almost all of the observed phenotypes of the

Parkin knockout, including indirect flight muscle/DA neuronal degeneration, impaired flight, and slow climbing ability. Subsequent genetic studies probing for the mechanism behind the phenotype similarity observed with Parkin and PINK1 mutants resulted in the discovery of an epistatic relationship between the two genes. Further studies revealed that PINK1 and Parkin are linked in a linear pathway involved in protecting the integrity and function of the mitochondria with Parkin acting downstream of PINK1 (Park et al. 2009). Together, these two models strongly implicate the role of mitochondrial dysfunction in PINK1 or Parkin-related PD pathogenesis.

To further elucidate the physiological role of PINK1 in mammalian cells and to gain insight into the disease mechanism of PINK1's involvement in PD pathogenesis, several labs have worked to understand novel phenotypes of PINK1-deficient mice. PINK1$^{-/-}$ mice have functional defects in the dopaminergic system, including a decrease in dopamine release in striatal slices. This functional defect could be rescued by treatment with dopamine receptor agonists or other agents that increase dopamine release (Kitada et al. 2007). These results suggest a critical role for PINK1 in providing a functional link between mitochondria and regulation of dopamine release and thus may provide insight into the pathogenesis of PINK1 in playing a role in causing PD-associated dopaminergic dysfunction. Unlike studies in both *Drosophila* and *C. elegans* models, loss of murine PINK1 resulted in no gross changes in the structure of mitochondria; however, the authors did report that the overall size of mitochondria increased in the PINK1-deficient mice compared to control (Gautier et al. 2008). While no gross changes in mitochondrial structure were observed, significant defects in mitochondrial respiration were detected in complexes I, II, III, and IV. At 3–4 months of age, this respiration defect was specific for the striatum; however, mitochondrial respiration activity was decreased in other areas, including the cerebral cortex, at 2 years of age compared to control. Similar mitochondrial defects in other regions outside of the striatum could also be induced following induction of ROS formation through the treatment of H_2O_2 or mild heat shock, suggesting that ROS accumulation as a consequence of aging may exasperate the mitochondrial dysfunction (Gautier et al. 2008).

Mitochondrial Function of PINK1

Mitochondrial Morphology

Mitochondria are dynamic organelles that require active fission and fusion to maintain a distinct morphology, not only to maintain mitochondrial homeostasis but also to maintain changing cellular energy demands (Thomas and Cookson 2009). Work performed in *Drosophila* and mouse models have found that loss of PINK1 results in enlarged/swollen mitochondria, suggesting a potential role for PINK1 in regulating mitochondrial morphology. The distinct morphology of the mitochondria is tightly regulated through two opposing process: mitochondrial fission and fusion. These two processes have also been shown to play important roles in maintaining mitochondrial maintenance and function, along with regulating the stabilization of the mitochondrial genome in response to the changing cellular environment (Okamoto and Shaw 2005). This regulation will be described briefly below, but for a more detailed review behind the mechanism of mitochondrial fission and fusion, readers are encouraged to refer to Chan et al. for a comprehensive overview of the mechanism of fission and fusion (Chan 2006).

Capable of undergoing several fission/fusion events, mitochondria are frequently changing shape in response to their surrounding cellular energy demands. Conserved dynamin-related GTPases are responsible for maintaining the balance between mitochondrial fission and fusion. Two highly conserved proteins, the outer mitochondrial membrane GTPases Mitofusins (MFN 1 or MFN 2) and the inner membrane GTPase OPA1, are responsible for controlling mitochondrial fission. Mitofusins are large GTPases embedded in the outer mitochondrial membrane (OMM) that initiate interaction between the two mitochondria. Fusion of the inner mitochondrial membrane (IMM) is predicted to be regulated by OPA1, a dynamin-related GTPase that localizes to the inner mitochondrial space (IMS) and associates with the IMM (Chan 2006).

Mitochondrial fission is controlled by two proteins: Drp1 and hFIS1. The small protein, hFIS1, uniformly localizes to the OMM and is responsible for recruiting Drp1 to sites of intended mitochondrial fission. Drp1 is a large dynamin-related GTPases found in the cytosol that localizes to the mitochondria to initiate mitochondrial fission. Current theories suggest that upon

recruitment to the mitochondria, Drp1 forms a ring around the mitochondria and acts as a mechanochemical enzyme that uses GTP hydrolysis to drive mitochondrial constriction and fission. Interestingly, Drp1 has been reported to be recruited to the mitochondria in the absence of hFIS1, and thus hFIS1 is not required for Drp1 localization to the mitochondria (Chan 2006).

While it has been proposed that PINK1's function in the cell is to regulate mitochondrial dynamics, the exact mechanism of PINK1's involvement with mitochondrial fission and fusion remains to be elucidated. Knockdown of PINK1 in *Drosophila* models have demonstrated that loss of PINK1 results in elongated mitochondria, while studies in *C. elegans* resulted in heavily fragmented mitochondria. Studies in mammalian cell models have been even more controversial where loss of PINK1 has been reported to result in either excess fusion, excess fission, or result in no effect on mitochondrial morphology, depending on the cell model and the method of knockdown (Thomas and Cookson 2009; Jendrach et al. 2009). Mitochondrial fission and fusion are important processes which allow the mitochondria to control the structure and distribution of the mitochondria network. Given the proposed role of mitochondrial defects in the pathology of PD, a better understanding of the involvement of PINK1 in mitochondrial biology and homeostasis may provide important insight into the specific pathogenic pathways that leads to mitochondrial dysfunction in PD.

Mitophagy

PINK1 and Parkin have previously been reported to interact genetically and function within the same linear molecular pathway (Park et al. 2009). The mechanistic details of how a serine/threonine kinase and an E3 ligase function to protect mitochondrial dynamics has remain largely unknown, until recently, with the discovery that PINK1 may play a direct role in the elimination of mitochondria through interaction with Parkin (Geisler et al. 2010). In an elegant set of experiments, Geisler et al. demonstrated that PINK1's kinase activity and its mitochondrial localization sequences are both required to translocate Parkin to depolarized mitochondria. From there, Parkin subsequently mediates the formation of two distinct polyubiquitin chains, and degradation of the damaged organelle is further promoted through the addition of the autophagic adaptor p62 (SQSTM1), whose presence is essential for the clearance of mitochondria (Geisler et al. 2010).

Following mitochondria depolarization, indicative of mitochondrial damage, PINK1 interaction with Parkin is significantly enhanced. Furthermore, modulations of PINK1 expression levels either through siRNA knockdown or expression of kinase deficient PINK1 results in a reduction of Parkin translocation to depolarized mitochondria and thus the subsequent degradation of the damaged mitochondria. Therefore, PINK1 appears to serve as an important sensor for mitochondria damage upstream of Parkin (Geisler et al. 2010). Many questions still remain to further elucidate the recently identified novel role for PINK1's involvement in mitophagy. In particular, it is still unclear how the kinase activity of PINK1 is regulated following mitochondrial damage and whether PINK1 can mediate phosphorylation of Parkin to stimulate its E3 ligase activity. Given the role of both Parkin and PINK1 in autosomal recessive PD, this model provides an attractive hypothesis to provide a common pathomechanism in which loss of either protein leads to the onset of hereditary PD.

Mitochondrial Trafficking

Mitochondrial trafficking is a critical process to ensure proper distribution of the mitochondria within the cell. Mitochondrial transport occurs in both anterograde and retrograde directions within the cell and is controlled by a combination of cytoskeleton and mitochondrial proteins, including the atypical GTPase Miro and the adapter protein Milton (Weihofen et al. 2009). Miro and Milton complex on the outer mitochondrial membrane, facing the cytosol where they link to the heavy chain of a kinesin to drive anterograde transport of the mitochondria along microtubules within the cell. Work published by Weihofen et al. showed that PINK1 forms a multiprotein complex through interactions with the two cytoplasmic proteins Miro and Milton, and this suggests a novel role for PINK1 in mitochondrial trafficking (Weihofen et al. 2009). This model depends on the topology report of Zhou et al., as it requires the kinase to be anchored to the OMM with its kinase domain facing the cytoplasm to ensure interactions with Miro and Milton. Mitochondrial transport is also tightly regulated by mitochondrial dynamics, including fission and fusion (Okamoto and Shaw 2005). PINK1, therefore, in addition to direct interactions with Miro and Milton, may also regulate mitochondrial transport

through its roles in mitochondrial fission and fusion. The proposed role of PINK1 in regulating mitochondrial transport provides yet another means by which PINK1 can protect the cell from oxidative stress or other forms of mitochondrial crisis.

PINK1 and Parkinson's Disease

Parkinson's disease is a progressive neurodegenerative disorder in which dysregulation of mitochondrial structure and function has come to the forefront as one of the central factors in the pathogenesis of PD (Chu 2010). Characterized by a loss in dopaminergic neurons in the *Substantia nigra*, as well as the presence of ubiquitin-positive Lewy neuritis and Lewy bodies, PD is progressive disease with no current therapy to slow progression of the disease. Understanding the molecular pathways that result in PD pathology remains an important goal to facilitate development of more effective therapeutic strategies. While the majority of PD cases appear to be sporadic, there is a significant amount of PD cases that are caused by specific genetic defects linked to familial forms of PD, which have provided important insight into the pathology underlying PD. Loss of function of PINK1 has been implicated in autosomal recessive PD as most of the identified pathogenic mutations occur within the kinase domain and result in decreased kinase activity.

Neurons are highly specialized cells that have very specific energy demands, and thus proper mitochondrial function and distribution play a critical role in maintaining neuronal function. As previously discussed, mitochondrial fission and fusion play a critical role in both mitochondrial homeostasis and trafficking (Okamoto and Shaw 2005). Therefore, modulation of the fission and fusion process due to PINK1 mutants found in autosomal recessive PD may result in an inability to properly traffic mitochondria along the length of the neuron to the synapse. This would result in an energy deficit throughout the neuron and could culminate in the degeneration of the DA neurons. Additionally, given the interaction between PINK1 and characterized mitochondrial trafficking proteins, Miro and Milton, loss of PINK1 may have a more direct means to modulate mitochondrial trafficking (Weihofen et al. 2009).

PINK1 also appears to play a critical role in maintaining mitochondria function as it may serve as an important role in ensuring that the mitochondria population remains maximally functional (Geisler et al. 2010). Given recent insight into the potential role of PINK1 and Parkin in mitophagy, as described in the section above, PINK1 may also be directly involved in the clearance of damaged mitochondria. Loss of PINK1 may therefore result in an inability to segregate and remove damaged mitochondria, thus leading to accumulation of mitochondrial dysfunction within the neuron (Geisler et al. 2010). The inability to maintain energetic demands of the neuron would therefore result in neuronal degradation and may provide a molecular pathway to explain the mitochondrial dysfunction observed as one of the classic pathologies of PD (Thomas and Cookson 2009; Chu 2010). It will be interesting to see if the molecular pathways by which Parkin mutations lead to PD are the same as PINK1 given the linear epistatic relationship between the two proteins.

Summary

Several recent publications have implicated PINK1 in playing a role in regulating mitochondrial morphology, mitochondrial homeostasis, and mitochondrial trafficking. Insights from the Parkinson's field have also demonstrated that PINK1 appears to function to protect the cell from stresses, such as oxidative stress, that would otherwise compromise the mitochondria and lead to cellular distress or death. Given the role of the mitochondria in cellular metabolism, it could be proposed that altered mitochondrial bioenergetics through the disruption of PINK1 function may play an important role in PD pathology. However, there remains much to be done to further understand the role of PINK1 in PD. More mechanistic studies focusing on the localization and processing of PINK1 remain to be elucidated. Most likely, the reason behind the controversy related to the localization of PINK1 is due in some part to the inability to detect PINK1 endogenously with commercially available antibodies. Therefore, researchers are often forced to tag the protein or overexpress it to such a level that is no longer biologically relevant. Similarly, PINK1 interactors and substrates remain largely undetermined, probably somewhat due for the same reason as it is difficult to study protein interactions and kinase activity at the endogenous single-cell level. Likewise, the exact mechanism by which PINK1

regulates mitochondrial dynamics is beginning to become clear; however, more work is required to further identify the specific substrates and interactors of this serine/threonine kinase. Clearly, PINK1 is involved in several pathways aimed at maintain mitochondrial homeostasis. A better understanding of how PINK1 is modified or processed, along with an awareness of how these changes alter the function of the kinase both under normal and stressed conditions, will provide important clues into the mechanism by which PINK1 protects cells from mitochondrial crisis.

Historical Background

Phosphorylation of tyrosine residues in proteins is one of the better-studied molecular mechanisms for regulating protein structure and function and with it – the function of cells and organisms. Tyrosine phosphorylation is a reversible process that is controlled by the opposing activities of protein tyrosine kinases (PTKs) and protein tyrosine phosphatases (PTPs). The numbers of PTKs and PTPs are similar and small relative to the numbers of their potential substrates; there are 81 and 85 genes that yield active, protein-specific PTPs and PTKs, respectively (Alonso et al. 2004). As a result, individual PTPs and PTKs each target multiple substrates and fulfill distinct roles in different physiological systems. Although PTPs were first described in molecular terms in 1988, about a decade after PTKs, both protein superfamilies are now recognized as critical regulators of protein phosphorylation and cellular physiology (Alonso et al. 2004).

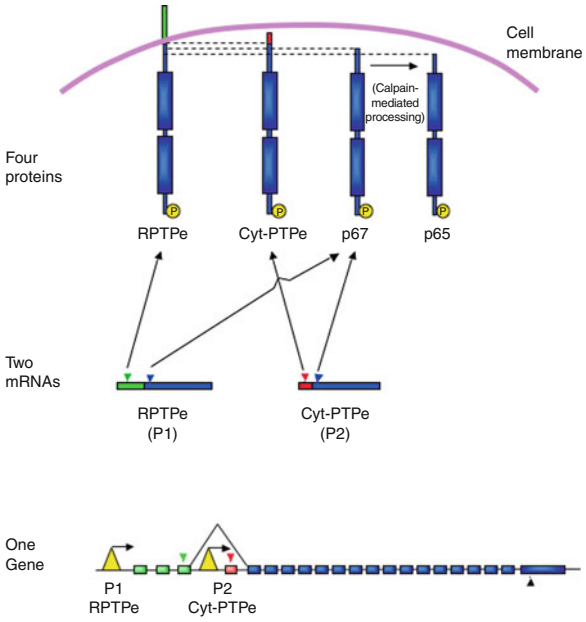
The several dozen members of the PTP superfamily can be subdivided into smaller groups based on their structures and substrate specificities (Andersen et al. 2001b; Alonso et al. 2004). The first subfamily of PTPs that was identified and characterized was the "classical" tyrosine-specific subfamily of PTPs. This subfamily is now known to contain 38 genes; 21 of these encode receptor-type products that are integral membrane proteins, while the remaining 17 encode non-receptor-type proteins. Use of alternative promoters, alternative splicing, and posttranslational processing are fairly common among PTPs, hence the 38 "classical" PTP genes give rise to a larger number of protein products. All members of this family contain one or two PTP domains that contain the PTP signature motif "(I/V)HCSXGXGR(S/T)G"; in PTPs that contain two PTP domains, typically only the N-terminal of the two is catalytically active (Andersen et al. 2001b; Alonso et al. 2004). Studies conducted during the past two decades have shown that PTPs participate in regulating many distinct physiological processes, that they target specific substrates, and that they can activate or inhibit signaling processes in a context-dependent manner (Tonks 2006; Hendriks et al. 2008).

Protein tyrosine phosphatase Epsilon (PTPe), which is the focus of this review, was first identified in 1990 as a receptor-type PTP within the so-called type IV subfamily of the "classical" family of PTPs (Krueger et al. 1990). Subsequent work revealed that there is a single PTPe gene that gives rise to at least two mRNA and four protein species. More recent work, which is outlined below, has described roles for PTPe in regulating various processes at the levels of the cell and the organism.

PTPe – The Gene and its Protein Products

Humans and similar higher organisms possess a single gene for PTP Epsilon, which maps to the distal part of chromosome 10 (band 10q26.2; chromosome 7 in mouse). The *PTPRE* gene contains two known promoters, each of which gives rise to a distinct major protein product. The proximal P1 promoter gives rise to the mRNA for the receptor-type form of PTPe noted above, RPTPe, while the distal P2 promoter produces the mRNA for the non-receptor form, cyt-PTPe ((Elson and Leder 1995a; Nakamura et al. 1996; Tanuma et al. 1999); Fig. 1). Since both mRNAs are derived from the same gene, they share most of their sequences; differences exist only at their 5′ ends. A similar situation exists at the protein level: RPTPe and cyt-PTPe share a large segment of their protein sequence, which includes the two PTP catalytic domains. The N termini of both forms are, however, distinct: the membrane-spanning domain and the short (27 AA in humans) and heavily-glycosylated extracellular domain of RPTPe are replaced by a 12 AA-long hydrophilic sequence in cyt-PTPe (Fig. 1). As a result, RPTPe is an integral membrane protein; in contrast, cyt-PTPe is predominantly cytosolic, although about 20% of cyt-PTPe molecules are found in association with the cell membrane and a further 10% are detected in the cell nucleus (Elson and Leder 1995a; Nakamura et al. 1996). Two additional shorter protein forms of PTPe exist. These are p67, which is produced from the mRNAs for RPTPe and for cyt-PTPe by initiation of translation at an internal initiation codon located in the sequence identical in both mRNAs, and p65, which is produced from RPTPe, cyt-PTPe, or p67 proteins by calpain-mediated proteolytic processing (Gil-Henn et al. 2000; Gil-Henn et al. 2001). Finally, a fifth form of PTPe (cyt-PTPePD1) has been suggested to exist. This form, which is believed to be produced by alternative splicing of cyt-PTPe mRNA, contains only the first (D1) PTP domain followed by a unique C-terminal tail (Wabakken et al. 2002).

The cell- and tissue-specificity of the two promoters of the *PTPRE* gene differ significantly to the point where RPTPe and cyt-PTPe are rarely co-expressed



PTPe (RPTPe and Cyt-PTPe), Fig. 1 PTPe: gene, mRNAs and proteins. *Gene*: The single *PTPRE* gene (*bottom*) contains two promoters (P1, P2; *yellow* triangles) and 21 exons. The distal P1 promoter produces the RPTPe transcript that links the first three unique exons (1–3, *green*) directly to exon 5 (*blue*). The proximal P2 promoter produces the cyt-PTPe transcript that starts at exon 4 (*red*), linking it to exon 5 and beyond (*blue*). Exons 5–21 (*blue*) are common to both transcripts. *Green* and *red* triangles denote the respective initiator ATG codons of both mRNAs; the black triangle in exon 21 denotes the termination codon. Exons and introns are not drawn to scale. *mRNAs*: the RPTPe and cyt-PTPe mRNAs are shown. The *green* and *red* regions depict sequences unique to RPTPe or cyt-PTPe that are derived from genomic exons 1–3 or 4, respectively. Regions marked in *blue* are derived from exons 5–21. Triangles mark the initiation codons used for producing RPTPe (*green*), cyt-PTPe (*red*) or p67 (*blue*). *Proteins*: Four major protein forms of PTPe are shown. The *green* and *red* regions of RPTPe and cyt-PTPe, respectively, are unique to each form; regions drawn in *blue* are common to all forms and are derived originally from exons 5–21 in the *PTPRE* gene. The C-terminal phosphorylation site (Y695 in RPTPe = Y638 in cyt-PTPe) is marked in all forms by a *yellow* circle. p67 is produced from both RPTPe and cyt-PTPe mRNAs by initiation of translation at an ATG codon located in the sequence common to both (*blue* triangle, mRNA level). p65 is produced by calpain-mediated proteolytic processing of RPTPe, cyt-PTPe or p67

in the same cell type. RPTPe is expressed predominantly in neurons, testes, and lungs, while cyt-PTPe is found mainly in hematopoietic cells (B- and T-lymphocytes, macrophages, erythrocytes), osteoclasts, Schwann cells, and muscle cells. Along with their distinct subcellular localization, their different expression patterns among cell types argue strongly that RPTPe and cyt-PTPe are physiologically nonequivalent.

Regulation of PTPe Activity

In general, PTPs are active enzymes. Many of the mechanisms that regulate PTP activity do so therefore either by inhibiting the activity of the enzyme or by directing it to specific substrates or to particular subcellular regions (den Hertog et al. 2008). In the case of PTPe, several regulatory mechanisms have been described:

A. Expression: The divergent expression patterns of the two promoters of the *PTPRE* gene among cells types and tissues and their distinct localization patterns within cells ensure that RPTPe and cyt-PTPe are present at specific locations and encounter particular substrates. Importantly, the two promoters also differ in their ability to respond to physiological signals. Little is known about how the activity of the P1 promoter, which drives expression of RPTPe, is controlled. In contrast, the P2 promoter is readily activated by growth factors and activators of mitogenic signaling, such as serum, TPA, EGF, and basic FGF. Differentiation of human promyelocytic leukemia HL60 cells with TPA causes a massive increase in cyt-PTPe expression, while treatment of M1 mouse myeloid leukemia cells with IL6 increases cyt-PTPe expression and reduces expression of RPTPe (Elson and Leder 1995a; Tanuma et al. 1999).

B. Oxidation: The signature motif (I/V) HCSXGXGR(S/T)G present in PTPs contains at its core a cysteine residue, which is essential for dephosphorylation to occur. Oxidizing this residue by, for example, reactive oxygen species that are produced during the normal course of signaling processes is sufficient to abolish PTP catalytic activity (den Hertog et al. 2008). All forms of PTPe are susceptible to oxidation, which inhibits their activity (Toledano-Katchalski et al. 2003).

C. Dimerization: Dimerization of PTPs has been suggested to inhibit their catalytic activity; this sets PTPs apart from PTKs, where dimerization typically stabilizes the active form of the enzyme (den Hertog et al. 2008). RPTPe and cyt-PTPe undergo spontaneous inhibitory dimerization and higher-order aggregation in cells. In the case of cyt-PTPe, dimerization can be induced by physiological signals, such as increased oxidative stress and following activation of the EGF receptor (Toledano-Katchalski et al. 2003).

D. Phosphorylation: A major phosphorylation site exists at the C-terminus of PTPe (Y695 in RPTPe = Y638 in cyt-PTPe). This site undergoes phosphorylation in various physiological situations, including in the presence of Neu in mouse mammary tumor cells (Berman-Golan and Elson 2007) and following activation of integrins in osteoclasts (Granot-Attas et al. 2009). Phosphorylation most likely does not affect the specific activity of PTPe (Berman-Golan and Elson 2007). It does, however, drive the phosphatase to activate ▶ Src in osteoclasts and in mammary tumor cells, probably by allowing phosphorylated PTPe to bind the Src SH2 domain, thus releasing the inhibitory interaction between this domain and Y527 of the kinase (Berman-Golan and Elson 2007; Granot-Attas et al. 2009). C-terminal phosphorylation of PTPe also promotes its association with other molecules, as in its inhibitory association with tubulin (Sines et al. 2007).

E. Cleavage: RPTPe, cyt-PTPe, and p67 can undergo proteolytic processing by calpain to generate p65, an N-terminally-truncated form of PTPe that is catalytically active and entirely cytosolic (Gil-Henn et al. 2001). Processing of RPTPe or of cyt-PTPe, which are entirely or significantly membrane-associated proteins, effectively removes PTPe from the cell membrane and may control its access to substrates.

F. Other mechanisms: RPTPe possesses an extracellular domain, which suggests that its activity or physiological role may be affected by binding of extracellular ligands. However, as is the case with most RPTPs, no extracellular ligands of RPTPe are known, and the functional role of the extracellular domain of this PTP is not clear. RPTPe also undergoes massive glycosylation, but the roles of this modification, if any, are also unknown.

Physiological Roles of PTPe

Cancer

PTKs often activate signaling processes, and many are *bona fide* oncogenes. As a result, PTPs are often perceived as inhibitors of signaling processes and of malignant transformation. While this is true in many instances, in several cases, including that of PTPe, PTPs can activate signaling processes and support malignant transformation. Moreover, such roles are often specific for a given physiological system; a particular PTP may support signaling and transformation in one context but inhibit it in another. Along these lines, RPTPe is expressed at high levels in mouse mammary tumors initiated in vivo by transgenic Neu or Ras proteins (Elson and Leder 1995b), suggesting that RPTPe participates in the transformation processes induced by these two oncogenes. In support of this conclusion, overexpression of RPTPe in mouse mammary glands leads to massive mammary hyperplasia and associated tumorigenesis (Elson 1999). At the molecular level, RPTPe activates the Src PTK in mammary tumors initiated by Neu, by dephosphorylating Src at its inhibitory Y527. Activation of Src is important for these cells to manifest their full malignant properties; in mammary tumors initiated by Neu in mice lacking PTPe (EKO mice), Src is less active and the transformed phenotype of the resulting mammary tumor cells is weakened (Gil-Henn and Elson 2003; Berman-Golan and Elson 2007). On the other hand, overexpression of cyt-PTPe (but not of RPTPe) in M1 murine leukemia cells inhibited JAK-STAT signaling that was induced by interleukins 6 or 10, and led to reduced tumorigenicity of these cells following their implantation in SCID or in nude mice (Tanuma et al. 2001; Tanuma et al. 2003). The various protein forms of PTPe can therefore either support or inhibit signaling events in a context- and system-specific manner.

Myelination in the Nervous System

Experimental evidence has shown that PTPe helps regulate myelination in the nervous system. Cyt-PTPe is expressed in Schwann cells, which are responsible for axon myelination in the peripheral nervous system. In mice that genetically lack PTPe, myelination of axons in the sciatic nerve is significantly delayed, indicating that this form of PTPe supports the myelination process (Peretz et al. 2000). Molecular studies have established that the delayed-rectifier, voltage-gated potassium channels Kv2.1 and Kv1.5 are substrates of cyt-PTPe in Schwann cells, and that dephosphorylation by cyt-PTPe downregulates channel activity. In agreement, Kv2.1 and Kv1.5 are hyper-phosphorylated, and the activity of Kv channels in general is elevated in EKO Schwann cells, suggesting that loss of cyt-PTPe in Schwann cells affects their function by dysregulating Kv channel activity (Peretz et al. 2000). In separate studies, expression of PTPe, presumably RPTPe, was significantly up-regulated during differentiation of CG4 progenitor cells into oligodendrocytes, the cells that drive

myelination in the central nervous system. Expression in mice of an inactive mutant of RPTPe under the direction of the myelin protein 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNP) promoter delayed myelination of the optic nerve, most likely due to dominant-negative effects of the transgene (Muja et al. 2004). The limited scope of the phenotype in this case suggests that lack of RPTPe does not significantly affect the myelination capability of most oligodendrocytes.

Macrophages, Osteoclasts, and Bone Degradation

Cyt-PTPe is expressed in cells of various hematopoietic lineages, including in cells of the monocyte lineage that gives rise to macrophages and osteoclasts. Macrophages from mice lacking PTPe are defective in their ability to mount a respiratory burst in response to exposure to lipopolysaccharide (LPS) or tumor necrosis factor alpha (TNF alpha). Bone marrow cells from these mice also produce more interleukin-10 and less TNF alpha in response to LPS treatment (Sully et al. 2001). These findings indicate that cyt-PTPe plays an important role in regulating macrophage activity, although the molecular basis for this remains unknown at present.

Cyt-PTPe also plays a major role in regulating the function of osteoclasts, the resident cells that degrade bone. Bone mass is regulated by the opposing activities of osteoblasts, which produce bone matrix, and osteoclasts, which degrade it. Both cell types coexist and function in close proximity, ensuring that the resulting bone is of the proper mass and physical properties. Mice lacking PTPe exhibit increased amounts of bone that are secondary to reduced activity of their osteoclasts. Osteoclasts lacking cyt-PTPe do not adhere to bone well in vivo and display significant defects in the structure, organization, and stability of podosomes, the adhesion structures of these cells (Granot-Attas et al. 2009). At the molecular level, cyt-PTPe helps dephosphorylate and activate Src downstream of integrins, which are activated when osteoclasts make physical contact with bone or matrix. Lack of cyt-PTPe results in reduced Src activation in osteoclasts; normal Src activity can be restored by expression of cyt-PTPe in the cells. Importantly, the defects in podosomal organization and stability can be rescued in PTPe-deficient osteoclasts not only by expressing cyt-PTPe but also by expressing Src, which functions in this system downstream of cyt-PTPe. This finding demonstrates that the integrin-cyt-PTPe-Src axis is critical for proper structure and function of osteoclasts (Granot-Attas et al. 2009).

Insulin Receptor Signaling, Glucose Homeostasis and Body Weight Regulation

A number of studies have suggested that PTPe negatively regulates the activity of the insulin receptor PTK. Accordingly, RPTPe, but not cyt-PTPe, has been shown to down-regulate the insulin receptor in baby hamster kidney (BHK) cells (Andersen et al. 2001). Later studies showed that expression of exogenous RPTPe down-regulates the insulin receptor in primary hepatocytes, possibly by targeting the insulin receptor itself. Expression of the phosphatase also reduced the extent of activation by insulin of downstream signaling molecules, such as ERK, AKT, and GSK3 (Nakagawa et al. 2005). A third study showed that cyt-PTPe negatively regulates the insulin receptor in muscle cells. Treating L6 skeletal muscle cells with insulin induced association of the insulin receptor with cyt-PTPe, while expression of exogenous cyt-PTPe resulted in decreased phosphorylation of the insulin receptor, IRS-1, AKT and GSK3, and decreased glucose uptake. In agreement, opposite results were obtained when expression of endogenous cyt-PTPe was inhibited in these cells. Phosphorylation of the insulin receptor and or IRS-1 were also increased in primary muscle cells from PTPe-deficient mice (Aga-Mizrachi et al. 2008). Examination of mice genetically lacking PTPe revealed improved glucose clearance in both lean and obese mice, particularly in males, indicating that PTPe plays a role in regulating glucose homeostasis on the level of the intact organism (Rousso-Noori et al. 2011). RPTPe and cyt-PTPe are therefore inhibitors of insulin receptor signaling, although more studies are required to determine whether organ-specific roles exist for various isoforms of PTPe.

Female mice lacking PTPe are leptin hypersensitive and are resistant to weight gain that normally follows physiological challenges, such as a high-fat diet. This is most likely caused by down-regulation of leptin receptor signaling by RPTPe in the hypothalamus; RPTPe performs this role by directly dephosphorylating and inhibiting Jak2, a tyrosine kinase that is activated downstream of the leptin receptor and which plays a key role in leptin signaling (Rousso-Noori et al. 2011).

Additional Roles

PTPe is expressed in endothelial cells (Thompson et al. 2001; Nakagawa et al. 2004). The role of PTPe in these cells appears to be isoform-specific, since expression of RPTPe activated Src and stimulated migration and survival of porcine aortic endothelial cells, while expression of cyt-PTPe had the opposite effect (Thompson et al. 2001; Nakagawa et al. 2004). RPTPe is expressed in erythrocytes; erythrocytes of EKO mice exhibit abnormal morphology, increased calcium-activated K+ channel activity, and increased activity of the Src family PTKs Fyn and Yes. These findings indicate that RPTPe plays an important role in erythrocyte physiology and provide an example where this PTP down-regulates, instead of activating, PTKs of the Src family (De Franceschi et al. 2008). Finally, RPTPe is expressed in bone marrow–derived mast cells (BMMC), where it participates in downregulating FceRI-mediated mast cell function (Akimoto et al. 2009). RPTPe most likely targets the Syk PTK downstream of the FceRI receptor, leading ultimately to decreased calcium mobilization and MAPK activation. Accordingly, EKO mice display elevated levels of passive systemic anaphylaxis induced by antigen and IgE. EKO mice contain normal numbers of mast cells, indicating that lack of PTPe affects the function, but not production, of these cells (Akimoto et al. 2009).

Summary

Like other PTPs and PTKs, PTPe is a multifaceted participant of signaling processes. The single PTPe gene produces several distinct protein isoforms, which act in different cell types, in distinct areas within a given cell, and target various substrates. It is therefore not surprising that PTPe supports the transduced signal in some cases while inhibiting it in others. It is very well established that dysregulation of protein phosphorylation is a cause for disease in human beings; indeed, increasing numbers of novel drugs are becoming available, which treat a particular disease by specifically targeting molecules that play key roles in its etiology. Design of reagents that target a particular PTP for medical gain remains a worthy, albeit elusive, goal. For this to occur, continued studies that will characterize in full the functions of PTPe and of other PTPs at the molecular, cellular, and whole-organism levels are required. Studies of this type should also address functional redundancies between PTPs, making it clear which other PTPs should also be targeted to obtain a particular outcome, and which PTPs perform opposite roles in this context and should not be targeted. A related challenge is to fully decipher the repertoire of proteins that PTPe acts upon in cells. Traditional biochemical methods address this issue at the level of the individual substrate protein, while advanced proteomic techniques, such as mass spectrometry, may provide unbiased data on a cell-wide basis.

Historical Background

A common event in cellular signal transduction pathways is the phosphorylation of proteins on tyrosine residues. Tyrosine phosphorylation is reversible. The forward reaction is mediated by protein tyrosine kinases. By contrast, the reverse reaction is performed by protein tyrosine phosphatases (PTP). The PTP family consists of 107 genes whose protein products are diverse in form and specificity (Alonso et al. 2004). PTPN3 and PTPN4 constitute two members of this family that were initially identified by PCR amplification using primers specific to conserved regions of the catalytic domain of canonical PTP. PTPN3 was initially cloned from a HeLa cell cDNA library, whereas PTPN4 was cloned from a megakaryoblastic cell line, (Gu et al. 1991; Yang and Tonks 1991). PTPN3 and PTPN4 are 50% identical and 67% homologous at the amino acid level.

Structure and Expression Studies

PTPN3 and PTPN4 are cytosolic proteins that localize to the plasma membrane. Structurally, each PTP comprises of an amino-terminal FERM (band 4.1, Ezrin, Radixin, and Moesin) domain, a central PDZ (PSD-95, Dlg, ZO-1) domain, and a carboxy-terminal PTP domain. FERM and PDZ domains are protein–protein interaction domains that commonly bind the cytosolic tail of transmembrane proteins and can also interact with the phospholipid, phosphatidylinositol 4,5 bisphosphate, $PI(4,5)P_2$. The FERM domains of PTPN3 and PTPN4 are required for plasma membrane association (Gjorloff-Wingren et al. 2000).

PTPN3 and PTPN4 are expressed ubiquitously (Pilecka et al. 2007; Bauler et al. 2008). Both PTP are expressed at high levels in the thalamus. In addition, PTPN4 is highly expressed in testes. A recent comprehensive examination of the PTP transcriptome in the murine immune system reported expression of PTPN3 in all immune cell types examined, with elevated transcript levels in immature dendritic cells (DC), NKT cells, activated CD4 cells, and intestinal intraepithelial CD8 cells (Arimura and Yagi 2010). The same study reported elevated transcript levels for PTPN4 specifically in immature DC, NK cells, and B cells, and also found that PTPN4 transcript levels in DC were increased following LPS stimulation. Alterations in PTPN3 expression levels have been associated with esophageal cancer, and mutations of PTPN3 have been found in colorectal cancer cell lines (Wang et al. 2004). However, a subsequent examination of primary colorectal cancer samples did not detect mutations in PTPN3 (Wood et al. 2007).

Enzymatic Substrates and Protein–Protein Interactions

PTPN3 has been shown to associate with and dephosphorylate several different target proteins. In COS-7 cells, PTPN3 was demonstrated to dephosphorylate cotransfected T cell antigen receptor (TCR) ζ chain (Sozio et al. 2004). Furthermore, in a T cell line, overexpressed PTPN3 was shown to inhibit TCR-induced activation of the promoter of the gene for the cytokine interleukin-2 (Han et al. 2000). Physical association of PTPN3 with TCRζ has also been described (Sozio et al. 2004). PTPN3 interacts with phosphorylated growth hormone receptor in vitro, and overexpression of PTPN3 in cell lines modulates signaling from this receptor (Pasquali et al. 2003; Pilecka et al. 2007). Expression of PTPN3 in fibroblasts can inhibit cellular growth. This effect has been attributed to the ability of PTPN3 to dephosphorylate p97/valosin-containing protein, an established regulator of the cell cycle (Zhang et al. 1999). In contrast to this, PTPN3 binding to and dephosphorylation of p38γ mitogen-activated protein kinase has been recently demonstrated to promote cellular proliferation (Hou et al. 2010). Oncogenic human papillomavirus E6 protein binds PTPN3 and targets it for degradation by the proteasome (Jing et al. 2007). Other proteins that PTPN3 has been shown to interact with include tumor necrosis factor alpha-convertase, the cardiac sodium channel $Na_v1.5$, and 14-3-3β protein (Zhang et al. 1997; Jespersen et al. 2006).

PTPN4 has also been characterized as having multiple binding partners. Like PTPN3, PTPN4 has been demonstrated to bind and dephosphorylate TCRζ in vitro, and when over-expressed in a T cell line, it inhibits TCR signaling (Young et al. 2008). PTPN4 has been shown to bind the δ and ε subunits of the glutamate receptor, signaling from which is required for learning and coordination (Hironaka et al. 2000). Interaction of PTPN4 with attenuated rabies virus glycoprotein is associated with apoptotic death of infected cells (Prehaud et al. 2010).

Generation and Characterization of PTPN3- and PTPN4-Deficient Organsims

So as to understand the importance of PTPN3 and PTPN4 in normal physiological processes, organisms deficient in expression of these PTP were generated. *Drosophila* has a single homologue of PTPN3 and PTPN4, termed PTPMEG. Flies that lack expression of full length PTPMEG were observed to become trapped alive in their food, suggesting a neuronal defect. Subsequent examination of neural connectivity patterns in the brain revealed roles for PTPMEG in the establishment and maintenance of axon projections in *Drosophila* (Whited et al. 2007).

PTPN3-deficient mice have been shown to be grossly normal, although subtle phenotypes have been observed. One group has reported that male PTPN3-deficient mice have a higher body mass and reduced working memory compared to wild-type littermates, whereas female PTPN3-deficient mice exhibit motor learning deficiencies (Pilecka et al. 2007; Patrignani et al. 2008). These mild phenotypes have not been replicated in PTPN3-deficient mice generated by an independent group (Bauler et al. 2008). A function for PTPN3 in TCR signal transduction has not been observed in primary murine T cells, contrary to the aforementioned evidence generated in cell lines (Bauler et al. 2007). Potential subtle roles for PTPN3 in spontaneous pain perception and the positive regulation of LPS-induced cytokine release in mice have been recently reported (Patrignani et al. 2010).

PTPN4-deficient mice have also been shown to be largely normal. Two independent groups demonstrated that T cell function remained intact in PTPN4-deficient mice (Bauler et al. 2008; Young et al. 2008). One other group reported that motor learning and cerebellar synaptic plasticity were impaired in PTPN4-deficient mice, although altered motor learning was not confirmed by an independent group (Kina et al. 2007; Bauler et al. 2008).

Owing to the high degree of homology between PTPN3 and PTPN4 and broad expression patterns of both PTP, it remained possible that loss of either protein was functionally compensated for by the other, thus accounting for the lack of discernible phenotypes in single PTP-deficient mice. However, double PTPN3-PTPN4-deficient mice are also indistinguishable from wild-type mice when considering T cell function, body mass, and motor learning (Bauler et al. 2008).

Summary

PTPN3 and PTPN4 are homologous, ubiquitously expressed PTP that have been implicated as regulators of diverse cellular signaling cascades through interactions with a variety of protein substrates. However, definitive physiological roles for PTPN3 and PTPN4 have not yet been described in higher organisms. Further study of these PTP may reveal nonredundant functions that can be readily demonstrated in gene-targeted mice. Given the high degree of similarity and between PTPN3 and PTPN4, both in terms of structure and expression, it is likely that such functions will be revealed only in double PTP-deficient animals.

Synonyms

Hematopoietic cells phosphatase (HCP); Protein tyrosine phosphatase 1 C (PTP1C); Protein tyrosine phosphatase, non-receptor type 6 (PTPN6); Src homology region 2 (SH2)-domain phosphatase or Src homology region 2 domain-containing PTP-1 (SHP-1 or SH-PTP1)

Gene Location

Mouse chromosome: 6; Location: 6 60.22 cM
Human chromosome: 12; Location: p12p13

Historical Background

The Src homology region 2 (SH) domain-containing protein tyrosine phosphatase-1 (SHP-1) is a member of the large family of protein tyrosine phosphatase (PTP). SHP-1 was identified in hematopoietic cells and organs involved in immune responses such as the spleen, thymus, lymph node, and bone marrow. SHP-1 is also known as hematopoietic cell phosphatase (HCP) because of its expression in these cells. Herein the nomenclature SHP-1 will be used. Back to the beginning of the 1990s, the study of tyrosine kinases was very well advanced; however, knowledge about their

natural counterpart, the tyrosine phosphatases, was still greatly unraveled. Early on, different research groups isolated and identified a protein that contains two SH2 domains with phosphotyrosine phosphatase activity. Soon after, the PTPN6 gene that encodes SHP-1 was mapped to chromosomes 6 and 12 of mouse and human, respectively. Chromosome 6 (and its homologue in human chromosome 12) was also correlated with the autosomal recessive motheaten ("me") phenotype that affects mice to develop a severe combined immunodeficiency and systemic autoimmunity (Tsui et al. 2006). The association of "me" mutation and SHP-1 was confirmed by Shultz et al. (1993) and Tsui et al. (1993). In line with those findings, the involvement of SHP-1 in diseases was earliest described 15 years before its discovery. The first study to report the motheaten mice was done by Green and Shultz (1975), in which they described a recessive mutation in C57Bl/6 mice in the Jackson Laboratory. Those "me" mice exhibit a motheaten phenotype, consisting of disseminated fur-free patches. In addition, these mice were found to develop skin lesion as early as 3 weeks after birth, which progress rapidly and mice did not survive over 8 weeks (Green and Shultz 1975). Subsequently, a similar mutation in the *PTPN6* loci was described, called viable motheaten ("mev") as mice can survive longer than "me" mice, up to 9–12 weeks. This mutation, different of "me" (that does not express SHP-1), provides a protein with small deletion or insertion in the PTP domain which results in around 20% of the phosphatase activity of the cells expressing wild-type SHP-1 (Tsui et al. 2006). Both "me" and "mev" mice develop an unusual pneumonia with a progressive infiltration of macrophages, neutrophils, and lymphocytes, as well as spontaneous inflammatory disorder in many organs such as the kidney and joints (Zhu et al. 2010).

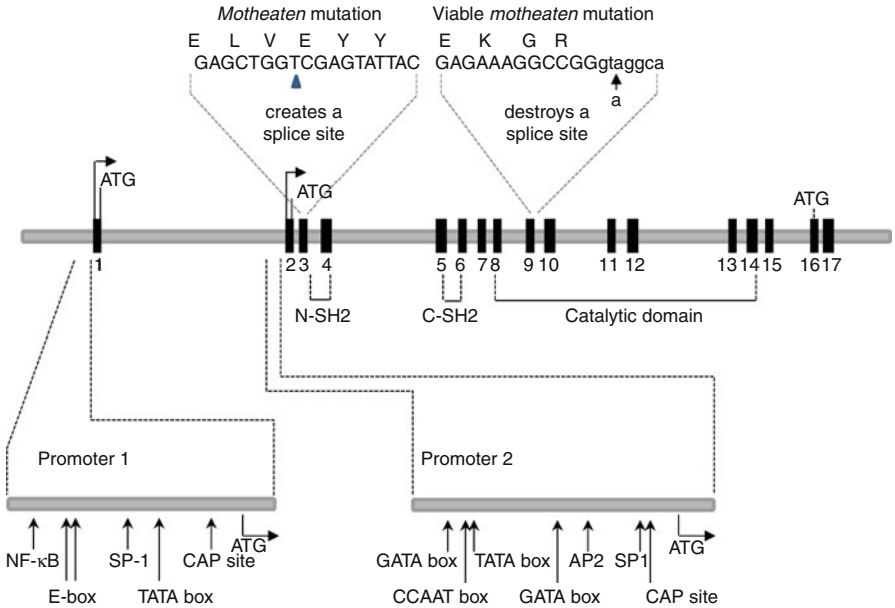
PTPN6 Gene, SHP-1 Protein Expression and Structure

Human PTPN6 gene consists of 17 exons, approximately 17 kb in length, leading to the formation of transcripts of 2.4–2.6 kb. The gene has two promoter regions (within exon 1 and 2) hence encodes two forms of proteins that do not show significant difference in their phosphatase activity (Fig. 1). However, there are differences in the initial sequence of the protein and in SHP-1 tissue expression. Promoter 1 (located 7 kb before promoter 2) encodes MLSRG amino acid sequence in the N-terminal of the form 1 of SHP-1, (I)SHP-1, and promoter 2, MVR in the form 2 of SHP-1, (II)SHP-1. The promoter 1 has two E-boxes (regulated by USF1 and/or 2), a NF-κB and SP1 binding site, as well as a TATA box. The promoter 2 has two GATA sequences, a CCAAT box, a TATA box, an AP2 and SP1 binding sites. The first promoter is active in non-hematopoietic tissue and the second, in the hematopoietic cells. Therefore, (I)SHP-1 is expressed in human epithelial cells and can be induced by PMA via ▶ NF-κB activation and (II)SHP-1, in cells related with the immune system such as macrophages, neutrophils, mast cells, lymphocytes, and so on (Wu et al. 2003; Tsui et al. 2006). In addition to immune cells, it was shown recently that SHP-1 is expressed in hepatocytes, and myocytes (Dubois et al. 2006). Concerning its cellular localization, (I)SHP-1 is located within the nuclear compartment and the (II) SHP-1 in the cytoplasm of resting cells, suggesting that the two forms of SHP-1 might have different targets (Poole and Jones 2005). The other exons of *PTPN6* are responsible for encoding different domains of the protein, hence exons 3 and 4 encode the N-terminal SH2 domain; exons 5 and 6, the C-terminal SH2 domain; and exons 8–10, the catalytic domain (Figs. 1 and 2).

Structurally the SHP-1 protein, similar to SHP-2, is constituted by two SH2 domains in the N-terminal region (N-SH2 and C-SH2), followed by a classical catalytic PTP domain and the C-terminal region containing two tyrosyl (Y536 and Y564) and one serine (S591) phosphorylation sites (Fig. 2). In addition, in the latter region, SHP-1 has a phosphatidic acid–binding active site, a functional nuclear localization signal (NLS), and a potential lipid raft-targeting motif (Poole and Jones 2005; Pao et al. 2007). Furthermore, the C-terminal region of SHP-1 can be longer in the SHP-1 L (long form of SHP-1), having 66 amino acids more than SHP-1, due to an alternative splicing (Poole and Jones 2005).

Function of SHP-1 Domains, Regulation of SHP-1 Activity and Targets

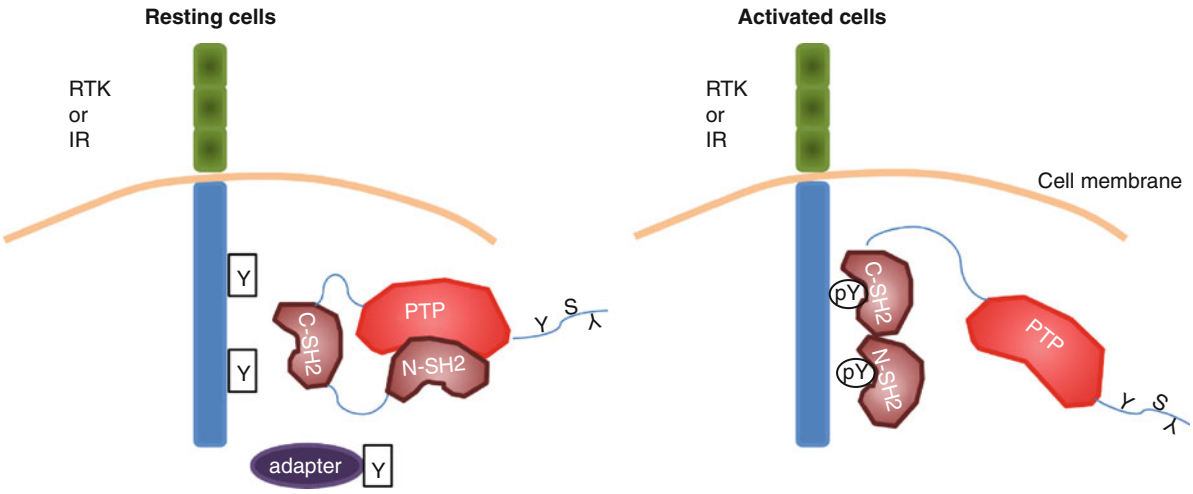
The different domains of SHP-1 protein have specific functions. Crystallographic study revealed that the N-SH2 is bound to the catalytic site in the resting



PTPN6, Fig. 1 Schematic diagram of *PTPN6* gene and mutation of murine *SHP-1*. The schematic representation of *PTPN6* gene shows introns in gray and exons in black. Exons which are responsible for encoding the N-terminus SH2 (3, 4), C-terminus SH2 (5, 6), and catalytic (8–14) domains are also shown in numbers. The bottom part represents the promoter regions 1 and 2 that encode slightly different SHP-1 proteins with comparable activity. The upper part denotes the feature of *motheaten* and viable *motheaten* mutations. The first phenotype, caused by the *motheaten* mutation, is generated by deletion of the C at position 288 that creates a cryptic 5′ splice site consensus. Once activated, the mutation leads to the deletion of 101 bp that creates a frame shift and the stop codon occurs 81 bp downstream of the deleted fragment. The second phenotype, caused by the viable *motheaten* mutation, occurs due to the substitution of T with A in the phosphatase domain. This mutation disrupts a GT dinucleotides creating two cryptic 5′ splice sites – one 15 bp before and the other 69 bp after the normal donor splice site, generating a short (less than five amino acids) and a long SHP-1 (with 23 amino acids or more), respectively. For further review see Wu et al. (2003) and Tsui et al. (2006)

state of the protein. The interaction of N-SH2 and the PTP domain is achieved via charge–charge interaction and has a bidirectional inhibitory effect. Thus N-SH2 inhibits PTP activity and the catalytic domain impedes the binding of the N-SH2 with phosphotyrosyl targets. On the other hand, C-SH2 has a minimum interaction with the PTP domain. The latter information indicates that C-SH2 can effectively serve as a sensor for the targeted phosphotyrosine residue. Once activated, the protein changes its conformation and releases the phosphopeptide-binding pocket of N-SH2 and also the catalytic site of the PTP domain (Poole and Jones 2005; Pao et al. 2007).

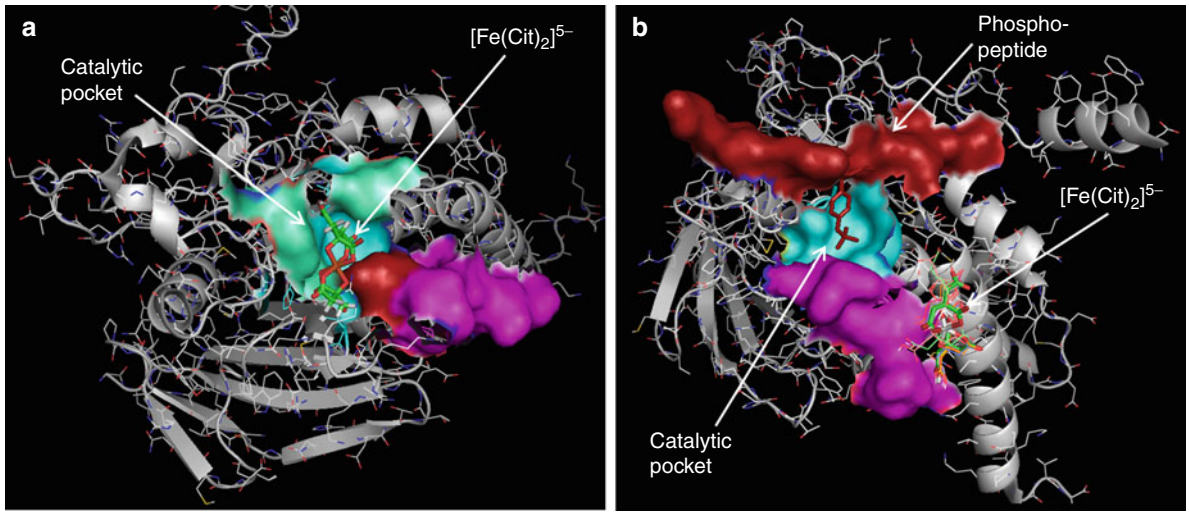
SH2 domains of SHP-1 interact with phosphotyrosyl residues present in different molecules such as scaffold proteins, receptor tyrosine kinases (RTKs), cytokine receptors, and immune inhibitory receptors. The latter are transmembrane proteins with the immunoreceptor tyrosine-based inhibitory motifs (ITIMs) or the immunoreceptor tyrosine-based switch motif (ITSM). The first domain contains six amino acid stretches – V/L/IxpYxxL/V – and the second – TxpYxxV/I – both are phosphorylated upon receptor stimulation and recruit SHP-1. A combinatorial phosphotyrosine study revealed that SHP-1 C-SH2 domain binds selectively to (V/I/L)xpYAx(LV), whereas N-SH2 to LxpY(M/F)x(F/M) and LXpYAXL. In addition, N-SH2 binding can be increased with hydrophobic or positively charged residue at the position pY + 4 and/or pY + 5 (Pao et al. 2007; Lorenz 2009). More recently, it has been reported that several kinases of the JAK, IKK, and ▶ MAP kinase families have similar ITIM motif found mainly in the catalytic domain of the kinase allowing SHP-1 to interact with the kinase via a kinase tyrosine-based inhibitory motif (KTIM) (Abu-Dayyeh et al. 2008) and therefore conferring a better regulation over the kinase activity at resting state.



PTPN6, Fig. 2 Mechanism of SHP-1 activation. *Left* panel shows SHP-1 in its "closed" form in steady state (resting) cells. The C-SH2 domain acts as an antenna to search for phosphorylated tyrosyl residues and the N-SH2 domain interacts with the catalytic domain (PTP) preventing its activity. The C-terminus of SHP-1 consists of two tyrosine (Y) residues and one serine (S) residue, which positively or negatively regulate the SHP-1 activity. Once cells are activated (*right* panel), a receptor tyrosine kinase (RTK), an inhibitory receptor (IR), or scaffolding adapters become phosphorylated in their tyrosine residues (pY). The C-SH2 domain then binds to pY, changing the conformation of the protein and freeing the catalytic domain to act in to the substrate. For further review see Pao et al. (2007) and Poole and Jones (2005)

In addition to SH2 domains, the C-terminal of SHP-1 also controls the SHP-1 activity. As stated above, the C-terminal region contains two tyrosyl (Y536 and Y564) and one serine (S591) residues. The phosphorylation of Y536 upon insulin stimulation or apoptosis inducer reagent increases SHP-1 activation in lymphoblast, ovary, hepatoma, and monocytic cell lines (Lorenz 2009). Zhang et al. (2003) observed a 4- to 8-fold increase of Y564 phosphorylation concomitant with a 1.6-fold augmented activity of the PTP by using a protein ligation approach to install a non-hydrolyzable phosphomimetic (phosphonate) analog on Y536 and Y564 of SHP-1. On the other hand, phosphorylation of S591 negatively regulates SHP-1 activity. In human platelets SHP-1 is constitutively associated with protein kinase C (PKC) alpha and ▶ Vav1, inhibiting Vav1 function. However, when platelets are activated via a thrombin receptor, PKCα is activated and phosphorylates the S591 residue of SHP-1 inhibiting its activity; consequently Vav1 is phosphorylated. In addition to the negative regulation of SHP-1, S591 phosphorylation is also involved in determining its sub-cellular localization. It has been observed that in T cells that phosphorylated S591 SHP-1 displayed reduced translocation to lipid raft and nuclear compartment (Poole and Jones 2005). More recently, S591 phosphorylation has been implicated in the negative regulation of SHP-1 and its nuclear translocation in response to hypertonic solution (Zhang et al. 2010). To sum up, while phosphorylation of C-terminal of SHP-1 in S591 appears to negatively regulate the phosphatase, phosphorylation of Y536 and Y564 residues increase its activity.

Once activated, the catalytic domain of SHP-1 is freed and dephosphorylates its substrate by releasing phosphate. The catalytic domain of SHP-1 contains the PTP signature motif (I/V)HCxxGxxR(S/T) with an essential cysteinyl residue that can mediate hydrolysis via a thio-phosphate intermediate formation. SHP-1 can be reversibly inactivated when the cysteine residue is oxidized by reactive oxygen species (ROS). Oxidized PTP domain can be reactivated via glutathione or thioredoxin pathway (Pao et al. 2007). More recently, Gomez et al. (Gomez et al. 2010) elegantly demonstrated a new negative regulation of SHP-1 activity, as well as other PTPs, mediated by iron (Fig. 3). The iron dicitrate complex was found to compete with phosphotyrosine substrate for the catalytic pocket of the PTP, leading to inhibition of PTPs and increase of MAPK signaling pathway. In this line of thought, SHP-1 activity can be self-regulated and regulated by external oxidation or mechanism involving iron.



PTPN6, Fig. 3 Computational docking of SHP-1 and phosphotyrosyl substrate/iron citrate complexes. (**a**) Docking experiment depicts that the dicitrate iron complex C7 $[Fe(Cit)_2]^{5-}$ resides in the catalytic pocket of SHP-1 (PDB code: 1GWZ). (**b**) In vitro co-crystallization of SHPS-1 (PDB code: 1FPR) and tyrosine phospho-peptide substrate pY459) exclude the C7 complex, suggesting a possible competition between C7 complex and the phosphotyrosyl peptide for the catalytic pocket

Concerning the target of SHP-1, this phosphatase can regulate many signaling pathways triggered by different receptors such as T cell receptors (TCR), B cell receptors (BCR), and toll-like receptors (TLR). In T cells SHP-1 has been shown to directly regulate the TCR or associated co-receptor; however, the exact mechanism is unclear. It has been proposed an antagonism mechanism of SHP-1. A study done with T cells bearing TCR with different specificity revealed that stimulation of these cells with an agonist protein for one receptor and an antagonist to a second receptor lead to the binding of Lck to the agonist-activated receptor, whereas SHP-1 is recruited to the antagonist-activated TCR. In addition, in the presence of weak antigen Lck phosphorylates SHP-1 on Y564 residue, recruiting SHP-1 to associate and dephosphorylate Lck. However, in the presence of a strong ligand binding, ERK is activated and phosphorylates Lck, in this way Lck does not interact with SHP-1 and triggered signaling continues (Pao et al. 2007; Lorenz 2009). Other SHP-1 substrates such as Zap-70, SLP-76 and Vav have been proposed, those substrates and other important signaling molecules are localized constitutively or after stimulation in the lipid raft as well as SHP-1. In T cells, around 20–30% of SHP-1 is found constitutively in the lipid raft and has a negative regulation role on Lck phosphorylation and IL-2 production. Furthermore, T cells express inhibitory receptors such as the carcinoembryonic antigen–related cell adhesion molecule-1 (CEACAM-1), CD5, the cytotoxic T-lymphocyte antigen-4 (CTLA4), and the leukocyte-associated immunoglobulin-like receptor-1 (LAIR-1) that can recruit or are constitutively associated with SHP-1, resulting in its activation and consequent inhibition of T cell signaling and function (Lorenz 2009).

SHP-1 is also known to regulate BCR. In B cells it has been proposed that SHP-1 is interacting with different inhibitory receptors such as CD22, CD72, CD5, and PIR-B, as well as with various substrates like ▶ PI3K, Vav, Btk, SLP-76/65, Syk, and 3BP2. For instance, CD22 is an ITIM containing receptor member of the sialic-acid-binding immunoglobulin-like lectin (Siglec) family. CD22 associates and negatively regulates BCR response via SHP-1, as in CD22 or SHP-1 deficient B cells were found to display higher intracellular calcium mobilization and IgM secretion. However, the role of sialic acid, CD45, or IgM as ligand to CD22 is still controversial. In addition, SHP-1 activity is down-regulated in activated B cells, suggesting that SHP-1 in resting cells is active through an unknown mechanism. The production of ROS has been proposed as a mechanism of transient negative modulation of SHP-1 activity in activated B cells.

Conversely, it was shown in the same study that the production of ROS was still higher when the SHP-1 activity came back to baseline levels, suggesting that other mechanism could be regulating the phosphatase activity (Pao et al. 2007; Nitschke 2009).

Concerning TLR signaling, recently it has been demonstrated in an infectious experimental model that SHP-1 associates and rapidly inhibits the interleukin-1 receptor-associated kinase 1 (IRAK-1) and LPS-mediated macrophage functions upon TLR4 stimulation, as well as in response to other ligands targeting other TLRs utilizing IRAK-1 in their signaling cascades. SHP-1 was found to interact with an evolutionarily conserved KTIM motif on IRAK-1 (Abu-Dayyeh et al. 2008).

SHP-1 and Diseases

As discussed above, studies demonstrating implication of SHP-1 in different diseases has been based in part on phenotypes observed in "me" or "mev" mice. These mice are known to spontaneously develop inflammatory abnormalities in multiple organs such as skin, kidney, and lungs, which drive attention to certain diseases such as respiratory disorders. Of utmost interest, involvement of SHP-1 in cancer, infectious diseases, and diabetes has been reported and will be discussed in the following sections.

Respiratory Diseases

Studies done with "mev" mice revealed higher infiltration of macrophages, eosinophils, as well as neutrophils and lymphocytes in the lungs. These mice developed an allergic-type inflammatory response similar to allergic asthma, including mucus hyperproduction, metaplasia of Goblet cells, and increased airway hyperresponsiveness. Additionally, the concentration of Th2 type cytokines such as IL-4, IL-5, and IL-13 was found to be elevated, as well as chemokines (CCL2/MCP-1 and CCL11/eotaxin) that are important for recruitment of monocytes and eosinophils. As Th2 response seemed to be predominant in "mev" mice, further investigation on mast cells was done due to their capacity to produce IL-4 and IL-13, comparable to basophils and eosinophils. In vitro study using IL-13 as a growth factor showed that cells from "mev" mice grow less than their WT counterpart indicating that SHP-1 controls the number of mast cells progenitors (c-kit/FcεRI double-positive cells) and its maturation. Furthermore mast cells from these mice were found to be resistant for apoptosis, possibly due to the increased expression of the anti-apoptosis gene Bcl2. In vitro experiments with mast cells from "mev" mice showed higher production of IL-4 and IL-5 in response to superoxide, as well as to spontaneously produce those cytokines being dependent on ROS production. The role of ROS in the regulation of SHP-1 activity is well known; therefore it is not surprising that it could regulate the residual 20% of SHP-1 activity found in cells from "mev" mice. In addition to cytokines, SHP-1 also regulates mast cell degranulation as revealed by bone marrow–derived mast cells from "mev" mice that spontaneously releases β-hexosaminadase and also has greater response to IgE stimulation in comparison to WT cells. In conclusion, in experimental models SHP-1 seems to modulate lung disorders; however, correlation of human lungs disease and SHP-1 expression has still not been found. Nevertheless, low expression of SHP-1 has been correlated with human chronic myeloid leukemia and psoriasis (Zhu et al. 2010).

Cancer

SHP-1 is known to negatively regulate intracellular signaling necessary to many cellular functions including cell growth and division; therefore, it is not surprising that many cancer cells have been found not to express SHP-1. For instance, cell lines derived from T cell, B cell, and natural killer (NK) cell lymphomas (all classified as non-Hodgkin's lymphomas), as well as leukemia, were found in majority not to express or to have a reduced expression of SHP-1. However, some other cancerous cell lines such as BJAB, HUT102B, HUB102B2, AG876BL, KK124, Kem III, and WW1BL do indeed express SHP-1. Expression of SHP-1 in lymphomas has been proposed to be related with the progression, aggressivity, and the stage at which the cell is (Wu et al. 2003). Clinically, an analysis of 207 patient samples having different malignant lymphomas/leukemia revealed that 100% of NK/T cell lymphomas and 95% of samples from patients with malignant lymphomas bore complete abrogation of SHP-1 expression. One mechanism found to be responsible for the latter event is the methylation of PTPN6 promoter. DNA methyl-transferase, together with STAT3 and histone diacetylase I promote the silencing of SHP-1 in lymphoma and leukemia cells. However, methylation of PTPN6 promoter might not

be the only mechanism as treatment with demethylation drugs increase SHP-1 RNA, but not protein expression, suggesting that other posttranscriptional modification of SHP-1 could be involved (Wu et al. 2003; Tsui et al. 2006). In contrast to hematopoietic cancer, SHP-1 protein and RNA expression are increased in epithelial cancer such as ovarian and prostate cancer. In the case of prostate cancer, SHP-1 expression and activity is related with the production of somatostatin that has a paracrine/autocrine inhibitory effect on cell proliferation via SHP-1. In this way, SHP-1 expression is related with proliferation and aggressiveness. Interestingly, it has been reported in the last few years that the use of PTP inhibitors such as peroxovanadium can greatly abrogate the progression of ovarian cancer in mice (Caron et al. 2008).

Infectious Diseases

As stated above in regard to cancer, SHP-1 has an important anti-proliferative function; in this line of thought its absence is essential for the progression of the disease. However, during the course of certain infectious diseases, it has been found that the negative regulatory action of SHP-1 can be exploited by pathogens to favor their survival and development into the host cells. Two examples are the intracellular pathogens of *Leishmania* genus and *Mycobacterium tuberculosis* known to infect phagocytes of the monocyte/macrophage lineage. These cells play a critical role in innate immune response being responsible to engulf invading microorganisms and to terminate them. Macrophages display many microbicidal molecules such as ROS, nitric oxide (NO), and pro-inflammatory mediators. Even with such an impressive defense system, they can become infected by different intracellular parasites, as mentioned above. In the case of *Leishmania*, a protozoan parasite responsible for causing leishmaniasis, is known to interact with macrophages and to rapidly inactivate the IFNγ-inducible kinase JAK-2, as well as several members of the MAP kinase family, and the LPS-induced IRAK-1 kinase (critical to TLR pathway). This multiple signaling alteration results in the inhibition of several macrophage microbicidal functions. One of the mechanisms exploited by the parasite is the inactivation of the host cell by inducing macrophage SHP-1 activity upon its cleavage by *Leishmania* metalloprotease GP63 in its C-terminal portion (Gomez et al. 2010). Interestingly, as mentioned above in the text, SHP-1 was found to interact with an evolutionarily conserved kinase tyrosyl-based inhibitory motif (KTIM) being present in various kinases such as JAK-2, IRAK-1, and ERK-1/2, all being targeted by SHP-1 inhibitory action upon *Leishmania* infection (Abu-Dayyeh et al. 2008). The role of SHP-1 in leishmaniasis has been further demonstrated in an experimental model by a pharmacological intervention using the bis-peroxovanadium bpV(phen) and genetically using the "mev" mice. Treatment of mice with PTP inhibitors reduced both parasite load and skin lesion of *Leishmania* major-infected mice, and completely protected mice from the visceral *L. donovani* infection. The same phenotype was observed in "mev" mice, which developed a significantly reduced cutaneous lesion (Mansfield and Olivier 2001).

Another intra-macrophage pathogen is the bacteria *Mycobacterium tuberculosis*, which is the causative agent of tuberculosis. This bacterium enters through the respiratory airway and infects the lungs' macrophages. How the bacillus survives inside of the macrophages is not very clear. It has been proposed that *M. tuberculosis* inhibits the macrophage functions by the action of its bacterial cell wall glycolipid (LAM). LAM was reported to inhibit ERK1/2 kinase by the activation of SHP-1 (Nandan et al. 2000). LAM was also found to inhibit *M. tuberculosis*–induced apoptosis and to involve SHP-1, as LAM-induced apoptosis was shown to be absent in SHP-1 deficient "me" cells. This latter effect was shown to be related with increased LAM-induced NO production in the absence of SHP-1 (Rojas et al. 2002).

In addition to those pathogens, filarial nematodes can release excretory-secretory products (ES) influencing the immune cell functions. The ES is secreted by a majority of filarial nematodes affecting humans including *Wuchereria bancrofti*, *Brugia malayi*, and *Onchocerca volvulus*, and by *Acanthocheilonema viteae* affecting rodents. ES protein has been found to inhibit the B cell functions by inducing SHP-1 recruitment to the BCR and therefore altering its signaling activity (Mansfield and Olivier 2001).

Glucose Metabolism (Diabetes)

Diabetes mellitus is described as a defect in the glucose metabolism, hence hyperglycemia, because of insufficient production of insulin or its tolerance. Recently the role of SHP-1 in the glucose homeostasis and diabetes-related pathology has been explored. A study using "mev" mice demonstrated that in the

normal condition SHP-1 collaborates to the insulin resistance profile due to its negative modulation of the insulin receptor substrate-1 (IRS-)-related signaling pathway PI3K/AKT, possibly by modulating PTEN. Furthermore, SHP-1 was also found to downregulate the transmembrane glycoprotein carcinoembryonic antigen-related cell adhesion molecule-1 (CEACAM-1) that controls insulin clearance. Liver cells from "mev" showed a hyperphosphorylation of CEACAM-1. This adhesion molecule is also co-immunoprecipitated with SHP-1. Furthermore, SHP-1, but not PTP1B or PTP-PEST, can specifically dephosphorylate CEACAM-1. In vivo experiment showed a slower clearance of radiolabeled insulin in "mev" mice favoring the increase of glucose (Dubois et al. 2006).

One common diabetic consequence is the retinopathy and other microvascular complications due to a hyperglycemia-induced apoptosis process. The latter involves the activation of PKCα that regulates NF-κB activation (via ROS generation) and p38 MAPK. This MAPK induces SP-1 activation and consequently enhancement of SHP-1 expression. SHP-1 negatively regulates the pro-survival growth factor receptor PDGFR-β resulting in pericyte apoptosis (Geraldes et al. 2009).

Summary

Collectively, it is possible to conclude that SHP-1 – a member of the PTPs superfamily – is a critical negative regulatory phosphatase of kinases controlling several functions of immune cells. Its involvement in the development of many diseases, such as cancer, allergy, diabetes, and infection diseases, has been clearly established, and found to be related to its inability to perform its regulatory functions or to be exploited by pathogens to evade immune responses. An in-depth understanding on how it is regulated could bring about the discovery of very innovative ways to treat various pathologies.

R7 Binding Protein (R7BP); RGS9 Anchor Protein (R9AP)

Introduction and Historical Background

Regulator of G protein signaling (RGS) proteins constitute a diverse family with more than 30 members that contain the hallmark RGS domain. Most members serve as negative regulators of G protein signaling by catalyzing the GTP hydrolysis on Gα subunits leading to their inactivation (Ross and Wilkie 2000; Hollinger and Hepler 2002). Based on their structural organization and sequence homology RGS proteins are divided into 5–6 families (Ross and Wilkie 2000; Hollinger and Hepler 2002). The R7 RGS family (R7 RGS) contains multidomain proteins conserved from *C. elegans* to humans that, in mammals are represented by four members: RGS6, RGS7, RGS9, and RGS11. R7 RGS proteins play important roles in the nervous system by controlling neurotransmitter action at rhodopsin, μ-opioid, D2 dopamine, and GABA(B) receptors (Anderson et al. 2009a).

The unique feature of this group is that they form obligatory complexes with Gβ5, an atypical member of the G protein beta subunit family (Sondek and Siderovski 2001; Slepak 2009). The stability of all R7 RGS proteins crucially depends on this interaction and knockout of Gβ5 in mice leads to severe downregulation in the levels of all four R7 RGS proteins (Chen et al. 2003). Localization of R7 RGS-Gβ5 complexes in discrete membrane compartments in native cells in parallel with cytoplasmic distribution in heterologous expression systems have prompted speculations that their membrane anchoring is mediated by unidentified proteins (Hu and Wensel 2002; Lishko et al. 2002). This led to searches for additional binding partners.

For R7 RGS proteins, these studies were very productive and resulted in the identification of two homologous binding partners: RGS9 Anchor Protein (R9AP) and R7 Binding Protein (R7BP), novel proteins that now constitute a two-member family. First, proteomics search for RGS9 binding partners in the retina identified a transmembrane protein R9AP (Hu and Wensel 2002). Three years later, a homologous R7BP protein was found as a binding partner of RGS9 in the brain

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

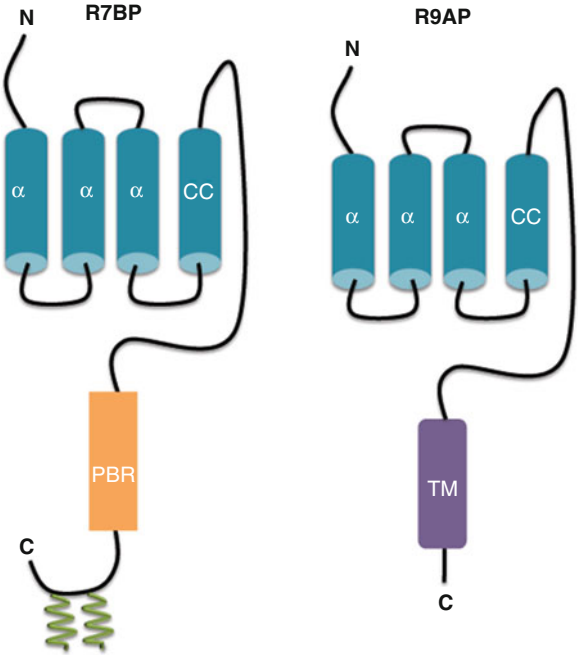
using similar approach (Martemyanov et al. 2005). R7BP was also independently discovered as a universal anchor for all R7 RGS proteins by Ken Blumer's group by in silico BLAST searches (Drenan et al. 2005).

Structural Organization

Both R7BP and R9AP are small membrane proteins that show distant homology to SNARE proteins involved in the regulation of exocytosis (Keresztes et al. 2003; Martemyanov et al. 2003). N-termini of R9AP and R7BP are predicted to contain 4 alpha helices organized in the bundle with the fourth helix containing prominent heptad repeats, a feature underlying coiled coil interactions (Fig. 1). This helical bundle region mediates binding to the R7 RGS proteins (Anderson et al. 2009a; Jayaraman et al. 2009). From the side of the RGS proteins, N-terminal DEP (Dishevelled, Egl-10, Pleckstrin) and DHEX (DEP Helical Extension) domains were found to be essential for the association (Anderson et al. 2009a; Jayaraman et al. 2009) although no high-resolution information of the determinants involved in binding have been reported. The C-termini of R7BP and R9AP contain membrane anchoring elements. In R9AP this is presented by transmembrane region, while R7BP is anchored through palmitoylation of two conserved cysteine residues which are additionally aided by a polybasic stretch with a sequence resembling membrane attachment motif of Ras proteins (Drenan et al. 2005; Song et al. 2006). In summary, while differing in amino acid composition, both R9AP and R7BP contain two domains: the N-terminal RGS binding region and C-terminal membrane localization domain.

Distribution, Subcellular Localization, and Interactions with R7 RGS Proteins

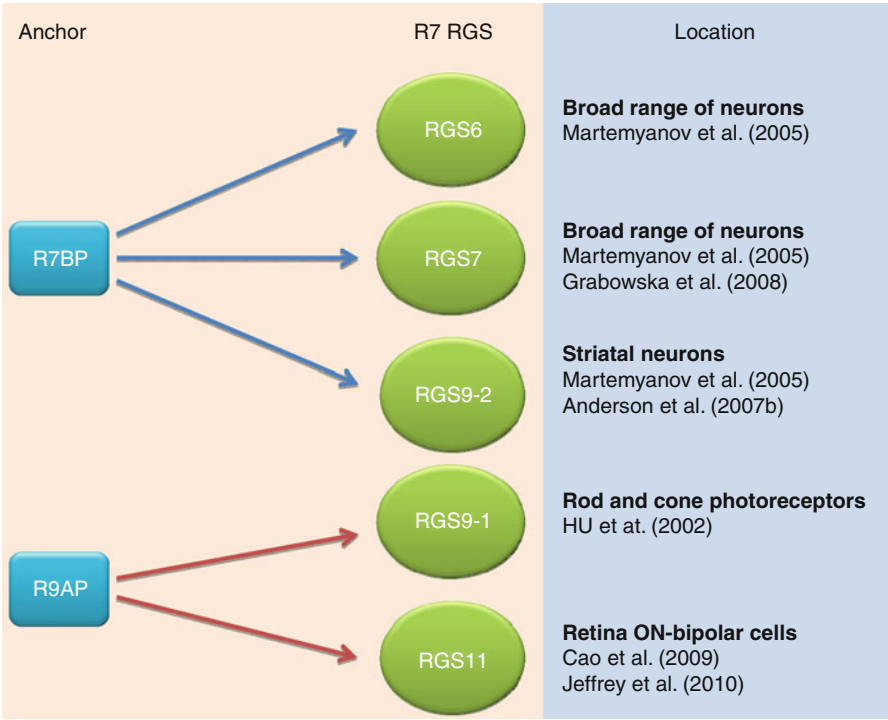
In mammals, expression of both R9AP and R7BP proteins appears to be confined to the neuronal tissues (Martemyanov et al. 2005; Grabowska et al. 2008). However, only limited set of non-neuronal tissues have been investigated and it remains possible that the proteins could be expressed more broadly, as for example, ample amounts of R9AP mRNA are found across various tissues in birds (Keresztes et al. 2003). While R7BP is expressed broadly in all regions of



R7BP/R9AP, Fig. 1 *Schematic structure of R7BP and R9AP proteins*. Membrane attachment of R7BP is mediated by palmitoylated cysteines (wavy lines) acting in conjunction with polybasic region (PBR). R9AP is anchored to the membrane by transmembrane segment (TM). Blue cylinders designate predicted alpha helical regions. CC label designates heptad repeats-containing region that is predicted to engage in coiled-coil interactions

central and peripheral nervous system, R9AP is more restricted and appears to be reliably found only in the retina, where it is found in three cell types: rod and cone photoreceptors (Hu and Wensel 2002) and ON-bipolar cells (Cao et al. 2009; Jeffrey et al. 2010).

At the subcellular level, R9AP is targeted to the disc membranes of the outer segments, a ciliated compartment of the photoreceptors and dendritic tips of the ON- bipolar neurons (Hu and Wensel 2002; Cao et al. 2009; Jeffrey et al. 2010). Likewise, R7BP was also found to be localized predominantly in the membrane compartments. Its significant fraction is found in the postsynaptic density and extrasynaptically at the plasma membrane of the spines and dendrites (Anderson et al. 2007b; Grabowska et al. 2008). Although to a lesser extent, some R7BP immunoreactivity is also present pre-synaptically in axons (Grabowska et al. 2008). Subcellular tartgeting of R7BP and R9AP to their membrane compartments requires the membrane attachment sequence at the C-terminus (Drenan et al. 2006; Song et al. 2006).



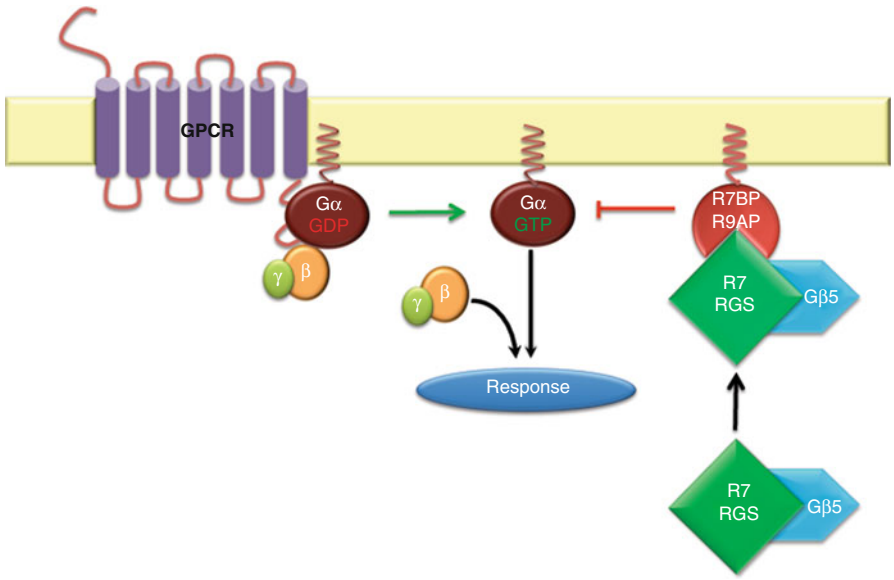
R7BP/R9AP,
Fig. 2 Physiologically relevant complexes of R7BP and R9AP in vivo

While plasma membrane compartment is the sole localization site of R9AP, R7BP has been reported to have an alternative destination – nucleus. It possesses two active nuclear localization sequences that are masked by palmitoylation (Drenan et al. 2005; Song et al. 2006). When palmitoylation is abolished, R7BP undergoes translocation to the nucleus, a phenomenon most readily demonstrated in cultured cells (Drenan et al. 2005; Song et al. 2006). However, the fraction of R7BP in the nucleus is very small and no studies have yet reported translocation in vivo under physiological conditions.

R7BP and R9AP anchors show differential selectivity in their association with individual R7 RGS members. This is determined by both their interaction specificity and co-expression patterns. At the biochemical level, R9AP can bind only to RGS9 and homologous RGS11, but not to RGS6 or RGS7 (Martemyanov et al. 2005). In contrast, R7BP associates with all R7 RGS proteins (Drenan et al. 2005; Martemyanov et al. 2005). However, the distribution of R7 RGS protein subtypes does not always overlap with that of R7BP and R9AP making some combinations physiologically irrelevant. For example, although R9AP can bind to RGS9-2, it is not expressed in the striatum, where RGS9-2 is instead found in complex with R7BP. Similarly, RGS11 can bind to R7BP, but because it is present exclusively in bipolar cells where R9AP is more abundant, most of it is found in complex with R9AP (Cao et al. 2008). See Fig. 2 for details on physiologically relevant configurations of R7BP and R9AP complexes with R7 RGS proteins.

Regulation of the RGS Protein Localization and Activity

Studies with transfected cells indicate that R7 RGS-Gβ5 complexes are predominantly cytoplasmic (Drenan et al. 2005; Song et al. 2006). In contrast, co-transfection with R7BP (or R9AP for RGS9-1) targets R7 RGS proteins to the plasma membrane (Hu and Wensel 2002; Drenan et al. 2005; Song et al. 2006). A similar situation is observed in striatal neurons in vivo for RGS9-2 that becomes mis-localized from post-synaptic densities and plasma membrane compartments upon elimination of R7BP (Anderson et al. 2007b). In striatal neurons, R7BP is also involved



R7BP/R9AP, Fig. 3 Role of membrane anchors R7BP and R9AP in G protein signaling regulation

in targeting RGS7 to the post-synaptic density (Anderson et al. 2009b). Likewise, the role of R9AP in localization of RGS9-1 to the disc membranes of the photoreceptor outer segments is also well established (Hu and Wensel 2002). Nevertheless, mechanisms governing localization of R7 RGS proteins appear to be complex and anchor-independent targeting has been observed for both RGS7 and RGS11 in the bipolar cells of the retina (Cao et al. 2008; Cao et al. 2009)

The nucleus has been repeatedly reported to be an alternative destination for relatively minor fraction of several R7 RGS proteins (Burchett 2003). Consistent with its nuclear shuttling, R7BP is capable of targeting R7 RGS to the nucleus of the transfected cells upon depalmitoylation (Drenan et al. 2005). Furthermore, knockout of R7BP abolishes nuclear localization of a significant fraction of RGS7 in the central nervous system neurons (Panicker et al. 2010). However, the functional significance of plasma membrane – nuclear shuttling of R7 RGS proteins or their functional role at this location is currently unknown.

In addition to localization, association with R9AP and R7BP influences the efficiency of R7 RGS to catalyze G protein GTPase (GAP) activity. For instance, R9AP has been shown to potentiate the ability of RGS9-1 and RGS11 to stimulate GTPase of Gαt and Gαo, respectively (Hu et al. 2003; Masuho et al. 2010). The most straightforward explanation for the stimulatory effects is facilitation of the R7 RGS complex compartmentalization with membrane bound G proteins and receptors. The restriction of the diffusion of the complex from the three-dimensional cytoplasm to the two-dimensional plane of the plasma membrane is expected to speed up Gα-GTP encounter. However, the mechanism is likely to be more complex, as at least R9AP action was shown to provide an allosteric modulation of the RGS9 and RGS11 complexes (Baker et al. 2006; Masuho et al. 2010).

Effects on the Proteolytic Stability of the R7 RGS Complexes

Perhaps the most pronounced effects of membrane anchors are on regulation of post-translational stability of R7 RGS proteins. These effects are observed only with two RGS proteins: RGS9 and RGS11. Studies with genetic knockouts indicate that elimination of R9AP severely compromises proteolytic stability of RGS9 (Keresztes et al. 2004) and RGS11 (Cao et al. 2008) in the retina. Likewise, knockout of R7BP leads to destabilization of RGS9-2 in the brain (Anderson et al. 2007a). This explains why loss-of-function mutations in R9AP produce the same phenotype as RGS9-1

mutations – slow adaptation to both light and dark conditions and difficulty in tracking moving objects (Nishiguchi et al. 2004). Similarly, knockout of R7BP causes motor co-ordination deficits characteristic of severe reduction in levels of RGS9-2 (Anderson et al. 2010). Loss of R7BP has been shown to facilitate recruitment of the destabilizing chaperone Hsc70 (Posokhova et al. 2010) to RGS9-2 and trigger its proteolysis by cellular cysteine proteases (Anderson et al. 2007b). Association of RGS9-Gβ5 with R7BP is controlled dynamically and is sensitive to changes in oxygenation and neuronal excitability (Anderson et al. 2009b). Because the abundance of R7 RGS proteins controls the extent of the G protein signaling and has direct behavioral implications, regulation of R7 RGS degradation and coupling to R7BP can be viewed as a plasticity mechanism.

Summary and Conclusions

In summary, R7BP and R9AP proteins play very important roles in controlling stability, localization and functional activity of R7 RGS proteins and as a result critically contribute to the regulation of G protein signaling (Fig. 3). There are currently a number of outstanding questions pertaining to the role of R7BP and R9AP in regulation of (1) G protein signaling selectivity, (2) RGS catalytic activity and (3) physiological processes in the nucleus. Finding answers to these questions would help gain a better understanding of G protein signaling.

AtRabC1-C2b (*Arabidopsis thaliana*); Rab18b (*Danio rerio*); Rab-RP4 (*Drosophila melanogaster*)

Historical Background

Interest in the RAB proteins stems from early work on yeast that identified essential roles for the RABs Ypt1p (Rab1) and Sec4p in pre- and post-Golgi membrane trafficking (Salminen and Novick 1987; Segev et al. 1988). These findings prompted efforts to clone other members of the RAB gene family and it was quickly established that this family had undergone significant expansion in mammals. As each new RAB was discovered, it also became clear that different RAB proteins could adopt specific subcellular localizations, associating with particular membrane compartments and regulating the functions of these organelles. RAB18 was partially cloned in 1992, and then fully cloned in 1993 (Chavrier et al. 1992; Yu et al. 1993). Initial characterization showed that it was widely expressed in different tissues and localized to endosomes in polarized epithelia (Lutcke et al. 1994). Subsequent research has suggested, however, that it adopts various different subcellular localizations and can function in a cell-type-specific manner (Dejgaard et al. 2008; Hashim et al. 2000; Hashimoto et al. 2008; Martin et al. 2005; Ozeki et al. 2005; Vazquez-Martinez et al. 2007). Currently, little is known about the protein-protein interactions that regulate and mediate RAB18 activity, but genetic evidence has linked it to the regulation of RAB3 isoforms. In a recent study, loss-of-function mutations in *RAB18* were found to cause Micro syndrome, a disorder previously associated with mutations in *RAB3GAP1* or *RAB3GAP2* (Aligianis et al. 2005, 2006; Bem et al. 2011).

RAB18 in Disease

Micro syndrome is a rare autosomal recessive disorder with both developmental and degenerative features. Patients present with micropthalmia, atonic pinpoint pupils, and congenital cataracts. Even with early cataract surgery, most have only light perception due to severe cortical visual impairment characterized by normal electroretinogram (ERG), but virtually absent visually evoked potentials (VEPs). Affected individuals have severe developmental delay and do not learn to sit independently, walk, or talk. They suffer from postnatal growth retardation, microcephaly, and hypothalamic hypogenitalism and can have cerebral anomalies including polymicrogyria and hypoplasia or agenesis of the corpus callosum. In addition to initial muscular hypotonia, they go on to develop ascending spastic paraplegia and contractures.

The pathogenesis of Micro syndrome indicates that RAB18 function is important in eye and lens development, neurotransmission and neuronal migration and homeostasis. Knockdown of rab18b in zebrafish produces a phenotype reminiscent of Micro syndrome, suggesting that RAB18 has conserved roles in these processes and that animal models might offer a valuable resource in future studies (Bem et al. 2011). Further, as it is now clear that specific physiological systems are particularly susceptible to loss of functional RAB18, characterization of this deficit at a cellular and molecular level can be better targeted. In turn, this work may inform the development of therapeutics for Micro syndrome and related disorders. However, it is important to note that the physiological roles of RAB18 may in fact be much broader than can be inferred from the effects of its absence. RAB proteins can show a varying degree of functional redundancy in different tissues, either as a result of the different expression patterns of RABs with overlapping cellular roles, or because a given RAB may mediate responses through tissue-specific effector proteins. Furthermore, RAB18 expression may be regulated in concert with other factors. Dysregulation of RAB18 expression has been observed in a number of different cancers and has been extensively studied in the context of pituitary tumors (Vázquez-Martínez and Malagón 2011). In these tumors, its downregulation has been linked to the hypersecretion of human growth hormone (hGH) that contributes to acromegaly in sufferers (Vazquez-Martinez et al. 2008). However, Micro syndrome patients who do not express any functional RAB18 do not show abnormal hGH secretion.

Rab18 Expression and Subcellular Localization

Several reports show that RAB18 mRNA is ubiquitously expressed, implying that it has a general cellular role (Lutcke et al. 1994; Schafer et al. 2000; Yu et al. 1993). However, other evidence suggests that its role is more specialized. It appears to be expressed at different levels in the different tissues examined, with it being highly expressed in the brain and the heart. Immunohistochemistry suggests that the protein is enriched in polarized epithelia (Lutcke et al. 1994). Furthermore, in a number of situations, its expression is reported to be inducible. For example, it is induced in endothelial cells stimulated with histamine (Schafer et al. 2000), in differentiating adipocytes (Pulido et al. 2011), and in the brains of alloxan-treated rats (Karthik and Ravikumar 2011). The most convincing evidence that the protein serves discrete cellular roles, though, comes from a series of divergent reports on its cellular localization and function.

RAB18 has been reported to associate with endosomes in polarized epithelia where it has been suggested to function in endocytosis (Lutcke et al. 1994). In a macrophage cell line, it localized to a specialized phagocytic compartment and was suggested to function in immune evasion (Hashim et al. 2000). Several reports have found that the protein can localize to lipid droplets in adipocyte, fibroblast, and epithelial cell lines (Martin et al. 2005; Ozeki et al. 2005; Pulido et al. 2011) and this has been linked to roles in lipogenesis (Pulido et al. 2011) and lipolysis (Martin et al. 2005; Pulido et al. 2011). However, in the same cells, it can localize to endoplasmic reticulum (ER) and Golgi under some circumstances (Dejgaard et al. 2008; Martin et al. 2005), and one report has suggested that it functions in Golgi to ER trafficking (Dejgaard et al. 2008). In endocrine cell lines and in pituitary melanotropes, it has been found associated with secretory granules, and suggested to function in modulation of the secretory response (Vazquez-Martinez et al. 2007). These reports are

difficult to reconcile. However, a common feature of several of them is that the recruitment of RAB18 to intracellular organelles can be enhanced by cellular stimulation. In adipocytes, for example, recruitment of RAB18 to lipid droplets was promoted by treatment with insulin, which stimulates lipogenesis (Pulido et al. 2011), or by the β-adrenoceptor agonist isoproterenol, which stimulates lipolysis (Martin et al. 2005; Pulido et al. 2011). Similarly, in PC12 and AtT20 cells, stimulation with KCl led to redistribution of RAB18 from the cytosol to a subpopulation of secretory granules (Vazquez-Martinez et al. 2007). It will be important to establish the extent to which different molecular interactions underlie the functions of RAB18 in different cell types, and reciprocally, that to which common molecular interactions underlie its function at diverse intracellular compartments.

Regulator and Effector Proteins

Following synthesis and posttranslational prenylation, RAB proteins are regulated by four classes of protein: GDP-dissociation inhibitors (GDIs), GDI displacement factors (GDFs), Guanine-nucleotide exchange factors (GEFs), and GTPase-activating proteins (GAPs). GDIs and GDFs are thought to be general regulators of multiple RABs, while GEFs and GAPs are thought to show more specificity for particular RAB proteins. GDIs can sequester GDP-bound RABs in the cytosol by binding to their hydrophobic prenyl groups, but also coordinate with GDFs in the delivery of RABs to membranes. GEFs catalyze the exchange of bound GDP for GTP, and so can serve to concentrate RABs on a particular cellular compartment because RAB proteins are not susceptible to GDI-mediated membrane extraction when GTP-bound. GAPs stimulate a RAB's intrinsic GTP-hydrolysis activity, which converts bound GTP to GDP, thus rendering them susceptible to extraction once again.

The GEF(s) and GAP(s) that regulate RAB18 are not known. However, the identification of these proteins may be key to understanding how it can be recruited to a wide range of organelles in a cell-type-specific manner. It is possible that a single RAB18GEF might be differentially localized in different cells. However, in some cases, specific RABs are the substrates for multiple GEFs, and so differential expression of RAB18GEFs with different localizations might offer another explanation for this phenomenon. Alternatively, RAB18 localization might be regulated by its GAP(s). The presence of a RABGAP on a particular membrane compartment can effectively exclude its target RAB from this compartment by promoting GTP hydrolysis and GDI-mediated membrane extraction at this location. Thus, the translocation of the RABGAP away from a given compartment can indirectly promote RAB recruitment there.

The function of *RAB18* is genetically linked to that of *RAB3GAP1* and *RAB3GAP2*, mutations in which can also cause Micro syndrome (Aligianis et al. 2005, 2006; Bem et al. 2011). RAB3GAP1 and RAB3GAP2 form a heterodimeric RAB3GAP complex that regulates the activity of RAB3 isoforms (Fukui et al. 1997; Nagano et al. 1998). However, the activity of Rab3GAP against many other RABs, including RAB18, is unknown. Work is underway to determine whether RAB3GAP is a regulator of RAB18 function. However, it is also possible that it is a mediator of this function. RAB proteins mediate cellular responses via interacting partners generically called "effectors," and it has been proposed that RABGAPs acting on one RAB protein are frequently effectors of another (Kanno et al. 2010).

While it remains to be established whether RAB3GAP is a regulator and/or an effector of RAB18 function, several candidate RAB18-interacting proteins have previously been identified in the literature. A weak interaction between RAB18 and mammalian suppressor of Sec4 (Mss4) was found in a screen for RABs that interact with this protein (Wixler et al. 2011). Investigators used copurification of exogenously expressed proteins from HEK293 cells to identify this interaction. However, though Mss4 is proposed to be either a GEF or a RAB chaperone, they found that the protein showed no GEF activity toward RAB18 and that it interacted much more strongly with other RAB proteins. Therefore, the physiological relevance of this finding is unclear. In another screen, this time for novel RAB-binding proteins, a pull-down assay with GST-Rab18 identified a potential interaction with N-ethylmaleimide-sensitive factor (NSF), a protein involved in the disassembly of *cis*-SNARE complexes following membrane fusion (Kanno et al. 2010). This finding may implicate RAB18 in the fusion process, though it should be noted that NSF is thought to regulate fusion even in the absence of RAB proteins. In a third study, the *Arabidopsis* RAB18 orthologue

AtRabC2a was shown by yeast 2-hybrid (Y2H) and by in vitro binding assays to interact with a class V myosin, *Arabidopsis* myosin XI (Hashimoto et al. 2008). Since myosins function as molecular motors, transporting cargoes along actin filaments, this interaction may suggest a mechanism by which RAB18 could direct organelle mobility. However, because of sequence divergence of both RABs and myosins between plants and mammals and the presence of multiple RAB18 orthologues in *Arabidopsis*, it will be necessary to show that the interaction is conserved in mammals before any such conclusions can be drawn. Clearly, the validation of proposed effectors, and the identification of novel effectors, will help to better define the role of RAB18 in cells.

Structure

A RAB18 orthologue is not present in yeast, but its orthologues are found in plants, nematodes, and flies (Pereira-Leal and Seabra 2001). Despite this high degree of conservation, however, attempts to classify the protein on the basis of phylogeny and active conformation have not yielded any clues as to its function (Pereira-Leal and Seabra 2001). It has been suggested in the literature that RAB18 is one of a group of RAB proteins with a putative exocytotic role (Vázquez-Martínez and Malagón 2011; Wixler et al. 2011). However, the systematic application of phylogenetic algorithms and principal components analysis to the RAB protein family did not place the protein in this group (Collins 2005). Thus, it remains to be shown whether RAB18 is part of some larger functional subgroup of RAB proteins or possesses a distinct role.

One feature that sets RAB18 apart from most other RAB proteins is its differential posttranslational modification. Most RAB proteins have a C-terminal dicysteine motif that is subject to modification by two geranylgeranyl lipid groups. In contrast, RAB18, like RAB8, RAB13, and ▶ RAB23, has a C-terminal CAAX motif like that of RAS and RHO proteins. This motif is monoprenylated, and then sequentially cleaved and carboxymethylated by ER-resident enzymes (Leung et al. 2007). As methylation affects the susceptibility of RAB proteins to GDI-mediated membrane extraction, and is a potentially reversible modification, this may represent an additional level of RAB18 regulation.

Summary

To summarize, many questions remain to be answered about RAB18. In the context of the other members of the RAB gene family, it appears unusual in terms of the sequence determinants that aid classification, and it is subject to atypical posttranslational modification (Leung et al. 2007; Pereira-Leal and Seabra 2001). However, it is conserved in all but the simplest eukaryotes, and so future work should determine whether it is truly novel, or an unrecognized member of an established subgroup.

The function of RAB18 has been strongly liked to that of RAB3GAP1 and RAB3GAP2, as loss-of-function mutations in each of these proteins causes clinically indistinguishable Micro syndrome in humans (Aligianis et al. 2005, 2006; Bem et al. 2011). Therefore, a primary aim of future work will be to define the relationship between these proteins. Further, since this finding implicates RAB18 in a primarily neurological pathology, work in animal models and neuronal cell lines should seek to establish its role in these processes.

Historical Background

Rab23 (Ras-related protein Rab 23) belongs to the Rab family of monomeric small guanosine triphosphatases (GTPases) involved in the regulation of membrane traffic. Rab GTPases are conserved from yeast to humans and coordinate the delivery of cargo to its correct destination within eukaryotic cells. Rab proteins regulate many membrane trafficking steps, including vesicle formation, budding, motility along the cytoskeleton, docking, and membrane fusion (Zerial and McBride 2001; Stenmark 2009). More than 60 members of the Rab family have been identified in humans to date (Zerial and McBride 2001). Rab proteins function as molecular switches cycling from an active GTP (guanosine triphosphate)-bound form to an inactive GDP (guanosine diphosphate)-bound form. The GDP/GTP exchange factors (GEFs) catalyze the conversion from GDP to GTP-bound forms, whereas GTP hydrolysis to GDP is catalyzed by GTPase-activating proteins (GAPs). Once in their active state, GTP-bound Rabs can recruit specific effector

molecules to transduce signals in the transport pathway. These effectors include sorting adaptors, tethering factors, kinases, phosphatases, motor proteins, GEFs, and GAPs. Crosstalk between Rab GTPases through their effectors allows the spatiotemporal regulation of vesicle trafficking (Zerial and McBride 2001; Stenmark 2009). Post-translational modification by protein prenylation of C-terminal cysteines is generally required for membrane association and biological function of Rab proteins. (Zerial and McBride 2001; Stenmark 2009).

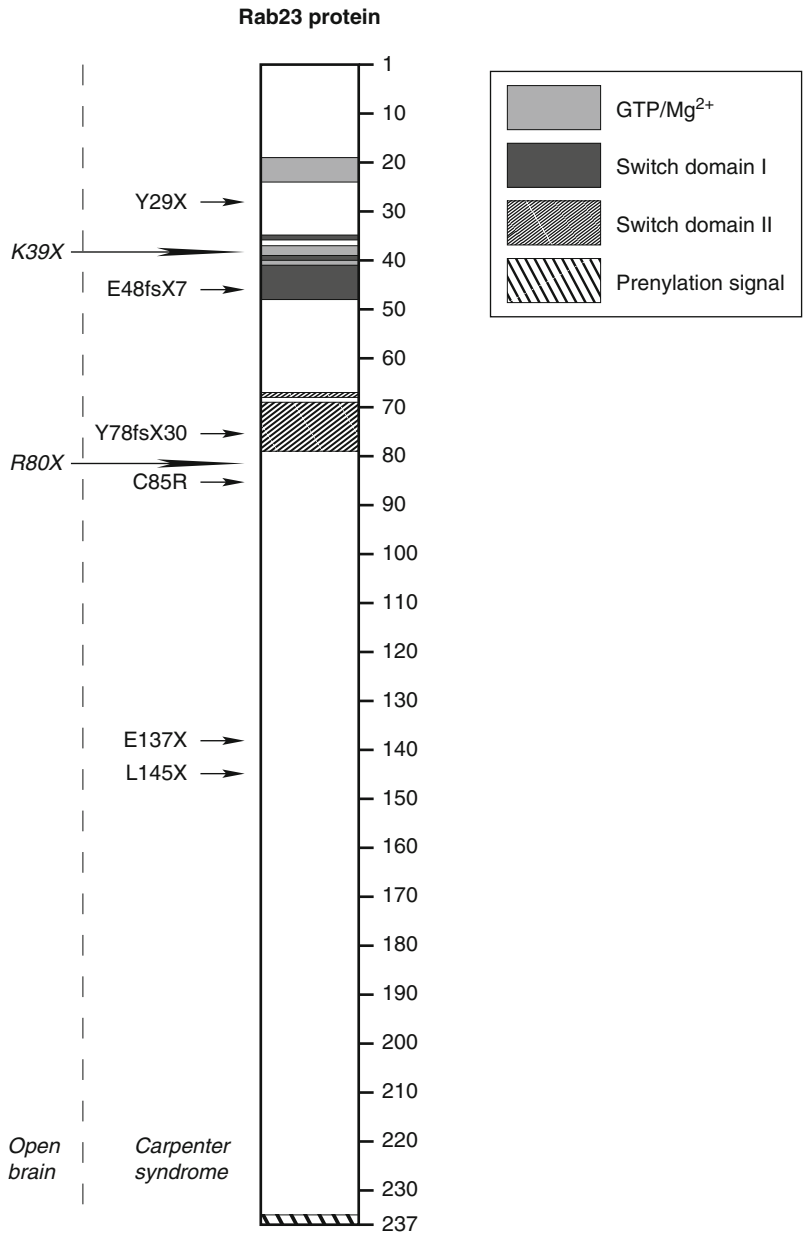
Rab23 was first identified in 1994 using a PCR-based homology cloning approach, and although it is expressed ubiquitously in many tissues, its predominant site of expression is the brain (Olkkonen et al. 1994). The human *RAB23* gene localizes to chromosome 6p11, is conserved in evolution back to *Drosophila*, and encodes a 237 amino acid protein. The Rab23 protein contains a CAAX-motif ("C" is Cysteine, "A" is an aliphatic amino acid, and "X" is variable) in its C-terminus, which acts as substrate for the post-translational prenylation modifications required for membrane anchoring (Fig. 1) (Olkkonen et al. 1994; Leung et al. 2007). As described below, several mutations in the *Rab23* gene have been described in both mouse and human (Fig. 1), providing insight into the physiological function of Rab23 (Eggenschwiler et al. 2001; Jenkins et al. 2007; Alessandri et al. 2010).

Rab23 and Hedgehog Signaling

Homozygous mutation of the *Rab23* gene is responsible for the mouse *open brain* (*opb*) phenotype (Eggenschwiler et al. 2001). There are two independent *opb* alleles, both of which encode truncated proteins (Eggenschwiler et al. 2001). The opb^1 allele is a natural mutation, while opb^2 was experimentally induced by *N*-ethyl-*N*-nitrosurea (ENU). *Opb* mice are characterized by severe defects in neural tube closure and patterning (Gunther et al. 1994), related to a failure in the correct specification of neurons along the dorsoventral axis of the neural tube. This process is highly dependent on the correct activity of ▶ Sonic hedgehog (SHH), a morphogen secreted from the notochord and floorplate (Ericson et al. 1997). The hedgehog (HH) pathway is one of the most pivotal signaling pathways directing embryonic development, and at the cellular level is regulated by trafficking events at the primary cilium (Huangfu et al. 2003). Genetic studies in mice revealed that the *opb* mutation rescues the *Shh* mutant phenotype, demonstrating that Rab23 acts as a cell autonomous negative regulator of HH signaling (Eggenschwiler et al. 2001). Since Rab proteins typically regulate vesicle trafficking, Rab23 was initially presumed to have a role in the trafficking of HH pathway components. Localization studies in a range of mammalian cell types showed distribution of exogenously expressed GFP-tagged Rab23 at the plasma membrane and on the endocytic pathway in transferrin-positive endosomes, where it co-localized with the HH receptor patched (PTCH1), but not with the co-receptor smoothened (SMO) (Evans et al. 2003). However, further genetic studies suggested a regulatory role for Rab23 downstream of both PTCH and SMO and upstream of the transcriptional regulators of the HH pathway, the Gli proteins (named after glioblastoma from where they were first isolated) (Eggenschwiler et al. 2006; Yang et al. 2008). Of the three vertebrate Gli proteins, Gli1 and Gli2 generally act as transcriptional activators, while Gli3 is primarily processed to a truncated transcriptional repressor. Studies in the mouse neural tube led to the suggestion that Rab23 negatively regulates HH signaling through trafficking of a molecule that mediates the effects of SMO on the formation of Gli2 activators and Gli3 repressors (Eggenschwiler et al. 2006). To date the identity of such a factor remains elusive, but increasing evidence suggests that the activation and processing of Gli proteins, and hence possibly Rab23 function, is intricately linked to the primary cilium.

Rab23 and Primary Cilia

The discovery that the primary cilium is an essential organelle for mammalian HH signaling (Corbit et al. 2005; Huangfu et al. 2003) is arguably one of the most significant findings in the fields of cell and developmental biology over the past decade. The primary cilium is a microtubule-based organelle that projects from the surface of virtually every vertebrate cell type. The major components of the HH pathway, including the Gli proteins, localize to the ciliary axoneme extension and shuttle in and out in a dynamic fashion (Rohatgi et al. 2007; Kim et al. 2009). The intraflagellar transport (IFT) system is primarily



Rab23, Fig. 1 *Rab23 domains and mutations.* Functional domains of the 237 amino acid protein Rab23. Human mutations responsible for Carpenter syndrome are located on the right column, and those causing the mouse *open brain* phenotype are situated on the left. All mutations produce truncated proteins except C85R, which causes a non-conservative substitution from uncharged to charged amino acid, possibly impairing normal folding of the protein. Rab23 structure was analyzed with Cn3D 4.1 software from NCBI. (http://www.ncbi.nlm.nih.gov/Structure/cdd/cddsrv.cgi)

responsible for trafficking of cargo between the cell body and the cilia tip, but a number of other accessory proteins also mediate ciliary trafficking. A screen for Rab GTPases involved in primary cilium formation identified Rab8 as the sole Rab localized on primary cilia. However, in the same study, biochemical analysis of Rab GTPase-activating proteins (Rab GAPs) and their attendant Rabs suggested a role for Rab23 and Rab17 in primary cilia formation (Yoshimura et al. 2007). More recently, exogenously expressed wild-type Rab23 was shown to localize to the primary cilium in Madin-Darby Canine Kidney (MDCK) epithelial cells (Boehlke et al. 2010). In these cells, shRNA-mediated depletion of Rab23 or expression of a GDP-bound form of Rab23 decreased the steady state level of SMO at the cilium, suggesting a role for Rab23 in ciliary turnover. Thus, the precise role of Rab23 at the primary cilium has yet to be determined, but the findings to date hint at a potential role in trafficking cargo to or from the cilium.

Rab23 and Planar Cell Polarity

The planar cell polarity (PCP) pathway coordinates cell polarization in a given plane across a cell layer, a process essential for the correct formation of certain highly ordered differentiated tissues during development (Fanto and McNeill 2004). A recent study in *Drosophila* provides new evidence for Rab23 as a PCP regulator (Pataki et al. 2010). Mutations in the *Drosophila Rab23* gene resulted in abnormal trichome orientation and the formation of multiple hairs on the wing, leg, and abdomen. This work also showed that Rab23 associates with the PCP protein Prickle, likely contributing to its asymmetric cellular accumulation to regulate the hexagonal packing of *Drosophila* wing cells and the orientation of cuticular hairs. Since components of the PCP pathway are important for the correct formation and positioning of cilia in vertebrate cells (Park et al. 2006), these data potentially provide a further link between Rab23 and cilia. However, cilia do not appear to be important for PCP or HH signaling in *Drosophila*, and a role for Rab23 in vertebrate PCP signaling has not yet been elucidated.

Rab23 in Human Disease

The physiological relevance of Rab23 has been highlighted by its involvement in a number of human disorders. Homozygous loss-of-function mutations in *RAB23* are responsible for Carpenter syndrome, a pleiotropic disorder with autosomal recessive inheritance, characterized by premature closure of the cranial sutures, polysyndactyly, obesity, and cardiac defects (Jenkins et al. 2007). Six independent mutations in *RAB23* have been identified in Carpenter syndrome patients (Alessandri et al. 2010; Jenkins et al. 2007). Five of the six mutations are predicted to result in premature protein truncation, and one is a missense mutation thought to interfere with protein folding (Fig. 1). They show no apparent clustering to specific domains within the RAB23 protein and all are likely to represent loss-of-function alleles. While craniosynostosis and obesity are not classic features of perturbed HH signaling, obesity in particular has been associated with disrupted cilia in humans and mice (Sheffield 2010), again reinforcing a role for Rab23 in ciliogenesis.

Rab23 appears to have functions beyond mammalian embryonic development, as overexpression of *Rab23* has been associated with human cancers. In the gastric cancer cell line Hs746T, siRNA-mediated silencing of Rab23 significantly reduced cellular migration and invasion, whereas overexpression of *Rab23* enhanced invasion in gastric epithelial (AGS) cells (Hou et al. 2008). *Rab23* expression is also upregulated in hepatocellular carcinoma (Liu et al. 2007). The finding that *Rab23* is upregulated in a number of human cancers seems contradictory given that Rab23 antagonizes HH signaling, and enhanced expression would be expected to result in pathway inhibition. In a wide range of tumor types, activation of HH signaling, rather than inhibition, is generally associated with tumorigenesis. It is possible that the role of Rab23 in cancer is unrelated to its regulation of HH signaling, or alternatively that a fine balance of Rab23 is required for correct functioning in the tumor environment. Future elucidation of the precise role of Rab23 in regulating HH signaling, ciliogenesis, and other cellular events will shed light on its involvement in cancer and other disease states.

Summary and Perspectives

Genetic and biochemical studies have implicated Rab23 in embryonic development, thus highlighting the role of vesicular trafficking in regulating embryogenesis at the cellular level. However, no Rab23 effectors or interacting partners have been identified to date in vertebrates, and as a result no molecular mechanism for Rab23 action has yet been elucidated. It may be that Rab23 acts indirectly to inhibit HH signaling. The key to Rab23 function might be found at the primary cilium, as the two signaling pathways in which Rab23 is involved (PCP and HH), converge at this organelle (Veland et al. 2009). Rab23 is not essential for *Drosophila* development (Pataki et al. 2010) but it is possible that, unlike Rab23 involvement in HH signaling, the Rab23-PCP link is evolutionarily conserved. PCP genes are required for neural tube closure, a characteristic phenotype of Rab23 and ciliogenesis mouse mutants (Doudney and Stanier 2005). Taken together, these observations suggest a key role for Rab23 at the intersection of the cilia-related HH and PCP pathways. Elucidation of such a link, along with the more precise definition of Rab23 function, is likely to come from future detailed studies at both the whole organism and cellular levels.

Rab7 Historical Background and Function

Mammalian Rab7 was first identified in a rat liver cell line as BRL-Ras [X12535; NM_023950] and subsequently named Rab7 when it was recognized to be a member of an emerging, separate branch of Ras-related GTPases now well known as the Rab family of GTPases [NP_004628.4; P51149; P09527]. Rab7a is the most widely studied form and encoded on human chromosome 3q21.3 (mouse chromosome 6) as two splice variants differing in the 3′ untranslated region. The most intensively studied mammalian forms of Rab7a (mouse, canine, rat, and human) are 99.5% identical with only a single conservative change among the 207 amino acids (D/E 196). A more recently discovered homolog, Rab7b/Rab7L1, is encoded on human and mouse chromosome 1q32 and functions in late endosome to Golgi trafficking [Q96AH8; Q8VEA8]. Human Rab7b is only 47% identical and 82% homologous to human Rab7a across its 199 aa length. Following the initial demonstration of Rab7a function in regulating membrane transport from early to late endosomes, Rab7a has been found to have critical roles in autophagy, lipid metabolism, growth factor signaling, bone resorption, and phagolysosome biogenesis (Fig. 1) (Agola et al. 2011).

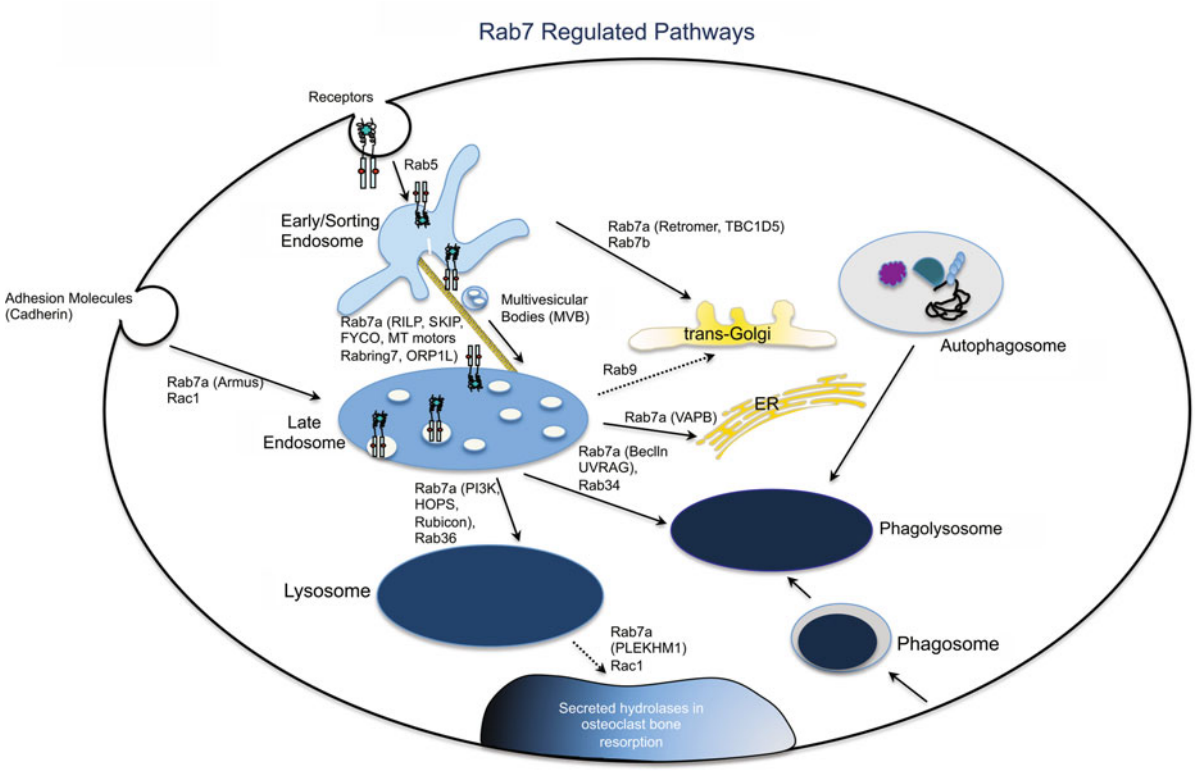
Rab7a Activation and Localization

Typical of Ras-related GTPases, Rab7a undergoes a cycle of membrane association and dissociation that is closely linked to nucleotide binding and hydrolysis (Fig. 2) (Agola et al. 2011). In the membrane-associated state, Rab7a is GTP bound and active, while upon hydrolysis the GDP-bound Rab7a is inactive and recycles to the cytoplasm. The GDP-/GTP-dependent activation cycle is regulated by two sets of proteins, the guanine nucleotide exchange factors (GEFs) that catalyze the GTP binding and conversion to the active GTP-bound state and the GTPase-activating proteins (GAPs) that stimulate the GTPase activity of the Rab protein to convert it to the inactive GDP-bound state. Early reports suggested Vps39 functioned as a Rab7a GEF. More recently, studies in yeast and *C. elegans* indicate that Ypt7p/Rab7 activation is linked to endosome conversion involving coordinate inactivation and loss of the early endosomal Rab5 and acquisition and activation of the late endosomal Rab7a through large multimeric complexes with overlapping components (Fig. 3a) (Wang et al. 2011a). SAND-1 (Mon1a-Mon1b in vertebrates) binds to the CORVET components (Vps11, VPS16A, Vps18, and Vps33) and functions to displace the Rab5 GEF (RABX-5). Subsequent recruitment of Ccz1 through Mon1 and cooperation with Vps39 is central to the endosomal recruitment and activation of Ypt7p in yeast and Rab7 *C. elegans* enabling binding to the HOPS complex (Vps11, Vps16A, Vps18, Vps33, and Vps41) (Fig. 2). Mon1 and Ccz1 are conserved in mammals (Wang et al. 2011a), though mammalian Rab7a GEF activity remains to be demonstrated.

The activation of Rab7a is dynamically regulated through differential interactions of proteins first identified to be important in autophagy called Rubicon *(RUN domain and cysteine-rich domain containing Beclin 1-interacting protein*) and UVRAG (Liang et al. 2008; Zhong et al. 2009) (Fig. 2). Rubicon, a regulatory component of the ▶ phosphatidylinositol 3-kinase complex (PI3KC3; hVps34/hVps15), can bind and sequester UVRAG and thereby block Rab7a-mediated transport (Sun et al. 2010, 2011; Lin and Zhong 2011). Conversely, membrane-bound, active Rab7a can relieve the inhibition of its activation by binding Rubicon (Sun et al. 2010).

Proteins of the Tre-Bub-CDC16 (TBC) family function as GTPase-activating proteins that stimulate nucleotide hydrolysis. Three family members (TBC1D2/Armus, TBC1D5, and TBC1D15) have all been shown to stimulate Rab7a nucleotide hydrolysis and may regulate Rab7a involvement in discrete functions in coordination with specific signaling (Seaman et al. 2009; Frasa et al. 2010; Peralta et al. 2010). For example, on endosomes the recycling of mannose 6-phosphate receptor to the Golgi via retromer is thought to be regulated by Rab7a/TBC1D5, while the disassembly of adherens junctions and degradation of E-cadherin depends on signal integration of Arf6 and a Rac1/TBC1D2/Rab7a complex. As illustrated by the specific examples given, the facilitated nucleotide binding and hydrolysis cycle brings about conformational changes in Rab7a that modulate its activity and localization.

Membrane localization is dependent on posttranslational modification with a lipid anchor (prenylation) (Fig. 2). Nascent Rab7a synthesized on cytosolic ribosomes is inactive and GDP bound. Prenylation on two C-terminal cysteine residues is mediated by the

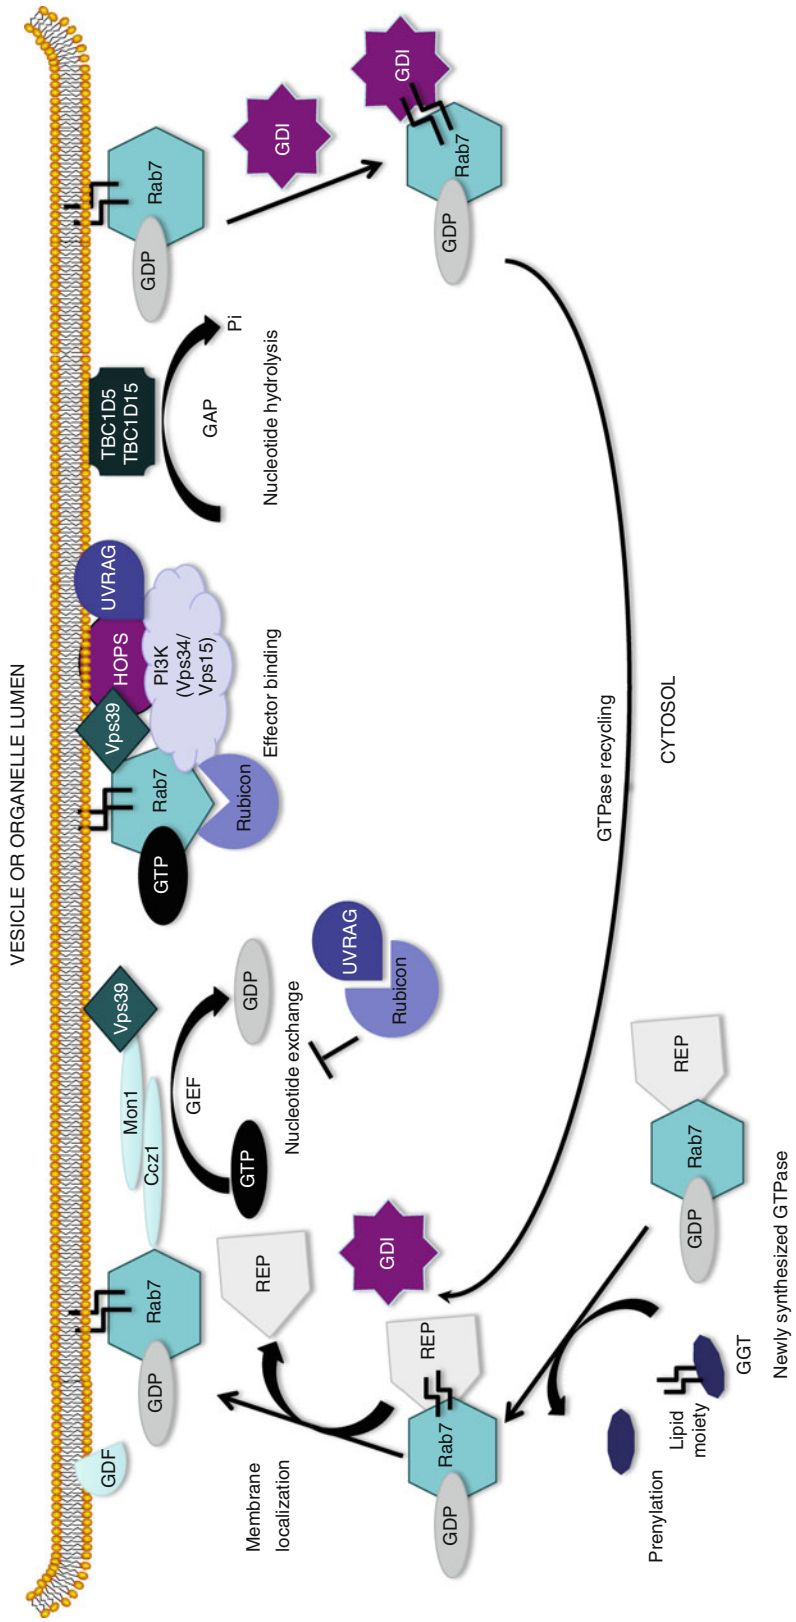


Rab7a in Endocytosis and Signaling, Fig. 1 *Rab7a-regulated pathways.* Rab7a regulates endocytic transport from early to late endosomes in a process requiring Rab5 to Rab7a conversion. Rab7a also cooperates with other Rab GTPases to facilitate late endosome-lysosome fusion and phagolysosome formation (see Table 1). Key Rab7a effectors involved on individual pathways are noted in parentheses. Rab7a cooperates with Rac1 in epithelia to promote internalization of cell adhesion molecules and in osteoclasts to promote localized hydrolase secretion for bone resorption

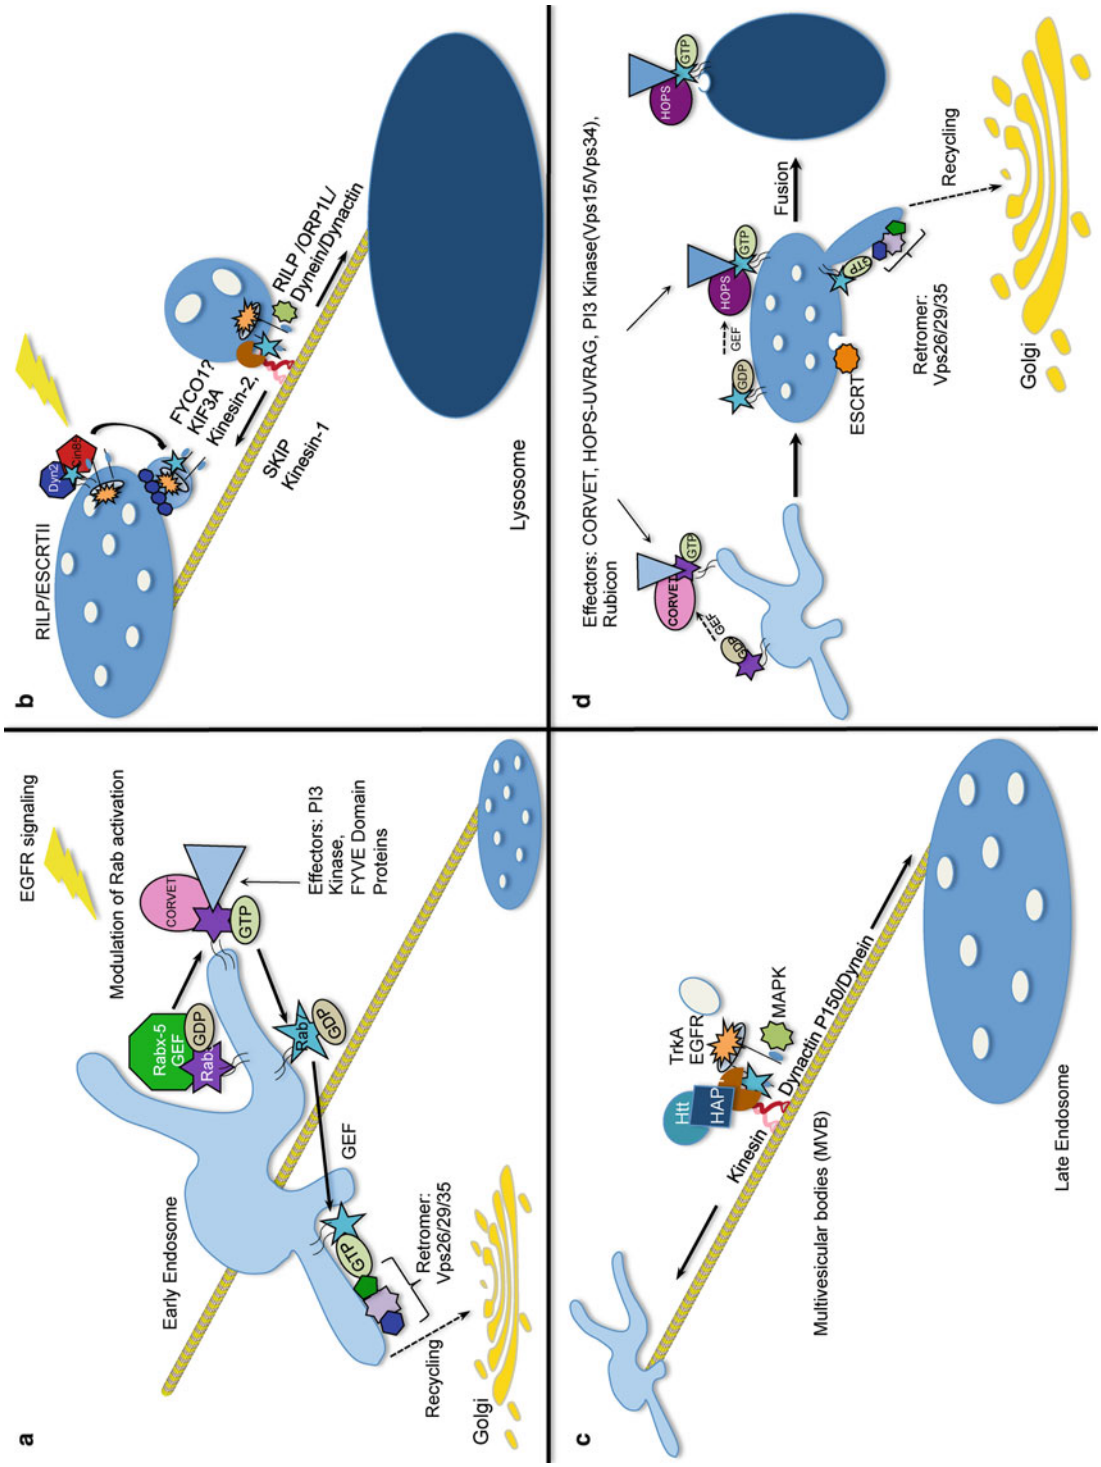
universal Rab geranylgeranyl transferase, through recognition of the last nine amino acid residues of Rab7a (Wu et al. 2009). The Rab escort protein (REP) serves as the intermediary for Rab7a presentation to the prenylating enzyme and first-time membrane association (Zhang et al. 2009; Agola et al. 2011). GDP dissociation inhibitor (GDI) functions as a universal Rab recycling factor, binding preferentially to doubly prenylated, GDP-bound Rab7a (Wu et al. 2007). GDI binding masks the isoprenyl anchor in the cytosol and renders Rab7a membrane association a reversible process that is closely linked to the nucleotide bound status, based on the fact that GDI has a 3 order of magnitude higher affinity for Rab7a-GDP than Rab7a-GTP (Wu et al. 2010). A GDI-displacement factor (GDF) has been implicated in GDI release during endosomal Rab membrane association, though GEF proteins may also perform this function in conjunction with nucleotide exchange (Wu et al. 2010). Once on the membrane and in the GTP-bound state, Rab7a interacts with diverse effectors to carry out specific functions.

Rab7a Effectors in the Control of Endocytic Trafficking

Over the years, many effector proteins have been identified to interact specifically with active GTP-bound Rab7a (Table 1). Rab7a effectors orchestrate events ranging from cargo selection to microtubule translocation to downstream membrane tethering and endosomal membrane fusion (Fig. 3). Emerging concepts are that Rab7a activation contributes to the dynamic assembly of large protein complexes in a spatially and temporally regulated manner (Wang et al. 2011a). Specific protein complexes serve discrete functions in the transport process, yet handoffs and



Rab7a in Endocytosis and Signaling, Fig. 2 *Rab7a activation cycle.* Newly synthesized Rab7a is prenylated by geranylgeranyl transferase (GGT) and delivered to endosomal membranes by rab escort protein (REP), thereafter Rab7a membrane cycling is facilitated by GDP dissociation inhibitor (GDI); pathways that are common to all Rab GTPases. A GDI displacement factor (GDF) has been implicated in membrane transfer of late endocytic Rab9 and Rab7a. Rab7a activation is closely linked to Rab5 inactivation in a conversion process that involves Mon1. A Vps39-Mon1-Ccz1 complex likely acts as a guanine nucleotide exchange factor (GEF) to promote activation, while TBC1D5 or TBC1D15 act as GTPase-activating proteins (GAPs) to promote hydrolysis and inactivation. Active, GTP-bound Rab7a acts as a scaffold for sequentially binding multiple effectors phosphoinositide 3-kinase (PI3K, Vps34/Vps15), HOPS, Rubicon, UVRAG, among others (see Table 1) to promote cargo selection, cytoskeletal translocation, and membrane fusion



Rab7a in Endocytosis and Signaling, Fig. 3 (continued)

multiple layers of regulation are common. The importance of maintaining transport fidelity is evidenced by the increasing numbers of human diseases attributable to defects in endosomal trafficking and Rab7a specifically (Charcot-Marie-Tooth disease type 2) (Cogli et al. 2009; Zhang et al. 2009; Agola et al. 2011).

On early endosomes, Rab7a functions in cargo sorting by recruiting the retromer complex (Vps26/29/35), which enables retrieval of cation-independent mannose 6-phosphate receptor, TGN38, Wntless among other cargo from early endosomes to the Golgi (Rojas et al. 2008; Seaman et al. 2009; McGough and Cullen 2011) (Fig. 3a). Interaction of retromer with Snx proteins and actin-binding proteins couples sorting with membrane tubulation (Harbour et al. 2010; McGough and Cullen 2011). Dysregulation of retromer is associated with neurologic diseases, including Alzheimer's disease, underscoring the importance of the Rab7a-retromer link.

On multivesicular bodies and late endosomes, Rab7a facilitates coordinate cargo sorting and bidirectional transport on microtubules through interactions with effectors that differentially associate with dynein or kinesin motors (Fig. 3b–c). Lysosomal sorting and perinuclear transport are mediated by the Rab7a-interacting lysosomal protein (RILP) effector (Zhang et al. 2009; Wang et al. 2011b). RILP interacts with components of the endosomal sorting complex required for transport (ESCRT-II) (Vps22 and Vps36) and based on depletion studies, RILP is shown to participate in the sorting of ubiquitinated receptors into intraluminal vesicles (Zhang et al. 2009; Wang et al. 2011b). In this manner, RILP sorts and sequesters the receptors from the cytosolic signaling machinery and targets them for lysosomal degradation. RILP is also targeted by bacterial pathogens to create a specialized intracellular niche for replication (Zhang et al. 2009). In a tripartite complex, Rab7a, RILP, and a second effector known as oxysterol-binding protein-related protein 1 L (ORP1L) serve to recruit a dynein/dynactin motor complex that in association with betaIII spectrin facilitates the perinuclear transport of endosomes on microtubules (Wang et al. 2011b) (Fig. 3b).

Dynein-/dynactin-mediated perinuclear positioning of late endosomes has also been shown to depend on the membrane-associated scaffolding protein, Huntingtin (Htt), which when mutant causes Huntington's disease, though the link between Htt and Rab7a remains unclarifed (Agola et al. 2011; Caviston et al. 2011). Htt and the Huntingtin-associated protein of 40 kDa (HAP40) are known effectors of Rab5 that facilitate transfer between microtubule-and actin-based networks (Agola et al. 2011). Parallel in vitro studies testing Rab7a did not provide evidence for a direct Rab7a-Htt or a Rab7a-HAP40 interaction, although Huntingtin-associated protein 1 (HAP1) binds dynactin p150Glued (Agola et al. 2011). Therefore, it is speculated that an Htt interaction with the Rab7a dynein/dynactin complex may occur through HAP1 (Fig. 3c). In light of the disease relevance, further study of the potential interfaces between Htt, HAP1, and Rab7a is warranted.

Anterograde movement of endosomes to the cell periphery along the microtubular network is incompletely characterized. Plus-end motility of autophagosomes is dictated by the recently identified Rab7a effector FYVE and coiled-coil domain protein 1

R

Rab7a in Endocytosis and Signaling, Fig. 3 *Rab7a trafficking and signaling complexes.* (**a**) Recycling from early endosomes to the Golgi. Cargo recycling from early endosomes to the Golgi entails sequential Rab5 (via CORVET) and Rab7a activation and Rab7a-mediated recruitment of a complex of Vps proteins (26/29/35) known as retromer. Rab5 activation can be positively modulated by EGF receptor signaling. (**b**) Transport to lysosomes. Rab7a cooperates with the Dyn2-CIN85 complex to regulate signaling and lysosomal degradation of the ligand-receptor (EGF-EGF receptor) complex. Bidirectional transport on microtubules depends on kinesin and dynein motors. (**c**) Transport from early to late endosomes. Growth factor receptor signaling is intimately coupled to endocytic transport. As illustrated, nerve growth factor receptor TrkA and EGF receptor associate with MAPK on endosomes are translocated bidirectionally on microtubules. Transport toward perinuclear late endosomes occurs through association with the Rab7a effector RILP and the p150/dynein motor complex. Association with HAP1/Htt contributes to perinuclear late endosome positioning. Transport to the cell periphery is mediated in association with kinesin motor complexes (Kif3a/Kinesin-2 via FYCO1 or Kinesin-1 via SKIP). (**d**) Distinct multi-protein complexes regulate transport to and from late endosomes. Rab5-Rab7a conversion involves coordinate inactivation of Rab5 and activation of Rab7a, transition of CORVET complex to HOPS complex, which ensures seamless cargo transport to late endosomes. Handoff to ESCRT machinery enables membrane invagination and sequestration of growth factor receptors on intraluminal vesicles of multivesicular bodies. Rab7a-retromer complex enables Golgi recycling. Rab7a HOPS complex enables late endosome-lysosome fusion

(FYCO1) and an unknown kinesin (Wang et al. 2011a). Late endosome movement is known to depend on kinesin-2 KIF3A heavy chain, while the Rab7a link and effector remain enigmatic (Loubery et al. 2008). Evidence from studies on *Salmonella* suggest that Rab9 and Rab7a associate with distinct domains on SifA and kinesin-interacting protein (SKIP), implicating kinesin-1 in anterograde motility and late endosomal sorting (Jackson et al. 2008). In sum, the function of the Rab7a-RILP complex in sorting and cytoskeletal transport is best characterized, while other Rab7a effector interactions including those with kinesins and disease relevant proteins (Htt and HAP1) await further characterization. Bacterial proteins from *Salmonella* with identified functions in interfering with Rab7a motor proteins or linkers may offer unique tools for further dissecting Rab7a motor protein interactions.

Endosomal lipids such as cholesterol and phosphoinositides are critical regulators of cargo sorting and transport on the late endosomal pathway that are integrated through Rab7a and associated motor proteins. In particular, cholesterol sensing is integrated with transport through the Rab7a effector ORP1L (Wang et al. 2011a). When cholesterol levels are low, ORP1L promotes the association of late endosomes with the endoplasmic reticulum via the dissociation of minus-end motor proteins. The ER protein VAPB contributes to motor dissociation and the peripheral movement of late endosomes. Being more peripherally localized, late endosomes are poised to receive cholesterol and other cargo internalized through early endosomes or association with the endoplasmic reticulum (ER). Conversely, when cholesterol levels are high, the conformation of ORP1L is altered and perinuclear transport is favored. In Niemann-Pick type C disease, where endosomal cholesterol levels are constitutively high, the bidirectional motility of endosomes/phagosomes and activation of Rab7a are perturbed (Chen et al. 2008; Zhang et al. 2009). The perturbations contribute to disease pathology and can be reversed by overexpression of Rab9 or Rab7a (Zhang et al. 2009).

Similar to Rab5 on early endosomes, GTP-bound Rab7a is required for class-III ▶ phosphatidylinositol 3-kinase (consisting of the hVps34 catalytic, the hVps15/p150 Rab7a-binding adaptor, and the Rubicon regulatory subunits) activation on late endosomes (Agola et al. 2011; Ho et al. 2012). The local synthesis of PI(3)P on late endosomes enables the recruitment of FYVE domain–containing proteins that promote membrane remodeling (including intraluminal vesicle formation) and eventually terminate the signal. FYVE domain–containing factors include the PI(3,5)P(2)-producing kinase PIKfyve, myotubularin lipid phosphatases, among others (Table 1). Together these downstream effectors control endolysosome morphology, membrane trafficking, acidification, among other functions. Rab7a together with the early endosomal myotubularin lipid phosphatases (MTM1) and late endosomal myotubularin-related protein 2 (MTMR2) acts as a molecular switch controlling the sequential synthesis and degradation of endosomal PI(3)P (Cao et al. 2008). Direct binding of the phosphatases to the phosphatidylinositol 3-kinase complex leads to inactivation of the myotubularins. The lipid kinase-myotubularin interaction also precludes the interaction of the activated Rab7a with the lipid kinase, illustrating the importance of protein handoffs in phosphoinositide 3-phosphate homeostasis on late endosomes. Together, the examples cited provide evidence for Rab7a function in endosomal lipid homeostasis in both metabolism and signaling, the disruption of which leads to human disease.

Two Rab7a effectors participate directly in the regulation of cargo degradation. Rabring7 (Rab7a-interacting ring finger protein) functions as an E3 ligase in conjunction with the Ubc4 and Ubc5 as E2 proteins (Zhang et al. 2009; Wang et al. 2011a). Functionally, overexpression of Rabring7 increases epidermal growth factor receptor degradation and lysosome biogenesis. The proteasome alpha-subunit XAPC7 or PSMA7 in mammals has been found to interact specifically with Rab7a and is recruited to late multivesicular endosomes (Zhang et al. 2009; Agola et al. 2011). Overexpression of XAPC7 impairs late endocytic transport of EGF receptor and hence is a negative regulator of trafficking. Together, Rabring7 and XAPC7 may coordinate the degradation of ubiquitinated growth factor receptors via a link to the proteasomal degradation machinery though further studies are required to elucidate mechanistic details.

In addition to the described Rab7a effectors whose functional activities have been detailed, there are many more putative effectors whose characterization remains to be documented (Table 1). Therefore, further complexity in Rab7a-mediated regulation of cargo

Rab7a in Endocytosis and Signaling, Table 1 Rab7 GTPase regulators and effectors, and their functions

Rab7 isoform and nucleotide-bound state	Rab7 effector/binding partner	Regulator or effector function[a]
Rab7a	ANKFY1 (ankyrin repeat and FYVE domain containing 1)/ANKHZN/ Rabankyrin-5	Possible role in vesicular trafficking. Novel interactor of Rab7. Specific role yet to be established
Rab7a	ATP6V0A1	Component of vacuolar ATPase that regulates organelle acidification required for protein sorting, receptor-mediated endocytosis, zymogen activation, and synaptic vesicle proton gradient. Novel interactor of Rab7. Specific role yet to be established
Rab7a-GDP	Ccz1 (vacuolar protein trafficking and biogenesis-associated homolog)	Recruited to endosomes by Mon1a/Mon1b and acts as Rab7 GEF in yeast. Possible human homolog C7orf28B also some similarity to HPS4 involved in biogenesis of lysosome-related organelles
Rab7a-GTP	FYCO1 (FYVE and coiled-coil domain containing 1)	Promotes microtubule plus end transport of autophagosomes presumably by functioning as a kinesin adapter
Rab7a	GNB2L1 (guanine nucleotide binding protein (G protein), beta polypeptide)	Role in intracellular signaling and activation of protein kinase C and possible interaction with Rab7 via WD40 domain. Novel interactor of Rab7. Specific role yet to be established
Ypt7p/ Rab7a-GTP	HOPS complex (Vps11,-16,-18,-33,-39, and-41)	Involved in vacuolar tethering and fusion in yeast and conserved mammalian homologs function in mammalian endolysosomal fusion. Interfaces with CORVET complex to promote rab5 to rab7 conversion in yeast. Vps39 subunit binds Mon1-Ccz1 complex that serves as a Rab7 GEF in yeast and *C. elegans*
Rab7a	hVps39	In yeast Vps39p, cooperates with Mon1-Ccz1 complex to promote Ypt7p nucleotide exchange, function of mammalian protein remains to be determined
Rab7a	IMMT (Mitofilin)	Maintains mitochondrial morphology and suggested role in protein import. Novel interactor of Rab7. Specific role yet to be established
Rab7a	KIF3A (kinesin + adapter?)	Kinesin2 heavy chain associates with late endosomes along with dynein, Rab7, and dynactin. Possible mediator of Rab7-regulated anterograde transport coordinated by Rab7-interacting adapter such as FYCO1 or other as-yet-unidentified protein
Rab7a-GDP	Mon1a-Mon1b	Mammalian homologs of *C. elegans* SAND1. Mon1a-Mon1b causes Rab5 GEF displacement and Mon1b interacts with the HOPS complex. Mon1 is an effector of Rab5, but only interacts with Rab7 when complexed to Ccz1
Rab7a-GTP	ORP1L ([oxysterol-binding protein, OSBP]-related protein 1)	Required for cholesterol sensing and regulation of dynein/ dynactin motor with Rab7 and RILP, regulates late endosome/lysosome morphogenesis and transport
Rab7a-GTP	Phosphoinositide 3-kinase complex (hVps34/hVps15)	Type III ▶ PI 3-kinase that generates phosphoinositide 3-phosphate to control endosomal trafficking and signaling. Forms complex with myotubularins for negative regulation
Rab7a-GTP	Plekhm1 (pleckstrin homology domain containing, family M [with RUN domain] member)	Regulates lysosomal secretion in osteoclasts for bone resorption by interacting with LIS1 to control microtubule transport and Rab7 and ▶ PI 3-kinase to recruit effectors for fusion
Rab7a	Prohibitin	Negative regulator of cell proliferation and a possible tumor suppressor. Novel interactor of Rab7, specific role yet to be established

(*continued*)

Table 1 (continued)

Rab7 isoform and nucleotide-bound state	Rab7 effector/binding partner	Regulator or effector function[a]
Rab7a-GTP	Rabring7	Rab7-interacting ring finger protein, functions as E3 ligase that ubiquitinates itself and controls EGF receptor degradation
Rab7a-GDP	REP1 (Rab escort protein 1)	Presents Rab7 to Rab geranylgeranyl transferase for addition of prenyl group that acts as a membrane anchor
Rab7a-GTP	Retromer (Vps26, Vps29, Vps35)	Regulates retrograde transport from late endosome to trans-Golgi network (TGN) through direct interaction with Vps26
Rab7a-GTP	RILP (Rab7-interacting lysosomal protein)	Involved in late endosomal/lysosomal maturation. Recruits dynein-dynactin motor protein complex
Rab7a-GTP	Rubicon	Regulates endosome maturation through differential interaction with UVRAG and Rab7. Rubicon binding inhibits UVRAG. Rubicon binding to active Rab7 frees UVRAG to activate the hVps34/hVps15 ▶ PI 3-kinase and HOPS, thereby simultaneously increasing the active pool of Rab7 and PI3P signaling
Rab7a-GTP	SKIP (SifA and kinesin-interacting protein)	Homolog of PLEKHM1 that binds Rab7, Rab9 and kinesin-1, and may regulate anterograde motility of late endosomes. Target of *Salmonella* SifA protein
Rab7a	Spg21	Loss of function causes autosomal recessive hereditary spastic paraplegia. Involved in vesicular transport. Novel interactor of Rab7. Specific role yet to be established
Rab7a	STOML2 (Stomatin-like 2)	Negatively modulates mitochondrial sodium calcium exchange. Novel interactor of Rab7. Specific role yet to be established
Rab7a-GTP	TBC1D2 ([tre-2/USP6, BUB2, cdc16] domain family, member 5)/Armus and Rac1	Regulates cytoskeleton organization, ruffled border formation in osteoclasts, and E-cadherin/adherens junction degradation in conjunction with Rac1, inactivates Rab7 through C-terminal GAP activity
Rab7a-GTP	TBC1D5 ([tre-2/USP6, BUB2, cdc16] domain family, member 5)	Negatively regulates retromer recruitment and causes Rab7 to dissociate from membrane and may have Rab7 GAP activity
Rab7a-GTP	TBC1D15 ([tre-2/USP6, BUB2, cdc16] domain family, member 15)	Functions as Rab7 GAP and reduces interaction with RILP, fragments lysosomes, and confers resistance to growth factor withdrawal-induced cell death
Rab7a-GTP	TrkA (neurotrophic tyrosine kinase receptor)	Interacts with Rab7 and regulates endocytic trafficking and nerve growth factor signaling as well as influencing neurite outgrowth
Rab7a-GTP	UVRAG (UV radiation resistance-associated gene)/Beclin1	UVRAG/C-Vps complex positively regulates Rab7 activity via ▶ PI 3-kinase (PI3KC) during autophagic and endocytic maturation
Rab7a-GTP	VapB ([vesicle-associated membrane protein]-associated protein B)	Involved in mediating endosome-ER interaction in response to ORP1L conformation sensing low cholesterol levels
Rab7a	Vps13c (vacuolar protein sorting 13c)	Vacuolar protein sorting and novel interactor of Rab7. Specific role yet to be established
Rab7a-GDP, GTP	XAPC7/PSMA7 (proteasome subunit, alpha type 7)	Negative regulator of late endocytic transport. Overexpression inhibits EGF receptor degradation
Rab7b	SP-A (Surfactant protein A)	Transiently enhances the expression of Rab7 and Rab7b and makes them functionally active to increase the endolysosomal trafficking in alveolar macrophages

[a]Agola, JO thesis provides reference listing for effectors

sorting, cytoskeletal transport, and membrane fusion will emerge through continued study. An important area for investigation is how Rab7a interactions with tethering factors and SNARE proteins control late endosomal fusion events which have primarily been characterized for the yeast homolog Ypt7p (Zhang et al. 2009; Wang et al. 2011a).

Rab7a in Endosomal Signaling

At the late endosome, Rab7a coordinately regulates intracellular signaling through special scaffolds, selective endosome positioning, and control of growth factor receptor trafficking. Epidermal growth factor receptor (EGF receptor), vascular endothelial growth factor receptor (VEGFR2), and nerve growth factor receptor (TrkA) all depend on Rab7a for their signaling and downregulation (Agola et al. 2011). For example, upon EGF stimulation, K-Ras is endocytosed and sorted to late endosomes where Rab7a and the p14-MP1-p18 scaffolding proteins recruit and activate ▶ MEK-Erk on late endosomes (Lu et al. 2009; Nada et al. 2009). ▶ MAP kinase signaling is further regulated by Rab7a-dependent late endosome positioning through dynactin such that peripheral mislocalization results in prolonged EGF receptor activation and downstream Erk and p38 signaling. The localization of two signaling mediators of the TGF-β superfamily to Rab7-positive late endosomes (p-Smad1 and p-Smad2) is also suggested to be critical for regulation of growth factor signaling (Rajagopal et al. 2007). At the conclusion of signaling, Rab7a may act cooperatively with dynamin 2 and CIN85 (cbl-interacting protein of 85 kDa) to promote the transfer of signaling receptors from late endosomes to lysosomes for degradation (Fig. 3b) (Schroeder et al. 2010).

In neuronal cells, the receptor tyrosine kinase, TrkA is activated by nerve growth factor (NGF). On NGF stimulation, Rab7a interacts with TrkA as it transits through early and late endosomes. Cells expressing Rab7a T22N, which is predominantly GDP bound, showed prolonged Erk1/2 signaling due to impaired trafficking of activated TrkA (Agola et al. 2011). Disease-causing Rab7a mutants that are constitutively activated have also been shown to exhibit enhanced NGF-stimulated Erk1/2 signaling (BasuRay et al. 2010). This apparently contradictory result can be explained by the duality of Rab7a in regulating transfer of cargo to lysosomes and interacting with scaffold proteins. Thus, Rab7a plays a significant role in growth factor transport by controlling both signaling scaffolds and trafficking to degradative compartments.

Phosphorylation of Rab7a in response to growth factor suggests a further layer of regulation. Large-scale proteomics analyses have identified Rab7a to be both serine and tyrosine phosphorylated. In mouse liver extracts, Rab7a was found phosphorylated on serine 72 within a highly conserved sequence near the GTP-binding pocket (Villen et al. 2007). Rab7a was phosphorylated in response to EGF stimulation on tyrosine 183 in the C-terminal region. Enhanced tyrosine 183 phosphorylation of Rab7a was also associated with mutant EGF receptor and HER2 overexpression in non–small cell lung carcinoma and mammary epithelia, respectively (Guo et al. 2008). The functional consequences of Rab7a serine and tyrosine phosphorylation with respect to membrane trafficking, GTP binding, and hydrolysis remain to be established.

Ubiquitination of activated growth factor receptors plays a crucial role in the endosomal sorting and lysosomal targeting to downregulate receptor levels. Such ubiquitination may depend on interaction with Rab7a and the Rabring7 E3 ubiquitin ligase. The sorting of ubiquitinated receptors into luminal vesicles of multivesicular bodies depends on the ESCRT0, ESCRTI, ESCRTII, and ESCRTIII complexes (Raiborg and Stenmark 2009). EGF receptor and TrkA endolysosomal degradation are both ubiquitin and proteasome dependent. The K63-linked polyubiquitin chain on activated TrkA receptors gets shuttled by the p62 scaffolding protein, possibly in association with Rab7a/XAPC7, to the proteasome for deubiquitination prior to degradation in lysosomes (Geetha and Wooten 2008). TrkA deubiquitination prior to lysosomal degradation may allow crucial recycling of ubiquitin since the ubiquitin tagging is essential for optimum interaction of activated TrkA with the transport machinery and its delivery along the long axonal route from the tip to the cell body. Only after TrkA reaches the cell body, the termination of signaling calls for deubiquitination of the cargo prior to its lysosomal degradation. As illustrated, the reversible ubiquitination is an important component of growth factor receptor downregulation.

The Rab7a-regulated, interdependent late endocytic trafficking, and signaling pathways are indispensible for translating growth factor signals into appropriate cell responses. The development of suitable in vivo models will therefore be crucial to elucidate how impaired trafficking of growth factor receptors and consequent alterations in signaling lead to neurodegenerative diseases and cancer.

Summary

Since its discovery over 20 years ago, Rab7a and its functions in late endocytic trafficking and signaling have remained under active investigation. Unflagging interest is attributed to the diverse processes that are regulated by Rab7a together with a demonstrated role in human disease. The list of Rab7a effector proteins continues to grow, though the exact functions of many recent interacting partners remains to be elucidated. Rab7a helps to coordinate signaling through the temporal and localized assembly of signaling scaffolds and a close coupling to degradative pathways. Elucidating how Rab7 nucleotide exchange and hydrolysis are regulated and how Rab7 is selectively recruited to specific macromolecular complexes to regulate individual pathways remain important areas for further investigation.

Rab8

Heather H. Ward and Angela Wandinger-Ness
Department of Pathology and Cancer Center, MSC08-4640, University of New Mexico Health Sciences Center, Albuquerque, NM, USA

Synonyms

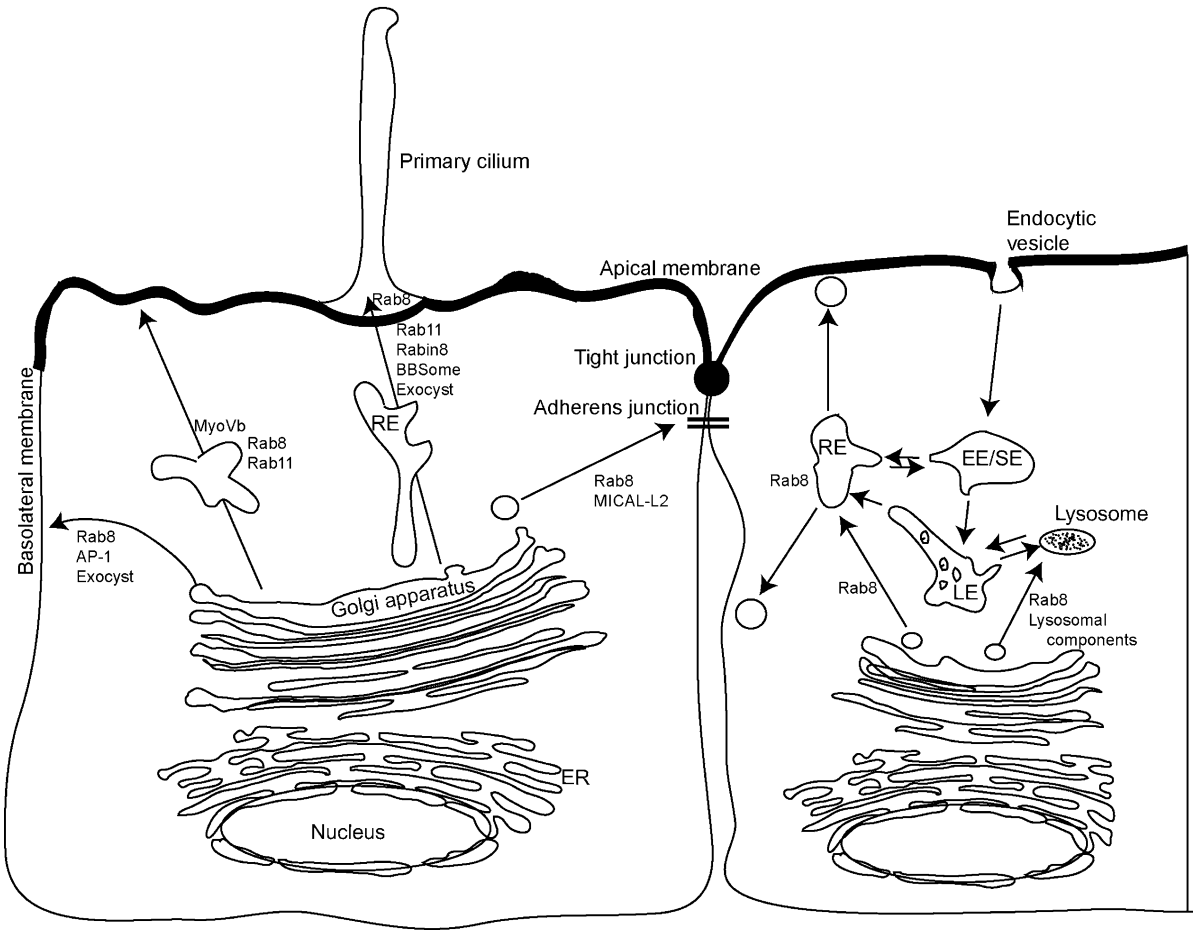
Dmel; Mel transforming oncogene (RAB8 homolog); MEL; MGC124948; Oncogene c-mel; Rab8a; Ras-related Rab8; Ras-associated protein RAB8; Ras-related protein Rab-8A

Historical Background

Ras-like Rab GTPases (guanosine triphosphatases) are regulators of membrane trafficking. Identification of two Ras-like GTPases, Sec4p and Ypt1p, which are involved in regulating secretion in yeast, rapidly led to the discovery of additional small GTPases in mammalian cells. Rab8 was among the first group of mammalian Rab GTPases to be identified and is a close functional and sequence homolog of the yeast proteins Ypt2 and Sec4p. A second isoform, Rab8b (b for basophil), was cloned from mast cells in 1996. Rab8b shares 83% sequence identity with MEL/Rab8 (now also termed Rab8a) primarily over amino acids 1–152. The two isoforms display significant overlap in tissue distribution (coexpressed in liver, skeletal muscle, and testis), though Rab8 is much more abundant in lung and kidney, while Rab8b is more prevalent in heart, brain, and spleen. This review presents a synopsis of recent developments on Rab8 function. As detailed in the following sections, Rab8 regulates transport from the trans-Golgi network to the basolateral plasma membrane of epithelia, neuronal dendrites, and the ciliary membrane. Rab8 is required in cellular polarization, cellular signaling and development. Consequently, alterations in Rab8 expression and localization affect numerous cellular events and organ systems.

Rab8 Function

Analyses of Rab8 function across diverse cell types demonstrate that Rab8 plays a pivotal role in exocytic and endocytic pathway interfaces and is particularly important in exocytic events (Fig. 1). Rab8 predominately localizes to budding vesicles at the trans-Golgi network, recycling endosomes, exocytic vesicles, and ruffling plasma membrane domains. From the trans-Golgi network, Rab8 regulates delivery of newly synthesized lysosomal enzymes to endosomes (del Toro et al. 2009), exocytosis of regulated secretory vesicles and melanosomes (Faust et al. 2008; Wandinger-Ness and Deretic 2008; Sun et al. 2010), and plasma membrane export to neuronal dendrites, as well as to the basolateral, apical and ciliary membrane domains of epithelia (Bravo-Cordero et al. 2007; Wandinger-Ness and Deretic 2008). An emerging theme is that Rab8-mediated transport of newly synthesized ciliary



Rab8, Fig. 1 *Rab8 trafficking routes*. Rab8 plays an important role in both exocytic and endocytic pathway interfaces and is particularly important in exocytic events. Through interactions with different protein complexes, Rab8 regulates delivery of newly synthesized lysosomal enzymes to endosomes, exocytosis of secretory vesicles, and cargo export basolateral, apical and ciliary membrane domains of epithelial cells. *RE* recycling endosome, *EE/SE* early endosome/sorting endosome, *LE* late endosome

membrane proteins, basolateral and apical cargo frequently occurs via recycling endosomes in coordination with Rab10 and Rab11a (Schuck et al. 2007; Cramm-Behrens et al. 2008; Wandinger-Ness and Deretic 2008; Knodler et al. 2010; Ward et al. 2011; Westlake et al. 2011). On the endosomal circuit, Rab8 may cooperate with Arf6, Rab11a or Rab13 to regulate externalization of recycling receptors (transferrin and glutamate), cell adhesion molecules (integrins and E-cadherin), and lipid regulators (ABCA1), often to specialized domains such as membrane protrusions, junctions and postsynaptic membranes (Hattula et al. 2006; Nagabhushana et al. 2010; Rahajeng et al. 2010; Roland et al. 2011).

Rab8 function in membrane trafficking is intimately connected to the cytoskeleton. Rab8 is associated with microtubules, actin and intermediate filaments, and expression of mutant Rab8 variants results in significant perturbations of both microtubule and actin networks (Omori et al. 2008; Wandinger-Ness and Deretic 2008). Rab8 has not been shown to bind microtubule-based motors, and the perturbation of microtubules induced by mutant Rab8 may be linked to Rabin8-dependent activation of Rab8 at centrosomes and the dependence of microtubule-based cilia on Rab8 membrane transport (Wandinger-Ness and Deretic 2008; Knodler et al. 2010; Westlake et al. 2011). On the other hand, Rab8-dependent actin

filament association depends on direct Rab8 interactions with myosin V(a,b,c) or myosin VI motor proteins, which in turn facilitate directed vesicle trafficking (Wandinger-Ness and Deretic 2008; Roland et al. 2009, 2011). Rab8-myosin VI interactions direct basolateral cargo to the plasma membrane (Wandinger-Ness and Deretic 2008). Rab8/Rab27/myosin Va regulate the final stages of melanosome docking to the plasma membrane via actin filaments (Wandinger-Ness and Deretic 2008). Rab8-Rab11-myosin Vb and Rab8-myosinVb interactions are involved in apical lumen formation and insulin-dependent GLUT4 exocytosis, respectively (Ishikura and Klip 2008; Roland et al. 2011). Rab8 and myosin Vc likely cooperate in the early stages of regulated secretion involving tubule-dependent transport to the cell periphery of exocrine epithelia followed by hand-off in the cell periphery to Rab27a vesicles whose cortical actin anchoring depends on myosin Vc (Jacobs et al. 2009). The three isoforms of myosin V also act as scaffolds for the binding of multiple Rab GTPases cooperating on linked pathways, including Rab8, Rab10, Rab11a, and Rab27 (Roland et al. 2009). For example, Rab8 as well as Rab10 interact via an alternatively spliced exon D in myosin Va and Vb or an exon D-like domain in myosin Vc, while Rab27a interacts via exon F in myosin Va (Roland et al. 2009). Thus, regulated interactions of distinct myosin isoforms with distinct combinations of Rab GTPases may partially explain cell-type-specific regulation of Rab8-dependent pathways (Roland et al. 2009, 2011). However, questions remain as to how Rab8 functions cooperatively with other GTPases and how specific functions are regulated, for example: Is Rab8 bound simultaneously with multiple Rab GTPases to individual myosin motors? Are there hand-offs between Rab8 and other GTPases at discrete locations and how do they occur? How are specific effectors involved in discrete transport steps enriched at Rab8-positive membranes?

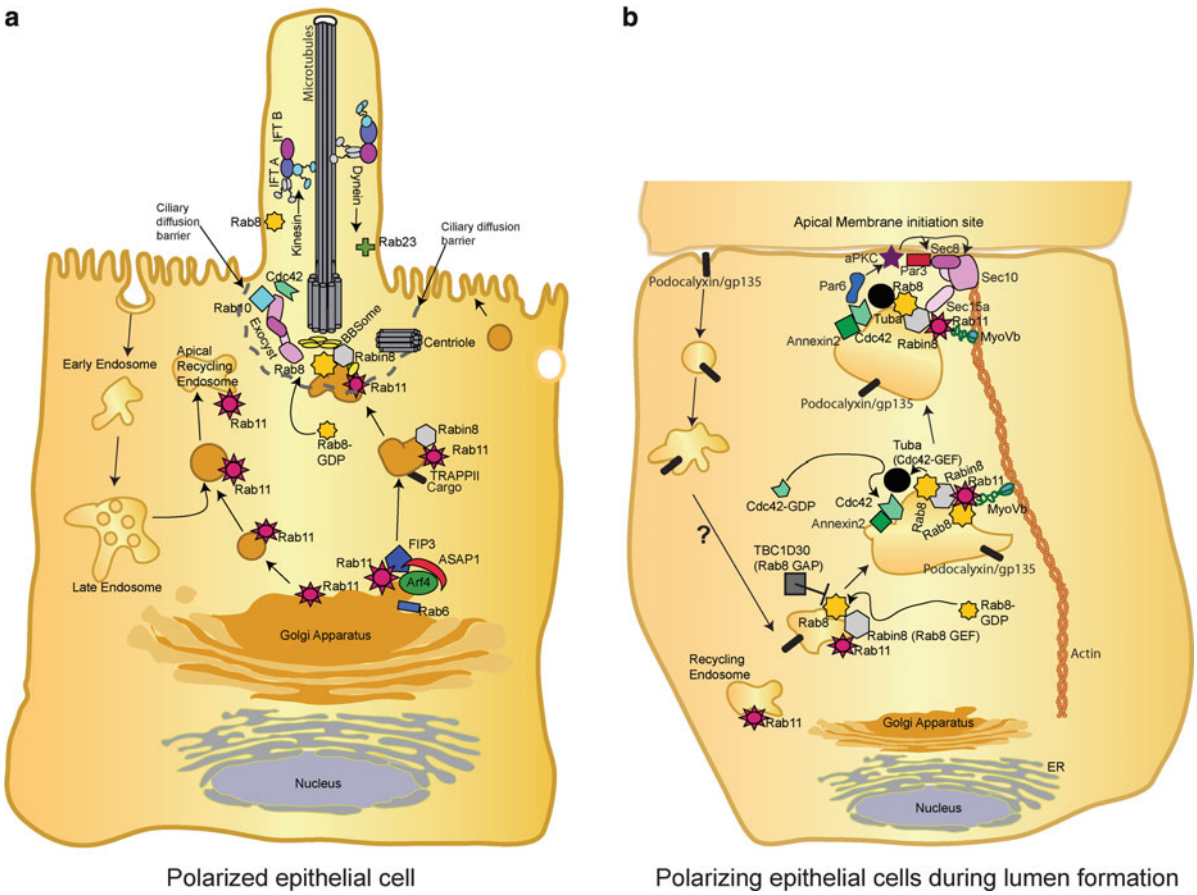
As illustrated by the given examples, Rab8 serves as a key regulator in communication between membrane transport circuits, the cytoskeleton and cellular signaling. Due to the critical role that Rab8 plays in multiple cellular pathways, loss of Rab8-protein interactions and regulation can result in numerous human diseases including open angle glaucoma, retinitis pigmentosa, microvillus inclusion disease, Huntington's disease, and cystic kidney disease.

Rab8 Regulation

As with other Rab family members, Rab8 cycles through membrane-associated, GTP-bound "on" states and cytoplasmic, GDP-bound "off" states. Membrane association depends on isoprenylation by protein geranylgeranyl transferases (primarily REP/GGTase II or GGTase I, minor pathway) [reviewed in (Wandinger-Ness and Deretic 2008)]. Activation of membrane-bound Rab8 through GTP binding may be facilitated by one of several guanine nucleotide exchange factors (GEFs) such as MSS4, Rabin8/Rabin3, Rabin 3-like GRAB, or retinitis pigmentosa GTPase regulator (RPGR). In the activated state, Rab8 is a scaffold for numerous effectors and kinases that cooperatively serve in the temporal and spatial regulation of Rab8 transport. Upon completion of the transport cycle, nucleotide hydrolysis and Rab8 inactivation can be mediated by two known GTPase activating proteins (GAPs), AS160 (Akt substrate)/Tbc1d4 (Tre-2/Bub2/Cdc16) domain containing protein or Tbc1d30/XM_037557, for which multiple isoforms may exist (Wandinger-Ness and Deretic 2008). Interestingly, AS160 also serves as a GAP for Rab10 and Rab13 suggesting that GTPases that function on interrelated pathways may also be coregulated (Ishikura and Klip 2008; Sun et al. 2010). Inactive Rab8-GDP is bound and recycled from membranes to the cytosol by GDP dissociation inhibitor-2 (GDI-2) (Shisheva et al. 1999). Given Rab8 involvement in multiple transport pathways, some of which are highly cell type specific, it remains to be clarified if and how Rab8 function is regulated in a site-specific manner.

Rab8 Effectors, Signaling Integration, and Disease

Spatial and temporal regulation of Rab8 trafficking is partially dependent on signaling receptors, as well as effector and cargo protein interactions, thereby conferring specificity to Rab8-mediated targeting in accordance with cell need and cell type (Wandinger-Ness and Deretic 2008). For example, Rab8 interactions differentially regulate α_{2B}- and β2-adrenergic receptor transport from the trans-Golgi network to the plasma membrane (Dong et al. 2010). Triggered by integrin-mediated adhesive events, Rab8 controls the polarized and regulated exocytosis of matrix metalloprotease MT1-MMP/MMP-14, which is critical for collagen degradation and tumor cell invasion (Bravo-Cordero et al. 2007). Specific cell types use conserved



Rab8, Fig. 2 *Rab8 exocytic trafficking in ciliated and polarizing epithelial cells*. (**a**) Ciliogenesis and cilial transport is regulated in part by Rab8-mediated vesicle trafficking. Vesicular transport of membranous protein cargo such as polycystin-1 begins with formation of a Golgi-exit complex consisting of Arf4 and Rab11 and recruitment of the Arf4 GAP (ASAP1) and Rab11 effector FIP3. TRAPPII components and Rab11 are required for recruitment and vesicular trafficking of Rabin8. Near the centrosome Rabin8 recruits and activates Rab8, which facilitates transit and docking with BBSome. Vesicle fusion is thought to require Rab8, Rab10, the exocyst complex and Cdc42. Kinesin and dynein motor protein isoforms transport proteins within the primary cilium, though the link between Rab GTPases and motor proteins within the cilium has not been defined. (**b**) Rab8, Rabin8, exocyst components and Cdc42 also participate in Rab11-mediated vesicle transport (recycling endosome transition to exocytic vesicle) in polarizing epithelial during the formation of tubule lumens. These vesicles interact with myosin Vb to transport to the apical surface via the actin cytoskeleton. Rab11 interacts with Rabin8, which in turn recruits and activates Rab8. Rab8 recruits Tuba, the Cdc42 GEF, which activates Cdc42. Cdc42 and Par6 recruit aPKC, which then recruits Par3-Sec8 and Sec10. Interactions with the exocyst and Rab GTPases promote association with the plasma membrane

trafficking mechanisms during different stages of polarization. For example, Rab8, Rab11, Rabin8, and the exocyst complex are used with different effectors to traffic apical protein cargo during lumen formation and ciliary protein cargo during ciliogenesis upon reaching a fully polarized, ciliated state (Fig. 2). Loss of cargo, especially signaling proteins, to the proper target membrane results in aberrant signaling and disease. Although an assortment of diverse Rab8a effectors and cargo are known, further study is needed to determine if Rab8a activity is regulated by distinct sets of regulators within specific cellular compartments.

Rab8-mediated trafficking is required to maintain cellular polarity and homeostasis, which when altered can lead to tumor formation and malignancy. Membrane type 1-matrix metalloproteinase (MT1-MMP, also known as MMP-14) plays a key role in tumor

invasiveness by participating in proteolytic degradation of surrounding tissues through activation of MMP2. MT1-MMP is exocytosed via Rab8, and trafficking to the plasma membrane is enhanced with expression of constitutively active Rab8 mutants, whereas RNAi knockdown of Rab8 prevents MT1-MMP from reaching the plasma membrane and thus prevents collagen degradation (Bravo-Cordero et al. 2007). Of note, MT1-MMP activation of MMP2 and MMP9 from pro- to active form is dependent upon interaction between MSS4 (a Rab8 GEF) and α-integrin chains (Knoblauch et al. 2007). The MSS4 binding sites for α-integrin chains and Rab8 are likely competitive. Decreased expression of MSS4 affects assembly and remodeling of the extracellular matrix. Rab8 expression can be up-regulated in breast cancer malignancies and associated lymph node metastases, and further studies on Rab8 mechanisms in tumorigenesis and malignancy may pave the way for the development of small molecule treatments with Rab8 or associated effectors as therapeutic targets.

Rab8 mediates basolateral trafficking and protein transport to adherens and tight junctions. Rab8 and Rab13 interact with effector MICAL-L2 (Molecule Interacting with CasL-Like 2) via competitive binding and formation of distinct independent Rab8a-MICAL-L2 and Rab13-MICAL-L2 protein complexes. Rab-MICAL-L2 protein interactions dictate trafficking specificity by regulating E-cadherin recycling to adherens junction (further evidenced by Rab8 knockdown causing delay of E-cadherin delivery to adherens junctions in calcium switch assays), and Rab13-MICAL-L2 interactions mediate recycling of occludin to tight junctions (Rahajeng et al. 2010). MICAL-1, MICAL-2, MICAL-3, MICAL-L1, and MICAL-L2 make up a family of large proteins with two to three common domains that mediate vesicular transport and cytoskeleton organization (Rahajeng et al. 2010). Rab8 interacts with at least three MICAL family members. Rab6-dependent recruitment of Rab8 to exocytic vesicles involves a MICAL3 intermediate in Rab8-ELKS interactions (Grigoriev et al. 2011). A related MICAL-like protein, MICAL-L1, regulates Rab8 in endocytic recycling. MICAL-L1 is proposed to serve as a Rab8 effector that serves to stably link Rab8 and EHD1 (Eps15 homology domain 1) on endocytic recycling vesicles (Rahajeng et al. 2010). EHD ATPase scaffolding proteins localize to tubular and vesicular membranes, regulate endocytic trafficking, and coordinate activity with Rab GTPases through interaction with Rab effectors. EHD also mediates GLUT4 recycling. Thus, Rab8 in conjunction with MICAL and EHD proteins form scaffolds that are crucial for integrating basolateral and endocytic pathways.

Over the last 3 years insulin-dependent signaling has been linked with Rab-mediated vesicle trafficking. Insulin-dependent glucose uptake is mediated by regulation of the surface recycling of GLUT4 transporters. AS160/TBC1D4 serves as a Rab GAP and AKT signaling target and is phosphorylated in response to insulin. Upon phosphorylation AS160 GAP activity is likely inhibited to allow activated Rab targets to function, thereby releasing the brakes on vesicle docking and fusion and allowing GLUT4 insertion at the plasma membrane of myoblasts (Randhawa et al. 2008). TBC1D1 is a second GAP that coregulates Rab activation in response to insulin stimulation. Rab8a and Rab14 are targets of the GAP TBC1D1 in skeletal myotubes and AS160, along with Rab13, in myoblasts (Ishikura and Klip 2008; Sun et al. 2010). The Rab8, Rab10, and Rab14 GTPases are required for insulin-induced GLUT4 trafficking, with GTP loading stimulated by insulin in a cell-type-specific manner (Ishikura and Klip 2008; Sun et al. 2010). Rab8 and Rab13 act as a Rab regulatory cascade that is activated sequentially to promote GLUT4 translocation in muscle cells, while Rab10 functions in adipocytes. Downregulation of GLUT4 translocation is thought to be achieved through the interaction of active Rab8a with the myosin Vb motor protein, thereby altering Rab8a localization and negatively impacting GLUT4 translocation (Ishikura and Klip 2008; Sun et al. 2010). This example is illustrative of how signaling and Rab8-regulated membrane trafficking are closely intertwined and modulated through cell-type-specific processes.

Noc2, rabphilin, Rim2 and Slp4/granuphilin are members of the ▶ synaptotagmin-like family and all bind to multiple Rab GTPases, including Rab3a, Rab8a, and Rab27a. Noc2 and rabphilin bind to active, GTP-bound Rab8a suggesting that both may serve as Rab8a effector proteins. Rim2 has been predominately studied in regulated secretion within presynaptic nerve terminals and insulin-secreting cells, where it functions in regulated exocytosis (Yasuda et al. 2010). Rabphilin is expressed in neuronal, neuroendocrine, intestinal goblet cells and kidney podocytes. Slp4 is also expressed in neuroendocrine cell dense core

vesicles and additionally localizes to the insulin-containing vesicles of pancreatic beta cells. All the members of the synaptotagmin-like family are implicated in regulated secretion and are of interest due to the fact that synaptotagmin-like proteins also bind plus-end directed myosin motors and thus, may bridge Rab8-regulated vesicle docking and fusion to cytoskeletal translocation.

Further evidence for a link between Rab8 and myosin motors is provided by studies in enterocytes. Rab8a is essential for localization of apical proteins and maintenance of the small intestine (Fig. 1) (Sato et al. 2007). Microvillus inclusion disease of the small intestine is characterized by microvillar atrophy and malabsorption. Rab8 conditional knockout in mice causes microvillus inclusion disease and one case of human disease has been linked to decreased Rab8 mRNA and protein expression in the enterocytes of the small intestine. To date, no further work has been reported on the role of Rab8 in microvillus inclusion disease. However, several reports have linked myosin Vb mutations to microvillus inclusion disease, and myosin Vb mutations cause disruption of epithelial cell polarity, as evidenced by loss of microvilli on the surface of intestinal absorptive cells and microvilli present within intracellular inclusion (Ruemmele et al. 2010). Given that both Rab8a and myosin Vb defects can result in microvillus inclusion disease, it is interesting to speculate that, as is the case in insulin-dependent signaling, the motor protein myosin Vb may interact with Rab8a and direct trafficking to the apical surface, which when perturbed, inhibits surface expression of microvilli. Further roles for Rab8 and apical protein targeting were brought to light through the study of zymogen granules in the exocrine pancreas. Rab8 localizes to zymogen granules and facilitates delivery of digestive enzymes to the apical surface, evidenced by the fact that Rab8 knockdown decreases granule numbers and causes granule proteins to accumulate in the Golgi (Wandinger-Ness and Deretic 2008). The authors speculate that Rab8-zymogen trafficking may depend on a clathrin/AP-1/dynamin association at the Golgi.

At the Golgi, Rab8a interfaces with optineurin (FIP-2) to promote cargo export, which is mediated by clathrin adaptor complex AP-1 (del Toro et al. 2009). Optineurin localizes to the cytosol, Golgi, and recycling endosomes and participates in vesicular trafficking. Optineurin binds active, but not GDP-bound, Rab8, thus suggesting that optineurin serves as a downstream effector. Optineurin interacts with myosin VI, a minus-end directed motor, to link Rab8 positive membranes to the actin cytoskeleton [reviewed in (Wandinger-Ness and Deretic 2008)]. The optineurin E50K mutation causes glaucoma and has been shown to impair endocytic trafficking (as demonstrated by impaired transferrin uptake) and slows the velocity of Rab8-GFP positive vesicles (Nagabhushana et al. 2010). Interestingly, mutant E50K optineurin completely abolishes optineurin-Rab8 interactions at the Golgi (Chi et al. 2010). In mice, the E50K mutation causes massive apoptosis and degeneration of the retina, but not broader neuronal degeneration (Chi et al. 2010). The composite data suggest there may be a conserved mechanism for zymogen and optineurin-mediated trafficking in exocrine cells and neurons.

Optineurin-Rab8 interactions also come into play in Huntington's disease. Huntington's disease results from abnormal expansion of a polyglutamine tract in the N-terminus of the huntingtin protein and has defects in lysosome function. Huntingtin regulates post-Golgi trafficking of secreted proteins and interacts with the optineurin-Rab8 complex. Huntingtin links Rab8/optineurin vesicles to microtubules via interactions with via HAP1 (a Trio-like protein with a Rac1 GEF domain), dynactin (p150glued) and dynein [reviewed in (Wandinger-Ness and Deretic 2008)]. Expression of huntingtin mutants or decreased huntingtin expression decreases Rab8 and optineurin localization at the Golgi and inhibits clathrin and optineurin/Rab8-dependent trafficking to lysosomes (del Toro et al. 2009). Loss of huntingtin causes loss of Rab11 in isolated membranes, and Rab11-GDP was shown to interact with huntingtin ~30-fold greater than Rab11-GTP. Rab8 and Rab11 both play a role in polarized outgrowth and are preferentially located in the somatodendritic domain of neurons, and Rab8 functions in neuronal maturation and polarized transport. For example, Rab8 is required for the transport and insertion of (AMPA)-type glutamatergic receptors, which mediate the fast synaptic transmission throughout the nervous system, into the postsynaptic compartment. AMPA receptors are recycled back to the membrane via Rab11 recycling endosomes, suggesting a potential Rab11/Rab8 trafficking pathway similar to those found in neuronal photoreceptor cells. However, the generalizability of the mechanism remains to be studied further.

Rab8a in Cilial Transport

The role of Rab8 in cilial transport and cilial-mediated signaling was suggested approximately 16 years ago (Wandinger-Ness and Deretic 2008), and the body of literature supporting this hypothesis has grown significantly over the last 5 years. The primary cilium is a specialized organelle that sits atop most cell types in the body and serves as an antenna to sample the extracellular space and transmit signals to the cell body. Accordingly, components of several signaling pathways such as hedgehog, WNT and JAK-STAT, which regulate cellular growth, proliferation, differentiation, and polarization, are found within the primary cilium. Cilial structures are evolutionarily conserved but can have cell-type-specific modifications to detect and respond to various stimuli such as mechanical, physical, chemical, or temperature sensation. For example, the modified cilium in photoreceptor cells responds to light, whereas the primary cilia in kidney epithelia are thought to be chemo-mechano sensors. Loss or aberrant localization of membrane-bound and cytoplasmic ciliary proteins at the site of the primary cilia is associated with a group of inherited diseases known as the ciliopathies. Ciliopathies encompass a broad range of genetic mutations and phenotypes. Some genetic mutations cause single organ, adult onset and progressive disease such as autosomal dominant polycystic kidney disease (ADPKD) and retinitis pigmentosa, whereas other genetic mutations affect multiple organs. An example of a multiorgan disorder is Bardet-Biedl Syndrome (BBS), which exhibits phenotypes that include (but are not limited to) obesity, polydactyly, retinopathy, mental impairment, and kidney abnormalities.

Rab8 function aligns strongly with the defined responsibilities of primary cilia, namely, regulation of epithelial differentiation and maintenance, development and organ function through cellular signaling. Expression of GTP-locked Rab8 induces cilial extension, whereas depletion of Rab8 inhibits cilia formation and trafficking, which often results in renal and retinal defects (Nachury et al. 2010). Numerous studies have linked Rab GTPases to the transport of membrane-bound ciliary proteins to the primary cilium; however, the distinct mechanisms are not well defined. Many questions about ciliary trafficking have been brought to the forefront of basic cell biology research, such as: How many ciliary trafficking routes exist? How are they modulated for specific cell types? What are the signaling pathways that drive ciliary transport? What are the mechanisms that switch cellular transport to direct ciliary trafficking of molecules with multiple localization patterns? How do vesicular transport pathways cooperate with other trafficking pathways such as intraflagellar transport (IFT)?

In the context of cilial function, Rab8 trafficking is best characterized in the rhodopsin transport model. Rhodopsin requires several small GTPases, including Rab8, to shuttle from the Golgi to an elaborate primary cilium, known as the rod outer segment, of photoreceptor cells; a Rab8 GDP-locked mutant (Rab8-T22N) inhibits docking and fusion of rhodopsin-containing exocytic vesicles in transgenic frogs which results in dramatic retinal degeneration (Wandinger-Ness and Deretic 2008). Rab8 in concert with the Rab6, Rab11, and Arf4 GTPases is responsible for rhodopsin transport from the Golgi to the rod outer segment, in concert with regulatory proteins (e.g., ASAP, the Arf4 GAP) and effector proteins (e.g., FIP3) (Mazelova et al. 2009a). Mutations in the extreme C-terminus of rhodopsin impair interactions between rhodopsin and the GTPase trafficking complex, which leads to autosomal dominant retinitis pigmentosa. The altered interaction results in aberrant trafficking of rhodopsin to the rod outer segment, and explains at the molecular level the cause of retinitis pigmentosa. These careful studies were the first to reveal GTPase-mediated vesicular hand-offs in ciliary transport, beginning with interaction of a cargo protein with Rab6 and Rab11 in the Golgi. The cargo recruits and binds Arf4 via a specific targeting sequence to facilitate vesicle budding and Arf4 cooperates with Rab11. ASAP1, the Arf4 GAP, recognizes membrane curvature and is recruited to bind Arf4 to promote GTP hydrolysis and removal of Arf4 from the ciliary-targeted vesicle. FIP3, the Rab/Arf effector also bridges Arf and Rab GTPases via interactions with Rab11 and ASAP1 (Fig. 2a). The described pathway of rhodopsin transport prompted further questions about mechanism conservation between different cell types, the identification of other trafficking molecules that participate in the GTPase vesicle ciliary relay, and the composition of the coat complex of the ciliary transport vesicles.

Further studies in renal epithelial cells provided clues to conservation of Rab-mediated ciliary trafficking. In normal cultured renal cells, Rab8 can be found at the perinuclear Golgi region, whereas in cultured

ADPKD cells, Rab8 is mislocalized to disperse vesicles (Wandinger-Ness and Deretic 2008). Polycystin-1, a protein that when mutant causes ADPKD, uses the same GTPase transport mechanism as rhodopsin to traffic to primary cilia of renal epithelial cells (Ward et al. 2011). Thus, the trafficking mechanism consisting of Rab GTPases (Rab6, Rab11, Rab8), Arf4 GTPase, and Arf GAP ASAP1 is conserved between retinal photoreceptor cells and renal epithelial cells (Ward et al. 2011). In contrast, fibrocystin, a protein mutant in patients with autosomal recessive PKD, also utilizes Rab8 to traffic to the primary cilium, but the fibrocystin C-terminal sequence does not bind Rab6 and Rab11 (nor Rab17, Rab23, and IFT20), suggesting that Rab8 may serve as the common GTPase between different vesicular transport mechanisms leading to ciliary delivery (Follit et al. 2010).

Until recently, the mechanism of Rab8 recruitment and activation along the cilial trafficking route was an enigma. For example, in the sequential transport of cargo that traffics with Rab6, then Rab11, and finally with Rab8 vesicles, how is Rab8 recruited to the exocytic vesicle? Identification of the interaction between Rabin8, a Rab8 GEF, and a complex of Bardet-Biedl proteins (known as the BBSome) at the centriole provided insight into the GTPase coordination and localized GTPase activation required for ciliary formation. The BBSome-Rabin8 interaction was identified at the ciliary base within pericentriolar recycling endosomes, offering the first clue for spatial regulation (Wandinger-Ness and Deretic 2008). Here BBSome components assist in recruitment of Rab8 to the pericentriolar recycling endosome for nucleotide exchange and activation, presumably by Rabin8. Further studies revealed that transport protein particle II complex (TRAPPII) components (C3, C9 and C10) and Rab11 are required for vesicular trafficking of Rabin8 to the centrosome, where Rabin8 subsequently recruits and activates Rab8 (Fig. 2a) (Knodler et al. 2010; Westlake et al. 2011). Thus, Rabin8 serves both as a Rab11 effector and as a Rab8 activator and both Rab8 and Rab11 are required for ciliogenesis. Together, the data highlight the involvement of a spatially and temporally regulated GTPase cascade in cilial formation and ciliary membrane protein targeting.

The dissection of a specific Golgi to cilia pathway is revealing key players in a ciliary targeting, but there are numerous examples of Rab8 involvement in cilial targeting that do not seem to follow the above-mentioned GTPase sequence and the unifying mechanisms remain elusive. CEP290 mutations are linked to several inherited cystic diseases including Senior-Löken syndrome, nephronophthisis, Joubert syndrome, Meckel-Grüber syndrome, and BBS. CEP290 protein satellites the base of the primary cilium, interacts with pericentriolar material 1 (PCM-1), and CEP290 knockdown significantly inhibits Rab8 localization to the primary cilium (Kim et al. 2008); however, the mechanism that mediates CEP290/PCM-1 Rab8 recruitment to the primary cilium remains undefined. An alternate Rab8-mediated ciliary trafficking mechanism has been suggested in *Caenorhabitis elegans* worms in the context of the transmembrane olfactory receptor ODR-10 (Kaplan et al. 2010). Rab8 associates with AP-1 in the clathrin-dependent delivery of ODR-10 to dendritic sensory cilia. Overexpression of GTP-locked Rab8 or mutations in the clathrin heavy chain perturbed ODR-10 trafficking and caused ODR-10 to localize to all plasma membrane compartments. Therefore, AP-1 and Rab8 likely cooperate to direct ODR-10 to the dendritic cilium. The authors suggested that a default secretory pathway directs proteins to all plasma membrane regions, and that this default pathway can be re-routed by AP-1 and Rab8 activation. The level of Rab8 activity may serve as the determining factor in protein destination. If so, then active Rab8 may serve as the switch between a general secretory and cilial-directed transport pathway. The authors' leading model predicts that AP-1 functions at the trans-Golgi network in a clathrin-dependent manner, where the cargo is packaged into budding vesicles. Upon leaving the Golgi, the vesicle uncoats, fuses with Rab8 positive vesicles, and targets to the cilium. It is interesting to speculate that Rab8 vesicles that traffic ODR-10 from neuronal soma to the dendritic cilium may resemble secretory granules in exocrine cells and contain components of the pericentriolar recycling endosomes described in epithelial cells.

At site of the cilium, Rab8 serves as an evolutionarily conserved regulator of ciliary trafficking in several cell types. In turn, the exocyst complex, first identified in *Saccharomyces cerevisiae*, also serves as a conserved trafficking regulator and as an effector of several GTPases. The exocyst complex is comprised of several subunits and regulates polarized secretion via docking of intracellular vesicles to the plasma membrane. The exocyst also localizes to the primary cilium of renal cells, and Sec6 and Sec8 exocyst components

are overexpressed or diminished in ADPKD cells. The exocyst complexes with small GTPases including RalA, Rho1, and Rab8, and regulates function via interactions with GAPs and other molecules such as aPKCs and the Arp2/3 complex (Hertzog and Chavrier 2011). Rab8a-Sec6/8 interactions are thought to control vesicle docking and fusion with the basolateral plasma membrane, thus linking the exocyst with Rab GTPase trafficking. In photoreceptor cells, Rab8 cooperates with phosphatidylinositol (4,5)-bisphosphate, moesin, Rac1 and actin to tether and fuse vesicles to the base of the modified photoreceptor cell cilium. The Sec6/8 complex likely serves as a Rab8 effector during GTPase-mediated vesicular trafficking, as Sec8 colocalizes with Rab8 at fusion sites of vesicles transporting rhodopsin, and, like Rab8, the exocyst localizes to the primary cilia of renal epithelial cells (Fig. 2a) (Nachury et al. 2010). In the case of retinal cells, the Sec6/8 complex coordinates with syntaxin 3 and SNAP-25, whose interactions are regulated by omega-3 docosahexaenoic acid, to regulate rhodopsin delivery (Mazelova et al. 2009b).

Rab8, Rab11, Rabin8 and exocyst components play dual roles in renal epithelial cells. Once renal cells are polarized, Rab8, Rab11 and Rabin proteins participate in delivery of trans-membrane protein cargo to the primary cilium. However, during polarization and lumen formation, Rab11, Rabin 8 and Rab8 mimic a yeast trafficking pathway and traffic cargo, such as podocalyxin, from the trans-Golgi to the forming pre-apical membrane (Fig. 2b). Rab11 recruits Rabin8, which recruits and activates Rab8. Rab11 (and potentially Rab8) also recruits Sec15a, an exocyst component, which binds Sec10 at the plasma membrane. Rab8 recruitment to the transport vesicle enhances active Cdc42 localization, likely driven by Rab8 activity on Tube, the Cdc42 GEF. Cdc42 and Par6 recruit aPKC, which then recruits Par3-Sec8 and Sec10. Thus, similar Rab8 trafficking mechanisms are utilized throughout the cellular polarization process, but the role that Rab8 plays in the regulation and switch between different target destinations remains to be explored.

One important question in the field of ciliary trafficking is how the intraflagellar transport (IFT) system, which transports non-membranous particles to and within the primary cilium, interfaces with the Rab8 GTPase-mediated vesicular trafficking pathway. The IFT protein Elipsa provided one of the first links to IFT-vesicular cross talk. Elipsa localizes to primary cilia and interacts with Rab8 via the Rab8 effector, Rabaptin5 (Omori et al. 2008). Elipsa also directly interacts with IFT20, which has been shown to localize to the Golgi and within primary cilia, and when knocked down, decreases the amount of polycystin-2 delivered to primary cilia (Follit et al. 2010). Combined, these data suggest that IFT plays a role in the transport of membrane-bound proteins to the primary cilium. Taken together, one can speculate that membrane-bound proteins interact in a complex associated with GTPase-mediated vesicular transport, which in turn interacts via effector proteins, such as Rabaptin5, with IFT components. Of note, IFT molecules have been linked to the formation of the immune synapse in T-lymphocytes (Nachury et al. 2010), and immune synapse formation shares similarities with cilial trafficking, namely, the use of IFT20, IFT57, IFT88, Kif3a motor protein. In contrast, IFT transport was not affected when ODR-10 transport was perturbed by Rab8 and clathrin manipulation (Kaplan et al. 2010). Further studies are necessary to dissect out the overlapping and independent roles of IFT and Rab8-mediated vesicular transport pathways to cilia.

Though advances have been made in the context of Rab8 and cilial trafficking, numerous questions remain about coat complexes used by cilia-destined vesicles in various cell types. Since Rab8, along with FIP-2, facilitates AP-1-mediated cargo export from the Golgi and may be associated with AP-1 in zymogen granule transport, could AP-1 (an Arf4 effector) also serve to generate the exocytic vesicle coat in mammalian epithelial cells? Alternatively, going back to the Rab GTPase-mediated transport in epithelial cells (Fig. 2), note that Arf4 facilitates vesicle budding. Arf1 and Arf4 regulate COPI recruitment and TRAPPII components bind COPI (Angers and Merz 2011). Thus, COPI may serve as the initial vesicle coat for some ciliary targeted vesicles. The coat-like BBSome plays a role in Rab8 recruitment and activation at the pericentrosomal region and the complex shares similarities with the COPI and clathrin coat complexes (Nachury et al. 2010). Therefore, after initial budding, does the vesicle coat morph to resemble components of the BBSome, or can the BBSome itself become the late-stage Rab8-positive vesicle coat prior to fusion with the ciliary membrane? Further questions arise about how Rab8, a potentially central ciliary component, may play a role in recruitment of the motor proteins and tethering components for ciliary transport vesicles. Recently,

helical SNARE [Soluble NSF Attachment Protein (SNAP) Receptor] tethering proteins have been incorporated into the rhodopsin trafficking model (Mazelova et al. 2009b). Syntaxin 3 and SNAP-25 regulate rhodopsin delivery and localize to the base of the cilium, where Rab8 recruitment and activation is predicted to occur. SNARE proteins can function as Rab effectors or GEFs and future studies may reveal that SNARE proteins, in addition or as an alternative to the BBSome and Rabin8, may play a role in Rab activation at the primary cilium.

Summary

Vesicular transport can be simplified into three major steps: budding from the donor membrane, translocation of the trafficking vesicle along the cytoskeleton, and docking and fusion with the acceptor membrane compartment (Wandinger-Ness and Deretic 2008). Rab GTPases facilitate this process by serving as molecular scaffolds and interacting with cargo, proteins that promote vesicle budding and coat proteins, and through recruitment of motor protein complexes and tethering molecules. Rab8 is involved in several transport pathways and interfaces with endocytic pathways, regulates exocytosis, and coordinates regulation of the cytoskeleton and trafficking of diverse cargo to multiple subcellular destinations. Rab effectors, motor proteins and specific GEFs, GAPs and kinases mediate regulation of Rab8. Defects in Rab8-mediated trafficking have profound effects on cell morphogenesis, cytoskeletal organization, and cellular polarity. Rab8 serves to coordinate vesicle recycling and delivery of newly synthesized vesicle components to target membranes and functions as a nexus between vesicular endocytic and exocytic pathways. There are a number of unanswered questions in the field of vesicle trafficking: How do cells temporally and spatially regulate the sorting decisions for GTPases? What are the molecular switch mechanisms that cause a shift of shuttling cargo from one target to another? What signals cause Rab8 to associate with different effectors and how are these signals processed? Further investigation of Rab8 in diverse cell types and polarization states is predicted to reveal the unifying and diverse mechanisms of GTPase trafficking and lead to specific signaling targets for small molecule therapies for tumor invasion, cyst formation, and neurologic disease.

Rac GTPases

Diamantis Konstantinidis and Theodosia A. Kalfa
Cancer and Blood Diseases Institute, Cincinnati Children's Hospital Medical Center and University of Cincinnati College of Medicine, Cincinnati, OH, USA

Historical Background and Taxonomy

Rac GTPases comprise one of the eight subfamilies of the Rho (Ras homology) GTPases family, itself a subgroup of the Ras superfamily of small G proteins (Burridge and Wennerberg 2004). They were first identified as a substrate for the bacterial C3-like transferases that block Rho by ADP-ribosylation, although the C3-like transferases act on Rac rather inefficiently. More effective are the large clostridial cytotoxins (with prototypes the *Clostridium difficile* toxin A and B) which glycosylate Rac at Thr35, inhibiting its functions by preventing effector coupling (Aktories et al. 2000). Rac GTPases are preferred targets for bacteria since they act as molecular switches in a multitude of

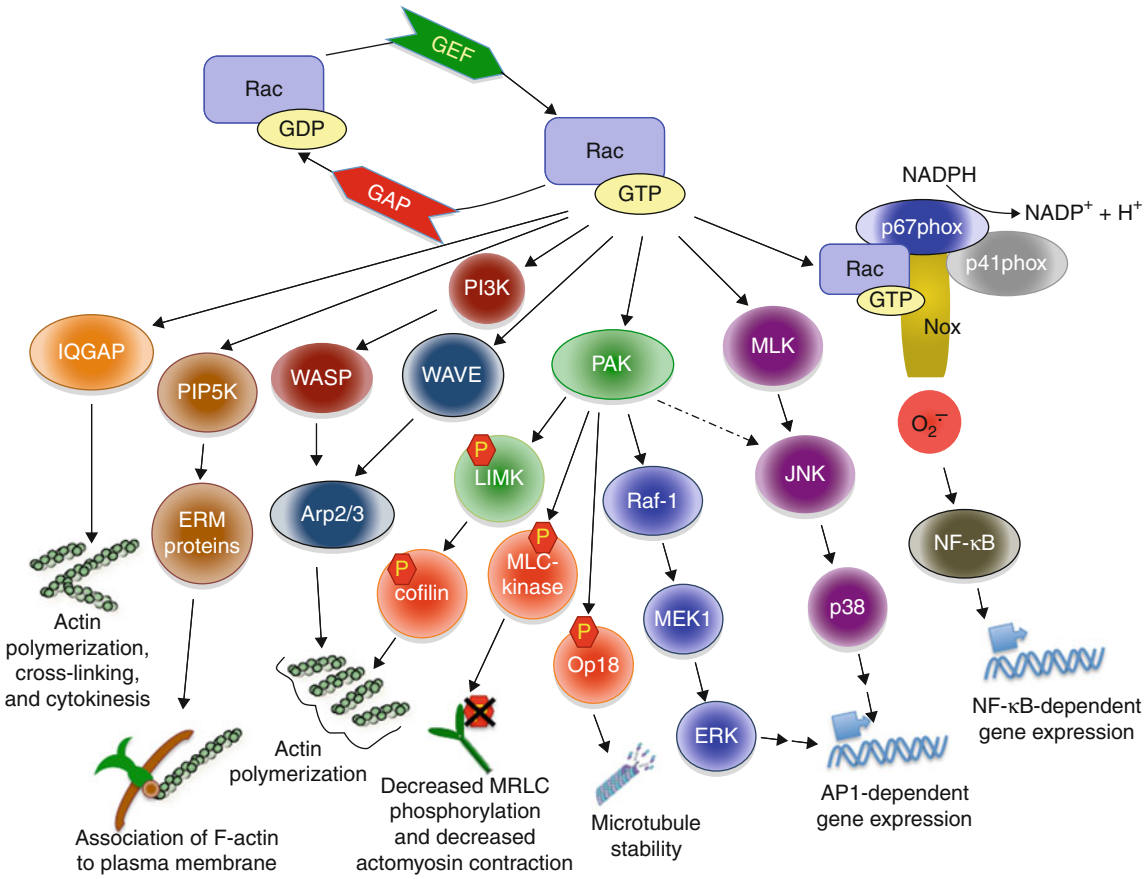
signaling processes, regulating many fundamental cellular functions, including actin cytoskeleton, cell adhesion, motility and migration, vesicular transport pathways and cytokinesis, ▶ reactive oxygen species (ROS) production via NADPH oxidase, as well as cell proliferation and survival (Hall 1998).

The Rac GTPase subfamily consists of four members; Rac1, Rac2, Rac3, and RhoG. They all have high homology, with the first three sharing over 90% amino acid sequence identity between them (Heasman and Ridley 2008). Despite this sequence similarity, studies using knockout mice indicate that many of their functions are nonredundant (Wang and Zheng 2007). Homologues of Rac GTPases have been found in all eukaryotic cells studied, but are totally absent in prokaryotes. In mammalian tissues, Rac1 is ubiquitously expressed while expression of Rac2 is restricted to hematopoietic cells. Rac3 is abundant in the brain but has also been identified in a variety of tissues including heart, placenta, and pancreas. RhoG (Ras homology growth-related) is widely expressed in a variety of organs but reaches a particularly high level in lung and placenta. Deletion of the Rac1 gene in mouse germline produces an early embryonic lethal phenotype and thus studies of Rac1 function have utilized tissue-specific conditional knockout. In contrast, Rac2, Rac3, and RhoG knockout mice are viable, fertile, and do not exhibit obvious developmental defects. Nevertheless, they do exhibit cell-type-specific functional defects and in the case of Rac3-null mice, a mild neurological phenotype (Wang and Zheng 2007; Heasman and Ridley 2008).

Activation of Rac GTPases and Downstream Signaling

Rac GTPases are classical Rho GTPases and as such act as molecular switches cycling between a GTP-bound active form and a GDP-bound inactive form. In their active form, they recognize target proteins, "turning on" signaling pathways, until they hydrolyze GTP to GDP, "switching off" (Etienne-Manneville and Hall 2002). The activation of Rac GTPases is mediated and regulated by guanine nucleotide exchange factors (GEFs), which exchange GDP for GTP on the Rac GTPase enzyme. GEFs exhibit a varied degree of specificity with some being able to activate a large number of different GTPases, while others specialize in activating only one particular isoform. GEFs are antagonized by GTPase-activating proteins (GAPs), which increase intrinsic GTPase activity resulting in GTP hydrolysis and the return of the GTPase to the inactive GDP-bound state. Another level of GTPase activity regulation is achieved through guanosine nucleotide dissociation inhibitors (GDIs), which inhibit nucleotide exchange and sequester small GTPases away from the membrane. Following the effect of specific stimuli such as soluble molecules, cell surface-bound ligands, or mechanical stress on cell surface receptors, GEFs and GAPs are mobilized accordingly to regulate the activation state of the Rac GTPases. Upon adopting an active conformation, Rac GTPases can bind to a wide variety of effectors and lead to initiation of the corresponding downstream signaling pathways (Bishop and Hall 2000; Schwartz 2004) (Fig. 1).

Rac GTPases bind and activate the p21-Activating Kinases (PAK1, PAK2, PAK3), serine/threonine kinases, which drive cytoskeletal remodeling (lamellipodia and membrane ruffling), cell adhesion and proliferation, and gene transcription. While PAK can activate c-Jun NH_2-Terminal Kinase (JNK), Rac1 activates JNK mostly independently of PAK (Westwick et al. 1997), and mainly through Mixed Lineage Kinases (MLKs). Pathways downstream PAK and MLK stimulate AP1-dependent gene expression. AP1 can upregulate the expression of genes that control cell cycle progression, such as cyclin D1 and c-myc, proteins that when overexpressed are associated with cell transformation and cancer (Bosco et al. 2009). Through PAK, Rac GTPases phosphorylate and activate ▶ LIMK, which in turn phosphorylates and inhibits cofilin, an actin filament severing protein, hence inducing actin polymerization into lamellipodia and membrane ruffling. Additionally, Rac stimulates the Wiskott–Aldrich syndrome protein (WASP)-family verprolin-homologous protein (WAVE) complex, which in turn activates actin-related proteins 2/3 complex (Arp2/3) that nucleates unbranched actin filaments (Heasman and Ridley 2008). Rac regulation of cell contractility includes PAK-mediated phosphorylation of myosin light chain kinase (▶ MLCK) and hence its inactivation causing decreased phosphorylation of the myosin regulatory light chain (MRLC) and reducing actomyosin assembly and contraction (Bishop and Hall 2000). PAK can also inhibit the microtubule



Rac GTPases, Fig. 1 Rac GTPases regulate their multiple functions within the cell via a variety of effectors, which initiate separate or interacting signaling cascades. Following the effect of specific stimuli GEFs and GAPs are mobilized accordingly to regulate the activation state of the Rac GTPases and direct Rac GTP to the appropriate effector

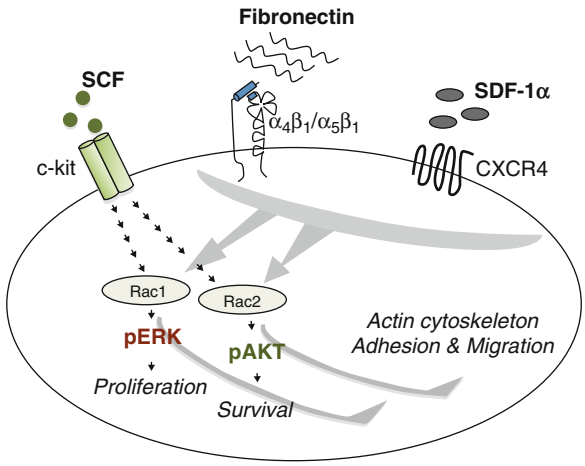
destabilizing activity of OP18/stathmin by phosphorylation. Other functions of Rac GTPases mediated by PAK are interactions with the myosin heavy chain, also leading to decreased actomyosin filaments, with filamin A to promote membrane ruffling, as well as with components of the paxillin-GIT/PKL-P1X complex to regulate cell adhesion and motility (Schwartz 2004). Independently of PAK, Rac binds to the actin-binding protein IQGAP (named GAP because of some homology with Ras GAP, but actually a Rac effector) which oligomerizes and cross-links F-actin in vitro and has been shown to arrange actin filaments into the cytokinetic contractile ring in yeast (Bishop and Hall 2000). Rac GTPases bind and activate Phosphatidylinositol-4-Phosphate 5-Kinase (PIP5K) leading to production of phosphatidylinositol (4,5)-bisphosphate (PIP_2) and activation of the ERM (ezrin, radixin, moesin) complex of proteins. ERM proteins have actin-binding domains as well as domains that bind to cytosolic domains of plasma membrane integral proteins and mediate the association of F-actin to plasma membrane. (Schwartz 2004). Phosphatidylinositol 3-Kinase (PI3K) is also a Rac effector with multiple actions. It stimulates WASP and Arp2/3, thus inducing actin polymerization and produces 3′-phosphorylated lipids that bind to and stimulate Rac GEFs, creating a positive feedback loop that maintains cell migration. In addition, it also activates AKT Ser/Thr kinase to support cell survival (Schwartz 2004; Bosco et al. 2009). Rac-GTP binds to the p67phox component of NADPH oxidase, activating the enzyme to produce superoxide. Superoxide and other reactive oxygen species (ROS) have multiple roles and effects to cells and

tissues, including signaling and stimulation of NFκB-dependent gene expression (Schwartz 2004; Hordijk 2006).

Rac GTPases in Hematopoiesis

Rac1 and Rac2 GTPases play distinct and overlapping roles in hematopoietic and mature blood cells, regulating homing, engraftment, actin cytoskeleton organization, ROS production, cell survival, and proliferation (Gu et al. 2003; Mulloy et al. 2010). Hematopoietic stem cells and progenitors (HSC/P) deficient of Rac1 demonstrate decreased proliferation when stimulated with stem cell factor (SCF), associated with nondetectable cyclin D1 levels and with decreased Extracellular Signal–Regulated Kinase (ERK) (p42/p44) phosphorylation. In contrast, loss of Rac2 activity leads to a pro-apoptotic phenotype in HSC/P as well as in mast cells, with reduced AKT activation in the presence of SCF. $Rac1^{-/-}$;$Rac2^{-/-}$ HSC/Ps display decreased adhesion to fibronectin, despite normal expression of α4β1 and α5β1 integrins on their surface and decreased migration in response to stromal-derived factor-1 (SDF-1), although they have significantly increased expression of CXCR4, the SDF-1 receptor (Gu et al. 2003) Since Rac GTPases are key components of the signaling pathways downstream of the SCF-ligand c-kit, the chemokine receptor CXCR4, and the β1 integrin-receptors for fibronectin, all significant mechanisms of interaction of HSC/Ps with the bone marrow microenvironment (Fig. 2), it is not surprising that combined Rac1 and Rac2 deficiency results in massive mobilization of progenitor colony-forming unit cells (CFU-C) into the peripheral circulation and results in increased homing of CFU-C in the spleen (Cancelas et al. 2005; Mulloy et al. 2010).

In neutrophils, Rac1 affects cell spreading and adhesion, while Rac2 regulates directed migration and superoxide production (Gu et al. 2003). Rac2-deficient mice exhibit a phagocyte immunodeficiency syndrome. Interestingly, after the description of this phenotype, the case of a patient with leukocytosis and neutrophilia but multiple, recurrent, life-threatening infections in infancy was described. A dramatic decrease of neutrophil infiltration (absence of pus) in areas of infections was noted. The neutrophils of the patient exhibited decreased chemotaxis and



Rac GTPases, Fig. 2 Rac1 and Rac2 GTPases mediate proliferation and survival, and regulate the actin cytoskeleton, adhesion, and migration of hematopoietic stem cells and myeloid and erythroid progenitors in the bone marrow microenvironment, in response to cell surface receptors triggered by cytokines (SCF), chemokines (SDF-1α), and extracellular matrix (fibronectin). Their deficiency results in massive mobilization of HSC/P and increased homing in the spleen, while it also disturbs the actin cytoskeleton of neutrophils and mature erythrocytes

superoxide generation in response to fMLP (*N*-formyl-methionyl-leucyl phenylalanine), as well as reduced rolling on the L-selectin ligand GlyCAM-1; the latter a defect that had been observed in $Rac2^{-/-}$ mouse neutrophils. After LAD (leucocyte adhesion disorder) was ruled out with normal presence of CD11b, CD11c, and CD18, the patient was found to have a p.Asp57Asn (D57N) mutation of Rac2 (Williams et al. 2000). This is a highly conserved position in Rac GTPases as well as in the Ras superfamily as a whole, since it is located in the GTP-binding pocket of the GTPase. The mutation creates a dominant negative protein that is not only dysfunctional but also antagonizes Rac1 and Rac3 for GTP.

Studies in gene-targeted mice demonstrated that Rac1 and Rac2 play an overlapping but essential role in organizing the erythrocyte cytoskeleton. Mice with combined deficiency of Rac1 and Rac2 GTPases in their hematopoietic cells develop hemolytic anemia, as evidenced by concurrent reticulocytosis. $Rac1^{-/-}$; $Rac2^{-/-}$ red blood cells exhibit a disorganized membrane cytoskeleton with increased actin-to-spectrin ratio, F-actin aggregates and meshwork gaps, irregular clamping of band 3, decreased content of the proteins adducin and dematin, and decreased cellular

deformability (Kalfa et al. 2006). These mice develop successful stress-erythropoiesis in the spleen while homeostatic erythropoiesis in the bone marrow is significantly compromised, implying different signaling pathways for homeostatic and stress erythropoiesis (Kalfa et al. 2010). Rac GTPases were also shown to play a role in enucleation by using constitutively active and dominant negative mutants of Rac1 and Rac2; both inhibited enucleation in cultured mouse fetal liver erythroblasts indicating that either inhibition or excessive activation of Rac GTPases inhibits enucleation via disruption of the contractile actin ring in enucleating erythroblasts (Ji et al. 2008).

Combined Rac1 and Rac2 deficiency has also been shown to impair T and B cell development, proliferation, survival, adhesion, and migration, while Rac1 deficiency compromises platelet aggregation, lamellipodia formation, granule secretion, and clot retraction (Mulloy et al. 2010).

Rac GTPases in Cancer

Rac GTPases have been implicated in cellular transformation, oncogenesis, cancer invasiveness, and metastasis. Rac1 can be induced by oncogenes like Ras and collaborates with p53 loss of function to promote transformation in primary fibroblasts. Although no Rac mutations have been reported in tumors, overexpression or increased activity of Rac1 have been found in breast, lung, and colon cancer (Bosco et al. 2009). Activated Rac3 was detected in the malignant precursor B-lymphoblasts in p190-BCR/ABL transgenic mice (Cho et al. 2005) while Rac1 and Rac2 gene targeting was found to significantly delay or abrogate disease development in a p210-BCR/ABL mouse model of chronic myelogenous leukemia (CML) (Thomas et al. 2007). These data suggest that targeting modulation of Rac GTPases activity may provide clinical benefit for patients with CML, Ph-positive ALL, or other cancers.

Summary

The Rac subfamily of Rho GTPases consists of four members: Rac1, Rac2, Rac3, and RhoG. Although they exhibit high-sequence similarity, a great number of their functions are nonredundant. Via proteins that activate them (guanosine exchange factors, GEFs) or deactivate them (GTPase-activating proteins, GAPs), they receive signals from the cell surface after soluble ligand-receptor binding, interaction with the extracellular matrix or mechanical stress on cell surface receptors and propagate them through the appropriate downstream signaling pathways. They regulate many fundamental cellular functions, including actin cytoskeleton, cell adhesion, motility and migration, vesicular transport pathways and cytokinesis, ROS production via NADPH oxidase, gene transcription, and cell proliferation and survival. They have been implicated in many physiological and pathological processes, including hematopoiesis and cancer, and their role continues to be investigated using gene-targeted mouse models.

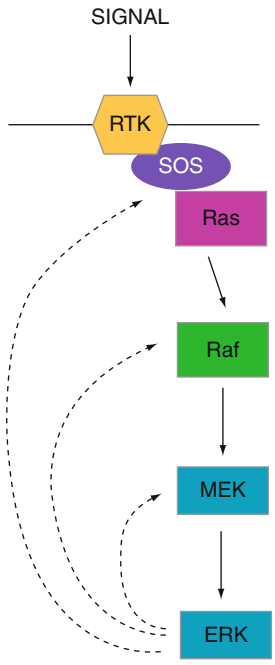
Synonyms

C-Raf; c-Raf-1; Murine leukemia viral (v-raf-1) oncogene homolog 1 (3611-MSV); Murine sarcoma 3611 oncogene 1; Raf1; Raf-1; v-Raf; v-Raf-1 leukemia viral oncogene 1

Historical Background

Raf-1, also known as C-Raf-1 or C-Raf, was identified about 30 years ago as the oncogene (*v-raf*) in the murine sarcoma virus 3611 (3611-MSV) and, in parallel, in the naturally occurring avian retrovirus Mill Hill 2 (MH2). The gene was named after its enhancing effect on fibrosarcoma induction in newborn mice: *R*apidly *a*ccelerated *f*ibrosarcoma, or Raf. The sequences of the oncogenes, *v-raf* (derived from 3611-MSV) and *v-mil* (derived from MH2), were found to encode a serine/threonine protein kinase containing the catalytic, but not the N-terminal regulatory domain of the enzyme. This deletion rendered the protein constitutively active and was responsible for its transforming effect, making Raf the first oncogenic serine/threonine kinase discovered. A pseudogene (*c-raf-2*) and two paralogues of *c-raf-1*, named *a-raf* and *b-raf*, were subsequently identified (Wellbrock et al. 2004; Niault and Baccarini 2010). About 20 years ago, Raf-1 was reported to be phosphorylated in response to growth factor stimulation and was identified as the activator of the ▶ MEK/ERK pathway, the first mitogen-activated protein kinase (MAPK) module discovered that acts downstream of receptor tyrosine kinases; and finally, the finding that Raf-1 could be recruited to the membrane and stimulated by active Ras, already then recognized as a human oncogene, made the picture complete and led to the "textbook" description of the pathway as it is known today. Briefly, pathway activation involves the growth factor–induced dimerization and tyrosine



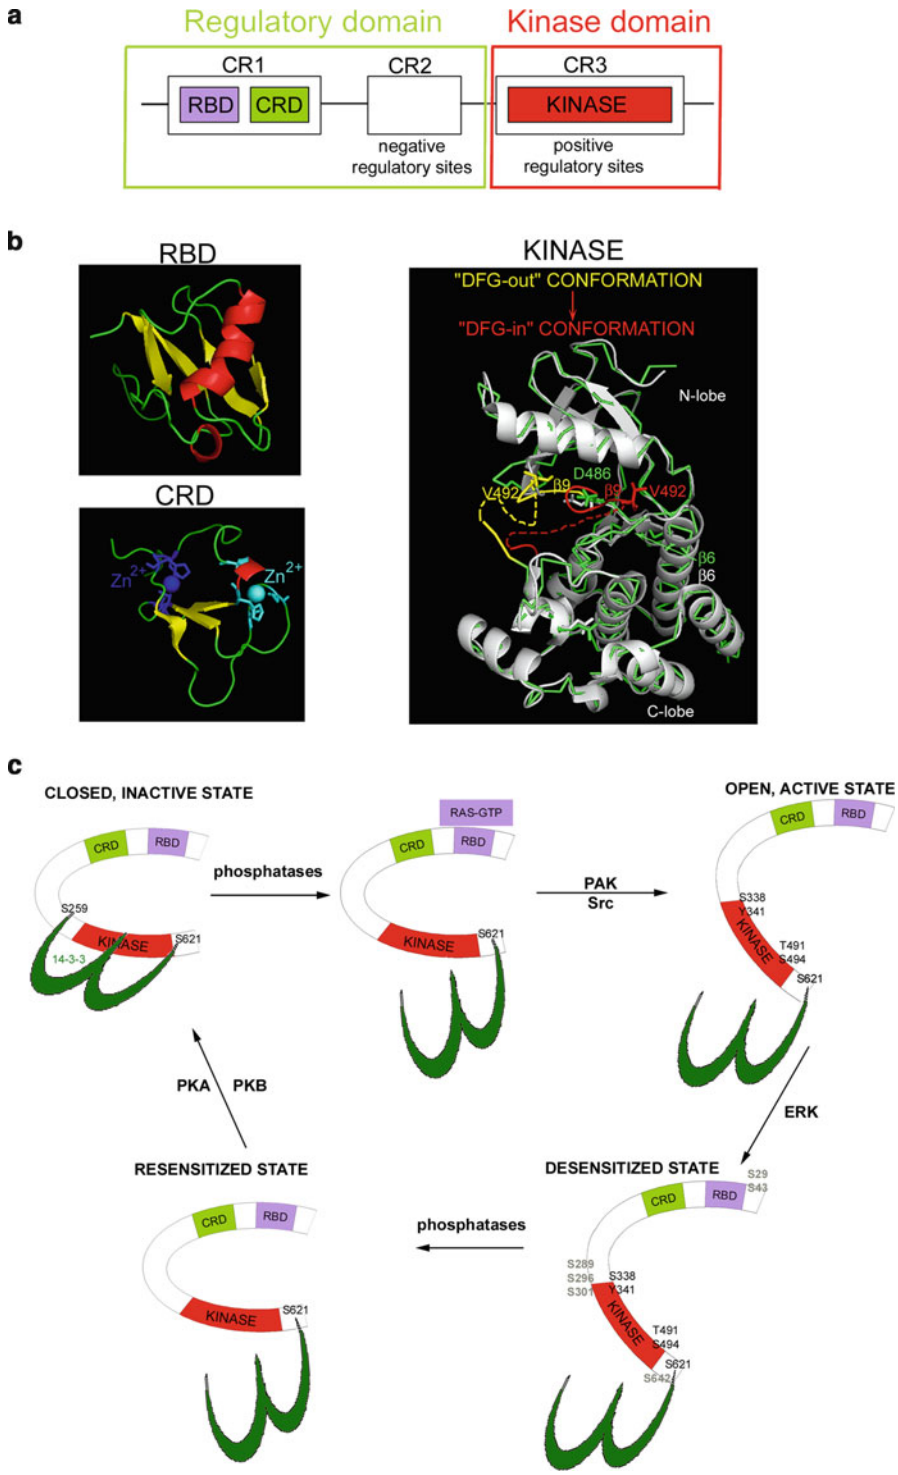
RAF-1 (C-RAF), Fig. 1 *Outline of the ERK pathway*. The Grb2-SOS complex is recruited via the binding of Grb2 to tyrosine phosphorylated residues in the cytoplasmic domain of activated Receptor Tyrosine Kinases (RTK). This brings Sos in the proximity of Ras, which is activated by the exchange of GDP for GTP. GTP-bound Ras recruits Raf to the membrane, where it is activated by phosphorylation (see Fig. 2 for more details on Raf-1 activation). From here, the signal is passed, in the form of phosphorylation, from Raf to MEK to ERK (solid arrows). ERK, in turn, quenches pathway activity at different levels by phosphorylating SOS, B-Raf, Raf-1, and MEK on negative regulatory residues (*broken arrows*)

phosphorylation of cell surface receptors, which in turn triggers the binding of a complex containing a scaffolding protein, Grb2, and a nucleotide exchange factor for Ras, SOS. The interaction with SOS catalyzes the exchange of GDP for GTP on Ras; with the help of scaffolding proteins (e.g. KSR), active, GTP-bound Ras can now induce the formation of membrane-associated Raf/MEK/ERK complexes. Each protein in the cascade can activate its downstream target via phosphorylation, i.e., Raf can phosphorylate MEK and MEK can phosphorylate ERK. Active ERK can induce the expression of several genes involved in cell proliferation, differentiation, and survival. In addition, active ERK feeds back on SOS, Raf, and MEK, providing a mechanism for signal attenuation [Fig. 1; reviewed in (Niault and Baccarini 2010)]. Adaptor proteins other than KSR have been reported to direct pathway components to distinct subcellular compartments, with potentially different signaling outcomes (Kolch 2005; McKay and Morrison 2007), and inhibitors of the pathway can regulate it at different levels (Kolch 2005).

The study of the essential functions of Raf-1 in conventional and conditional knockout mice [(Galabova-Kovacs et al. 2006) and references therein] has revealed that most of Raf-1's essential functions are not linked to the activation of the MEK/ERK pathway and to proliferation, but rather to pathways that counteract apoptosis and promote migration and differentiation. These new roles of Raf-1 are based on its interaction with three other kinases: the Rho-dependent kinase Rok-α, also known as ▶ ROCK2 (Ehrenreiter et al. 2005; Piazzolla et al. 2005; Ehrenreiter et al. 2009), involved in cytoskeletal rearrangements; the mammalian Sterile-20-like kinase-2, MST2 (O'Neill et al. 2004), homolog of *Drosophila*'s Hippo; and the apoptosis signal-regulating kinase 1, ASK1 (Yamaguchi et al. 2004), upstream regulator of the p38 and JNK pathways.

Structure of Raf and Activation of Its Kinase Function

Structure: The structure of Raf consists of three conserved regions [Fig. 2a; see also (Baccarini 2005) and references therein]. The regulatory/autoinhibitory domain of Raf is composed of two *C*onserved *R*egions, CR1 and CR2. CR1 contains the RBD – *R*as *B*inding *D*omain, which is required for membrane recruitment of the protein after activation by Ras; and the CRD – *C*ysteine-*R*ich *D*omain, which, besides being a secondary Ras binding site, is responsible for Raf-1 autoinhibition. CR2 is rich in Ser/Thr residues, whose phosphorylation can inactivate protein function (i.e., negative regulatory residues such as S259, whose dephosphorylation is prerequisite for Ras binding and Raf activation). CR3 is responsible for the catalytic activity and contains residues (S338, Y341) whose phosphorylation is involved in growth factor-induced kinase activation. The three-dimensional structure of the RBD [NMR structure, PDB 1RFA, (Emerson et al. 1995)], CRD [NMR, PDB 1FAR, (Mott et al. 1996)], and of the kinase domain [X-ray, PDB 3OMV, (Hatzivassiliou et al. 2010)] is known. The RBD domain fold resembles that of ubiquitin, while the CRD domain is an atypical C1 domain, which binds to phosphatidylserine and needs Zn^{2+} ions to preserve its folded



RAF-1 (C-RAF), Fig. 2 *Domain Structure of Raf-1 and mechanism of activation.* (**a**) Schematic representation of the domain structure of Raf-1. CR1, encompassing the RBD and the CRD, and CR2, containing some of the phosphorylation sites which restrain Raf-1 activity, comprise the regulatory domain; CR3 consists essentially of the kinase domain and contains the positive regulatory sites whose phosphorylation stimulates Raf-1 activity. (**b**) three-dimensional structure of the RBD, with its ubiquitin fold, of the Zn^{2+}-bound CRD, and of the Raf kinase domain. The inactive structure of the Raf-1 kinase domain

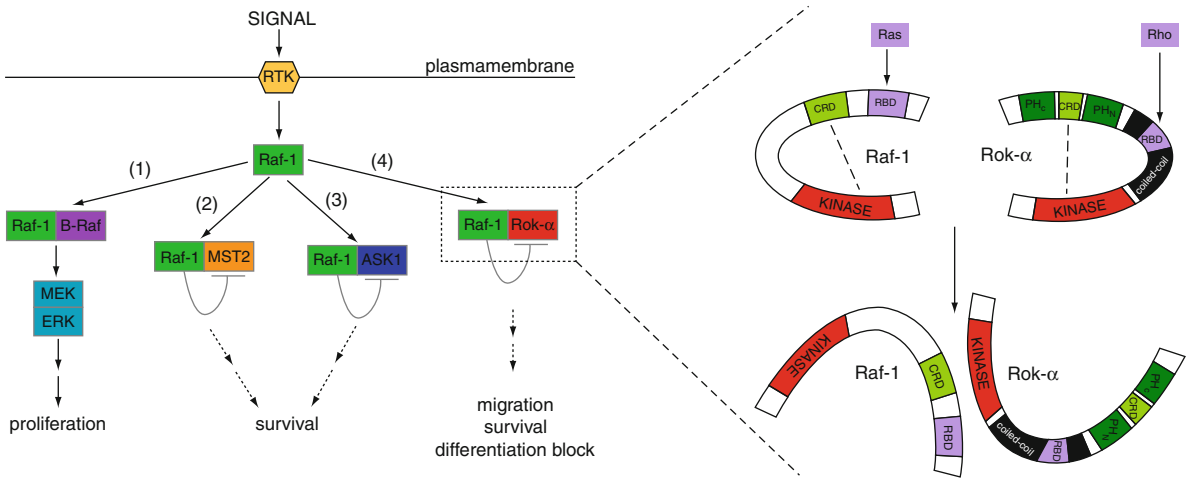
structure (Fig. 2b, left panel). The structure of the kinase domain consists of a smaller (N-terminal) and a larger (C-terminal) lobe. The latter contains the activation segment (the region between the DFG. . .APE motif, from D486 to E515), including the P-loop and β-strand 9 (β9). The P-loop is responsible for the correct positioning of both the adenosine and the gamma-phosphate of ATP for catalysis. The inactive conformation of the enzyme ("DFG-out", yellow) is stabilized by hydrophobic interactions between the P-loop and the activation segment (Fig. 2b, right panel). Kinase activation is mediated by phosphorylation of serine/threonine residues in the activation segment (T491 and S494), which results in a conformational change from the "DFG-out" to the "DFG-in" conformation (red). In the "DFG-in" conformation, the β9 strand of the N-lobe interacts with the β6 strand of the C-lobe of the kinase, closing the cleft between the two lobes and switching the enzyme to its active state. The β9 strand contains the V482 residue which corresponds to the B-Raf residue frequently mutated to E in human melanoma [V600E; activating B-Raf mutation (Wellbrock et al. 2004)]. Interestingly, corresponding mutations in Raf-1, which would have the same activating effect, have not been reported.

Activation–Inactivation: In the inactive state of Raf, the N-terminal, regulatory domain of the protein binds to its kinase domain and inhibits its activity [Fig. 2c; see also (Wellbrock et al. 2004; Niault and Baccarini 2010)]. This conformation is stabilized by the binding of 14-3-3 proteins, which recognize two phosphorylated Raf-1 residues: S259 on the N-terminal and S621 on the C-terminal part of the protein. The current model of Raf-1 activation postulates that this binding must be disrupted to enable Raf-1 activation. This process is accomplished by protein phosphatases 1 and 2A, which dephosphorylate residue S259. 14-3-3 proteins remain bound to the phosphorylated S621 and maintain a productive conformation of the kinase domain. After S259 dephosphorylation, Raf-1 can be recruited to the membrane by binding to activated Ras, primarily via the RBD. Ras binding is followed by disruption of the inhibitory interaction between the regulatory and the kinase domain of the protein. The activation process is completed by the phosphorylation of the activating residues in the CR3 region (T491, S494), which stabilizes the active, "DFG-in" conformation. Inactivation of Raf-1 occurs via the phosphorylation on its negative regulatory residues by ERK, which is followed by the dephosphorylation of activating residues by PP2A. Finally, PKA/▶ PKB rephosphorylates the residue S259, making the rebinding of 14-3-3 possible (Wellbrock et al. 2004; Niault and Baccarini 2010).

Raf-1-Containing Complexes and Their Biological Functions

Raf-1 can also be activated by (Ras-dependent) homodimerization or by heterodimerization with other Rafs, particularly B-Raf. As part of this complex, Raf-1 can stimulate the MEK/ERK pathway and therefore regulate cell proliferation and several other biological functions (Fig. 3, pathway 1). In most cells and tissues, however, Raf-1 is not essential for MEK/ERK activation and proliferation. Instead, Raf-1 is required to promote survival, either through the inhibition of proapoptotic kinases such as MST2 and ASK1 (Fig. 3, pathways 2 and 3) or by restraining the cytoskeleton-based kinase Rok-α, which regulates the trafficking of the death receptor Fas (Fig. 3, pathway 4; and right panel). Interaction with, and inhibition of Rok-α is also the molecular basis of Raf-1's role in cell migration, in keratinocyte differentiation, and in Ras-driven

RAF-1 (C-RAF), Fig. 2 (continued) (PDB: 3OMV, (Hatzivassiliou et al. 2010); ribbon representation, *in green*) is superimposed on the active structure of the B-Raf kinase domain (PDB: 2FB8, (King et al. 2006); cartoon representation, *in white*). The aminoacid numbering corresponds to the human Raf-1 protein. The inactive "DFG-out" conformation is shown in yellow, the active "DFG-in" conformation in red. Note the interaction of the β9 strand of the N-lobe (*red*) with the β6 strand of the C-lobe in the "DFG-in" conformation. The start of the DFG (D486) and the position of the V492 residue corresponding to the V600 in B-Raf frequently mutated in melanoma are indicated. (**c**) Mechanism of Raf-1 activation. In quiescent cells, intramolecular inhibition, stabilized by 14-3-3 binding to the phosphorylated S259 and S621 sites, prevents Raf-1 activation. The transition to the active state is mediated by the dephosphorylation of 259 and Ras binding, which recruits Raf-1 to the membrane, where phosphorylation of activating residues occurs. The Raf-1 signal is quenched by the phosphorylation of negative regulatory sites (*in grey*) mediated by active ERK, which results in kinase desensitization, followed by dephosphorylation of both positive and negative regulatory sites (resensitized state). Finally, rephosphorylation of S259 restores the close, inactive conformation of Raf-1. The residues phosphorylated at each step are shown at their approximate localization in the molecule. The kinases responsible for phosphorylation of the positive (PAK, Src) or negative (ERK, PKA, PKB) regulatory sites are shown



RAF-1 (C-RAF), Fig. 3 *Interactions of Raf-1 with different partners and their biological consequences. Left*, As part of a Raf dimer, Raf-1 functions as a MEK/ERK activator and stimulates many cellular functions, in particular proliferation (1). Most of the essential Raf-1 functions rely on protein/protein interaction and are independent of Raf-1 kinase activity. Binding of Raf-1 to the MST2 (2) and ASK-1 (3) kinases promotes survival by reducing the strength of the downstream proapoptotic signal. Interaction with the cytoskeleton-based kinase Rok-α (4) promotes migration and survival and restrains differentiation. *Right*, molecular basis of Rok-α inhibition by Raf-1. Raf-1 and Rok-α share similar autoinhibitory domains, which, in quiescent cells, interact with the kinase domains and restrain their activity. When the kinases are activated by the respective upstream GTPases, autoinhibition is relieved, and the regulatory domain of Raf-1 is free to bind to the kinase domain of Rok-α and modulate its kinase activity

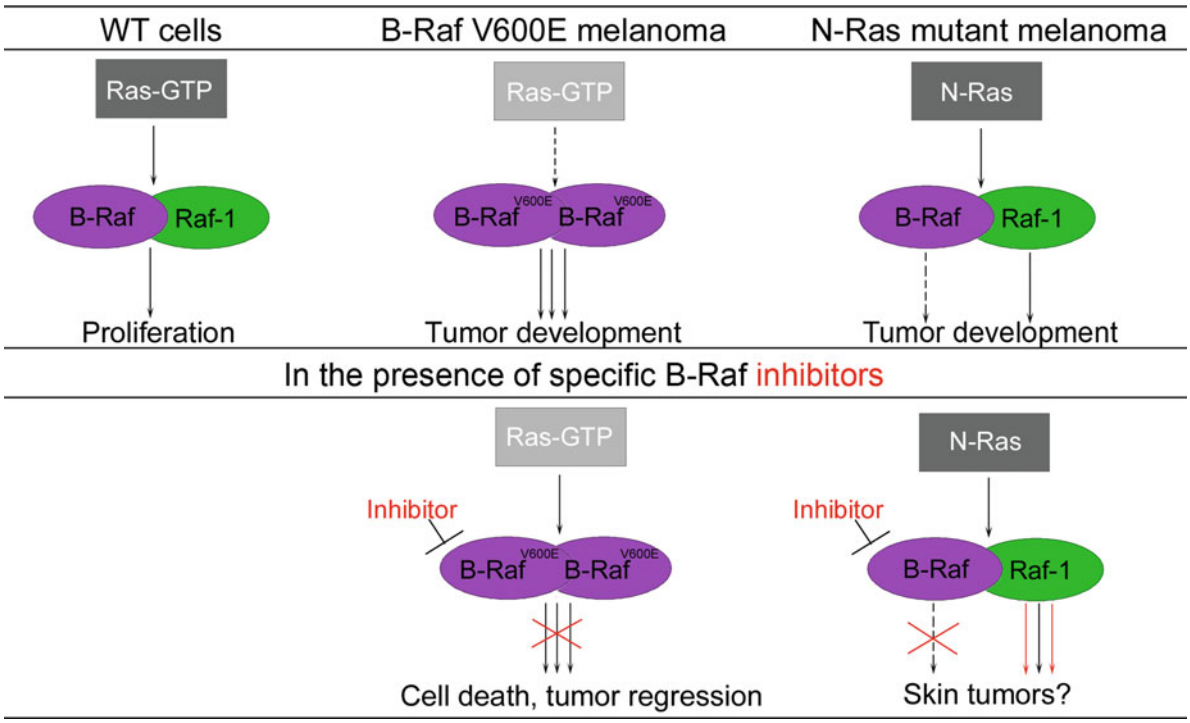
epidermal tumorigenesis (Niault and Baccarini 2010; Wimmer and Baccarini 2010; Kern et al. 2011).

The following section describes the individual Raf-1-containing complexes.

The Raf-1/B-Raf complex (Fig. 3, pathway 1): All three Raf isoforms, ▶ A-Raf, B-Raf, and Raf-1, can mediate MEK/ERK activation. Conditional mutagenesis has revealed that B-Raf is the essential MEK activator in various cells and tissues (Galabova-Kovacs et al. 2006; Niault and Baccarini 2010). A-Raf and Raf-1 can heterodimerize with B-Raf, yielding a MEK kinase more potent than the individual monomeric forms. Whether A-Raf or Raf-1 are preferred B-Raf partners in the context of the heterodimer is yet unknown; however, both A-Raf and Raf-1 must be ablated to reduce MEK/ERK phosphorylation in fibroblasts (Mercer et al. 2005), consistent with an interchangeable role of these two kinases as dimer subunits. The heterodimerization of Raf has been in the limelight since the discovery that B-Raf inhibitors currently in the process of being approved for the treatment of melanoma patients activate the Raf/MEK/ERK pathway, instead of stopping it (see below; and Fig. 4).

Raf-1 and MST2 (Fig. 3, pathway 2): In mammalian cells, MST2 is activated by stress signals and causes apoptosis acting upstream of the mammalian Hippo signaling pathway (Pan 2010). MST2 was identified as a Raf-1 interacting partner using mass spectrometry (O'Neill et al. 2004). In quiescent cells, MST2 is phosphorylated on two negative regulatory sites in its N-terminal and C-terminal region (Romano et al. 2010). This diphosphorylated form can interact with Raf-1 (region between amino acids 150–303) and this inhibits MST2 activation by preventing homodimerization. This interaction is disrupted by proapoptotic stimuli, enabling MST2 activation by the tumor suppressor RASSF1.

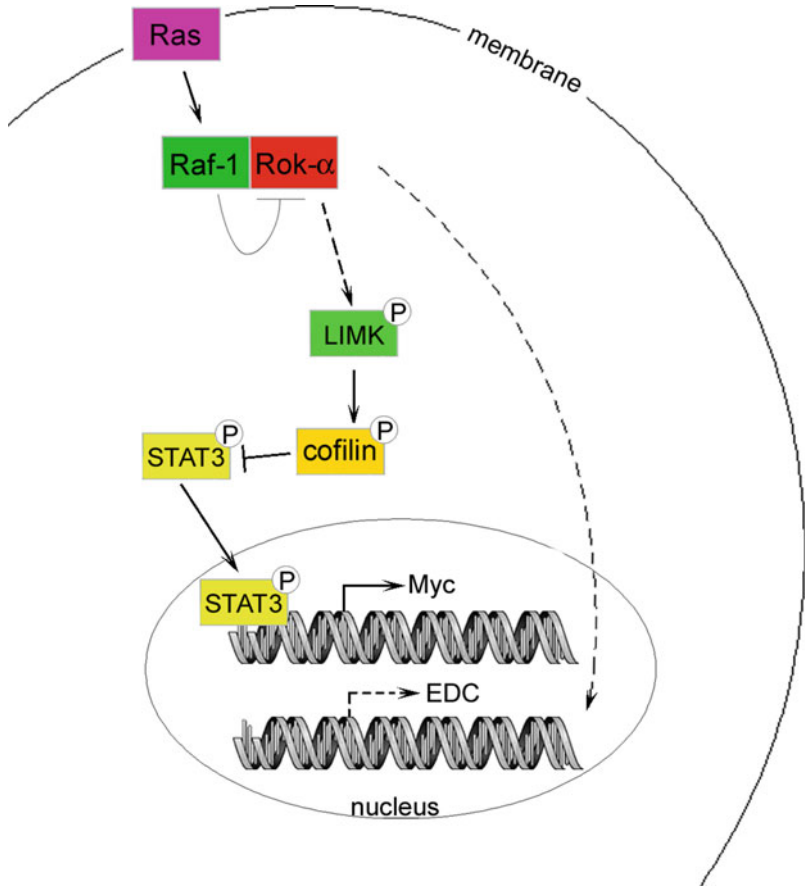
Raf-1 and ASK1 (Fig. 3, pathway 3): ASK1 is a Ser/Thr kinase which acts upstream of JNK and p38 and promotes apoptosis induced by stress or death receptors. Cardiac-specific ablation of Raf-1 induces apoptosis in the cardiac muscle in vivo and leads to a transient increase in ASK1, JNK, and p38 activity during postnatal heart development, without affecting the MEK/ERK pathway (Yamaguchi et al. 2004). Concomitant ablation of ASK1 rescues the phenotype of Raf-1 conditional knockout mice, indicating a causal role of ASK1 in the abnormalities observed in Raf-1 knockout hearts and suggesting that Raf-1 limits ASK1 activity in cardiomyocytes. How exactly Raf-1 inhibits



RAF-1 (C-RAF), Fig. 4 *Paradoxical activation of MEK/ERK pathway by B-Raf inhibitors. Upper panel*, in wild type (WT) cells, Raf dimer formation and MEK/ERK activation are stimulated by extracellular signals acting through RTKs and Ras. In melanoma cells harboring constitutively active B-RafV600E, MEK/ERK activation is Ras and Raf-1-independent; while melanoma cells harboring mutated N-Ras activate MEK/ERK by stimulating the formation of B-Raf-Raf-1 dimers. *Lower panel*, B-Raf inhibitors will block B-RafV600E kinase activity, reducing ERK activation and inducing a proliferation block and subsequent tumor regression. However, in cells harboring NRAS mutations, inhibitors can induce Raf dimerization and ERK activation. This is due to the fact that dimers containing only one functional kinase subunit are active as MEK kinases. Such dimers may arise if the inhibitors used have fast off-rates, or if low concentrations of inhibitors are used. In both situations, the conformational change induced by the inhibitors would suffice to stimulate dimerization, but not to completely inhibit the resulting dimeric kinase. This mechanism may be linked to the development of drug-related tumors observed in melanoma patients treated with B-Raf inhibitors

ASK1 has not yet been established, but it is known that this function of Raf-1 is independent of the MEK/ERK pathway, although the phosphorylation of the activating Raf-1 regulatory residues S338 and S339 is a prerequisite, at least in endothelial cells (Alavi et al. 2007). Raf-1 physically interacts with the N-terminal autoinhibitory domain of ASK1; it is therefore possible that by doing so it will promote and/or stabilize an inactive ASK1 conformation (Chen et al. 2001).

Raf-1 and Rok-α (Fig. 3, pathway 4): In mammalian cells, the Rho effector Rok-α is responsible for cytoskeletal rearrangements essential for cell adhesion and motility. Conditional gene ablation studies have revealed that Rok-α is hyperactive and mislocalized in the absence of Raf-1 (Ehrenreiter et al. 2005; Piazzolla et al. 2005). Importantly, chemical or genetic inhibition of Rok-α rescues all phenotypes of Raf-1 knockout mouse embryonic fibroblasts, defining Rok-α hyperactivity as the rate-limiting factor in this context (Piazzolla et al. 2005). In addition, both the cellular phenotypes and Rok-α hyperactivity could be rescued by complementation with Raf-1 mutants devoid of kinase activity, as well as by mutants featuring the isolated Raf-1 regulatory domain, indicating that the physical presence of at least part of Raf-1 is necessary for the inhibition of Rok-α activity (Ehrenreiter et al. 2005; Piazzolla et al. 2005). The molecular basis of Raf-1 interaction with Rok-α is understood in some detail. Both Raf-1 and Rok-α are modular kinases featuring a similar domain structure. In quiescent cells, the activity of Raf-1 and Rok-α is restrained by intramolecular inhibition. The negative



RAF-1 (C-RAF), Fig. 5 *Raf-1-mediated Rok-α inhibition is essential for the establishment and maintenance of Ras-induced epidermal tumors.* Activated Ras stimulates the interaction between Raf-1 and Rok-α. The resulting attenuation of Rok-α leads to decreased expression of the epidermal differentiation cluster genes (EDC) and reduces the phosphorylation of cofilin (via ▶ LIMK). Since phosphocofilin, in turn, inhibits the pro-proliferative STAT3/myc pathway, Raf-1-mediated Rok-α attenuation supports Ras-driven tumorigenesis

regulatory domain (cysteine-rich region, CRD) of each protein can interact with its own kinase domain and inhibit its activity, likely by preventing substrate binding. Upon mitogenic stimulation, binding to activated small G-proteins (Ras for Raf-1 and Rho for Rok-α) relieves autoinhibition and, at the same time, makes the interaction between the regulatory domain (CRD) of Raf and the kinase domain of Rok possible (Niault et al. 2009). In this situation, the autoinhibitory domain of Raf-1, much like an ill-fitting lego brick, can restrain the activity of the Rok-α kinase domain without blocking it completely (Fig. 3, right panel). This mechanism of inhibition in *trans* is the first example of kinase regulation mediated by physical interaction rather than phosphorylation on negative regulatory residues.

Raf-1 and Cancer

A wealth of reports has implicated Raf isoforms, particularly B-Raf, in different aspects of tumor development (Niault and Baccarini 2010; Maurer et al. 2011). The next chapters will focus on two recently described functions of Raf-1 in melanoma and squamous cell carcinoma, both of which relay on Raf-1's ability to form physical complexes with other kinases.

Raf-1-B-Raf interaction and melanoma: MEK/ERK signaling is particularly important in melanoma. Somatic mutations occur in B-Raf and N-Ras in ~50% and ~15% of cutaneous melanomas, respectively (www.sanger.ac.uk/genetics/CGP/cosmic/). The most frequent mutation in B-Raf is the V600E mutation, which causes constitutive activation of the kinase and thus of the MEK/ERK pathway. After this discovery, tremendous efforts were made to find inhibitors targeting the mutated form of B-Raf. Surprisingly, these inhibitors could inactivate the enzyme in vitro, but activated the RAF/MEK/ERK pathway in cells not harboring the V600E mutation. The molecular basis of the Raf-inhibitor paradox is the ability of Raf enzymes to heterodimerize and form a potent MEK kinase, even when only one dimer subunit is enzymatically active [Fig. 4; reviewed in (Cichowski and Janne 2010;

Wimmer and Baccarini 2010)]. Selective inhibitors cause a conformational change in the structure of B-Raf, which promotes the dimerization of this "inhibited" form of B-Raf with Raf-1 or A-Raf. This leads to the stabilization of an active MEK kinase and to the stimulation of the MEK/ERK pathway. Inhibitor-induced stabilization of Raf hetero- or homodimers is predicted to be particularly dangerous in cells containing mutations that stimulate dimer formation, such as melanoma cells with an N-Ras mutation, as indicated by a recent animal study (Heidorn et al. 2010), and also in any other tumor-prone cell. This mechanism might be the reason for the appearance of keratoacanthomas and squamous cell carcinomas in about 30% of patients treated with Raf inhibitors in clinical studies (Arkenau et al. 2011).

Raf-1-Rok-α interaction and Ras-driven epidermal carcinogenesis: To date, Raf-1 is the only Ras effector that has been shown to be essential for the maintenance of Ras-driven tumors. This has been achieved by conditional gene ablation experiments conducted in mice with epidermis-restricted Raf-1 ablation. Besides showing defects in wound healing, keratinocyte adhesion and migration (Ehrenreiter et al. 2005), these animals are refractory to epidermal tumors caused by Ras activation; more importantly, Raf-1 ablation causes the complete regression of established tumors. Thus, Ras-driven tumors are addicted to endogenous Raf-1, constituting a prime example of non-oncogene addiction. Mechanistically, Ras drives the formation of a complex between Raf-1 and Rok-α, ultimately resulting in Rok-α inhibition. In the absence of Raf-1, hyperactive Rok-α drives keratinocyte differentiation and tumor regression via a pathway involving phosphorylated cofilin, the inhibition of STAT3 phosphorylation, and of Myc expression (Fig. 5). Thus, inhibiting Raf-1-Rok-α complex formation, either by silencing the *Raf-1* gene or by using small molecule inhibitors which can disrupt the complex, may be a viable strategy for the (co-)therapy of Ras-driven epidermal tumors (Ehrenreiter et al. 2009).

Summary

Born as the first serine/threonine kinase oncogene and intensively studied as the link between Ras and the mitogenic MEK/ERK pathway, Raf-1 is coming of age as a versatile signal transducer with multiple partners impinging on cell motility, differentiation, and survival. The basis for this is its modular structure, featuring a kinase domain kept in check by an autoinhibitory domain. This autoinhibition is relieved by intricate regulatory mechanisms involving dephosphorylation of negative regulatory sites, Ras binding, and phosphorylation of activating sites. Once autoinhibition is relieved, Raf-1 can function as a MEK kinase, in the context of homodimers or of Raf heterodimers, but it can also exert kinase-independent functions by binding to, and directly regulating, serine/threonine kinases operating in distinct pathways. These functions in pathway cross-talk are the essential ones, as revealed by conventional and conditional gene ablation studies. One obvious unresolved question in this context is how extracellular cues direct Raf-1 (or, for that matter, other signal transducers) to the appropriate signaling complex in order to implement the correct biological response. One of the kinase-independent functions of Raf-1, the inhibition of the cytoskeleton-based kinase Rok-α, is essential for the development and maintenance of Ras-driven epidermal tumors. Will other Raf-1 interactions prove similarly essential in tumorigenesis, possibly in the context of other cell types/tissues? And if yes, will it be possible to design inhibitors for molecule-based therapy? The key to these questions lies in the further investigation of Raf-1's role in tumor models in vivo and in obtaining structural information on the complexes between Raf-1 and its interacting proteins.

Historical Background

The receptor activity-modifying protein (RAMP) family was first reported in 1998 during attempts to identify the cell surface receptor for a neuropeptide known as calcitonin gene-related peptide (CGRP) (McLatchie et al. 1998). Formerly, a protein known as the calcitonin receptor-like receptor (CLR) was thought to be the receptor for CGRP but no study had convincingly shown that this was the case. McLatchie and colleagues were able to show that CLR needs RAMP1 for a CGRP receptor to be formed. RAMP1 assists CLR in reaching the cell surface. Thus, RAMP1 and CLR together at the cell surface form the receptor for CGRP, which binds and activates this protein complex,

leading to downstream signaling events such as an accumulation of intracellular cAMP. In this same study, two other related proteins were found, named RAMP2 and RAMP3. Each of these proteins could also assist CLR in reaching the cell surface but remarkably, CGRP was less effective at activating these protein complexes. Instead, a peptide similar to CGRP, called adrenomedullin (AM), preferentially activated them. Thus, RAMPs can be considered as "pharmacological switches" by virtue of their ability to change the peptide hormone for which CLR has a preference.

Overview

The receptor complexes that are formed by RAMPs interacting with CLR are shown in Fig. 1. Since RAMPs were first identified, a great deal has been learned about their functions. It is now broadly understood how they change peptide recognition but also that they have other functions and interact with other receptors.

Pharmacological Importance of RAMPs

At first it was thought that the way RAMPs could change peptide preference was by changing the conformation of the receptor protein, CLR, but it is now known that RAMPs also play their own role in binding CGRP and AM and also small molecule drugs (Sexton et al. 2009). For instance, RAMP1 and CLR both participate in the binding of the drugs Olcegepant and Telcagepant. This makes the drugs extremely selective for the CGRP receptor; they have only low affinity for the two AM receptors or for the RAMP1-based AMY_1 receptor. RAMPs also change the pharmacology of another receptor, the calcitonin receptor (CTR). This is the closest protein relative to CLR and can also interact with all three RAMPs. In this case, CTR is a receptor for the peptide hormone, calcitonin, when it is expressed alone in cells. However, when CTR is expressed with RAMPs, the resulting RAMP/CTR complexes have a preference for a peptide hormone known as amylin (Fig. 1) (Poyner et al. 2002).

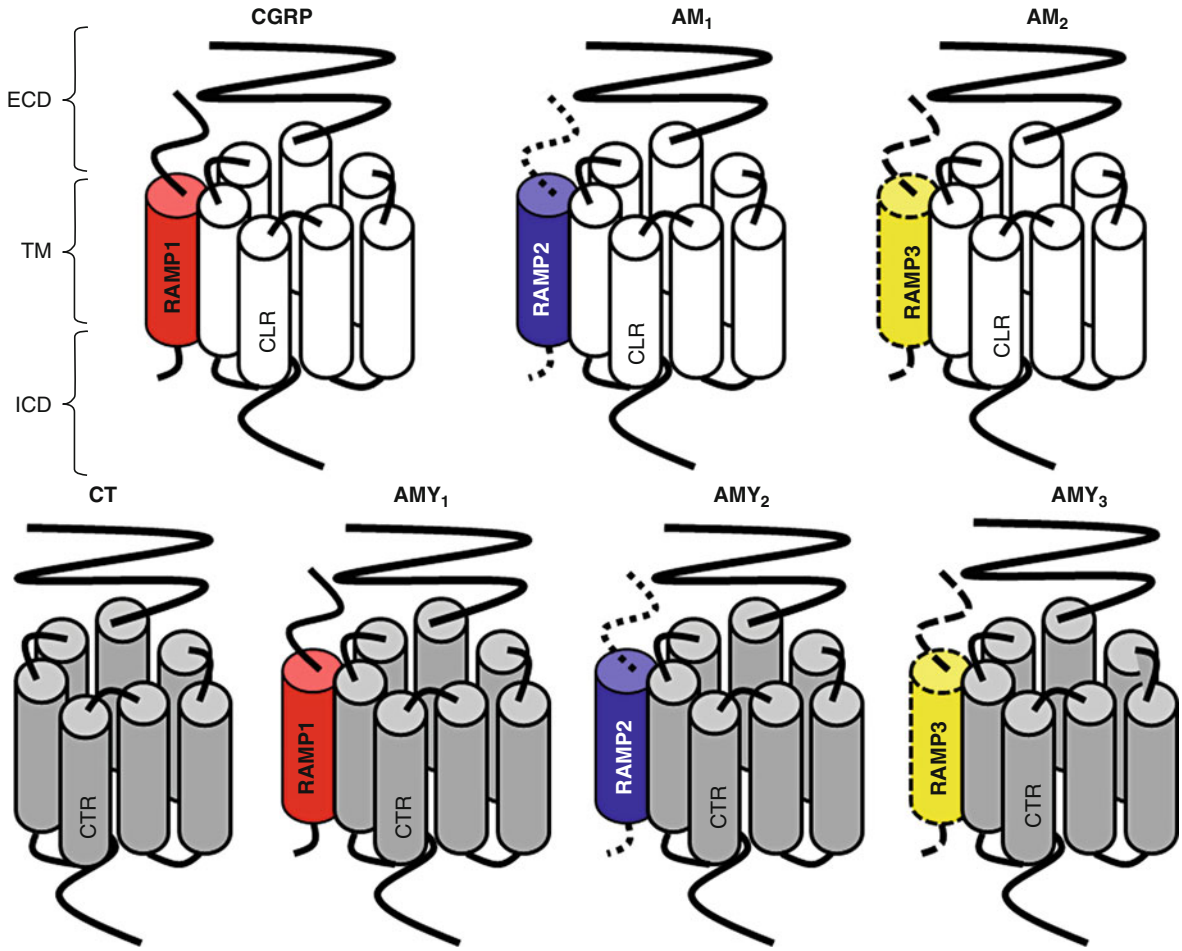
RAMPs and Cellular Signaling

CLR and CTR are proteins known as G protein-coupled receptors (GPCRs). As their name suggests, these proteins interact with G proteins (guanine nucleotide binding proteins) to initiate intracellular signaling. There are several types of G proteins that initiate different downstream signaling events and many receptors can interact with more than one G protein to regulate cellular function. For instance, G_s G proteins activate ▶ adenylate cyclase to cause increases in cAMP, while G_q G proteins activate phospholipase C to hydrolyze membrane inositol phosphates to form inositol trisphosphate (▶ IP_3 Receptors) and diacyl glycerol (DAG); these in turn mobilize intracellular calcium and activate various kinase proteins. Both CLR and CTR can couple to G_s and signal via adenylate cyclase/cAMP pathway. In the case of the RAMP/CTR complexes, that is the amylin receptors, the amount of amylin binding can be influenced by G protein type in a RAMP-dependent manner (Morfis et al. 2008), and conversely RAMP interaction with the CTR can change the receptor preference for different G proteins. For example, the RAMP1/CTR (AMY_1) and RAMP3/CTR (AMY_3) receptors have greater relative preference for G_s over G_q G proteins than the CTR when expressed alone (Morfis et al. 2008), and this may change to overall cellular response to receptor activation.

The activity of a GPCR must be carefully controlled to make sure that cells are kept responsive when they need to be. In many cases, a process called desensitization occurs after a GPCR has been activated, which reduces the amount of signal that the receptor can generate. Following this, GPCRs are often removed from the cell surface membrane; the receptors are internalized. The GPCR may then be returned to the cell surface and, thus, recycled or it can be degraded and not returned. RAMPs can also modulate these internalization and recycling processes. RAMP3 has a specific sequence of amino acids, a PDF-like domain, in its intracellular domain. This allows it to interact with different regulatory proteins to RAMP1 and RAMP2, such as N-ethylmaleimide-sensitive factor (Bomberger et al. 2005). Therefore, in model systems, RAMP3/CLR (AM_2 receptor) complexes can be recycled unlike AM_1 and CGRP receptors.

RAMP Interactions with Other Receptors

There is accumulating research which shows that RAMPs may have much broader roles and control aspects of the activity of many receptors. For example, the calcium sensing receptor which is unrelated to CLR or CTR requires RAMP1 or RAMP3 for it to reach the cell surface and therefore signal (Bouschet et al. 2005). The VPAC1 receptor can associate with RAMP2 and this leads to enhanced, agonist-mediated



Ramp, Fig. 1 Receptor complexes that are formed when CLR and RAMPs or CTR and RAMPs associate. CLR is the seven transmembrane (*TM*) protein in *white* and CTR is the seven TM protein in *gray*. RAMP1 is shown in *red*, RAMP2 in *blue*, and RAMP3 in *yellow*. RAMP1 with CLR is known as the CGRP receptor whereas RAMP2 or RAMP3 with CLR are known as AM_1 and AM_2 receptors, respectively. CTR is the receptor for calcitonin (*CT*) but with RAMP1 it is an AMY_1 (amylin subtype 1) receptor. AMY_2 and AMY_3 receptors are formed when RAMP2 and 3 associate with CTR. *ECD* extracellular domain, *ICD* intracellular domain

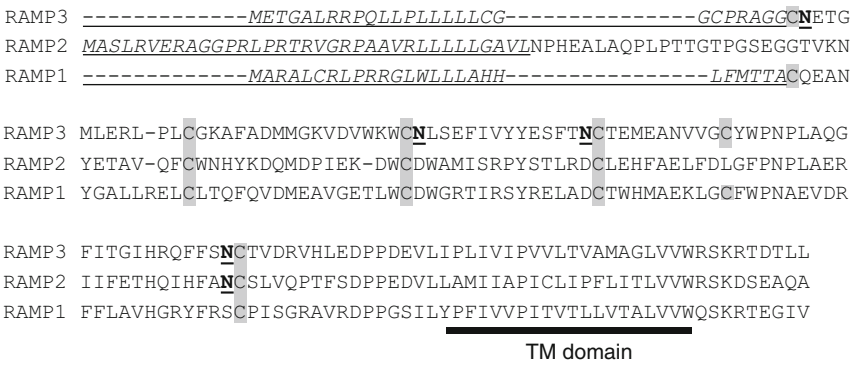
phosphoinositide breakdown but there is no effect on cAMP production (Christopoulos et al. 2003). The secretin receptor is another example of a RAMP-interacting GPCR but in this case the reason why these proteins associate has not yet been revealed.

The Structure of RAMPs

Sequence analysis shows that the RAMPs all have a single transmembrane region, with a small cytoplasmic tail of around 10 amino acids and a much larger N-terminus of around 100 amino acids (Figs. 1 and 2). All RAMPs have four cysteines that take part in formation of two disulfide bonds; RAMPs 1 and 3 have an extra cysteine pair which form a third disulfide. A crystal structure is available for the majority of RAMP1, both by itself and in combination with CLR (Kusano et al. 2008; Koth et al. 2010). The extracellular domain is a trihelical structure. Residues at the base of helix 2 and the C-terminus of helix 3, among others, appear to be important for making contact with CLR; the region connecting these two helices may be particularly important for peptide binding (Fig. 3).

RAMP Expression

RAMPs appear to be widely expressed in mammals, although there are actually very few studies where the



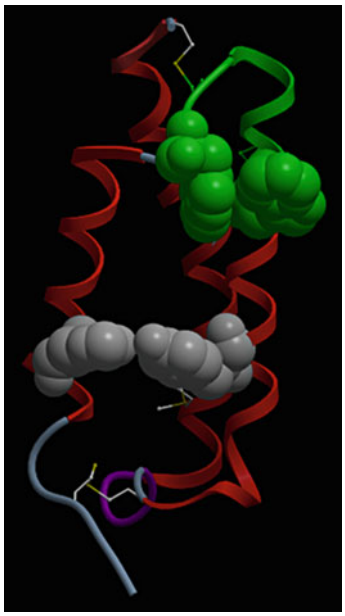
Ramp, Fig. 2 Amino acid sequences of human RAMPs. Comparison of the sequences of human RAMPs 1, 2, and 3. Signal peptides are shown in italics, potential glycosylation sites are in bold. Cysteines involved in disulfides are shaded. *TM* transmembrane

proteins themselves have been measured, rather than mRNA. This has been because there have been few reliable antibodies. This has meant that it has been difficult to properly colocalize RAMPs and receptors. A recent study has reported the co-expression of RAMP1 and CLR in neurons of the human and rodent trigeminal ganglion, which is involved in pain transmission (Eftekhari et al. 2010). More studies of this nature are needed to confirm the physiological significance of the AM and amylin receptor subtypes and the interactions of RAMPs with other receptors.

Several animal models of RAMP under or overexpression have been generated. Mice which selectively overexpress human RAMP1 in neurons are sensitized to CGRP, whereas those which overexpress RAMP2 in the smooth muscle were sensitized to the effects of AM (Tam et al. 2006; Zhang et al. 2007). These types of observation help to confirm that these are valid components of AM and CGRP receptors in vivo. Mice that genetically lack RAMP2 (RAMP2 knockout mice) have severe defects and show that RAMP2 is essential for the blood and lymphatic vascular systems to develop properly in the embryo (Fritz-Six et al. 2008). Interestingly, RAMP3 knockout mice do not have any obvious phenotype, suggesting that RAMP3, and the AM_2 receptors which it forms with CLR, has different functions to the AM_1 receptor (Dackor et al. 2007).

Evolutionary Considerations

There is some evidence that a form of CGRP first evolved in insects. In *Drosophila melanogaster*, the protein CG17415 shows homology to CLR. It is activated by the diuretic hormone DH31 and this response can be amplified when it is co-expressed with human RAMP1 or RAMP2 (Johnson et al. 2005). However,



Ramp, Fig. 3 Structure of the extracellular domain of RAMP1. Structure based on 2YX8 in the protein structure database. Helices are shown in *red*. Residues at the base of helix 2 and the C-terminus of helix 3 likely to be involved in CLR recognition are in *gray*; the region between helices 2 and 3 which may be important for ligand binding is in *green*

no ortholog of a RAMP has yet been identified in *Drosophila*. RAMPs are certainly present in bony fish, where they are found with homologues of CLR and AM. The functions of RAMPs have been best studied in the pufferfish, *Takifugu obscurus*. This expresses five forms of AM, three forms of CLR, and five RAMPs. The expanded AM/RAMP/CLR family appears to be involved in fluid homeostasis (Nag et al. 2006). The evolutionary history of RAMPs between insects and fish remains obscure.

Summary

This entry has provided a snapshot of what RAMPs are and what they are currently understood to do. Most of this research has been performed in isolated cellular systems because these have been the models that have been available. It is now important to move toward whole organism studies so it can be fully appreciated how broad the functions of these proteins may be in physiology and disease.

Historical Background

Ran is an abundant member of the Ras superfamily of small GTPases that is highly conserved across eukaryotes. Originally cloned from a human teratocarcinoma cell line as one of four novel genes with sequence homology to the GTP-binding domain of Ras (Drivas et al. 1990), the gene was initially named *TC4* (*t*eratocarcinoma *c*lone 4) and found to encode a protein of 216 amino acid residues. TC4 was markedly different

from other members of the Ras superfamily in two respects: it lacked the sites required for post-translational lipid modification and it was primarily localized to the nucleus. Accordingly, it was renamed Ran for *Ra*s-related *n*uclear protein. Ran was subsequently purified as an essential cofactor for nuclear protein import (Moore and Blobel 1993) and over the following years was extensively characterized for its role in regulating nucleocytoplasmic transport. Ran was later discovered to be critical for mitotic spindle assembly (Carazo-Salas et al. 1999; Ohba et al. 1999) and for the post-mitotic assembly of the nuclear envelope (Hetzer et al. 2000; Zhang and Clarke 2000) and of nuclear pore complexes (Walther et al. 2003). Ran has more recently been implicated in diverse processes, including centrosome duplication (Budhu and Wang 2005), apoptosis (Wong et al. 2009), injury response signaling in neurons (Yudin and Fainzilber 2009), and ciliary trafficking (Dishinger et al. 2010).

Regulation of Guanine Nucleotide State and Subcellular RanGTP Distribution

Like other GTPases, Ran undergoes cycles of GTP exchange and subsequent hydrolysis to GDP. The rates of nucleotide exchange and hydrolysis by Ran are intrinsically low, and in vivo these reactions require accessory factors to proceed at physiological rates. GTP hydrolysis is stimulated by a GTPase-activating protein, RanGAP, and further enhanced by the RanGTP-binding proteins RanBP1 and RanBP2, whereas the replacement of GDP with GTP is accelerated by a guanine nucleotide exchange factor, RanGEF, which is called Regulator of Chromosome Condensation 1 (RCC1) in vertebrates (Binding partners of Ran are summarized in Table 1). These proteins act together to define an enzymatic cycle whereby Ran hydrolyzes GTP to GDP, releases the GDP, and accepts a new molecule of GTP (Fig. 1). Importantly, the accessory factors that modulate this cycle are distributed asymmetrically in the cell. RanGEF has a high affinity for chromatin and is restricted to the nucleus during interphase, whereas RanGAP, RanBP1, and RanBP2 localize to the cytosol or to the cytosolic face of the nuclear envelope. This gives rise to an asymmetric distribution of Ran, with the GTP- and GDP-bound forms prevailing in the nucleus and cytosol, respectively.

The function of Ran depends on its conformation, which in turn is determined by the state of the guanine nucleotide bound to it (Fig. 2). As with other GTPases, the conformational changes in Ran involve two regions, called switch I and II, that are sensitive to the presence of the γ-phosphate of GTP (Wittinghofer and Vetter 2011). In addition, Ran possesses a 40-residue C-terminal extension which also displays a nucleotide-dependent conformation. In the GDP-bound state, the C-terminal extension folds intimately against the core domain of Ran; in the GTP-bound state, this region detaches from the core and becomes highly solvent accessible. Thus, the GDP- and GTP-bound conformations of Ran are strikingly different, allowing Ran-interacting factors to discriminate between RanGDP and RanGTP with high selectivity. Point mutations in Ran that either block GTPase activity or prevent RanGTP generation by inhibiting RanGEF-mediated nucleotide exchange have been instrumental in elucidating the role of Ran in diverse cellular pathways. These mutations are listed in Table 1.

Role in Nucleocytoplasmic Transport

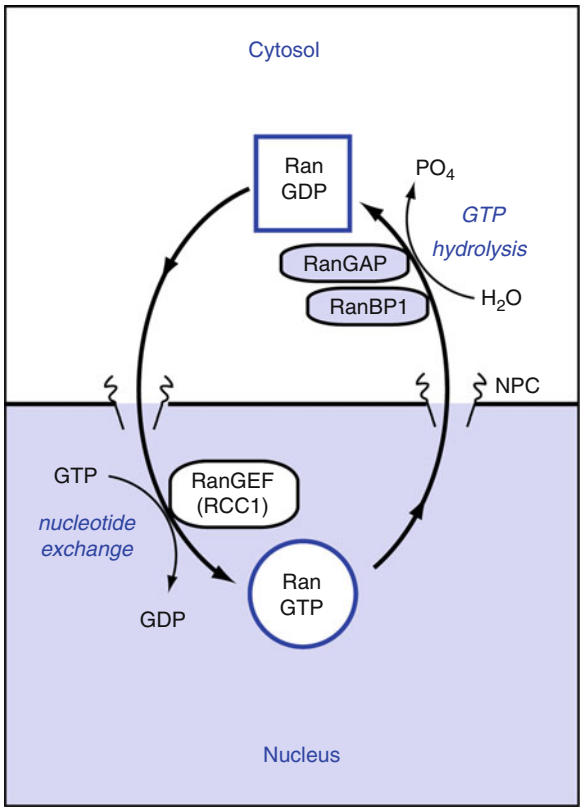
Ran regulates nuclear transport during interphase by acting as a molecular switch for the karyopherin-β family of nuclear transport receptors, also known as importins and exportins (Fried and Kutay 2003). Karyopherins are responsible for delivering various classes of macromolecular cargo through the nuclear pore complex (NPC). Representative members include Importin β, which cooperates with the adaptor protein Importin α to deliver proteins bearing a basic nuclear localization signal (NLS) from the cytosol to the nucleus; Transportin 1, which mediates the nuclear import of ribosomal proteins and heterogeneous nuclear ribonucleoproteins (hnRNPs); CRM1/Exportin 1, which mediates the nuclear export of proteins bearing a leucine-rich nuclear export signal (NES); and Xpot, which exports tRNA. Additional family members are listed in Table 1.

Crystal structures determined for a number of transport receptors, both in isolation and in complex with binding partners, have greatly elucidated how these proteins function (Cook and Conti 2010; Stewart 2007). Karyopherins are superhelical structures made of tandem HEAT repeats that interact with the

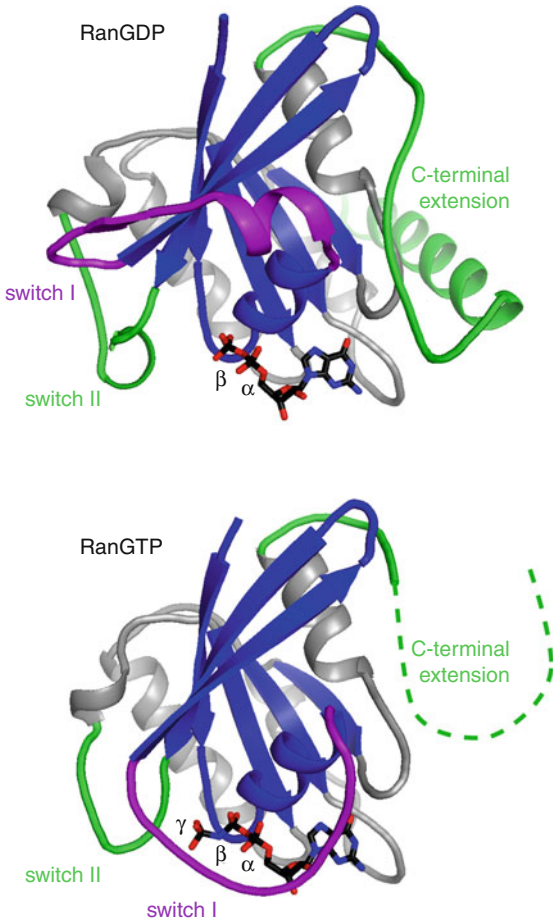
Ran, Table 1 Ran point mutants and binding partners

Protein	Function
Ran G19V, L43E, Q69L	Ran point mutants locked in the GTP-bound form due to lack of GTPase activity
Ran T24N	Ran point mutant that binds to RanGEF and inhibits its exchange activity, thereby preventing RanGTP generation
RanGAP	GTPase-activating protein for Ran. Localizes to the cytoplasm and nuclear pores during interphase and to mitotic spindle during mitosis
RanGEF/RCC1	Guanine nucleotide exchange factor for Ran. Associates with chromatin throughout the cell cycle
RanBP1	RanGTP-binding protein that localizes to the cytoplasm of nondividing cells. Acts as a cofactor for RanGAP, enhancing the rate of GTP hydrolysis on Ran
RanBP2/Nup358	Nucleoporin that localizes to the cytosolic face of the nuclear pore complex (NPC). Acts as a cofactor for RanGAP, enhancing the rate of GTP hydrolysis on Ran
RanBP3	Cofactor for CRM1-mediated nuclear export
RanBPM/RanBP9	Centrosomal protein that interacts with the GTP-bound form of Ran and is required for correct nucleation of microtubules
RanBP10	Tubulin-binding protein and cytoplasmic guanine nucleotide exchange factor for Ran
NTF2/p10	Import carrier for RanGDP
Mog1	Stimulates release of GTP from Ran. In combination with RanBP1 promotes GDP release and the selective binding of GTP to Ran
Dis3	Exoribonuclease subunit of the RNA-processing exosome complex that enhances the nucleotide-releasing activity of RCC1
Karyopherin-β family members	
Importin β/Importin β1	Associates with Importin α to mediate the nuclear import of proteins with a basic nuclear localization signal (NLS). Associates with Snurportin1 to mediate the import of UsnRNPs
Transportin 1/Importin β2	Nuclear import receptor for diverse RNA-binding proteins
	Transports the Kif17 motor protein and retinitis pigmentosa 2 protein to the primary cilium
Transportin SR	Nuclear import receptor for serine/arginine-rich (SR) proteins
Transportin SR2/ Transportin 3	Nuclear import receptor for SR proteins, stem-loop binding protein (SLBP), HIV integrase
Importin 4	Nuclear import receptor for histones, ribosomal proteins, vitamin D receptor, transition protein 2
Importin 5/Importin β3	Nuclear import receptor for histones, ribosomal proteins, recombinase protein RAG-2
Importin 7	Nuclear import receptor for ribosomal proteins, glucocorticoid receptor, HIV reverse transcriptase complex. Heterodimerizes with importin beta to import histone H1
Importin 8	Nuclear import receptor for Smad4 and signal recognition particle protein 19 (SRP19)
Importin 9	Nuclear import receptor for core histones and ribosomal proteins
Importin 11	Nuclear import receptor for ribosomal protein L12 and for the class III ubiquitin conjugating enzymes UbcM2, UbcH6, and UBE2E2
Importin 13	Nuclear import receptor for Ubc9, Rbm8, Mago-Y14, Pax6
	Export receptor for translation initiation factor eIF1A
CAS	Export receptor for Importin α
CRM1/Exportin1	Export receptor for proteins bearing a leucine-rich nuclear export signal (NES). Cooperates with Ran to recruit nucleophosmin to centrosomes
Exportin-t/Xpot	Export receptor for tRNAs
Exportin 4	Export receptor for eukaryotic translation initiation factor 5A (eIF5A) and Smad3. Import receptor for transcription factors Sox2 and SRY
Exportin 5	Export receptor for microRNA precursors and 60S ribosomal subunit
Exportin 6	Export receptor for profilin/actin complexes
Exportin 7	Export receptor for p50RhoGAP, 14-3-3σ

GTP-bound form of Ran. RanGTP binds to the N-terminal half of these proteins, while the cargo generally binds to the C-terminal half (Fig. 3a). RanGTP and cargo bind to importins in a mutually exclusive manner, whereas they bind to exportins cooperatively. This difference in binding mode, combined with the asymmetric distribution of RanGTP across the nuclear envelope, ensures the directionality of nuclear



Ran, Fig. 1 Regulation of Ran's guanine nucleotide state. The guanine nucleotide exchange factor RanGEF localizes to the nucleus, while the GTPase-activating protein RanGAP and the RanGTP-binding protein RanBP1 localize to the cytosol. This gives rise to an asymmetric subcellular distribution of RanGTP, which is at high concentration in the nucleus and at low concentration in the cytosol. *NPC* nuclear pore complex

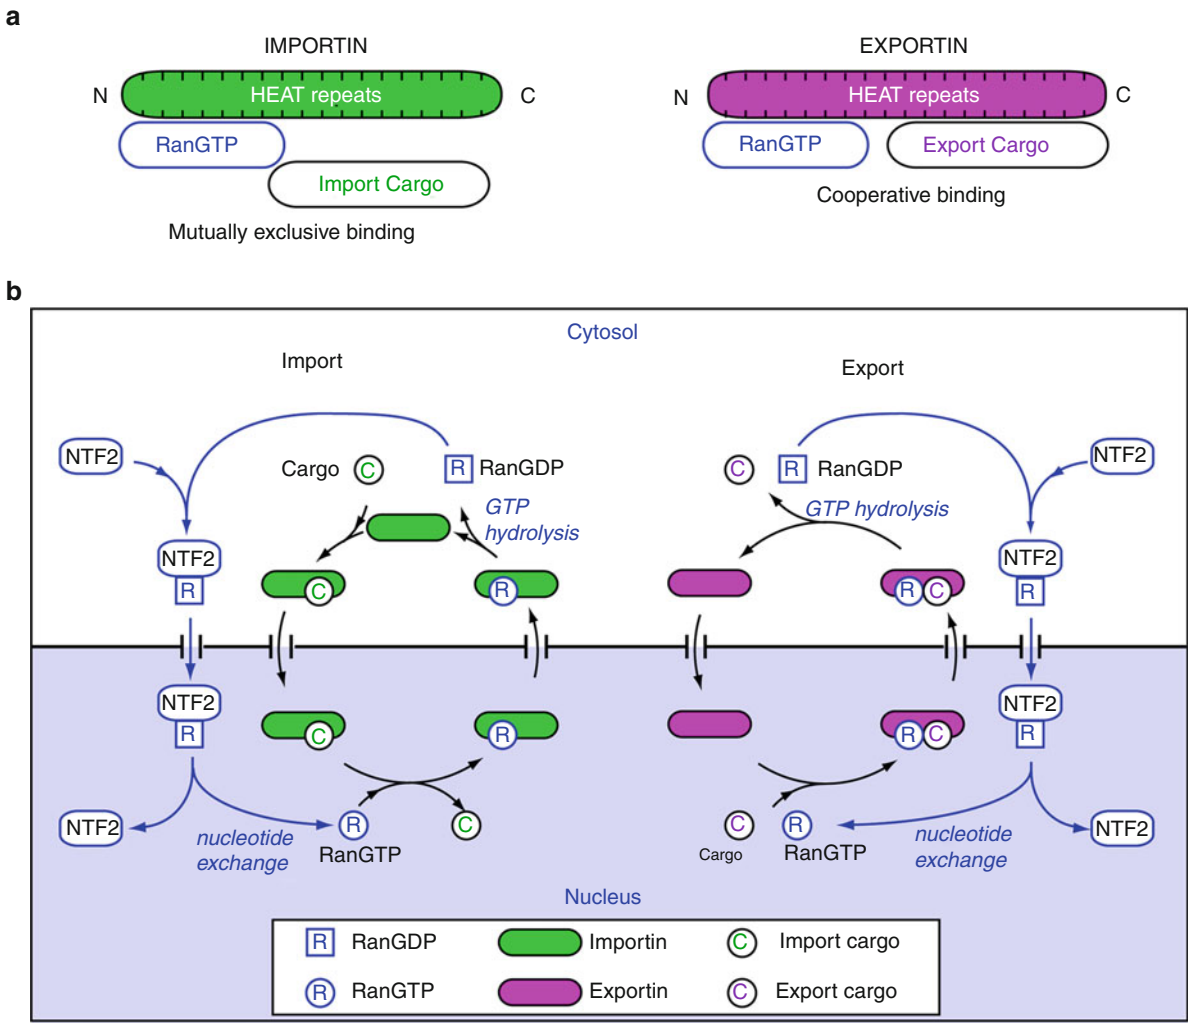


Ran, Fig. 2 Structure of Ran in the GDP- and GTP-bound states. The conformations of the switch I and II regions and of the C-terminal extension depend on the bound nucleotide. GDP and GTP are shown as stick models, with the α, β, and γ phosphate groups labeled. Structures shown are those of pdb entries 1BYU (RanGDP) and 1IBR (RanGTP)

transport. Thus, importins bind their cargo in the cytosol, translocate through the NPC, and release the cargo in the nucleus upon encountering RanGTP (Fig. 3b). In contrast, exportins associate with their cargo in the nucleus together with RanGTP, forming a ternary complex that traverses the NPC and subsequently dissociates in the cytosol. In the cytosol, the binding of RanBP1 releases RanGTP from importins and exportins, and rebinding is prevented by RanGAP-mediated hydrolysis of Ran to the GDP-bound state. Nuclear transport factor 2 (NTF2) recycles RanGDP to the nucleus, where RanGEF mediates conversion to the GTP-bound form. RanGTP, thus, acts as a positional cue that defines the nuclear compartment and directs the disassembly and assembly of import and export complexes, respectively.

Role in Mitotic Spindle Organization

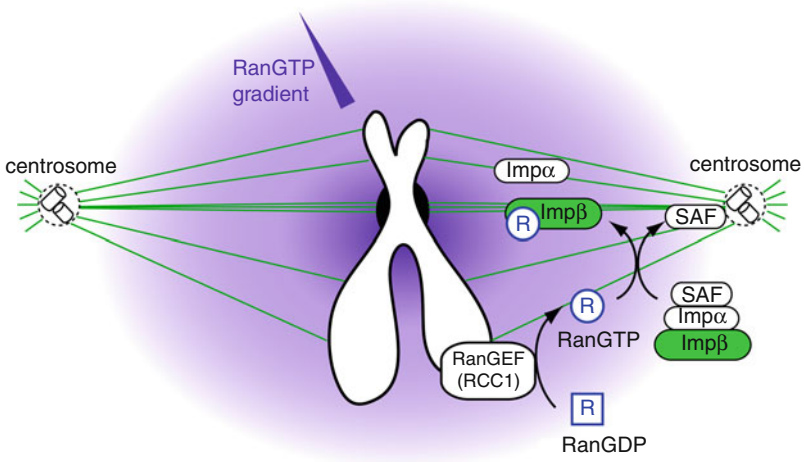
In addition to regulating nucleocytoplasmic transport during interphase, Ran plays an important role during mitosis, regulating several aspects of mitotic spindle assembly (Clarke and Zhang 2008; Gruss and Vernos 2004). These include microtubule nucleation, microtubule stability, production of antiparallel microtubule arrays, and the focusing of spindle poles. Many of these functions for Ran were discovered and characterized in studies using *Xenopus laevis* egg extracts. The importance of Ran during mitosis has been confirmed in mammalian somatic cells, where, for example, Ran regulates microtubule attachment to



Ran, Fig. 3 Role of Ran in nucleocytoplasmic transport. (**a**) Mode of interaction with importins and exportins. Whereas RanGTP and cargo associate with importins in a mutually exclusive manner, they associate with exportins cooperatively. (**b**) Generic import (*left*) and export (*right*) pathways mediated by karyopherin β members. Nucleotide exchange in the nucleus is mediated by RanGEF/RCC1, while GTP hydrolysis in the cytosol is promoted by RanGAP and RanBP1 or RanBP2

kinetochores, is required for microtubule nucleation by both centrosomes and kinetochores, and regulates centrosome cohesion during spindle pole formation (Arnaoutov and Dasso 2005; Roscioli et al. 2010).

The molecular mechanism by which RanGTP affects mitotic spindle assembly is closely related to that by which it regulates nucleocytoplasmic transport. After nuclear envelope breakdown at the onset of mitosis, RanGTP is concentrated near chromosomes by chromatin-bound RanGEF, while RanGAP and RanBP1 promote GTP hydrolysis by Ran distal to chromatin. This gives rise to a concentration gradient of RanGTP that is centered on chromosomes (Fig. 4). RanGTP influences the organization of the mitotic apparatus by activating spindle assembly factors (SAFs), which mediate microtubule stabilization and spindle assembly. One example of a RanGTP-activated SAF is TPX2 (*T*argeting *P*rotein for *X*klp2). TPX2 promotes spindle formation by targeting the kinesin-like motor protein Xklp2 to microtubule minus ends and by activating Aurora A kinase, which is involved in centrosome function. Another SAF activated by RanGTP is NuMA (*Nu*clear *M*itotic *A*pparatus protein). NuMA associates with the motor protein



Ran, Fig. 4 Role of Ran in mitotic spindle assembly. The binding of RanGTP to Importin β in the vicinity of chromosomes causes the release of spindle assembly factors such as TPX2 and NuMA. The gradient of RanGTP established by chromatin-bound RanGEF is indicated by the magenta shading. *SAF* spindle assembly factor, *Impα* importin α, *Impβ* importin β

dynein and its motility-activating complex dynactin, and translocates along microtubules to the spindle poles where it organizes and tethers microtubules to spindle poles. TPX2 and NuMA are inhibited by the Importin α/β heterodimer, which bind to the NLS motifs of these SAFs. Near chromatin, RanGTP binds and displaces Importin β, releasing and activating the SAFs. RanGTP, thus, acts as a positional marker that ensures the correct spatial regulation of spindle assembly in the vicinity of chromosomes.

Role in Nuclear Envelope Assembly

In higher eukaryotes, the nuclear envelope is reconstituted around the segregated DNA at the end of mitosis. This process occurs in three steps: first, membrane vesicles are recruited to the vicinity of chromatin; next, these vesicles fuse into a continuous nuclear membrane; and finally, nucleoporins assemble to form NPCs that insert into the nuclear envelope. Although the mechanisms underlying these events are not fully understood, Ran clearly plays an important role. RanGTP stimulates membrane fusion and nuclear pore assembly, while Importin β negatively regulates these events. More specifically, artificial beads coated with Ran and added to *X. laevis* egg extracts or other cell-free systems accumulate membrane vesicles that fuse into a continuous lipid layer, incorporate nucleoporins, and form NPCs in the absence of chromatin (Zhang and Clarke 2000). Both the generation of RanGTP by RanGEF/RCC1 and GTP hydrolysis by Ran are required for membrane fusion to occur (Hetzer et al. 2000). The generation of RanGTP is also required to release specific nucleoporins from Importin β, to target these proteins to chromatin and to allow the association of NPC subcomplexes (Walther et al. 2003).

Additional Functions of Ran

1. *Centrosome duplication*. Centrosomes, the major microtubule organizing center of mammalian cells, are duplicated once and only once during the G1/S transition of the cell cycle. Ran and the nuclear export receptor CRM1 help orchestrate this event through their effect on nucleophosmin (NPM), which has been implicated as a licensing factor that regulates centrosome synthesis (Budhu and Wang 2005). A fraction of Ran and CRM1 localizes to centrosomes, where they recruit NPM through the latter's leucine-rich NES motif to form a centrosomal CRM1/Ran/NPM complex. Mutation of the NES motif or inactivation of CRM1 leads to dissociation of NPM from centrosomes and to the premature initiation of centrosome duplication. Viral oncoproteins that cause abnormal centrosome duplication (e.g., adenovirus E1A and human papillomavirus E7 proteins) also interact physically with Ran and disrupt its centrosomal regulatory functions (Lavia et al. 2003).
2. *Apoptosis*. Apoptosis triggered by DNA damage leads to the redistribution of Ran from the nucleus to the cytosol and to an overall reduction in

RanGTP levels (Wong et al. 2009). This redistribution has been linked to the action of Mst1, a kinase localized primarily to the cytosol but which accumulates in the nucleus during apoptosis following caspase-mediated cleavage of its nuclear export signal. Nuclear Mst1 phosphorylates serine residue S14 on histone H2B. This leads to RanGEF becoming more tightly bound to chromosomes and to inhibition of its guanine nucleotide exchange activity toward Ran. The resulting dissipation of nuclear RanGTP blocks entry into the nucleus of ▶ NF-κB, a transcription factor with an important role in rescuing cells from apoptosis. Thus, dissipation of the RanGTP gradient due to histone phosphorylation prevents the initiation of an anti-apoptotic program.

3. *Ciliary trafficking*. The primary cilium is a microtubule-based organelle that projects from the cell surface and transduces environmental stimuli into intracellular signals. Entry of proteins into cilia appears to be regulated at the base of the cilia at a region known as the transition zone, where a structure analogous to the NPC has been proposed to exist. Studies of the microtubule motor Kif17 revealed a role for Ran in regulating protein entry into primary cilia which is strikingly similar to Ran's role in nucleocytoplasmic transport (Dishinger et al. 2010). Targeting of Kif17 to primary cilia depends on a short carboxy-terminal sequence that contains several basic residues and shares similarities with NLSs. This "ciliary localization signal" (CLS) mediates binding to the nuclear import receptor Transportin 1. The Kif17/Transportin 1 complex is then targeted to the intraciliary compartment, where high RanGTP concentrations release the motor protein from the importin. Ciliary import of Kif17 thus mirrors the nuclear import of an importin/cargo complex and its dissociation by nuclear RanGTP.
4. *Neuronal processes*. Ran appears to play an important role in neuron development, as RNAi knockdown of Ran revealed defects in neuron development in both drosophila and mouse neurons, while the Ran-binding protein RanBPM has been implicated in cytoplasmic signaling in neuronal processes and in the regulation of neuronal outgrowth (Yudin and Fainzilber 2009). A role for Ran has also been identified in the regulation of retrograde injury signaling in peripheral sensory neurons. In axons, RanGTP forms part of a multimeric complex that includes the nuclear export receptor CAS, Importin α, and the microtubule-associated motor protein dynein. Nerve injury causes an increase in the cytoplasmic levels of RanBP1, RanGAP, and Importin β. RanBP1 and RanGAP induce the release of RanGTP and CAS from the Importin α/dynein complex and promote the hydrolysis of RanGTP to RanGDP. This allows the newly translated Importin β to associate with Importin α/dynein, thereby creating a retrograde injury-signaling complex capable of binding (via Importin α) NLS-bearing signaling cargos. As with the ciliary trafficking example above, these findings show that Ran can act as a regulator of importin-dependent transport and signaling at sites that are distant from the nucleus.

Summary

Ran regulates several fundamental processes throughout the cell cycle, including nucleocytoplasmic transport during interphase, the organization of the mitotic apparatus after nuclear envelope breakdown, the reassembly of the nuclear envelope after mitosis, and duplication of the centrosome. Ran also plays a role in more specialized processes, such as ciliary trafficking, the apoptotic response to a variety of conditions, and neuronal development and injury signaling. In many of these processes, Ran functions as a spatial marker describing where the chromatin or nucleus is. A commonly observed feature is the role played by transport receptors of the karyopherin β family, which sequester different activators and inhibit their function until relieved by RanGTP. A challenge for the future will be to understand these Ran-regulated processes in detail, defining all the players involved and the molecular mechanisms by which these events are precisely orchestrated during the cell cycle.

RANK and RANKL Family Members

RANK; receptor activator of nuclear factor-κB, TNFRSF11A; tumor necrosis factor receptor superfamily, member 11a, CD265. RANKL; receptor activator of nuclear factor-κB ligand, TNFSF11; tumor necrosis factor (ligand) superfamily, member 11, OPGL; osteoprotegerin ligand, ODF; osteoclast differentiation factor, TRANCE; TNF-related activation-induced cytokine, CD254.

Historical Background

In the late 1980s, an in vitro coculture system for osteoclast formation was established. This system was shown to require cell-to-cell contact between calvarial cells and bone marrow cells for osteoclast differentiation (Suda et al. 1999). Based on this finding, it was proposed that osteoclastogenesis-supporting mesenchymal lineage cells express an osteoclast differentiation factor (ODF) in the form of a membrane-associated protein (Suda et al. 1999). In the late 1990s, the potential inhibitor of osteoclastogenesis osteoprotegerin (OPG) was cloned. OPG is a decoy receptor that associates with a transmembrane protein of the tumor necrosis factor (TNF) superfamily, OPGL, which turned out to be the long-sought ODF (Takayanagi 2007; Theill et al. 2002). Interestingly, immunologists cloned the same molecule as a stimulator of dendritic cells expressed by T cells, and named it receptor activator

of nuclear factor-κB ligand (RANKL), or TNF-related activation-induced cytokine (TRANCE) (Lorenzo et al. 2008). The receptor for RANKL is RANK, a type I transmembrane protein, which assembles into a functional trimer upon ligand binding, which is similar to other members of the TNF receptor family (Nakashima and Takayanagi 2009). The RANK and RANKL system currently provides a paradigm that enables the molecular understanding of the linkage among bone metabolism, the organization of lymphoid tissues, the regulation of body temperature, mammary gland development, and tumorigenesis.

The Role of RANKL in the Bone and the Immune Systems

Mice with a disruption of *Rank* or *Rankl* exhibit severe osteopetrosis accompanied by a defect in tooth eruption owing to a complete lack of osteoclasts. These genetic findings clearly demonstrate that RANK and RANKL are essential for osteoclastogenesis in vivo. In contrast, mice lacking *Opg* exhibit severe osteoporosis due to both an increased number and enhanced activity of osteoclasts (Takayanagi 2007; Theill et al. 2002). In humans, mutations in *RANK, RANKL*, and *OPG* have been identified in patients with bone disorders, including familial expansile osteolysis, autosomal recessive osteopetrosis, and juvenile Paget's disease of bone (Nakashima and Takayanagi 2009).

RANKL functions as a membrane-anchored molecule and is released from the cell surface as a soluble molecule following proteolytic cleavage by matrix metalloproteinases (MMPs) (Nakashima et al. 2000). Both the soluble and membrane-bound forms of RANKL function as agonistic ligands for RANK. However, previous reports have suggested that membrane-bound RANKL is more efficient than soluble RANKL (Nakashima and Takayanagi 2009). In addition, previous studies have indicated that RANKL serves as both a chemotactic and survival factor for osteoclasts, and that RANKL is mainly expressed in cells of mesenchymal lineage such as osteoblasts, bone marrow stromal cells, and synovial cells. RANKL expression can be upregulated by certain osteoclastogenic factors such as vitamin D_3, prostaglandin E_2, parathyroid hormone, interleukin (IL)-1, IL-6, IL-11, IL-17, and TNF-α (Nakashima et al. 2000; Theill et al. 2002). However, the major source of RANKL in vivo remains unclear, since RANKL is expressed by several different cell types in both the bone and bone marrow, including osteoblasts, osteocytes, bone marrow stromal cells, and lymphocytes. A recent report demonstrated that osteocytes embedded within the bone matrix both express a much higher amount of RANKL and have a much greater capacity to support osteoclastogenesis than osteoblasts or bone marrow stromal cells. Furthermore, the crucial role of RANKL expressed by osteocytes was confirmed by the severe osteopetrotic phenotype observed in mice specifically lacking RANKL in osteocytes. These results clearly indicate that the osteocytes are the major source of RANKL in bone remodeling in vivo (Nakashima et al. 2011).

Intriguingly, in addition to the defect in osteoclasts, both RANK- and RANKL-deficient mice are defective in the development and organization of secondary lymphoid tissue (Takayanagi 2007; Theill et al. 2002). However, RANKL-deficient mice also have a reduced thymus size and impaired thymocyte differentiation. Although the mRNA of RANK is present in the thymus of RANKL-deficient mice, RANK-deficient mice do not display any obvious defects in thymocytes. This phenotypic difference in the thymus is the only evident distinction between RANK- and RANKL-deficient mice (Lorenzo et al. 2008; Takayanagi 2007; Theill et al. 2002). This observation suggests that RANKL has the potential to act on another receptor during the course of thymocyte development, a subject which remains to be investigated further. Severe immunodeficiency is not observed in RANKL-deficient mice, nor are there any obvious adverse effects in the immune system due to the administration of anti-RANKL antibody in humans (McClung et al. 2006). The loss of RANKL in T cells seems to be compensated by CD40L in mice (Lorenzo et al. 2008). These observations initially suggested that the immunological function of RANKL is of lesser importance, but recent studies have revealed a crucial role for RANKL in the immune system. RANKL has been shown to play a critical role in a pathological model of inflammatory bowel disease by stimulating dendritic cells (Nakashima and Takayanagi 2009; Takayanagi 2007), suggesting that RANKL is distinctly involved in the activation of dendritic cells under certain autoimmune conditions. On the other hand, keratinocytes express RANKL in response to ultraviolet stimulation of the skin, which appears to activate Langerhans cells and trigger the

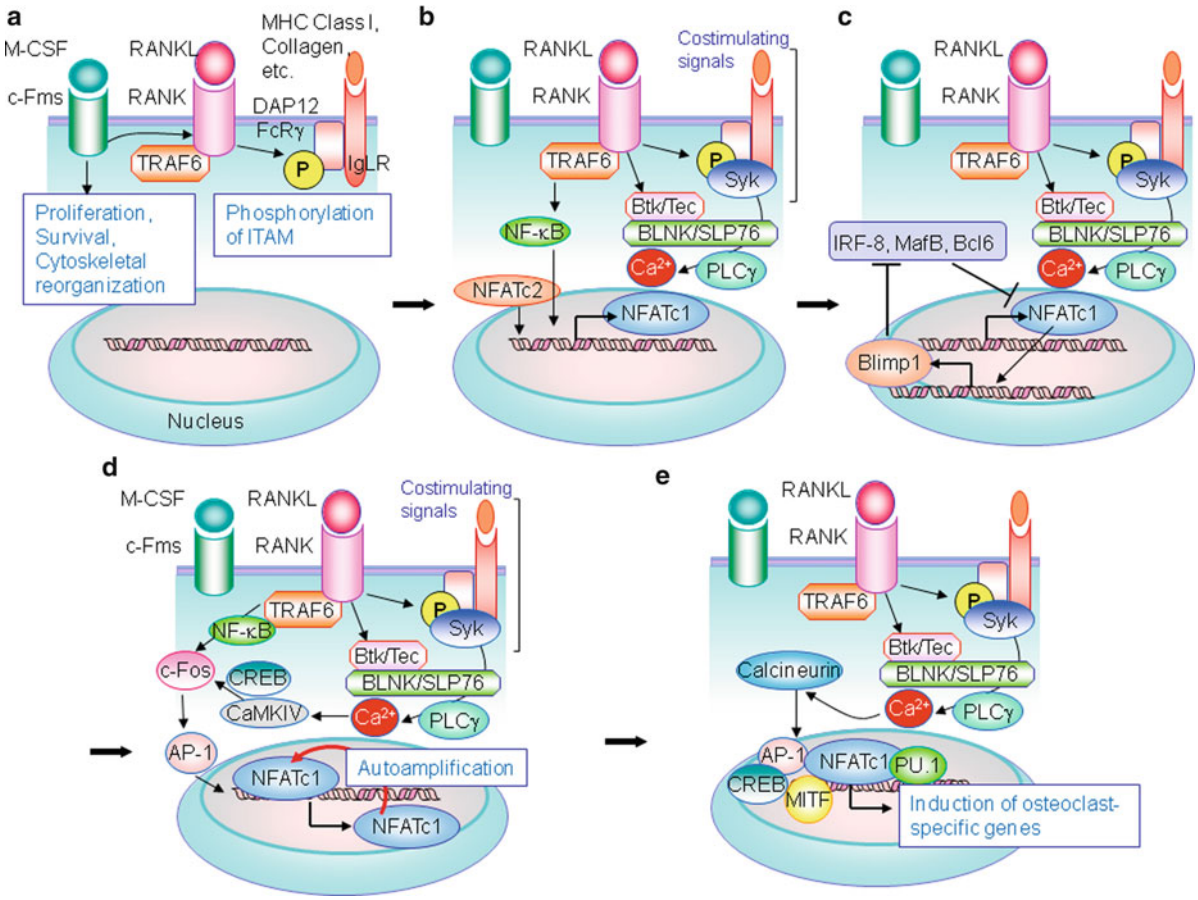
expansion of regulatory T (Treg) cells in draining lymph nodes (Nakashima and Takayanagi 2009). Vitamin D_3, which is produced in the skin in response to sun exposure, has long been known to have immunosuppressive functions and to induce RANKL on osteoclastogenesis-supporting mesenchymal cells in bone. Thus, the suggested role for RANK/RANKL might be the missing link which mediates sunlight-induced immunosuppression. In addition, recent reports suggest that RANK is a key molecule in the development of autoimmune regulator (Aire)-expressing medullary thymic epithelial cells (mTECs), and cooperation between RANK and CD40 also promotes mTEC development, thereby establishing self-tolerance (Nakashima and Takayanagi 2009). Although the functions of RANKL/RANK in the immune system need to be elucidated in greater detail, the discovery and subsequent functional analysis of RANKL has become the driving force behind advances in the understanding of the osteoimmune axis.

The Intracellular Signal Transduction of RANKL

RANK is a transmembrane molecule expressed on osteoclast precursor cells and mature osteoclasts. The ligation of RANK with RANKL results in the commitment of monocyte/macrophage precursor cells to the osteoclast lineage and the activation of mature osteoclasts. RANK lacks intrinsic enzymatic activity in its intracellular domain and transduces signals by recruiting adaptor molecules such as the TNF receptor-associated factor (TRAF) family proteins (Takayanagi 2007). Genetic approaches coupled with intensive molecular analyses have identified ▶ TRAF6 as the main adaptor molecule that links RANK to both osteoclastogenesis and lymph node development (Nakashima and Takayanagi 2009; Takayanagi 2007). By an as yet unknown mechanism, RANKL binding to RANK induces the trimerization of RANK and TRAF6, which leads to the activation of nuclear factor-κB (▶ NF-κB) and certain mitogen-activated kinases (MAPKs), including Jun N-terminal kinase (JNK) and p38. It has not yet been determined how RANK alone, among the TRAF6-binding receptors, is able to stimulate osteoclastogenesis so potently. Additional RANK-specific adaptor molecules may exist which link RANK signaling to other pathways. For example, the molecular scaffold Grb2-associated binding protein 2 (▶ Gab2) and four-and-a-half LIM domain 2 (FHL2) have been shown to be associated with RANK and to exert an important regulatory role in its signal transduction. On the other hand, recent investigation has revealed that the deubiquitinating enzyme CYLD negatively regulates RANK signaling by inhibiting TRAF6 ubiquitination and the activation of downstream signaling events (Nakashima and Takayanagi 2009). The control of the RANK signaling cascade during osteoclastogenesis is summarized in Fig. 1.

The essential role of NF-κB in osteoclastogenesis has been demonstrated genetically (Takayanagi 2007). NF-κB p50 and p52 double-deficient mice develop severe osteopetrosis because of a defect in osteoclastogenesis. The upstream kinase complex that mediates the phosphorylation and degradation of inhibitor of NF-κB (IκB) comprising the catalytic subunits IκB kinase α (IKKα), IKKβ, and the non-catalytic subunit IKKγ (also known as NEMO) are also important for RANK signaling and osteoclastogenesis. In mice, IKKβ is required for RANKL-induced osteoclastogenesis both in vitro and in vivo, whereas IKKα appears to be required only in vitro, not in vivo. Importantly, patients with X-linked osteopetrosis, lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID syndrome) bear a X420W point mutation in *IKKγ* (Nakashima and Takayanagi 2009).

The activator protein 1 (AP-1) transcription factor complex is also essential for osteoclastogenesis (Wagner and Eferl 2005). RANK activates AP-1 through an induction of c-Fos. Induction of c-Fos is dependent on the activation of calcium/calmodulin-dependent protein kinase type IV (CaMKIV) and cyclic AMP-responsive element-binding protein (▶ CREB) (Sato et al. 2006), but there are several reports that suggest NF-κB is involved in the c-Fos induction (Nakashima and Takayanagi 2009). In addition, c-Fos expression is induced by treatment with macrophage colony-stimulating factor (M-CSF). Recent investigation has revealed that peroxisome proliferator-activated receptor-γ (PPAR-γ) plays an unexpected role in osteoclastogenesis by directly regulating c-Fos expression (Nakashima and Takayanagi 2009). Thus, it appears that the induction of c-Fos is not regulated by a single pathway.



RANK and RANKL, Fig. 1 *Signaling cascades during osteoclastogenesis*. Osteoclastogenesis is cooperatively induced by M-CSF, RANKL, and its costimulatory factor, immunoglobulin-like receptor. (**a**) Precursor cell stage; the binding of M-CSF to its receptor, c-Fms, activates the proliferation, survival, and cytoskeletal reorganization of osteoclast precursor cells of the monocyte/macrophage lineage and induces RANK expression. The costimulatory receptors appear to be stimulated at early stages. Proximal RANK signals; RANKL binding to RANK results in the recruitment of TRAF6 and, at the same time, the phosphorylation of the ITAM in DAP12 and FcRγ, which are adaptor proteins associating with distinct immunoglobulin-like receptors. (**b**) Initial induction of NFATc1; NFATc1, a master transcription factor for osteoclastogenesis, is initially induced by the TRAF6-activated NF-κB and NFATc2 that are present in the cell before RANKL stimulation. RANK and ITAM signals cooperate to phosphorylate PLCγ and activate calcium signaling, which is critical for the activation of NFATc1. The tyrosine kinases Btk and Tec are activated by RANK and are important for the phosphorylation of PLCγ, thus linking the two pathways. (**c**) Disinhibition of NFATc1; NFATc1 activity is negatively regulated by other transcription factors such as IRF-8, MafB, and Bcl6. The expression of such negative regulators was observed to be repressed in osteoclastogenesis. Blimp1, which is induced by RANKL through NFATc1 during osteoclastogenesis, functions as a transcriptional repressor of anti-osteoclastogenic genes. (**d**) Autoamplification of NFATc1; calcium signal-mediated persistent activation of NFATc1, as well as cooperation with AP-1, is a prerequisite for the robust induction of NFATc1. AP-1 activation is mediated by the induction and activation of c-Fos by CaMKIV-stimulated CREB and c-Fms. The NFATc1 promoter is epigenetically activated through histone acetylation and NFATc1 binds to an NFAT-binding site on its own promoter. (**e**) Induction of osteoclast-specific genes; NFATc1 works together with other transcription factors, such as AP-1, PU.1, CREB, and MITF, to induce various osteoclast-specific genes

Importantly, RANKL specifically and potently induces nuclear factor of activated T cells, cytoplasmic 1 (▶ NFATc1), the master regulator of osteoclast differentiation, and this induction is dependent on both the TRAF6-NF-κB and c-Fos pathways (Takayanagi et al. 2002). The NFAT family of transcription factors was originally discovered in T cells, but its members are involved in the regulation of a variety of biological systems (Crabtree and Olson 2002). The activation of NFAT is mediated by a specific phosphatase,

calcineurin, which is activated by calcium-calmodulin signaling. The essential and sufficient role of the *Nfatc1* gene in osteoclastogenesis has been shown both in vitro and in vivo. The *Nfatc1* promoter contains NFAT binding sites and NFATc1 specifically autoregulates its own promoter during osteoclastogenesis, thus enabling the robust induction of NFATc1 (Takayanagi 2007). AP-1 containing c-Fos, together with continuous activation of calcium signaling, is crucial for this autoamplification (Takayanagi et al. 2002). NFATc1 regulates a number of osteoclast-specific genes in cooperation with other transcription factors such as AP-1, PU.1, and MITF (Takayanagi 2007). Osteoclasts mature into multinuclear giant cells by the fusion of numerous mononuclear osteoclasts. The expression of fusion-mediating molecules such as the d2 isoform of the vacuolar ATPase Vo domain (Atp6v0d2) and the dendritic cell-specific transmembrane protein (DC-STAMP) is directly regulated by NFATc1 (Nakashima and Takayanagi 2009). A previous study indicated that CREB, activated by CaMKIV, also cooperates with NFATc1 in the activation of osteoclast-specific genes (Fig. 1). On the other hand, NFATc1 activity is negatively regulated during osteoclastogenesis by other transcription factors, such as interferon regulatory factor-8 (IRF-8), B cell lymphoma 6 (Bcl6), and v-maf musculoaponeurotic fibrosarcoma oncogene family protein B (MafB) (Miyauchi et al. 2010; Nishikawa et al. 2010; Zhao et al. 2009). The expression of such negative regulators was observed to be repressed through osteoclastogenesis (Fig. 1). This repression is consistent with the notion that high NFATc1 activity is a prerequisite for efficient osteoclastogenesis, but the mechanism by which the expression of these anti-osteoclastogenic regulators is repressed during RANKL-induced osteoclastogenesis has remained obscure. Recent data indicate that B lymphocyte-induced maturation protein-1 (Blimp1), which is induced by RANKL through NFATc1 during osteoclastogenesis, functions as a transcriptional repressor of anti-osteoclastogenic genes such as IRF-8, Bcl6, and MafB (Nishikawa et al. 2010). Therefore, NFATc1 choreographs the determination of cell fate in the osteoclast lineage by inducing the repression of negative regulators as well as through its effect on positive regulators. However, compared with the wealth of information on RANK signaling in osteoclasts, it is as yet unclear whether RANK uses the same signaling mechanisms in the immune system and other systems.

Phospholipase Cγ (PLCγ), which mediates Ca^{2+} release from intracellular stores, is crucial for the activation of the key transcription factor NFATc1 via calcineurin (Takayanagi et al. 2002). However, despite the evident importance of the calcium-NFAT pathway, it had long been unclear how RANKL activates calcium signals. RANK belongs to the TNF receptor family, which has yet to be directly connected to calcium signaling. The activation of PLCγ by RANK requires the protein tyrosine kinase Syk, along with immunoreceptor tyrosine-based activation motif (ITAM)-bearing molecules, such as DNAX-activating protein (DAP12) and the Fc receptor common gamma chain (FcRγ) (Koga et al. 2004). In the osteoclast lineage, the immunoglobulin-like receptors (IgLR) associated with DAP12 include triggering receptor expressed in myeloid cells 2 (TREM-2) and signal-regulatory protein β1 (SIRPβ1) while those associated with FcRγ include osteoclast-associated receptor (OSCAR) and paired immunoglobulin-like receptor A (PIR-A). As ITAM signals are essential for osteoclastogenesis, but by themselves cannot induce osteoclastogenesis, these signals are most accurately described as costimulatory signals for RANK. The binding of M-CSF to its receptor c-Fms also generates a signaling complex comprised of phosphorylated DAP12 and the nonreceptor tyrosine kinase Syk (Nakashima and Takayanagi 2009). In addition, mutation of TREM-2 or DAP12 in humans leads to Nasu-Hakola disease, which is characterized by bone cysts (Koga et al. 2004; Takayanagi 2007). Thus, RANKL and M-CSF signals appear to converge on the ITAM signaling pathway (Fig. 1).

It is also conceivable that RANK activates an as yet unknown pathway that specifically synergizes with or upregulates ITAM signaling. Tec family tyrosine kinases such as Btk and Tec are activated by RANK and are involved in the phosphorylation of PLCγ, which leads to the release of calcium from endoplasmic reticulum (ER) through the generation of IP3 (Shinohara et al. 2008). An osteopetrotic phenotype in Tec and Btk double-deficient mice revealed these two kinases play an essential role in the regulation of osteoclastogenesis. Tec and Btk had already been reported to play a key role in proximal BCR signaling, but this study established their crucial role in linking the RANK and ITAM signaling pathways (Fig. 1).

This study also identified an osteoclastogenic signaling complex, composed of Tec kinases and scaffold proteins, which affords a new paradigm for understanding the signal transduction mechanisms involved in osteoclast differentiation.

Bone Destruction with Arthritis as a RANKL Disease

In rheumatoid arthritis (RA), a long-standing question is how abnormal T cell activation (characterized by the infiltration of $CD4^+$ T cells) mechanistically induces bone damage. The identification of osteoclast-like giant cells at the interface between synovium and bone in rheumatoid joints dates back to the early 1980s (Takayanagi 2009). These pathological findings led us to hypothesize that osteoclasts play an important role in the bone resorption that occurs in arthritis and that the osteoclasts are formed in the synovium (Takayanagi 2009). Can osteoclasts be generated from synovial cells alone? This question was answered in the affirmative by generating osteoclasts in synovial cell culture without adding any other cells, thus demonstrating that rheumatoid synovial cells contain both osteoclast precursor and osteoclastogenesis-supporting cells (Takayanagi 2009). Further studies indicated that synovial fibroblasts express membrane-bound factor(s) that stimulate osteoclastogenesis and induce the differentiation of synovial macrophages into osteoclasts, but it was not until RANKL was cloned that the membrane-bound factor in synovial cells was brought to light (Takayanagi et al. 2000a).

Importantly, inflammatory cytokines such as IL-1, IL-6, and TNF-α, which are abundant in both the synovial fluid and synovium of RA patients, have a potent capacity to induce RANKL on synovial fibroblasts/osteoblasts and to accelerate RANKL signaling, thus directly contributing to the bone destruction process. Several groups have demonstrated the high expression of RANKL in the synovium of RA patients (Takayanagi 2009). RANKL was shown to be expressed by synovial cells and T cells, both of which are found in the inflamed synovium (Takayanagi 2007, 2009). As RANKL is expressed in activated T cells, T cells may have the capacity to induce osteoclast differentiation by directly acting on osteoclast precursor cells under pathological conditions (Kong et al. 1999). However, ▶ interferon-γ (▶ IFN-γ), which is produced by T cells, potently suppresses RANKL signaling through a rapid degradation of TRAF6 (Takayanagi et al. 2000b). To fully understand the effects of T cells on osteoclastogenesis, it is absolutely necessary to elucidate the specific effects of the various cytokines which T cells produce. It has been shown that IL-17-producing Th17 cells are the exclusive osteoclastogenic T cell subset among the known Th subsets (Takayanagi 2007, 2009). Since even Th17 cells stimulate osteoclastogenesis mainly through RANKL induction on synovilal fibroblasts, it is as yet still unclear how T cell RANKL contributes to bone destruction in the face of synovial fibroblasts expressing RANKL to a higher extent.

Nevertheless, a series of reports has established that the bone damage associated with inflammation is the fundamental pathological condition caused by an abnormal expression of RANKL. Additionally, osteoclast-deficient mice and osteopetorosis patients are protected from bone erosion in arthritis (Kadono et al. 2009; Takayanagi 2009). In the absence of osteoclasts, bone destruction did not occur, despite a similar level of inflammation, indicating that RANKL and osteoclasts are indispensable for the bone loss associated with inflammation. Blocking RANKL by OPG treatment significantly prevented bone destruction in adjuvant arthritis (Kong et al. 1999). Consistent with this, anti-RANKL and anti-osteoclast therapies have been shown in clinical trials as well as in the treatment of an animal model of arthritis to be beneficial for the inhibition of bone loss without affecting the immune system (Takayanagi 2007).

RANK and RANKL in Mammary Gland Development and Tumorigenesis

During pregnancy, increased ductal side branching and the development of lobuloalveolar structures are the result of an expansion and proliferation of ductal and alveolar epithelium (Hennighausen and Robinson 2005). Previously, genetic findings demonstrated that mice with a disruption of *Rank* or *Rankl* fail to develop mammary glands during pregnancy, resulting in the death of newborns (Fata et al. 2000). These mice exhibit normal mammary development and normal ductal elongation and side-branching of the mammary epithelial tree into the mammary fat

pad during puberty. However, their mammary epithelium fails to proliferate and form lobuloalveolar structures during pregnancy (Fata et al. 2000). The mammary gland defect in female RANKL-deficient mice can be reversed by recombinant RANKL treatment. These data clearly indicate that RANKL is an essential regulator of alveolar epithelial cell proliferation. Although RANK is constitutively expressed on mammary epithelial cells, the expression of RANKL is absent in virgin glands, but gradually increases during pregnancy. RANKL expression in mammary epithelial cells is induced by pregnancy hormones such as prolactin, progesterone, and PTHrP (Fata et al. 2000). A previous report showed that kinase-dead IKKα mutant mice display a severe lactation defect due to the impaired proliferation of mammary epithelial cells (Cao et al. 2001). The phenotype can be rescued by mammary-specific overexpression of cyclin D1. These data suggest that IKKα activity in response to RANKL is required for NF-κB activation and cyclin D1 induction in mammary epithelial cells during pregnancy. However, it is reported that cyclin D1 is normally expressed in mammary epithelial cells of RANK-deficient mice, but in these animals there is a defect in nuclear translocation of the basic helix-loop-helix transcriptional regulator, inhibitor of DNA binding 2 (Id2) (Kim et al. 2006). Genetic deletion of Id2 results in a similar phenotype having a lactation defect. Id2 regulates the proliferation of mammary epithelial cells through a suppression of the cell cycle inhibitor p21 in response to RANKL. Thus, RANK/RANKL plays an essential role in mammary gland development, but further study is required to completely elucidate the signaling pathways and transcriptional regulators.

The mammary gland in the period from puberty to menopause develops through tightly choreographed stages of cell proliferation (Hennighausen and Robinson 2005). Steroid hormones such as estrogen and progesterone have a prominent role in both the healthy and diseased states of breast tissue. Reproductive history is the strongest risk factor for breast cancer, and increased risk of breast cancer is correlated with a greater number of ovarian hormone-dependent reproductive cycles (Beral et al. 2005). There is also an increased risk of breast cancer associated with pregnancy in the short term. Although a proliferative role for the steroid hormones in this gland is well accepted, it is still unclear how the mammary gland translates hormonal signals into cell proliferation. Recent studies have implied that RANK/RANKL functions in mammary stem cell (MaSC) biology. MaSC is defined as a cell that can both self-renew and propagate the full spectrum of cell types that make up the mammary gland (Shackleton et al. 2006). The MaSC activity that was increased in mice treated with steroid hormones and pregnancy led to a dramatically increased number of MaSC in mice (Asselin-Labat et al. 2010; Joshi et al. 2010). In contrast, ovariectomy or aromatase inhibitor treatment markedly reduced the MaSC number and outgrowth potential in vivo (Asselin-Labat et al. 2010). In aged mice, MaSCs also display stasis upon cessation of the reproductive cycle (Joshi et al. 2010). MaSCs carry no known receptors for estrogen or progesterone, but these stem cells are highly responsive to steroid hormone signaling. Studies have shown that neutralization of RANKL in pregnant mice reduces the capacity of the MaSC-enriched basal cell population to form colonies. These data suggest that RANKL, a known progesterone target, may act as a crucial molecule that links progesterone-responsive mammary cells to MaSCs.

Hormone replacement therapy (HRT) is associated with an increased risk of breast cancer (Beral et al. 2005). In particular, progesterones or their synthetic derivatives (progestins) such as medroxyprogesterone acetate (MPA) markedly increase the risk of an abnormal mammogram and breast cancer. Recently, it was revealed that MPA treatment triggers the induction of RANKL expression in progesterone receptor (PR)-positive luminal mammary epithelial cells, resulting in autocrine or/and paracrine stimulation of RANK signaling in the mammary epithelium (Schramek et al. 2010). Importantly, specific deletion of RANK in mammary epithelium cells prevents both the onset and progression of MPA-driven mammary cancer and impairs self-renewal of breast cancer stem cells. Tumorigenesis in an MPA-driven tumor model as well as in a spontaneous tumor model was also inhibited by a neutralizing antibody to RANKL (Gonzalez-Suarez et al. 2010). In contrast, mammary-specific overexpression of RANK results in the acceleration of preneoplasias of the mammary glands and an increase in mammary tumor formation after either multiparity or treatment with a carcinogen and progestin (Gonzalez-Suarez et al. 2010). These findings show that the RANK/RANKL system is crucial for tumorigenesis.

Bone is the most common site for the distal spread of breast and prostate cancer (Mundy 2002). Bone metastases result in serious morbidity, including skeletal-related events such as pain, fractures, and hypercalcemia, increasing the mortality risk. Therefore, the clinical priority is to prevent metastases and bone loss owing to excessive osteoclastic bone resorption. Indeed, many clinical trials have evaluated the potential activity of anti-osteoclastic agents in cancer having bone metastases. The representative anti-osteoclastic agents include bisphosphonates and a RANKL neutralizing antibody (Denosumab) (Fornier 2010). A recent clinical study showed that Denosumab is superior to bisphosphonates such as Zoledronic acid for the delay or prevention of skeletal-related events in patients with advanced breast cancer with bone metastases (Stopeck et al. 2010). Interestingly, RANK is highly expressed in several human breast cancer cell lines and primary human breast tumors (Jones et al. 2006). Functionally, it has been shown that RANKL can stimulate the directed migration of mammary epithelial cells as well as prostate cancer and melanoma cells toward a source of RANKL. Furthermore, in an in vivo metastasis model, OPG reduced the tumor burden in bones and ameliorated clinical paralysis, but did not affect the frequency of the spread of metastases into other tissues (Jones et al. 2006). A recent clinical study reported that the level of RANK expression in primary breast cancer positively correlates with the development of bone metastases and may be a predictive marker of bone metastasis risk (Santini et al. 2011). Similar to breast cancer, prostate cancer metastasizes to bone through RANK signaling. Previous reports showed that IKKα activation by RANKL inhibits the expression of Maspin, a metastasis suppressor in prostate epithelial cells. Maspin expression reduced metastatic activity, whereas Maspin ablation restored this activity (Luo et al. 2007). These findings suggest that RANK-expressing tumor cells might sense RANKL as a chemoattractant and migrate in a coordinated fashion to a source of RANKL produced in the bone.

Summary

Bone-related diseases such as osteoporosis and RA afflict a great number of patients. Women taking progesterone derivatives for contraception or HRT have been shown epidemiologically to have an increased risk of breast cancer. These diseases are presenting a tremendous burden to the health care costs. Genetic approaches have established that the RANKL/RANK system is the central regulator of osteoclastogenesis, lymph node organogenesis, mammary gland development, and thymic epithelial cell development. In addition, recent data have revealed an entirely novel and unexpected function for RANKL/RANK in female thermoregulation and the central fever response (Hanada et al. 2009). RANKL has attracted the attention of scientists and pharmaceutical companies, since it plays a pivotal role in the pathogenesis of osteoporosis, RA, tumorigenesis, and metastasis. Novel drugs specifically targeting RANK/RANKL and their signaling pathways provide a potential means to revolutionize the treatment of various diseases associated with this pathway (Kearns et al. 2008).

Rap GEF Family

Hoa B. Nguyen and Lawrence A. Quilliam
Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN, USA

Synonyms

Guanine nucleotide exchange factor

List of Discussed GEFs

RapGEF1: C3G
RapGEF2: PDZ-GEF1, RA-GEF, CnRasGEF, KIAA0313, nRapGEP
RapGEF3: Epac, cAMP-GEF I
RapGEF4: Epac2, cAMP-GEF II
RapGEF5: MR-GEF, Repac, GFR, KIAA0277
RapGEF6: PDZ-GEF2, RA-GEF2
RasGRP2: CalDAG-GEF I
RasGRP3: GRP3, CalDAG-GEF III, KIAA0846
NSP2: BCAR3 (human), AND34 (mouse)
NSP3: Chat, SHEP
SmgGDS: RAP1GDS1

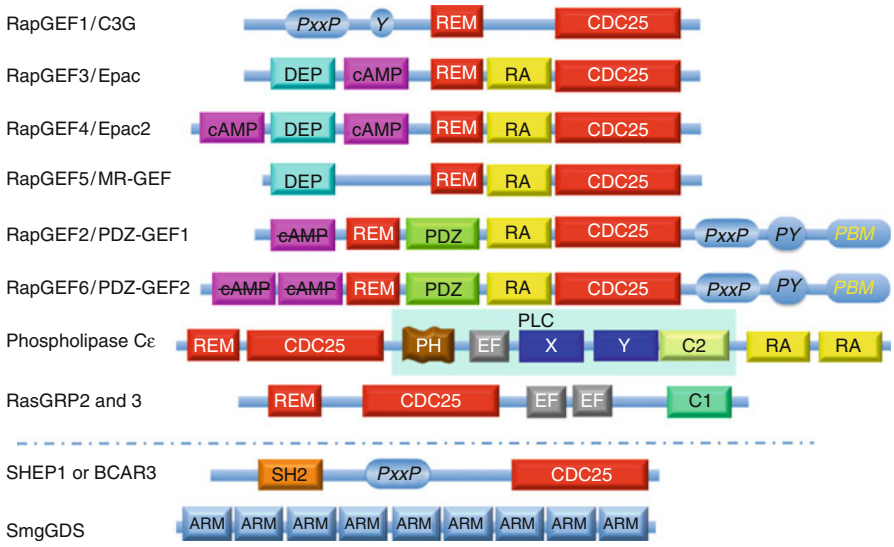
Historical Background

GTP binding proteins are extensively used in nature to regulate biological processes. Most of these proteins act as molecular switches that transition between inactive GDP-bound and active GTP-bound conformations. The largest family of GDP/GTP switches is the Ras superfamily of small-molecular-weight GTP binding proteins that constitute approximately 150 members in mammalian cells. This superfamily can be subdivided into Ras, Rho, Rab, ▶ Ran, and ARF families that regulate a myriad of cellular functions (Takai et al. 2001). True Ras proteins play major roles in coupling cell surface receptors to intracellular signaling pathways that control proliferation, differentiation, and survival. Due to their mutational activation in over 20% of human cancers, much research has focused on H-, K-, and N-Ras. In the shadow of these oncoproteins there are additionally over 30 Ras-related proteins that include the Rap proteins, Rap1A, 1B, Rap2A, 2B, and 2C. These proteins were initially discovered due to sequence similarity to Ras, their ability to revert the actions of Ras, and their abundance in leukocytes (Bokoch 1993). More recently Rap1 has been shown to play multiple roles that include inside-out signaling to control the affinity of integrins for extracellular matrix and consequently cell adhesion and migration. Rap1 also localizes to adherens junctions where it influences cell–cell adhesion and plays a number of additional roles in cell signaling, often overlapping with those of Ras (Raaijmakers and Bos 2009).

So how do Ras/Rap proteins act as molecular switches and how does the extracellular environment control their activity? Ras proteins normally exist in an inactive or resting GDP-bound state. To acquire an active GTP-bound confirmation they must exchange nucleotide. An intrinsic GTPase activity then hydrolyzes the terminal phosphate off the bound GTP enabling return to the inactive confirmation. The intrinsic rates of nucleotide exchange and GTP hydrolysis are in the order of minutes to an hour, not practical for rapid response to the extracellular environment. This means that additional factors must exist to both accelerate and tightly regulate these processes. Guanine nucleotide exchange factors (GEFs) promote the release of GDP whereas GTPase activating proteins (GAPs) have evolved to assist in the rapid hydrolysis of GTP (Quilliam et al. 2002). Whereas inhibition of GAPs and activation of GEFs both tip the balance in favor of Ras-GTP accumulation, nature most frequently uses GEFs to activate Ras proteins and enable biological responses. This article will focus on the nature and regulation of Rap family GEFs.

The baker's yeast CDC25 protein was the first Ras family GEF to be identified. Consequently the catalytic domain is referred to as a CDC25 homology domain. This region is conserved in approximately 35 mammalian GEFs, most of which also contain an REM (Ras exchange motif) that was required for a minimal CDC25 fragment to function in vitro (Quilliam et al. 2002; Raaijmakers and Bos 2009), see Fig. 1. Structural studies on the Ras GEF Sos1 and Rap GEF Epac demonstrated that the REM, which is located various distances N-terminal to the CDC25 homology region, contributes to the stabilization of the core catalytic domain.

Although there are approximately equal numbers of Ras subfamily members and GEFs, there is not a simple monogamous pairing of GEFs to Ras proteins.



Rap GEF Family, Fig. 1 *Schematic representation of Rap GEF functional domains*. The CDC25 homology domain (core catalytic unit) and associated Ras exchange motif (REM) are shown in red; protein kinase C-conserved region 1 (C1) and C2, Ca^{2+} binding motif are shades of light green; Armadillo (ARM) repeats are light blue; cAMP binding domains are pink; ~~cAMP~~ represents similar sequences not thought to bind cyclic nucleotide; DEP (Disheveled, Egl-10 and Pleckstrin) domains are turquoise; Ca^{2+}-binding EF hands are gray, PDZ (PSD-95, Dgl and ZO-1) domains are shown in green with PDZ-binding motifs (PDM), proline-rich SH3 binding motifs (PxxP), protein tyrosine kinase phosphorylation site (Y), and WW domain-binding PY site is shown in light blue. Pleckstrin homology (PH) domain is brown, Ras associated (RA) domains are shown in yellow, Src-homology (SH) 2 domain is orange, and the X and Y domains that form the catalytic domain of phospholipase C are dark blue

Interestingly more GEFs have evolved to regulate Rap than any other group. Rap GEFs contain multiple regulatory domains suggesting that Rap proteins are under the control of diverse extracellular stimuli. Regulation includes protein–protein or protein–lipid interactions, binding of second messengers, and/or posttranslational modifications. The need for so many GEFs may be to activate Rap in different tissues or different locations within a given cell, at key points in development, or in response to different hormones/growth factors, etc., that use unique signaling mechanisms. Recent knockout studies in mice have supported the notion that Rap1A and 1B play fundamental roles in mammalian development and function, and likewise, creation of mice lacking various Rap GEFs (discussed below) support the notion that individual exchange factors play equally critical functions.

RapGEF1/C3G

One of the earliest mammalian Ras family GEFs to be isolated was the *C*rk SH*3*-binding *g*uanine nucleotide exchange factor (C3G) (3, 4). In addition to the CDC25 homology and REM domains, C3G contains central proline-rich sequences that bind to the N-terminal SH3 domain of the Crk adapter protein, a more N-terminal proline-rich motif that associated with ▶ p130Cas, c-Abl, and Hck SH3s, and a central tyrosine residue (Y504) that is phosphorylated by Src family tyrosine kinases (Fig. 1). C3G is perhaps the most ubiquitously expressed Rap GEF. It is activated by numerous cell surface molecules that include integrins, T and B cell receptors, E-cadherin, and various growth factors and G-protein-coupled receptors.

C3G was initially found to activate Rap1 but has since been reported to also promote nucleotide exchange on several other small GTPases: Rap2, R-Ras, and TC10. Interestingly, TC10 is a member of the Rho family of GTPases that are typically regulated by a distinctly different family of GEFs. TC10 plays a role in insulin-stimulated glucose uptake and in 2010 a Korean study linked mutations within C3G to type II diabetes (Hong et al. 2009). Two C3G knockout mice were created and demonstrated embryonic lethality, exemplifying its important

biological role. C3G is frequently localized through its interaction with the Crk and CrkL SH2/SH3-containing adapter proteins. For example, the Abl tyrosine kinase can recruit a CrkL-C3G complex to the immune synapse.

RapGEF3 and 4/Epac1 and 2

The second messenger cyclic adenosine monophosphate (cAMP) exerts many effects on cell biology. While these were classically known to be mediated by the cAMP-dependent protein kinase/protein kinase A (PKA) and olfactory cyclic nucleotide–gated ion channels, two cAMP-activated Rap GEFs were discovered in 1998 that helped explain the PKA-independent actions of cAMP (Quilliam et al. 2002; Raaijmakers and Bos 2009; Gloerich and Bos 2010). They are called Epacs (exchange proteins activated by cAMP) 1 and 2 or cAMP-GEFs. While the former name is most popular (and used herein) their official gene names are RapGEFs 3 and 4.

In addition to the REM/CDC25 exchange region that acts on Rap1 and 2, Epac proteins have either one (Epac1) or two (Epac2) cyclic nucleotide–binding domains (CNBD), a Disheveled, Egl-10, Pleckstrin (DEP) domain, and an RA domain (Fig. 1). Structural studies on Epac2 indicate that the N-terminus folds over the C-terminus and hinders Epacs binding to its substrate Rap. This autoinhibition is relieved by the binding of cAMP to the CNBDs (Gloerich and Bos 2010). Epacs' CNBDs lack a glutamate residue found in PKA and cAMP-gated ion channels that typically interacts with the 2-OH group of the ribose of cAMP. Consequently, Epacs can bind bulky cAMP analogs such as 8-(4-chloro-phenylthio)-2'-*O*-methyladenosine-cAMP (8CPT) where the 2-OH group has been replaced with a O-Me to selectively activate Epac proteins versus other cAMP effectors. These compounds have proven to be very useful tools to implicate Epac in biological events and may have clinical potential (Gloerich and Bos 2010).

Epacs, like most other GEFs and GAPs, regulate Rap proteins in a spatial and temporal manner. For instance, localization of Epac1 and 2 is regulated by their distinct RA domains. The RA domain of Epac2 specifically binds K- and N-Ras (with weaker affinity for H-Ras), enabling Ras-GTP to translocate Epac2, but not Epac1, from the cytosol to the plasma membrane. Consequently, a pool of plasma membrane-bound Rap1 can become activated upon concurrent cAMP and Ras signaling (Li et al. 2006). Meanwhile, the RA domain of Epac1 interacts with Ran, a small G-protein best known for its role in regulating nuclear transport. Ran and its binding partner RanBP2 anchor Epac1 to the nuclear pore, allowing localized Rap1 activation at the nuclear envelope upon cAMP elevation (Liu et al. 2010). In a different scenario, Epac1 can be targeted to the plasma membrane via its DEP domain. This is necessary for Rap to regulate integrin-mediated adhesion at the membrane. However, in Rat1a fibroblasts, peripheral Rap1 activation by Epac1 is counteracted by high RapGAP activity, resulting in predominantly perinuclear Rap-GTP (Gloerich and Bos 2010). Furthermore, in both interphase and mitotic cells, Epac1 is targeted to microtubules by tubulin or the microtubule-associated protein 1 and may play a role in microtubule polymerization. Other reports show Epacs localizing to centrosomes, mitochondria, macrophage phagosomes, the apical epithelial membrane, and regulating the DNA damage–responsive kinase, DNA-PK, in the nucleus. Temporal expression also contributes to Epac action: As monocytes differentiate into macrophages, their Epac protein levels increase threefold and play a role in chemokine secretion.

Epacs regulate a variety of physiological processes that include secretion of insulin from pancreatic beta cells, permeabilization of vascular endothelium, transmigration of leukocytes, and regulation of cardiac calcium channels. Consequently, Epac activity has been associated with diabetes, vascular inflammation, and heart disease. Interestingly, PKA is also involved in these processes demonstrating the close partnership of Epac and PKA in mediating cAMP action.

Using Epac2 knockout mice, Seino's lab established that cAMP potentiates glucose-induced exocytosis via Epac2 rather than PKA. They later demonstrated that Epac2 is the direct target of the antidiabetic sulfonylurea drugs that promote insulin secretion (Zhang et al. 2009). A number of studies have implicated Epacs in inflammation both through regulation of leukocytes and vascular permeability (Borland et al. 2009). In cardiac myocytes, Epacs and another Rap GEF, phospholipase Cε both play critical synergistic roles in calcium-induced calcium release downstream of β-adrenergic receptors.

RapGEF2 and 6/PDZ-GEFI and II

Similar in structure to Epacs are PDZ-GEF-I and II, also called RA-GEF-1 and 2, or official names RapGEFs 2 and 6. PDZ-GEF-I has also been described as CNrasGEF or nRapGEP. Like Epacs, PDZ-GEFs have a REM-CDC25 GEF module, an RA domain, and a region sharing homology with CNBDs (Quilliam et al. 2002; Raaijmakers and Bos 2009) (Fig. 1). However, most reports indicate that cAMP does not bind to this latter region with high affinity. PDZ-GEFs have a PSD-95/DlgA/ZO-1 (PDZ) domain that can bind the β1 adrenergic receptor, potentially linking G-protein-coupled receptors to Ras activation. At its C-terminus, PDZ-GEFs have a proline-rich region and a PDZ-binding motif, which interact with the PDZ domains of cell junctional proteins, MAGI-1 and −2 (Sakurai et al. 2006). This links PDZ-GEF with ▶ β-catenin and contact-induced activation of Rap1 (Sakurai et al. 2006). In addition, two PY motifs at its C-terminus are responsible for binding to the WW domain of the ubiquitin protein ligase Nedd4. This interaction regulates PDZ-GEF protein turnover rate via proteasomal degradation.

PDZ-GEF1 and 2 functions have been studied through gene knockouts in both *Drosophila* and mice. In *Drosophila*, PDZ-GEF (Gef26) regulates DE-cadherin to control stem cell adhesion to its niche. Functional mutation of this GEF leads to loss of cell polarity, impaired adherens junctions, and thus reduction in stem cell number (Wang et al. 2006). Two labs found that PDZ-GEF knockout is embryonic lethal in mice. Kataoka's lab found that vascular development is impaired in PDZ-GEF1 knockout mice at around E7.5 with embryonic lethality occurring by E9.5, while Hou and colleagues found PDZ-GEF2$^{-/-}$ mouse embryos surviving to ~E11.5. Mice died of vasculature defects in the yolk sac and the allantois. Further analysis revealed dysregulation in B-Raf/ERK signaling, and a reduction in Scl/Gata transcription factor expression (Satyanarayana et al. 2010). These molecular signaling events underline the reduction of definitive hematopoietic CD41 cells. Hematopoietic progenitors isolated from these mouse embryos also lacked the potential to form erythroid or granulocyte/macrophage colonies, indicating that PDZ-GEF-2 plays a role in hematopoiesis development and progenitor functions. In addition, deletion of PDZ-GEF-2 late in embryogenesis resulted in defective fetal liver erythropoiesis. However, such deletion in the adult bone marrow, or specific deletion in B-cells, T-cells, hematopoietic stem cells, or endothelial cells had no impact on hematopoiesis (Satyanarayana et al. 2010). This reiterates the importance of temporal control and the role of various GEFs at different stages of development.

Conditional knockout of PDZ-GEF showed other crucial functions of this GEF in neural migration and in splenocyte responses. Mice with dorsal telencephalon-specific PDZ-GEF-1 knockout develop heterotopic cortical mass and commissural fiber defect. Meanwhile, PDZ-GEF-2 and Rap1 mediate TNFα-induced M-Ras activation in order to activate the integrin, lymphocyte function-associated antigen 1 (LFA-1), and subsequently, cell aggregation in response to inflammation (Yoshikawa et al. 2007).

Others also reported PDZ-GEF2 interacts through its PDZ domain with junctional adhesion molecule-A (JAM-A), which also interacts with Afadin/AF6 in human colonic epithelial cells. JAM-A and AF6 both act upstream of a signaling pathway that specifically activates Rap1A but not Rap1B in order to regulate β1 integrin and mediate cell migration (Severson et al. 2009). This is a rare report of differential signaling to Rap1A versus Rap1B.

RapGEF5/MR-GEF

MR-GEF was characterized by numerous groups, as a Rap-specific GEF (acting on Rap1 and 2) (Quilliam et al. 2002; Raaijmakers and Bos 2009). Due to sharing highest homology to Epacs it was referred to as Repac or alternatively as MR-GEF (*M*-Ras *r*egulated) due to the presence of an RA domain that selectively bound to M-Ras-GTP. M-Ras over-expression inhibited Rap1 activation but based on the experiences of us and others it is likely that M-Ras is specifically targeting the GEF to activate a plasma membrane pool of Rap1 at the expense of the activity of bulk GTPase (Li et al. 2006). An apparent splice variant that swaps the first 70 amino acid residues for an alternative 208 residue sequence (NP_036426) places a DEP domain at the extreme N-terminus that may play a role in membrane localization. A DEP domain is also found in Epacs a similar distance from the REM domain (Fig. 1). However, unlike Epacs, MR-GEF does not contain an intervening cAMP binding motif.

MR-GEF expression was induced by exposure to anthrax and expression is also turned on in developing rodent GABAergic neurons. Interestingly, MR-GEF expression is also altered in individuals with bipolar disorder. Correlation of the percentage of MR-GEF expressing neurons and 2D neuronal density between cortical layers II and IV in bipolar disorder support a growing body of evidence for its contribution to defects in cortical organization and communication in this disease (Bithell et al. 2010).

RasGRPs

In addition to RapGEFs 1–6, several other Rap1 exchange factors exist, if not implicitly acknowledged by their official gene names. The four RasGRP (Ras guanyl releasing proteins) or CalDAG-GEF gene products contain an N-terminal REM and CDC25 homology regions that are followed by two tandem Ca^{2+}-binding EF hands similar to those found in calmodulin (Quilliam et al. 2002; Raaijmakers and Bos 2009). Farther C-terminal is a C1 domain similar to the diacylglycerol (DAG)/phorbol ester binding domain found in classical and atypical protein kinases C – hence the CalDAG moniker. Both RasGRP2/CalDAG-GEF1 and RasGRP3 act as GEFs for Rap proteins. GRP2 is specific for Rap1/2 and activates it in a Ca^{2+}-dependent manner (although an N-terminally myristoylated splice variant was reported to also act on N- and K-Ras but to be inhibited by Ca^{2+} elevation). In contrast, RasGRP3 has the broadest substrate specificity of all Ras GEFs, acting on true Ras, R-Ras, and Rap subfamilies (Quilliam et al. 2002; Raaijmakers and Bos 2009). RasGRPs 1 and 4 are Ras-specific.

RasGRPs are highly abundant in brain: RasGRP2 is most highly expressed in the basal ganglia whereas RasGRP3 is found primarily in glial cells of the cerebral and cerebellar white matter. Both GRPs are also highly expressed in cells of hematopoietic origin. GRP2/Cal-DAG1 is particularly abundant in platelets (that are also replete with Rap1b) where they play a major role in coupling chemoattractant receptors to αIIbβ3 integrin activation during "inside-out" signaling as well as in thromboxane A2 release. Leukocyte adhesion deficiency (LAD) syndrome III, characterized by an inability of leukocytes to adhere and migrate during inflammatory and host defense reactions was initially attributed to mutations in RasGrp2 but recent studies suggest that kindlin-3 rather than GEF mutation is the true culprit behind this rare disease.

Phospholipase Cε

Like other phospholipases C (PLCs) PLCε contains X and Y regions that make up the phospholipase catalytic domain. This enzyme cleaves phosphatidyl inositol 4,5 bisphosphate (PIP_2) into the second messengers inositol 3,4,5 trisphosphate (IP_3) and DAG. PLCε similarly possesses, a PH domain, C2 domain, and EF hands that bind to phospholipids and Ca^{2+} (see Fig. 1). However, unlike other PLC isozymes, PLCε is also a Rap GEF. PLCε has both an N-terminal REM/CDC25 Rap GEF module and tandem RA domains located at its C-terminus (Fig. 1). The GEF function of PLCε helps maintain persistent Rap1-GTP levels following G-protein-coupled receptor stimulation (Suh et al. 2008). The C-terminal RA domain (RA2) interacts with activated Ras and Rap1 enabling PLCε recruitment to either the plasma membrane or the perinuclear area, respectively, following growth factor stimulation. Meanwhile, the other RA domain confers protein stability and possibly also autoinhibition.

Significant crosstalk between PLCε and other RapGEFs has been reported and further scenarios can readily be imagined. For example, Ca^{2+} and DAG generated by PLCε activity might promote the activation of GRP2 or 3. Additionally, upon adrenaline or prostaglandin E2 stimulation, G-protein-coupled receptors elevate cAMP levels and activate Epac. This results in Rap2B activation that in turn associates with RA2 of PLCε and induces PIP_2 hydrolysis. PLCε can also be activated by other ligands such as lysophosphatidic acid or sphingosine 1-phosphate that couple to Gα12 and Gα13. In addition, Gα12 and Gα13 can activate various RhoGEFs. GTP-loaded RhoA can bind directly to the phospholipase Y domain and stimulate PLCε activity.

PLCε knock-down or mutation is embryonic lethal in *Caenorhabditis elegans* due to its role in epidermal morphogenesis while $PLC\varepsilon^{-/-}$ mice exhibit multiple cardiac defects. These include ventricular dilation, aortic and pulmonary valve defects, and stenosis due to the thickening of valve leaflets. Additionally, cardiac myocytes from PLCε null mice have a decrease

in contractile response to acute β-adrenergic stimulation. Human kidney development also requires PLCε and truncating mutations in PLCε were found in nearly 30% of children having the nephrotic syndrome, diffuse mesangial sclerosis (Suh et al. 2008). However, loss of PLCε can be advantageous to mice, resulting in reduced susceptibility to carcinogen induced skin tumor formation (Suh et al. 2008). This is likely the result of PLCε mediating both direct agonist-dependent proliferation and an indirect inflammatory response. PLCε both mediates PDGF-, EGF-, and Rho-dependent cell growth and inhibits EGF receptor down-regulation via PIP_2-derived second messengers. Furthermore, PLCε can transduce mitogenic signals through its Rap1 GEF activity. On the other hand, PLCε-null mice have a reduction in phorbol ester-induce edema, granulocyte infiltration, and expression of the proinflammatory cytokine, interleukin-1α.

Additional Potential Rap GEFs

Dock4 is a member of the Dock180/CZH family of Rho GEFs and, in partnership with ELMO, is known to regulate the activity of Rac1. However Dock4 was reported to effectively activate Rap1 in a mouse osteosarcoma cell line (Yajnik et al. 2003). A dominant inhibitory mutant of Rap1 blocked the biological consequences of Dock4 expression and a constitutively active Rap1-63E mutant mimicked Dock4-induced adherens junction formation; however, there is no direct demonstration of RapGEF activity in vitro. Since Rap1 is intimately associated with Rac and adherens junction regulation the effect of Dock4 reported here may have been indirect.

NSP1-3 (novel SH2-containing proteins) have a C-terminal CDC25 homology domain, an N-terminal SH2 domain, and a central proline-rich region that may interact with SH3 domains (Quilliam et al. 2002) (Fig. 1). They have various alternate names such as BCAR3, AND-34, SHEP1, and Chat and have been reported to associate with Rap1. While exchange activity was attributed to NSP2/BCAR3/AND34 in one study, this was likely indirect due to its association with Crk/Src to influence Rap1 and Rac GEF activity. NSPs were identified in breast cancer (BCAR3 = breast cancer antiestrogen resistance gene 3) or associated with receptor tyrosine kinases (EGFR for NSP1, EphB2 for NSP3/SHEP1/Chat). All 3 NSPs associate with the scaffold protein p130 Cas, implicating them in adhesion. Surprisingly the CDC25 homology domain is responsible for this interaction. Thus although NSPs likely play a pivotal role in coupling adhesion receptors and tyrosine kinases to actin cytoskeletal organization their CDC25 domains act as adapter modules rather than as Rap GEFs.

SmgGDS (small-molecular-weight G-protein guanine nucleotide dissociation stimulator) is relegated to last place in this article but was the first mammalian Rap (or Ras family) GEF to be discovered in 1990, reviewed in Quilliam et al. (2002). It is comprised of ARM/armadillo repeats (similar to, e.g., catenins or importins) rather than having a CDC25 homology domain (Fig. 1) and selectivity is based on the presence of positively charged residues in C-terminal tail of Ras proteins: target substrates include Rap1, K-Ras, Rac1, RhoA, and Ral that each have multiple lysine residues in their C-terminal hypervariable regions. SmgGDS (gene name RAP1GDS1) expression is critical during development and appears to possess weak GEF activity and to promote the malignant phenotype of certain cancer cells. However, whether it acts as a true GEF in vivo has always been in question. A recent study suggests that two splice variants of smgGDS increase the activity of polybasic-region-containing GTPases such as Rap1 by facilitating their posttranslational modification by lipids and subsequent transit to the plasma membrane (Berg et al. 2010).

Summary

Multiple Rap GEFs have been characterized at both the molecular level and frequently also in mouse models of development/disease. However there is much still to be learned from animal models. The number of GEFs and variety of regulatory domains suggest that Rap plays key roles in cell signaling that need to be activated in unique spatiotemporal scenarios. While Rap1 plays many roles in cell biology and likely represents a poor drug target, targeting Rap GEFs might result in specific regulation of Rap1 in certain diseases. The 8CPT-cAMP molecule represents a specific activator of Epacs that may impact signaling events in vascular disease and diabetes, but to date no Rap GEF inhibitors have been developed.

Historical Background

Evidence that viral genes were translated in virus-transformed cells was first reported in the early 1970s (Green et al. 1971). Following on from these observations, it was discovered that certain 21 kDa proteins encoded by viral genes and possessing guanine nucleotide binding properties (Scolnick et al. 1979) were essential for the maintenance of transformation in cells infected with the Kirsten and Harvey sarcoma viruses (Shih et al. 1979). Intriguingly, sequences containing a very high degree of homology to genes encoding these transforming proteins were found in normal rat, mouse, and human genomes, suggesting a physiological role, unrelated to disease, for these proteins. Mutant versions of the oncogenes associated with the Kirsten sarcoma virus (K-ras) and the Harvey sarcoma virus (H-ras) were found in cancer cell lines of various tissue origins (Der et al. 1982). The majority of these contained point mutations that resulted in the replacement of the guanosine residue at position 12. A third Ras family member termed "N-ras," also containing activating point mutations, was subsequently identified in leukemia and neuroblastoma cell lines (Hall et al. 1983). Indeed, it was soon realized that the Ras family of proto-oncogenes are among the most frequently mutated genes in human cancers. The field of Ras research is now a large and complex enterprise owing to the discovery of this protein family's fundamental roles in cell and cancer biology, development, and disease.

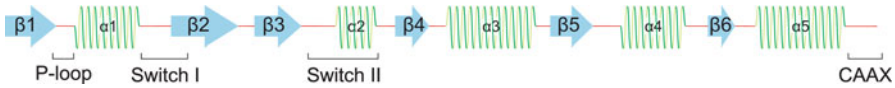
Structure and Function of Ras Proteins

The Ras proteins are 21 kDa small G proteins with intrinsic GTP binding and GTPase properties (Sweet et al. 1984). The three-dimensional structures of Ras in the GTP- and GDP-bound forms determined by crystallography were published in 1990 and revealed that Ras consists of a six stranded β-sheet and five α-helices forming a hydrophobic core and linked together by ten loops. Five of these loops mediate the high-affinity interactions between Ras and GTP and act by stabilizing the γ-phosphate of the bound GTP (Brunger et al. 1990). The p-loop, which contains the guanosine-12 often mutated in cancers, directly binds the γ-phosphate of GTP. The structures of GTP-bound and GDP-bound Ras differ in two regions called switch I and switch II (Fig. 1), which are crucial for the interaction of Ras with both its upstream regulators and downstream effector partners that mediate its function and intracellular localization.

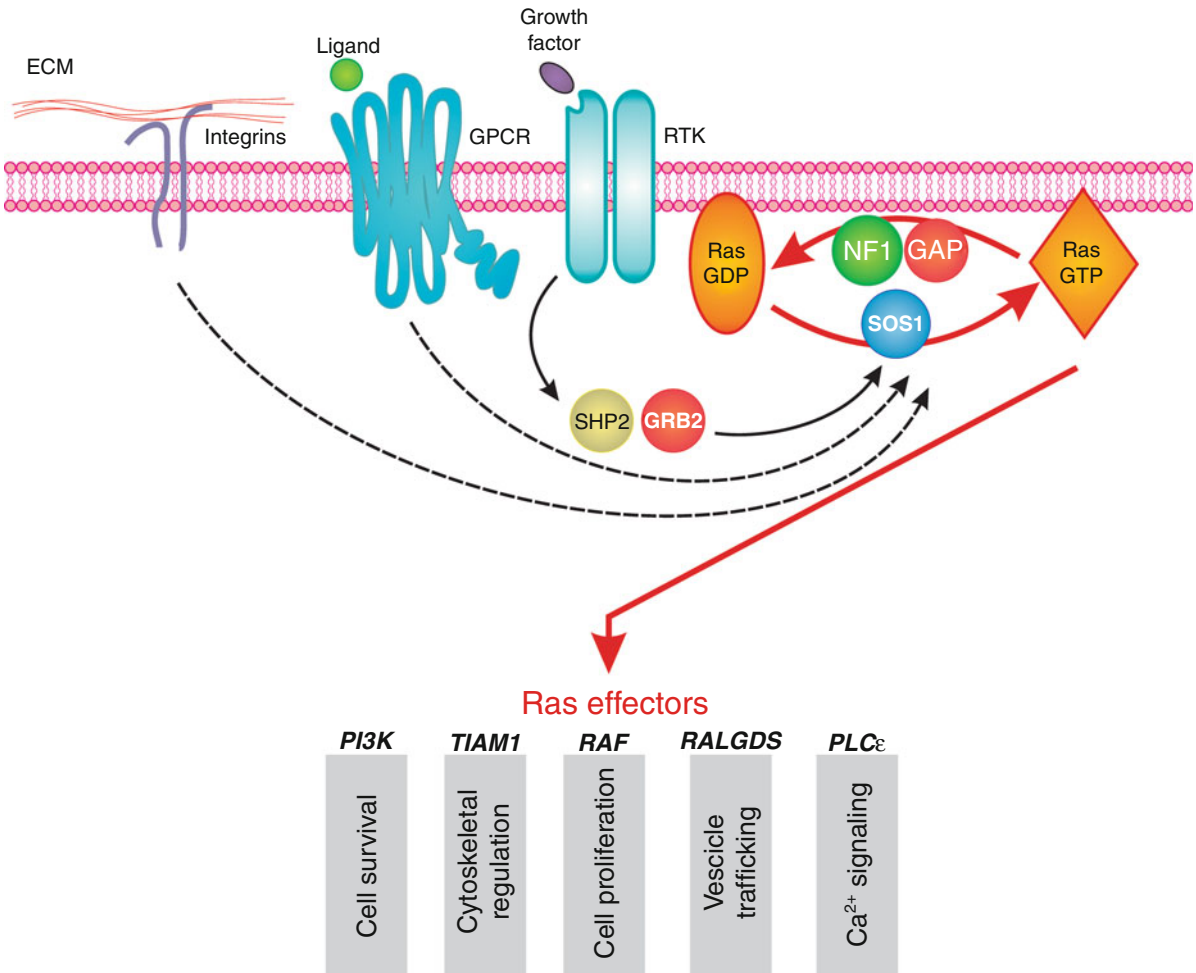
In the GTP-bound state, Ras proteins are in an active conformation and can participate in high-affinity interactions with Ras effector proteins. These proteins are usually enzymes that transduce downstream signaling cascades. However, the intrinsic GTPase activity of Ras proteins results in the hydrolysis of GTP to GDP, with which Ras proteins associate only weakly. Following hydrolysis and loss of the γ-phosphate, the GDP molecule is released and the Ras protein returns to an inactive state. This GTPase cycle is facilitated by the Ras GTPase-activating proteins (Ras GAPs) and the Ras guanine nucleotide-exchange factors (Ras GEFs) (Fig. 2). The Ras GAP proteins promote the GTPase activity of Ras and facilitate its transition from the active to the inactive state, resulting in the switching off of Ras signaling. The Ras GEF proteins, on the other hand, bind inactive Ras-GDP and promote the exchange of GDP for GTP, triggering the activation of Ras. Ras GEF proteins contain many protein-protein interaction domains that mediate their activation. One way in which Ras GEFs are activated is in response to ligand binding to receptors with which they are associated. Similarly, GAPs Ras proteins are often large and complex and contain a variety of signaling motifs that enable them to associate with the many interacting partners that regulate their activity. Mutant versions of Ras proteins often found in cancers exhibit attenuated affinity for GTP, but maintain an active conformation enabling them to interact with and activate effector proteins and signal constitutively downstream in the absence of upstream activating signals (Karnoub and Weinberg 2008).

Regulation of Ras Activity

In addition to the action of Ras GEFs and GAPs, the activity of Ras is regulated by a variety of other mechanisms. These include posttranslational modifications such as the addition of fatty acid side chains and proteolytic processing, which determine its localization. Palmitoylation of Ras at the C terminus facilitates its association with the cell membrane (Sefton et al. 1982) and this particular localization is essential for its function. A C-terminal CAAX motif within Ras is the target of a prenylation reaction by farnesyl transferase,



RAS (H-, K-, N-RAS), Fig. 1 *Linear representation of the domain structure of the Ras proteins*. The α-helices are denoted α1–α6 and the six strands making up the β-sheet are denoted β1–β6. The P-loop between β1 and α1 stabilizes the γ-phosphate of GTP and is a region often mutated in oncogenic versions of the protein. The Switch 1 and Switch 2 regions are important for protein-protein interactions and the CAAX region is a target of posttranslational modifications



RAS (H-, K-, N-RAS), Fig. 2 *Signaling through Ras*. This schematic illustration of the Ras signaling pathway highlights the modes of Ras activation and the effector pathways downstream of Ras that regulate cellular processes. Binding of growth factor to receptor tyrosine kinases (RTK) activates proteins such as GRB2 and SHP2, which activates SOS1, a Ras GEF, resulting in the accumulation of GTP-bound active Ras. GPCR and Integrin signaling can also indirectly activate Ras. NF1 and other GAPs in turn bind active Ras and catalyze its conversion to the GDP-bound inactive form, turning off Ras signaling. Downstream, Ras-GTP signals through a variety of effector pathways to regulate many cellular processes

which is followed by cleavage of the AAX sequence, leaving a C-terminal cytosine residue. This cytosine residue is then carboxy-methylated as an essential step for full Ras function. There are slight variations in the specific modifications to K-Ras, H-Ras, and N-Ras proteins, but the final outcome of these modifications is the secure tethering of the Ras protein to the cell membrane, which is essential for its association with both upstream and downstream signaling partners (Downward 2003).

Operating upstream, GEFs such as son of sevenless (SOS) that interact with and activate Ras proteins are themselves activated by various signals including those arising from receptor tyrosine kinases (RTK) such as the EGF Receptor. However, Ras may also be activated more indirectly by signals from Integrins or G protein-coupled receptors (GPCR) (Fig. 2). The function of Ras as a major signaling node is attested to by the multiple GEFs that activate it, as well as by the even larger numbers of Ras GEF binding partners that regulate their function.

Ras Signaling Pathways

MAP Kinase Signaling

Activated Ras interacts directly with the RAF1 protein, a Ser-Thr kinase, and stimulates its kinase activity. Most notable of the substrates of Raf are the mitogen-activated protein kinase kinases (MAPK, also known as MEKs) which phosphorylate the extracellular signal-regulated kinases (ERKs) to regulate the transcription of target genes through the E26-transcription factor proteins (ETS) (Fig. 2). The Ras-MAP kinase effector pathway regulates cell proliferation and is required for Ras-induced cell transformation (Khosravi-Far et al. 1995). Signaling through the MAP kinase pathway is frequently enhanced in cancers by the somatic acquisition of activating mutations in the Ras proteins or their effector Raf proteins. However, activating mutations in both Ras and Raf are only rarely seen together, illustrating the importance of abnormal signaling through the MAP kinase pathway in cancer (Karnoub and Weinberg 2008; Downward 2003).

PI3 Kinase Signaling

Upon activation, Ras proteins are capable of interacting with the catalytic subunit (p110) of the class I phosphoinositide 3-kinases (▶ PI3Ks), which results in the production of phosphatidylinositol-3,4,5-trisphosphate (PtdIns(3,4,5)P_3). This second messenger molecule binds a large number of proteins including PDK1 and the Ras homology family protein Rac, and regulates their activity. One of these pathways downstream of PtdIns(3,4,5)P_3 regulates cell survival through the serine/threonine kinase AKT/Protein Kinase B (AKT/PKB) (Fig. 2) (Downward 2003). Like the MAP kinase pathway, the PI3 kinase signaling pathway is also indispensible for Ras-mediated cell transformation (Rodriguez-Viciana et al. 1997).

Other Ras Effector Pathways

While Ras is capable of activating RalGDS, the GEF for the Ras-like (RalA/B) small GTPases, conflicting evidence exists for the involvement of the RalA/B effector pathway in transformation. This pathway was originally considered of minor importance to transformation, but new evidence suggests that signaling through RalA/B is sufficient for transformation of some human cell types (Hamad et al. 2002). Rac1 (Khosravi-Far et al. 1995; Samuel et al. 2011), tumor invasion and metastasis inducing protein (TIAM1, a Rac GEF protein), the epsilon form of phosphoinositide-specific phospholipase C (PLCε), and RASSF have all been shown to be Ras effectors, but much remains unknown of their functions downstream of Ras.

Ras in Disease

Cancers are the disease manifestations most commonly associated with aberrant signaling through Ras. Mutations in one or more of the Ras isoforms are frequently observed in cancers, with codon 12/13 mutations making up the majority of these (Loriot et al. 2009). These forms of Ras are usually able to associate with and activate effector proteins in the absence of GTP binding and indeed mutant Ras has attenuated affinity for GTP. Both the MAP kinase and PI3-kinase effector pathways are required for Ras-mediated transformation and increased signaling through both these pathways been implicated in providing cancer cells with a survival advantage.

Different isoforms of Ras are preferentially expressed in different organs, leading to isoform-specific disease manifestations resulting from aberrations in Ras activity. For instance, most pancreatic cancers exhibit K-Ras mutations, but H-Ras mutations are almost never observed in this disease. Furthermore, N-Ras mutations are common in skin cancers, but K-Ras mutations are not. That this is likely the result of differences in the expression levels of Ras isoforms, which may nevertheless function similarly in different cell types, is supported by the observation that the H-Ras coding sequence

placed under the transcriptional control of the endogenous K-Ras promoter can rescue the embryonic lethality resulting from K-Ras deficiency (Potenza et al. 2005).

Ras in Development

Aberrant signaling downstream of Ras has been identified as being the cause of several developmental disorders. Collectively termed cardio-facio-cutaneous diseases, neurofibromatosis type-1 and the Noonan and Costello syndromes are characterized by inherited lesions in effectors, GAPs or GEFs of Ras (Loriot et al. 2009) or infrequently by acquired somatic mutations in Ras genes. People suffering from these syndromes generally exhibit abnormalities in the bones of the face, insufficiency in cardiac function, stunted growth, and an increased cancer risk (Schubbert et al. 2007). The fact that activating germ-line K-Ras mutations are rarely observed in genetic syndromes is strong evidence that unregulated Ras activation is highly disruptive during development and is consistent with the embryonic lethality associated with inherited activating K-Ras mutations in mice.

Therapeutic Inhibition of Ras Signaling

Antagonizing the activity of mutant Ras has always been an attractive therapeutic modality for cancer. Many of these therapies have focused on disrupting the posttranslational modifications essential for the localization of Ras to the cell membrane, but have suffered from lack of selectivity. Agents such as farnesyl transferase inhibitors (FTI) also interfere with the processing of other proteins such as RhoB. Approaches to therapeutic targeting of Ras expression using antisense oligonucleotides are currently under trial. These approaches have run into problems associated with delivery and the lack of efficient take-up into cancer cells (Downward 2003). Small molecule inhibitors of the MAP kinase pathway protein Raf, such as Sorafenib (Sebolt-Leopold et al. 1999; Iyer et al. 2010), have been more successful, but only target a single Ras effector pathway. Sorafenib has been approved for the treatment of renal cell and hepatocellular carcinomas. Inhibitors of MEKs such as U0126 and PD98059 are effective in inhibiting activation of the MAP kinase pathway and are also currently under trial.

Summary

The Ras genes were first discovered in viruses that possess cell transforming ability before it was realized that very similar genes exist in untransformed cells. The Ras proteins have important physiological functions in transducing signals that regulate cell proliferation and survival. They constitute signaling hubs that integrate and link growth factor signals from upstream to the appropriate effector pathways downstream. Activating mutations in Ras genes or in components of Ras effector pathways are commonly observed in cancer, leading to increased cell proliferation and survival. Germ-line mutations of Ras effector pathways underlie a group of developmental disorders including the Noonan and Costello syndromes, collectively termed cardio-facial-cutaneous syndromes. Ras antagonizing therapies are beginning to be used effectively to treat cancers.

Historical Background

The small, membrane-tethered G-protein Ras plays an important role in many cellular processes, including growth, differentiation, and survival (Wennerberg et al. 2005). Ras acts as a molecular switch which is bound to GDP in its inactive state, and GTP in its active state. When Ras is active, it can directly associate with the serine/threonine kinase Raf, which can be activated by phosphorylation upon recruitment to the membrane. Raf can then activate the dual-specificity protein kinase MEK1/2, which in turn activates the

Mitogen-Activated Protein Kinase (MAPK) ERK1/2. Since Ras controls multiple cellular outcomes, its activity is tightly regulated. Inactive, GDP-bound Ras can be activated by interaction with Guanine-nucleotide Exchange Factors (GEFs), which eject GDP from the nucleotide binding site of Ras and allow GTP to bind, which is present at a much higher molar concentration than GDP in the cytoplasm. Examples of Ras GEFs include Son of Sevenless (SOS) and Ras Guanyl-Releasing Protein 1 (RasGRP1). Active, GTP-bound Ras is inactivated by association with GTPase-Activating Proteins (GAPs), which enhance the low intrinsic GTPase activity of Ras by several orders of magnitude, resulting in hydrolysis of GTP to GDP (Iwashita and Song 2008). Ras p21 Protein Activator 1 (RASA1) was the first GAP to be characterized at the molecular level. The discovery of RASA1 was initially based on the observation that Ras-GTP levels in vivo were much lower than expected based on the intrinsic GTPase activity of Ras (Trahey and McCormick 1987). Subsequently, the ubiquitously expressed RASA1 protein was purified and its cDNA cloned from human and bovine tissue (Trahey et al. 1988; Vogel et al. 1988). At least 14 Ras GAPs have since been discovered in mammals, including neurofibromin (NF1), Ca^{2+}-promoted Ras inactivator (CAPRI), and Synaptic Ras GTPase-activating protein 1 (SYNGAP1) (Bernards 2003).

Structure

GAPs are modular proteins, with numerous distinct domains in addition to the conserved, catalytic GAP domain. The RASA1 molecule is composed of six such modular domains. These include two Src-homology-2 (SH2) domains and a Src-homology-3 (SH3) domain (which recognize phospho-tyrosine residues and proline-rich sequences, respectively), a pleckstrin homology (PH), and PKC2 homology (C2) domain (both implicated in membrane phospholipid binding, the latter in a calcium-dependent manner), and a GAP domain, which confers GTPase-enhancing activity (Takai et al. 2001). The SH2-SH3-SH2 domains of RASA1 are responsible for binding to cytoplasmic proteins, which include p190 RhoGAP and Dok-1 (Iwashita and Song 2008). Dok-1 is an adapter protein that plays a role downstream of tyrosine kinase signaling, and p190 RhoGAP acts as a GAP for the Rho family of G proteins. The number of protein-binding and membrane-binding domains in RASA1 suggests that it is involved in a complex signaling network.

The GAP domain of RASA1 contains three conserved motifs that are shared with all GAP proteins. These include an arginine-finger loop, a phenylalanine-leucine-arginine region, and an α7/variable loop, with the arginine residue in the arginine-finger loop being critical for the transition state of GTP hydrolysis (Iwashita and Song 2008).

RASA1 is known to be phosphorylated by a number of protein tyrosine kinases in multiple cell types. However, the stoichiometry of phosphorylation is generally low, and no effect of phosphorylation on GAP activity or subcellular localization has been reported (Takai et al. 2001).

Function

The only known enzymatic function of RASA1 is to accelerate the hydrolysis of GTP to GDP by Ras. While the isolated GAP domain of RASA1 is sufficient to promote GTP hydrolysis of purified Ras in vitro, full activity in vivo requires the SH2-SH3-SH2 domains, suggesting that protein-protein interactions are critical for RASA1 function (Marshall et al. 1989; Gideon et al. 1992). Indeed, RASA1 interacts with active, phosphorylated PDGF Receptor and EGF Receptor via its SH2 domains, negatively regulating their activity by suppressing Ras signaling (Margolis et al. 1990; Ekman et al. 1999). PDGF Receptor and EGF Receptor are not closely related by sequence, suggesting that RASA1 associates with a broad range of growth factor receptors.

Despite being the prototypical RasGAP, RASA1 is not simply a negative regulator of Ras. In addition to controlling Ras activation, RASA1 controls certain cellular functions in a GAP-domain-independent and a Ras-independent manner. For example, RASA1 has been implicated in the control of cell motility through its interaction with p190 RhoGAP. In cell monolayer wounding assays, RASA1-deficient embryonic fibroblasts were impaired in establishing cell polarity and migration into the wound. These functions appear to require the interaction of RASA1 with p190 RhoGAP, and are independent of Ras regulation (Kulkarni et al. 2000). The Rho proteins, for which p190 RhoGAP

is a negative regulator, are known to control the formation of focal adhesions and actin fibers necessary for directed cell movement. This association between RASA1 and p190 RhoGAP implies that RASA1 can act as a positive mediator of signaling, in addition to its negative-regulator role as a RasGAP.

Another GAP-domain-independent function of RASA1 is the regulation of apoptotic cell death. In fibroblasts subjected to mild apoptotic stress, RASA1 is cleaved by activated Caspase 3. The free N-terminal fragment of RASA1 is able to directly activate AKT, a major kinase in the apoptotic pathway, via its SH2 and SH3 domains (Yang et al. 2005). Under these conditions, RASA1 is thought to provide anti-apoptotic signals that permit survival of the stressed cell. However, under more severe apoptotic stress, the N-terminal fragment of RASA1 is further cleaved by Caspase 3, resulting in two shorter N-terminal fragments. The result of this cleavage is a reduction in AKT activity, which leads to efficient apoptotic death of the cell. Therefore, the second cleavage event of RASA1 functions to abrogate the anti-apoptotic function of the longer N-terminal fragment.

RASA1-Deficiency

A null allele of mouse *rasa1* has been generated, and mice homozygous for the null allele die at embryonic day 10.5 (E10.5) (Henkemeyer et al. 1995). These embryos appear to develop normally until E9.25, at which time they display a defect in posterior elongation. No abnormal cell proliferation is observed in RASA1 deficient embryos, and in fact by E9.5 are significantly smaller than littermate controls. This is most likely due to a severe vascular developmental defect, in which blood vessel endothelial cells fail to organize into a vascular network in the yolk sac. The blood vasculature in the embryo proper is also affected, and ultimately develops local ruptures leading to leakage of blood into the body cavity. Eventually the pericardial sac becomes distended, leading to a labored heartbeat and reduced blood flow. RASA1-deficient embryos also display extensive apoptotic cell death in the brain, with large numbers of dead and dying cells as early as E9.0 in the hindbrain, optic stalk, and telencephalon.

A recently developed conditional RASA1 mouse model has been used to define a role for RASA1 in the development and survival of T cells (Lapinski et al. 2011). In this model, exon 18 of *rasa1*, which encodes the catalytic arginine-finger loop of the GAP domain, was flanked by LoxP sites (floxed). The floxed allele permits normal RASA1 expression, and thus circumvents embryonic lethality. However, excision of the floxed exon in mice by transgenic Cre recombinase results in nonsense-mediated RNA decay, and a complete loss of RASA1 expression. This system permits the study of RASA1 deficiency in adult mice with the use of transgenic tissue-specific or inducible Cre recombinase. Specific deletion of RASA1 early in thymocyte development by Cre expressed under the control of the proximal LCK promoter resulted in increased death of CD4+ CD8+ double positive thymocytes. Surprisingly, RASA1-deficient thymocytes showed increased positive selection on a Major Histocompatibility Complex (MHC) Class II background, which was associated with increased Ras/MAPK signaling. RASA1 was found to be dispensable during T cell receptor stimulation by agonist peptide/MHC complex in peripheral T cells, as measured by cytokine secretion, proliferative capacity, and activation-induced cell death. However, absence of RASA1 led to substantially reduced numbers of naive T cells in the peripheral lymphoid organs. This phenomenon was due, at least in part, to a reduced sensitivity to the pro-survival cytokine IL-7.

RASA1 in Disease

Mutations in Ras are closely linked to development of human cancer, with up to 90% of certain tumors harboring an oncogenic Ras allele. Commonly, an oncogenic Ras mutation renders it refractory to GAP activity, which leaves Ras trapped in its active, GTP-bound state (Scheffzek et al. 1997). In addition, RASA1 nonsense mutations have been associated with basal cell carcinomas in humans (Friedman et al. 1993).

A recently described human clinical disorder known as capillary malformation-arteriovenous malformation (CM-AVM) has been shown to be caused by mutations of the *RASA1* gene (Boon et al. 2005; Revencu et al. 2008). This condition is characterized by multiple randomly distributed pink lesions that result from the malformation of skin capillaries. Approximately one third of patients develop fast-flow

vascular lesions, including Parkes Weber syndrome, arteriovenous fistulas, and intracranial arteriovenous malformations. Arteriovenous fistulas are abnormal connections between arteries and veins, where the two are directly connected without branching into capillaries, and ParkesWeber Syndrome is characterized by cutaneous flush, and multiple underlying arteriovenous fistulas. It is also associated with soft tissue and skeletal hypertrophy, usually of an affected limb. Thus far, 140 individuals with RASA1 mutations have been identified, and all but 6 of these have CM-AVM. Forty-two different mutations in the RASA1 gene have been described, including insertions and deletions resulting in frame-shifts, disruption of splice sites, and nonsense, missense, or splice-site substitutions. The mutations are randomly distributed throughout the RASA1 gene, and only one germline RASA1 gene is affected in CM-AVM patients (mutation of both alleles of RASA1 would presumably result in embryonic lethality). CM-AVM is hypothesized to arise from loss of function of the intact RASA1 allele by somatic mutation, which is consistent with the focal nature of the lesions. At least two CM-AVM patients have developed chylothorax or chylous ascites, rare conditions in which lipid-laden lymph fluid, or chyle, leaks from lymphatic vessels into the thoracic or abdominal cavities, respectively. Thus, RASA1 has been found to play a role in the formation and maintenance of the blood and/or lymph vasculature in both mice and humans.

Consistent with the blood vascular phenotype of RASA1-null embryos and in RASA1-mutant humans, RASA1 has been found to play a role in the angiogenic switch (Anand et al. 2010). In this process, new blood vessels are stimulated to grow from existing ones in response to growth factor stimulation. RASA1 expression has been found to be suppressed by microRNA (mIR)-132, a genome encoded, noncoding RNA regulator of gene expression. In a human embryonic stem cell model of vasculogenesis, mIR-132 was found to be highly expressed. mIR-132 was also upregulated in the epithelium of human tumors and hemangiomas, but not in normal epithelium. RASA1, which was expressed in normal epithelium, but not tumor epithelium, was found to be a major target of mIR-132. Suppression of RASA1 expression by mIR-132 led to increased Ras activation in endothelial cells and the induction of neovascularization. This result suggests that mIR-132 acts as an angiogenic switch by downregulating RASA1 expression, and consequently increasing Ras signaling in endothelial cells. Anti-mIR-132, a specific antagonist of mIR-132, was found to restore RASA1 expression in tumor endothelium. Taken together, these results suggest that mIR-132, or RASA1 itself, might be viable targets for therapeutic anti-vasculogenesis treatments in patients.

Summary

RASA1, the prototypical Ras GAP, plays an important role in the negative regulation of Ras in growth factor receptor signaling. In addition, a number of positive regulatory roles for RASA1 have been described. Despite being the first GAP discovered, there remain many unanswered questions about its function. How RASA1 controls angiogenesis and lymphangiogenesis is unknown, but disregulated Ras signaling through one or more growth factor receptors is the most likely mechanism. The receptors VEGFR1, VEGFR2, and/or VEGFR3 are strong candidates. In addition, the precise mechanism by which RASA1 regulates naïve T cell survival remains to be elucidated. With the use of recently developed tools described above, these questions will likely be the subject of intensive study for years to come.

Historical Background

The Ras guanine nucleotide releasing factor (RasGrf) proteins were isolated in an effort to find mammalian homolog(s) of the yeast CDC25 Ras activator protein. The search for mammalian Ras GEFs during the early 1990s led to the discovery and isolation of the Son of sevenless (Sos) and the RasGrf proteins. Whereas the Sos proteins had ubiquitous expression, RasGrf expression was restricted mainly to the central nervous system. Soon after the discovery of the first member of the RasGrf family (RasGrf1) in neural tissues, a second highly homologous member of this family was isolated from embryonic stem cells (RasGrf2). Later on, a number of distinct, alternatively spliced isoforms have been described for both genes in a variety of tissues or developmental stages. RasGrf1 and RasGrf2 are large, modular proteins composed by multiple functional domains accounting for protein–protein or protein–lipid interactions which are responsible for coupling to upstream and downstream signaling as well as for fine regulation of their intrinsic exchange activity (Santos and Fernandez-Medarde 2008, 2009).

Early biochemical characterization of the RasGrfs yielded identification of their specific targets in different Ras GTPase families, as well as initial characterization of their contribution to specific cellular signal transduction pathways. Whereas both RasGrf1 and RasGrf2 are able to activate canonical Ras proteins (H-Ras, N-Ras or K-Ras) and Rac1, only RasGrf1 is able to activate members of the R-Ras subfamily (R-Ras, TC21, M-Ras)

(Santos and Fernandez-Medarde 2008, 2009). Furthermore, both RasGrfs are known to be activatable in response to different signals including increases of intracellular levels of calcium or cAMP, activation of heterotrimeric G-protein-coupled receptors, or NGF receptor stimulation. More recent work using genetically modified animal models has provided significant clues to physiological roles played by the RasGrfs. Analysis of RasGrf1 and RasGrf2 knockout mice show the implication of RasGrf1 in memory and learning processes, light perception, glucose homeostasis, and substance addiction (Brambilla et al. 1997; Fernandez-Medarde et al. 2009; Font de Mora et al. 2003; Tonini et al. 2006), and the participation of RasGrf2 in memory formation and immunological responses (Li et al. 2006; Ruiz et al. 2007).

RasGrfs Protein Structure and Domain Distribution

The RasGrfs are large, highly homologous proteins (sharing ca. 80% homology and 63% identity in their sequences). RasGrf1 is slightly larger than RasGrf2 (respective molecular weights of the full-length proteins: 140 kDa and 135 kDa in mice; 145 kDa and 140 kDa in humans). These two proteins share multiple functional domains which are essential for fine regulation and control of their intrinsic catalytic activity and protein stability as well as subcellular localization and functional link to upstream/downstream signals (Fig. 1). From N- to C-terminus, these domains include:

PH1 domain- Although many PH domains are reported to mediate protein targeting to membranes, a RasGrf1 construct lacking this domain retains partial plasma membrane localization. The PH1 domain is reported to interact with G-protein β/γ subunits, and is required for normal G-protein induced ERK1/2 activation (Innocenti et al. 1999). In addition, together with the adjacent IQ and coiled coil domains, the PH1 domain is involved in interaction with scaffold proteins such as JIP2 or Spinophilin or with ribosomal proteins (Santos and Fernandez-Medarde 2009). Separate studies have also shown that this domain is necessary for complete calcium- and LPA-mediated activation of RasGrf1, and it is phosphorylated upon interaction with the TrkA NGF receptor (Innocenti et al. 1999; Robinson et al. 2005).

Coiled coil (cc) domain- All functional roles for this domain have been described in association with the flanking PH1 and IQ domains. As described above, its contribution is important for complete ERK1/2 activation upon intracellular calcium increase and for interaction with the JIP2 scaffold protein (Santos and Fernandez-Medarde 2009).

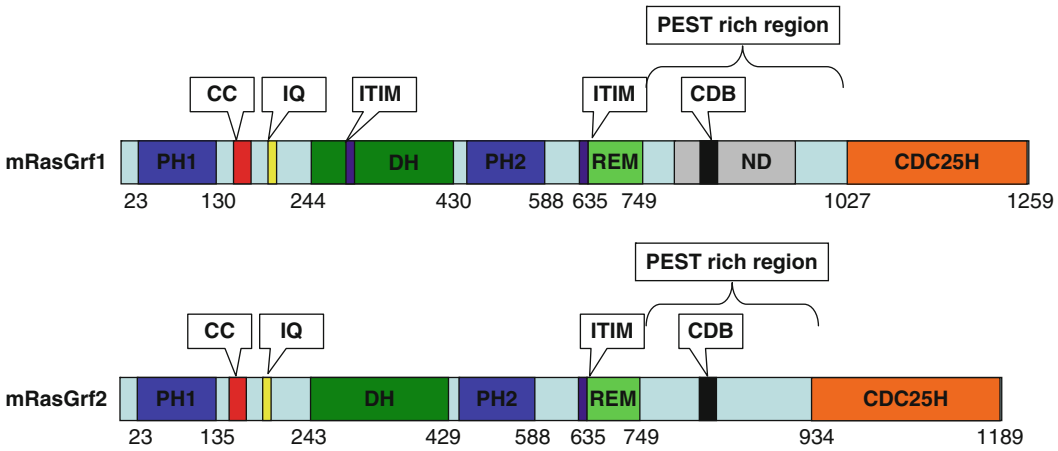
IQ domain- The main role of this domain is the interaction with Calmodulin, which is essential for activation of both RasGrfs by increases of intracellular calcium concentration. Mutations in this domain abolish ionomycin-mediated activation of RasGrf1 and stimulation of the Ras-ERK pathway. It is also involved, jointly with the PH1 and CC domains, in the interaction with the JIP2 scaffold protein (Santos and Fernandez-Medarde 2009).

DH domain- The DH-PH2 domain tandem constitutes the typical catalytically active domain facilitating GDP/GTP exchange on GTPases of the Rho subfamily. In the RasGrf proteins, this region is responsible for activation of Rac1 (Santos and Fernández-Medarde 2008, 2009). The DH domain also exerts a regulatory role on Ras activation by RasGrf1, and may also be important for Ras-independent, ionomycin-induced ERK activation (Freshney et al. 1997). This domain also mediates protein–protein interactions of RasGrf1 with β−tubulin and SCLIP and it is involved in homo- and hetero-oligomerization of the RasGrf1 and RasGrf2 proteins.

PH2 domain- A defined functional role for this domain remains unclear. In RasGrf1, some reports indicate that it is required for proper Ras and ERK activation, whereas studies in different cellular systems suggest that this domain is dispensable for Ras or ERK activation. Further work is needed to clarify these discrepancies analyzing RasGrf function in more physiological environments.

REM motif- This region is common to all Ras Guanine Nucleotide Exchange Factors and it is responsible for GEF–Ras interaction. It is likely that the REM motif has a similar role in all the Sos, ▶ RasGRP, and RasGrf1 families of GEF proteins.

CBD motif- This short domain usually targets proteins for degradation by the proteasome. It is located between the REM and CDC25H domains. Its involvement with ubiquitination and subsequent proteolytic degradation has been shown experimentally only for RasGrf2.



RasGrf (RAS Protein-Specific Guanine Nucleotide-Releasing Factor), Fig. 1 RasGrf1 and RasGrf2 domain distribution: *PH* pleckstrin homology domain, *CC* coiled coil domain, *IQ* isoleucine (I)/glutamine (Q) motif, *DH* Dbl homology domain, *ITIM* immuno tyrosine–based inhibition motifs, *REM* Ras exchanger motif, *DB* destruction box, *ND* neurological domain, *PEST Rich Region* (P)-proline, (E)-glutamic acid, (S)-serine, and (T)-threonine rich region, *CDC25H* CDC25 homology domain

PEST motif rich region- PEST [Proline (P), Glutamic acid (E), Serine (S), Threonine (T)] regions are known targets for ▶ calpain-type protease degradation, a role that has been experimentally demonstrated in RasGrf1 (Santos and Fernandez-Medarde 2009). This area is also targeted in RasGrf1 for phosphorylation by PKA or upon muscarinic receptor–mediated activation (Mattingly 1999). It is also phosphorylated by CDK5 in both RasGrfs, inhibiting the GEF activity toward Rac1 (RasGrf2) or Ras (RasGrf1) (Kesavapany et al. 2006).

Neuronal domain- Only found in RasGrf1, it is responsible for RasGrf1 binding to the NR2B subunit of the NMDA receptors and subsequent activation of downstream signaling pathways (Krapivinsky et al. 2003).

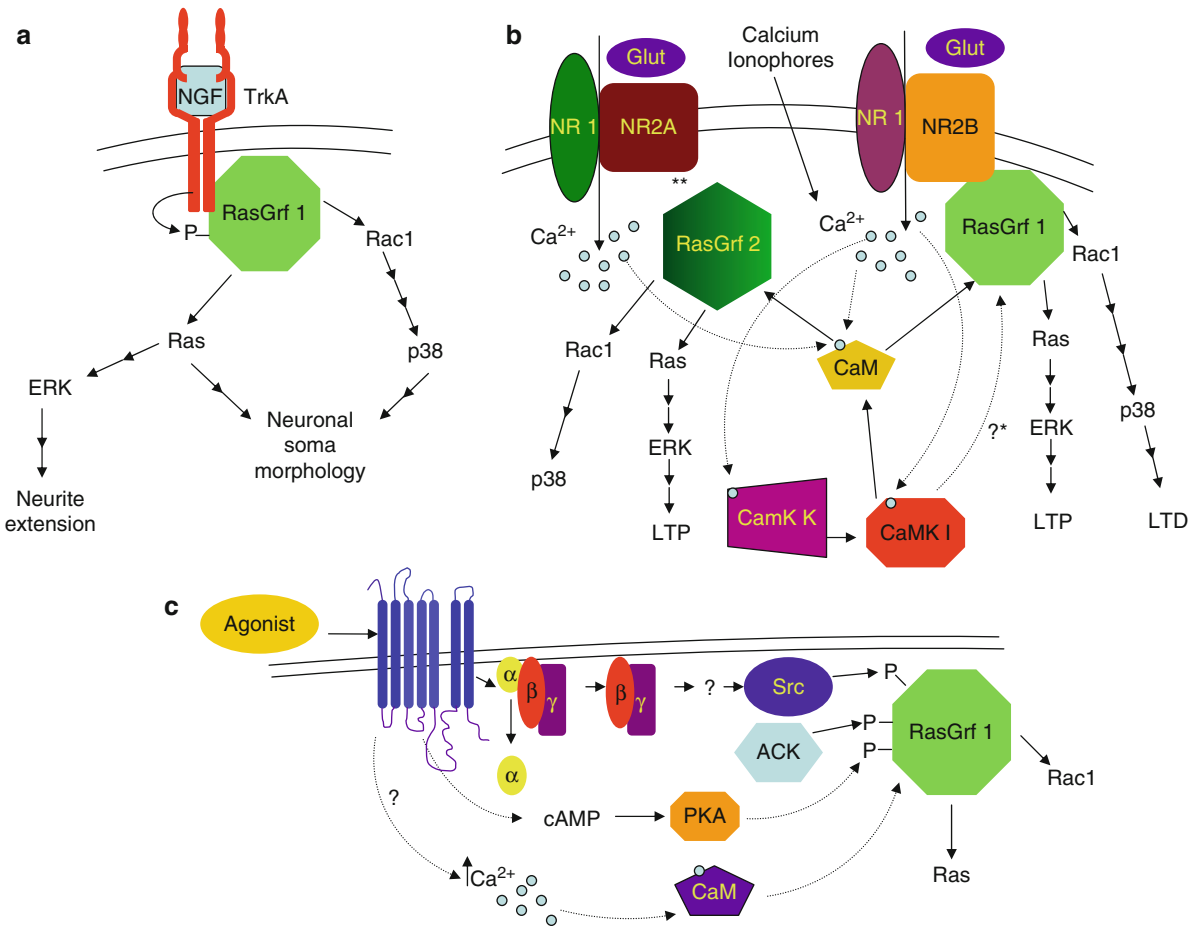
CDC25H domain- This C-terminal domain contains the catalytic region responsible for GDP/GTP exchange (GEF activity) on Ras family members. It is shared by all GEFs acting on canonical Ras proteins and shows a markedly high degree of conservation through evolution. This domain is necessary and sufficient for "in vitro" Ras activation by RasGrf1, and it is also responsible for Ras activation by RasGrf2. "In vivo" modulation of the GEF activity of the CDC25H domain in the context of full-length RasGrf proteins can be exerted through various intramolecular interactions or biochemical modifications (Santos and Fernandez-Medarde 2009, 2008).

Signaling Through the RasGrfs

Activation of RasGrfs in Response to Increase in Intracellular Calcium Concentration

Cellular calcium influx can modulate the activation of the RasGrfs through a mechanism involving Calmodulin binding to their IQ domains (Fig. 2). Mutations in this domain abolish ionomycin-mediated activation of RasGrf1 and stimulation of the Ras-ERK pathway. In addition, the N-terminal region of RasGrf1 cooperates synergistically with the IQ domain to potentiate RasGrf1-mediated activation of ERK1/2 upon stimulation by LPA or calcium (Santos and Fernandez-Medarde 2009).

RasGrf2 can also be activated by increased intracellular calcium concentration. In 293T cells, calcium influx causes translocation of RasGrf2 to the cell periphery, localizing it in close proximity to membrane GTPases, through a mechanism not yet fully understood. Although RasGrf2 interacts with calmodulin through its IQ domain, a full, functionally productive interaction appears to need the additional cooperation of other N-terminal domains (de Hoog et al. 2000). Interestingly, a RasGrf2 construct lacking the IQ domain is still able to activate Ras, suggesting that interaction with calmodulin is not necessary for RasGrf2 GEF activity, although both the IQ domain and Calmodulin interaction with RasGrf2 are indispensable for ERK activation.



RasGrf (RAS Protein-Specific Guanine Nucleotide-Releasing Factor), Fig. 2 The main upstream factors activating RasGrf proteins include the NGF receptor (**a**), NMDA receptors, intracellular increases of calcium (**b**), non-receptor protein kinases, PKA or G-protein coupled receptors (**c**). *CaMK1 activation of RasGrf1 has been proposed, but not demonstrated. **No physical interaction has been demonstrated between NR2A and RasGrf2

These observations suggest the existence of Ras-independent mechanisms of ERK1/2 activation, or the need of other interacting partners for full coupling of Ras and ERK1/2 activation (Santos and Fernández-Medarde 2008).

Activation of RasGrfs in Response to G-Protein Coupled Receptors (GPCR)

The intrinsic activity of intracellular RasGrf1 can be enhanced by stimulation with LPA or serum, but not with PDGF. This activation is inhibited by pretreatment with pertussis toxin, but not with genistein, suggesting that GPCRs, but not receptor tyrosine kinases (RTK) play a role in serum activation of RasGrf1 (Zippel et al. 1996). LPA treatment of NIH3T3 cells overexpressing RasGrf1 induces phosphorylation of RasGrf1 in serine residues, and calcium is also needed for full GEF activation (Fig. 2). Besides LPA, other GPCRs can also activate RasGrf1. Overexpression of subtype 1 human muscarinic receptor induces RasGrf phosphorylation and its GEF activity upon carbachol stimulation. This activation is prevented by phosphatases and G-protein α-subunit overexpression, and is constitutively established when G-protein βγ subunits are overexpressed. The 5-HT4 serotonin receptor is another GPCR able to activate RasGrf1. Its overexpression induces RasGrf1 phosphorylation by PKA (at Serine 916) and

IQ-dependent activation upon serotonin stimulation, suggesting that the complete activation of RasGrf1 by these receptors involves both cAMP and calcium/calmodulin-dependent signaling (Fig. 2) (Norum et al. 2007).

Overexpression of G-protein βγ subunits and LPA treatment are also known to induce RasGrf1 GEF activity toward Rac1, leading to JNK and c-fos promoter activation, but to fully activate Rac1, RasGrf1 needs to be phosphorylated in tyrosine by ▶ Src (Kiyono et al. 2000) (Fig. 2).

Activation of RasGrfs in Response to Receptor and Non-receptor Tyrosine Kinases

In PC12 cells, the TrkA nerve growth factor (NGF) receptor has been reported to interact with, and induce phosphorylation of, RasGrf1 in its PH1 domain (Robinson et al. 2005) (Fig. 2). In addition, RasGrf1 potentiates NGF-induced differentiation of PC12 cells in a process dependent on H-Ras and ERK1/2, but independent of Rac1 or ▶ PI3K pathways. On the other hand, RasGrf1 coordinates H-Ras and Rac1 pathways in a PI3K/AKT-dependent manner, to induce soma expanded morphology in PC12 cells (Santos and Fernandez-Medarde 2009).

The Src tyrosine kinase can also mediate transduction of G-protein-dependent signals from RasGrf1 to Rac1 proteins, but not to Ras canonical proteins (Kiyono et al. 2000). Other tyrosine kinases, such as ▶ ACK1 and Lck, are also able to phosphorylate RasGrf1, resulting in enhanced Ras GEF activity (Santos and Fernandez-Medarde 2009). In particular, ACK1 is known to be activated by Cdc42, which in its inactive GDP-Cdc42 conformation is also able to inhibit RasGrf1 activation of Ras (Arozarena et al. 2001). A similar mechanism may be applicable to RasGrf2, as the expression of dominant negative Cdc42 (Cdc42N17) abolishes RasGrf2 recruitment to the plasma membrane, Ras activation and ERK phosphorylation (Santos and Fernández-Medarde 2008). RasGrf2 and RasGrf1 are activated upon T-cell receptor stimulation, a process requiring the contribution of tyrosine kinase(s) of the Src family. Activation of RasGrf2 induces Ras-dependent and PLC-γ1-mediated signaling pathways, producing the activation of ▶ NF-AT, a transcriptional factor crucial for T-cell activation and differentiation (Ruiz et al. 2007).

Control of RasGrf Expression and Cellular Protein Levels

Transcriptional Control

RasGrf1 is an imprinted gene expressed only after birth. In mice, the paternal allele of the *RasGrf1* locus is methylated on a differentially methylated domain (DMD) located 30 kbp 5′ of the promoter. In mouse neonatal brain, RasGrf1 expression occurs exclusively from the paternal allele and accounts for ca. 90% of the total RasGrf1 expressed. A repeat sequence located immediately downstream of the DMD controls its methylation and is therefore required to establish RasGrf1 methylation in the male germ line. CTCF (a CCCTC-binding factor) binds to the DMD in a methylation-sensitive manner, acting as an "enhancer blocker." In the unmethylated maternal allele, CTCF is bound to DMD thus silencing expression, whereas CTCF cannot bind to the methylated paternal allele, thus allowing expression. The repeats and the DMD thus constitute a dual switch regulating RasGrf1 imprinting and timing of expression (Yoon et al. 2005).

Although *RasGrf2* appears not to be an imprinted gene, genomic methylation may still play a significant role in control of expression of this locus. The shortage of specific studies on RasGrf2 expression determines that the mechanisms controlling expression in the postnatal brain remain largely unknown. Interestingly, in colon, pancreatic and lung (NSCLC) tumors and cell lines, hypermethylation of *RasGrf2* locus and reduced protein expression are frequently associated (Santos and Fernández-Medarde 2008).

Some external factors are also known to modulate postnatal RasGrf1 expression. Cocaine induces overexpression in dorsal and ventral striatum, whereas the Alzheimer-related amyloid precursor protein with the Swedish mutation (APPSw) or oncogenic ErbB2/Neu and luteinizing hormone repress its expression in hippocampus and mammary gland, respectively (Santos and Fernandez-Medarde 2009).

Control of Proteolytic Degradation

The intracellular concentration of the RasGrf proteins is also posttranslationally regulated by cellular proteases. Both RasGrf1 and RasGrf2 contain a type A cyclin destruction box (CDB), located between the REM and CDC25 domains (Fig. 1). These domains have been reported to trigger ubiquitination and degradation of RasGrf2 by the proteasome upon Ras

binding. There is no direct experimental evidence showing a similar role of this domain in RasGrf1, although the interaction between RasGrf1 and the deubiquitinating enzyme mUBPy results in increased RasGrf1 half-life, and in M2 melanoma cells, the actin-binding protein Filamin A induces destabilization and ubiquitination of RasGrf1 with a subsequent reduction of MMP9 expression (Santos and Fernandez-Medarde 2009).

Calpain can also cleave RasGrf1, but the functional significance of such cleavage is unclear. Some reports described that this cleavage increases RasGrf1 GEF activity toward Ras proteins by releasing the C-terminus from inhibition by the N-terminal portion, whereas other studies show that phosphorylation by p35/CDK5 targets RasGrf1 for proteolysis by ▶ m-calpain, resulting in reduced Ras activation and AKT phosphorylation (Santos and Fernandez-Medarde 2009; Kesavapany et al. 2006). Phosphorylation of RasGrf2 by p35/CDK5 is also reported to result in accumulation and increased local concentration of RasGrf2 protein in the body of neurons (Santos and Fernández-Medarde 2008).

Genetically Modified Animal Models of the RasGrfs

RasGrf1

Analysis of the phenotypes of a number of independent RasGrf1 KO strains generated in different laboratories has contributed to a better understanding of the functional "in vivo" roles of RasGrf1. Two main types of phenotypes have been reported: those related to defects in memory consolidation and learning, and those related to growth retardation and glucose homeostasis responses.

An initial report on *RasGrf1*-KO mice (Brambilla et al. 1997) described LTP defects and associated impairment of amygdala-dependent learning, whereas later studies on a separate KO strain reflected LTD defects and impairment of hippocampus-dependent learning (Li et al. 2006). The discrepancy may be due to the use of different gene targeting strategies or different mouse genetic backgrounds. In any event, a role of RasGrf1 in memory and learning is supported by separate studies of the hippocampus of RasGrf1 KO mice that showed specific transcriptional alterations involving genes related to those neural processes. RasGrf1 also shows a role in cannabinoid tolerance, as the KO mice show lower tolerance to Δ9-tetrahydrocannabinoid, probably through alterations in cannabinoid receptor- and cAMP-mediated signaling (Tonini et al. 2006). Finally, RasGrf1 is also important to maintain normal photoreception, as the RasGrf1 KO mice develops light perception problems worsening with age progression (Fernandez-Medarde et al. 2009).

Analysis of the knockout mice has also revealed the role of RasGrf1 in the control of postnatal growth. Adult RasGrf1 null mice are 15–25% smaller than wild-type controls. The reduced size is probably directly associated to the lower levels of growth hormone and circulating plasma insulin observed in *RasGrf1*-deficient mice pituitary. The association between hypoinsulinemia and reduced pancreatic beta-cell mass observed in the KO mice is indicative of a role of RasGrf1 in control of beta cell proliferation and neogenesis (Font de Mora et al. 2003).

RasGrf2

RasGrf2 is dispensable for mouse development, postnatal growth, fertility, and normal aging, as the RasGrf2 KO mice are morphologically indistinguishable from their wild-type controls. A more subtle, brain phenotype is suggested by studies of a different RasGrf2 KO strain, pointing to lower levels of ERK activation upon NMDA-induction, and linking the absence of RasGrf2 to defective LTP in the CA1 region of the hippocampus (Li et al. 2006). Additional insights into the role of RasGrf2 "in vivo" have been obtained through the analysis of mice harboring combinations of a disrupted *RasGrf2* locus with null mutations for other GEFs. Thus, elimination of both RasGrf2 and RasGrf1 results in higher sensitivity to the neurotoxic effects of ischemia in the mouse brain (Santos and Fernandez-Medarde 2009). Furthermore, analysis of RasGrf2/▶ Vav3 and RasGrf2/▶ Vav1 null mice suggest a role for RasGrf2 in T-receptor signaling responses in lymphocytes (Ruiz et al. 2007).

Summary

The RasGrfs are the main GEF activators of mammalian Ras GTPases in the adult central nervous system. The experimental in vivo evidence indicates that both RasGrfs are able to activate the canonical Ras proteins (H-, N- and K-Ras) and Rac1. RasGrf1 and RasGrf2 are

large, highly homologous proteins sharing a modular structure composed of multiple distinct, functional domains which are instrumental for regulation of their intrinsic GEF activity and for modulation of their participation in signal transduction connecting a variety of upstream signals to their respective, specific downstream targets and elicited cellular responses. The GEF activity of the RasGrfs becomes activated in response to a variety of cellular signals including LPA, increased cytosolic concentration of calcium or cAMP, and activation of cell surface receptors for various signaling molecules such as ▶ NMDA, AMPA, serotonin, muscarinic agonists (G-protein coupled receptors), or NGF (trkA) (Fig. 2). Known downstream effects of the participation of the RasGrfs in cellular signaling pathways include control of cellular shape and nuclear organization, neurite extension, neuronal synaptic plasticity, induction of LTP or LTD, and neuroprotection against ischemia. Analysis of genetically modified animal models has uncovered the specific functional roles of RasGrf1 in memory and learning, postnatal growth, pancreatic beta cell proliferation, retinal photoreception, and neuroprotection against ischemia. Likewise, RasGrf2 has also been implicated in memory formation, neuroprotection, and immunological responses in lymphocytes. The participation of the RasGrfs in processes leading to human disease is also suspected. Increased RasGrf2 gene methylation is frequently observed in various human tumors and cancer cell lines. Other observations suggest the implication of RasGrf1 in visual defects, drug addiction, and Alzheimer-like neurodegenerative diseases.

In spite of the vast amount of published information on the RasGrf proteins, a number of key questions still remain unanswered. Because of their prevalent expression in the CNS, most functional studies on the RasGrfs have been restricted to neural tissues and cell lineages. However, as both RasGrfs are also expressed outside the CNS, their functional roles at those external locations remain less defined and require further, extensive studies. Another poorly understood area is the functional significance of the great variety of small RasGrf transcripts and peptides detected for both RasGrf1 and RasGrf2 in many tissues and/or states of development. An interesting hypothesis would be that such an assortment of RasGrf isoforms may contribute to the fine-tuned regulation of the activation of their cellular Ras/Rho targets at the spatial and temporal level. A better understanding of the mechanisms linking functional observations made for the RasGrfs at the cellular level with those made at the organism level would also be desirable. This pertains questions such as: Is the participation of RasGrf1 in cytoskeleton remodeling necessary for neuritogenesis? Is there a connection between the role of RasGrf1 in neuritogenesis and its contribution to memory formation processes? Finally, future work efforts should be strongly aimed at getting definitive answers to the current hints linking the RasGrf proteins to the development of different human illnesses and pathological processes.

Historical Background

Antigen receptor stimulation of T cells and B cells results in the rapid conversion of the small GTPase Ras from its "inactive" GDP-bound form to its "active" GTP-bound form (Alberola-Ila and Hernández-Hoyos 2003). However, the mechanisms of Ras regulation in lymphocytes, particularly by phorbol esters, had long remained a mystery as known signaling pathways could not account for its activation. The discovery of the Ras guanyl-nucleotide exchange factor RasGRP1, cloned by two groups searching for novel Ras activators in rat brain and murine T cells, was a major advance leading to a better understanding of Ras regulation in lymphocytes (Stone 2011). Ectopic expression of RasGRP1 in rodent fibroblasts was found to be capable of activating Ras and inducing cellular transformation. Subsequently, investigations of human T cells and RasGRP1-deficient mice have corroborated key roles for RasGRP1 in both T-cell receptor- and phorbol ester-induced Ras activation (Stone 2011). Originally coined RasGRP (Ras guanyl nucleotide-releasing protein), RasGRP1 is the prototypic member of the RasGRP family of proteins that share a number of conserved elements that have been implicated in its function and regulation (Stone 2011), including REM (Ras exchange motif) domain, ▶ CDC25 (cell division cycle 25)-related domain, calcium-binding "EF-hand" motif, and diacylglycerol-binding "C1" domain (Fig. 1). Besides RasGRP1, the RasGRP family also comprises of RasGRP2, RasGRP3, and RasGRP4.

RasGRP1 Functions in Developing T Cells

The small GTPase Ras acts as a molecular switch, cycling between GDP-bound "off" and a GTP-bound "on" conformations, and serves to link signals from cell surface receptors to intracellular effector pathways. Ras activation can be modulated by its own intrinsic GTPase activity, converting GTP to GDP, and guanine nucleotide exchange. However, the Ras' rates of GTP hydrolysis and nucleotide exchange are

RasGRP1, Fig. 1 Conserved domains of RasGRP1. Domain structure of human RASGRP1 protein (NCBI accession: AAH67298; 765 aa), annotated by NCBI Blast Search, is schematically shown. REM (Ras Exchange Motif; E-value: 1.44e-15) and ▶ CDC25 (also known as RasGEF; E-value: 1.44e-15) domains participate in the catalytic activity of the exchange factor. The Protein kinase C conserved region 1 (C1; E-value: 1.54e-12) domain binds diacylglycerol and phorbol esters. EF-hand domains (E-value: 8.42e-04) are suspected to act as calcium sensors and calcium signal modulators

very low unless paired with catalytic proteins. Guanine nucleotide exchange factors (Ras GEFs) control the activation of Ras by catalyzing GDP release from Ras and facilitating its association with more prevalent cellular GTP. Conversely, Ras GTPase-activating proteins (Ras GAPs) accelerate GTP hydrolysis reaction converting Ras-GTP to its inactive GDP-bound form. Tight control of Ras activity is essential for regulating cell activation, proliferation, differentiation, and apoptotic programs in multiple cell types. By associating with various effector proteins, activated Ras initiates signaling through multiple downstream pathways such as the mitogen-activated protein kinase (MAPK) cascade.

T-cell receptor (TCR) stimulation results in the rapid activation of the small GTPase Ras whose signals are essential for the development of T cells in the thymus (Alberola-Ila and Hernández-Hoyos 2003). Taking cues from Ras studies on non-lymphocytes, the Ras GEF SOS (Son of Sevenless) has been postulated to regulate Ras upon TCR activation. SOS proteins are ubiquitously expressed and their functions are modulated through their association with the adaptor GRB2 (growth factor receptor-bound protein 2). Moreover, the SH2 domain of GRB2 targets SOS to phosphorylated tyrosine residues of surface receptors and adaptor proteins.

According to the SOS-based model, the following sequence of events leads to Ras activation in T cells: TCR ligation activating the ▶ Src protein tyrosine kinases (PTKs) LCK (lymphoid cell kinase) and Fyn leading to the phosphorylation of CD3s ITAMs (immunoreceptor tyrosine-based activation motifs), these phosphorylated ITAMs mobilizing the Syk PTK ▶ ZAP-70 (zeta-associated protein – 70 kDa) by way of ▶ ZAP-70s SH2 domain and becoming activated through the action of ▶ Src PTKs, activated ▶ ZAP-70 phosphorylating multiple tyrosine residues on the docking adaptor transmembrane protein ▶ LAT (Linker for Activated T cells) and phosphorylated ▶ LAT recruiting the GRB2/SOS complex in close proximity of plasma membrane–bound Ras and facilitating its displacement of GDP. However, a SOS based model of Ras activation cannot explain at least two T-cell phenomena: (1) Why phorbol esters or their analogs activate Ras? and (2) Why PKC inhibitors dampen Ras activation?

The cloning of RasGRP1 identified the first of a novel class of Ras guanyl nucleotide-releasing proteins that possessed calcium- and diacylglycerol (DAG)-responsive elements and elucidated a critical mechanism by which TCR signal transduction and phorbol ester stimulation is linked to the activation of the Ras-MAPK cascade in T cells (Stone 2011). TCR signaling incorporates RasGRP1 function through the mobilization and enzymatic activities of PLCγ1. Similarly to GRB2/SOS, PLCγ1 is recruited to phosphorylated ▶ LAT through its SH2 domain and becomes phosphorylated by Tec family protein kinases. Subsequently, the action of activated PLCγ1 converts PIP2 (phosphatidylinositol 4, 5 bisphosphate) into IP3 (inositol 3, 4, 5 triphosphate) and DAG, a second messenger previously thought to solely activate PKC through its DAG-binding C1 domain. However, DAG also causes RasGRP1 to become membrane localized through its own DAG-binding C1 domain. Furthermore, DAG indirectly impacts RasGRP1 as activated PKC regulates RasGRP1 activity through its phosphorylation (Roose et al. 2005). As a consequence, the integration of RasGRP1 into T-cell signaling provides an explanation for the well-documented activation of Ras by DAG analogs and phorbol esters such as PMA (phorbol myristate acetate). In addition, the integration of RasGRP1 also provides a mechanism for why PKC inhibitors block Ras activation.

Ras-MAPK signaling downstream of the pre-TCR and TCR is critical for two developmental checkpoints as thymocytes undergo an ordered series of maturation steps within the thymic microarchitecture (Alberola-Ila and Hernández-Hoyos 2003). Thymocyte development is most often tracked through the variable expression of the cell surface markers CD4 and CD8. After productive rearrangement of the TCRβ chain and pairing with the pre-TCRα, pre-TCR expression by the most immature $CD4^-$ $CD8^-$ double-negative (DN) thymocytes drives ligand-independent Ras-MAPK

signaling at the first developmental checkpoint and differentiation into $CD4^+$ $CD8^+$ double-positive (DP) thymocytes. Accompanying rearrangement and expression of the TCRα chain, TCR-dependent Ras-MAPK signaling at the second developmental checkpoint (called "thymocyte selection") becomes contingent upon the recognition of self-antigens (i.e., self-peptides presented in the context of self-MHC molecules). The intensity of TCR interaction with self-antigens on thymic cortical epithelial cells and bone marrow–derived cells is presumed to determine the strength of signal and the fate of the developing DP thymocyte. According to the strength of signal hypothesis, cells that do not recognize self-antigens fail to receive TCR signaling resulting in death by neglect; cells that recognize self-antigens robustly receive strong TCR signaling dying via active apoptosis (negative selection); and cells that recognize self-antigens weakly receive moderate TCR signaling differentiating into mature $CD4^+$ $CD8^-$ or $CD4^-$ $CD8^+$ single-positive (SP) T cells (positive selection).

DP thymocytes discriminate graded TCR-dependent Ras-MAPK signals and translate them into a cell fate decision (Alberola-Ila and Hernández-Hoyos 2003). TCR-induced Ras signaling results in the activation of three distinct families of MAPKs: ERK (extracellular signal-regulated kinases), JNK (c-Jun N-terminal kinases), and p38. The activation of the MAPKs plays qualitatively and quantitatively distinct roles in thymocyte selection: ERK has been most often paired with positive selection whereas JNK and p38 are associated with negative selection. How might different MAPKs selectively pair and become activated upon TCR-induced Ras signaling was not clear. To elucidate the role of RasGRP1 in T-cell development, analyses of *RasGRP1*$^{-/-}$ mice revealed a near-normal number of DN and DP thymocytes but a severe deficiency in mature thymocytes, suggesting a block in thymocyte selection (Stone 2011). Furthermore, *RasGRP1*$^{-/-}$ thymocytes failed to activate both Ras and ERK upon phorbol ester stimulation. In addition, one-month old *RasGRP1*$^{-/-}$ mice had very few splenic T cells. As a consequence of the T-cell phenotype present in *RasGRP1*$^{-/-}$ mice along with the governing role that TCR signaling plays in T-cell development, RasGRP1 was hypothesized to link Ras activation with TCR signaling.

To examine the role of RasGRP1 in thymocyte selection, two lines of *RasGRP1*$^{-/-}$ TCR transgenic mice were generated to determine the effect of RasGRP1 under conditions of defined TCR signaling strength (Priatel et al. 2002). Results from these experiments indicated that positive selection, particularly a weakly selecting TCR, and TCR-induced ERK activation are critically dependent on RasGRP1. By contrast, RasGRP1-deficiency had no effect on negative selection or JNK and p38 MAPK activation. These conclusions were consistent with complementary findings from another study investigating *Grb2*$^{+/-}$ mice (Gong et al. 2001). Halving of the amount of GRB2/SOS led to decreased Ras, JNK, and p38 activation and impaired negative selection. However, ERK activation and positive selection were unaffected by *Grb2* haploinsufficiency, suggesting that the RasGRP1-ERK pathway may have a lower threshold of activation than GRB2/SOS. The rationale for TCR signaling to employ two different Ras GEFs may be to subject Ras to differential regulation or to pair it with a unique subset of effectors. Based on the findings from the above studies, a hypothesis was formulated that the Ras GEFs RasGRP1 and GRB2/SOS may serve to selectively pair Ras activation with differential MAPKs pathways. According to this model, DP thymocytes expressing a positively selecting TCR will activate Ras and solely the MAPK ERK via RasGRP1 whereas DP thymocytes expressing a negatively selecting TCR will activate Ras and the full range of MAPKs (ERK, JNK, and p38) via the use of both GRB2/SOS and RasGRP1 pathways.

RasGRP1 Functions in Other Blood Cells

RasGRP1 was originally envisioned to have very restricted expression, transcripts being detected solely in T cells and some neuronal cell lineages (Stone 2011). More recent studies have found that RasGRP1 has a much broader tissue distribution than previously thought. RasGRP1 is also expressed in B cells and is presumed to couple the B-cell antigen receptor (BCR) to Ras-ERK signaling in an analogous fashion to the way it functions in TCR signal transduction (Coughlin et al. 2005). However, RasGRP1 function in BCR signaling appears to be partially masked through the coexpression of RasGRP3 and the sharing of some redundant functions with this RasGRP family member. Studies using the immature B cell line WEHI-231 have linked

a RasGRP1-pathway that is ERK-independent to BCR-induced apoptosis (Guilbault and Kay 2004). Analyses of human NK (natural killer) cells using RNA interference have demonstrated that RasGRP1 regulates ITAM-dependent cytokine production and NK cell cytotoxicity (Lee et al. 2009). In addition, RasGRP1 knockdown in NK cells was found to result in dampened Ras, ERK, and JNK activation.

RasGRP1 is also expressed by mast cells and signals downstream of the high affinity IgE receptor FcεR1 (Liu et al. 2007). Moreover, FcεR1 degranulation and cytokine production were greatly reduced in *RasGRP1*$^{-/-}$ mast cells relative to wild type and *RasGRP1*$^{-/-}$ mice failed to elicit anaphylactic allergic reactions. Interestingly, RasGRP1 in mast cells was found to link FcεR1-mediated Ras signaling to ▶ PI3K (phosphatidyl inositol 3-kinase) pathway rather than to ERK activation. By contrast, a concentrated effort to establish a connection between RasGRP1 signaling and ▶ PI3K activation in lymphocytes has been unsuccessful (Stone 2011). In addition, RasGRP1 expression and function has been recently described outside of the hematopoietic system, although those studies are described elsewhere (Stone 2011).

RasGRP1 Activity and Subcellular Localization

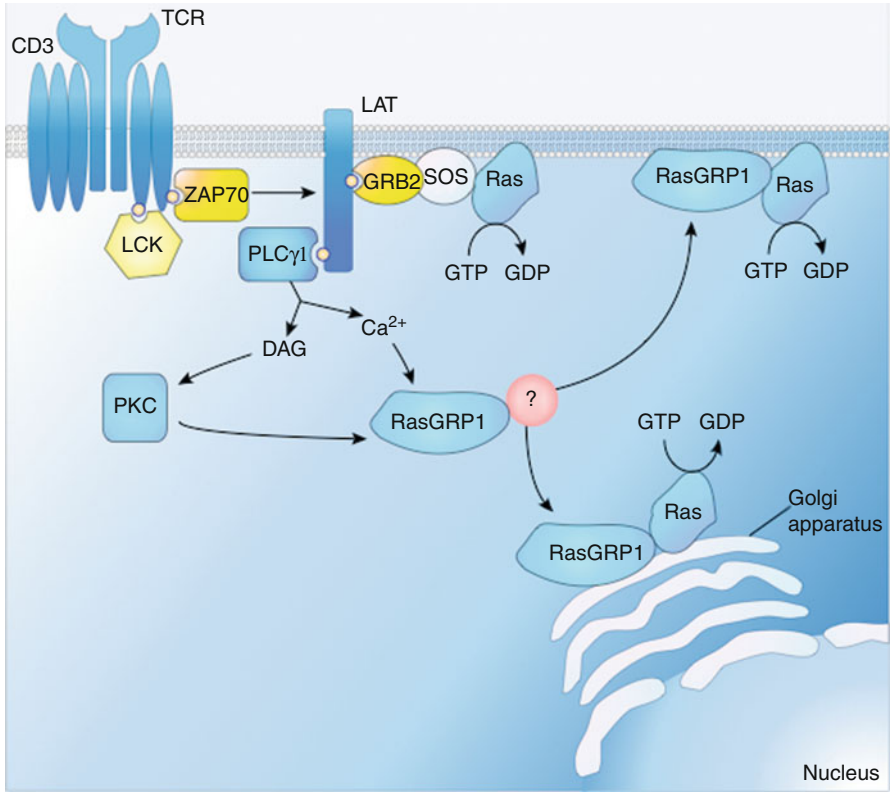
The most controversial issue regarding RasGRP1 is its subcellular locale when active. Long-held dogma asserts that Ras operates at the plasma membrane, however, a number of reports have challenged this belief by arguing that TCR-induced Ras activation occurs at the Golgi in a PLCγ1- and RasGRP1-dependent fashion (Mor and Philips 2006). As Ras proteins transit through endomembranes on their way to the plasma membrane, there is the potential for subcellular compartmentalization of Ras activation to add another dimension of complexity to Ras signaling and possible cellular responses (Fig. 2). Nevertheless, other studies have found evidence solely for plasma membrane-associated-Ras and -RasGRP1 upon TCR and BCR ligation (Stone 2011), raising the question of whether observations of active RasGRP1 and activated Ras at internal membranes are an artifact of protein overexpression or the tracking of fluorescently tagged rather than native endogenous molecules.

An exquisite investigation monitoring endogenous signaling molecules has suggested that subcellular compartmentalization of the Ras/RasGRP1/ERK pathway plays a key role in developing thymocytes undergoing selection (Daniels et al. 2006). Using OT-1 TCR transgenic preselection $CD4^+CD8^+$ thymocytes and specific peptides that span the boundary of positive and negative selection, it was revealed that negatively selecting peptides targeted Ras, ▶ Raf-1, and RasGRP1 to the plasma membrane, whereas these molecules colocalized to endomembranes when thymocytes were stimulated with peptides mediating positive selection. Notwithstanding, as this study determined the localization of total Ras rather than active Ras (i.e., Ras-GTP), it is conceivable that sufficient signaling necessary to mediate positive selection is initiated via trace amounts of RasGRP1 and Ras that is situated at the plasma membrane.

A recent study utilizing novel high affinity probes for Ras-GTP imaged in live Jurkat T cells was capable of discerning the accumulation of endogenous Ras-GTP solely at the plasma membrane (Rubio et al. 2010). In addition, the failure of a palmitoylation-defective mutant of N-Ras that is restricted to endomembranes to become activated upon TCR stimulation further asserts that plasma membrane localization is required for Ras activation. Future studies will require sophisticated tools like the one discussed above and high-resolution microscopic imaging to settle the debate over the localization of active RasGRP1 and Ras-GTP.

RasGRP1 and Autoimmunity

T cells are a vital component of the body's defense system and their capacity to differentiate self- from foreign-antigens is crucial to protect against both pathogenic challenge and autoimmune-mediated self-destruction. The dependence of T-cell development, T-cell function, and T-cell tolerance on TCR signaling suggests that mutations affecting TCR signal transduction may cause a multitude of deleterious health-related effects. Immunodeficiency may arise from alterations to the TCR repertoire and T-cell function. In addition, aberrant TCR signaling may promote autoimmunity by influencing central- (deletion of autoreactive T cells in the thymus) and peripheral-T-cell tolerance (T-cell anergy, activation-induced



RasGRP1, Fig. 2 The activation of Ras by T-cell receptor signal transduction. T-cell receptor stimulation induces the activation of the protein tyrosine kinases LCK (lymphoid cell kinase) and ▶ ZAP-70 (zeta-associated protein – 70 kDa) and subsequently, phosphorylation of ▶ LAT (Linker for Activated T cells). Phosphorylated ▶ LAT results in the GRB2 (Growth factor Receptor-Bound protein 2)/SOS (Son of sevenless) complex being targeted to the plasma membrane through Grb2's SH2 (Src homology 2) domain. Simultaneously, phosphorylated LAT also recruits PLCγ1 (phospholipase Cγ1), resulting in its activation. Activated PLC-γ1 leads to the production of DAG (diacylglycerol) and increases in cytosolic calcium. DAG and perhaps rises in cytosolic calcium cause the cytoplasmic protein RasGRP1 to become translocated, localizing at the plasma membrane or endomembranes such as the Golgi apparatus. The concentrations of these two second messengers along with phosphorylation of RasGRP1 by PKC (protein kinase C) are speculated to determine the cellular site of RasGRP1's mobilization. The subcellular compartmentalization of Ras signaling may serve to subject Ras to differential regulation or to pair it with a unique subset of effectors

cell death [AICD] and suppression by regulatory T cells). Importantly, abnormal Ras-ERK signaling in T cells has been described in a number of autoimmune diseases in humans and animal models.

One reported consequence of decreased activation of Ras-ERK pathway in T cells is reduced DNA methyltransferase I (DNMT1) expression causing the derepression of autoimmune genes (Gorelik et al. 2007). Recently, two microRNAs, miRNA-21 and miRNA-148a, overexpressed in T cells from both patients with systemic lupus erythematosus (SLE) and lupus-prone MRL/lpr mice have been found to downmodulate DNMT1 directly and indirectly by turning down Ras-ERK signaling and targeting RasGRP1 transcripts (Pan et al. 2010). By contrast, defective RasGRP1 expression in a subset of SLE patients has been proposed to result from aberrant RNA splicing (Stone 2011). Additionally, dysregulated RasGRP1 expression has been implicated in another autoimmune disease through genome-wide association studies linking RasGRP1 variants to type 1 diabetes (Stone 2011).

The severely impaired T-cell maturation in the thymus of young *RasGRP1*-deficient mice is correlated with a small but activated population of peripheral T cells, particularly of the CD4 lineage (Layer et al. 2003; Priatel et al. 2007). However, with age, *RasGRP1*-deficient mice (on a mixed

C57BL/6:129SvJ genetic background), derived through a classical gene targeting approach (*RasGRP1*$^{-/-}$) and a spontaneous mouse mutant of RasGRP1 (*RasGRP1*^{lag}; *lag* is an acronym representing *l*ymphoproliferation-*a*utoimmunity-*g*lomerulonephritis), were found to exhibit massive lymphoproliferation and autoimmunity with similarity to SLE (Layer et al. 2003). At 5 months of age, *RasGRP1*^{lag} and *RasGRP1*$^{-/-}$ mice displayed splenomegaly, lymphadenopathy, glomerulonephritis, lymphocytic infiltrates within many organs, elevated antinuclear antibodies (ANAs), anorexia, and lethargy. However, the penetrance of a severe autoimmune phenotype within one animal colony of *RasGRP1*$^{-/-}$ mice disappeared after successive backcrossing of the targeted mutation onto the C57BL/6 background. C57BL/6 *RasGRP1*$^{-/-}$ mice remained lymphopenic and free of severe autoimmune disease up to 1 year of age despite high-serum ANA levels (Priatel et al. 2007). It is possible that genetic modifiers from the 129/SvJ genetic background or environmental factors, such as distinct microfloral, may synergize with *RasGRP1*-deficiency to promote fulminant disease.

The lack of RasGRP1 in developing thymocytes may push the balance toward autoimmunity. It has been proposed that DP thymocytes capable of maturing into mature SP thymocytes need to express more strongly self-reactive TCRs if they lack RasGRP1 to overcome their signaling deficits (Priatel et al. 2002; Layer et al. 2003). As TCR transgenic studies have argued that RasGRP1 is not necessary for central tolerance (Priatel et al. 2002), the affinity/avidity of TCRs expressed by *RasGRP1*$^{-/-}$ mature SP thymocytes perhaps straggle the boundary between positive and negative selection. In addition, RasGRP1 has been shown to play a critical role in the formation of natural Foxp3-expressing regulatory T cells, suggesting that impaired development or function of this lineage may contribute to disease in RasGRP1 mutant mice (Stone 2011).

There are also a number of peripheral mechanisms by which RasGRP1-deficiency may collude with defective thymocyte development to cause disease. Firstly, the lymphopenic compartment within *RasGRP1*$^{-/-}$ mice that results from decreased thymic output may favor oligoclonal T-cell outgrowth and generation of T-cell effectors through abundance of cytokines like IL-7 and increased availability of self-peptides/self-MHC molecules. Notably, *RasGRP1*$^{-/-}$ T cells have a distinct TCR repertoire relative to wild type animals resulting from altered T-cell development or peripheral T-cell homeostasis (Priatel et al. 2007). Secondly, aberrant TCR signaling or TCR repertoire in mature T cells may lead to weakened immune responses, chronic infections, and proinflammatory conditions. Viral challenge experiments demonstrated that *RasGRP1*$^{-/-}$ mice generate drastically fewer antigen-specific T cells and delayed pathogen clearance as compared to wild type mice (Priatel et al. 2007). Thirdly, the resistance to AICD exhibited by RasGRP1-deficient T cells in vitro has been postulated to enhance their pathogenicity in vivo by escaping apoptosis (Layer et al. 2003). Fourthly, the function or maintenance of regulatory T cells may be impacted by diminished IL-2 production observed for *RasGRP1*$^{-/-}$ T-cell effectors (Layer et al. 2003; Priatel et al. 2010). Collectively, these findings suggest multiple means by which aberrant RasGRP1 signaling may enhance susceptibility to immunologic disease.

RasGRP1 and Cancer

Ras signaling regulates proliferation, differentiation and survival and activating Ras mutations are present in approximately 30% of all human cancers. As the original descriptions of RasGRP1 documented its capacity to transform rodent fibroblasts in vitro (Stone 2011), it raises the question as to whether altered RasGRP1 expression or activity can lead to tumorigenesis. To date, findings from several studies have supported this hypothesis.

The observation that the RasGRP1 is a frequent site of proviral insertion in retrovirus-induced murine T-cell lymphomas suggests that RasGRP1 can act as an oncogene (Stone 2011). Corroborating these findings, overexpression of RasGRP1 in the thymus was able to initiate thymic lymphomas in a pre-TCR/TCR-independent manner (Klinger et al. 2005). An investigation into genes able to induce acute myeloid leukemia (AML) found that RasGRP1 can act alone as a leukemic initiator/driver or act in concert with other leukemic causing genes to cause disease (Vassiliou et al. 2011). In addition, therapeutically targeting the Ras-ERK pathway using MEK inhibitors in a mouse model of AML revealed that increased RasGRP1 expression correlated with tumor resistance to the drug, although the precise mechanism of action

remained unclear (Lauchle et al. 2009). Besides its association with blood cancers, RasGRP1 overexpression in murine epidermal keratinocytes led to spontaneous development of squamous cell papillomas in the absence of chemical tumor initiators (Diez et al. 2009). Consequently, RasGRP1 is relevant to tumorigenesis in hematopoietic and non-hematopoietic cells.

Summary

RasGRP1 is the prototypical member of the RasGRP family of guanyl nucleotide exchange factors whose function is to couple surface receptor signaling to the activation of the small GTPase Ras and downstream MAPK pathways. The activity of RasGRP1 is regulated through its mobilization to membranes and pairing with Ras by the second messenger DAG (diacylglycerol). RasGRP family members are composed of a REM (Ras exchange motif) and ▶ CDC25 (cell division cycle 25)-related domains, functioning in Ras recognition and catalysis of GDP exchange, and "EF-hand" and DAG-binding "C1" motifs, serving to modulate its recruitment to membranes. Initial investigations revealed that RasGRP1 links TCR signaling to the activation of Ras-ERK pathway, playing crucial roles in both T-cell development and mature T-cell function. More recent studies have found that RasGRP1 mediates critical regulation of surface receptor signaling and effector functions in B cells, NK cells, and mast cells. Perturbations in RasGRP1 function are suspected to underlie immunodeficiency, autoimmunity, and blood cell malignancies.

Ras-Related Associated with Diabetes

Jose-Luis González de Aguilar
Laboratory of Molecular Signaling and Neurodegeneration, INSERM, Faculty of Life Sciences, University of Strasbourg, Strasbourg, France

Synonyms

Rad; Ras associated with diabetes; RRAD

Historical Background

Ras associated with diabetes (Rad) was identified in the beginning of the 1990s as a clone differentially expressed in two subtraction cDNA libraries prepared from skeletal muscle of normal individuals and patients with Type II (non-insulin-dependent) diabetes mellitus (Reynet and Kahn 1993). Analysis of the newly identified clone revealed about 50% identity at the nucleotide level with members of the Ras superfamily, which consists of more than a hundred low-molecular-weight guanine nucleotide–binding proteins, also referred to as small GTPases. The major feature of this class of molecules is their ability to cycle between a GDP-bound inactive and a GTP-bound active conformation. Small GTPases are divided into six subfamilies: Ras, Rho, Arf, Rab, ► Ran, and RGK, in which Rad is included. They participate in important cellular processes such as growth and differentiation, cytoskeletal dynamics, membrane trafficking, vesicle transport, and signal transduction. In their seminal report, Reynet and Kahn observed that the expression of Rad is typically highest in skeletal muscle, cardiac muscle, and lung of normal individuals. They also found that Rad mRNA levels appeared increased in Type II diabetes muscle as compared to Type I diabetes or nondiabetic muscle (Reynet and Kahn 1993). These findings provided the framework for follow-up studies on the comprehension of the biology of Rad in relation to muscle (patho) physiology and cancer.

Structure and Regulation of the Activity of Rad

The human Rad gene is localized in chromosome 16q22, spans 3.75 kb, and is composed of five exons and four introns. Translation presumably starts from an in-frame ATG codon in the second exon, which gives rise to a protein of 269 amino acids with a predicted molecular weight of 29,266 kDa (Caldwell et al. 1996). Rad is the prototype member of the small GTPases in the RGK family, which also includes Rem, Rem2, and Gem/Kir. From a structural point of view, Rad possesses the five highly conserved GTPase domains G1 to G5, characteristic of the Ras-related proteins, but it also displays particular features distinct from that commonly observed in other small GTPases. First, Rad exhibits several nonconserved amino acids in G1, G2, and G3 domains that may affect its GTPase function. Second, Rad shows longer NH_2 and COOH termini of 88 and 31 amino acids, respectively. Third, The COOH terminus of Rad does not present the typical CAAX isoprenylation motif that usually facilitates the attachment to cell membranes (Reynet and Kahn 1993).

Rad has been shown to interact with a variety of proteins that can thereby determine its function and/or subcellular distribution. For example, overexpressing Rad in a neuroblastoma cell line triggers cellular flattening and neurite extension, and it has been proposed that these effects are the consequence of binding of Rad to the Rho-associated protein kinase ROCK, which is known to regulate the shape and movement of cells by acting on the cytoskeleton. Such an interaction impedes ROCK activity which, in turn, results in the inhibition of contraction and retraction (Ward et al. 2002). The subcellular distribution of Rad greatly depends on the interactions with the Ca^{2+}-binding protein calmodulin (CaM) and the multifunctional regulatory protein 14-3-3. It has been reported that

the lack of binding to CaM induces the accumulation of Rad in the nucleus, whereas the association with 14-3-3 maintains Rad within the cytoplasm (Mahalakshmi et al. 2007). Interestingly, Rad presents several consensus phosphorylation sites in the extended COOH terminus, which are close to the CaM-binding domain. Rad can be phosphorylated on serine residues by Ca^{2+}-/CaM-dependent protein kinase II (CaMKII), PKA, ▶ casein kinase II and PKC. These post-translational modifications do not seem to affect the ability of Rad to hydrolyze GTP but alter its affinity to bind CaM and 14-3-3, thus interfering with the subcellular localization of the protein (Moyers et al. 1998; Mahalakshmi et al. 2007).

Little is known about the mechanisms controlling the expression of Rad at the transcriptional level. Early studies indicated the localization of Rad to thin filaments in skeletal muscle, as well as its increased expression during myoblast fusion (Paulik et al. 1997). In agreement with these observations, subsequent studies showed that several transcription factors involved in myogenesis, including MEF2, MyoD, and Myf5, stimulate the transcriptional activity of the Rad promoter (Hawke et al. 2006). Increased Rad expression has also been observed in experimental conditions characterized by acute accumulation of toxic reactive oxygen species in skeletal muscle, such as hind limb ischemia–reperfusion and sciatic nerve axotomy–induced muscle denervation (Halter et al. 2010).

Role of Rad in Tissue Remodeling

In vascular proliferative diseases, such as atherosclerosis, the formation of vascular lesions is mainly provoked by aberrant migration, attachment, and proliferation of vascular smooth muscle cells. Multiple factors may contribute to produce this pathological remodeling. Using adenovirus-mediated gene delivery, it has been reported that the expression of Rad is able to inhibit the migration and attachment of vascular smooth muscle cells, and that this effect is dependent on GTP loading. Experimental evidence supports that Rad reduces the formation of stress fibers and focal contacts necessary to the remodeling process, by interfering with the Rho/ROCK signaling pathway (Fu et al. 2005).

Pathological remodeling is also observed in heart in response to injury and stress, and it leads to myocardial hypertrophy and fibrosis, and subsequent heart failure. The expression of Rad is normally high in the myocardium but decreases in diseased heart. Transgenic mice lacking the Rad gene are more prone to develop cardiac hypertrophy, and this is associated with an increase in the phosphorylation of CaMKII. Through its interaction with CaMKII, it has been proposed that Rad decreases the phosphorylation and activity of this kinase, and hence reduces cardiac hypertrophy (Chang et al. 2007). Rad-deficient mice also show severe myocardial fibrosis. By binding the transcription factor C/EBP-δ, Rad impedes the expression of connective tissue growth factor, which is a key stimulator of the production of extracellular matrix leading to fibrosis. Rad therefore acts as a negative regulator of fibrosis in the heart (Zhang et al. 2011).

Role of Rad in Cancer

First reports indicated that Rad may be an oncogenic protein, since it increases the rate of growth of breast cancer cells in vitro. In addition, the ability of these cells to trigger the formation of tumors in nude mice is also exacerbated in the presence of Rad. The oncogenic potential of Rad resides within the NH_2 and COOH termini and seems not to be dependent on its GTPase activity. However, the metastasis suppressor gene, nm23, which stimulates GTP hydrolysis by Rad, is able to diminish its tumor-promoting effect (Tseng et al. 2001).

Other studies postulated that Rad is a tumor suppressor factor, because its expression appears frequently inhibited in lung and breast cancers (Suzuki et al. 2007). In support of this notion, it has been shown that Rad is a direct transcriptional target of the tumor suppressor p53 and, thus, can reduce migration and invasiveness of cancer cells by acting on cytoskeleton reorganization (Hsiao et al. 2011). Moreover, Rad triggers the apoptotic death of cardiomyocytes in vitro by stimulating the phosphorylation of p38 MAPK and by decreasing the levels of the pro-survival molecule Bcl-x_L (Sun et al. 2011).

Role of Rad in Ca^{2+} Channel Activity

Rad is a potent inhibitor of Ca^{2+} currents through L-type voltage-dependent channels. This occurs via the interaction of Rad with auxiliary $Ca_V\beta$ subunits,

which are involved in the trafficking toward the cell surface of the principal subunits forming the channels. The interaction between Rad and the $Ca_V\beta$ subunit prevents channel expression on the cell surface, by sequestering $Ca_V\beta$ subunits to the nucleus. The interaction depends on critical amino acid residues in the COOH terminus, and is facilitated by the absence of 14-3-3 and CaM binding, both of which allow relocalization of Rad within the cytoplasm (Finlin et al. 2003; Béguin et al. 2006). On the other hand, heart-specific overexpression of a dominant negative form of Rad, that binds GDP but not GTP, leads to an increase in the number of L-type voltage-dependent Ca^{2+} channels on the cell surface and, subsequently, cardiac arrhythmogenesis (Yada et al. 2007).

Role of Rad in Skeletal Muscle Metabolism, Development, and Disease

Rad was initially identified as being upregulated in diabetic patients. Follow-up studies did not confirm this finding, since Rad expression appeared normal in particular populations of diabetic patients and in the Zucker rat model of diabetes and obesity (Paulik et al. 1997). Of note, however, additional in vitro and in vivo experimental evidence strongly suggests the implication of Rad in glucose metabolism. First, overexpressing Rad in C2C12 and L6 myocyte cell lines reduces insulin-stimulated glucose uptake (Moyers et al. 1996). Second, using mice that overexpress Rad in muscle, it was shown that the increase in the expression of Rad acts synergistically with a high-fat diet to induce insulin resistance as observed in Type II diabetes (Ilany et al. 2006).

Rad is expressed during normal rat muscle development and in regenerating muscle in response to injury. Such an expression is located in the myogenic progenitor cell population, as well as in the newly regenerated myofibers as occurs in the *mdx* mouse model of Duchenne muscular dystrophy (Hawke et al. 2006). Extending these observations, it was also found that Rad is upregulated in skeletal muscles affected by the chronic neuromuscular degenerative condition, amyotrophic lateral sclerosis. In this disease, however, the upregulation of Rad is intimately associated with muscle atrophy, since it takes place within the myofibers that suffer from the degenerative process (Halter et al. 2010).

Summary

Rad is a multifunctional GTPase involved in many different molecular and cellular processes, mainly in muscle tissue, during development, and under normal adult and disease conditions. A major feature of Rad is the ability to interact with a variety of proteins, which determine not only the activity but also the specific role of this GTPase in a given physiological or pathological context (see Fig. 1). Rad can exert different inhibitory and stimulatory actions and, intriguingly, it can exhibit opposite roles for a particular situation. Thus, studies on the contribution of Rad to cancer showed both pro- and antitumoral activity. Not all the functions of Rad have been completely deciphered, such as its implication in muscle metabolism. In addition, the molecular mechanisms underlying Rad functions remain unclear and sometimes controversial. Finally, further efforts are needed to elucidate the regulatory factors, either

extra- or intracellular, that control Rad actions. From a pathological point of view, a better knowledge of these aspects of the biology of Rad would provide the basis for future therapeutic interventions.

A-protein; Cancer-associated retinopathy antigen; CAR-antigen; 23 kDa photoreceptor cell-specific protein; p26; p^{26}; S-modulin

Historical Background

In 1989, P. Philipopov's group from M.V. Lomonosov Moscow State University invented a method for purification of the visual G-protein transducin (G_t) and some other G-proteins. The idea of the method was based on the ability of visual rhodopsin to bind and to release transducin in the absence and in the presence of GTP, respectively. For this aim, a column with delipidated visual rhodopsin immobilized on Concanavalin A Sepharose was used. Chromatography of a crude extract of bovine rod outer segments on the column allowed one to obtain a set of transducin subunits with a slight contamination of cGMP-phosphodiesterase. Also, an admixture of an unknown protein with an apparent molecular weight of 26 K could be seen on the electrophoregram. The unknown protein attracted the attention of the group since the capability of binding to rhodopsin had been a characteristic feature of several key photoreceptor proteins, such as transducin, ▶ rhodopsin kinase, and arrestin. That is why the group decided to study this protein in more detail. The protein named "p26" was purified to a homogeneous state and used to arise specific antibodies. Screening of the retina and a number of other tissues for the presence of p26 with the use of the antibodies detected this protein only in the retina, in particular in the photoreceptor layer. It was also demonstrated that the amino acid sequence of p26 exhibited several calcium binding sites of the EF-hand type and the ability of p26 to bind Ca^{2+} was confirmed by experiments with calcium-45. In addition, p26 was suggested to be a Ca^{2+}-specific regulator of photoreceptor ▶ guanylate cyclase, a key enzyme of photoreceptors recovery, and due to this ability it was rechristened as "▶ recoverin." Afterward, a 26 K protein named "S-modulin" was purified from frog rod outer segments and shown to have a primary structure similar to bovine recoverin. Later it became clear that the binding of recoverin to rhodopsin is not quite specific as recoverin, due to its Ca^{2+}-myristoyl switch, is capable of binding to hydrophobic substances, e.g., to Phenyl-Sepharose, in a Ca^{2+}-dependent manner. That recoverin is capable of activating guanylate cyclase was, however, disproved in subsequent works. The mistake in the initial assignment of the recoverin function might apparently be explained by the presence of endogenous guanylate cyclase activator(s), GCAP1 and/or GCAP2, in the recoverin preparations used in the preceding works. Nevertheless, recoverin continues to be considered as a participant of the photoreceptor recovery but now as a Ca^{2+}-sensor of rhodopsin kinase, the enzyme catalyzing phosphorylation and thus desensitization of the visual receptor rhodopsin (for reviews, see Senin et al. 2002; Philippov et al. 2006). After the discovery of recoverin, a large number of other EF-hand-containing Ca^{2+}-binding proteins were described, which form a family of the neuronal calcium sensor (NCS) proteins. The expression of the NCS proteins is restricted within neurons and neuroendocrine cells, in which these proteins provide a Ca^{2+}-sensitivity to a number of protein targets (for a review, see Burgoyne and Weiss 2001; Philippov et al. 2006).

Another line of the recoverin research was started in 1987, when an antigen with an apparent molecular weight of 23 K was found in sera of patients with cancer-associated retinopathy (CAR). This antigen named "CAR-antigen" was then purified from bovine rod outer segments and shown to be identical to recoverin. These works have sprung an intensive recoverin study as a paraneoplastic antigen in cancer (for reviews, see Senin et al. 2002; Adamus 2006; Philippov et al. 2006). More recently, recoverin has become the first member of a new group of cancer-specific antigens designated as "cancer-retina antigens." In addition to recoverin, this group includes several key retinal proteins, such as rhodopsin, transducin, rhodopsin kinase, and some others. In health, these proteins are highly specific for the retina, but in cancer they can be expressed in malignant tumors localized outside the retina (Bazhin et al. 2007).

Tissue and Cellular Distribution of Recoverin

Immunochemical analysis demonstrated the presence of recoverin in the adult retina of all investigated species. Among these are: man, bull, monkey, mouse, rat, rabbit, frog, chameleon, and newt. In the case of the chicken retina, contradictory data were obtained: recoverin-positive immunoreaction was described in one case, but it was not found in another work. In addition to the retina, recoverin immunoreactivity was observed in the ocular ciliary epithelium, pinealocytes of the pineal organ, and rat olfactory epithelium. Within the retina, recoverin-positive reaction was found in photoreceptor cells as well as in higher order neurons (bipolar and ganglion cells) of a number of species and in amacrine cells of lamprey *Lampetra fluviatilis*. As already noted, recoverin is suggested to function in photoreceptors as a Ca^{2+}-sensor of rhodopsin kinase, but its role in neurons different from photoreceptors and in tissues different from the retina remains unknown (for reviews, see Senin et al. 2002; Philippov et al. 2006).

Within photoreceptors, recoverin is detected in the outer and inner segments, cell bodies, and synaptic pedicles. Most of the protein is localized in rod inner segments, with approximately 12% present in the outer segments in the dark and less than 2% remaining in that compartment in the light (Strissel et al. 2005). Thus, light causes a reduction of recoverin in rod outer segments, accompanied by its redistribution toward rod synaptic terminals.

Recoverin Structure

Recoverin is a compact (23.4 K, 201 amino acids) protein consisting of two globular N- and C-terminal domains, separated by a short linker. N-terminal glycine of recoverin is acylated predominantly with the myristic acid residue (C14:0) or, to a lesser extent, with one of the following fatty acid residues: C14:1 (5-*cis*), C14:2 (5-*cis*, 8-*cis*), or C12:0. Each of recoverin domains contains a pair of potential Ca^{2+}-binding sites of the EF-hand type: in total, the recoverin molecule contains four potential Ca^{2+}-binding sites that are disposed evenly along the amino acid chain of the protein. Of these, only two – EF-hand 2 and EF-hand 3 – are capable of binding calcium ions. Whereas EF-hand 1 and EF-hand 4 are inactive in this respect due to the following structural "defects": (1) in the sequences of EF-hand 1 and EF-hand 4, residues of negatively charged amino acids critical for the coordination of Ca^{2+} are missing in the 1st and 3rd positions of the 12-mer Ca^{2+}-binding loops, (2) EF-hand 1 cannot accept the conformation needed for the binding of calcium as P40 is present in the fourth position of the EF-hand 1 loop, (3) EF-hand 4 contains a salt bridge between the side chains of the K161 and G171 in the 2nd and 12th positions of the Ca^{2+}-binding loop, and (4) the highly conserved glycine at position 6 of the loop is replaced by the aspartic acid residue (D165) (for reviews, see Senin et al. 2002; Philippov et al. 2006).

The comparison of the structural data for apo- and Ca^{2+}-containing forms of myristoylated recoverin obtained by X-ray diffraction and NMR-spectroscopy revealed structural changes in the protein molecule, accompanying the binding of calcium (Fig. 1). In the apo-form, the myristoyl moiety of recoverin is buried into a deep hydrophobic cavity or hydrophobic "pocket," consisting of a cluster of aromatic and other nonpolar amino acid residues (L28, W31, Y32, F35, I44, F49, I52, Y53, F56, F57, Y86, L90, W104, and L108) of the protein molecule. Binding of calcium by recoverin leads to a 45° rotation of the N- and C-terminal domains around G96 and to significant conformational changes in the N-terminal domain. As a result (1) initially antiparallel α-helices of EF-hand 2 become perpendicular one to another and (2) α-helices of EF-hand 1 turn around G42, allowing myristoyl group to move outward from the hydrophobic environment. The consequence of these changes is the exposure of the hydrophobic amino acid cluster of the pocket and the myristoyl group of recoverin in solution – the so-called "Ca^{2+}-myristoyl switch" mechanism. The exposed myristoyl group allows recoverin to associate to membranes, while the amino acid cluster of the pocket participates in the interaction with the target enzyme, rhodopsin kinase (G-protein-coupled receptor kinase 1, GRK-1) (for reviews, see Senin et al. 2002; Philippov et al. 2006).

It should be added that the C-terminus of recoverin, in addition to ten α-helices "A-J" normally present in other NCS proteins, contains a variable C-terminal segment with an extra α-helix "K." Recent studies have demonstrated that C-terminal segment in recoverin is involved in regulating its Ca^{2+}-binding properties, as well as in recognizing and regulating of rhodopsin kinase (Weiergräber et al. 2006; Zernii et al. 2011).

Molecular Properties of Recoverin

Recoverin molecule is characterized by a set of key properties required for the signaling activity of the protein. Among them the most important are calcium binding, N-terminal myristoylation and the ability to bind to phospholipid membranes. In recombinant non-myristoylated recoverin, the binding of calcium to EF-hands 2 and 3 occurs independently with different affinities: $K_d = 6.9$ and 0.11 μM, respectively. In contrast, the binding of calcium to recombinant myristoylated recoverin is a cooperative sequential process (Hill coefficient = 1.75), wherein EF-hand 3 is occupied first, facilitating the subsequent filling of EF-hand 2 (an apparent K_d of the complex formed is equal to 17 μM). Thus, N-terminal myristoylation confers onto recoverin the cooperativity in calcium binding to EF-hands 2 and 3. Also, the myristoyl residue significantly stabilizes the conformation of the Ca^{2+}-free protein during the stepwise transition toward the fully Ca^{2+}-occupied state (for reviews, see Senin et al. 2002; Philippov et al. 2006).

Myristoylated recoverin is capable of binding to hydrophobic surfaces, such as the photoreceptor and artificial lipid membranes. Depending on calcium concentration, compartmentalization of recoverin reversibly changes from a soluble Ca^{2+}-free form to a membrane-bound Ca^{2+}-containing form. This process is due to the mechanism of the Ca^{2+}-myristoyl switch that operates in recoverin: after EF-hand 3 is filled by calcium, EF-hand 2 is subsequently filled, which triggers the exposition of the myristoyl group that attaches recoverin to the membrane. Solid-state nuclear magnetic resonance studies revealed that the Ca^{2+}-bound protein is positioned on the membrane surface so that its long molecular axis is oriented 45° with respect to the normal membrane. The myristoyl group is buried inside the membrane, whereas the N-terminal region of recoverin points toward the

membrane surface, with close contacts formed by basic residues K5, K11, K22, K37, R43, and K84. This orientation of the membrane-bound protein allows an exposed hydrophobic crevice, near the membrane surface, to serve as a binding site for the target protein, rhodopsin kinase (Valentine et al. 2003). The half-maximal binding of recoverin to photoreceptor membranes in vitro occurs at 2.5 μM of a free calcium concentration ($[Ca^{2+}]_f$), which is slightly out of the physiological range of cytoplasmic $[Ca^{2+}]_f$. However, extrapolation to in vivo conditions in rod outer segments, which bear stacks of densely packed membranes, reveals that the apparent affinity of recoverin to calcium is in the submicromolar (i.e., physiological) range of $[Ca^{2+}]_f$ (for reviews, see Senin et al. 2002; Philippov et al. 2006). The binding of recoverin to membranes depends on their lipid composition: it is enhanced with the elevation of the content of phosphatidylserine (Senin et al. 2007), polyunsaturated phospholipids (Calvez et al. 2011), and most notably cholesterol. High cholesterol content in photoreceptor disk membranes found at the base of rod outer segments might favor the affinity of recoverin to the membranes and shift its binding to the physiological range of $[Ca^{2+}]_f$ (for a review, see Philippov et al. 2006). The Ca^{2+}-dependence of the recoverin binding to photoreceptor or artificial lipid membranes is also regulated by the C-terminal segment of recoverin, which serves as an internal modulator of its Ca^{2+}-sensitivity and functional activity (Weiergräber et al. 2006; Senin et al. 2007; Zernii et al. 2011).

Along with Ca^{2+}-binding, which is a key molecular property of recoverin, the protein can bind Zn^{2+} with stoichiometry of 1:1 and apparent K_d of 30 and 7.1 μM for apo- and Ca^{2+}-loaded protein forms, respectively (Permyakov et al. 2003). Also, recoverin molecules are able to form a disulfide dimer and thiol oxidized monomer under mild oxidizing conditions, using unique C39 highly conserved within NCS family (Permyakov et al. 2007). It is unclear yet, whether the above properties have the physiological significance.

Targets and Functions of Recoverin

A major intracellular target of recoverin in rod outer segments is suggested to be rhodopsin kinase (GRK-1). The filling of EF-hand 2 with calcium (in myristoylated recoverin the filling of EF-hand 2 occurs only after EF-hand 3 is already filled) results in the exposition of a cluster of the hydrophobic amino acids that provides recoverin with an ability to interact with rhodopsin kinase and thus inhibits the activity of the enzyme. According to the surface plasmon resonance studies, the half-maximal binding of rhodopsin kinase to immobilized recoverin occurs at approximately 0.51 μM of rhodopsin kinase. Myristoylation has a little effect on the binding of recoverin to the kinase, but it shifts the half-maximal effect of calcium on the binding from 150 nM for non-acylated recoverin to 400 nM for myristoylated recoverin (for reviews, see Senin et al. 2002; Philippov et al. 2006). Recoverin binds to a region of residues 1–15 at the N-terminus of rhodopsin kinase (Higgins et al. 2006). Nuclear magnetic resonance studies of the complex between Ca^{2+}-bound recoverin and a N-terminal fragment of rhodopsin kinase, residues 1–25 ($RK^{1\text{-}25}$) revealed that the hydrophobic face of the $RK^{1–25}$ helix (L6, V9, V10, A11, A14, and F15) interacts with an exposed hydrophobic groove on the surface of recoverin, lined by side chains of the residues W31, F35, F49, I52, Y53, F56, F57, Y86, and L90. In that structure, the first eight residues of recoverin at the N-terminus are solvent-exposed, enabling the N-terminal myristoyl group to interact with target membranes (Ames et al. 2006). The half-maximal inhibition of rhodopsin kinase by recoverin is observed at 2–3 μM and 1.5–1.7 μM of calcium in the case of non-acylated and myristoylated recoverin, respectively. At saturating calcium concentrations, the half-maximal inhibition of rhodopsin kinase occurs at 6.5–8 μM of non-myristoylated recoverin and at 0.8–3 μM of myristoylated recoverin, suggesting that photoreceptor membranes enhance inhibitory effect of recoverin upon rhodopsin kinase. The inhibition of rhodopsin kinase by recoverin is facilitated when the cholesterol content of membranes is increased. As the cholesterol content in photoreceptor disk membranes changes along the axis of rod outer segment from 5% at the tip to 30% at the base, the above-mentioned effect of cholesterol might be of physiological importance (for reviews, see Senin et al. 2002; Philippov et al. 2006). The activity of recoverin as a Ca^{2+}-sensor of rhodopsin kinase is also regulated by the C-terminal segment of recoverin (Weiergräber et al. 2006; Zernii et al. 2011).

Therefore, a number of the in vitro data suggest that recoverin functions as a Ca^{2+}-sensor of rhodopsin

kinase in photoreceptor cells. According to these data, at high calcium, corresponding to a dark state of photoreceptor cells, rhodopsin kinase forms a complex with recoverin and becomes inactive; at low calcium, corresponding to the bleached state of photoreceptor cells, the complex dissociates allowing activation of the enzyme (for reviews, see Senin et al. 2002; Philippov et al. 2006). However, the in vivo data on recoverin function are contradictive. On the one hand, recoverin is suggested to be implicated in the light adaptation of photoreceptor cells by Ca^{2+}-dependent prolongation of the photoresponse due to (1) regulating the lifetime of photoactivated rhodopsin through feedback on rhodopsin kinase and (2) regulating the speed of the light-induced change of $[Ca^{2+}]_f$ through a Ca^{2+}-buffering mechanism (for a review, see Philippov et al. 2006). On the other hand, there are data suggesting that the effect of recoverin on the photoresponse could not be explained by its effect on phototransduction as such. Instead, the prolonged signal transmission that enhances visual sensitivity is the effect of recoverin downstream of phototransduction in rods (Sampath et al. 2005). Recent data have advanced a new argument in favor of recoverin as a Ca^{2+}-sensor of rhodopsin kinase in vivo (Chen et al. 2010). According to these data, (1) background light accelerates inactivation of photoexcited rhodopsin and (2) recoverin is required for the light-dependent modulation of the photoexcited rhodopsin lifetime, probably due to its capability to regulate rhodopsin kinase in a Ca^{2+}-dependent manner.

The function(s) of recoverin in the structures different from photoreceptor outer segments still remains unknown, but it is possible that the following data could help to provide a clue to this issue. In the ribbon synapse of photoreceptors, recoverin is co-localized with membrane palmitoylated protein-4 (MPP4), a retina-specific scaffolding protein, which has been implicated in organizing presynaptic protein complexes. Western blot analysis of bovine retinal anti-recoverin precipitates detects co-precipitating MPP4, supporting an association between the MPP4-containing protein complex and recoverin in vivo. However, immunoprecipitation experiments do not show a direct interaction between recoverin and MPP4 in 293-BNA cells co-transfected with both proteins (Förster et al. 2009). More recently, pull-down assay and surface plasmon resonance study have revealed a neuron-specific Ca^{2+}-binding protein caldendrin as a potential target for recoverin in retinal bipolar cells and pineal gland. In particular, both proteins are co-localized in these structures and an increase of intracellular calcium facilitates the translocation of caldendrin to intracellular membranes, which is under control of the complex formation with recoverin (Fries et al. 2010).

Recoverin in Cancer

In health, the expression of recoverin is mainly restricted within the retina. In cancer, recoverin can also be a paraneoplastic (or onconeural) antigen which expressed in tumors localized outside the nervous system. The aberrant expression of recoverin in malignant cells causes an autoimmune response in some cancer patients what is followed by the development of paraneoplastic retina degeneration or cancer-associated retinopathy, CAR. Autoantibodies against recoverin (AAR) are detected in patients with different kinds of cancer (for reviews, see Adamus 2006; Bazhin et al. 2007).

A model of antibody-induced apoptosis of photoreceptor cells, underlying the CAR syndrome, has been proposed (for a review, see Adamus 2006). Serum AAR should be in sufficiently high titers to enter the eye and cause retinopathy. Circulating AAR cross the blood-retinal barrier and penetrate into retinal layers, where AAR attack photoreceptors which express recoverin. AAR then penetrate into retinal cells by an active process of endocytosis. Once in the cell, AAR block the recoverin function in phototransduction, which results in the enhancement of rhodopsin phosphorylation and an increase in the concentration of intracellular calcium ions. The high intracellular calcium activates the mitochondria-dependent and caspase-9-dependent activation of caspase 3, leading to DNA fragmentation and cell death. Massive death of photoreceptor cells leads to retinal dysfunction and degeneration.

The CAR syndrome, similar to other paraneoplastic neurological syndromes, is a very rare event: its occurrence is of the order of 1%. However, underlying AAR might occur much more frequently (Bazhin et al. 2004). An important feature of the CAR syndrome, as well as other paraneoplastic syndromes, is that it can be manifested long before the clinical diagnosis of the underlying tumor (for a review, see Adamus 2006).

Such a feature of the CAR syndrome and underlying AAR could be useful to clinicians to predict the future development of a particular cancer.

Summary

Recoverin, initially named "p26," is a Ca^{2+}-binding protein with a predominantly retinal localization, which belongs to the neuronal calcium sensor (NCS) protein family. The recoverin molecule consists of 201 amino acid residues and contains four potential EF-hand Ca^{2+}-binding sites, of which only two – EF-hands 2 and 3 – are capable of binding calcium. The N-terminus of recoverin is acylated, mainly myristoylated. Due to the mechanism of the Ca^{2+}-myristoyl switch, compartmentalization of recoverin is changed from a soluble Ca^{2+}-free form to a membrane-bound Ca^{2+}-containing form, and vice versa, depending on an external calcium concentration. In the Ca^{2+}-free form, the N-terminal myristoyl moiety of recoverin is buried into the hydrophobic pocket of the protein; on calcium binding, the myristoylated N-terminus is exposed, providing membrane association of recoverin. Recoverin is suggested to operate as a Ca^{2+}-sensor of rhodopsin kinase (G-protein-coupled receptor kinase 1, GRK-1), which catalyzes phosphorylation and thus desensitization of the visual receptor rhodopsin. In cancer, recoverin can also be a paraneoplastic (or onconeural) antigen, the aberrant expression of which in malignant tumors of some patients causes an autoimmune response and the development of paraneoplastic retina degeneration or cancer-associated retinopathy. An important feature of the CAR syndrome and underlying autoantibodies against recoverin is that they can be detected long before the clinical diagnosis of the corresponding tumor. Such a feature of the autoantibodies could be useful to clinicians to predict the future development of a particular cancer.

Regulator of Calcineurin 1 (RCAN1)

Masakazu Fujiwara and Mohammad Ghazizadeh
Department of Molecular Pathology, Institute of Development and Aging Sciences, Graduate School of Medicine, Nippon Medical School, Kawasaki, Kanagawa, Japan

Synonyms

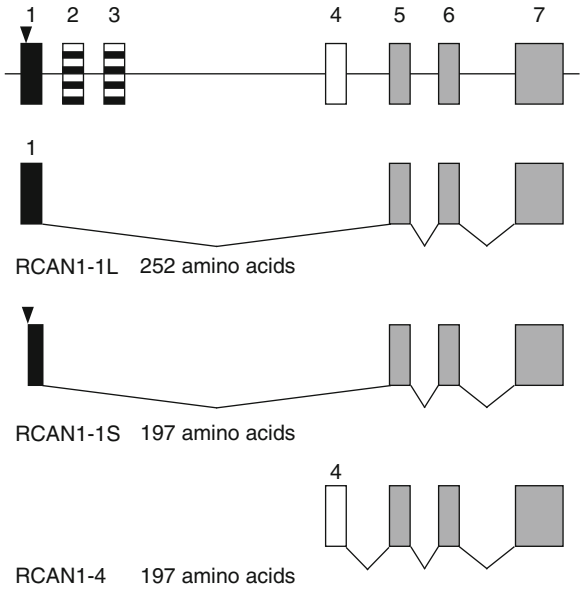
ADAPT78; Calcipressin1; CBP1; Down syndrome candidate region 1 (DSCR1); Down syndrome critical region 1 (DSCR1); MCIP1; Nebula; RCN-1; Sarah

Historical Background

Regulator of calcineurin 1 (RCAN1) was first isolated by Fuentes et al. in 1995 during a search for genes associated with clinical features of Down syndrome (e.g., mental retardation and congenital heart disease) (Fuentes et al. 1995). Coding sequences of RCAN1 were identified from the 21q22.1–q22.2 region of human chromosome 21 by an Alu-splice PCR method. It was initially thought that RCAN1 was significantly associated with the Down syndrome phenotype (Fuentes et al. 1997b), thus RCAN1 was first designated Down Syndrome Critical Region 1 (DSCR1). Future studies showed that the DSCR1 gene product is a calcineurin regulator, and the new name "regulator of calcineurin (RCAN)" was adopted to describe the gene function. Although RCAN1 is still referred to as DSCR1, ADAPT78, MCIP1, Calcipressin1, RCN-1, Nebular, Sarah, or CBP1, both the HUGO Gene Nomenclature Committee (HGNC) and the Mouse Genomic Nomenclature Committee (MGNC) (Davies et al. 2007) have adopted the RCAN1 nomenclature.

RCAN1 is an endogenous inhibitor of the serine phosphatase calcineurin (Fuentes et al. 2000; Gorlach et al. 2000; Kingsbury and Cunningham 2000). Calcineurin is a heterodimer that is composed of the catalytic subunit calcineurin A (CnA) and regulatory subunit calcineurin B (CnB). RCAN1 directly binds to CnA and inhibits the catalytic activity of calcineurin. Calcineurin controls the phosphorylation/dephosphorylation of several transcription factors, such as the nuclear factor of activated T cells (NFAT) (Crabtree and Olson 2002), CREB (Liu and Graybiel 1996), and the MEF2 transcription factor families (Mao and Wiedmann 1999). Dephosphorylation of NFAT by activated calcineurin promotes translocation of NFAT to the nucleus, where the transcription factor binds to DNA and activates gene transcription (Crabtree and Olson 2002). A wide variety of physiological processes, such as lymphocyte activation (Fruman et al. 1995), neurite outgrowth (Chang et al. 1995), aging (Mair et al. 2011), heart development (Yang et al. 2000), skeletal muscle fiber type differentiation (Olson and Williams 2000), and cardiac function (Ryeom et al. 2003) are regulated by calcineurin-activated transcription factors. Thus, RCAN1, which controls calcineurin activity, regulates various physiological functions.

RCAN1 is highly conserved from unicellular eukaryotes to multicellular animals, and orthologs have been identified in *Saccharomyces cerevisiae* (Kingsbury and Cunningham 2000), *Cryptococcus neoformans* (Gorlach et al. 2000), *Caenorhabditis elegans*



Regulator of Calcineurin 1 (RCAN1), Fig. 1 The human *RCAN1* mRNA isoforms. The 252-amino acid RCAN1-1 L, 197-amino acid RCAN1-1 S, and 197-amino acid RCAN1-4 each have different ATG start codons

(Lee et al. 2003), and *Drosophila melanogaster* (Chang et al. 2003). The human *RCAN1* gene contains seven exons, where exons 1–4 can be alternatively transcribed or spliced to produce different mRNA isoforms (Fuentes et al. 1997a). Among the four potential transcripts, the major transcripts are *RCAN1-1* and *RCAN1-4*, which have exon 1 and exon 4 for the first exon, respectively (Fig. 1). Additionally, there are two start codons in exon 1; the long form of RCAN1-1, which encodes 252 amino acids, is referred to as RCAN1-1 L (Genesca et al. 2003), and the short form of RCAN1-1, which encodes 197 amino acids, is referred to as RCAN1-1 S (Fuentes et al. 1997a).

RCAN1 Expression

RCAN1 is highly expressed in the human fetal brain and adult heart. Lower expression levels have been detected in the adult brain, lung, liver, skeletal muscle, kidney, and pancreas. The fetal lung, liver, kidney, and placenta also have low RCAN1 expression (Fuentes et al. 1995). RCAN1 expression in rat and mice is similar to the associated human tissues, and there is high expression in the rodent brain and heart (Fuentes et al. 1995, 1997a). In the rat brain, the in situ hybridization signal for *RCAN1* expression was high in the olfactory bulb, the piriform cortex, the dentate granule cell layer, the pyramidal cell layer of the hippocampus, the striatum and the cerebellar cortex. No signal for *RCAN1* expression was detected in the white matter (Fuentes et al. 1995). The brains of 2–7-day-old neonatal rats had higher *RCAN1* expression in the neocortex and the hypothalamus compared to adults rat older than 16 days (Fuentes et al. 1995).

RCAN1 expression is diverse throughout many different cell and tissue types and is regulated by various stimuli. Vascular endothelial growth factor (VEGF) (Minami et al. 2004; Yao and Duh 2004), thrombin (Minami et al. 2004), oxidative stress (Crawford et al. 1997), Ca^{2+}-mediated stress (Cano et al. 2005), ß-amyloid fragments (Ermak et al. 2001), TNFα (Minami et al. 2004; Yao and Duh 2004), and endoplasmic reticulum stress (Zhao et al. 2008) have been reported to induce RCAN1 expression. Oxidative stress in hamster HA-1 cells induced RCAN1 expression as early as 90 min after peroxide exposure, indicating that the transcriptional response of RCAN1 is rapid and robust. A previous study indicated that the maximal increase in RCAN1 expression was 7.8-fold after 5 h of initial exposure (Crawford et al. 1997). Similarly, rapid and robust RCAN1 expression occurs with other types of stimuli, such as VEGF and thrombin. After 1 h of treatment, VEGF and thrombin stimulation increased RCAN1 expression in human endothelial cells by 22.3-fold and 17.7-fold, respectively (Minami et al. 2004).

RCAN1 transcription is regulated via a negative feedback loop with RCAN1-4, which is an isoform that is abundant in the fetal kidney, adult heart, placenta, and skeletal muscle (Ermak et al. 2002; Fuentes et al. 1997a, 2000). RCAN1 expression is induced by the transcription factor NFAT, and NFAT activation and nuclear translocation are regulated by calcineurin phosphatase activity. Therefore, an excessive amount of RCAN1 inhibits calcineurin and attenuates the calcineurin–NFAT signaling pathway, thereby establishing a negative feedback loop that suppresses its own expression. Calcineurin/NFAT signal-dependent RCAN1-4 transcription is controlled by a promoter region that is located upstream of exon 4 (between nucleotides −350 and −166); this promoter region also contains putative NFAT and AP-1 binding

sites (Cano et al. 2005; Yang et al. 2000; Zhao et al. 2008). In contrast, RCAN1-1 L, which is the isoform that is predominantly expressed in the fetal and adult brains (Ermak et al. 2002; Fuentes et al. 1997a, 2000) is controlled by a conserved muscle-specific CAT (M-CAT) site located 1,426 bp upstream of exon 1 (Liu et al. 2008). Transcription enhancer factor 3 directly interacts with the M-CAT site in the promoter and is required for RCAN1-1 L expression (Liu et al. 2008).

Inhibitory and Stimulatory Effects of RCAN1

RCAN1 is an endogenous inhibitor of calcineurin; RCAN1 overexpression inhibits NFAT-mediated calcineurin signaling by directly binding to the catalytic subunit of calcineurin (Fuentes et al. 2000). However, RCAN1 gene disruption also inhibits calcineurin–► NFAT signaling instead of stimulating the signaling. In yeast, disruption of the *RCAN1* orthologus gene (*RCN1*) results in significantly decreased calcineurin–NFAT signaling (Kingsbury and Cunningham 2000). In $RCAN1^{-/-}$ mice, calcineurin activity is decreased in response to cardiac hypertrophy induced by pressure overload (Vega et al. 2003). These conflicting results suggest that reciprocal effect of RCAN1 to the calcineurin activities, as high RCAN1 expression is associated with calcineurin inhibition, while physiological levels of RCAN1 expression are associated with calcineurin stimulation.

A number of reports have indicated that phosphorylation of RCAN1 is important for RCAN1-mediated biphasic effects on calcineurin. Using both human and yeast RCAN1, Hilioti et al. showed that RCAN1-mediated calcineurin stimulation requires phosphorylation at the conserved FLISPPxSPP motif when RCAN1 is expressed at low concentrations (Hilioti et al. 2004). Moreover, Liu et al. also showed that phosphorylation of low concentrations of RCAN1 activates calcineurin–NFAT signaling (Liu et al. 2009). Because the phosphorylated FLISPPxSPP RCAN1 motif is rapidly degraded by the SCF^{Cdc4} ubiquitin ligase complex (Genesca et al. 2003; Kishi et al. 2007), it has been hypothesized that phosphorylated RCAN1 rapidly degrades and releases calcineurin from the inactive complex (Kishi et al. 2007). RCAN1-mediated stimulation of calcineurin activity is observed only at physiological RCAN1 expression levels because the net balance of phosphorylated RCAN1 is much higher. On the other hand, when RCAN1 is overexpressed, a majority of the protein is not phosphorylated; this stable RCAN1 binds to calcineurin, which covers the catalytic domain and inhibits phosphatase activity. Overexpressed RCAN1 also increases calcineurin proteolysis (Lee et al. 2009), which also contributes to RCAN1-mediated inhibition. Collectively, RCAN1 inhibits calcineurin signaling by binding to calcineurin and interfering with substrate binding; phosphorylated RCAN1 has a shorter half-life and appears to be stimulatory when expressed at low levels.

Domains and Motifs of RCAN1

Structural and functional analysis of RCAN1 indicates that specific domains or motifs are required to modulate calcineurin activity (Fig. 2). Both the N- and C-terminals of RCAN1 contain motifs that can bind to calcineurin and inhibit calcineurin catalytic activity (Fuentes et al. 2000; Vega et al. 2002). In the C-terminal, the PxIIxT motif at exon 7 is required for calcineurin binding and inhibition (Chan et al. 2005). The CIC motif (consensus sequence in mammals is LGPGEKYELHA(G/A)T(D/E)(S/T)TPSVVVHVC (E/D)S) at the C-terminal is also necessary for inhibition of calcineurin–NFAT signaling (Mulero et al. 2009). The PxIxIT-like motif within the CIC motif efficiently blocks calcineurin activity by binding to the calcineurin surface with the help of the LxxP motif when RCAN1 is overexpressed. At the N-terminal, a domain that resembles three-dimensional structures of RNA recognition motifs binds and inhibits calcineurin activity (Mehta et al. 2009).

The PxIxIT-like and LxxP motifs appear to be important for the stimulation of calcineurin signals at low RCAN1 expression level in addition to their roles in inhibition at high expression level. The TxxP motif, which is adjacent to the PxIIxT motif at exon 7, is only required for the stimulatory effects (Mehta et al. 2009). Together with the FLISPPxSPP motif phosphorylation site (see section "Inhibitory and Stimulatory Effects of RCAN1"), these motifs are important for RCAN1-mediated stimulation of calcineurin signaling (Fig. 2).

Role of RCAN1 in Angiogenesis

Patients with Down syndrome have an extremely low incidence of solid tumors, which indicates that RCAN1 plays an important role in both angiogenesis and tumor development (Hasle 2001). RCAN1 gain-of-function studies show that constitutive expression of RCAN1 in endothelial cells impairs NFAT nuclear localization, proliferation, and tube formation. RCAN1 also reduces vascular density in Matrigel plugs and melanoma tumor growth in mice (Minami et al. 2004). Another study with transgenic mice with three copies of RCAN1 showed that these mice have significantly suppressed growth of Lewis lung carcinoma and B16F10 melanoma cells in vivo. Moreover, a study by Baek et al. showed that a modest increase in RCAN1 expression (2.4-fold increase in mRNA relative to littermate controls) is sufficient for tumor growth suppression (Baek et al. 2009). In Xenopus laevis, overexpression of RCAN1 decreased the number of branching points that sprouted from intersomitic vessels and decreased the vascular density of the microvessels (Fujiwara et al. 2011).

Consistent with the previous loss-of-function studies, studies in *RCAN1*$^{-/-}$ mice have shown that RCAN1 inhibits angiogenesis. *RCAN1* deletion suppressed subcutaneous and metastatic tumor growth, and endothelial cells isolated from these knockout mice showed decreased VEGF-induced proliferation (Ryeom et al. 2008). Specific knock down of *RCAN1* expression by antisense oligonucleotides also inhibited VEGF-stimulated migration of endothelial cells (Iizuka et al. 2004). Researchers have hypothesized that the appropriate RCAN1 expression level, as well as the phosphorylation state influences RCAN1 regulation of calcineurin activity. High RCAN1 expression may reduce calcineurin activity and block proliferation of endothelial cells, whereas low RCAN1 expression may hyperactivate calcineurin activity and trigger apoptosis (Ryeom et al. 2008).

RCAN1 and Down Syndrome

Because RCAN1 is highly expressed in the brains of Down syndrome patients, it is thought to be associated with the Down syndrome phenotype (Fuentes et al. 1995). Overexpression of the *Drosophila* ortholog of *RCAN1* (*nebula*) causes neuronal defects that are similar to Down syndrome, such as impaired synaptic development, synaptic terminal structure, vesicle recycling, and locomotor activity (Chang and Min 2009). Additionally, reduced or overexpression of nebula impairs mitochondrial enzyme activity, the number and size of mitochondria, and accumulation of toxic reactive oxygen species (ROS) in the fly brains, which are all characteristic of pathologies associated with Down syndrome (Chang and Min 2005). These results strongly suggest that altered expression of RCAN1 contributes to the neurological defects in Down syndrome. Furthermore, cardiac defects, which are another common feature associated with Down syndrome, have been reported in *RCAN1*/*DYRK1A* double transgenic mice. A craniofacial defect was also reported in Nfatc2$^{-/-}$/Nfatc4$^{-/-}$ double-knockout mice, which have impaired RCAN1-calcineurin–NFAT signaling (Arron et al. 2006). These results indicate that *RCAN1* is an important gene that is associated with the Down syndrome phenotype.

RCAN1 and Alzheimer's Disease

Overexpression of RCAN1 has been observed in Alzheimer's disease patient brains, where RCAN1 expression was twofold higher in the cerebral cortex and threefold higher in the hippocampus (Ermak et al. 2001). Of the RCAN isoforms that are expressed in the brain, RCAN1-1 L is upregulated in the neurons of Alzheimer's disease patients (Harris et al. 2007). Overexpressed RCAN1 colocalizes with the neurodegenerative disease-associated proteins huntingtin (Q148) and ataxia-3 (Q84) in cultured primary neurons (Ma et al. 2004). Additionally, RCAN1 expression is directly stimulated by the aggregated amyloid Aß peptide, which is a peptide that plays a role in neuronal degeneration in Alzheimer's disease and human neuroblastoma cell lines (Ermak et al. 2001).

Functional analyses of RCAN1 further indicate that it is closely associated with Alzheimer's disease. Hypomorphic fly mutants with RCAN1 overexpression have decreased long-term memory compared to control *D. melanogaster*, which display 40% memory retention 24 h after training. Correspondingly, calcineurin activity is 40% higher in these RCAN1 mutants (Chang et al. 2003). Inside the cell, RCAN1 regulates the number of vesicles undergoing exocytosis and the speed of vesicle fusion, which opens and closes the pore (Keating et al. 2008). These data indicate that RCAN1 is highly associated with neuronal memory and learning and is thus a strong candidate for Alzheimer's disease neuropathology.

Other Unique Functions of RCAN1

Interestingly, female-specific RCAN1 functions have been reported in non-vertebrates, such as *C. elegans* and *D. melanogaster*. In *C. elegans*, the *RCAN1* ortholog (*RCN-1*) is expressed in the vulva epithelial and muscle cells, and overexpression of RCN-1 results in egg retention (Lee et al. 2003). Calcineurin null mutants, which carry a large deletion in the calcineurin B-regulatory subunit gene, have similar defects in fertility and egg-laying. In *D. melanogaster*, the *RCAN1* ortholog (*sarah*) is expressed in the oocytes and nurse cells of normal flies and is critical for ovulation and female courtship behavior. Inhibition of sarah expression decreases the number of eggs laid, and a majority of the eggs arrest at metaphase I of meiosis (Ejima et al. 2004). Moreover, misexpression affects female courtship behavior, and *D. melanogaster* virgin mutant females frequently display extrusion behavior (Ejima et al. 2004). These studies indicate that RCAN1 may exert female-specific effects via regulation of calcineurin signaling.

Summary

RCAN1 plays an important role in the cell by regulating the multifunctional phosphatase calcineurin. RCAN1 function remains an area of ongoing investigation, although a number of reports have identified several RCAN1 molecular mechanisms. However, there is little information regarding the functional difference(s) between the RCAN1 isoforms, which are differentially expressed by various human tissues. Previous reports have indicated that RCAN1-1 L overexpression activates the transcription factor NFAT and promotes pathologic angiogenesis in human endothelial cells, while RCAN1-4 inhibits angiogenesis (Qin et al. 2006). The mechanism for these opposing effects of the two isoforms remains unknown because this data does not agree with the current model of dual RCAN1 function. Moreover, additional analyses of the nonconserved N-terminal are needed. The N-terminus of RCAN1 contains an aggregation-prone domain, and overexpression of RCAN1 results in the formation of aggresome-like aggregates in cultured primary neurons, and the number of synapses is reduced in these neurons (Ma et al. 2004). Therefore, studies of the RCAN1 N-terminus may be informative for neurodegenerative diseases, such as Down syndrome or Alzheimer's disease. In conclusion, RCAN1, which is an endogenous inhibitor of calcineurin, has wide variety of physiological functions; future studies are necessary to identify the molecular mechanisms of RCAN1.

Historical Background: Relaxin Family Peptides and Their Receptors

Relaxin was one of the first reproductive hormones to be identified, following the observation that a factor in the serum of pregnant guinea pigs induced relaxation of the birth canal (Hisaw 1926). Until recently, relaxin was considered purely a hormone of pregnancy and little was known of its potential roles in males and nonpregnant females; the purification of relaxin from animal sources led to the determination of its peptide structure, biological actions, and development of reliable bioassays (Schwabe and McDonald 1977; James et al. 1977; John et al. 1981), and this knowledge precipitated the use of recombinant DNA techniques to clone the rat (Hudson et al. 1981) and pig (Haley et al. 1982) relaxin

genes, followed soon after by human gene-1 (RLN1) (Hudson et al. 1983) and gene-2 relaxin (RLN2) (Hudson et al. 1984). The identification of additional relaxin peptides (including the neuropeptide relaxin-3), in addition to the recent de-orphanization of multiple G protein-coupled receptors (GPCRs) for relaxin, more than 75 years after the identification of the peptide itself, stimulated a resurgence of interest in this pleiotropic hormone.

Relaxin is a two-chain peptide with a high level of structural homology to insulin. This established the structural determinants of the insulin/relaxin peptide family, and precipitated a search for related peptides containing similar structural motifs. Additional mammalian peptides were revealed: insulin-like growth factor (IGF)-I and IGF-II, and the insulin/relaxin-like peptides (INSL) INSL3, INSL4, INSL5 and INSL6.

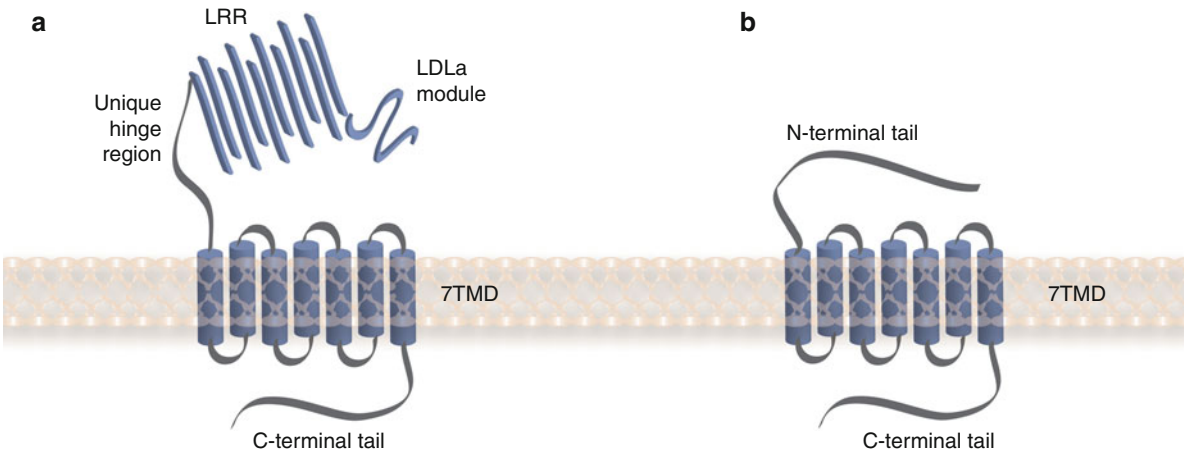
Since the publication of the human genome, many orphan GPCRs including the relaxin family peptide receptors were de-orphanized following sequence-based prediction of a seven transmembrane-spanning domain structure. A search of the human genome for paralogs of the orphan GPCR, leucine-rich repeat-containing GPCR (LGR) 7 (RXFP1), identified an additional orphan GPCR, LGR8 (RXFP2) (Hsu et al. 2002). Based upon the phenotypic similarities of mice lacking either INSL3 or the mouse LGR8 (GREAT) gene, the insulin/relaxin peptides were tested for activity at the two orphan receptors; both LGR7 and LGR8 responded to relaxin with a dose-dependent increase in cAMP production, and the expression patterns of LGR7 were consistent with known relaxin binding sites (Hsu et al. 2000). The de-orphanization of LGR7 led the way for ligand identification for the highly similar orphan GPCR, LGR8; thus INSL3 was identified as the specific peptide ligand that bound LGR8 and stimulated cAMP production (Hsu et al. 2002; Kumagai et al. 2002). In addition, receptor mRNA expression was found in tissues that express INSL3, and humans with a deletion in the LGR8 gene displayed cryptorchidism phenotypically identical to that seen in INSL3-knockout mice. These receptors, and two additional orphan GPCRs, were later renamed ▶ relaxin family peptide receptors (RXFP) 1–4, where RXFP1 is the relaxin receptor, RXFP2 is the receptor for INSL3, RXFP3 is the receptor for relaxin-3, and RXFP4 is the INSL5 receptor (see RXFP3/4 page for further information; reviewed in [Bathgate et al. 2006; Halls et al. 2007; Ivell and Anand-Ivell 2009]).

Molecular Biology of RXFP1 and RXFP2

Human RXFP1 is located on chromosome 4q32.1, and RXFP2 is located on 13q13.1. The receptors share 60% amino acid sequence identity and 80% homology. Both RXFP1 and RXFP2 have multiple alternatively spliced isoforms (reviewed in [Halls et al. 2007]). Thus far, 29 splice variants of RXFP1 and RXFP2 have been identified; four of these variants have been studied in greater detail, and show a wide range of tissue expression, but cannot bind either relaxin or INSL3 or increase cAMP accumulation. Although one isoform was highly expressed (RXFP2.1; deletion of exon 11, corresponding to leucine-rich repeat [LRR] 7), others were expressed either at very low levels (RXFP1.10; deletion of exon 3, flanking the low-density lipoprotein class a [LDLa] module), retained within the cell (RXFP1.2; deletion of exon 12 and 13, corresponding to LRRs 8 and 9), or in the case of one variant (RXFP1.1; stop codon in exon 6, resulting in only the LDLa module and two LRRs), secreted, raising interesting questions regarding their role in endogenous regulation of full-length RXFP1 (reviewed in [Halls et al. 2007]). Another even smaller secreted variant, RXFP1-truncate, has been identified in mouse, rat, and pig (reviewed in [Halls et al. 2007]). RXFP1-truncate consists of the receptor signal peptide, the LDLa module, 33 residues of the LRR flanking sequence, and a nonhomologous sequence of seven residues. When a construct encoding the truncate peptide was transiently expressed in HEK293T cells, RXFP1-truncate was secreted and inhibited relaxin-stimulated cAMP signaling mediated by the full-length receptor, acting as a functional "antagonist" of relaxin. Expression of RXFP1-truncate is increased during pregnancy in both mouse and rat, suggesting a functional role of localized antagonism of relaxin.

Structural Features and Functional Domains of RXFP1 and RXFP2

Although all receptors of the RXFP family are classified as family A GPCRs, similar to the rhodopsin receptor, they can be further subdivided into two distinct subgroups: the LGRs (Fig. 1a), and the small peptide GPCRs (Fig. 1b). Generally, LGRs comprise a LRR domain, a hinge region, seven transmembrane-spanning domains, and a C-terminal tail. The type



Relaxin Family Peptide Receptors (RXFP) 1 and 2, Fig. 1 *Schematic diagram of the structure of relaxin family peptide receptors (RXFP)*. (**a**) The relaxin and INSL3 receptors, (RXFP1 and RXFP2, respectively) are G protein-coupled receptors composed of the seven transmembrane spanning domains (*7TMD*), with a large N-terminal ectodomain consisting of a unique hinge-like region, 10 leucine-rich repeats (*LRR*), and a low-density lipoprotein class A (*LDLa*) module. (**b**) The relaxin-3 and INSL5 receptors (RXFP3 and RXFP4, respectively) are also G protein-coupled receptors that contain the 7TMD but lack the LRR structure found in RXFP1 and RXFP2

C LGRs, RXFP1 and RXFP2, are differentiated from the type A and type B LGRs by the presence of a low-density lipoprotein class A (LDLa) module at the extreme N-terminus, leading into 10 LRRs and a unique hinge region.

While relaxin binds to both RXFP1 and RXFP2, INSL3 is unable to bind RXFP1. Furthermore, rat relaxin is unable to bind RXFP2 suggesting that the relaxin interaction with RXFP2 is a species-specific event (Halls et al. 2005). RXFP1 and RXFP2 form constitutive homodimers (and may form heterodimers); dimerization is dependent upon the transmembrane region, with stabilization provided by the ectodomain (Svendsen et al. 2008a, b). Both receptor homodimers exhibit negative cooperativity in ligand binding (INSL3 at RXFP2; relaxin at RXFP1) (Svendsen et al. 2008a, b). RXFP1 is also glycosylated, and this plays a role in receptor cell surface expression and activation of cAMP (reviewed in [Bathgate et al. 2006; Halls et al. 2007]).

Both RXFP1 and RXFP2 contain two ligand-binding sites: a high-affinity site within the ectodomain, and a lower-affinity site within the transmembrane region (Halls et al. 2005; Sudo et al. 2003). Molecular modeling of the LRR region of RXFP1 has revealed a likely binding cassette for relaxin, which occurs at an angle of 45° across five of the parallel LRRs (Bullesbach and Schwabe 2005). Deletion of any of these residues within the receptor abolished relaxin binding (Bullesbach and Schwabe 2005).

Despite the RXFP2 sequence containing all of the residues required for the binding of relaxin to RXFP1, a number of recent studies have suggested that these amino acids are not essential for INSL3 binding (Bullesbach and Schwabe 2006; Rosengren et al. 2006; Scott et al. 2007). Thus, at RXFP2, relaxin and INSL3 use subtly different B-chain residues and thus bind to different, but overlapping sites of the receptor. Although five of the identified RXFP2 residues that interact with INSL3 are conserved in RXFP1, the only two non-conserved residues interact with the residues within INSL3 (Arg^{B20} and Trp^{B27}) that are critical for peptide binding and activity (Scott et al. 2007), thus providing an explanation for the lack of INSL3 binding at RXFP1.

Mutagenesis studies of the LDLa region highlighted the essential role of this module in receptor signaling. Mutation of conserved residues, those that compromise correct folding, or entire deletion of the LDLa module from either RXFP1 or RXFP2, results in receptors that retain binding of their cognate peptide but are unable to signal by increasing cAMP (Hopkins et al. 2007; Kern et al. 2007). The LDLa module also plays a role in receptor maturation and delivery to the cell surface (Kern et al. 2007).

Signal Transduction Pathways of RXFP1 and RXFP2

Constitutively active mutants of both RXFP1 and RXFP2 (transmembrane helix 6: D637Y) increase cAMP accumulation in a ligand-independent manner (Hsu et al. 2000; Hsu et al. 2002). Consequently, much research has focused on the cAMP accumulation modulated by these two receptors (reviewed by [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008; Du et al. 2010]) (Figs. 2 and 3).

Both RXFP1 and RXFP2 couple to $G\alpha_s$ to increase cAMP, which is negatively modulated by coupling to $G\alpha_{oB}$. Only RXFP1 can also couple to $G\alpha_{i3}$ to activate further cAMP accumulation via a $G\beta\gamma$-phosphatidylinositol 3-kinase (PI3K)-protein kinase C (PKC) ζ pathway to stimulate adenylyl cyclase 5. Activation of the $G\alpha_{i3}$ pathway is dependent upon the final 10 amino acids of the RXFP1 C-terminal tail (requiring Arg^{752}) and localization within lipid-rich membrane domains.

For RXFP1, there is also evidence for activation of other signaling pathways in response to relaxin (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008; Du et al. 2010]). In THP-1 and human endometrial stromal cells, both of which endogenously express RXFP1, there is evidence for tyrosine kinase or mitogen-activated protein kinase (MAPK)-dependent cAMP accumulation, which may involve relaxin-mediated inhibition of a phosphodiesterase. A number of cell types that express RXFP1 rapidly activate extracellular regulated kinase (ERK)1/2 (< 5 min) upon relaxin stimulation, including human endometrial stromal cells, THP-1 cells, and primary cultures of human coronary artery cells, pulmonary artery smooth muscle cells, and renal myofibroblasts. There is also evidence for relaxin-mediated increases in nitric oxide both acutely and chronically, and in renal myofibroblasts, activation of a nitric oxide pathway mediates the effects of relaxin/RXFP1 on differentiation and collagen production. Relaxin has also been reported to interact with the glucocorticoid receptor.

In cell systems that endogenously express RXFP2, the receptor appears to mediate a variety of responses (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008; Ivell and Anand-Ivell 2009]). In gubernacular cells, stimulation with INSL3 causes an increase in cAMP. However, and conversely, in both male and female germ cells, stimulation of RXFP2 causes inhibition of cAMP accumulation mediated by pertussis toxin (PTX)-sensitive G-proteins. Thus, it appears that the signaling outcomes mediated by these receptors may vary greatly depending upon the cell type, and perhaps reflecting differences in the population of G proteins expressed.

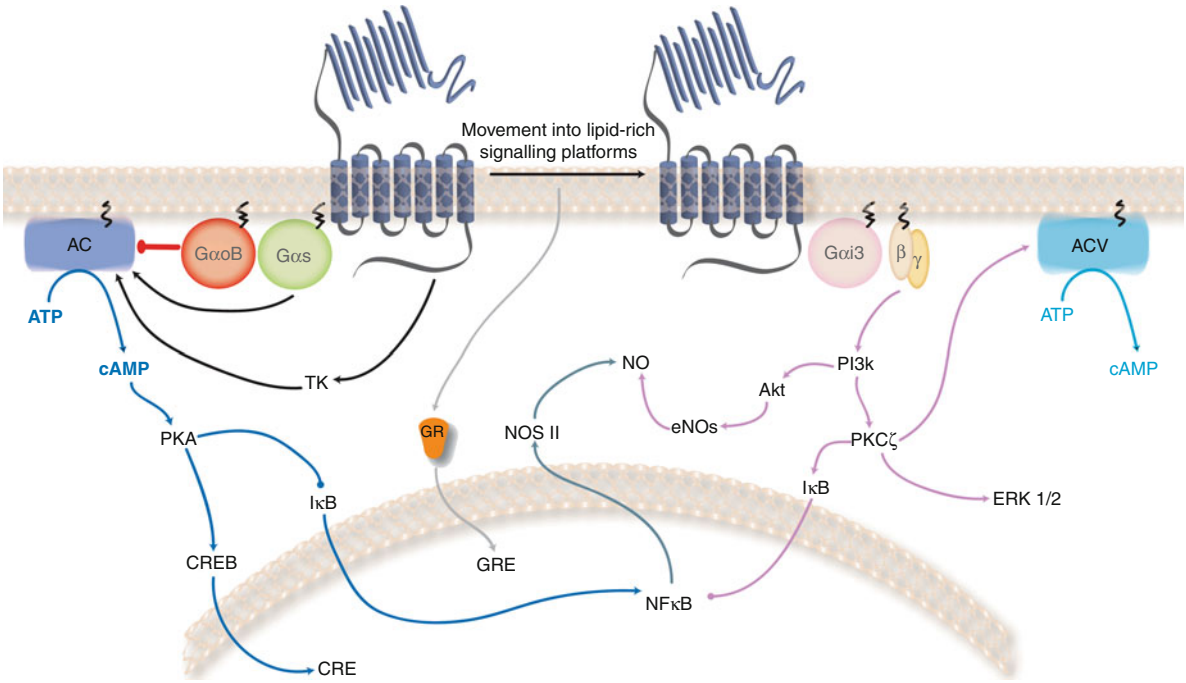
Localization of RXFP1 and RXFP2 Receptors

RXFP1 is present in a variety of tissues (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008]). Northern blots of human tissue identified relaxin receptor mRNA in ovary, uterus, placenta, testis, prostate, brain, kidney, heart, lung, liver, adrenal gland, thyroid gland, salivary glands, muscle, peripheral blood cells, bone marrow, and skin (Table 1). An additional shorter length receptor mRNA was also identified in oviduct, uterus, colon, and brain. Human relaxin receptor protein expression has been identified by immunohistochemical analysis in uterus, cervix, vagina, nipple, and breast (Table 1). Studies using Northern blots of rat tissue have additionally identified receptor mRNA in small intestine and oviduct, and LacZ reporter expression was also identified in oviduct in a relaxin receptor knockout mouse model.

INSL3 receptor mRNA expression in human (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008; Ivell and Anand-Ivell 2009]) occurs in the uterus, testis, brain, pituitary, kidney, thyroid, muscle, peripheral blood cells, and bone marrow as determined by reverse transcriptase-polymerase chain reaction (RT-PCR). Additional expression was identified in the ovary and gubernaculum in the mouse as determined by RT-PCR and specifically in the mesenchymal and cremaster muscle of the gubernaculum using immunohistochemistry, in the rat gubernaculum using RT-PCR and Northern blot analysis, and in the rat ovary using RT-PCR, Northern blot analysis, and in situ hybridization (Table 1).

Physiological Roles of Relaxin/RXFP1 and INSL3/RXFP2

Initially, the principal role of relaxin was thought to involve preparation of the birth canal for parturition, as

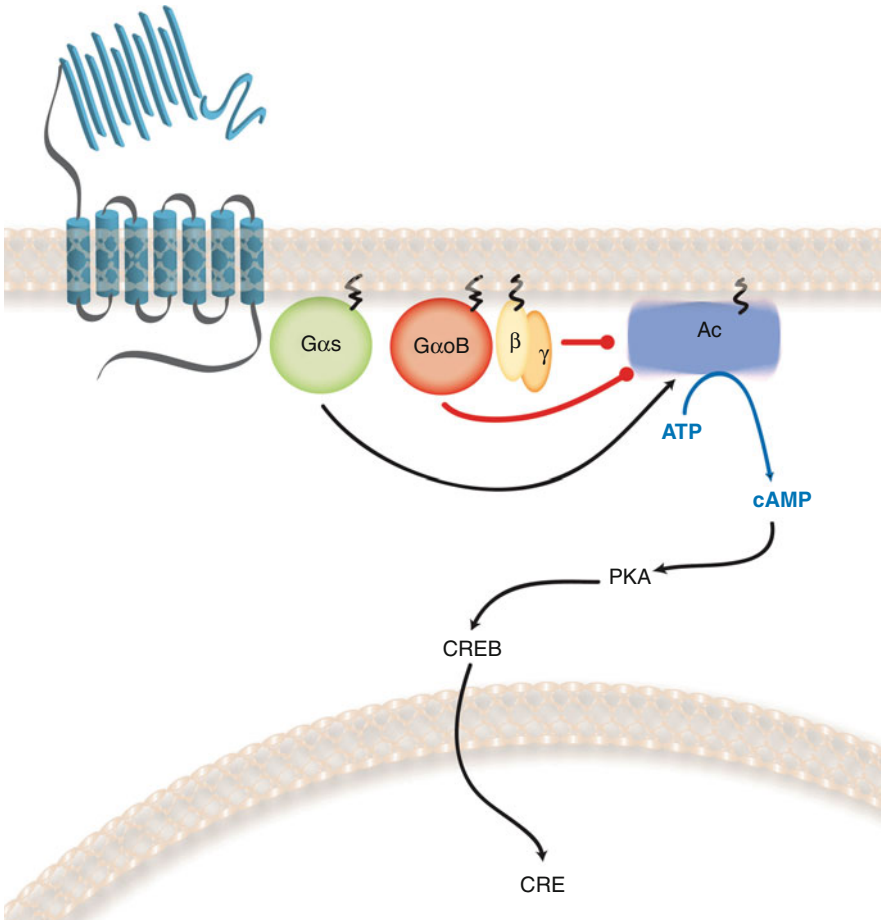


Relaxin Family Peptide Receptors (RXFP) 1 and 2, Fig. 2 *Signaling pathways activated by RXFP1*. Activation of RXFP1 by relaxin promotes receptor coupling to $G\alpha_s$ (to stimulate) and $G\alpha_{oB}$ (to inhibit) cAMP accumulation by modulating adenylyl cyclase (*AC*) activity. The receptor may also increase cAMP accumulation by a tyrosine kinase (*TK*) dependent mechanism. The cAMP downstream of $G\alpha_s$ and $G\alpha_{oB}$ activates protein kinase A (*PKA*) and cAMP response element binding protein (*CREB*) to increase the transcriptional activity of the cAMP response element (*CRE*) transcription factor. PKA may also inhibit inhibitor κB (*IκB*), allowing increased activity of the nuclear factor κB (*NFκB*), and production of nitric oxide (*NO*) via nitric oxide synthase II (*NOSII*). RXFP1 also couples to $G\alpha_{i3}$ (dependent upon lipid-rich microdomains) allowing activation of a Gβγ, phosphoinositide 3-kinase (*PI3K*), protein kinase C (*PKC*)ζ pathway, to increase cAMP via activation of AC5. As a result of $G\alpha_{i3}$ coupling, PI3K activation may also activate an Akt, eNOS pathway to increase NO, and PKCζ may activate extracellular regulated kinase (*ERK*) 1/2, or activate IκB to inhibit the activity of NκB

first described in pregnant guinea pigs (Hisaw 1926). Although this special endocrine function is found in species such as rodents and some mammals, it is now apparent that it is of reduced importance in higher species. Currently it is established that in women, maximum circulating levels of relaxin occur during the first trimester of pregnancy, and thus the role of relaxin in pregnancy is likely to be associated with first trimester physiological events such as embryo implantation. The peptide also causes a number of additional physiological changes associated with pregnancy, including uterine growth and development, myometrial contractility, central control of plasma osmolality, and cardiovascular adaptations (reviewed in [Sherwood 2004]).

Away from the reproductive system, relaxin is postulated to exert a local influence upon the circulation by increasing vasodilation and passive compliance (reviewed in [Du et al. 2010]). Recent observations suggest that relaxin exerts these local effects upon vasodilation through the synthesis and production of nitric oxide, particularly in situations of natural or induced myocardial infarction. Furthermore, recent phase II clinical trials have shown efficacy for relaxin as a vasodilator in acute heart failure.

Another physiological effect of relaxin with therapeutic potential is its effect upon connective tissue regulation and fibrosis. Importantly from a therapeutic viewpoint, relaxin is able to decrease excess collagen deposition in fibrotic lesions, with a conservation of endogenous connective tissue structure. Relaxin also exerts anti-inflammatory effects (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008]), can inhibit the activation of human neutrophils by pro-inflammatory agents and prevents histamine and granule release by activated basophils and mast cells. These studies



Relaxin Family Peptide Receptors (RXFP) 1 and 2, Fig. 3 *Signaling pathways activated by RXFP2*. Activation of RXFP2 by INSL3 or relaxin causes increased cAMP accumulation via $G\alpha_s$-mediated adenylyl cyclase (*AC*) activation. The receptor also couples to $G\alpha_{oB}$, and both $G\alpha$ and $G\beta\gamma$ subunits negatively modulate AC activity. The cAMP pool (downstream of $G\alpha_s$ and $G\alpha_{oB}$) activates protein kinase A (*PKA*) and cAMP-response element binding protein (*CREB*) to modulate the transcriptional activity of the cAMP response element (*CRE*)

indicate a protective effect of relaxin during allergic inflammatory responses. In rodent models of angiogenesis and wound healing, relaxin treatment resulted in increased vascularization and neoangiogenesis of ischemic wound sites. There was no effect of relaxin upon cytokine expression in cells taken from non-wound sites, indicating promising specificity for therapeutic applications.

In a manner that mirrors its effects in fibrosis, evidence suggests that relaxin is recruited as an endogenous factor for tissue remodeling in cancer cells (reviewed in [Klonisch et al. 2007]). Increased expression of relaxin (but not RXFP1) has been detected in both tissue from prostate carcinoma and prostate cancer cell lines. Interestingly, downregulation of either relaxin or RXFP1 caused significant inhibition of growth and invasiveness, in addition to increased apoptosis. A human prostate cancer cell line engineered to express relaxin exhibited increased tumor volume and vascularization compared to controls. Relaxin is associated with increased invasiveness of endometrial, breast, and thyroid carcinomas. Serum relaxin concentrations are also elevated in patients with bone metastasis, and relaxin is a potent stimulator of osteoclastogenesis (Ferlin et al. 2010).

The major physiological effects of INSL3 are observed within the reproductive system (reviewed in [Bathgate et al. 2006; Halls et al. 2007; van der Westhuizen et al. 2008; Ivell and Anand-Ivell 2009]). Lack of INSL3 (or alternatively, lack of RXFP2) in mice results in cryptorchidism, or failure of the testes to descend during development. Female INSL3-knockout mice exhibit only a mild phenotype of disturbed cycle length and increased ovarian apoptosis, whereas overexpression of the peptide leads to ovarian descent and bilateral inguinal hernia. The influence of the peptide extends beyond early development, as INSL3 serum levels increase with the onset of puberty in males, and

are dependent upon the level of luteinizing hormone stimulation of Leydig cells. Luteinizing hormone also stimulates expression of INSL3 in ovarian theca and testicular Leydig cells, which through activation of the INSL3 receptor, causes meiotic progression of arrested oocytes in preovulatory follicles, and suppresses male germ cell apoptosis. Interestingly, in a manner similar to relaxin, the INSL3/RXFP2 system has also been

identified in human prostate carcinoma cell lines and human thyroid carcinomas, and treatment of the tumor cell lines with INSL3 resulted in increased tumor cell motility. INSL3 and RXFP2 may also have a role in osteoporosis.

Summary

RXFP1 is coupled to cAMP and many other signaling pathways in different cell types. Linking these effectors of RXFP1 activation to specific physiological end points should allow the design and development of targeted therapies. RXFP1 has therapeutic potential for treatment of fibrosis, cancer metastasis, and is currently in Phase III clinical trials for heart failure. Although not as extensively studied, RXFP2 appears to have a simpler physiological role, and fewer downstream effectors compared to RXFP1. RXFP2 has possible therapeutic potential for the treatment of some types of cryptorchidism and could be used to control fertility; however, more extensive research is required to assess its true therapeutic potential.

Historical Background: Relaxin Family Peptides and Their Receptors

Relaxin family peptides including the relaxins 1–3, insulin-like peptides (INSL) 3–6, and insulin-like growth factors I and II have a similar architecture to insulin. These peptides are generally involved in the regulation of cell growth and metabolism. Relaxin was originally identified as a hormone important during pregnancy but is also now known to have roles in collagen remodeling, wound healing, cardiovascular responses, and as a brain neuropeptide. In the human, three independent genes produce three relaxin peptides, named relaxin-1, relaxin, and the recently discovered relaxin-3 (Bathgate et al. 2002). Relaxin-3 is primarily expressed in the brain as a neuropeptide that mediates stress and feeding responses in rats (Tanaka et al. 2005; McGowan et al. 2005, 2007). Relaxin-3 peptide sequences from different species are well conserved (Bathgate et al. 2002; Wilkinson et al. 2005) and the degree of sequence identity between the relaxin-3 peptides suggests that it is the ancestral relaxin peptide from which the other relaxin and insulin-like peptides evolved (Wilkinson et al. 2005).

The receptors for the relaxin family peptides are G protein-coupled receptors (GPCRs), named relaxin family peptide receptors (RXFP) 1–4, where RXFP1 is the relaxin receptor, RXFP2 is the INSL3 receptor, RXFP3 is the relaxin-3 receptor, and RXFP4 is the INSL5 receptor. RXFP3 was discovered by probing a human cortical cDNA library (Matsumoto et al. 2000). Although it has high amino acid sequence similarity to the somatostatin and the angiotensin II receptors, it was not activated by these ligands, and therefore it was initially named somatostatin and angiotensin-like peptide receptor (SALPR). The ligand for RXFP3 was later discovered by using the receptor as bait to fish for peptides in extracts derived from various rat tissues (Liu et al. 2003b). Only the brain extracts increased GTPγS binding (Liu et al. 2003b), and purification led to the identification of relaxin-3 (Liu et al. 2003b). RXFP4 was subsequently identified by searching the human genome database (Genbank™) with the RXFP3 sequence (Liu et al. 2003a). Since RXFP4 had 43% amino acid sequence identity with RXFP3 it was hypothesized that these receptors may share or have similar ligands (Liu et al. 2003a). Relaxin-3 was also found to activate RXFP4 (Liu et al. 2003a); however, RXFP4 was later identified as the receptor for INSL5 (Liu et al. 2005).

Molecular Biology of RXFP3 and RXFP4

Human RXFP3 is located on chromosome 5p15.1-5p14 (Matsumoto et al. 2000) and human RXFP4 is located on chromosome 1q22, and both receptors are coded by a single exon sequence. In the

rat RXFP3 gene, there are two potential start codons (ATG) that are not seen in the human or the mouse genes (Wilkinson et al. 2005). Transcription initiating from the first potential start codon produces rat RXFP3-long, with seven additional residues at the amino terminus. Transcription initiation from the second potential start codon produces rat RXFP3-short, which is equivalent to the human and mouse RXFP3 sequences. The mouse RXFP4 sequence has 74% homology with the human RXFP4 sequence, however, the gene equivalent to RXFP4 in the rat is a pseudogene that does not code a functional protein (Chen et al. 2005), suggesting the INSL5-RXFP4 system is redundant in rats.

Structural Features and Functional Domains of RXFP3 and RXFP4 Receptors

The relaxin family peptide receptors (RXFPs) belong to two distinct subclasses of family A GPCRs, the leucine-rich repeat-containing GPCRs (LGRs) and the small peptide receptor-like GPCRs (RXFP3 and RXFP4) (Fig. 1). RXFP3 and RXFP4 consist of seven transmembrane spanning domains (7TMDs), an extracellular amino-terminal tail, and an intracellular carboxy-terminal tail.

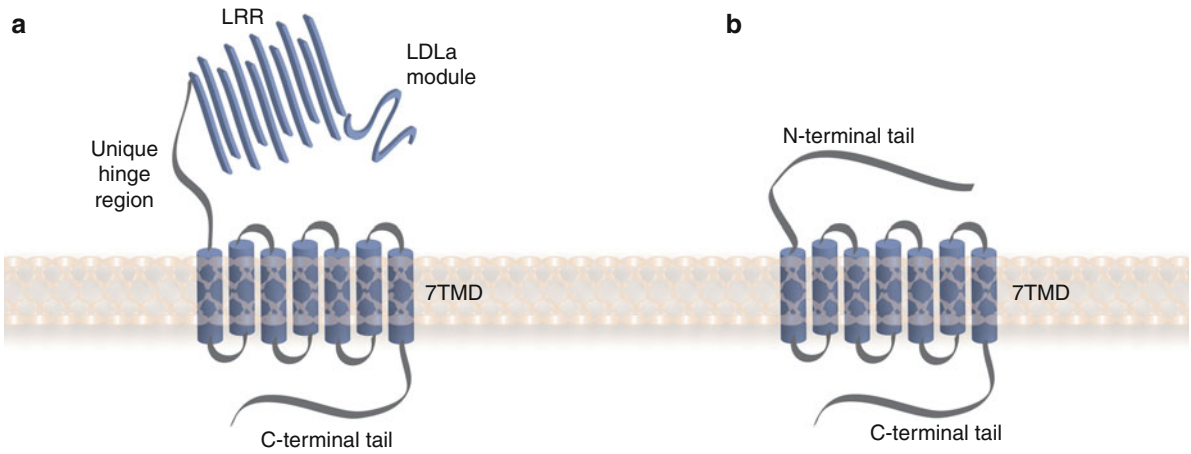
Receptor chimeras between RXFP3 and RXFP4 identified the amino-terminal tail and extracellular loop 2 as important regions of the receptors for binding to relaxin-3 or INSL5, respectively (Zhu et al. 2008). These regions are also important for the activation of RXFP3 by relaxin-3 (Zhu et al. 2008); however, transmembrane helicies 2, 3, 5 and extracellular loop 2 are important for activation of RXFP4 by INSL5 (Zhu et al. 2008).

Human relaxin-3 has a similar affinity for mouse, rat, and human RXFP3 receptors, likewise, mouse/rat relaxin-3 have similar affinities for human, mouse, and rat RXFP3 (Chen et al. 2005). The potency of human, mouse, and rat relaxin-3 at human, mouse, and rat RXFP3 is similar in cAMP, GTPγS binding, and calcium assays (Chen et al. 2005), suggesting the minor variations in the ligand and receptor amino acid sequences do not affect the function of the receptor. The dog and rat INSL5 DNA sequences contain a frameshift mutation, resulting in multiple stop codons within the exonic sequence; therefore, INSL5 is considered to be a nonfunctional pseudogene in both the dog and the rat (Wilkinson et al. 2005). The INSL5 gene is functional in mice; however, mouse INSL5 is not expressed in the brain. Since the expression pattern of RXFP4 and INSL5 overlap and are pseudogenes in the dog and rat this suggests they are a ligand–receptor pair (Liu et al. 2005); however, the roles of both INSL5 and RXFP4 remain to be determined.

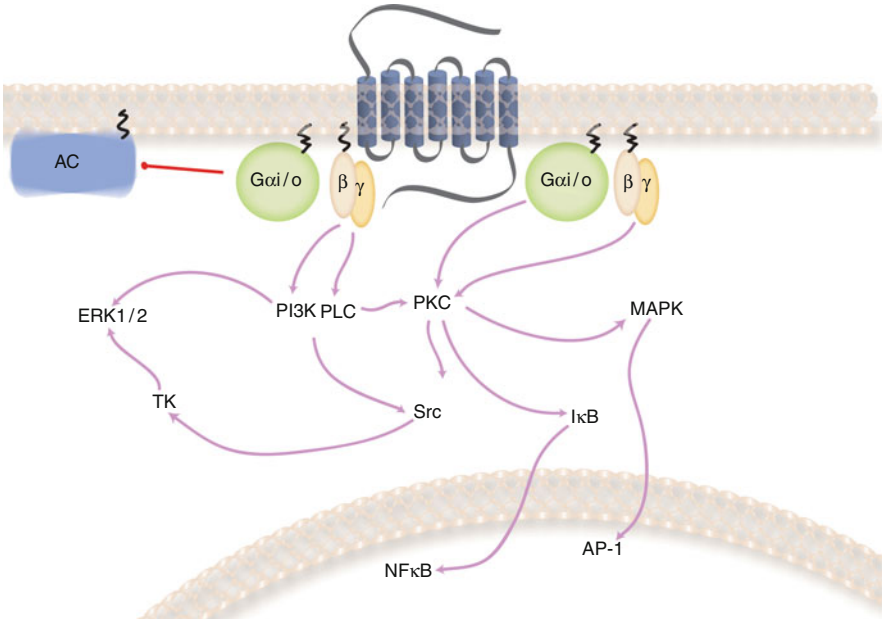
Signal Transduction Pathways of RXFP3 and RXFP4

Relaxin-3 interacts with both RXFP3 and RXFP4 to increase GTPγS binding, suggesting that it initiates G protein-mediated signaling events in cells that express the receptors (Liu et al. 2003a,b). Unlike RXFP1 and RXFP2 that increase cAMP in cells when treated with relaxin or INSL3, respectively, none of the relaxin family peptides tested increased cAMP levels in cells expressing RXFP3 or RXFP4 (Liu et al. 2003a, b, 2005; van der Westhuizen et al. 2010). In fact, relaxin-3 inhibited forskolin-stimulated cAMP accumulation in RXFP3-expressing cell lines in a concentration-dependent manner (Liu et al. 2003b; van der Westhuizen et al. 2010) (Fig. 2). Weaker inhibition of forskolin-stimulated cAMP accumulation occurs in CHO-K1, HEK293, or SN56 cells expressing RXFP3 receptors when treated with the B-chain of relaxin-3 (Liu et al. 2003b), or with human relaxin or porcine relaxin (van der Westhuizen et al. 2010). INSL5 also inhibits forskolin-stimulated cAMP accumulation in cells expressing RXFP4 but not in cells expressing RXFP3 (Liu et al. 2005).

In addition to inhibition of the cAMP signaling pathway, RXFP3 also activates ERK1/2 when stimulated with relaxin-3, the B-chain of relaxin-3 or relaxin. ERK1/2 activation involves Gαi/o proteins and either a PI 3-kinase or PKC-dependent pathway (van der Westhuizen et al. 2007; 2010) (Fig. 2). Increased transcription of AP-1 reporter genes is also observed in RXFP3-expressing cells following stimulation with relaxin-3, human relaxin, or porcine relaxin in a cell-type and peptide-dependent manner, potentially through activation of ERK1/2, ERK5, p38 MAPK, or JNK (van der Westhuizen et al. 2010) (Fig. 2). Increased transcription of NF-κB reporter genes was also observed in RXFP3-expressing cells following stimulation with relaxin-3 but not with



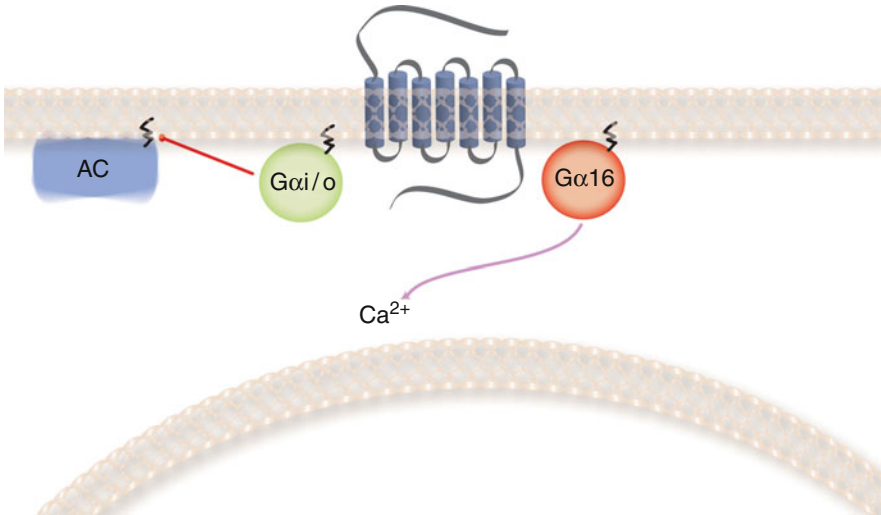
Relaxin Family Peptide Receptors (RXFP) 3 and 4, Fig. 1 Schematic diagram of the structure of relaxin family peptide receptors (RXFPs). (**a**) The relaxin and INSL3 receptors, (RXFP1 and RXFP2, respectively) are G protein-coupled receptors composed of the seven transmembrane spanning domains (7TMDs), with a large N-terminal ectodomain consisting of a unique hinge-like region, 10 leucine-rich repeats (LRRs) and a low-density lipoprotein class A (LDLa) module. (**b**) The relaxin-3 and INSL5 receptors (RXFP3 and RXFP4, respectively) are also G protein-coupled receptors that contain the 7TMDs but lack the LRR structure found in RXFP1 and RXFP2



Relaxin Family Peptide Receptors (RXFP) 3 and 4, Fig. 2 Signaling pathways activated downstream of RXFP3. RXFP3 inhibits cAMP production via inhibitory G proteins (Gαi/o) and activates extracellular signal-regulated kinase (ERK) 1/2 via Gαi/o proteins and either a phosphatidylinositol 3-kinase (PI3K) or protein kinase C (PKC)-dependent pathway. RXFP3 is coupled to increased gene transcription from nuclear factor (NF)-κB and activator protein (AP)-1 transcription factors. MAPK indicates either ERK, p38 MAPK, or JNK, and TK indicates receptor tyrosine kinase

human relaxin, porcine relaxin, or human INSL3 (van der Westhuizen et al. 2010). Thus, RXFP3 couples to at least four different signaling pathways to elicit responses in cells; ligand-biased signaling is also observed at this receptor, with some pathways activated exclusively by relaxin-3, while others are activated by relaxin-3, human relaxin, porcine relaxin, and human INSL3 (van der Westhuizen et al. 2010).

RXFP4 is potentially coupled to the calcium signaling pathway as INSL5 or relaxin-3 stimulation of CHO-K1 cells co-transfected with RXFP4 and



Relaxin Family Peptide Receptors (RXFP) 3 and 4, Fig. 3 Signaling pathways activated downstream of RXFP4. RXFP4 inhibits cAMP production via inhibitory G proteins (Gαi/o) and releases calcium via Gα16 proteins

Gα16 increased intracellular calcium, suggesting that RXFP4 couples to Gα16 signaling pathways in cell lines that express this G protein (Liu et al. 2003a, 2005) (Fig. 3). RXFP3 on the other hand, does not activate calcium signaling (Liu et al. 2003b).

Localization of RXFP3 and RXFP4

RT-PCR and in situ hybridization studies showed that RXFP3 is principally expressed in the rat brain (Table 1), with strongest expression in the hypothalamus, paraventricular nucleus, cortex, septal nucleus, preoptic area, supraoptic nucleus, periaqueductal gray, nucleus insertus, and central gray regions in the brainstem (Sutton et al. 2004; Ma et al. 2007). The mouse ortholog of RXFP3 is also expressed in the brain, as shown by Northern blots (Boels et al. 2004; Sutton et al. 2005; Lein et al. 2007). In the periphery, however, RXFP3 mRNA was only detected in the testis (Liu et al. 2003b). Direct radioligand binding studies have also mapped RXFP3 binding sites in the rat brain (Table 1) (Sutton et al. 2004; Ma et al. 2007) (RXFP4 is a pseudogene in the rat, therefore not expressed). This study used an INSL5 A-chain/relaxin-3 B-chain chimeric peptide (that does not bind to RXFP1 or RXFP2) to identify RXFP3 binding sites in many regions involved in sensory perception. The INSL5/relaxin-3 chimera binding sites may have terminating projections from rat relaxin-3-containing neurons, suggesting that relaxin-3 produced locally by the brain, acts at regions where RXFP3 is expressed (Sutton et al. 2004; Ma et al. 2007).

RT-PCR demonstrated RXFP4 expression in human colon, thyroid, salivary gland, prostate, placenta, thymus, testis, kidney, uterus, and brain (Table 1) (Conklin et al. 1999; Liu et al. 2003a; Boels and Schaller 2003). In situ hybridization did not show INSL5 or RXFP4 mRNA expression in the mouse brain and mouse INSL5 did not displace [^{125}I]-INSL5/relaxin-3 binding, suggesting that there were very few if any RXFP4 sites in the mouse brain (Sutton et al. 2005). RXFP4 mRNA is expressed in the human colon, thyroid, salivary gland, prostate, placenta, thymus, testis, kidney, and brain (Table 1) (Liu et al. 2003a; Boels and Schaller 2003).

Physiological Roles of Relaxin-3

The strongest expression of relaxin-3 mRNA occurs in the nucleus incertus (Sutton et al. 2004). In neurons, relaxin-3 is found in vesicles, suggesting that it is a neurotransmitter released from activated neurons (Tanaka et al. 2005). Based on the location of the projections of relaxin-3-containing neurons, the peptide is potentially important in motivational and emotional behaviors, and may have a role in motor function, sensory perception, processing sensory

information and in learning and memory (Sutton et al. 2004; Tanaka et al. 2005). However, whether these physiological roles are dependent upon the RXFP3 receptors around the terminal regions of the relaxin-3-containing neurons remains to be determined. Injection of relaxin-3 into rat brain cerebral ventricles, the paraventricular nucleus, supraoptic nucleus, arcuate nucleus, or the anterior preoptic area increased food intake in rats (McGowan et al. 2005, 2007), possibly by acting at RXFP3 receptors in these areas.

Summary

RXFP3 activates many signaling pathways in various cell lines and exhibits different but overlapping signaling profiles dependent upon the activating ligand. On stimulation with relaxin family peptides, RXFP3 inhibits cAMP production and activates MAP kinase signaling pathways. RXFP3 also increases gene transcription from AP-1 and NF-κB promoters, which may be important in regulating feeding and stress responses mediated by relaxin-3 in rats. Linking these signaling pathways to pathophysiology should encourage the design and development of antianxiety and antiobesity therapies that specifically target particular RXFP3 signaling pathways. Extensive study of RXFP4 is required to determine its physiological role, its importance in pathophysiology, and to assess its potential as a drug target.

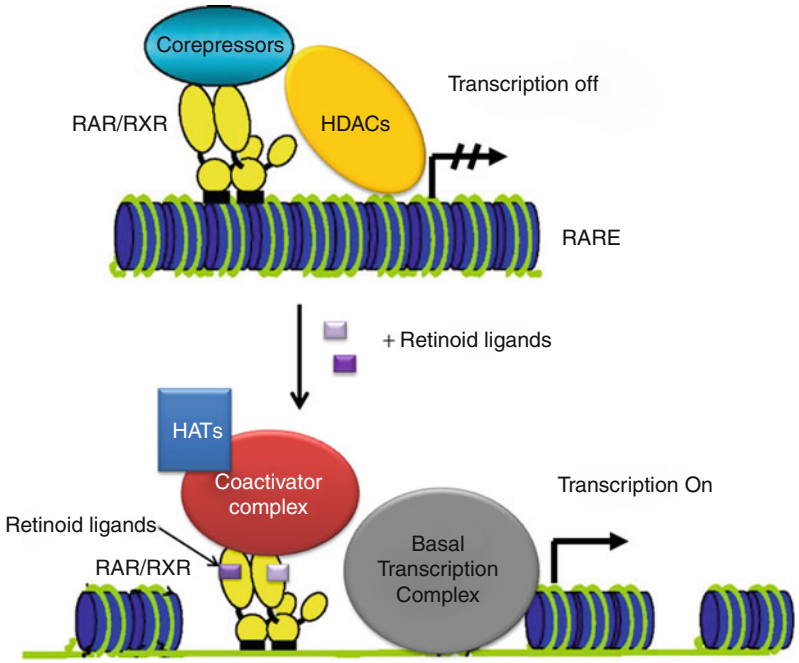
NR1B1; NR1B2; NR1B3; RARα; RARβ; RARγ

Historical Background

The retinoic acid receptors (RARs) are ligand-dependent transcription factors that belong to the NR1B subtype of the nuclear receptor (NRs) superfamily and have broad roles in development, cell growth and survival, vision, spermatogenesis, inflammation, and neural patterning. These receptors act in *trans* mainly as heterodimers with retinoid X receptors (RXRs). The actions of RARs are stimulated by the binding of cognate natural ligands (all *trans* retinoic acid and 9-*cis* retinoic acid) as well as a number of synthetic ligands. In the presence or absence of ligand, RAR/RXR heterodimers associate with retinoic acid DNA response elements (RAREs) present in the promoter or enhancer regions of target genes. When no ligand is present, corepressor proteins and histone deacetylases interact with the receptor DNA complexes and prevent transcription from occurring. When retinoid ligands are present, they bind and activate the RARs by initiating a conformation more favorable to the association of coactivator proteins and subsequent recruitment of histone acetyltransferases (HATs) and the components of the basal transcriptional machinery that initiate transcription of the RARE (Fig. 1). These consensus site DNA sequences generally consist of two directly repeated half sites of AGGTCA separated by two or five base pair spacers (DR2 or DR5 elements). Due to



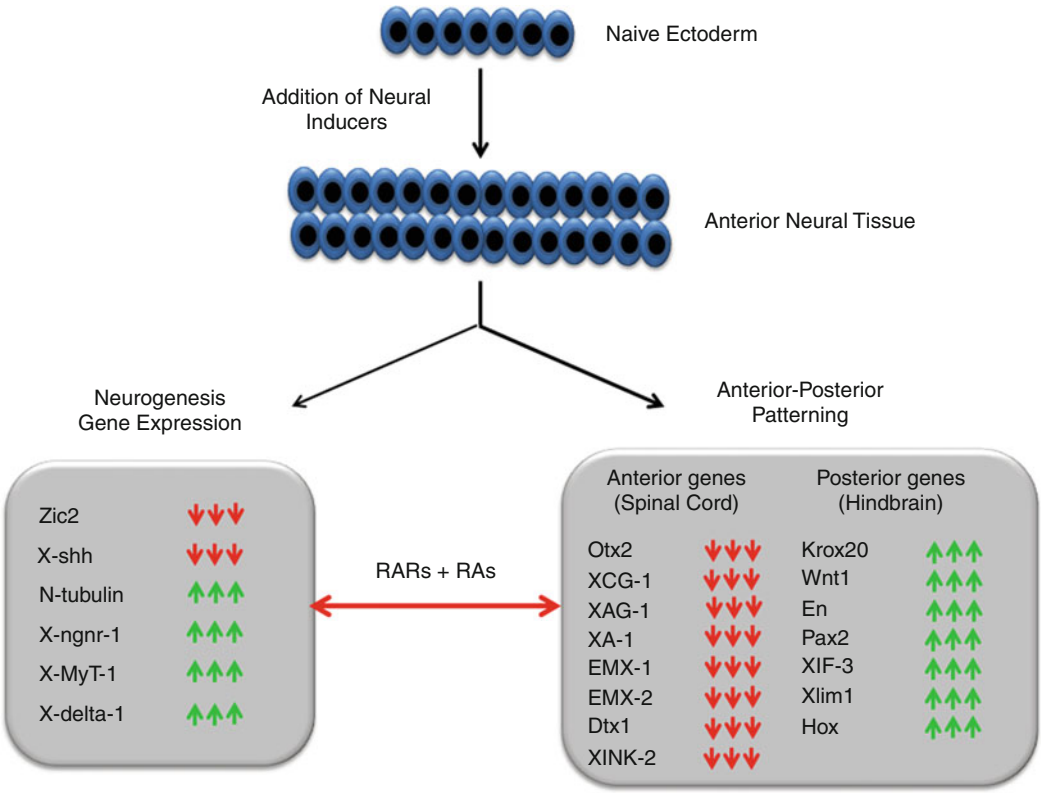
Retinoic Acid Receptors (RARA, RARB, and RARC), Fig. 1 Activation model of RARs. In the presence or absence of ligand, RAR/RXR heterodimers associate with retinoic acid response elements (RAREs) present in the promoter or enhancer regions of target genes. When no ligand is present, corepressor proteins and histone deacetylases interact with the receptor DNA complexes and prevent transcription from occurring. When retinoid ligands are present, they bind and activate the RARs by initiating a conformation more favorable to the association of coactivator proteins and subsequent recruitment of histone acetyltransferases (HATs) and the components of the basal transcriptional machinery to initiate transcription

their broad action in diverse cell and tissue populations, RARs are essential signaling proteins for basic and clinical research.

Role of RARs in Embryonic Development

Research from the 1950s implicated vitamin A deficiencies as a cause for a number of congenital malformations and defects observed in the development of animals. These results were known long before the discovery of retinoic acids as the most biologically active forms of vitamin A. Later research then investigated the role of retinoic acid in early embryonic development and in the early 1990s led to the discovery of the retinoic acid receptors (RARs). Since then much work has been done to determine the role that RARs play in embryonic development.

Genetic studies were conducted in the early 1990s to investigate the role of all three RAR isoforms in embryonic development by generating single and double RAR mutant mice. While mice with a mutation deleting only one RAR isoform contained certain developmental abnormalities, they were still viable, indicating a certain redundancy among isoforms (Mark et al. 2009). However, RAR double null mutants, containing genetic deletions of any two of the RAR isoforms, died in utero or at birth due to severe developmental deficits mainly in the vertebrae, brain, and limbs indicating the importance of the expression of the RARs on the formation of these structures. The same deficits were observed by a number of investigators where various components of retinoic acid signaling were knocked out such as retinaldehyde-synthesizing enzyme RDH10 (Sandell et al. 2007), RA-synthesizing enzyme RALDH2 (Halilagic et al. 2007), or RALDH3 (Dupe et al. 2003). In addition, treatment of wild-type animals with synthetic pan-specific RAR antagonists also produced the same defects (Kochhar et al. 1998; Wendling et al. 2001). This demonstrated that not only expression of RARs was essential for normal development



Retinoic Acid Receptors (RARA, RARB, and RARC), Fig. 2 RAR-mediated RA signaling mediates neurogenesis and anterior-posterior patterning of central nervous system. Diagram showing RAR-mediated up- and downregulation of genes involved in both neurogenesis and anterior-posterior which are vital in the development of neurons, spinal cord, and hindbrain

but that the receptors required activation by retinoic acid ligands to mediate their important roles in developmental signaling programs.

Using combined strategies of selective RAR isoform knockouts and mutations in the RA signaling pathways, much has been learned about the crucial roles that RARs play in specific stages of organ and brain development. For instance, RARs are involved in formation of a number of limb structures and control the antero-posterior axis of the limbs (Dupe et al. 1999). Moreover, RAR-mediated RA signaling is responsible for both neurogenesis as well as the anterior-posterior patterning of the developing central nervous system through a complex mechanism of gene activation and repression by RARs (Maden 2002) (Fig. 2). Several studies have shown that RARs are required for the formation of a number of eye structures as well as histogenesis and physiological apoptosis in the retina. Moreover, it has been discovered that RARs play important roles in cardiac development, respiratory system development, as well as the formation of important structures in the kidneys and urogenital tract.

While much has been learned about the important roles played by the RARs in embryonic development, research is now shifting toward elucidating the roles played by these receptors during the postnatal development. To do this, new strategies have emerged to allow for the selective mutation of the retinoid receptors in specific cell types so as to further understand the functions of these receptors in the postnatal animal as it develops and grows (Metzger and Chambon 2001; Metzger et al. 2003).

Role of RARs in Regulating Cell Proliferation and Cancer

In addition to the effects that retinoic acids and the RARs have on developmental pathways, a large

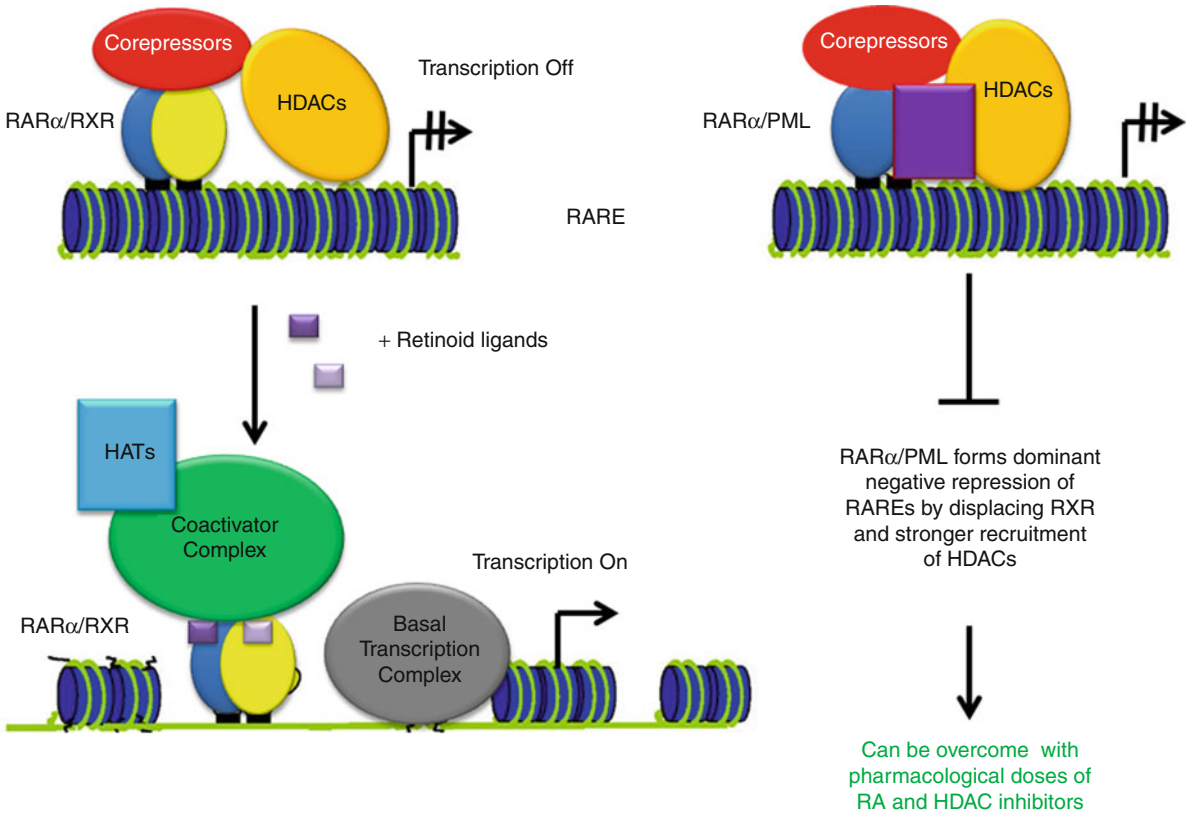
amount of evidence has emerged implicating RARs in the control of cell-cycle pathways and cellular proliferation. In normal cells, retinoic acids generally inhibit cell-cycle progression by instituting a block in the G1 phase of the cell cycle (Mongan and Gudas 2007). Of all the RAR isoforms, these effects are mostly mediated by RARβ_2 following binding and activation by retinoic acids (Faria et al. 1999). Several studies have shown in a number of cell types that activation of RARβ_2 leads to the transactivation of several genes involved in cell-cycle arrest such as $p21^{CIP1}$ and $p27^{KIP1}$ (Li et al. 2004; Suzui et al. 2004). In addition to activating cell-cycle arrest proteins, RARs also mediate both the downregulation of mRNA expression as well as protein ubiquitination and degradation for both the Cyclin D and E families which prevents progression of the cell cycle from the G1 to S phase (Tang and Gudas 2011). Moreover, RARs induce apoptosis following binding of retinoids in a number of cell types as a guard against tumor formation. Retinoic acid binds to RARα and induces apoptosis in both acute lymphoblastic leukemia cells as well as myeloid leukemia cell lines (Chikamori et al. 2006; Luo et al. 2009). In addition, it has been reported that RARγ induces apoptosis upon binding to retinoids in both skin keratinocytes as well as pancreatic adenocarcinoma cells (Hatoum et al. 2001; Pettersson et al. 2002). Finally, RARβ_2 has been implicated in the induction of apoptosis in breast cells. Taken together, these observations have provided clear evidence that RARs play key roles in the regulation of cell-cycle progression and cell growth as well as apoptosis and therefore when RAR-mediated signaling pathways are disturbed, there can be major implications for the development and progression of cancer.

One of the most well-studied examples of aberrant RAR signaling leading to cancer is acute promyelocytic leukemia (APL). It has been shown in a number of reports that APL is the result of a genetic rearrangement of the RARα gene that fuses it to the promyelocytic leukemia gene (PML) or other PML-related genes (Tang and Gudas 2011). These PML/RARα fusion proteins lead to dramatic increases in expression of both HDACs and DNA methyltransferases that cause reductions in gene expression for retinoid-regulated genes such as those involved in differentiation (Fig. 3). As previously stated, under normal conditions retinoid-regulated genes regulate cellular proliferation mainly through inhibiting cell-cycle progression and promoting cellular differentiation. When the expression of these genes is reduced, the regulatory controls on these functions are lost resulting in uncontrolled proliferation. In addition to inducing epigenetic silencing, the PML/RARα fusion protein can also repress important RAR target genes such as RARβ_2 itself by binding the RAR response element (RARE) on the RARβ_2 promoter and recruiting corepressors such as NuRD that keep RARβ_2 from being expressed.

The loss of retinoic acid signaling is not restricted to APL and in fact reduction in expression of both RARα and RARβ_2 has been shown to occur in several types of cancer such as embryonal carcinomas, acute myeloid leukemia, and breast cancer (Mongan and Gudas 2007; Altucci et al. 2007). In contrast to APL where RARα is mutated into the PML/RARα fusion protein, most cancer cell types do not contain mutated RARs but rather have dramatically downregulated expression of these receptors. Understanding the underlying mechanisms behind the silencing of RARs in cancer cells has been a major focus of recent research and several mechanisms have been uncovered. For example, it was reported that the RARβ_2 promoter in many cancer cell types is silenced by hypermethylation at CpG regions of its promoter. In addition, corepressors such as PRAEME, meningioma 1, acinus-S', HACE1, and SMRT have all been shown to inhibit expression of either RARβ_2 or RAR response genes either due to overexpression of these corepressors or a greater affinity for the RARβ_2 response elements concomitant to changes caused by aberrant AKT signaling in a variety of cancer cell types (Tang and Gudas 2011). In contrast, repression of RAR coactivator expression has also been observed to downregulate expression of RARs in neuroblastoma cells. Taken together, these reports indicate that a multitude of mechanisms are at work in various cancer cell types that all result in the repression of RARs and their downstream target genes. Regardless of mechanism, the end result is an absence of RAR-mediated balances between differentiation and proliferation and demonstrates the vital roles RARs play in the progression of cancer.

Development of RAR Ligands for Use as Therapeutics

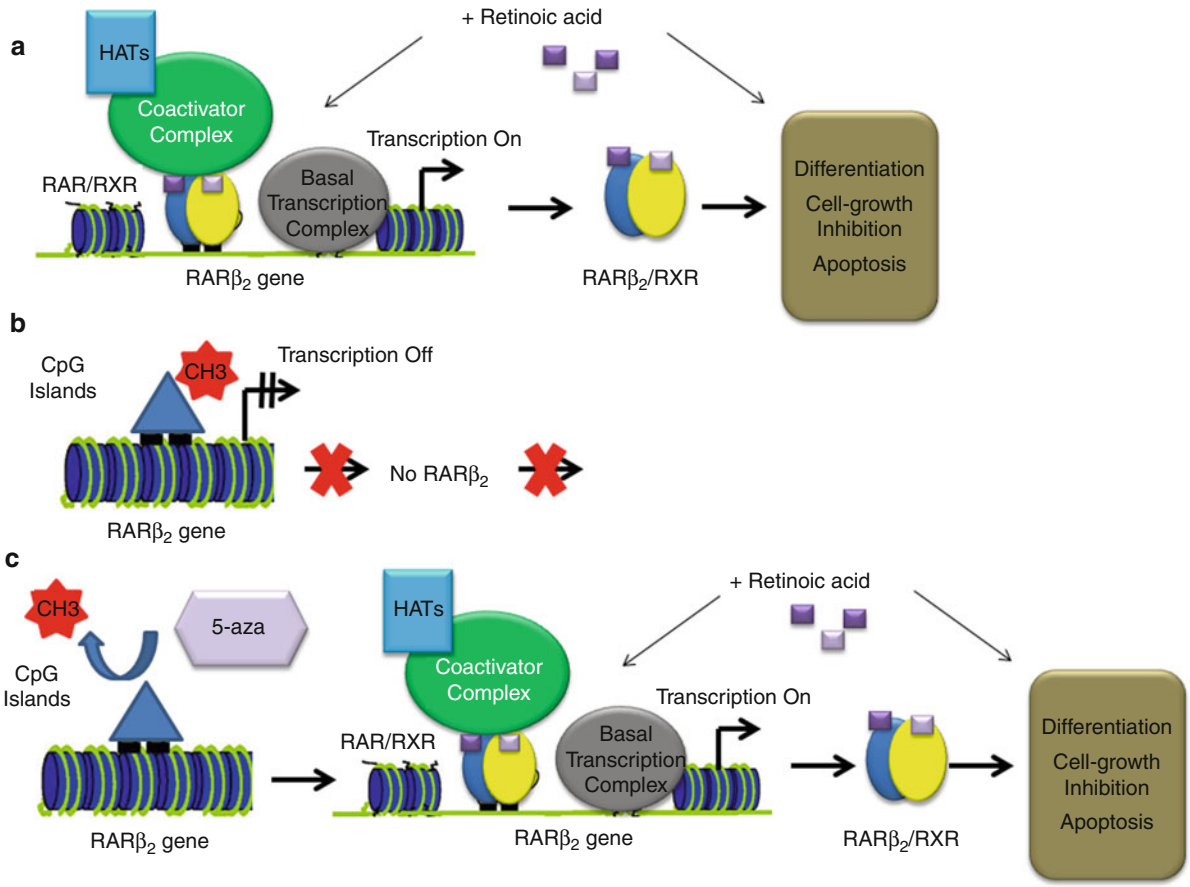
Given the correlation between the reduction in RAR-mediated retinoic acid signaling and the progression of



Retinoic Acid Receptors (RARA, RARB, and RARC), Fig. 3 Model of aberrant repression of RAR gene activation by the PML/RARα fusion protein. Schematic comparing the ligand-dependent activation of RAR response genes in normal tissues expressing the wild-type RARα/RXRα heterodimer compared to the APL model where that is replaced by the PML/RARα fusion protein. The PML/RARα fusion protein forms a dominant negative repressive complex onto the RAREs due to the lack of RXRα and the enhanced recruitment of HDACs to the PML portion of the fusion protein. Reversing this phenomonon requires HDAC inhibitors or excess amounts of retinoic acids

a number of cancers, therapies have been developed to treat cancer patients with natural retinoids such as all-trans retinoic acid (ATRA) to induce differentiation and cell growth arrest. This strategy has been extremely successful in the treatment of APL as pharmacological doses of retinoic acid stimulate irreversible differentiation of leukemic cells into granulocytes. Moreover, it has been reported that pharmacological doses of retinoic acid also trigger growth arrest and differentiation of leukemia stem cells known as leukemia-inducing cells (LICs) (Tang and Gudas 2011). When combined with other apoptosis-inducing chemotherapeutic drugs such as anthracyclins, retinoic acid treatment reverses gene silencing and leads to induced cell death of the cancer cells curing 70–80% of APL patients (Altucci et al. 2007). This treatment is successful since the expression of the PML/RXRα fusion protein is high and the RARα portion of this protein contains a functioning ligand-binding domain and coactivator recruitment site that allows for the retinoic acid-mediated activation of a number of RARα genes that stimulate differentiation.

Differentiation therapy involving treatment with natural retinoids has been developed for many cancers such as breast, ovarian, renal, head and neck, melanoma, and prostate. However, the success of this approach has been much less successful in these other types of cancers where the expression of RAR genes themselves are downregulated by events such as DNA methylation of their promoters as previously discussed. Combination therapies have been adopted with some success to overcome these limitations with the coadministration of HDAC inhibitors and DNMTase inhibitors in addition to retinoic acid



Retinoic Acid Receptors (RARA, RARB, and RARC), Fig. 4 Schematic model of the benefit of combination therapy to reverse the repression of RARβ$_2$ expression in various cancers. (**a**) Normal tissue where RAR/RXRs regulate expression of RARβ$_2$ which is vital for the balance between cell proliferation and differentiation and inducing apoptosis when necessary (**b**) Tumor tissue where hypermethylation of CpG islands on the promoter of RARβ$_2$ prevent its expression and in turn repress genes involved in regulation of cellular proliferation and apoptosis leading to the cancer phenotype. (**c**) Treatment of tumors with combinations of retinoic acid and other inhibitors such as DNA methyltransferase inhibitors (DNMTase inhibitor) that first remove the detrimental hypermethylation and then restore normal expression of RARβ$_2$ which is activated by retinoic acids

(Tang et al. 2009). This strategy first reverses the repressive effects of protein acetylation and DNA methylation on RAR gene expression and then once expressed, provides the natural agonist to activate RAR target genes to induce growth arrest and apoptosis (Fig. 4).

While cell differentiation therapies using high levels of natural retinoids such as ATRA have proven to be very successful in the treatments of some cancers, there are significant drawbacks to their therapeutic use. Retinoids are powerful teratogens that at pharmacological concentrations can induce congenital defects and toxicity in all vertebrate species. In addition, there are some cancers such as prostate cancer where ATRA and other synthetic retinoid agonists are not effective in inducing growth arrest and/or apoptosis. Moreover, a common feature of many cancers is the development of resistance to the growth inhibitory effects of retinoids limiting the utility of these therapies. Even APL, which responds well to differentiation therapy, has several variants that display retinoid resistance and does not respond to this therapy. For these reasons, efforts have been underway to develop new types of synthetic ligands for RAR that can promote the positive effects of retinoids without the detrimental side effects.

A number of synthetic retinoids have been developed as potential therapeutics for a variety of cancers.

These are often referred to as atypical retinoids or retinoid-related molecules because they are based on the retinoic acid structure and have been shown to bind and transactivate RARs. Many of these compounds have been approved for the treatment of a number of diseases such as cancer, acne, and psoriasis (Altucci et al. 2007). The majority of these atypical retinoids are RAR agonists; however, there have been some RAR antagonists that have also been synthesized. In some cancers such as prostate cancer, pan-specific antagonists of RAR such as AGN194310 demonstrated much more significant anti-proliferative and pro-apoptotic effects than any RAR natural or synthetic agonist. In fact a number of synthetic molecules known as the retinoid-related molecules such as MX781, AGN 194310, and ST1926 have demonstrated potent anti-proliferative activities against large panels of human tumor cells (de Lera et al. 2007). Until recently, all of the synthetic retinoid-related molecules reported that directly bind and modulate RAR activity share structural similarities to the natural agonist retinoic acid. This means that while some have proven efficacious in the treatments of a number of important cancers, they could still be susceptible to the same limitations regarding retinoid resistance as the natural retinoids. Interestingly, a recent report has identified the first synthetic non-retinoid, non-acid RAR modulator that binds and activates all three isoforms of RAR (Busby et al. 2011). Synthetic structures such as these may provide the basis for novel chemical scaffolds of non-retinoid, non-acid RAR modulators that may be developed that are potent and efficacious toward restoring RAR signaling while at the same time overcome the challenges of toxicity and resistance seen with use of natural retinoids such as ATRA.

Summary

The retinoic acid receptors (RARs) are ligand-dependent transcription factors that belong to the NR1B subtype of the nuclear receptor (NR) superfamily. RARs are ligand-dependent transcription factors that bind to retinoids, the most potent biologically active forms of vitamin A, and heterodimerize with the rexinoid X receptor (RXR) to regulate many genes involved in the regulation of cellular growth and differentiation. RARs play significant roles in a number of developmental cascades from formation of limbs and organs to the central nervous system. In addition, all three RAR isoforms are instrumental in the control of a cellular growth through the inhibition of the cell cycle. That combined with the activation of genes involved in differentiation provides multiple pathways that RARs regulate cellular growth. Given these critical roles in cellular growth, it is not surprising that a great deal of evidence has emerged that either mutations or reductions in RAR expression are correlated with a number of cancers. This has led to the development of differentiation therapies alone or in combination with other types of drugs to restore RAR-mediated retinoic acid signaling in a number of cancers. Due to the potential toxicity and emergence of retinoid resistance in some cancers, synthetic retinoid-related molecules have been developed including one novel non-acid non-retinoid chemical scaffold that may provide safer, more efficacious ways to treat cancer by restoring normal RAR-mediated RA signaling. Further understandings of the roles of the various RAR isoforms in the progression of cancer and how to modulate the activities of RARs may provide important clues to develop novel therapies to treat cancer.

RGS 12/Regulator of G-Protein Signaling 12 (AGS6)

► Activators of G-Protein Signaling (AGS)

RGS Protein Family

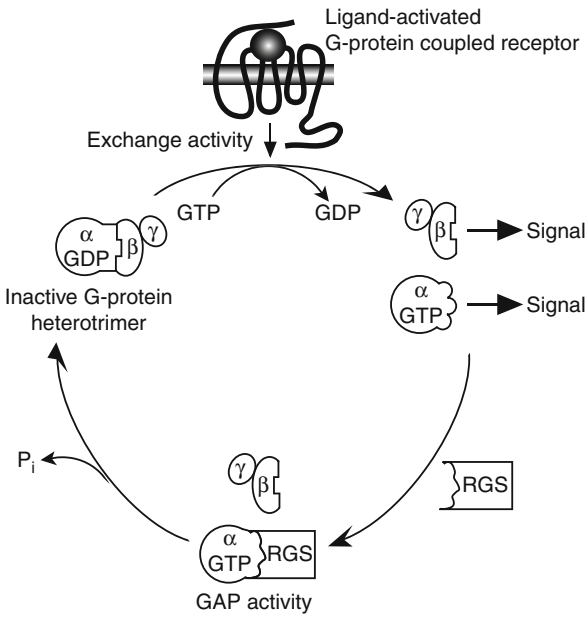
David P. Siderovski and Adam J. Kimple
Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Synonyms

Gα GAPs; Regulators of G-protein signaling; RGS proteins

Historical Background

Signal transduction by G protein–coupled receptors (GPCRs) was considered for many years (Gilman 1987) to be a three-component system: the cell-surface receptor to receive external input from hormones and neurotransmitters, the heterotrimeric G protein to transduce this input to the intracellular compartment by its structural changes upon the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP), and effector proteins (such as ► adenylyl cyclase, phospholipase C, and ion channels) to propagate the signal forward as changes in cell membrane potential and/or intracellular second messenger levels. However, for many physiological responses mediated by GPCRs, including the visual response controlled by the photoreceptor, rhodopsin (Arshavsky and Pugh 1998), intracellular signaling was known to be far shorter in duration than the time observed for the isolated components to revert to ground state in vitro (i.e., the time required for the heterotrimeric G-protein α subunit to hydrolyze GTP and return to its GDP-bound, inactive state). A critical fourth component to this system was discovered to be a large family of "regulators of G-protein signaling" proteins, also known as RGS proteins (Willard et al. 2008), that dramatically accelerate GTP hydrolysis by Gα subunits and thereby hasten signal termination (Fig. 1).



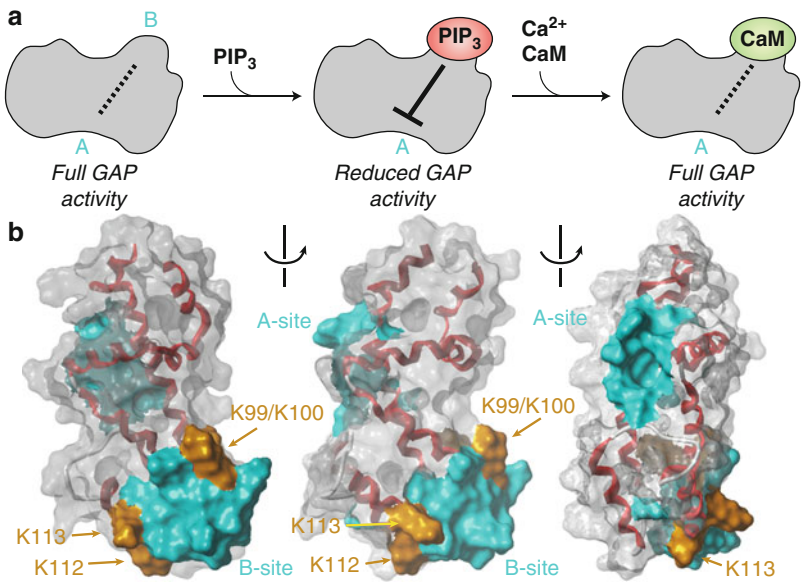
RGS Protein Family, Fig. 1 *Role of RGS proteins in GPCR signaling as negative regulators*. Ligand-activated GPCRs act as guanine nucleotide exchange factors for the inactive, GDP- and Gβγ-bound Gα subunit. The resultant release of GDP, and subsequent binding of the more abundant GTP, leads to a conformational change within Gα, eliminating the high-affinity binding site for Gβγ. The GTP-bound Gα and released Gβγ subunits are then able to bind effector proteins to propagate intracellular signaling. The intrinsic GTP hydrolysis activity of Gα subunits is greatly accelerated by the binding of RGS proteins, leading to the release of inorganic phosphate (P_i) and reassembly of the inactive Gα·GDP/Gβγ heterotrimer

One of the earliest reports of cloning a human RGS protein-encoding gene was that of *G0S8* (now known as *RGS2*) in 1990. Trapped as one of a number of putative "G0/G1-switch genes" from mitogen-treated, primary human T-lymphocytes (Siderovski et al. 1990), *G0S8*/*RGS2* was subsequently observed to encode a protein with sequence similarity to kinases specific for activated GPCRs (e.g., β-adrenergic receptor kinase, ▶ rhodopsin kinase) and to the yeast "supersensitivity-to-phermone" protein SST2 (Siderovski et al. 1994). Functional complementation of yeast deficient in SST2 by overexpression of the human *G0S8*/*RGS2* gene (Siderovski et al. 1996) provided one of the first clues that this emergent gene family encoded negative regulators of signal transduction acting downstream of GPCR activation; other groups working in disparate systems came to the same conclusion contemporaneously (Druey et al. 1996; Koelle and Horvitz 1996). These reports were quickly followed by a definitive demonstration of the biochemical activity underlying the negative regulatory function of RGS proteins: namely, acceleration of the intrinsic GTPase activity of Gα subunits using purified proteins and radiolabeled GTP (Berman et al. 1996a).

RGS Protein Activities

The signature enzymatic activity of RGS proteins is the acceleration of GTP hydrolysis by activated, GTP-bound Gα subunits. This acceleration can be made on certain GTPase-deficient Gα mutants as well (e.g., point mutation to the arginine, such as Arg-178 of $G\alpha_{i1}$, that helps stabilize the γ-phosphate leaving group) but not on classical, GTPase-dead, Gln-to-Leu Gα mutants (e.g., $G\alpha_{i1}$ Q204L) (Berman et al. 1996a). Following discovery of this signature biochemical activity of RGS proteins, a crystal structure of RGS4 bound to $G\alpha_{i1}$ in a transition state-mimetic form was reported (Tesmer et al. 1997). The ability to observe the interaction between a RGS protein and its Gα target to high-resolution solidified early speculation that RGS proteins employ solely their highly conserved, ~120 amino-acid "RGS domain" to stabilize Gα in its transition state along the path to GTP hydrolysis (Berman et al. 1996b); this "GTPase-accelerating protein" or "GAP" mechanism is distinctly different from that exhibited by the GAPs of Ras-superfamily GTPases. The GAP activity of certain RGS proteins, including RGS4, is thought to be modulated in a cellular context by the binding of phosphatidylinositol head-groups or calmodulin to a "B-site," within the RGS domain but distinct from the Gα-binding interface (or "A-site") (Fig. 2); engagement of the B-site with phosphatidylinositol-3,4,5-trisphosphate (PIP_3) is considered to inhibit A-site GAP function in an allosteric fashion, whereas the binding of calmodulin (in a calcium-dependent manner) to the B-site removes the inhibitory influence of PIP_3 (Tu and Wilkie 2004).

Observations of RGS protein overexpression leading to accelerated *on-rates* of GPCR signal transduction without affecting response sensitivity or amplitude have been presented in the literature



RGS Protein Family, Fig. 2 *Predicted structural determinants of the allosteric control over RGS protein GAP activity.* (**a**) For some RGS proteins, the binding of the RGS domain "B-site" with phosphatidylinositol-3,4,5-trisphosphate (PIP_3) is thought to allosterically inhibit the GTPase-accelerating activity of the RGS domain Gα-binding "A-site"; in a calcium-dependent fashion, the binding of calmodulin to the B-site is thought to remove the inhibitory influence of PIP_3 on A-site GAP function. (**b**) Visualization of the predicted functional sites within the RGS domain of RGS4 (Protein Data Bank id 1AGR) responsible for allosteric control of GAP activity. Highlighted (orange/dark grey) regions depict lysines thought to be required for PIP_3 binding, while solid surface (cyan/light grey) areas depict the proposed A- and B-sites. The alpha-helical secondary structure that comprises the conserved RGS domain fold is displayed in red/black as ribbon tracing within the translucent surface rendering of the domain. Rotation about the vertical axis by 90° and 180° are shown in consecutive panels from left to right

(e.g., Doupnik et al. 1997) as paradoxical findings that run counter to expectations that RGS protein GAP activity should only serve to accelerate the off-rate of GPCR signaling and, thereby, blunt signaling. It is possible that RGS proteins contribute more than just GAP activity to the functioning of the GPCR/G–protein/effector axis, especially since many RGS proteins contain multiple protein/protein-interaction domains in addition to the signature RGS domain (see below). More recently, by combining Gα mutations that accelerate intrinsic GTPase activity and that eliminate sensitivity to RGS domain GAP activity (while preserving all other Gα functions), it has been definitively demonstrated that accelerated GTP hydrolysis alone is sufficient to elicit observations of increased signaling onset and recovery times (Lambert et al. 2010). This finding, however, does not exclude the possibility that conventional ("GAP-active") RGS proteins and/or other RGS domain-containing proteins exhibit additional functional effects on GPCR-initiated signal transduction in a cellular context.

The Conventional RGS Protein Subfamilies

The "conventional" members of the RGS protein family (Table 1) exhibit Gα-directed GAP activity and have been numbered from RGS1 to RGS21 (excluding RGS15, which turned out to be RGS3). The majority of these proteins target Gα subunits of the $G\alpha_i$ and $G\alpha_q$ subfamilies (Soundararajan et al. 2008), albeit with notable exceptions as described below. These proteins have been divided into subfamilies based on overall protein architecture and RGS domain sequence similarity (Willard et al. 2008). The R4-subfamily is the largest by membership, consisting of RGS1, -2, -3, -4, -5, -8, -13, -16, -18, and -21, yet the smallest by individual protein size; most members merely consist of the ~120 amino-acid RGS domain with short N- and C-terminal polypeptide extensions (e.g., RGS21 is only 152 amino acids in length). An exception to this small size is the R4-subfamily member RGS3, given that alternative isoforms of this protein are expressed that include

RGS Protein Family, Table 1 The conventional RGS proteins

Family	Name	GenBank locus	UniProt id	Entrez gene id	Distinguishing characteristic(s)
R4	RGS1	NM_002922	Q08116	5996	Implicated in multiple sclerosis
R4	RGS2	NM_002923	P41220	5997	Selective for $G\alpha_q$; modulator of anxiety and vasoconstrictor signaling
R4	RGS3	NM_144489	P49796	5998	Isoforms can contain PDZ and C2 domains
R4	RGS4	NM_005613	P49798	5999	Associated with susceptibility to schizophrenia
R4	RGS5	NM_003617	O15539	8490	Expressed in pericytes; associated with neovascularization
R7	RGS6	NM_004296	P49758	9628	Potential modulator of parasympathetic activation in heart
R7	RGS7	NM_002924	P49802	6000	Implicated in CNS opioid and muscarinic acetylcholine signaling
R4	RGS8	NM_033345	P57771	85397	Directly binds GPCR loops (or indirectly via spinophilin); may control stable cell-surface GPCR expression
R7	RGS9	NM_003835	O75916	8787	Key deactivator of retinal phototransduction cascade
R12	RGS10	NM_002925	O43665	6001	Phosphorylation and palmitoylation control nuclear localization and Gα substrate selectivity
R7	RGS11	NM_183337	O94810	8786	Modulator of retinal ON-bipolar cell light response
R12	RGS12	NM_198229	O14924	6002	Contains PDZ, PTB, RBD, and GoLoco domains; scaffold for Ras/Raf/MAPK cascade
R4	RGS13	NM_002927	O14921	6003	Modulator of GPCR signaling in mast cells / allergic responses
R12	RGS14	NM_006480	O43566	10636	Contains RBD and GoLoco domains; scaffold for Ras/Raf/MAPK cascade
R4	RGS16	NM_002928	O15492	6004	Feeding and fasting controls expression in periportal hepatocytes
RZ	RGS17	NM_012419	Q9UGC6	26575	Implicated in lung tumorigenesis
R4	RGS18	NM_130782	Q9NS28	64407	Expressed in leukocytes, megakaryocytes, and platelets
RZ	RGS19	NM_005873	P49795	10287	Implicated in Wnt/β-catenin signaling
RZ	RGS20	NM_170587	O76081	8601	Modulator of mu-opioid receptor signaling
R4	RGS21	NM_001039152	Q2M5E4	431704	Expressed in lingual taste buds

N-terminal PDZ and C2 domains. Within the R4-subfamily, RGS2 is unique in acting as a potent GAP solely on $G\alpha_q$ subfamily members (and not $G\alpha_i$ subunits) in vitro (Kimple et al. 2009), although inhibition of Gi-coupled GPCR signaling can be observed in a cellular context upon RGS2 overexpression (Ingi et al. 1998). RZ-subfamily members (RGS17, -19, and -20) are also small polypeptides but are distinct from the R4-subfamily in containing cysteine-rich N-termini thought to be reversibly palmitoylated for differential subcellular trafficking. As the name suggests, RZ-subfamily members have particular selectivity for $G\alpha_z$ subunits, although this is not exclusive, and binding of (and GAP activity on) $G\alpha_i$ subunits is also manifested (e.g., Soundararajan et al. 2008).

R7-subfamily members (RGS6, -7, -9, and -11) are known to play key roles in the regulation of various neuronal processes such as nociception, motor control, reward behavior, and vision. These four proteins share an expression pattern biased to neuronal tissues, as well as a unique multi-domain protein architecture composed of DEP (*D*ishevelled/*E*GL-10/*P*leckstrin) and GGL (*G*-*g*amma-*l*ike) domains present N-terminal to a central RGS domain. The DEP domain mediates interaction with unique membrane anchor proteins R7BP and R9AP, whereas the GGL domain (as its name implies) binds a neuronal-specific Gβ subunit, Gβ5, to form an obligate dimeric configuration akin to conventional Gβ/Gγ subunits (Snow et al. 1998). While the R12-subfamily member RGS10 consists of little more than an RGS domain, the other two members of this subfamily (RGS12 and RGS14) share elaborate multi-domain architectures. C-terminal to their RGS domains, both RGS12 and RGS14, possess a tandem repeat of Ras-binding domains (RBDs) and a single GoLoco motif; the first of the two RBDs binds selectively to activated H-Ras (Willard et al. 2007), whereas the GoLoco motif is known to bind $G\alpha_i$ subunits in their GDP-bound inactive state (Kimple et al. 2002). Unlike RGS14, RGS12 also possesses N-terminal PDZ and PTB domains which play important

roles in the functional organization of an H-Ras-Raf-MAPK signaling cascade required for nerve growth factor (NGF)-mediated axonogenesis by dorsal root ganglion neurons (Willard et al. 2007).

Other RGS Domain-Containing Proteins

There are an equivalent number of "nonconventional" RGS proteins (Table 2) that, while possessing the highly conserved nine alpha-helical structure of the RGS domain (Tesmer et al. 1997; Soundararajan et al. 2008), either have already been identified in other functional contexts or have yet to be identified as bona fide Gα-directed GAPs. With respect to the latter situation, AKAP-10 (also known as D-AKAP2) and RGS22 possess more than one RGS domain, but to date neither have been convincingly shown to bind to (nor accelerate the GTPase activity of) Gα subunits; this is also true of three sorting nexins (SNX13, -14, and -25) and the RA-subfamily members (Axin, Axin2) that each possess a single, central RGS domain of poorly characterized or controversial Gα-modulatory function.

As previously mentioned, early reports of the discovery of the RGS protein family highlighted the presence of an N-terminal RGS domain within the known family of serine/threonine kinases (GRK1 to 7; Table 2) that are specific for activated GPCRs (Siderovski et al. 1994; Siderovski et al. 1996); subsequent examination of this N-terminal RGS domain within GRK2 revealed in vitro $G\alpha_q$ binding selectivity and a cellular function in inhibiting Gq-coupled GPCR signaling, albeit with little (if any) $G\alpha_q$-directed GAP activity. N-terminal RGS domains were also identified in guanine nucleotide exchange factors for the small GTPase RhoA (i.e., the GEF-subfamily of RGS proteins; namely, p115-RhoGEF/ARHGEF1, PDZ-RhoGEF/ARHGEF11, and LARG/ARHGEF12). This identification helped to explain the ability of $G_{12/13}$-coupled GPCRs to activate RhoA in a cellular context; therefore, the GEF-subfamily of RGS proteins

RGS Protein Family, Table 2 Other proteins containing RGS domain(s)

Family	Name	GenBank locus	UniProt id	Entrez gene id	Distinguishing characteristic(s)
	AKAP10	NM_007202	O43572	11216	Contains 2 RGS domains which interact with Rab4 and Rab11 GTPases
	RGS22	NM_015668	Q9BYZ4	26166	Contains 3 RGS domains; specifically expressed in testes
SNX	SNX13	NM_015132	Q9Y5W8	23161	Also known as RGS-PX1; controversial report of $G\alpha_s$-directed GAP activity
SNX	SNX14	NM_153816	Q9Y5W7	57231	Also known as RGS-PX2
SNX	SNX25	NM_031953	Q9H3E2	83891	Sorting nexin-25; speculated to bind phosphatidylinositols with its PX domain
RA	Axin	NM_003502	O15169	8312	Involved in Wnt signaling; component of β-catenin destruction complex
RA	Axin2	NM_004655	Q9Y2T1	8313	Also known as conductin; regulator of centrosome cohesion
GRK	GRK1	NM_002929	Q15835	6011	Also known as rhodopsin kinase
GRK	GRK2	NM_001619	P25098	156	Also known as β-adrenergic receptor kinase-1 (βARK1); RGS domain binds activated $G\alpha_{q/11}$
GRK	GRK3	NM_005160	P35626	157	Also known as β-adrenergic receptor kinase-2 (βARK2)
GRK	GRK4	NM_182982	P32298	2868	Linked to genetic and acquired hypertension
GRK	GRK5	NM_005308	P34947	2869	Modulator of NFκB signaling via IκBα interaction
GRK	GRK6	NM_002082	P43250	2870	Involved in phosphorylation and desensitization of CXCR4
GRK	GRK7	NM_139209	Q8WTQ7	131890	Involved in cone phototransduction
GEF	ARHGEF1	NM_004706	Q92888	9138	Also known as p115 RhoGEF; $G\alpha_{12/13}$-dependent exchange factor for RhoA GTPase
GEF	ARHGEF11	NM_014784	O15085	9826	Also known as PDZ-RhoGEF
GEF	ARHGEF12	NM_015313	Q9NZN5	23365	Also known as LARG or "leukemia-associated RhoGEF"

are emblematic of RGS domain-containing proteins that serve as effectors (i.e., propagating the signal forward) even while they also serve as GAPs for their upstream activators (i.e., activated $G\alpha_{12}$·GTP and $G\alpha_{13}$·GTP subunits).

Summary

Originally discovered as negative regulators of GPCR signal transduction owing to their Gα-directed GAP activity, the RGS proteins are now appreciated to possess multifaceted functions in cellular signaling networks. These multiple functions can arise from elaborate, multiple protein-domain architectures, unique binding partners, and their individual abilities to coordinate and/or modulate other signal transduction components, such as small Ras-superfamily GTPases. Unique expression patterns and Gα-binding selectivities of the RGS proteins underlie their individual involvement in distinct physiological and pathophysiological phenomena. What remains to be determined is whether RGS proteins can be selectively inhibited by small molecules and, even more speculatively, whether their activity could be enhanced by small molecules that usurp normal allosteric control over the Gα-binding A-site.

Regulator of G-protein Signaling 13

Historical Background

Regulator of G-protein signaling (RGS) is a protein superfamily discovered in the mid-1990s (Druey et al. 1996; Watson et al. 1996; Hunt et al. 1996). Since that time more than 30 members in the family have been identified. The major physiological function of RGS molecules is to negatively modulate G-protein coupled receptor (GPCR)-mediated signaling and biology (Bansal et al. 2007; Neitzel and Hepler 2006; Thompson et al. 2008). ▶ RGS13 was first identified in 1996 and is one of the smallest molecules in the family (Druey et al. 1996). Full length human RGS13 cDNA was cloned and deposited into gene bank in 1997 by Chatterjee and Fisher. In 2002, the first functional studies of human RGS13 were reported. RGS13 was shown to inhibit muscarinic M1- and M2 receptor-induced ▶ MAP kinase activation (Johnson and Druey 2002). Concurrently, a separate study characterized mouse RGS13, which was cloned from B cells. RGS13 expression was demonstrated in germinal center regions of mouse spleen and shown to inhibit chemokine receptor CXCR4 and CXCR5-mediated signaling pathways, suggesting a function of RGS13 in B cell migration and trafficking (Shi et al. 2002).

More recently, GPCR-independent functions of RGS13 were revealed. RGS13 suppressed IgE receptor-induced mast cell degranulation through interaction with the p85 subunit of ▶ phosphoinositide 3-kinase (Bansal et al. 2008b). Mice deficient in RGS13 have enhanced IgE-mediated anaphylaxis after antigen challenge. RGS13 was also shown to regulate cAMP-dependent pathways. RGS13 bound phosphorylated cAMP responsive element binding protein (▶ CREB) in the nucleus and inhibited CREB-mediated gene transcription (Xie et al. 2008).

Expression Pattern

RGS13 has very restricted tissue distribution expressed mainly in B cells (Shi et al. 2002), mast cells (Bansal et al. 2008b), and enteroendocrine cells (Xie et al., unpublished observation). Central nervous system expression of RGS13 mRNA has been observed in rat brain by in situ hybridization (Grafstein-Dunn et al. 2001), but not in the human brain (Larminie et al. 2004). The expression level of RGS13 may vary considerably under physiological or pathological conditions. For example, although RGS13 is highly expressed in germinal center B cells and Burkitt lymphoma, it is absent in mantle cell lymphoma (Islam et al. 2003). Upregulated RGS13 mRNA has been reported in malignant T cells from acute T cell leukemia (ATL) patients by gene expression profiling (Pise-Masison et al. 2009); however, it was not detected in normal human tonsil T cells or in Jurkat and MOLT-4 T cell lines (Shi et al. 2002). In BXD2 autoimmune mice, increased IL-17 production is associated with elevated RGS13 mRNA expression and the suppression of B cell chemotactic responses to the chemokine CXCL12 (Hsu et al. 2008). Restricted tissue distribution and apparent disease relevance make RGS13 an excellent target for drug development.

Regulation of RGS13 Expression

Similar to many RGS molecules, RGS13 expression is relatively low in quiescent cells, which may be necessary for allowing adequate GPCR signaling to maintain cell homeostatic functions. Incubation of bone marrow–derived mast cells (BMMCs) with IgE-antigen for 24 h results in a four- to fivefold increase in RGS13 mRNA and protein (Bansal et al. 2008a), which may have a negative feedback role to amplify the inhibitory effect of RGS13 on antigen-mediated mast cell degranulation. In other words RGS13 may desensitize mast cells to antigen stimulation. Interestingly exposure of human LAD2 mast cells to cAMP decreases RGS13 mRNA quantities (Xie et al. 2010), suggesting that RGS13 expression is differentially regulated by distinct ligands or signaling pathways.

In human tonsillar B lymphocytes, anti-► CD40 antibody augments RGS13 mRNA expression (Shi et al. 2002), suggesting a role of RGS13 in B cell activation. Consistent with its expression in splenic germinal center B cells, human Burkitt lymphoma cell lines Ramos, HS-Sultan, and Raji express abundant RGS13, as do immunized mouse spleen B cells (Shi et al. 2002). Notably, the tumor suppressor ► p53 inhibits RGS13 mRNA transcription in mast cells by binding to its promoter region (Iwaki et al. 2011).

RGS13 is also regulated at the posttranslational level. RGS13 protein undergoes proteasome-mediated degradation. Phosphorylation of RGS13 on Thr41 by protein kinase A (PKA) protects it from degradation, resulting in elevated steady-state RGS13 protein levels (Xie et al. 2010), which could promote the inhibitory function of RGS13 on transcription factor CREB.

Biological Functions

GPCR-Dependent Functions

RGS proteins interact with α subunit of the heterotrimeric G-protein in its activated (GTP-bound) state, leading to increased intrinsic GTPase activity of Gα. This GTPase activating protein (GAP) activity increases the rate of GTP hydrolysis, which hastens deactivation/termination of GPCR signaling and functions (Patel 2004). RGS13 interacts with the α subunit of Gi and Gq, but not ► Gs, accelerating the GTPase activity of Gα (7,8). MAP kinase Erk1/2 activation stimulated by Gq-coupled muscarinic M2 receptor is significantly inhibited by overexpression of RGS13 in human embryonic kidney (HEK) 293 T cells (Johnson and Druey 2002). Overexpression of RGS13 in Chinese Hamster Ovary (CHO) cells inhibited the Gi-coupled chemokine receptor CXCR4-mediated cell migration (Shi et al. 2002).

SiRNA-mediated knockdown of endogenous RGS13 in HS-Sultan cells results in enhanced Ca^{2+} flux and chemotaxis induced by the chemokines CXCL12 and CXCL13, which utilize Gi-coupled GPCRs CXCR4 and CXCR5, respectively (Han et al. 2006). Depletion of RGS13 in the human mast cell lines LAD2 and HMC-1 by shRNA increases degranulation evoked by the GPCR ligand sphingosine-1-phosphate (S1-P), and greater Ca^{2+} mobilization in response to several GPCR ligands including C5a, adenosine, and S1P (Bansal et al. 2008a).

GPCR-Independent Functions

In recent years, GPCR-independent cellular functions of RGS13 have been characterized, which do not involve classical RGS13 GAP activity. Cross-linking of the IgE receptor FcεRI by antigen on mast cells activates signaling molecules including Syk kinase, phospholipase Cγ, ► LAT, and PI3 Kinase, leading to mast cell degranulation and cytokine production (Gilfillan and Tkaczyk 2006). Mice lacking RGS13 displayed enhanced systemic and local cutaneous anaphylactic responses when challenged with IgE/antigen (Bansal et al. 2008b). BMMCs from $Rgs13^{-/-}$ mice degranulated much more than those from wild-type littermates. Interestingly cytokine generation by BMMC after IgE/antigen stimulation were not affected by RGS13 protein deficiency, indicating that RGS13 specifically regulates IgE-mediated mast cell degranulation. Further analysis revealed that RGS13 binds to the p85 subunit of PI3 kinase enzyme, which is a critical downstream effector in the degranulation pathways. RGS13 inhibited formation of an FcεRI-associated p85-► Gab2-Grb2 signaling complex, which is required for mast cell degranulation (Bansal et al. 2008b). Reconstitution of RGS13 deficient BMMC with a GAP-inactive RGS13 mutant suppressed antigen-stimulated degranulation similar to wild-type RGS13, indicating that RGS13 GAP activity is not required for its inhibition of mast cell function (Bansal et al. 2008b).

A separate set of studies led to the discovery that although RGS13 does not interact with Gαs, it inhibits Gs-mediated signaling through the β2-adrenergic receptor downstream of the G protein (Johnson and Druey 2002). Further studies revealed that PKA activation induced by Gs-coupled β2-adrenergic receptor stimulation leads to RGS13 accumulation in the nucleus. RGS13 binds to the phosphorylated transcription factor CREB in the presence of its co-activator CREB-binding protein (CBP). Binding of RGS13 to phosphorylated CREB eventually inhibited CREB transactivation, resulting in decreased CREB target gene expression (Xie et al. 2008).

Summary

RGS13 acts as a signaling modulator, playing critical roles in both GPCR-dependent and GPCR-independent cellular processes. The high expression

of RGS13 in murine germinal center B cells and its suppression of chemokine-induced B cell migration suggests a potential role of RGS13 in adaptive immune responses. Altered expression of RGS13 in conditions of autoimmunity or malignancy suggests disease relevance. In the light of negative regulatory roles of RGS13 in mast cell functions, upregulated RGS13 expression in mast cells repeatedly exposed to antigen could increase inhibition of IgE/antigen-mediated mast cell degranulation and/or anaphylactic responses. Mast cell degranulation, which leads to release of granular contents such as histamine, plays a key role in many diseases including allergy, asthma, mastocytosis, and anaphylaxis. Therefore, RGS13 could be a potential therapeutic target, especially given its limited tissue distribution. Since most of the studies conducted thus far have been in mice or in murine cell lines, further investigations of human subjects, such as expression patterns of RGS13 in health and disease, will be of utmost importance.

Acknowledgments This study was supported by the Intramural Research Program of the NIH, NIAID.

ARH9; ARHC; Ras homolog gene family, member C

Historical Background

RhoC was originally identified, together with its homologues RhoA and RhoB, as a Ras-related small GTPase (Madaule and Axel 1985). RhoA, RhoB, and RhoC together comprise the Rho subfamily of small GTPases characterized by their high homology within the Rho GTPase family. The human *rhoc* gene is on chromosome 1p13.1-p21. The *rhoc* gene is proposed to originate from a duplication of *rhoa* during evolution (Boureux et al. 2007). RhoA and RhoC are 93% identical at the protein level; the divergence is mainly concentrated in the so-called hypervariable region of the proteins at the C-terminus. Although multiple Rho subfamily GTPases exist in many eukaryotic organisms, specific RhoC orthologs do not exist outside vertebrates (Boureux et al. 2007). This together with the fact that, like RhoA, when RhoC is overexpressed in cells it induces the formation of actin stress fibers means that its specific functions were not investigated until relatively recently. It was originally described to regulate reorganization of the actin cytoskeleton and cell shape, attachment, and motility in a similar way to RhoA. The focus of attention shifted when it was discovered that RhoC but not RhoA specifically contributes to cancer metastasis (Clark et al. 2000). Since then many studies have investigated the different functions of RhoA, RhoB, and RhoC in cell biology and disease processes.

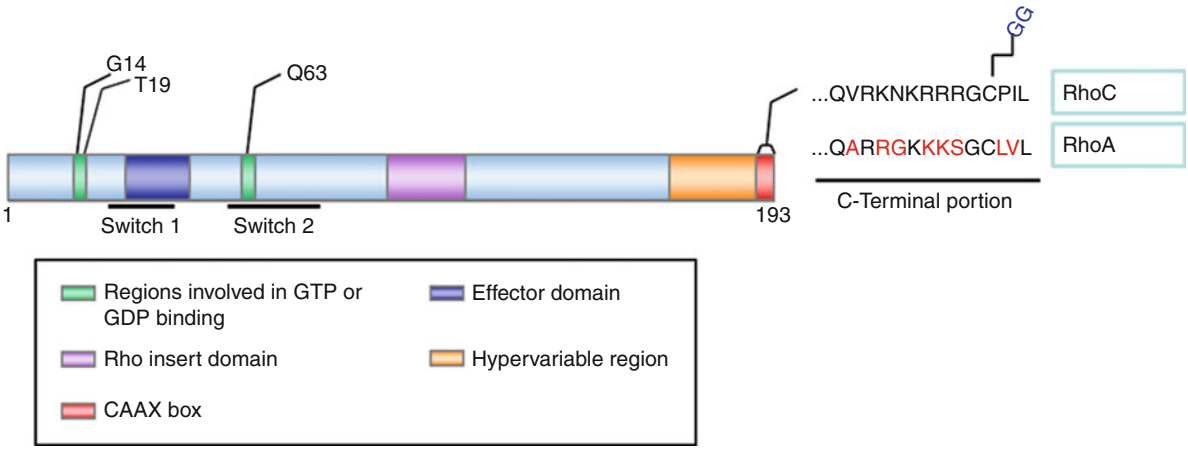
Tools for the Study of RhoC Function

Classic tools for the study of Rho GTPases, including RhoC, took advantage of some conserved amino acids essential for GTP hydrolysis to make dominant negative (T19N substitution) or constitutively active (G14V or Q63L substitutions) forms of the protein (Fig. 1; Wheeler and Ridley 2004). However, these mutations have the disadvantage that they probably do not allow the functional specificity of closely related Rho GTPases like RhoA and RhoC to be explored. Bacterial toxins, like *Clostridium Botulinum* exoenzyme C3 transferase or Toxin B, efficiently inhibit Rho activity by covalently modifying the protein in key residues, but again they target all Rho subfamily proteins and, although they were central to establishing the role of these proteins in actin cytoskeletal organization, they cannot be used to study RhoC-specific functions. More recently, RNA interference (RNAi) has been used to differentiate the functions for RhoA, RhoB, and RhoC in cells. This has shown that RhoA and RhoC regulate cytoskeletal dynamics, cell morphology, migration, and invasion in different ways (Bellovin et al. 2006; Wu et al. 2010; Bravo-Cordero et al. 2011; Vega et al. 2011).

Spatio-temporal regulation of Rho GTPase activity is crucial to cell migration and invasion. The combined use of live-cell imaging and fluorescence biosensors is now helping to decifer how the activity of RhoC and other Rho GTPases is tightly regulated on a subcellular level. For example, using a RhoC -specific biosensor in cancer cells, dynamic RhoC activation in invadopodia has been visualized (Bravo-Cordero et al. 2011).

Regulation of RhoC Activity

RhoC is a GTPase that act as a molecular switch, cycling between a GDP-bound inactive state and a GTP-bound active state. When active it interacts with effector proteins to regulate a variety of different processes (Wheeler and Ridley 2004). Its activation is positively regulated by guanine nucleotide exchange factors (GEFs), which stimulate the exchange of GDP for GTP on the protein, and negatively regulated by GTPase-activating proteins (GAPs), which stimulate its intrinsic GTPase activity. RhoC is also posttranslationally modified at the C-terminus by prenylation with the addition of a geranylgeranyl group (Fig. 1). This modification allows its anchorage to membranes and is likely to be essential for its biological function. Similar to several other Rho GTPases, RhoC associates with Rho GTPase dissociation inhibitor proteins (RhoGDIs),



RhoC (RHOC), Fig. 1 RhoC domain structure and features. Schematic of RhoC protein showing the different domains and residues important for its activity and used to create dominant negative and constitutively active mutations as described in the text. The C-terminal 14 amino acids, including the CAAX box, and comparison with the equivalent region of RhoA is shown. *Red* amino acids indicate nonconserved residues. GG depicts the prenylation site; following geranylgeranlylation the last three amino acids are cleaved off

which sequester the protein in the cytoplasm by interacting with the C-terminal geranylgeranyl group. These modes of regulation are shared with the other Rho proteins, RhoA and RhoB. The different functions of RhoC compared to RhoA and RhoB are thought to be achieved through RhoC-specific GEFs and/or GAPs and by its binding to specific effector proteins.

Most regulators of Rho subfamily proteins have only been tested on RhoA, and based on the sequence similarity with RhoC would be predicted to act on both proteins. The ones that have been specifically tested on RhoC are the GEFs Tim and Scambio, the GAPs p190RhoGAP, GRAF, p50RhoGAP and Myr5 and the 3 RhoGDI proteins (Bos et al. 2007). Few regulators have been compared for their activity on RhoA versus RhoC. One of the few examples of a specific regulator comes from studies of the RhoGEF ARHGEF3 (also known as XPLN), which acts on RhoA and RhoB but not RhoC, but no RhoC-selective GEFs or GAPs have been described so far (Arthur et al. 2002; Bos et al. 2007). A report described enhanced RhoC activity compared to RhoA in pancreatic carcinoma cells which correlated with an increase of RhoC membrane localization (Dietrich et al. 2009); this might reflect differential regulation of Rho isoform interaction with RhoGDIs.

RhoC expression is ubiquitous but its levels are variable between different tissues. Overexpression of *RhoC* has been reported in a variety of pathological conditions, particularly in more aggressive metastatic cancers, and this indicates that its expression is regulated and plays a role in its physiological function. A newly discovered way in which *RhoC* expression and activity can be regulated in cells is by the action of noncoding microRNAs. In breast cancer, for example, the overexpression of the microRNA miRNA-10b induces the upregulation of RhoC by inhibiting the translation of the messenger RNA encoding HOXD10, and this in turn promotes invasion and metastasis (Ma et al. 2007). In squamous cell carcinoma, the downregulation of microRNA-138 induces metastasis by reducing direct *RhoC* mRNA degradation (Jiang et al. 2010).

Some Rho proteins are subject to posttranslational modifications that regulate their stability or activity. Notably, the residue Ser188 present in RhoA that is subject to protein kinase A and protein kinase G phosphorylation is not conserved in RhoC (Ellerbroek et al. 2003). RhoA is also ubiquitinated and thereby targeted for proteasomal degradation, but RhoC does not appear to be regulated similarly (Chen et al. 2009). It is possible that as-yet-identified residues in RhoC could be subject to phosphorylation, ubiquitination, or other posttranslational modifications.

RhoC Effectors

Because RhoA, B, and C possess a high level of identity at the protein level, they share many common downstream effectors (Wheeler and Ridley 2004).

The affinity of these interactions may vary due to their amino acid sequence differences. These interactions all involve the Rho switch I and II regions (see Fig. 1) and Rho-binding domains (RBDs) of their effectors, which include Rho-associated kinase (▶ ROCK-1 and-2), Protein kinase N (PKN1-3, also known as PRKs), Citron kinase, mDia1-3, Rhotekin, and Rhophilin-1. RhoC and RhoA also interact with Phospholipase C ε (PLC-ε) via its catalytic core. RhoC, but not RhoA, has recently been reported to bind to the Formin-like family members FMNL2 and FMNL3 (Kitzing et al. 2010; Vega et al. 2011). RhoC also binds to IQGAP1 (Wu et al. 2011).

RhoC Functions in Tumorigenesis

Formation of Metastases

RhoC expression and activity is often increased in cancer and correlates with progression, metastasis formation and therefore a poor prognosis for patients (Vega and Ridley 2008). Increased *RhoC* expression in cancer was first identified in a screen for genes upregulated in melanoma metastases (Clark et al. 2000). *RhoC* expression was subsequently found to be upregulated in a variety of cancers including prostate cancer, breast cancer, gastric cancer, ovarian cancer, bladder cancer, hepatocellular cancer, pancreatic ductal adenocarcinoma, non-small cell lung carcinoma (NLCLC), oesophageal squamous cell carcinoma, head and neck squamous cell carcinoma, and skin squamous cell carcinoma (Karlsson et al. 2009). RhoC has been shown to play a causal role in metastasis in animal models. Initial studies found that overexpression of dominant and negative forms of RhoC correlated with the formation or the inhibition of experimental lung metastases, respectively (Clark et al. 2000). Subsequently, it was shown using RhoC-null mice that RhoC was dispensable for breast cancer initiation and growth but confirmed that RhoC is critical for formation of metastases (Hakem et al. 2005). The inhibition of RhoC has since been described to reduce cancer cell invasion and metastasis in several in vitro and in vivo cancer models. RhoC is now proposed to be a marker for poor prognosis in many different cancers.

No genomic or somatic mutations in human cells have been described for RhoC. Somatic mutations have been reported in the RhoA and RhoC downstream effector ▶ ROCK-1 (Lochhead et al. 2010).

Migration and Invasion

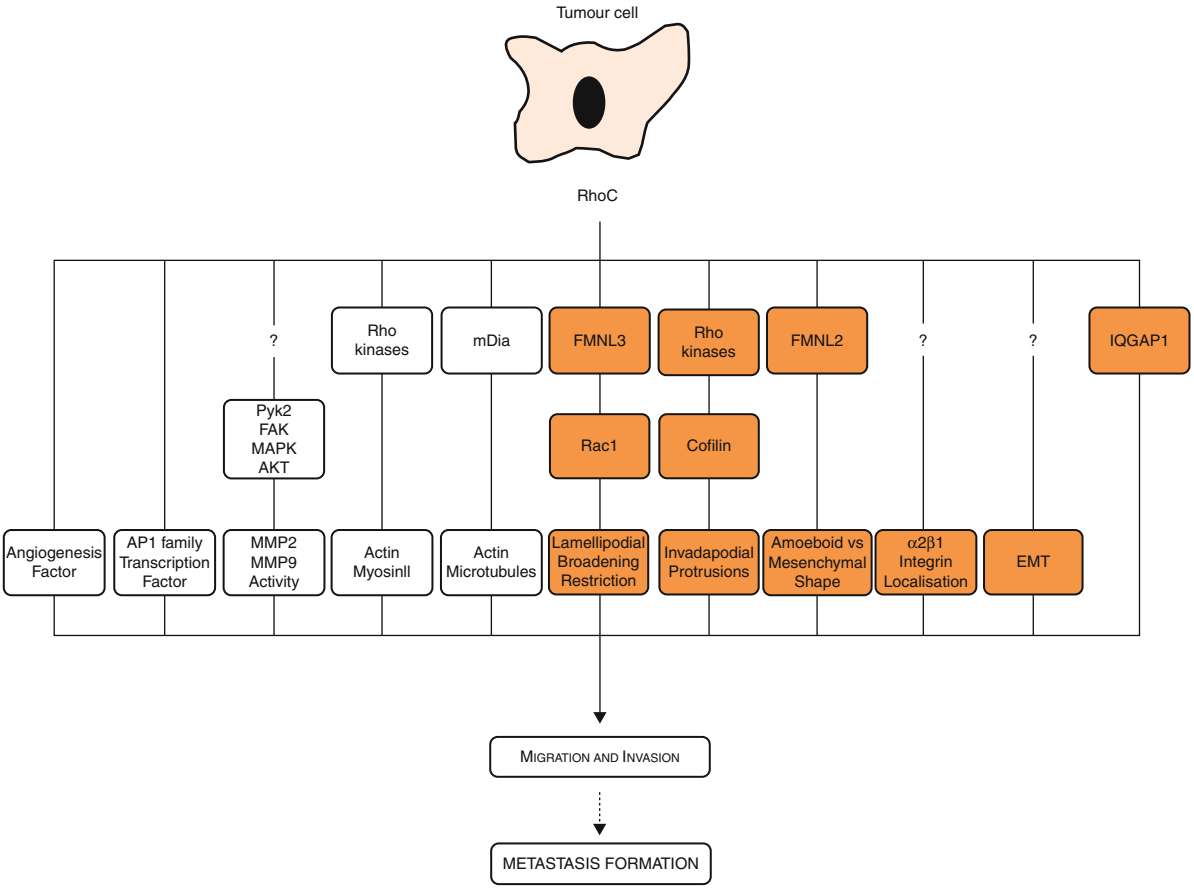
Recent studies show that RhoC has a unique role in cell migration, distinct from RhoA, which could underlie its specific contribution to cancer cell invasion and metastasis (Fig. 2). For example, *RhoC* expression is increases during colon carcinoma cell epithelial-mesenchymal transition (EMT) and regulates EMT-induced migration (Bellovin et al. 2006). RhoC promotes polarized cell migration and invasion by controlling cell spreading and Rac1 activation around the cell periphery hence restricting lamellipodial broadening (Vega et al. 2011). RhoC regulates breast cancer cell adhesion to the extracellular matrix and motility and invasion by modulating the expression and co-localization of α2 and β1 integrins on collagen I (Wu et al. 2011). RhoC is also implicated in the degradation of extracellular matrix as it is involved in the formation of matrix-degrading invadopodia in cancer cells: an active ring of RhoC restricts Cofilin activity and focuses invadopodial protrusion and matrix degradation (Bravo-Cordero et al. 2011). In addition, RhoC coordinates prostate cancer cell invasion in vitro by activating the protein kinases Pyk2, FAK, MAPK, and AKT, which results in activation of the matrix-degrading metalloproteinases 2 and 9 (MMP2 and MMP9; Fig. 2) (Iiizumi et al. 2008). RhoC is also involved in the transcriptional program that controls the TGFß1-induced switch from cohesive to single-cell motility in breast cancer cells (Giampieri et al. 2009).

Angiogenesis

RhoC can stimulate the production of pro-angiogenic factors by breast cancer cells (Merajver and Usmani 2005). RhoC is a downstream effector of vascular endothelial growth factor (VEGF) in endothelial cells and cancer cells. RhoC is thus essential for VEGF-mediated angiogenesis induced by hepatocellular carcinoma cells (Wang et al. 2008). These pro-tumoral functions could potentiate the vascularization of tumors that express RhoC and also may facilitate cancer cell intravasation and extravasation during tumor metastasis.

Proliferation and Apoptosis Resistance

Contradictory studies have been reported concerning the role of RhoC in cancer cell proliferation and apoptosis resistance, which remain to be clarified. On the one hand, RNAi-mediated suppression of RhoC in



RhoC (RHOC), Fig. 2 RhoC functions in cancer. Schematic of RhoC protein showing the different functions of RhoC in cancer and its downstream effectors. Noncolored functions and interactors are shared with RhoA while *orange*-colored functions and interactors are RhoC-specific. Note the *arrow* between migration/invasion and metastasis formation is a *dotted line* because not all of the RhoC effectors have been tested in vivo

hepatocellular carcinoma cells showed that RhoC does not regulate cancer cell proliferation in mice and that depletion of RhoC in endothelial cells does not affect their apoptosis (Wang et al. 2008). On the other hand, RhoC depletion in human gastric carcinoma cells was reported to inhibit proliferation and increase apoptosis in vitro (Sun et al. 2007); and RhoC promoted human oesophageal squamous cell carcinoma and breast cancer cell proliferation in mice in vivo (Faried et al. 2006).

RhoC Regulates Transcription Factors

RhoA is well known to regulate transcription through actin-dependent and actin-independent effects on a variety of transcription factors (Jaffe and Hall 2005). Recent evidence indicates that RhoC also plays a role in transcriptional regulation (Fig. 2). RhoC is induced in melanoma cells by the transcriptional regulator ETS-1. RhoC then indirectly stabilizes the AP-1 family transcription factor c-Jun through the actin cytoskeleton (Spangler et al. 2011). c-Jun is an oncogene which is a critical mediator of tumor development.

Summary

RhoC is a member of the small family of Rho GTPases that is very closely related to RhoA and RhoB. It is best known for its role in cell migration regulation and control of actin cytoskeleton dynamics. Although RhoC was originally considered to act similarly to RhoA and share the same partners and functions, there is now good evidence that RhoC has unique functions in cells and is probably regulated by specific

partners. Recently, some RhoC-specific downstream effectors have been described and the analysis of these interactions gave new insights into RhoC function in cells. This is reflected by studies in mouse models, where RhoC has distinct functions to RhoA in cancer metastasis. RhoC is upregulated in many types of cancer and is a critical regulator of cancer progression and metastasis formation. It is likely to be useful as a prognostic marker in many types of cancer and could be a possible target in cancer therapy. The understanding of RhoC function in cells and organisms will be advanced in the future by the use of biosensors and fluorescence resonance energy transfer methods to decipher where and when RhoC is active and interacts with its partners.

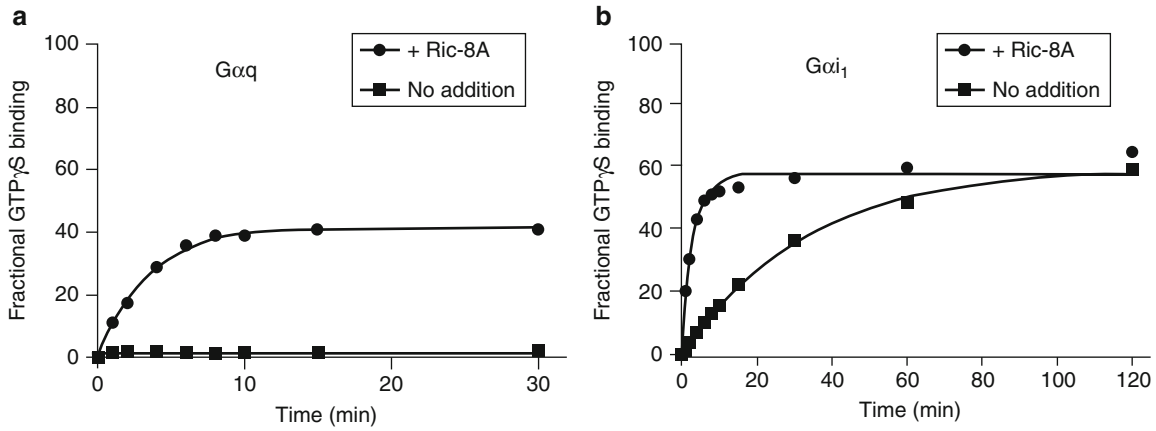
Historical Background

Discovery of Ric-8 proteins: The *Caenorhabditis elegans* RIC-8 gene and a homologous mouse gene that was later termed Ric-8A (or a synembryn) were discovered by Miller and Rand using a genetic screen to obtain *C. elegans* mutants that were resistant to the inhibitor of cholinesterase, aldicarb (Miller et al. 1996). Aldicarb treatment of wild-type worms leads to neurotoxic accumulation of postsynaptic acetylcholine and subsequent death. Ric mutants lived in the presence of aldicarb because they contained gene defects that restored normal acetylcholine levels, primarily by decreasing neurotransmitter secretion or release. Through epistasis analyses, the gene complementing the ric-8 mutant allele was predicted to elicit action upstream of or parallel to the gene encoding G protein α q in a diacylglycerol-dependent synaptic-vesicle-priming pathway (Miller et al. 2000a). Miller and Rand also first showed that centrosome (spindle pole) movements in the dividing *C. elegans* zygote were perturbed in ric-8 mutants, a phenotype shared by G protein αo(i) mutants (Miller and Rand 2000b).

Ric-8 proteins were first linked physically to ▶ G protein α subunits when two mammalian Ric-8 homologues were identified by the ability to bind Gαo and Gαs directly in yeast two-hybrid screens and in purified protein–protein binding and functional assays (Tall et al. 2003). The two homologues are the products of separate genes and were named mammalian Ric-8A and Ric-8B. Ric-8A binds Gαi, Gαq, and Gα12/13 class G protein α subunits, whereas Ric-8B binds the Gαs, Gαq, and Gα12/13 classes. Preliminary experiments demonstrating a preferred interaction of Ric-8A with the GDP-bound form of G protein α led to the hypothesis that Ric-8A might alter G protein catalysis by serving as an alternative guanine nucleotide dissociation inhibitor (GDI), or a non-receptor guanine nucleotide exchange factor (GEF). Purified Ric-8A stimulated intrinsic G protein α GDP release dramatically leading to accelerated, observed GTP(γS) binding kinetics (G protein activation) (Fig. 1). The mechanism of Ric-8A-stimulated guanine nucleotide exchange was elucidated. Ric-8A initially interacted with GDP-bound G alpha and stimulated rapid GDP release. In the absence of GTP, Ric-8A formed a stable nucleotide-free transition state complex with Gα. Addition of GTP and magnesium dissociated this complex to produce free Ric-8A and activated Gα-GTP. Currently, a biochemical characterization of Ric-8B has not been made. Ric-8B is predicted to be a Gαs and Gαq-class GEF based on



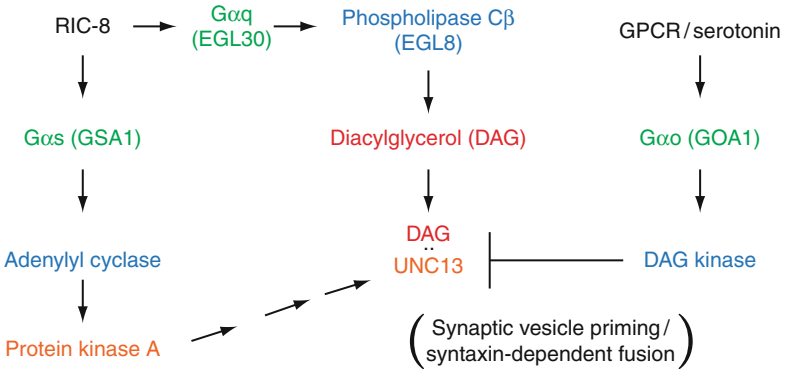
Ric-8, Fig. 1 Ric-8A is a Gα subunit GEF and accelerates the kinetics of (**a**) Gαq and (**b**) $G\alpha i_1$ GTPγS binding. Purified Gα subunits (200 nM) were incubated in reactions containing radiolabeled GTPγS with (*squares*), or without (*circles*) purified Ric-8A (200 nM). At the indicated times, Gα and its bound nucleotide were trapped on nitrocellulose filters and the amount bound GTPγS was measured by scintillation counting. This research was originally published in the *Journal of Biological Chemistry* (4) © the American Society for Biochemistry and Molecular Biology

its Gα binding preferences. Since these initial observations of Ric-8 function, the field has endeavored to understand how Ric-8 GEF activity regulates G protein function in cells. Many of the predicted Ric-8 physiological functions have been acquired from genetic studies in model organisms. These include functional interactions with varied G protein species to regulate neurotransmission, asymmetric cell division, olfaction, and G protein residence at the plasma membrane.

C. elegans RIC-8 and Gαq/Gαs/Gαo modulate neurotransmission. The original function ascribed to the *C. elegans* RIC-8 gene was made by its identification in the ric mutant screen designed to isolate mutants of genes whose products positively regulated neurotransmission (Miller et al. 1996). Gαq is one other such gene. Various genetic and biochemical tests confirmed that ric-8 mutants acted epistatically (upstream) to other Gαq-pathway-dependent synaptic-vesicle-priming defects. Gαq gain of function alleles, diacylglycerol (DAG) kinase mutants (deregulates DAG by phosphorylation), or application of phorbol esters (DAG analogs) all suppressed the ric-8 mutant neurotransmission defect (Miller et al. 2000a). These and other collective observations indicated that the RIC-8 protein likely acted upstream of Gαq to promote neurotransmission through phospholipase Cβ-dependent DAG production and subsequent UNC13 stimulation (see Fig. 2). UNC13 is a DAG binding protein/sensor that interacts with the membrane in a DAG-dependent manner. UNC13 also interacts with syntaxin proteins and may regulate SNARE-dependent vesicle fusion.

Ric-8 was later shown to be epistatic to Gαs through genetic suppression experiments. Gain of function mutants in Gαs, ▶ adenylyl cyclase, or protein kinase A individually suppressed the ric-8 paralysis defect (Reynolds et al. 2005; Schade et al. 2005). This showed that *C. elegans* RIC-8 gene action intersected with a second G protein, Gαs, to provide a cAMP second messenger input into the neurotransmitter release process. Collectively the *C. elegans* RIC-8 gene acts upstream of at least Gαq and Gαs and may maintain both G protein signaling pathways in activated states. It is not understood precisely how RIC-8 acted upon these divergent G proteins. The proposed role was gathered from the observation that mammalian Ric-8A acted as a Gαq GEF and directly activated these G proteins in a manner apart from the action of G protein–coupled receptors (GPCRs).

Ric-8 and G protein αi control of (asymmetric) cell division: Asymmetric cell division (ACD) is a process by which stem cells or progenitor cells divide such that the two daughter cells adopt unique characteristics and cell fate determinants during division (intrinsic ACD), or acquire these characteristics after division by influence of the surrounding tissue/niche (extrinsic ACD). ACD allows one daughter cell to retain stem/progenitor potential and the other to adopt a committed fate. Ric-8 and members of the G protein αi class of



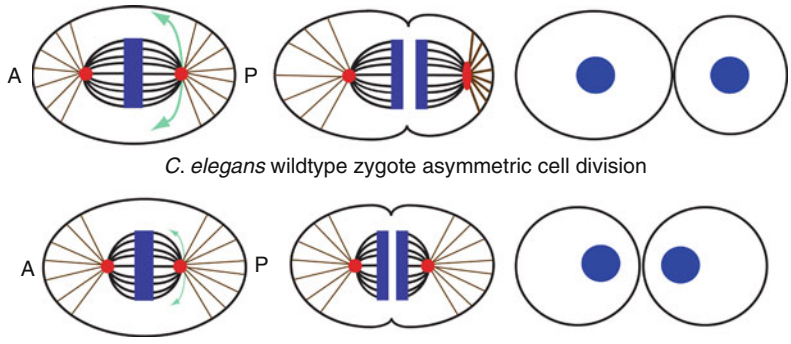
Ric-8, Fig. 2 Proposed pathways depicting *C. elegans* RIC-8 control of Gαq- and Gαs-dependent neurotransmission (*Arrows*: activation, *Bars*: inhibition). Genetic experiments showed that the requirement of the RIC-8 gene for neurotransmission was manifested before the action of the Gαq and Gαs genes. G proteins αq and αs provide divergent inputs to regulate neurotransmitter release through the activation of phospholipase Cβ and adenylyl cyclase, respectively. These two pathways converge to modulate UNC13 function/localization and regulation of synaptic vesicle priming. G protein αo provides an inhibitory input into the pathway, perhaps through diacylglycerol kinase that is regulated by a serotonin responsive GPCR. Gαo regulation was not necessarily thought to involve RIC-8 (5–7)

G proteins have an essential role in directing intrinsic asymmetric-, and perhaps normal-cell division. Gαi regulation in this context is thought to be GPCR-independent, as Gαi-family members reside not only on the plasma membrane, but on intracellular mitotic structures including spindle poles (centrosomes), spindle microtubules, and the cytokinesis midbody (Blumer et al. 2006).

The protein machinery that works with Gαi to control cell division is conserved and consists of components discovered in worms, flies, and mammals. Gαi, Ric-8(A), and orthologous GoLoco- or GPR-domain containing proteins, GPR1/2, PINS, or LGN/AGS3 in mammals are required for asymmetric cell division (ACD) of multiple cell types, including human adult progenitor cells. These and other conserved proteins in the pathway, including NuMA/Lin5/MUDs receive signals from cell polarity determinants to differentially regulate the strength of pulling forces on the two sets of aster microtubules during mitosis (for review and a comprehensive account of primary references, see Siderovski and Willard (2005), Siller and Doe (2009), Wilkie and Kinch (2005), and Yu et al. (2006)). This force differential pulls the entire mitotic spindle and metaphase plate as a unit toward one side of the cell. The asymmetric location of the metaphase plate marks the position of the cleavage plane for cytokinesis. Figure 3 depicts in cartoon format, the original observations demonstrating that the Ric-8, Gαi/o, and GPR1/2 genes were required for *C. elegans* zygote ACD. When these genes were mutated individually, zygotic cell division proceeded symmetrically, leading to developmental catastrophe and death at gastrulation.

The majority of the genetic and cell biological work delineating the influence of this nontraditional G protein pathway on mitotic spindle dynamics has been learned from ACD model systems including the *C. elegans* zygote, *Drosophila* neuroblast, and sensory organ precursor cell. It is clear that the network also operates in mammals to direct *both* symmetric and ACD because homologous and orthologous components of the pathway influence keratinocyte (skin) progenitor cell ACD (LGN, NuMA), neural precursor development (LGN, AGS3, G protein subunits) (for review of primary literature see Siller and Doe (2009)), and division of COS and HeLa cells (Gαi, AGS3) (Blumer et al. 2006; Cho and Kehrl 2007). Recently, Ric-8A and Gαi were shown to recruit LGN, NuMA, and the dynein microtubule motor to the plasma membrane of mitotic HeLa cells. Perturbation of Ric-8A expression, or its interaction with Gαi resulted in defective orientation of the HeLa mitotic spindle to the substratum and aberrant cell division (Woodard et al. 2010).

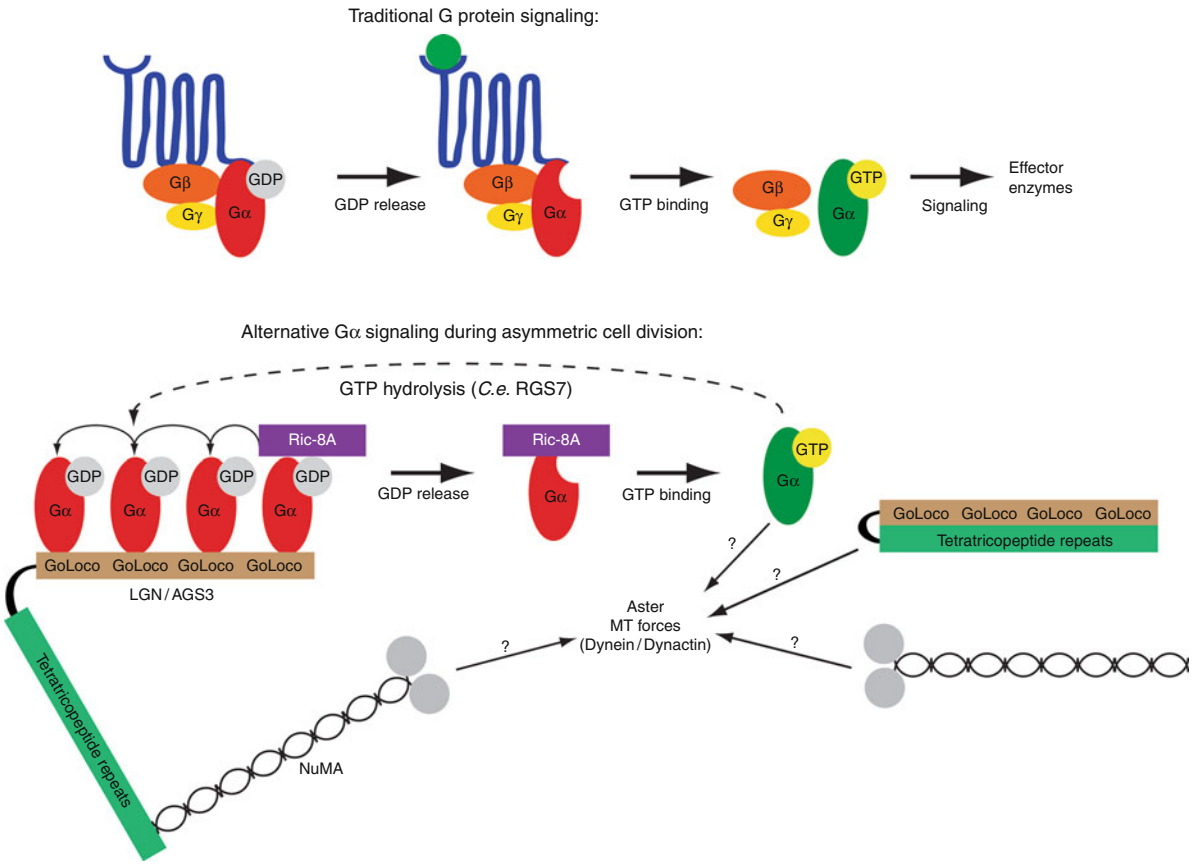
A biochemical demonstration of Ric-8A, Gαi, and GoLoco protein concerted function accounts for how Ric-8 GEF activity could supplant the lack of apparent GPCR-mediated G protein activation in ACD and provides one cellular context for the GoLoco component



Ric-8, Fig. 3 *C. elegans* zygote asymmetric cell division is perturbed in ric-8, gαo, or gpr1/2 mutants. Zygote polarity is determined by the site of sperm entry and designates the posterior (*P*), and anterior (*A*) sides of the zygote. During prophase the mitotic spindle (*black microtubule bundles*) rotates 90° (not depicted) to orient the spindle poles (*red color*) along the anterior and posterior axis of the zygote. Spindle rotation is an aster microtubule (*brown color*)-dependent process and is slowed in ric-8, gαo, or gpr1/2 mutants. Chromosomes (*blue color*) are shown aligned at the metaphase plate with intact mitotic spindles. The distance between spindle poles is reduced in ric-8, gαo, or gpr1/2 mutants. During meta/anaphase, the posterior spindle pole flattens and adopts a violent up and down rocking motion in relation to the A-P axis (*green arrow*) as it and the entire mitotic spindle is pulled toward the posterior side of the zygote by forces generated from the posterior aster microtubules. Overall aster microtubule force and the force differential between the anterior and posterior aster microtubules are considerably weaker in ric-8, gαo, or gpr1/2 mutants. The mutants exhibit a very weak rocking motion of the posterior spindle pole and reduced movement of either spindle pole toward the cell cortex. As chromosome segregation occurs, the cytokinetic cleavage plane appears asymmetrically in wild-type zygotes, closer to the posterior side. Ric-8, gαo, and gpr1/2 mutants lack asymmetrically oriented spindles and subsequently divide symmetrically

as an atypical guanine nucleotide dissociation inhibitor (GDI). In conditions where traditional GPCR signaling is turned off, Gβγ subunits serve as a Gα protein GDI and prevent GDP release. During nontraditional G protein signaling in mitosis and ACD, LGN (GoLoco) binds plasma membrane-bound Gαi-GDP subunits as a GDI. The nuclear mitotic apparatus protein (NuMA) is recruited in allosteric fashion to a binding site on LGN that becomes available when LGN is bound to Gαi (Du and Macara 2004). NuMA is not active in this complex with respect to its incapacity to participate in direct interactions with microtubules (Du et al. 2002). However, complexed NuMA may interact with the dynein microtubule motor complex (Siller and Doe 2009). Ric-8A dissociated a purified Gαi/GoLoco/NuMA complex by removing Gαi-GDP from LGN or AGS3 (GoLoco) through stimulation of nucleotide exchange and production of free Gαi-GTP (Tall and Gilman 2005; Thomas et al. 2008). Once Gαi was dissociated from LGN, the ability of NuMA to bind GoLoco domains was decreased and NuMA was released. Whether the intact GoLoco protein complex or any of the released species (NuMA, GoLoco ortholog, and/or Gαi-GTP) regulate aster microtubule pulling forces to direct spindle asymmetry is not completely clear and is an area of considerable interest. It is unlikely that a static, plasma membrane–bound Gα-GDP:GoLoco complex is the sole form of the G protein responsible for force generation, as rounds of nontraditional G protein guanine nucleotide consumption seem to be required (Wilkie and Kinch 2005). Gαi-GTP is inactivated by RGS GTPase-activating-proteins, which presumably resets the system for another cycle of Ric-8-mediated activation (Hess et al. 2004). Important unresolved questions remain. Does Ric-8(A) actually perform this function in cells and dissociate Gαi/GoLoco/NuMA complexes in the context of aster microtubule force regulation? What is the precise ordering of molecular events that occur downstream of Ric-8A, the intact GoLoco complex, or the dissociated Gαi-GTP, GoLoco, and/or NuMA species that directly signal to the dynein motor complex force generator (Fig. 4)?

Ric-8B and Gαolf regulation of olfaction: The second mammalian Ric-8 homologue was named Ric-8B after it was discovered in yeast two-hybrid screens intended to uncover Gαs-interacting proteins (Tall et al. 2003; Klattenhoff et al. 2003). Mammalian Ric-8/synembryn was renamed Ric-8A at this time. Ric-8A and Ric-8B share ~40% overall amino acid identity.



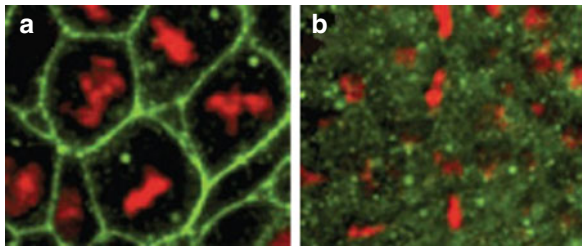
Ric-8, Fig. 4 Biochemical model comparing traditional GPCR-mediated activation of Gαβγ trimers and alternative Ric-8(A) activation of Gαi/GoLoco/NuMA complexes. In the traditional G protein signaling paradigm, inactive G protein trimers are bound to GDP. Gβγ serves as a GDI and prevents Gα subunit GDP release in the absence of GPCR activating ligand (●). Gβγ is also obligate for ligand-receptor complex stimulation of G protein GTP for GDP nucleotide exchange of the Gα subunit. Activated Gα-GTP and Gβγ transduce signals to downstream effector enzymes. In the proposed alternative Gα signaling model that regulates aster microtubule force generation during ACD, Gα-GDP is bound to the alternative GDI GoLoco. A mammalian GoLoco ortholog, LGN, contains four carboxyl-terminal GoLoco domains, and an amino-terminal tetratricopeptide repeat region that binds NuMA. Ric-8A binds Gαi-GDP, and in the process dissociates GDP from Gαi, and Gαi processively from GoLoco domains. GTP then rapidly binds the Ric-8A:Gα nucleotide-free complex producing free Ric-8A and Gα-GTP. As a consequence of Gα:GoLoco dissociation, NuMA is released from LGN and could be available to participate in enhanced interactions with microtubules or microtubule motors. Elucidation of the complete repertoire of molecules, or direct events that result in aster microtubule force generation is not entirely clear (10). Evidence in favor of G protein α i catalytic cycle involvement in this process comes from the finding that mutants of *C. elegans* RGS7 (an activator of G protein GTP hydrolysis) have many opposed phenotypes to ric-8, gαo, and gpr1/2 mutants during ACD (19)

The amino-terminal ~400 amino acids are more divergent (34% identity) and have been predicted to be highly α-helical in content and consist of weakly scoring Armadillo repeats (Wilkie and Kinch 2005). Ric-8A and Ric-8B share greater amino acid identity between the carboxyl-terminal 130–160 amino acids (~56% identity). No obvious protein sub-domains are present in the predicted α-helical Ric-8 carboxyl-termini, but the region in Ric-8B is alternatively spliced.

Ric-8B binds all G protein alpha classes in vitro with the exception of the Gαi-class, and unlike Ric-8A, uniquely binds members of the Gαs-family (Tall et al. 2003; Klattenhoff et al. 2003). Evidence supports a role for Ric-8B in the regulation of Gαolf during olfaction (Von Dannecker et al. 2006). Gαolf is the olfactory/brain-specific Gαs homologue that activates adenylyl cyclase to stimulate olfactory nerve firing. Malnic and colleagues portrayed functional differences between two expressed Ric-8B splice variants

(full length, FL and deleted exon 9, Δ9). Overexpression of Ric-8BFL, but not Ric-8BΔ9 enhanced Gαolf-dependent adenylyl cyclase activation (Von Dannecker et al. 2006). When Gαolf, Gβ, Gγ, odorant receptors, receptor co-factors, and Ric-8BFL, but not Ric-8BΔ9, were co-transfected into a heterologous system (HEK cells), functional odorant receptor coupling was achieved. Application of odorants activated Gαolf-dependent signaling (Von Dannecker et al. 2006; Zhuang and Matsunami 2007). The unresolved question raised from these studies is: Does Ric-8B promote odorant receptor signaling because it activates Gαolf/Gαs as a guanine nucleotide exchange factor, or because it facilitates functional Golf membrane expression in the heterologous system, thereby enhancing Golf coupling to odorant receptors? Overexpression of Ric-8BFL did increase the amount of overexpressed Golf in a crude membrane fraction (Kerr et al. 2008). It was later reported that the single copy of RIC-8 in *Xenopus* appeared to stimulate mammalian Gαs GTPγS binding, although the intrinsic rate of Gαs GTPγS binding reported in this study was negligible (Romo et al. 2008). A positive demonstration of mammalian Ric-8B protein function as a Gαs-class GEF has not been made as of yet (Nagai et al. 2010). Ric-8B is hypothesized to be a Gαs and Gαq-class GEF since it interacts with these subunits in vitro, and by analogy (and homology) to the described activities of Ric-8A. Ric-8A is a GEF for all Gα subunits that it can bind.

Ric-8 proteins support heterotrimeric G protein membrane expression: An alternative hypothesis of Ric-8 protein function was proposed from work performed on the sole copy of the *Drosophila* and *C. elegans* RIC-8 genes. Attenuation of *Drosophila* RIC-8 expression caused nearly complete and pleotropic loss of multiple Gα subunits and the major Gβ (and presumably Gγ) subunit from the plasma membrane (for review and primary literature references see Matsuzaki (2005)). *Drosophila* Gαi (Fig. 5), Gαo, and Gβ13F subunits were expressed in the cytosol or vesiculated compartments of *Drosophila* embryonic epithelial cells derived from larvae possessing both a maternal and zygotic P-element disruption of RIC-8. Overall steady-state expression levels of the mis-localized Gαi and Gβ were reduced in the absence of RIC-8. These findings were corroborated at the same time in *C. elegans* when cortical Gpa16 (a Gαi homologue) localization was attenuated

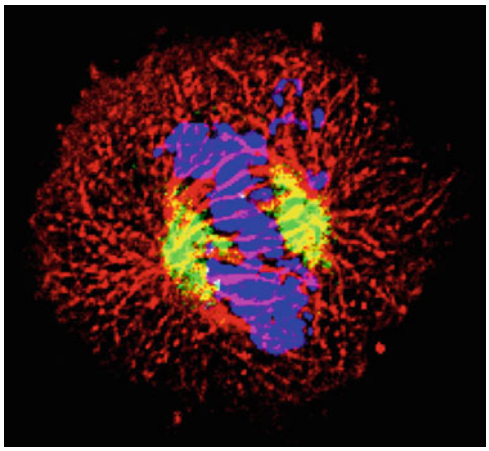


Ric-8, Fig. 5 *Drosophila* Gαi was mis-localized and not expressed on the plasma membrane when RIC-8 was P-element disrupted. Epithelial cells from (**a**) wild-type or (**b**) ric-8 mutant *Drosophila* embryos were stained with an anti-Gαi antibody (*Green*) and a DNA stain (*Red*) (Adapted by permission from Macmillan Publishers Ltd: Nature Cell Biology, (28). 2005)

in mitotic ric-8 mutant embryos (Afshar et al. 2005). More recently, RNAi-mediated reduction of mammalian Ric-8B resulted in reduced Gαs expression, and Ric-8B overexpression protected Gαs from ubiquitin-mediated degradation (Nagai et al. 2010). The provocative hypothesis arising from these findings is that the function of Ric-8 protein(s) may be to serve as key factors required for G protein subunit biosynthesis, or trafficking to, or retention at the plasma membrane. It is known that cytosolic G proteins are less stable than membrane-bound G proteins, so a shift of G proteins from the membrane to the cytosol in the absence of Ric-8 would be realized as a reduction in G protein steady-state expression levels. Aside from the finding that Ric-8B overexpression reduced levels of ubiquitinated Gαs, there is little understanding of the mechanism by which Ric-8-proteins mediate G protein membrane localization.

Summary

The hypothesis that Ric-8 proteins are required for efficient G protein membrane expression provides a potential explanation, in part, for the findings that Ric-8 proteins seem to exert affects upstream of divergent G protein signaling pathways (i.e., Gαq, synaptic transmission, Gαi, cell division, Gαolf olfaction, etc.). The one observation that cannot be explained intuitively by the idea that Ric-8 proteins are simply factors required for G protein expression is that Ric-8(A) is a mitotic spindle (pole) binding protein (Fig. 6 and Woodard et al. 2010; Hess et al. 2004). This result suggests that Ric-8A might participate as



Ric-8, Fig. 6 Ric-8A localizes proximally to the mitotic spindle poles. HeLa cells were transfected with YFP-Ric-8A (*Yellow-green*) and stained with DAPI (*Blue*) and by immunofluorescence with anti-α-tubulin monoclonal antibody (*Sigma*) and an anti-mouse Alexafluor-568 antibody. The tricolor images were captured using a Zeiss epifluorescence microscope with appropriate filters and subjected to nearest-neighbors deconvolution using Slidebook 4.0 software (unpublished observations)

a non-receptor GEF to activate intracellular Gαi-class G proteins that are localized on mitotic structures, including the mitotic spindle.

There are multiple regulatory points where Ric-8 proteins could act to promote or stabilize G protein membrane expression. Ric-8 proteins might act during G protein biosynthesis in positive fashion to promote stable membrane expression, or they could exert a protective role upon mature membrane–bound G proteins as these G proteins cycle between the plasma membrane and endo-membranes. Biosynthetic (forward) trafficking of G proteins to the plasma membrane requires two basic events: (1) G protein heterotrimer assembly on the endoplasmic reticulum (ER) and/or Golgi and (2) covalent attachment of lipid moieties to Gα and Gγ subunits (Marrari et al. 2007). Chaperone proteins including phosducin-like protein-1 (PhLP) and DRIP78 bind nascent Gβ and Gγ proteins, respectively, prior to Gβγ dimer formation (Dupre et al. 2007; Lukov et al. 2005). No component is known that binds nascent Gα after its synthesis, and aids its assembly into G protein trimers. Ric-8 proteins could fulfill such a role. In the absence of Ric-8 expression, Gα subunits not assembled into trimers would not reach the plasma membrane and would be more susceptible to degradation.

Ric-8 proteins could also potentially function in a capacity to counteract G protein downregulation by promoting G protein subunit recycling to the membrane. Debate exists whether G protein subunits become "solubilized" from membranes or clustered into membrane micro-domains upon activation by hormone receptors. Ric-8A and Ric-8B reside predominantly in the cytosol. Perhaps Ric-8 proteins function to "scavenge" cytosolic Gα subunits to restore membrane association. Upon experimental perturbation of Ric-8 protein expression, Gα subunits might slowly "leach off" the membrane over time due to tonic GPCR stimulation. If the pace of Gα biosynthesis does not keep up, this would be realized as a reduction in steady-state G protein expression. G proteins also cycle between the plasma membrane and Golgi membranes, perhaps as a means to receive reversible palmitoylation at the Golgi. Heterotrimeric G protein retrograde movement to the Golgi occurs at a rate faster than that predicted of a vesicular-transport-mediated event ($t_{1/2}$ <1 min) (Chisari et al. 2007; Tsutsumi et al. 2009). As such, G proteins were predicted to transit diffusively through the cytosol to the Golgi. It is not entirely clear whether G proteins transit as heterotrimers, or as free Gα or Gβγ species. If the latter, one could easily envision that an escort factor would be required to transit Gα (and Gβγ) to the proper intracellular membranes lest it signal inappropriately during transport. Small G proteins including Ras and Rab homologues share this type of membrane cycling principle. Rab GTPases utilize a combination of soluble GDI, GEF, and "escort" factors to shuttle unlipidated Rabs throughout the cell, present Rabs to the lipidation machinery, and target the lipidated Rabs to the correct cellular membrane compartment (Ali and Seabra 2005).

Given the known in vitro biochemical function of Ric-8 proteins as soluble G protein α subunit GEFs, it is a challenge, although conceivable, to envision a role for Ric-8 protein involvement in any one of these G protein subunit trafficking or biosynthetic processes. In this context, Ric-8 "GEF activity" could serve simply as a mechanism to regulate Gα:Ric-8 binding/dissociation. In this highly prospective role, Ric-8 would bind Gα subunits (either nascent chains, or mature membrane Gα) and traffic/escort the Ric-8:Gα nucleotide-free complex to the proper destination (the Golgi, or Gβγ on the ER or plasma membrane). At the destination, Ric-8 would be

invoked to stimulate GTP binding to Gα and release an activated-Gα species. Gα would hydrolyze its bound GTP, return to the inactive state, and reassociate with Gβγ or GoLoco.

Rin (Ras-Like Protein in Neurons)

Weikang Cai, Jennifer L. Rudolph and Douglas A. Andres
Department of Molecular and Cellular Biochemistry, University of Kentucky College of Medicine, Lexington, KY, USA

Synonyms

Small G-protein; Small GTPase; Small GTP-binding protein

Historical Background

Ras superfamily small GTP (guanosine triphosphate)-binding proteins function as molecular switches, responding to extra- and intracellular stimuli to control the activity of diverse signaling cascades. To date, over 150 different small GTPases have been identified and are classified into six distinct subfamilies: Ras (Rat sarcoma), Rho (Ras homolog gene family), Rab (Ras-related GTP-binding protein), ARF (ADP-ribosylation factor), Ran (Ras-related nuclear protein), and RGK (Rad/Gem/Kir family), based upon both sequence homology and the regulation of common cellular functions (Colicelli 2004). Rin (Ras-like protein in neurons), along with Rit (Ras-like protein in many tissues) and *Drosophila* Ric (Ras-related protein which interacted with calmodulin), comprise the Rit subfamily of Ras-related small GTPases (Lee et al. 1996). Rin is expressed exclusively within neurons and has been characterized as regulating neuronal differentiation by controlling distinct signaling cascades (Lee et al. 1996; Shi et al. 2005, 2008; Spencer et al. 2002). Rin contributes to nerve growth factor (NGF)-mediated neurite outgrowth via ERK (extracellular signal regulated MAP kinase) and p38 MAP kinase pathways (Shi et al. 2005), whereas in pituitary adenylate cyclase-activating polypeptide 38 (PACAP38)-mediated neuronal differentiation, Rin controls the cAMP (cyclic adenosine monophosphate) /PKA (protein kinase A) signaling cascade (Shi et al. 2008). In addition, Rin is involved in Brn-3a and Plexin signaling (Calissano and Latchman 2003; Hartwig et al. 2005). Rin also associates with the polarity protein PAR6 and has been found to display modest transforming ability (Hoshino et al. 2005).

Biochemical Characterization of Rin GTPase

Rin was originally isolated from mouse retina, and both Northern analysis and in situ hybridization studies indicated that it is expressed solely in neurons (Lee et al. 1996). Rin possesses most of the common characteristics of Ras subfamily members, including a high degree of amino acid conservation within the five Ras core regions (the G1-G5 domains) which are essential for GTP binding and hydrolysis (Colicelli 2004). However, Rin also contains a number of unique features including calmodulin (CaM) binding (Harrison et al. 2005), the lack of prenylation consensus sites or other lipidation signals within the C-terminus, and an effector domain that differs from other Ras subfamily proteins (Lee et al. 1996). These features have generated speculation that Rin might regulate important aspects of neuronal growth and differentiation (Hoshino and Nakamura 2003; Shi et al. 2005, 2008; Spencer et al. 2002).

Recombinant Rin has been shown to specifically bind guanine nucleotides (guanosine triphosphate or guanosine diphosphate, GTP/GDP) in the presence of

Mg^{2+} and to exhibit low intrinsic GTPase activity (Shao et al. 1999). Surprisingly, the guanine nucleotide dissociation rates for purified Rin protein are significantly different when compared with the majority of Ras-related GTPases. Rin displays higher k_{off} values for GTP than GDP (Shao et al. 1999). These GTP dissociation rates are five- to tenfold faster than most Ras-like GTPases. Since the cellular concentration of GTP is much higher than that of GDP, these biochemical studies suggest that a relatively high percentage of Rin may remain in the GTP-bound state under basal conditions. Despite these unique biochemical properties, the available data indicate that Rin functions as a nucleotide-dependent molecular switch, and as predicted, only a very low in vivo level of GTP-bound Rin is found in unstimulated cells (Shi et al. 2008; Spencer et al. 2002). Therefore, these in vitro studies do not appear to accurately represent Rin activity in the normal cellular environment. It is possible that the presence of cellular regulatory proteins contribute to these differences.

Rin Cellular Distribution and Trafficking

For the majority of Ras-related GTPases, association with specific cellular membranes is essential for their biological activities (Colicelli 2004). Conserved C-terminal cysteine-rich motifs are used to direct covalent modification by isoprenoid lipids (prenylation). Prenylation is the initial step in the attachment of these proteins to the cytoplasmic leaflets of a variety of cellular organelles. However, specific membrane localization often requires additional targeting signals, provided either by a cluster of basic amino acids or the palmitoylation of internal cysteine residues (Heo et al. 2006). For example, adjacent to the CAAX prenylation motif ("C" is Cysteine, "A" is an aliphatic amino acid, and "X" is variable), H-Ras and N-Ras have a cysteine residue for palmitoylation, directing the protein to the plasma membrane via the Golgi apparatus. In contrast, K-Ras4A has a lysine-rich polybasic motif, which leads the protein to the plasma membrane more rapidly through a Golgi-independent route (Colicelli 2004).

Surprisingly, analysis of an over-expressed GFP (green fluorescent protein)-tagged protein indicates that Rin primarily localizes to the nucleus, although a detectable amount of GFP protein is also found at the plasma membrane in these studies (Heo et al. 2006). Investigation of the Rin C-terminus has provided key insights into this unique subcellular distribution. Distinct from the majority of G-proteins, the Rit and RGK family GTPases lack a CAAX motif, and instead contain a polybasic cluster at the C-terminus (Heo et al. 2006). Interestingly, sequence analysis of the Rin polybasic motif reveals a canonical nuclear localization signal (NLS) (K-K/R-x-K/R). Additionally, Heo et al. have demonstrated the importance of the polybasic C-terminal region in targeting the protein to the plasma membrane via interactions with phosphatidylinositol 4,5-bisphosphate ($PI4,5P_2$) and phosphatidylinositol 3,4,5-trisphosphate ($PI3,4,5P_3$) lipids (Heo et al. 2006). Thus, Rin appears capable of shuttling between the nucleus and plasma membrane in a PIP-lipid dependent fashion, allowing for a novel cellular trafficking pattern, which may contribute to the physiological function of Rin.

The C-terminus of Rin has also been reported to direct Ca^{2+}-dependent interactions with calmodulin (CaM) (Hoshino and Nakamura 2002; Lee et al. 1996). Although CaM binding has been shown to be important for neurite outgrowth mediated by Rin (Hoshino and Nakamura 2003), the exact signaling mechanism as well as the physiological significance of CaM binding still needs to be elucidated. The Rin homolog *Drosophila* Ric was originally identified as a CaM binding protein, and genetic studies suggest that CaM association contributes to the regulation of Ric signaling (Harrison et al. 2005).

Regulation of Rin Activity

Like most Ras GTPases, Rin is activated by exchanging GDP with GTP in the nucleotide binding pocket, which results in conformational changes that expose the effector domain and promote the recruitment of proteins responsible for signal transduction cascade activation. This classic GTPase cycle is regulated by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs), which are responsible for the release of bound GDP and the induction of intrinsic GTPase activity, respectively. However, to date no Rin-specific GEFs or GAPs have been identified.

Several Rin point mutations have been reported to block intrinsic GTPase activity or GTP/GDP

exchange, leading to a protein locked in the active or inactive state, respectively. Mutation of Gln78 to Leu (Rin^{Q78L}), equivalent to the oncogenic Ras^{Q61L} mutation, causes complete inhibition of GTP hydrolysis, resulting in a constitutively active Rin mutant. Meanwhile, the Rin^{S34N} mutation, equivalent to dominant-negative Ras^{S17N}, is predominantly GDP-bound (Shao et al. 1999), and disrupts signal transduction when over-expressed (Shi et al. 2005). Both of these mutations have proved useful in the analysis of Rin GTPase function.

Rin Effectors

The G2 domain of Ras GTPases is known as the "effector domain" and serves as the primary region of interaction responsible for directing downstream effector protein binding following G-protein activation. Rin shares a conserved effector domain (HDPTIEDAY) with Rit, and this domain is evolutionarily conserved within the subfamily, as there is only a single amino acid substitution in the *Drosophila* Ric effector loop (HDPTIEDSY). In addition, the Rin effector domain shares seven out of nine residues with the Ras effector loop (YDPTIEDSY) (Shao et al. 1999). This high rate of conservation has led to the suggestion that Rin is likely to control distinct, but perhaps partially overlapping, downstream signaling pathways compared to Ras.

A variety of proteins have been implicated as candidate Rin effectors using yeast two-hybrid screens (Shao et al. 1999). These studies first identified the Ras-binding domain (RBD) from the Raf kinases as binding partners for constitutively active Rin^{Q78L}. Recent in vivo co-immunoprecipitation analyses in pheochromocytoma cells (PC6) support these initial findings by demonstrating that active Rin preferentially associates with B-Raf, suggesting that B-Raf functions as a valid downstream target of Rin (Shi et al. 2005). However, whether B-Raf directly binds Rin in vivo, thus acting as a true effector, has yet to be determined. Rin also interacts with the Ras interacting domains (RID) of two Ral exchange factors, RalGDS and RLF, in yeast two-hybrid screens suggesting that Rin may regulate Ral GTPase signaling (Shao et al. 1999), although this hypothesis has not been formally tested. While Rin appears capable of associating with a number of known Ras effectors, in agreement with Rin's distinct G2 domain sequence, not all known Ras effectors demonstrate Rin binding. For example, active Rin does not bind to RIN1 or p110, the catalytic subunit of PI3K (Shao et al. 1999). More interestingly, Rin directly associates with the PDZ domain of PAR6, a cell polarity-regulating molecule, in a GTP-dependent fashion. This interaction requires an intact Rin G2 effector domain, suggesting that PAR6 may represent the first authentic Rin effector that does not also associate with Ras (Hoshino et al. 2005).

The identification of effectors for Ras-like small GTPases is not only important for understanding their physiological functions, but the minimum GTPase binding domain of select effector proteins have been adapted for use in pull-down activity assays. In the case of Rin, both the Raf-RBD and the RalGDS-RID have been used to examine in vivo Rin activity (Hoshino and Nakamura 2002; Spencer et al. 2002).

Functions of Rin GTPase

Rin can be activated by a variety of extracellular stimuli, including NGF, epidermal growth factor (EGF), ionomycin, and tocopherol acetate (Hoshino and Nakamura 2002; Spencer et al. 2002), suggesting that Rin controls the activation of a variety of signaling pathways and cellular functions. Indeed, a significant amount of work has been performed to understand the physiological role of Rin GTPase-mediated signaling.

Hoshino et al. first demonstrated that GTP-bound Rin associated with the PDZ domain of PAR6 (Hoshino et al. 2005), which has previously been shown to bind the GTP-bound active forms of the Rho family GTPases Rac and Cdc42 (Qiu et al. 2000). In contrast, despite the high homology to Rin, Rit associates in a GTP-independent fashion with PAR6C, one of the three PAR6 isoforms, which is preferentially expressed in the brain. Unlike Rin/PAR6 binding, the Rit/PAR6C interaction does not require an intact PAR6C PDZ domain (Rudolph et al. 2007). These differences suggest distinct mechanisms in Rit/Rin-mediated PAR6 signaling. More importantly, these same studies suggested that Rin can promote the formation of a larger Rin-PAR6-Rac/Cdc42 ternary complex scaffolded by PAR6 (Hoshino et al. 2005). Enlightened by the role of Rac/Cdc42 in tumorigenesis, Hoshino and colleagues have further explored the role of Rin in cell transformation and

demonstrated that the Rin-PAR6-Rac/Cdc42 complex was capable of enhancing the formation of foci in NIH-3T3 cells (Hoshino et al. 2005). Although the lack of endogenous Rin expression in fibroblasts complicates the interpretation of this study, these data suggest that Rin may function in tumorigenesis. Moreover, since PAR6 is known to contribute to the regulation of axon specification (Shi et al. 2003), it is possible that the Rin-PAR6-Rac/Cdc42 complex plays a pivotal role in axonal/dendritic growth.

The exclusive expression of Rin in neurons indicates a critical role for Rin in the central nervous system. Indeed, over-expression of a constitutively active Rin mutant alone is capable of inducing neurite outgrowth in PC6 cells (Hoshino and Nakamura 2003; Shi et al. 2005), suggesting a physiological role for Rin signaling in neuronal differentiation and development. shRNA-mediated knockdown of Rin dramatically reduces NGF-mediated neurite outgrowth in PC6 cells, suggesting that Rin is a pivotal component of NGF signaling by regulating both ERK and p38 MAPK pathways (Shi et al. 2005). Further detailed mechanistic studies have revealed that Rin activates ERK through B-Raf. Rin selectively regulates the p38α MAPK isoform in vitro; however, the mechanism of Rin-mediated p38 activation has yet to be determined (Shi et al. 2005). The identification of a Rin-PAR6-Rac/Cdc42 complex suggests a putative pathway (Hoshino et al. 2005), since Rac and Cdc42 are known to serve as upstream regulators of p38 MAPK signaling (Shin et al. 2005).

PACAP38 potently induces neuronal differentiation through the activation of PACR1, a heterotrimeric G-protein-coupled receptor (GPCR). Rin is activated downstream of PACAP38 and appears to play a critical role in PACAP38-mediated neuronal differentiation. Typically, PACAP38-mediated PACR1 activation results in stimulation of a $G\alpha_s$-adenylate cyclase (AC)-cAMP signaling cascade. However, PACAP38-dependent Rin activation is mediated by Src downstream of $G\alpha_{s/i}$ and functions upstream of the cAMP/PKA signaling cascade, which in turn regulates heat shock protein 27 (HSP27) phosphorylation (Shi et al. 2008). HSP27 serves as a chaperone to facilitate correct protein folding, has been reported to regulate cytoskeleton stability, and has known roles in neuronal morphology and survival signaling (Stetler et al. 2009). Indeed, RNAi-mediated silencing of HSP27 is sufficient to block PACAP38- and Rin^{Q78L}-induced neurite outgrowth (Shi et al. 2008), further supporting the notion that HSP27 serves as a critical downstream target of Rin in neuronal differentiation.

Rin has also been found to associate with the intracellular domain of Plexin B3, a member of the Plexin family of semaphorin receptors (Hartwig et al. 2005). Semaphorins are secreted or membrane-bound proteins that provide critical guidance signals to redirect or inhibit axonal growth (Vanderhaeghen and Cheng 2010). Given the ability of Rin to promote neurite outgrowth, an intriguing possibility is that Rin signaling contributes to Plexin B3-mediated axonal extension/retraction. Indeed, Plexin B1 has been shown to function as a GAP, down-regulating R-Ras GTPase activity to induce axonal retraction (Oinuma et al. 2004). Despite the report of the direct interaction of Rin with Plexin B3, it remains to be determined whether Plexin B3 functions as a RinGAP.

Calissano et al. used a yeast two-hybrid screen to identify a putative interaction between Rin and the N-terminus of Brn-3a, a transcriptional factor widely expressed in the peripheral nervous system. Surprisingly, Brn-3a preferentially associated with GDP-bound Rin (Calissano and Latchman 2003), and only GDP-bound Rin was shown to induce Brn-3a-mediated gene transcription. However, unstimulated neurons contain high basal levels of GDP-Rin, and additional studies are needed to determine whether transient in vivo fluctuations in GDP-Rin levels contribute to Brn-3a-mediated neuronal gene transcription.

Summary

To our knowledge, Rin is the only Ras subfamily GTPase to be expressed exclusively in neurons. In keeping with this unique expression pattern, in vitro studies indicate that Rin serves as a critical mediator of pheochromocytoma cell neurite outgrowth, acting to couple diverse extracellular stimuli (e.g., NGF, PACAP38) to the activation of ERK and p38 MAPK pathways, cAMP/PKA cascade signaling, and the PAR6-Rac/Cdc42 polarity pathway. In addition, preliminary reports suggest that Rin contributes to both Plexin- and Brn-3a-mediated neuronal differentiation. Despite this progress, much remains to be elucidated concerning the molecular mechanisms that govern these diverse actions. To date, our understanding of Rin function comes from

over-expression and RNAi silencing studies in mammalian cell lines, and future studies must investigate the neuronal effects of Rin ablation making use of genetically engineered Rin null animals. A deeper understanding of in vivo Rin regulation, together with the identification of additional Rin effector proteins, will be critical to define the physiological function of this novel neuronal regulatory protein.

Historical Background

The RIN1 and RIN2 genes were first identified in a selection for expressed human cDNAs that suppress

phenotypes associated with oncogenic RAS mutations in a yeast model system (Colicelli et al. 1991). Subsequent analysis demonstrated that RIN1 binds specifically to activated (GTP-bound) human HRAS (Han and Colicelli 1995; Han et al. 1997), suggesting that RIN1 is a downstream effector of RAS family proteins. RIN2 and RIN3 also bind to activated HRAS (Rodriguez-Viciana et al. 2004). All three RIN proteins contain a carboxy terminal RAS association (RA) domain that mediates this interaction (Colicelli (2004)).

It was subsequently reported that RIN1 encodes a VPS9-related guanine nucleotide exchange factor (GEF) function specific for the RAB5 family of early endocytosis GTPase (Tall et al. 2001). RIN2 and RIN3 also encode VPS9-type GEF domains upstream of the RA domain. This suggests that RIN family proteins are RAS effectors that promote RAB5 function, connecting RAS activation to receptor endocytosis.

Another defining feature of RIN proteins is their amino terminal SRC homology 2 (SH2) domain. The RIN1 SH2 domain mediates binding to activated receptor tyrosine kinases (Barbieri et al. 2003), which likely facilitates endocytosis and downregulation of these receptors. The RIN2 and RIN3 SH2 domains show some species variation (discussed below).

RIN1 also binds and activates ABL1 and ABL2 tyrosine kinases (Cao et al. 2008; Hu et al. 2005). This capacity requires an amino terminal fragment of RIN1, which may not be functionally conserved in RIN2 and RIN3.

RIN Family: Evolution and General Properties

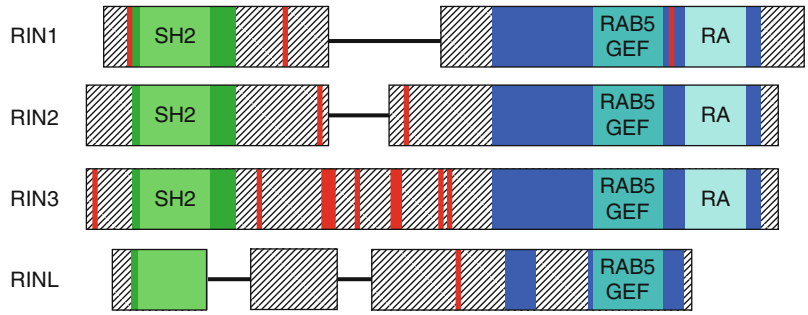
The RIN family of genes likely evolved from a progenitor represented in arthropods by the fruit fly *Drosophila melanogaster* gene Sprint (Szabo et al. 2001) and in echinoderms by the sea urchin *Strongylocentrotus purpuratus* gene annotated as Rin2L (www.spbase.org). The fruit fly and sea urchin gene products show strong conservation with vertebrate RIN proteins in the amino terminal SH2 domain and the carboxy terminal GEF domain. However, the fruit fly and sea urchin RIN proteins show no significant alignment with vertebrate RIN proteins in the central region or in the RA domain. This suggests that the gene expansion that gave rise to a RIN family in vertebrates was accompanied by the development of RAS effector capability. A recently described vertebrate RINL gene (Woller et al. 2011) encodes a protein that aligns with RIN1-3 but has no RA domain (Fig. 1), and may represent the vestige of a pre-vertebrate RIN gene.

Specific properties of each are described in the following sections.

RIN1

RIN1, the defining member of the RIN protein family, is a RAS effector that couples cell signaling with receptor trafficking and cytoskeletal remodeling. It is localized to the cytoplasm and the plasma membrane. Binding of RIN1 to RAS is GTP-dependent and mediated by the carboxy-terminal region of RIN1 (Han et al. 1997). RIN1 overexpression suppresses fibroblast transformation by $HRAS^{G12V}$, likely by competing with RAS effectors that promote mitosis and suppress apoptosis (Wang et al. 2002). RIN1 localizes in cytoplasmic and membrane compartments, and this partition is regulated through a 14-3-3 interaction. Phosphorylation of RIN1-Ser^{351} by ▶ PKD enhances 14-3-3 binding, and mutation of this residue shifts RIN1 localization to the plasma membrane (Wang et al. 2002). This result suggests that 14-3-3 binding reduces access to RAS proteins, which are membrane tethered.

RIN1 encodes a VPS9 subfamily GEF domain that mediates endosome fusion and receptor endocytosis through activation of RAB5 family proteins (Tall et al. 2001). RIN1 preferential associates with and activates the RAB5A isoform (Chen et al. 2009). The SH2 domain of RIN1 binds to activated (tyrosine phosphorylated) EGFR to promote receptor downregulation (Barbieri et al. 2003). Through a proline-rich domain, RIN1 may recruit STAM2, a component of the ESCRT (endosomal sorting complex required for transport) machinery, and facilitate trafficking of ubiquitinated EGFR to lysosomes (Kong et al. 2007). RIN1 also promotes internalization of the TGF-β receptor through RAB5 activation. In this case, however, the result is increased signaling through SMAD2/3 and the transcription repressor SNAI1 (Hu et al. 2008). The contribution of RIN1 to growth factor receptor internalization and signaling may account for the observed silencing of RIN1 in breast tumor cells (Milstein et al. 2007) and enhanced expression in non-small cell lung adenocarcinoma cells (Tomshine et al. 2009).



RIN Family Proteins (RIN1, RIN2, and RIN3), Fig 1 RIN Protein Family in Vertebrates. Conserved domains include SRC Homology 2 (SH2), Guanine nucleotide Exchange Factor (RAB5 GEF) and RAS Association (RA). Regions of sequence conservation are shown in green and blue. Lines indicate gaps in alignment. Red bars are used to denote proline-rich motifs common to SH3 ligands ([RKHYFW]xxPxxP and PxxPx[RK]) and WW domain ligands (PPxY and PPPPP)

Other downstream effectors of RIN1 are the ABL family non-receptor tyrosine kinases. The ABL SH3 domain mediates binding to a proline-rich motif in RIN1, leading to ABL-mediated phosphorylation of RIN1-Y^{36} and subsequent association with the ABL SH2 domain (Han et al. 1997; Afar et al. 1997). Binding of RIN1 to ABL relieves autoinhibition and stimulates ABL tyrosine kinase activity (Cao et al. 2008; Hu et al. 2005). As a positive regulator of ABL activity, RIN1 regulates actin remodeling. Mammary epithelial cells from $Rin1^{-/-}$ mice show extensive peripheral-actin networks, enhanced attachment to fibronectin, and increased cell motility (Hu et al. 2005). RIN1 potentiates the catalytic and transforming activity of the BCR-ABL1 fusion oncogene, and RIN1 over-expression increases BCR-ABL1 mediated leukemogenesis in a mouse model system (Afar et al. 1997). Importantly, the $ABL1^{T315I}$ mutant resistant to therapeutic kinase inhibitors remains responsive to positive regulation by RIN1 (Cao et al. 2008), and *Rin1*$^{-/-}$ bone marrow cells were refractory to transformation by BCR-$ABL1^{T315I}$ (Thai et al. 2011). These results suggest that the RIN1::ABL1 interaction may be a drugable vulnerability of oncogenic ABL fusion proteins.

Rin1 is most strongly expressed in mature forebrain neurons, with moderate expression in hematopoietic and epithelial cells (Dzudzor et al. 2010). This restricted expression of Rin1 is mediated in part by SNAI1. The Rin1 promoter sequence also contains a consensus recognition site for the transcription repressor REST. Deletion of this region surprisingly led to a reduction in reporter gene expression, suggesting that elements in this region enhance expression and may be positively regulating Rin1 expression in neuronal cells (Dzudzor et al. 2010).

$Rin1^{-/-}$ mice are viable and fertile and show no gross morphological abnormalities. However, they have elevated amygdala LTP (long-term potentiation) and enhanced fear conditioning, suggesting that Rin1 normally acts as a negative regulator of synaptic plasticity in this region (Dhaka et al. 2003). In addition, $Rin1^{-/-}$ mice are deficient in conditioned fear extinction and latent inhibition (Bliss et al. 2010). $Rin1^{-/-}$ mice have normal hippocampal-dependent learning, as well as normal motor learning, anxiety, and exploratory behavior, suggesting that $Rin1^{-/-}$ mice may be a useful model for studying neuropsychiatric conditions such as PTSD (post-traumatic stress disorder).

RIN2

The RIN2 gene is widely expressed in mouse, based on analysis of mRNA levels ((Kajiho et al. 2003), BioGPS.gnf.org). The SH2, GEF, and RA domains first characterized in RIN1 are well conserved in RIN2, which has demonstrable guanine nucleotide exchange activity on RAB5 (Saito et al. 2002) and RAS interaction properties (Rodriguez-Viciana et al. 2004). However, RIN2 gene products in primates (human and chimpanzee) differ from their orthologs in other vertebrates (cow, dog, mouse, opossum, chicken, frog, and fish) in two notable aspects. First, the amino termini of primate RIN2 proteins extend about 50 residues beyond other vertebrate RIN2 gene products. Second, an arginine residue critical for the phosphotyrosine binding function of SH2 domains (mouse Rin2: $FLVR^{122}$) is instead a histidine in primate RIN2 (human RIN2: $FLVH^{171}$).

Loss of function mutations in RIN2 are associated with two related human connective tissue disorders referred to as MACS (Basel-Vanagaite et al. 2009) and RIN2 Syndrome (Syx et al. 2010).

RIN3

RIN3 was first described as a novel RAB5 guanine nucleotide exchange factor, isolated from a human leukocyte cDNA library based on a yeast two-hybrid screen for $RAB5B^{Q79L}$ interacting proteins (Kajiho et al. 2003).

RIN3 contains the GEF, RA, and SH2 domains conserved throughout the RIN gene family. It demonstrates guanine nucleotide exchange activity for RAB5 (Kajiho et al. 2003) and associates with activated RAS (Rodriguez-Viciana et al. 2004). The SH2 domain sequence of RIN3, like that of RIN2, shows a curious divergence at the FLVR motif. The sequences of most vertebrates, including human, encode the arginine residue critical for phosphotyrosine binding. But several species (pig, cow, cat, rat, and mouse) have a cysteine substitution at this key position, implying that RIN3 in these organisms may function somewhat differently.

RIN3 also associates with BIN1 (a.k.a. amphyphisin II), a membrane-bending protein involved in endocytosis (Kajiho et al. 2003). RIN3 can translocate to RAB5 positive endosomes and deletion of the RA domain caused RIN3 to be constitutively located to endocytic vesicles, suggesting that the RA domain has an autoinhibitory effect on RIN3's endosomal localization (Yoshikawa et al. 2008).

In mice, RIN3 expression is highly enriched in mast cells with lower expression levels in other hematopoietic tissues including lymph node, bone, and T cells (http://symatlas.gnf.org). Protein levels in established human cell lines also indicate enrichment in mast cells (CJ and JC, 2011).

Summary

RIN1-3 proteins connect RAS signal transduction with RAB5 activation and receptor endocytosis. RIN1 has a special role in ABL tyrosine kinase regulation, with a likely contribution to cytoskeleton remodeling. A mouse knockout model suggests RIN1 involvement in stimulation-induced signal transduction in multiple cell types. Mouse models of RIN2 and RIN3 deficiencies have not yet been described.

There are several outstanding questions to be answered regarding the biochemistry of RIN proteins. Particularly curious is a species-specific divergence in the SH2 domain arginine residue required for phosphotyrosine binding. Does this imply an alternate function for these SH2 domains? Further study is also needed to identify the full range of protein partners, and to determine the location and consequence of these interactions.

Evidence for the involvement of RIN proteins in human pathologies is just beginning to emerge. RIN1 appears to collaborate in tumorigenesis at multiple levels in ways that are complex and cell type specific. In addition, the fear learning and extinction phenotypes of $Rin1^{-/-}$ mice suggest that reduced RIN1 function in forebrain neurons could contribute to post-traumatic stress disorder. The correlation of RIN2 deficiency with connective tissue disorders provides another clear indication that RIN proteins play diverse and essential roles in human physiology.

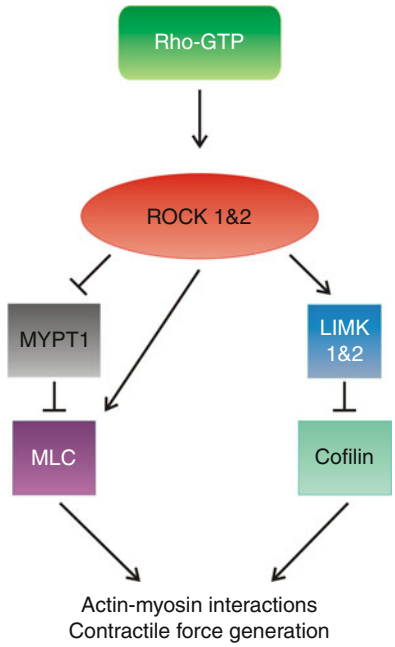
Historical Background

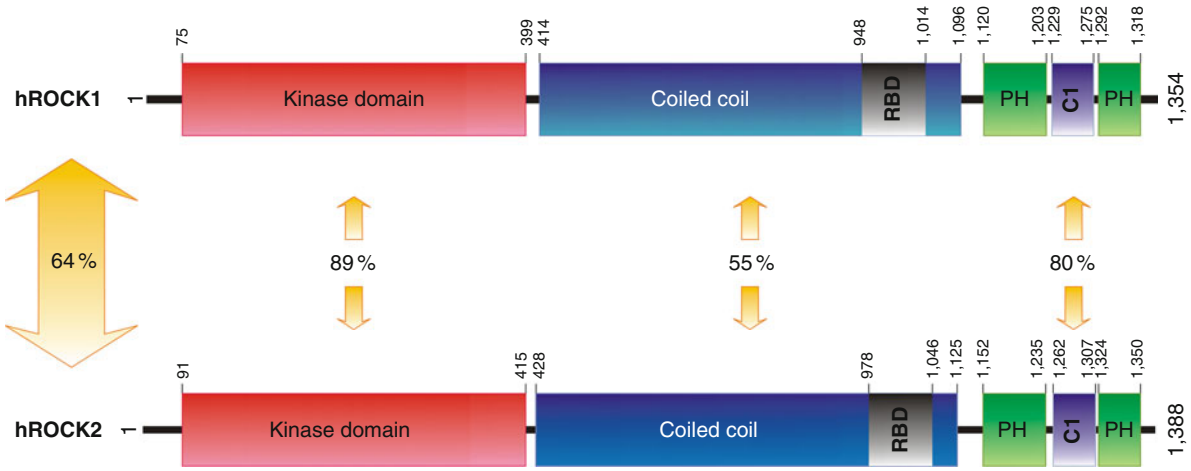
The small molecular weight GTP-binding proteins of the Rho family, which comprises 22 proteins including RhoA, Rac1, and Cdc42, were originally isolated based on their high degree of homology with the Ras proto-oncogenes (Rho = Ras homologue). Following their identification, a variety of approaches were used to isolate interacting proteins that might convey signals downstream to regulate numerous biological processes. One approach was to use GTP-loaded RhoA as a high-affinity reagent to fish for interacting proteins, and the ROCK kinases were identified in this way (Leung et al. 1995; Ishizaki et al. 1996; Matsui et al. 1996). A number of different names have been used to describe the two kinases and early reports were sometimes not careful in accurately describing which isoforms were actually used in the studies. However, the official gene names have been set as ROCK1 and ROCK2. The function of ROCK kinases downstream of active RhoA was quickly determined to be the regulation of actin-myosin contractile force generation (Fig. 1), mediated via the phosphorylation of a number of substrates including ▶ LIMK (which in turn phosphorylates cofilin and inactivates its actin-severing function), myosin light chain (MLC), and the myosin-binding subunit of the MLC phosphatase (MYPT1). In cultured cells, ROCK activation leads to the formation of actin stress fibers and focal adhesions. The discovery of the selective ROCK inhibitor Y27632 (Uehata et al. 1997) rapidly advanced the understanding of ROCK contributions to numerous biological functions.



ROCK Kinases, Fig. 1 ROCK pathways leading to increased actin–myosin contractility. Active GTP-bound Rho associates with ROCK and increases specific activity with the consequence of increased phosphorylation of proteins including the MYPT1 myosin-binding subunit of the myosin light chain phosphatase. ROCK phosphorylation of MYPT1 affects both its substrate binding and catalytic activity, resulting in inhibition of myosin light chain dephosphorylation. MLC has also been reported to be a directly phosphorylated and activated by ROCK. ROCK phosphorylation of LIMK1 and LIMK2 increases their specific activity, resulting in phosphorylation and inactivation of cofilin family proteins. Cofilin phosphorylation inhibits its filamentous actin-severing activity. The sum total of these events is stabilization of filamentous actin and increased actin–myosin contractility

Structure and Function of ROCK Kinases

The ROCK kinases are both 160 kDa serine-threonine kinases with identical domain organization. The primary sequence of the kinase domains places ROCK in the AGC family, their closest relatives being the myotonic dystrophy kinase (DMPK) and the myotonic dystrophy kinase-related CDC42-binding kinases (MRCK). As depicted in Fig. 2, the ROCK kinases are composed of an N-terminal kinase domain,



ROCK Kinases, Fig. 2 ROCK functional domains. Common functional domains in human ROCK1 and ROCK1 with the positions of starting and ending residues. The percentage identities between matched regions were determined by pairwise BLAST comparisons. *RBD* Rho-Binding Domain; *PH* Pleckstrin Homology domain; *C1* Protein kinase C conserved region 1 (Not to scale)

a coiled-coil region that contains the Rho-binding domain (RBD), and a pleckstrin homology (PH) domain that is split into two portions on either side of a cysteine-rich C1 domain. The high degree of homology between the ROCK1 and ROCK2 kinase domains suggests that they probably phosphorylate the same substrates and experimental data bears out this conclusion. Differences in substrate phosphorylation or biological functions observed in vivo likely result from different sub cellular localization and/or protein/protein interactions. Although there are no three dimensional structures of either entire protein, crystal structures of the kinase domains alone or liganded with various small molecule inhibitors have been reported. These structural studies have revealed some novel aspects of the kinase domain. In comparison to other related kinases, there are extensions to both N-terminal and C-terminal ends that promote dimerization. Also, unlike most other AGC kinases, phosphorylation in the kinase activation loop or hydrophobic motifs does not appear to be required for ROCK activation. Instead, dimerization appears to allow the kinase to adopt an active conformation without the need for phosphorylation. NMR structural information for the PH and C1 domains of ROCK2 has also been reported (Wen et al. 2008). Activity of the kinase domain is autoinhibited by the C-terminus, which can be relieved through binding to RhoA, B, or C (Leung et al. 1995; Ishizaki et al. 1996; Matsui et al. 1996) or through proteolytic cleavage (Coleman et al. 2001; Sebbagh et al. 2005). Multiple sites in the C-terminus appear to interact with the kinase domain to regulate activity (Lochhead et al. 2010). Interestingly, a single Proline to Serine amino acid substitution within the first portion of the split PH domain was sufficient to activate ROCK1, suggesting that the conformation of the C-terminal region is important for kinase regulation (Lochhead et al. 2010). ROCK1 activity may be inhibited by another Rho family member RhoE (Riento et al. 2003), which in turn can be antagonized by the kinase PDK1 in a manner independent of its catalytic activity (Pinner and Sahai 2008). Given the key role that ROCK kinases play in promoting contractile force generation, it is not surprising that they have been found to make important contributions to fundamental processes including: motility, adhesion, cytokinesis, apoptosis, phagocytosis, smooth muscle contraction, and neurite retraction.

ROCK in Development

Genetic deletion of either ROCK1 (Shimizu et al. 2005) or ROCK2 (Thumkeo et al. 2003) in mice resulted in similar phenotypes, which helped reveal that a major function of the ROCK kinases in vivo is the regulation of epithelial cell motility. The homozygous deletion of ROCK1 still allowed for the birth of mice at the expected Mendelian ratios, indicating that

there were no major problems during growth and development in utero but newborns had defects in eyelid and ventral body wall closure that gave rise to eyes-open at birth (EOB) and omphalocele (organs such as the liver and gut not being contained with the abdomen) phenotypes, respectively. EOB and omphalocele were also observed in homozygous ROCK2 knockout mice, but in this case a sub-Mendelian incidence of ROCK2$^{-/-}$ mice resulted from defects in the placental labyrinth layer, causing decreased blood flow to developing ROCK2$^{-/-}$ embryos (Thumkeo et al. 2003, 2005). Given these results, it seems consistent that ROCK1$^{+/-}$; ROCK2$^{+/-}$ double heterozygous mice also exhibited EOB and omphalocele, indicating that both kinases contribute to the same actin-driven movement and reorganization of epithelial sheets for eyelid and ventral body wall closure (Thumkeo et al. 2005). That being said, homozygous ROCK1 knockout mice were also independently generated, showing no obvious phenotypic differences from wild-type littermates, which suggests that strain background differences may contribute to the penetrance of the ROCK1 deficient phenotype (Zhang et al. 2006).

ROCK in Disease

The ready availability of potent and selective ROCK inhibitors has made it possible to examine whether ROCK kinases are involved in a wide variety of pathological conditions, including cancer, hypertension and cardiovascular disease, neuronal degeneration, kidney failure, asthma, glaucoma, osteoporosis, erectile dysfunction, and insulin resistance. However, the areas that have attracted the most research effort are cancer, hypertension/cardiovascular disease, and glaucoma.

Interest in ROCK as a cancer target stems from its wide range of activities that contribute to the growth and progression of tumors including proliferation, survival, and metastasis (reviewed in [Wickman et al. 2010]). Early studies revealed that Rho GTPs are over-expressed in a variety of tumors, consistent with increased signaling through the ROCK pathway being a contributory factor. In addition, elevated ROCK expression has been reported in bladder (Kamai et al. 2003) and testicular cancers (Kamai et al. 2002) and correlates with poor survival (Kamai et al. 2003). Large scale sequencing efforts directed at the identification of genetic alterations in human cancers revealed a number of activating somatic ROCK1 mutations in human tumors and tumor cell lines (Lochhead et al. 2010). A current concept is that it would be advantageous to develop ROCK2 selective inhibitors for the treatment of cancer to avoid the pronounced hypotension that is a side effect of ROCK1 inhibition.

The connection between ROCK and hypertension was revealed with the development of ROCK selective inhibitors. Inhibition of ROCK with Y-27632 and related compounds was shown to relieve hypertension in rats by inhibiting the calcium sensitization of smooth muscle contraction. Since that time, numerous studies have built on these observations to show that ROCK activity mediates increased smooth muscle contraction principally via modulation of MLC phosphorylation. In particular, ROCK appears to contribute to aberrant vascular contraction, for example, during coronary vasospasm, cerebral vasospasm following subarachnoid hemorrhage, pulmonary hypertension, and Raynaud's phenomenon, a condition in which the blood supply to distal extremities such as fingers and toes is decreased to the point of numbness or pain and which is the result of vasospasms.

Glaucoma is a disease in which damage to the optic nerve progressively leads to impaired vision and possibly blindness. One way that optic nerve damage may occur is through elevated intraocular pressure. ROCK inhibition helps to relieve this pressure by increasing aqueous outflow by reducing MLC phosphorylation in cells lining the trabecular meshwork. Significant research by pharmaceutical companies in this area has resulted in several promising clinical trials.

Within the nervous system, ROCK has been shown to be an important trigger of neuronal growth cone collapse and neurite withdrawal. As a result, there has been considerable interest in the possibility that ROCK inhibition would actually promote neurite outgrowth and dendrite formation. Possible applications for this include recovery from spinal cord injury by assisting the re-establishment of neural connections across the lesion and Alzheimer's disease treatment through the decreased production of amyloid precursor protein.

ROCK and Stem Cell Survival

When human embryonic stem cells (hESC) are dissociated or plated at low density they often undergo

apoptotic death. Chemical biology screens to identify agents that would promote survival identified the ROCK selective inhibitor Y-27632 as a particularly potent agent. Mechanistic studies revealed that ROCK-mediated actin–myosin contraction makes epiblast derived hESCs die during low density growth and validate the use of inhibitors of ROCK or actin–myosin contractility for the propagation and genetic manipulation of hESCs for eventual therapeutic use (Samuel and Olson 2010).

ROCK Inhibitors

1. HA-1077 (fasudil) and hydroxyfasudil have been in clinical use in Japan for cerebral vasospasm since 1995 (Olson 2008). Since it has been used for such a long period, there is positive post-marketing safety data, which has encouraged trials for a number of indications, including angina, acute ischemic stroke, cerebral blood flow, stable angina pectoris, coronary artery spasm, heart failure associated vascular resistance and constriction, pulmonary arterial hypertension, essential hypertension, atherosclerosis, and aortic stiffness (Olson 2008).
2. Y-27632 was the first published selective ROCK inhibitor (Uehata et al. 1997) and its ready availability has made it the inhibitor of choice. Although this inhibitor is not strictly specific for ROCK kinases, ROCK1 and ROCK2 siRNA experiments have not revealed significant off-target effects in cells.
3. H-1152 was developed as an improved version of HA-1077 with greater ROCK selectivity over PKA and PKC. Although also readily available from commercial sources, H-1152 is less often used than HA-1077 to corroborate results from experiments in which Y-27632 was used, despite the improved selectivity.
4. SLx-2119 was developed as a potential cancer therapeutic initially, but more recently has gone into preclinical development for the treatment of metabolic disease.

A number of studies have highlighted the fact that no inhibitor is entirely specific. Therefore, greater robustness can be built into studies that make use of ROCK inhibitors if a number of additional conditions were satisfied including:

1. Structurally unrelated inhibitors should produce the same biological effects at concentrations that produce equivalent kinase inhibition. The lowest effective doses should be used to reduce off-target effects.
2. Dose-response experiments to establish rank order of potency for a set of inhibitors, i.e., the most potent ROCK inhibitors should be the most effective if a biological response is mediated by ROCK.
3. Examination of the relationship between ROCK inhibitor dose, substrate phosphorylation and biological endpoint.
4. Where possible additional methods should be used to inhibit ROCK function, such as RNAi-mediated knockdown.

Although there is no doubt that inhibitors are useful and convenient research tools, care should be taken in interpreting the results. The substantial knowledge base of the biological functions of ROCK has been made possible due to the ready availability of such inhibitors. Their greatest utility is actually in excluding a possible involvement of ROCK in specific biological responses when there are adequate positive controls in place.

Summary

The most important and central cellular function of ROCK kinases is to regulate morphology, largely through actin–myosin contractility. Due to its profound influence on morphology and contractility, ROCK directly influences numerous activities, such as cytokinesis, adhesion, motility, endothelial barrier function, and membrane blebbing. In addition, via direct or indirect pathways, the ROCK kinases also influence biological processes including gene transcription, proliferation, regulation of cell size, and survival. There has been considerable interest in ROCK kinases as potential therapeutic targets for cancer, hypertension/cardiovascular disease, and glaucoma, and a number of potent and selective inhibitors have been discovered. In fact, one ROCK inhibitor fasudil has been used clinically in Japan for a number of years for the treatment of cerebral vasospasm. Although there is a substantial literature on ROCK function, largely generated due to the availability of pharmacological inhibitors, greater knowledge at the tissue and organismal levels will result from conditional knock-out and conditional-activation mouse models (Samuel et al. 2009). In vivo experiments

using these types of genetically modified models will validate the role of ROCK in various pathological conditions, and will highlight additional indications for the use of ROCK inhibitors. Although quite a few ROCK substrates have been identified and well-characterized, recent phosphoproteomic studies have identified a large number of previously unknown ROCK substrates. As a result, a significant opportunity awaits to characterize the biological outcomes of ROCK-mediated phosphorylation on these novel substrates and ultimately to determine their possible contributions to human disease.

PSMD7; S12

Background

The gene *PSMD7* encodes the protein RPN8, also known as S12. RPN8, the human homologue of Mov-34, is a non-ATPase component of the 19S regulatory complex (Dubiel et al. 1995). Two 19S regulatory complexes bind to each end of the 20S proteasome to form the 26S proteasome.

The Proteasome

The proteasome plays an important role in the cell, but its mechanism of action is not well understood. Although the proteasome was first isolated in 1979 (DeMartino and Goldberg 1979), the essential role the proteasome plays within a cell was not realized until 1990 (Fujiwara et al. 1990). The proteasome is the main component in the intracellular protein degradation pathway. This pathway was once thought to be a relatively unimportant part of the cell, but is now recognized to play an important role in regulating the lifetime of cellular proteins (Spataro et al. 1998).

Degradation is an important process within the cell (Glickman and Ciechanover 2002). The ultimate state of a cell is governed by the set of cellular proteins that exist within it. Cellular proteins are regulated both through creation (transcription/translation) and through degradation (ubiquitin–proteasome pathway). The degradation of proteins is just as important as the creation of them when studying regulatory processes within the cell. Since the understanding of the proteasome is immature, fundamental studies on assembly, activity, and control within the proteasome may well reveal important information about the complex and, in turn, the regulation of cellular proteins.

The proteasome plays an important role in regulating protein concentrations inside eukaryotic cells through the ubiquitin–proteasome pathway (Hochstrasser 1995). Ubiquitin is a small (76 amino acid) protein that may be specifically conjugated to lysine residues on a protein. This ubiquitin conjugation signals the proteasome to degrade the protein into short polypeptides. Proteins are ubiquitinated through a process that involves three classes of enzymes called E1, E2, and E3 (Weissman 2001). First an E1 enzyme activates the ubiquitin by modifying the C-terminal glycine residue. Simultaneously, an E3 enzyme binds to the target protein. Finally, an E2 enzyme transfers the activated ubiquitin to the E3/target complex, resulting in a ubiquitin tagged target protein that will be degraded by the 26S proteasome in eukaryotic cells. There are many (dozens) of each class of enzyme, and the combination of E2/E3 enzyme is thought to give specificity to the degradation (Glickman and Ciechanover 2002).

The eukaryotic proteasome consists of several components. The entire complex is known as the 26S proteasome. The 26S complex is composed of a single 20S proteasome (total mass 700 kDa, composed of 28 subunits) and two 19S multi-subunit complexes. The 20S proteasome has a cylindrical shape, and the 19S complexes form caps for the two ends of the 20S proteasome (Orlowski and Wilk 2000). The activity of

the proteasome can be modified by the substitution of different subunits. In cultured cells, stimulation by gamma interferon changes the composition of the proteasome (Tanka 1994). A sub-complex known as the 11S regulator replaces the entire 19S sub-complex. Three of the 28 proteins in the 20S proteasome are replaced with completely different proteins. It is thought that these changes enhance the production of polypeptides suitable for MHC class I antigen presentation. This form of the proteasome is called the immunoproteasome (Van den Eynde and Morel 2001).

A heterogeneous population of proteasomes exists within cells. A structural study using transmission electron microscopy of individual 26S proteasomes isolated from both *Drosophila melanogaster* and *Xenopus laevis* revealed that the 19S cap has an extraordinary flexible attachment to the 20S proteasome core (Walz et al. 1998). This study also revealed that one portion of the 19S cap has at least four different conformations. The heterogeneous population implies that the proteasome is used as a general framework for protein degradation machinery.

The standard model of the proteasome's protein degradation mechanism works like this: a protein binds to the 19S subunit at one end of the proteasome, the protein is unfolded and fed into the 20S proteasome, the protein is cleaved inside the 20S barrel, and the cleavage products pass out the other end of the proteasome. The model is based upon structural (Walz et al. 1998; Unno et al. 2002) and kinetic measurements (Stein et al. 1996; Akopian et al. 1997; Kisselev et al. 1998; Nussbaum et al. 1998; Peters et al. 2002) of the proteasome. However, there are other models consistent with this data. For instance, some (Nussbaum et al. 1998) suggest that degradation products may exit through the sides of the 20S proteasome. The structural data (Walz et al. 1998; Unno et al. 2002) makes it clear that the 20S proteasome is symmetric, with no preferred direction.

Polyubiquitinated proteins can be degraded by the proteasome. The 26S proteasome is a large (approximately 2,000 kDa) complex composed of three different components. The core component, called the 20S proteasome is a barrel-shaped protease, with the active sites protected inside the barrel. The 20S core is regulated through several mechanisms. A complex termed the 19S binds to the top and bottom of the 20S core to form the 26S proteasome (Fukunaga et al. 2010; Isono et al. 2004). The 19S complex is thought to recognize, bind, and unfold poly ubiquitinated proteins. These proteins are then fed into the barrel of the 20S proteasome, where they are degraded into polypeptide chains. Other complexes, such as the PA28 complex, can also bind to the 20S core, and these are thought to regulate the proteasome in different ways (Bochtler et al. 1999; Wigley et al. 1999).

Structure

Several domains and motifs for RPN8 have been identified. These include the C-terminal KEKE motif, a putative site of protein–protein interaction (Realini et al. 1994), the Jun activation-domain binding protein (JAB) domain, originally described as a regulator of transcription, the MPR1p and PAD1p N-terminal (MPN) domain which, along with surrounding sequence, has been shown to be important for pairing with S13 (Rpn11/POH1) (Fu et al. 2001), and possibly even weak homology to a MAPKK activation loop motif (Seeger et al. 1998).

The RPN8 MPN domain has been crystallized and the crystal structure has been solved. This structure showed that the MPN domain contains a metalloprotease fold, as expected, but this metalloprotease fold is surprisingly unable to coordinate a metal ion (Sanches et al. 2007).

Localization

RPN8 is cytosolic and localized around the nucleus. This was determined using an antibody raised against amino acids 1–205 of recombinant RPN8 to localize the 26S proteasome in human JU77 mesothelioma cells (Seeger et al. 1998). Furthermore, phosphorylated RPN8 was found by using an anti-RPN8 antibody that reacted with both the phosphorylated and unphosphorylated forms from 26S proteasomes immunoprecipitated from human L-132 cells (Mason et al. 1998). These data identified phosphorylated RPN8 migrating above 50 kDa, whereas unphosphorylated RPN8 migrates at 40 kDa (Braun et al. 1999).

Roles in Human Disease

The proteasome has been implicated in multiple diseases. Defects in proteasome activity are associated

with chronic human neurodegenerative diseases. Protein aggregates are found in some patients with Alzheimer's (Ciechanover and Brundin 2003), Parkinson's (Dauer and Przedborski 2003), and Huntington's (Rubinsztein 2006) diseases. These aggregates are thought to form when the proteasome is unable to keep up with the amount of ubiquitinated protein being produced by the cell. The ubiquitin–proteasome pathway of protein degradation is also the target of cancer-related deregulation. Proteasome inhibitors form a new class of anticancer drugs and are under study for use in pancreatic, colon, lung, breast, prostate, and ovarian cancers (Voorhees and Orlowski 2006). One proteasome inhibitor, Velcade, has been approved by the FDA for treatment of multiple myeloma.

Certain mutations in the gene BRCA1 are known to lead to a predisposition to developing breast cancer. These cases account for less than 10% of all breast cancers. The protein product of BRCA1 exhibits E3 (ubiquitin protein ligase) activity. Furthermore, it was shown that cancer-predisposing mutations in BRCA1 also lead to a loss of this E3 activity (Ruffner et al. 2001). This clearly implicates the ubiquitin–proteasome pathway as a potential mechanism in the development of breast cancer. Other defects leading to the aberrant regulation of the ubiquitin–proteasome pathway (e.g., E1, E2, E3, or proteasome subunits) may be responsible for a greater percentage of breast carcinomas.

RPN8/PSMD7 is one of a cohort of 231 genes whose expression levels were significantly associated with clinical outcome in breast cancer patients (van't Veer et al. 2002).

In cell line studies, RPN8 appears to be functionally related to transformed cells. RPN8 was posttranslationally modified in six normal breast epithelial cell lines, but not four transformed cell lines. Rpn8 was unique among proteasome subunits in this characteristic. Modified RPN8 has identical mass, but different isoelectric points then unmodified RPN8, see Fig. 3 in (Thompson et al. 2004). Modified RPN8 does not associate with the 26S proteasome, but does associate with a separate high molecular weight complex, see Fig. 5 in (Thompson et al. 2004). Finally, modified RPN8 is localized to the nuclei of normal cells, whereas unmodified RPN8 is only present in the cytoplasm.

The differential RPN8 protein expression and nuclear localization observed between the normal and cancer cell lines suggests that RPN8 has multiple functions associated with normal and cancer phenotypes. For instance, while mRNA levels are essentially the same between normal and cancer cell lines, the difference in levels of modified RPN8 is great. Thus, mechanisms that modulate posttranslational modifications of RPN8 in normal cells are disrupted in each of the cancer cell lines studied. Furthermore, no differences exist in the protein expression pattern of six other proteasome subunits between the ten cell lines, with the exception of S10a, lending significance to the differences observed with RPN8.

Summary

In summary, RPN8 exists in normal cell lines with at least two different posttranslational modifications, but in transformed cell lines with only one. The modified form of RPN8 does not associate with the 26S proteasome, but does associate with the immunoproteasome. These data suggest a differential nuclear function of modified and unmodified RPN8 in cancer cells.

Department of Microbiology and Cell Science, University of Florida, Gainesville, FL, USA

Synonyms

Rpt, *R*egulatory *p*article *t*riple-A (Rpt) subunits of 26S proteasomes; triple-A (or AAA) is a family of proteins within the AAA+ superfamily of ATPases associated with various cellular activities

Historical Background

*R*egulatory *p*article *t*riple-A (Rpt) subunits are associated with the ubiquitin-proteasome system, a central mechanism of protein breakdown with a rich historical background. Aaron Ciechanover, Avram Hershko, and Irwin Rose were awarded the 2004 Nobel Prize in Chemistry for their "discovery of ubiquitin-mediated protein degradation" by proteasomes and have outlined some of this history in reviews (e.g., Ciechanover 2010). The term "proteasome" was first coined by Arrigo et al. (1988) for a "large alkaline multifunctional protease" known to mediate energy-dependent intracellular protein breakdown, once it was clear that this protease was related to the ring-shaped "prosomes" of unknown function commonly found in eukaryotic cells. The Rpt nomenclature was later proposed by Finley et al. (1998) to designate the subunits of the yeast 26S proteasome that cluster to the *A*TPases *a*ssociated with various cellular *a*ctivities (AAA) family of the AAA+ superfamily (Wollenberg and Swaffield 2001). AAA+ proteins are required for the degradation of folded proteins by self-compartmentalized proteases such as proteasomes.

Proteasomes and Rpt Subunits

Protein degradation by proteasomes is a major regulatory mechanism in eukarya, archaea, and actinobacteria. Proteasomes can degrade short-lived proteins that control cell division, apoptosis, DNA repair, information processing (transcription and translation), and other cellular processes (Navon and Ciechanover 2009). Proteasomes are also important in maintaining protein quality by destroying improperly synthesized, foreign, and damaged proteins (Schrader et al. 2009).

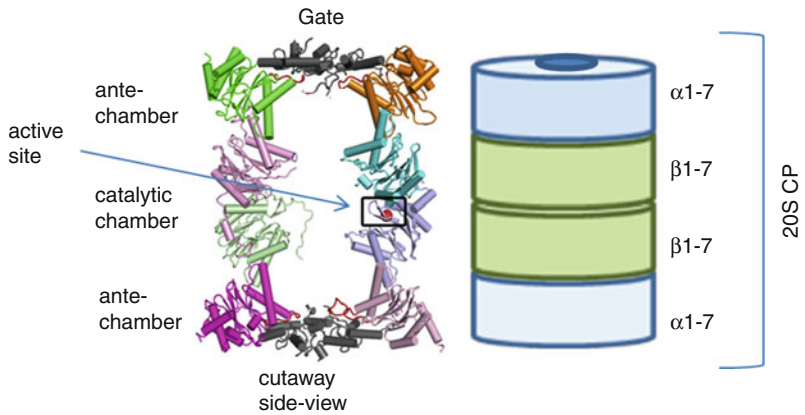
All proteasomes are composed of a 20S core particle (CP) lined on its interior with proteolytic active sites that are sequestered away from the cytosol (Stadtmueller and Hill 2011) (Fig. 1). CPs are barrel-like and formed from four-stacked heptameric rings of α- and β-type subunits. The α-type subunits form the outermost rings, while the β-type subunits form the inner two rings. The N-terminal tails of α-type subunits can gate the pores on each end of CPs and limit substrate access to the proteolytic active sites formed by β-type subunits.

CPs associate with various regulators (Stadtmueller and Hill 2011). In eukarya, CPs bind 19S regulatory particles (RPs) to form an energy-dependent protease known as the 26S proteasome (Fig. 2). Substrates of 26S proteasomes include proteins covalently conjugated to chains of ubiquitin (Ub) through a process termed ubiquitylation (Ravid and Hochstrasser 2008). The primary roles of 19S RPs are to recognize, unfold, and translocate substrate proteins to the catalytic central chamber of CPs for protein degradation. In yeast, the 19S RP can be separated into base and lid subcomplexes by deletion of the gene encoding the *r*egulatory *p*article *n*on-ATPase Rpn10 subunit (Tomko and Hochstrasser 2011). The base subcomplex is composed of three Rpn subunits (Rpn1, Rpn2, and Rpn13) and six proteins termed *r*egulatory *p*article *t*riple-A subunits (Rpt1-6) that cluster to the AAA family of the AAA+ superfamily. Rpt1-6 form a heterohexameric ring that directly interacts with 20S CPs and are arranged in Rpt1-Rpt2-Rpt6-Rpt3-Rpt4-Rpt5 order in 26S proteasomes (Tomko and Hochstrasser 2011). The lid subcomplex is composed of nine other Rpn subunits and harbors the deubiquitylating enzyme Rpn11 that removes polyubiquitin chains from substrate proteins.

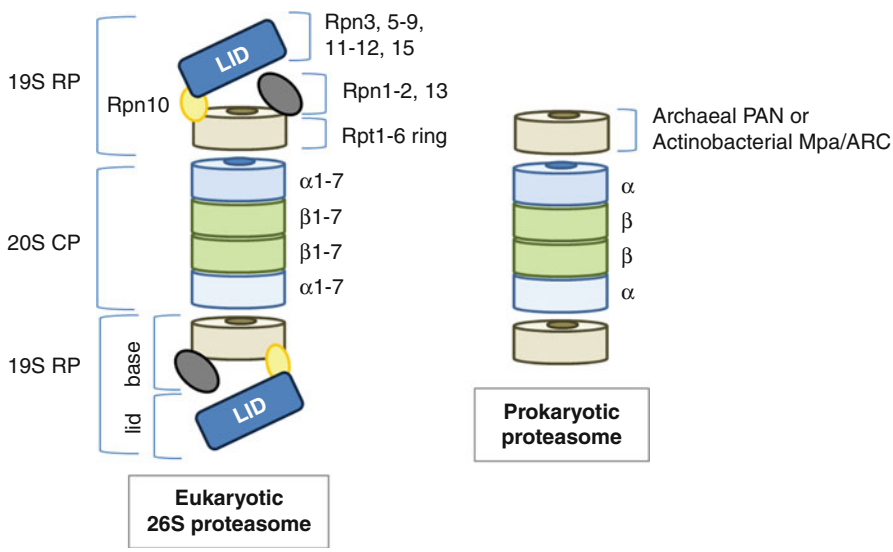
Archaea and actinobacteria synthesize proteasomes that are relatively simple in subunit complexity, yet these proteases share many basic structural and functional features with eukaryal 26S proteasomes (Bar-Nun and Glickman 2011). Like eukarya, the CPs and proteasomal AAA+ proteins of archaea and actinobacteria can associate together in vitro and catalyze the energy-dependent degradation of folded proteins (Fig. 2). The prokaryotic AAA+ proteins are often hexameric rings formed from a single protein including the archaeal proteasome-associated nucleotidase (PAN) and actinobacterial AAA ATPase forming ring-shaped complexes (ARC) or mycobacterium proteasome ATPase (Mpa). The archaeal PAN is closely related to the eukaryal Rpt subunits, while the actinobacterial ARC/Mpa proteins are divergent members of the AAA family. It has been proposed that the six different types of eukaryal Rpt proteins (Rpt1-6) evolved from a single archaeal PAN ancestor, which over time was duplicated and diversified (Wollenberg and Swaffield 2001).

Rpt and Related AAA+ Proteins in Proteolysis

While the hydrolysis of peptide bonds is exergonic, ATP binding and hydrolysis by AAA+ proteins (or domains) is needed to fuel the regulated degradation



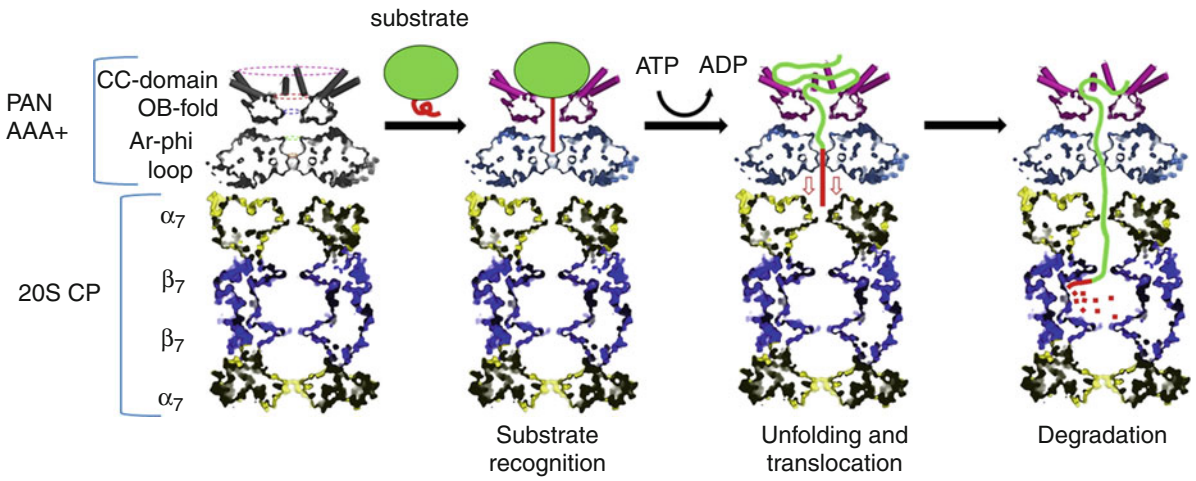
RPT, Fig. 1 20S proteasomes. The central proteolytic component of all proteasomes is a cylindrical 20S core particle (CP) formed from four-stacked heptameric rings. The outer rings are of α-type subunits and inner rings are of β-type subunits. The N-terminal tails of α-type subunits gate substrate access to the central channel that connects three chambers (two antechambers and one catalytic chamber). The proteolytic active sites are sequestered from the cytosol and formed by the N-terminal threonine residues of β-type subunits that are exposed by autocatalytic processing of the β-type proteins during complex assembly (Modified with permission from Stadtmueller and Hill (2011))



RPT, Fig. 2 ATP-dependent proteasomes. Proteasomal CPs can associate on each end with heptameric rings of AAA+ proteins including eukaryal Rpt1-6, archaeal PAN, and actinobacterial ARC (or Mpa). In eukaryotes, Rpt1-6 are the ATPase subunits of the 19S regulatory particles (RPs) that together with CPs form 26S proteasomes. In yeast, the 19S RP can be dissociated into lid and base subcomplexes by deletion of the *RPN10* gene

of folded proteins by self-compartmentalized proteases such as 26S proteasomes. The AAA+ rings can bind substrate proteins, open the gates of the protease chamber (closed-gates limit substrate access to the proteolytic active sites), unfold substrate proteins, and facilitate the translocation of protein substrates into the proteolytic center of the protease.

Subdomain X-ray crystal and cryo-electron microscopy structures of proteasomal AAA+ proteins are now available and provide valuable insight into how this group of ATPases might function at the atomic level (Bar-Nun and Glickman 2011). Details on the related bacterial AAA+ proteases such as ClpXP and HslUV have also guided proteasomal models (Sauer and Baker 2011). In general, proteasomal ATPases have a central channel that is coaxial to the 20S CP channel (Fig. 3). On the distal face of the proteasomal ATPase ring are six protruding and paired N-terminal coiled-coil (CC) domains that are required for substrate binding. Moving down the ATPase channel, one finds a conserved interdomain region with an oligonucleotide-binding (OB)-fold domain that is



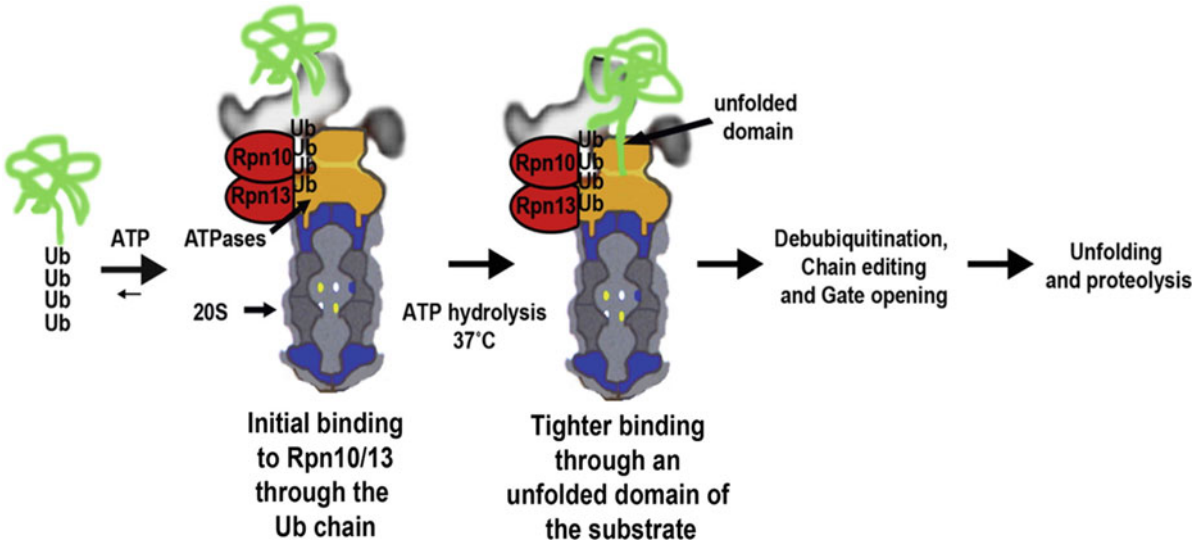
RPT, Fig. 3 Model of proteasome-mediated degradation of folded proteins. Model is based on archaeal PAN, a close relative of the Rpt1-6 subunits of eukaryal 26S proteasomes. Substrate proteins are thought to be unfolded on the distal face of the proteasomal ATPase, translocated through the central ATPase channel, and ultimately reach the central chamber of CPs for destruction. The N-terminal coiled-coil (CC) domain, oligonucleotide-binding (OB)-fold domain, and aromatic-hydrophobic (Ar-phi) loop discussed in text are indicated (Modified with permission from Zhang et al. (2009))

important for AAA+ ring formation. The OB-fold domain also appears to serve as a rigid entryway for substrates that traverse the ATPase channel. The archaeal PAN and eukaryal Rpt1-6 proteins have a single OB-fold (as depicted in Fig. 3), while the actinobacterial ARC/Mpa has a double OB-fold that forms two separate ring-like structures within the ATPase channel. The C-terminal AAA+ domain mediates cycles of ATP hydrolysis and harbors a highly conserved aromatic-hydrophobic (Ar-phi) loop within its channel. The Ar-phi loop is common to energy-dependent AAA+ proteases and is thought to grab onto hydrophobic tails of substrates that may extend into the ATPase channel. Once bound, cycles of ATP hydrolysis around the ATPase ring are thought to mediate conformational changes in the Ar-phi loop that result in the tugging and unfolding of the substrate protein. The rigid OB-fold pore is believed to serve as a platform for this unfolding process. Thus, the protein substrate is thought to be unfolded and translocated through the ATPase and into the CP for destruction.

Many of the proteasomal ATPases (e.g., archaeal PAN and eukaryal Rpt2, 3 and 5) have C-terminal hydrophobic-tyrosine-any residue (HbYX) motifs that bind to pockets between the α-type subunits of CPs and induce CP gate opening. The proteasome-associated regulator Blm10 and α-ring assembly factor Pba1-Pba2 also have penultimate tyrosine (or phenylalanine) residues that appear important for binding within the α/α-intersubunit interface (Stadtmueller and Hill 2011; Kusmierczyk et al. 2011).

Substrate Recognition by Proteasomes

Protein degradation is a highly regulated process. In order to ensure that only the desired proteins are degraded, eukaryotes and prokaryotes have evolved various strategies for identifying proteins for degradation. Specific degradation signals or "degrons" within the protein often initiate the process of proteolysis. Degrons range from the phosphorylation or glycosylation status of a protein to the exposure of destabilizing N- or C-termini (Ravid and Hochstrasser 2008). In eukaryotic cells, the ubiquitylation system often recognizes these degrons and results in the covalent attachment of polyubiquitin (Ub) chains. While all seven lysine residues of Ub can form chains, Ub chains linked through Lys48 commonly target proteins for destruction by 26S proteasomes (Xu et al. 2009). These ubiquitylated proteins are thought to first bind the Rpn10 and Rpn13 subunits of 26S proteasomes by a mechanism stimulated by ATP binding to the Rpt subunits (Peth et al. 2010) (Fig. 4). Next, Rpt-mediated ATP hydrolysis is thought to unfold and expose unstructured portions of the substrate protein for tighter binding to 26S proteasomes. Ultimately, this is thought to ready the substrate for the editing or



RPT, Fig. 4 26S proteasome-mediated degradation of ubiquitylated proteins. Initially, the 26S proteasomal subunits Rpn10 and 13 (Ub receptors) bind the Ub chain of ubiquitylated substrate proteins by a mechanism that is stimulated by ATP binding. In the next phase, ATP is hydrolyzed by the Rpt subunits and an unfolded domain of the substrate protein is exposed, resulting in tighter binding to 26S proteasomes. After these binding events, deubiquitylation, Ub-chain editing, substrate unfolding, CP gate opening, translocation, and proteolysis can occur (Modified with permission from Peth et al. 2010)

removal of polyUb chains by deubiquitylases. The Rpt subunits would unfold and translocate the protein while opening the CP gates for protein degradation.

In actinobacteria and archaea, the covalent attachment of small protein modifiers to substrate proteins appears to be linked to proteasome-mediated proteolysis– much like the process of ubiquitylation in eukaryotic cells. It has recently been shown in *Mycobacterium tuberculosis* that a small protein termed Pup can covalently modify proteins at lysine residues (Burns and Darwin 2010). While the mechanism of pupylation differs from ubiquitylation and the disordered structure of Pup is not like the highly ordered beta-grasp fold of Ub, Pup can target proteins for proteasome-mediated degradation (Burns and Darwin 2010). Interestingly, the mycobacterial proteasomal AAA+ Mpa (required for cellular resistance to reactive nitrogen intermediates) binds and induces formation of an alpha helix within Pup and is required for degradation of pupylated substrates by proteasomes (Burns and Darwin 2010). The haloarchaeon *Haloferax volcanii* can also attach small archaeal protein modifiers or SAMPs to substrate proteins (Humbard et al. 2010). However, unlike Pup, the archaeal SAMPs have a predicted beta-grasp fold structure similar to Ub and require the presence of an E1 Ub activating homolog (UbaA) for attachment (Miranda et al. 2011). Other enzyme (E2 Ub conjugating and E3 Ub ligase) homologs for the attachment of SAMPs to protein targets have yet to be identified. Sampylation has not been directly linked to targeting proteins for proteasome-mediated degradation. However, the sampylome accumulates in strains deficient in the synthesis of the proteasomal Rpt-like PAN-A and CP α1 subunits, suggesting sampylation may trigger proteins for degradation by proteasomes. However, green fluorescent protein (GFP) derivatives with hydrophobic C-terminal tails that are not modified by sampylation or other types of posttranslational modification are degraded in vitro by proteasomal CPs in the presence of archaeal PAN and hydrolyzable ATP (Navon and Goldberg 2001). Therefore, by an ATP-dependent mechanism, Rpt-like proteins can bind and unfold non-sampylated protein substrates with exposed hydrophobic regions. Interestingly, in eukaryotic cells, the chaperonin-like activities of the proteasomal Rpt proteins appear to also serve non-proteolytic roles (Kodadek 2010).

Summary

Proteins of the AAA+ superfamily that include eukaryal Rpt, archaeal PAN, and actinobacterial

Mpa/ARC are structurally related and important in protein degradation. These proteasomal ATPases can unfold proteins, open CP gates, and translocate proteins for ultimate destruction within the self-compartmentalized 20S CP structure that protects cells from uncontrolled proteolysis. In eukarya, Rpt1-6 associate with non-ATPase subunits in complexes such as the 19S RP to form 26S proteasomes but also appear to serve non-proteolytic roles. Whether the archaeal PAN and actinobacterial Mpa/ARC are similar to eukaryal Rpt in their association with proteasomal CPs and other non-ATPase factors in vivo remains an exciting area of research.

RSK (p90 Ribosomal S6 Kinase)

Philippe P. Roux
Department of Pathology and Cell Biology, Institute for Research in Immunology and Cancer (IRIC), Université de Montréal, Montreal, QC, Canada

Synonyms

90 kDa ribosomal S6 kinase; p90RSK

Historical Background

The p90 ribosomal S6 kinase (RSK) family comprises four mammalian Ser/Thr kinases (RSK1-4) (Anjum and Blenis 2008; Carriere et al. 2008). The first RSK family member was identified as a kinase activity in maturating *Xenopus laevis* oocytes that phosphorylated the 40S ribosomal subunit protein S6 (rpS6) (Erikson and Maller 1985, 1986). Although the p70 ribosomal S6 kinases 1 and 2 (S6K1 and S6K2) were later shown to be the predominant S6 kinases operating in somatic cells (Blenis et al. 1991; Chung et al. 1992), RSK1 and RSK2 were found to phosphorylate rpS6 in response to ▶ MAP kinase pathway activation (Cohen et al. 2007; Roux et al. 2007). Interestingly, whereas S6K1/2 were found to phosphorylate all sites on rpS6 (Ser235, Ser236, Ser240, and Ser244), RSK1 and RSK2 were shown to specifically phosphorylate Ser235 and Ser236 (Roux et al. 2007). The role of this specific regulation is unknown, but some evidence suggests that rpS6 phosphorylation may be involved in fine-tuning the cellular response elicited by some growth factors (Meyuhas 2008). At the moment, little is known about specific and overlapping functions of the RSK isoforms, but the recent identification of specific RSK inhibitors (Cohen et al. 2005; Smith et al. 2005; Sapkota et al. 2007), the use of RNA interference, and the generation of mouse knockouts should help shed light on the contribution of each RSK isoform.

Structure of the RSK Isoforms

The RSK isoforms are 73–80% identical to each other and are mostly divergent in their amino- and carboxyl-termini sequences. The structure of RSK is complex and comprises two functionally distinct kinase domains, a linker region, and N- and C-terminal tails. While the N-terminal-kinase domain (NTKD) shares homology with kinases of the AGC family (PKA, PKG, PKC), the C-terminal kinase domain (CTKD) is homologous to the calcium/calmodulin-dependent protein kinases (CaMKs). It is thought that, during evolution, the genes for two different protein kinases have fused, generating a single polypeptide capable of receiving an upstream activating signal from the Ras/MAPK pathway to its CTKD and transmitting, with high efficiency and fidelity, an activating input to its NTKD. Thus, the CTKD appears to be only involved in autophosphorylation of RSK, resulting in its activation, and the NTKD is responsible for downstream substrate phosphorylation (Bjorbaek et al. 1995). The C-terminal tail contains an ERK1/2 docking motif, known as the D domain, and interaction of RSK with ERK1/2 was shown to depend on a short motif consisting of Leu-Arg-Gln-Arg-Arg (Smith et al. 1999; Roux et al. 2003). Finally, the C-terminal tail of all RSK isoforms contains a type 1 PDZ domain-binding motif, consisting of Thr-Xaa-Leu, where Xaa is any amino acid. This motif was shown to be functional with at least some PDZ domain-containing proteins (Thomas et al. 2005), but more will need to be done to fully determine its role and biological significance.

Activation Mechanisms

The RSK isoforms contain six phosphorylation sites that are responsive to mitogenic stimulation. Mutational analysis revealed that four of these sites (Ser221, Ser352, Ser369, and Thr562 in mouse RSK1) are essential for RSK activation (Dalby et al. 1998). Of these, Ser221 (located in the NTKD activation loop), Ser352 (turn motif), and Ser369 (hydrophobic motif) are located within sequences highly conserved in other AGC kinases (Newton 2003). The current model of RSK activation suggests that ERK and RSK form an inactive complex in quiescent cells that is mediated by the D domain on RSK (Hsiao et al. 1994; Zhao et al. 1996). After mitogenic stimulation, ERK1/2 phosphorylates Thr562 in the activation loop of the CTKD (Sutherland et al. 1993) and possibly Thr348 and Ser352 in the linker region

between the two kinase domains (Dalby et al. 1998). Activation of the CTKD leads to autophosphorylation at Ser369 (Vik and Ryder 1997), which creates a docking site for phosphoinositide-dependent protein kinase 1 (PDK1) (Frodin et al. 2000). In turn, PDK1 phosphorylates Ser221 in the activation loop of the NTKD (Jensen et al. 1999; Richards et al. 1999) and, along with phosphorylated Ser352 and Ser369, promotes an intramolecular allosteric mechanism that allows the NTKD to phosphorylate downstream substrates (Frodin et al. 2002). RSK also autophosphorylates at a C-terminal residue that releases ERK1/2 binding, presumably to allow these kinases to find their respective substrates throughout the cell (Roux et al. 2003).

The process of RSK activation is closely linked to ERK1/2 activity, and MEK1/2 inhibitors (U0126, PD98059, PD184352) have been widely used to study RSK function. Recently, three different classes of RSK inhibitors targeting the NTKD (SL0101 and BI-D1870) or the CTKD (FMK) have been identified (Cohen et al. 2005; Smith et al. 2005; Sapkota et al. 2007). While BI-D1870 and SL-0101 are competitive inhibitors with respect to ATP, FMK (fluoromethylketone) is an irreversible inhibitor that covalently modifies the CTKD of RSK1, RSK2, and RSK4. These compounds have been tested against a panel of protein kinases and found to be relatively specific for the RSK isoforms (Bain et al. 2007). There are alternate mechanisms of activation for RSK, but these appear to be cell type- and context-specific. One of these involves tyrosine phosphorylation by ▶ Src, which was shown to stabilize the interaction between ERK and RSK, and thereby increase the rate at which RSK becomes activated (Kang et al. 2008). Another mechanism involves the regulation of the hydrophobic motif of RSK by the related enzymes, MAPK-activated protein kinases 2 and 3 (▶ MK2/3), which can facilitate RSK activation upon stimulation of the stress-responsive p38 MAPK pathway (Zaru et al. 2007).

Biological Functions

RSK seems to be a multifunctional ERK effector because it participates in various cellular processes (Cargnello and Roux 2011). Although a number of RSK functions can be deduced from the nature of its substrates, data from many groups point toward roles for the RSKs in nuclear signaling, cell cycle progression and cell proliferation, cell growth and protein synthesis, and cell migration and cell survival. RSK was found to regulate several transcription factors, including SRF, c-Fos, and Nur77. On the basis of its substrates, RSK seems to have important functions in cellular growth control and proliferation. RSK may stimulate cell cycle progression through the regulation of immediate early gene products, such as c-Fos, which promotes the expression of cyclin D1 during the G0/G1 transition to S phase. RSK may also promote proliferation by regulating cell-growth-related protein synthesis. Indeed, RSK was found to regulate the tumor suppressor TSC2 (Roux et al. 2004), and thereby promote ▶ mTOR signaling. RSK has also been shown to regulate cell survival. RSK phosphorylates and inhibits the pro-apoptotic proteins Bad and ▶ DAPK, thereby promoting survival in response to mitogenic stimulation (Shimamura et al. 2000; Anjum et al. 2005). Many additional RSK substrates have been identified through the years, but at this point, very little is known regarding isoform specificity. Whereas more substrates have been identified for RSK2 than any other RSK isoforms, most studies have not determined isoform selectivity. Therefore, many known substrates of RSK2 may be shared by different RSK family members and more effort will be necessary to assess potential overlapping functions.

Physiological Functions

An important clue into the physiological roles of the RSK isoforms came from the finding that inactivating mutations in the *Rps6ka3* gene (which encodes RSK2) were the cause of Coffin-Lowry Syndrome (CLS) (Trivier et al. 1996). CLS is an X-linked mental retardation syndrome characterized in male patients by psychomotor retardation and facial, hand, and skeletal malformations (Pereira et al. 2010). *Rps6ka3* mutations are extremely heterogeneous and lead to loss of phosphotransferase activity in the RSK2 kinase, most often because of premature termination of translation. It was shown that individuals with CLS consistently presented markedly reduced total brain volume, with cerebellum and hippocampus volumes being particularly impacted in CLS patients. The physiological role of RSK2 was also studied in the mouse through the generation of a deletion model. These mice were

shown to have deficiencies in learning and cognitive functions, as well as having poor coordination compared to wild-type littermates (Dufresne et al. 2001; Poirier et al. 2007). The exact cause for these phenotypes remains unknown, but a recent study demonstrated that shRNA-mediated RSK2 depletion perturbs the differentiation of neural precursors into neurons and maintains them as proliferating radial precursor cells (Cargnello and Roux 2011). Evidently, more experimentation using RSK2-deficient animals will be required to fully understand the developmental role of RSK2 in the nervous system.

Mice deficient in RSK2 expression also develop a progressive skeletal disease, called osteopenia, due to cell-autonomous defects in osteoblast activity (David et al. 2005). Both c-Fos and ATF4 transcription factors were shown to be critical RSK2 substrates involved in these effects in osteoblasts (Cargnello and Roux 2011). In addition, RSK2 knockout mice are approximately 15% smaller than their wild-type littermates, with a specific loss of white adipose tissue that is accompanied by reduced serum levels of the adipocyte-derived peptide, leptin. RSK1/RSK2/RSK3 triple knockout mice are viable, but no other information regarding their phenotype has yet been reported (Cargnello and Roux 2011). The *Rps6ka6* gene (that codes for RSK4) is located on chromosome X and was suggested to be involved in nonspecific X-linked mental retardation, but definitive evidence remains to be provided. Interestingly, deletion of *Drosophila* RSK was found to result in defects in learning and conditioning (Putz et al. 2004), but whether these deficits result from the specific loss of RSK activity will require further investigation.

Summary

Many studies have now clearly established RSK as an important effector of the Ras/MAPK pathway, and it is becoming increasingly evident that deregulation of RSK signaling has a significant role in several human diseases (Romeo and Roux 2011). Recent studies have expanded the repertoire of biological functions linked to the RSK family of protein kinases, ranging from the regulation of transcription, translation, and protein stability to the control of cell survival, cell motility, cell growth, and proliferation. It has become clear that other AGC family members such as Akt and S6K have similar functions and often share similar protein targets. These findings emphasize the importance of a tight and intricate regulation by more than one pathway of cellular processes that are important for cell growth and cell survival. Ongoing systems approaches that aim to identify RSK phosphorylation targets using mass spectrometry should expand our understanding of RSK signaling and function. The generation of isoform-specific mouse knockouts will similarly help resolve the distinct functionality of these protein kinases. Combined, these studies will help to identify additional targets for therapeutic intervention in diseases that are associated with inappropriate signaling downstream of Ras and Raf, and reveal novel targets for biomarker development for disease detection.

Synonyms

Calcium Release Channel; Ryanodine Receptor; Ryanodine-sensitive Ca^{2+} Release Channels; Sarcoplasmic Reticulum Calcium Release Channels

Historical Background

The contraction of cardiac and skeletal muscles requires the release of Ca^{2+} from the sarcoplasmic reticulum (SR) through specialized membrane proteins. The ion channels responsible for the release were not identified until the late 1980s. Ryanodine is an alkaloid found in the South American plant *Ryania speciosa*, and has insecticidal activity. This compound was found to bind to the elusive Ca^{2+} release channel, which was subsequently named the Ryanodine Receptor (RyR) (Meissner 1986). Early biochemical evidence first showed that the channel exists as a homotetramer, with each monomer having a mass of ~550 kDa. This makes RyRs the largest known ion channels at ~2.2 MDa (Lai et al. 1988). They were shown to be located in the SR with a "foot" region that spans the gap between the transverse tubule and the SR. Work on SR vesicles showed that Ca^{2+} release can be observed from these channels and that they could be modulated by various small molecules like ATP, Mg^{2+}, and Ca^{2+}. Recordings made in planar lipid bilayers showed that RyRs are permeable only to small inorganic and organic cations and are completely impermeable to anions.

Mammalian organisms contain three known RyR isoforms. In 1989, Takeshima et al. reported the first primary sequence and cloning of cDNA of RyR derived from rabbit skeletal muscle (RyR1) (Takeshima et al. 1989). The following year, the group of MacLennan published the cloning of the human skeletal muscle RyR and rabbit cardiac muscle isoform (RyR2) (Otsu et al. 1990). A third isoform

(RyR3), distinct from both the cardiac and skeletal muscle isoforms, was originally cloned from brain tissue (Hakamata et al. 1992). The genes of all the isoforms are located on different chromosomes in humans. RyR1 is found on chromosome 19q13.2 spanning 104 exons. The gene encoding RyR2 is on chromosome 1q43 (102 exons) and RyR3 is encoded on 15q13.3-14 (103 exons). In addition to mammalian organisms, RyRs have also been identified in nonmammalian vertebrates with two isoforms, RyRα (homologous to RyR1) and RyRβ (similar to RyR3). Moreover, RyR genes have also been identified in invertebrates including *Caenorhabditis elegans* and *Drosophila melanogaster*.

Overall Function

RyRs are large (~2.2 MDa) ion channels that release Ca^{2+} from the endoplasmic (ER) or sarcoplasmic reticulum (SR) upon opening. In doing so, they play a major role in the contraction of both cardiac and skeletal muscle. Their expression in many cell types suggests they are involved in many diverse processes that are Ca^{2+} dependent. Three different isoforms have been found in mammalian organisms (RyR1, RyR2, RyR3). They are highly similar with amino acid sequence identities of ~70%. There are several divergent regions between the RyRs, with the greatest dissimilarity found near the C-terminus. RyR1 is known as the skeletal muscle form, whereas RyR2 is often referred to as the cardiac isoform. However, all three isoforms are expressed in many diverse cell types. RyRs display significant homology to another intracellular Ca^{2+} release channel, the inositol-1,4,5-trisphosphate receptor.

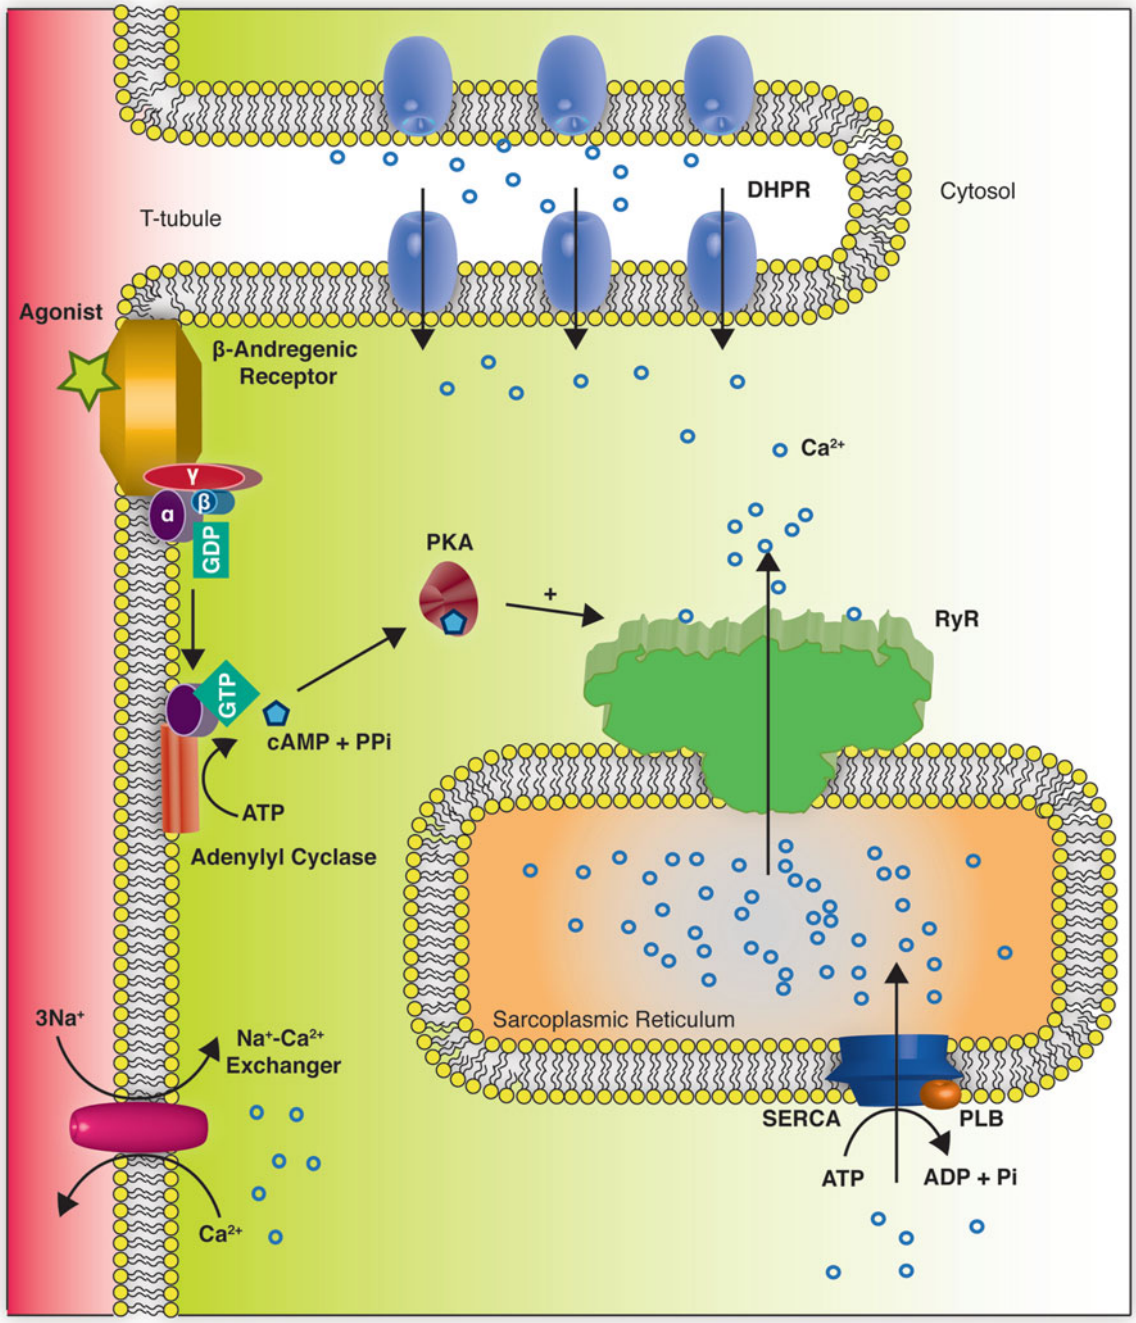
The primary signal to trigger the opening of RyRs is Ca^{2+}. This is especially relevant in cardiac myocytes, in a process known as Ca^{2+}-induced Ca^{2+} release (CICR) (Fig. 1). In this scheme, depolarization of the plasma membrane down the T-tubules leads to opening of L-type voltage-gated Ca^{2+} channels, resulting in the influx of Ca^{2+} from the extracellular space. This signal is detected by RyR2, which binds Ca^{2+}, opens and releases more Ca^{2+} from the SR. The RyR thus acts as a signal amplifier, by detecting small elevations in Ca^{2+} concentrations and increasing the signal. In addition, RyRs can be stimulated by rising Ca^{2+} levels in the ER lumen, in a process known as store overload induced Ca^{2+} release (SOICR) (Jiang et al. 2004). When Ca^{2+} levels in the cytoplasm rise too high, or when the lumenal Ca^{2+} levels drop too low, several mechanisms cause the channel to shut down.

A different situation occurs in skeletal muscle. Whereas RyR1 is also affected by Ca^{2+} levels, it can, in addition, detect conformational changes in the skeletal muscle variant of the voltage-gated Ca^{2+} channel ($Ca_V1.1$). It is thought that there is a direct link between an intracellular loop of $Ca_V1.1$, and the cytoplasmic face of RyR1(Block et al. 1988; Tanabe et al. 1990). Conformational changes in $Ca_V1.1$ can then directly cause structural changes in RyR1 in the absence of an initial Ca^{2+} signal.

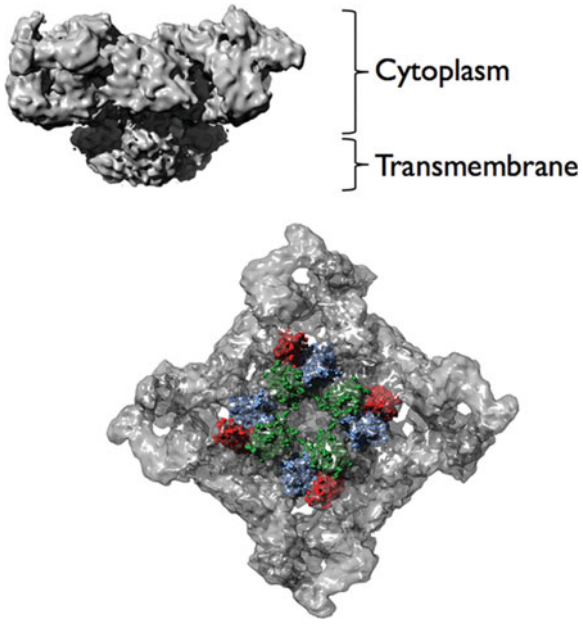
The importance of RyRs is evident from several knockout (KO) studies. RyR1 double KO mice die immediately after birth (Takeshima et al. 1994), whereas an RyR2 KO is embryonically lethal (Takeshima et al. 1998). RyR3 KO mice survive, but have impaired learning abilities (Balschun et al. 1999).

Structure

RyRs have been studied using both low- and high-resolution structural methods. Most notably, several cryo-electron microscopy (cryo-EM) studies have yielded high-quality images of the entire RyR1 isoform in the closed state, with a maximum reported resolution of 9.6 Å (Ludtke et al. 2005). This study, as well as many others on RyR2 and RyR3, revealed that RyRs display a mushroom-like shape (Fig. 2). The bulk of the protein (~90%) is located in the cytoplasm, with the remainder forming the transmembrane segments and ER lumenal portions. The cytoplasmic portion is often referred to as a "foot," and consists of several tubes and holes. This creates a maximum amount of exposed surface for the binding of auxiliary proteins and ligands. At least five α helices can be observed per monomer in the cryo-EM maps, but there is more volume to accommodate additional helices or possibly even β strands (Ludtke et al. 2005). In addition to the closed state architecture, cryo-EM studies have revealed the structure of RyR1 in the open state at 10.2 Å (Samso et al. 2009). Upon opening, the channel seems to undergo large conformational changes in the cytoplasmic region,



Ryanodine Receptor (RyR), Fig. 1 An overview of processes involved in RyR activation in cardiac myocytes. Particular voltage-gated calcium channels known as dihydropyridine receptors (*DHPR*) allow an influx of Ca^{2+} upon the arrival of an action potential. Through *CICR*, the RyR releases Ca^{2+} from the sarcoplasmic reticulum, triggering muscle contraction. Also shown is a PKA-dependent phosphorylation pathway which activates RyR upon β-adrenergic stimulation. The Sodium-Calcium Exchanger pumps remove one Ca^{2+} ion for 3 Na^{+} in return. The Sarco/endoplasmic Reticulum Ca^{2+}-ATPase (*SERCA*) allows for reuptake of Ca^{2+} from the cytosol. It is regulated by phospholamban (*PLB*) which is also a substrate target for PKA



Ryanodine Receptor (RyR), Fig. 2 (*Top*) A cryo-EM structure of RyR1 at 9.6 Å (Ludtke et al. 2005), as viewed from the side. A clear majority of the channel is located in the cytoplasm while only a fraction is embedded within the sarcoplasmic reticulum membrane. (*Bottom*) Top view of the RyR1 cryo-EM map, also showing the crystal structure of the first three N-terminal domains of RyR1, docked into the map (Tung et al. 2010). Shown are domains A (*blue*), B (*green*), and C (*red*). The domains form a four-fold symmetric vestibule of the channel that faces the cytoplasm. The RyR displays many tubes and holes for the binding of modulatory ligands and proteins

along with motions in the pore-forming part of the transmembrane region. The RyR is therefore a bona fide allosteric protein, whereby motions in the pore are coupled to regulatory domains in the cytoplasmic portion.

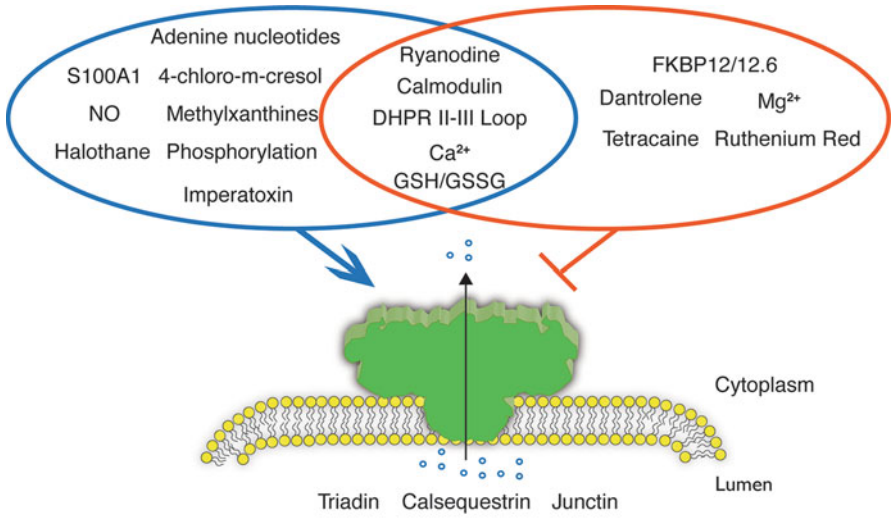
High resolution studies have been limited to individual domains of the RyR. The largest portion includes ~550 amino acids at the N-terminus of RyR1 (Fig. 2). This region folds up as three individual domains, including two β trefoil domains (domains A and B), and a bundle of five α helices (domain C). The three domains are located near the center at the cytoplasmic face, and connect to the corresponding domains in the neighboring subunits (Tung et al. 2010). These domains are predicted to undergo relative motions during opening and closing of the channel, thus being allosterically coupled to the pore region.

Protein and Ligand Interactions

As structural studies have shown, the majority of the volume of RyRs is exposed in the cytoplasm. The large surface area serves as a docking platform for numerous proteins and small molecules that are able to bind and modulate RyR function (Fig. 3). In addition, proteins in the ER lumen can also associate with the RyR. The precise sites of action for many of these interactions are still to be discovered.

Among the notable binding partners of RyRs is Calmodulin (CaM), a Ca^{2+}-binding protein that can provide Ca^{2+}-dependent feedback to RyRs and either stimulate or inhibit the channel depending on Ca^{2+} levels and the precise isoform. FK506-binding proteins (FKBPs) are known to bind tightly to RyRs and stabilize their closed-states. FKBP12 primarily associates with RyR1, while FKBP12.6 has the highest affinity for RyR2. Experimental evidence suggests that removal of FKBP results in subconductance states (Ahern et al. 1997). The ER lumen contains calsequestrin (CASQ), a Ca^{2+}-binding protein that can bind multiple Ca^{2+} ions and oligomerize. Together with the integral membrane proteins junctin and triadin, CASQ is thought to report on luminal Ca^{2+}-levels by providing feedback to the channel (Gyorke and Terentyev 2008). A peculiar interaction is present in skeletal muscle, where RyR1 is thought to interact directly with a protein in the plasma membrane, the voltage-gated calcium channel ($Ca_V1.1$) (Block et al. 1988; Tanabe et al. 1990). This allows for a direct link that couples electrical signals in the plasma membrane to Ca^{2+} release from the SR.

RyRs are the target of phosphorylation and dephosphorylation events. Enzymes implicated in this cycle include Protein Kinase A (PKA), which is anchored via an A kinase anchoring protein (AKAP), Protein Kinase G, protein phosphatases PP1 and PP2A, and the kinase CaMKII. Phosphorylation by both PKA and CaMKII has been found to increase the open probability of the channels, although a lot of controversy exists around the exact effect and mechanism (Bers 2004). Because RyRs are phosphorylated by PKA, they are under the control of β-adrenergic receptors, through a pathway involving G proteins, adenylate cyclase, cAMP, and PKA (Fig. 1). In addition to the proteins mentioned here, RyRs have been found to be modulated by many other binding partners (Fig. 3) (Kushnir and Marks 2010).



Ryanodine Receptor (RyR), Fig. 3 Multiple effectors modulate RyRs. Multiple agonists (*blue*) and antagonists (*red*) are known to affect both RyR isoforms. Some modulators have dual effects, depending on their concentration or specific RyR isoform. Modulation of RyRs can occur from either the cytoplasmic or lumenal side

Several small molecule ligands are also known to affect RyRs (Fig. 3). The receptor is sensitive to Ca^{2+}, in addition to other small cations. Notably, caffeine has a low-affinity binding site on the RyR and stimulates Ca^{2+} release. Ryanodine, a plant alkaloid that was originally found to affect the Ca^{2+} release channel, has dual effects on the channel. It stabilizes subconductance states at lower concentrations, but becomes inhibitory at higher levels (Lai et al. 1989). Various adenosine nucleotides are able to activate RyRs with ATP being the most potent. In addition, RyRs are sensitive to molecules present during oxidative stress such as NO.

Disease

Because Ca^{2+} is a very potent intracellular second messenger, it is not surprising that mutations in RyR genes can cause serious conditions. So far, only mutations in RyR1 and RyR2 have been associated with disease phenotypes (Betzenhauser and Marks 2010). The most commonly associated phenotypes are shown below.

Point mutations in RyR1 can lead to Malignant Hyperthermia (MH), Central Core Disease (CCD), and Multi Mini Core Disease (mmCD). MH manifests itself as severe rises in body temperatures upon the administration of volatile anesthetics, or under conditions of heat stress. CCD and mmCD are disorders with variable pathologies, but they are usually associated with cores of metabolically inactive tissue in the center of muscle fibers. Very often this results in muscle weakness.

In cardiac muscle, mutations in RyR2 are a cause of sudden cardiac death, mostly associated with two types of cardiac arrhythmias, catecholaminergic polymorphic ventricular tachycardia (CPVT) and arrhythmogenic right ventricular dysplasia type 2 (ARVD2). CPVT is associated with bidirectional VT, usually triggered by emotional or physical stress. ARVD2 results in the replacement of ventricular tissue with fibrofatty deposits. In addition, idiopathic ventricular fibrillation can be the result of loss of RyR2 function.

The bulk of the mutations characterized so far cause a gain of function, resulting in increased or prolonged Ca^{2+} signals in the cytoplasm. In cardiac myocytes, this may activate the Na^+/Ca^{2+} exchanger, situated in the plasma membrane, which exchanges one Ca^{2+} for 3 Na^+ ions. The net influx of additional positive charges causes a delayed after depolarization (DAD), underlying the arrhythmogenic nature of the mutations. In skeletal muscle, the activation of RyR1 by halogenated anesthetics can cause a massive release of Ca^{2+}, leading to activation of Ca^{2+} ATPases. This depletes the ATP reserve, driving the cell in a hypermetabolic state which causes acidosis and a lethal increase in temperature (Betzenhauser and Marks 2010).

Disease mutations in RyR1 and RyR2 seem to cluster in three different regions of the receptor genes (hot spots). These three locations in both receptors match, suggesting important functional roles for those portions. They are located near the N-terminus, in a central domain region, and a C-terminal

region covering the transmembrane segments. A high-resolution structure of the N-terminal hot spot shows that most mutations affect domain–domain interactions (Tung et al. 2010). As these domains likely move during opening of the channel, weakening their interfaces is thought to facilitate the opening, causing inadvertent leak of Ca^{2+} into the cytoplasm.

Summary

Ryanodine Receptors (RyRs) are large ion channels, located in the membrane of the ER, that release Ca^{2+} upon stimulation. Three isoforms are found in mammalian organisms. All form homotetrameric assemblies of up to 2.2 MDa in size, and have a very large cytoplasmic portion that contains phosphorylation targets and docking sites for multiple small molecules and protein binding partners. Ca^{2+} is the primary ligand that triggers opening, and the channel can sense both cytoplasmic and lumenal Ca^{2+} levels. They play a prime role in excitation-contraction coupling, whereby they amplify the signal generated by voltage-gated calcium channels. Mutations are known to cause devastating diseases originating either in skeletal or cardiac muscle, and most of them are responsible for a gain of function, leading to increased Ca^{2+} release.

Historical Background/General: S100 Family

S100 proteins were first discovered in 1965 by Moore as a major protein fraction (0.6% of total soluble protein) isolated from bovine brain (Moore 1965). The protein was given the name S100 due to its high solubility in saturated ammonium sulfate. Later experiments showed the S100 protein fraction constituted two different dimeric species comprised of two β protomers (S100B) or an α, β heterodimer (Isobe et al. 1977). Early members of the S100 protein family were frequently given suffixes based on their localization or molecular size and included S100P (placental), S100C (cardiac or calgizzarin), p11 (11 kDa), and MRP8/MRP14 (myeloid regulatory proteins, 8 and 14 kDa). In 1993, initial genetic studies showed that six of the S100 genes were clustered on chromosome 1q21 (Engelkamp et al. 1993), a number that has expanded since. Based on this observation most of the proteins were renamed according to the physical order they occupy on the chromosome. These include S100A1 (formerly S100α), S100A2 (formerly S100L), S100A10 (p11), S100A8/S100A14 (MRP8/MRP14). A few S100 proteins are found on other chromosomes including S100B (21q21). Currently there are 27 known S100 family members: S100A1-A18, S100B, S100G, S100P, S100Z, trichohylin, filaggrin, filaggrin-2, cornulin, and repetin (Table 1).

Role of S100 Proteins in Calcium Signaling

The S100 proteins are members of the EF-hand family of calcium-binding proteins that also includes calmodulin, ► recoverin, and troponin-C. The sequence similarity between S100 family members is very high ranging from 54% for distantly related family members such as S100B and S100A14 to 76% for S100B and S100A1, which are located in close proximity on the S100 phylogenetic tree (Marenholz et al. 2004). Each S100 protomer contains between 90 and 114 residues and two calcium-binding sites. The first

			Inflammation	RAGE

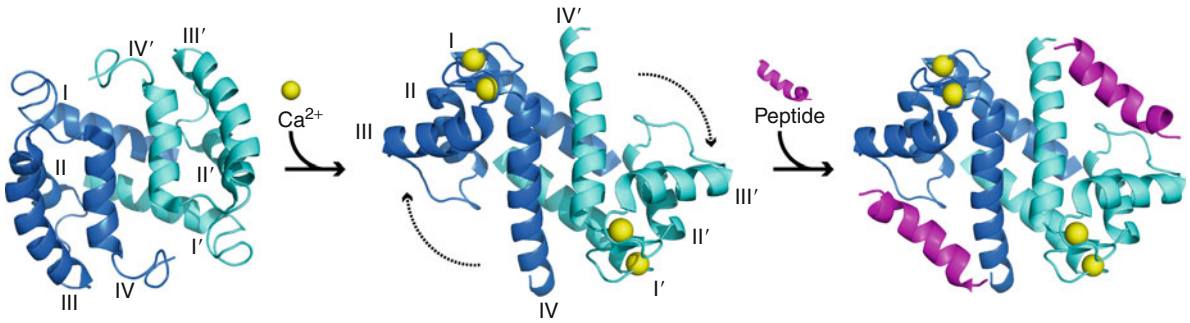
Only S100 proteins with known signaling functions have been included in this table. Where possible (+) and (−) signs indicate the positive and negative regulation of the signaling function by the S100

[a]5-hydroxytryptamine receptor (5HT4/5HT1B), acid-sensing ion-channel-1a (ASIC1a), actin-capping protein (CapZ), c-jun activation domain binding, protein-1 (Jab1), casein kinase (CKI/CKII), cell division control protein 42 (Cdc42), cyclophillin 40 (CyP40), dopamine D2 receptor (D2R), FGF receptor-1 (FGFR1), fibroblast growth factor-1 (FGF1), G-protein coupled receptor (GPCR), glial fibrillary acidic protein (GFAP), heat shock protein (HSP), hsp70/hsp90 organizing protein (HOP), immunophilin (FKBP52), interleukin-1 (IL1α), kinesin light chain (KLC), matrix metalloproteinase-2 (MMP2), methionine aminopeptidas-2 (METAP2), microtubules (MT), mitochondrial ATPase (F1-ATPase), murine double minute (MDM2), mylein-associated glycoprotein (MAG), myogenic differentiation transciption factor (MyoD), nicotinamide adenine dinucleotide phosphate (NADPH), nuclear Dbf2-related protein kinase (NDR kinase), nuclear factor kappa-light-chain-enhancer of activated B-cells (NFκB), p38 mitogen activated protein kinase (MAPK), peptidylarginine deiminase type III (PAD3), phospholamban (PLB), phospholipase A2 (PLA2), protein kinase C (PKCα), prothymosin-α (ProTα), Ras GTPase-activating-like protein-1 (IQGAP1), receptor for advanced glycation end-products (RAGE), Rho GTPase-activating protein (RhoGAP), Ryanodine receptor (RyR1/RyR2), S100A6 binding protein/Siah 1 interacting protein (CacyBP/SIP), sarcoplasmic reticulum ATPase (SERCA2a), sodium voltage channel 1.8 (NAV1.8), synaptotagmin-1 (Syt1), tissue Plg activator (tPA), transient receptor potential channel (TRPV5/TRPV6), TWIK-related acid-sensitive K-1 (TASK-1), vesicle-associated membrane protein-2 (VAMP2), zymogen plasminogen (Plg)



S100 Proteins, Fig. 1 A general calcium-signaling mechanism for the S100 proteins. The three-dimensional structure of calcium-free S100B (*left*) comprises a symmetric dimer (*cyan, purple*) with each protomer possessing four α-helices (I-IV, I′-IV′) (Malik et al. 2008). Upon influx of calcium to the cytosol, the S100 protein binds calcium to two sites in each protomer (middle) forming the "open" conformation. In this structure, helix III (and III′) rearrange by approximately 100° compared to helix IV. This structural change exposes a shallow hydrophobic cleft used to recruit a target protein such as the N-terminus of NDR kinase (residues 72–87 shown) (*right*) that functions with S100B in regulation of cell proliferation and maintenance of cell morphology (Bhattacharya et al. 2003)

three-dimensional structure of an S100 protein was determined for calcium-free S100A6 (Potts et al. 1995). Subsequent to this, more than 40 structures of calcium-free, calcium-bound, and S100-protein complexes have been determined. These structures have shown the S100 protomer comprises two helix-loop-helix EF-hand motifs (Fig. 1). The first EF-hand comprises a 14-residue non-canonical calcium-binding site with weak calcium affinity sandwiched between two α-helices (I, II). The second EF-hand contains helices III and IV along with a 12-residue canonical calcium-binding site that typically has a higher affinity for the metal ion. The S100 dimer is formed through interactions between helices I and IV (I′, IV′) from each protomer (Fig. 1).

Calcium signaling is propagated by an S100 protein through its calcium-binding properties. In the resting cell, intracellular calcium levels are at around 100 nM. Due to the relatively low calcium affinity of S100 proteins, they are likely found in the calcium-free or apo state at resting cellular calcium concentrations. As a result of an extracellular signal from ligand-receptor binding, stress, or injury, calcium concentrations within the cell increase about tenfold, high enough to allow an S100 protein to bind two calcium ions per S100 protomer. The binding of calcium results in a conformational change of the S100 protein. The rearrangement causes helix III of each monomer of the S100 protein to swing outward resulting in a more "open" conformation (Fig. 1). For example, in S100B helix III rotates by more than 100° in relation to helix IV, exposing several hydrophobic residues at the helix III-IV interface (Drohat et al. 1998) while other S100 proteins open to varying degrees (Malik et al. 2008). The large, flat nature of this hydrophobic patch is used to recruit a considerable number of other proteins in the cell, giving rise to varied biological responses (Bhattacharya et al. 2004). Because the S100 dimer is symmetric, the net result of the calcium-binding event is exposure of two ligand-binding sites per molecule.

S100 proteins play a role in regulation of protein phosphorylation, enzyme activities, transcription factor activation, and cytoskeletal reorganization (Donato 2001; Santamaria-Kisiel et al. 2006). For example, S100B acts to modulate the phosphorylation activity of Ndr kinase, an important cell division enzyme, through binding of the autoinhibitory region of Ndr kinase (Fig. 1) (Bhattacharya et al. 2003). This in turn causes the release of the catalytic domain allowing autophosphorylation of key Ser/Thr residues, and full activation of the kinase as a key step in the regulation of cell division. Similarly, the heterodimeric S100A8/S100A9 protein inhibits the phosphorylation activity of the enzymes Casein Kinases I and II that are involved in cell-cycle control (Murao et al. 1990). S100A1, S100A2, S100A4, S100A8, S100A10, and S100B have been shown to bind to components of the cytoskeleton including tubulin, intermediate filaments, actin, and ▶ myosin modulating the assembly of these proteins. For example, the interaction between S100B and CapZ regulates actin filament extension. Binding of CapZ inhibits S100B from associating with, and

disassembling, microtubles and intermediate filaments (Sorci et al. 2000).

In some cases, S100 proteins can bind to targets in the absence of calcium in which case expression levels, cellular localization and, ultimately, availability of the target protein control their signaling role. In one particular case, substitutions in the calcium-binding sites of S100A10 prevent it from binding calcium, yet the protein retains an "open" conformation similar to other calcium-bound S100 proteins. In an interesting turn S100A10 interacts with partner proteins such as Annexin A2, which itself is a calcium-binding protein. It is the calcium-binding properties of Annexin A2 that regulate formation of a complex with S100A10 that is proposed to bridge phospholipid membranes in fusion and repair processes (Gerke and Moss 2002).

Expression and Tissue Specificity

The members of the S100 protein family are expressed in a wide variety of tissue types. Some of the S100 proteins appear to have ubiquitous expression (S100A11, S100A16) while others are expressed in only one or two specific tissue types (Table 1). The S100 proteins are typically expressed in the cytoplasm within cells but can undergo nuclear localization and even translocation to the extracellular matrix, through an unknown mechanism. Determining the expression profile for the S100 proteins is complicated due to their regulation by various cellular stimuli. For example, the expression of S100A8, S100A9, and S100A11 is altered due to infection or DNA damage. In addition, the S100 gene cluster is frequently rearranged in cancer cell types, often resulting in either increased or decreased S100 protein expression. One of the more unique and well-studied S100 proteins is S100B, which is expressed predominantly in glial cells of the brain. Recently the Dopamine D2 Receptor, which is found almost exclusively in brain tissue, was identified as a new S100B binding partner and it appears that S100B can enhance the dopamine signal (Liu et al. 2008). S100A1 is another S100 with a very specific tissue distribution. It is highly expressed in cardiac muscle cells and helps to regulate calcium cycling and contractile performance by binding to the ▶ Ryanodine Receptor (RyR) and the sarcoplasmic reticulum ATPase (SERCA2a). Interestingly, calcium-bound S100A1 competes at an overlapping binding site on the ▶ RyR with another EF-hand signaling protein calmodulin. The binding of S100A1 to ▶ RyR enhances calcium release and cell contraction in heart muscle while CaM binding results in inhibited ▶ RyR function (Treves et al. 1997).

Several S100 proteins are involved in the immune response. For example, S100A7 and S100A15 have been implicated in inflammation pathways leading to psoriasis and are highly expressed in epithelial cells. The S100A8/A9 heterodimer is expressed in immune cell types such as macrophages, neutrophils, and monocytes and are part of an inflammation pathway that is often involved in arthritis (Odink et al. 1987). For example, the expression of these proteins is regulated by transcriptional events such as the upregulation of mRNA of S100A8 and S100A9 in response to bacterial infection. Interestingly, the expression of S100A8, S100A9, and S100A7 has also been shown to be repressed by the transcription factors BRCA1 and c-▶ Myc, which are known as strong anticancer genes and appear to bind to the promoter elements of these S100 proteins. Not surprisingly, expression of the S100A7 gene has been shown to be DNA-damage inducible where it likely functions to regulate cell cycle progression.

Some S100 proteins have either been found in the extracellular matrix, or have been implicated in a signaling path through binding to the extracellular domain of the receptor for advanced glycation endproducts (RAGE). The RAGE receptor transduces extracellular stimuli leading to the activation of ▶ NF-κB and the release of proinflammatory cytokines as part of the innate immune response. Currently 12 different S100 proteins (S100A1, S100A4-S100A9, S100A11, S100A12, S100A14, S100B, S100P) have been found to interact with RAGE and elicit a variety of cellular responses. Interestingly, none of the S100 family members are expressed with signal peptides, which are normally required for transport across the cellular membrane through ER/golgi targeting. Therefore, S100 translocation is likely occurring through an alternate, but unidentified, mechanism.

Several S100 proteins experience altered localization in order to perform specific functions. For example, DNA damage (double-strand breaks and/or cell stress-calcium) results in the translocation of S100A11 to the nucleus by the nuclear transport protein nucleolin. Once in the nucleus, S100A11 competes with Sp1 for binding to nucleolin (Sakaguchi et al. 2003).

Free Sp1 results in changes in the transcription factor p21 and termination of DNA synthesis. Likewise, when a calcium signal is received, cytoplasmic S100A10 is targeted to the inner surface of the cell membrane by its binding partner Annexin A2.

S100 Proteins and Disease

Many S100 proteins and their signaling pathways are linked to a variety of diseases such as cancer (including: breast, prostate, bladder, lung, colorectal, melanomas), inflammatory conditions (including arthritis, psoriasis, Crohns/colitis), neurological disorders (including Alzheimer's, Parkinson's, schizophrenia), and cardiomyopathies.

A large number of S100 proteins are associated with cancers. Altered levels of expression of the S100 proteins have been linked to the disease and therefore are being used as biomarkers for the measurement of patient outcome. The majority of the S100 genes are located in a cluster on human chromosome 1q21, called the epidermal differentiation complex. This gene cluster is frequently rearranged in a wide array of cancers. This link between S100 proteins and cancer is likely due to the role that many of the proteins play in signaling paths involved in differentiation and proliferation of cells. In addition to their direct involvement in cancer, some of the S100 proteins are involved in cancer metastasis through their functioning in the regulation of cell motility. S100A4, S100A7, S100A12, S100B, and S100P are all involved in signaling pathways tied to cell migration and as a result are often linked to poor prognosis in cancer. S100 proteins have potential to be used as biomarkers for cancer screening. For example, overexpression of S100B correlates with reduced survival in malignant melanoma patients. Levels of S100B expression are being used in a clinical setting as a diagnostic marker for staging the melanoma, determining prognosis, evaluating treatment, and predicting relapse (Harpio and Einarsson 2004).

Several S100 proteins alter the activity of the tumor suppressor protein, ▶ p53 (Salama et al. 2008). Some S100 proteins, such as S100A4 and S100B, inhibit the phosphorylation of ▶ p53 by binding to its C-terminus. This leads to a decrease in its transcriptional activity and inhibition of its tumor-suppressor function. Alternatively, other S100 proteins, such as S100A2, have been found to upregulate ▶ p53 activity and increase the expression of pro-apoptotic genes. S100A4 overexpression has been linked to several cancers including bladder, breast, thyroid, lung, prostate, and colorectal cancers. S100A4 plays role in the metastasis of cancer cells by potentially altering cell motility through its interactions with F-actin and ▶ myosin and increasing invasiveness through the regulation of matrix metalloproteinase (MMP) activity. S100A7 is overexpressed in breast, bladder, and skin tumors and its elevated levels indicate poor prognosis and reduced survival. Enhancement of breast cancer cell survival mechanisms through an interaction of S100A7 with Jab1 has been shown. S100A8 and S100A9 form a heterodimer and together are upregulated in gastric, prostate, and colorectal cancers. In prostate tumor cells, S100A8/A9 were found to induce activation of the ▶ NF-κB pathway and cause phosphorylation of ▶ MAP Kinase through an extracellular interaction with RAGE. In some cases, S100 overexpression is related to tumor suppression rather than promotion. For example, S100A2 is expressed in the prostate, but is downregulated in prostate cancer. Similar observations have been found in breast cancer, with normal mammary epithelial cells expressing S100A2 but not tumor cells. Overexpression of S100A11 has been linked to tumor suppression in bladder and renal carcinomas.

S100B is found in the cells of the brain and has been linked to a number of neurological disorders such as Alzheimer's disease (AD). In the example of AD, S100B protein is found to be overexpressed in the astrocytes of affected individuals. Similarly, patients with schizophrenia also have increased serum concentrations of S100B protein. S100B has been shown to interact with the Dopamine D2 Receptor and can increase receptor signaling. The D2-Receptor is involved in neuromodulation and is closely tied to the above-mentioned disorders.

Downregulation of S100A1 results in a diseased heart and can lead to heart failure. S100A1 binds calcium during the calcium oscillations of heart cells increasing the contractile performance of the cardiomyocytes. The use of S100A1 gene therapy for the treatment of heart failure is approaching clinical trial stages. Keratinocytes overexpress S100A7 in the skin disorder, psoriasis. S100A8/S100A9 are secreted by neutrophils and play a role in inflammatory diseases such as inflammatory arthritis.

The S100A10/Annexin A2 complex controls the recruitment and function of ion channels including CFTR in cystic fibrosis.

Summary

First discovered in the brain, the S100 proteins are expressed in a wide variety of tissues. There are a large number of S100 family members and each has multiple binding partners and functions. The members of the S100 protein family are EF-hand calcium-binding proteins, which utilize calcium to propagate a response through a signaling pathway. Binding of calcium to the S100 protein causes a structural rearrangement, exposing a target-binding surface. This surface in most S100 proteins is large and can accommodate multiple targets, sometimes at the same time. Target binding results in a range of responses from inflammation and cytoskeletal reorganization to control of cell growth and tumor suppression. Altered expression of S100 proteins has been found in a number of human cancers and these proteins are becoming recognized as important signaling molecules in this disease. In addition, some S100 proteins such as S100B, are linked to neurological diseases including Parkinson's, Alzheimer's, and schizophrenia. Future research focusing on the in vivo identification of new target proteins will help expand the knowledge of S100 signaling pathways and the mechanisms these proteins use to recruit molecules. This in turn may allow some of the S100 proteins to become valuable pharmacological targets.

Synonyms

HACS1

Historical Background

The gene encoding SAMSN1 maps to human chromosome 21q11.2 in a region that is frequently disrupted by translocation events in hematopoietic malignancies (Mitelman et al. 1997). The full-length cDNA of human SAMSN1 was first identified and cloned in 2001 by two groups from myeloma cells and human cord blood–derived mast cells, named as HACS1 and Nash1, respectively (Claudio et al. 2001; Uchida et al. 2001). The predicted protein showed unique primary structure with a nuclear localization signal (NLS), a sterile alpha motif (SAM), and a Src homology 3 domain (SH3). SAMSN1 belongs to a novel family of scaffolding and adaptor proteins that includes SASH3/SLY/HACS2 (Beer et al. 2001) and SASH1/KIAA0790 (Zeller et al. 2003). The function of this novel family is not well characterized. The mouse, rat, and chimp orthologs have been identified, and unnamed protein homologs exist in chicken, zebrafish, and fly.

Expression of SAMSN1

SAMSN1 is expressed in hematopoietic tissues, particularly in B cells, macrophages, mast cells, and dendritic cells (Claudio et al. 2001). In embryonic mouse (Gitton et al. 2002; Reymond et al. 2002), it is highly expressed in blood vessels at 9.5–10.5 days post coitum (dpc). It is also expressed in the brain, future spinal cord, dorsal root ganglia, otocyst, eye, limb, heart, surface ectoderm, and bronchial arch, albeit at lower levels. At 14.5 dpc, weak and regionally restricted expression in the skin and homogenous weak expression in mesenchyme can be detected by in situ hybridization, but expression can no longer be detected in the brain or arterial and venous systems. In human, it is also expressed in the adult heart, kidney, placenta, and lung, and major expression can be detected in the bone marrow, peripheral blood, and immune tissues, including lymph node, spleen, and thymus. The Gene Expression Atlas database (http://www.ebi.ac.uk/gxa) shows human SAMSN1 is differentially expressed in 95 experiments, 40 organism parts, 100 disease states, 37 cell types, 27 cell lines, 13 compound treatments, and 20 other conditions.

Protein and Splice Variants

SAMSN1 encodes a 441 amino acid protein containing two domains frequently associated with signaling molecules. An SH3 motif is in the middle half of the protein and a SAM domain is located toward the C-terminal end. The SH3 motif shares 39% homology with the well-characterized adaptor protein Crk. There are three predicted consensus nuclear localization signals. A tyrosine kinase phosphorylation motif is predicted at amino acids 221–228. The orthologous mouse *Hacs1* gene is located on murine chromosome 16, which encodes a protein of 364 aa with an overall 87% homology to human SAMSN1 at protein level.

Two major splice variants have been detected in both human and mouse. The difference between these major variants is the N terminus, but both contain the SAM and SH3 domains. These two variants suggest

that there are two different promoters. In addition to truncation of the N terminus, six additional transcripts appear to differ by truncation of the 3' end and the presence or absence of, or differential use of, boundaries of eight cassette exons (http://www.ncbi.nlm.nih.gov/IEB/Research/Acembly).

Function of SAMSN1 in Immune Responses

An in vitro study and immunoblotting analysis showed SAMSN1 expression is upregulated in activated human B cells treated with interleukin (IL)-4, IL-13, CD40L, and anti-immunoglobulin (Ig) M. In murine spleen B cells, *Samsn1* can also be upregulated by IL-4, lipopolysaccharide, but not IL-13 (Zhu et al. 2004). SAMSN1 associates with tyrosine-phosphorylated proteins after B cell activation and binds in vitro to the inhibitory molecule paired Ig-like receptor B (PIR-B). Overexpression of *Samsn1* in murine spleen B cells resulted in a downregulation of the activation marker CD23 and enhancement of CD138 expression, IgM secretion, and *Xbp-1* expression. Silencing *SAMSN1* in a human B lymphoma cell line by small interfering ribonucleic acid did not significantly change IL-4-stimulated B cell proliferation.

In vivo study was performed by generating *Samsn1* gene knockout mice ($Samsn1^{-/-}$) (Wang et al. 2010). *Samsn1* knockout mice were viable and fertile and had normal bone marrow B cell development and normal splenic T cell and B cell populations. However, similar to PIR-B-deficient mice, $Samsn1^{-/-}$ mice have an increased peritoneal B1 cell population, increased phosphorylation of *Lyn* kinase in B cells, and augmented adaptive immune responses, suggesting that *Samsn1* plays an important role in suppression of adaptive immunity. Interestingly, SASH3/Sly, another member in the same family of SAMSN1, which has a 50% amino acid identity with SAMSN1 and also similarly expressed in lymphocytes, was found to play an opposite role to *Samsn1* (Beer et al. 2005). Mice expressing a defective SLY ($SLY1^{d}$) protein exhibit impaired immune responses and prolonged allograft survival.

SAMSN1 and Cancer

SAMSN1 protein was detected from different hematopoietic malignant cells, including myeloid leukemia, lymphoma, and multiple myeloma. The function of SAMSN1 in those cells remains unknown. SAMSN1 was suggested as a candidate tumor suppressor in a recent extensive screening of a large panel of lung cancer cell lines (Yamada et al. 2008). In another study, SASH1, another member in this family, has been described as a candidate tumor suppressor gene downregulated in breast cancer (Zeller et al. 2003). SASH1 was also reported to serve as a candidate tumor suppressor in colon cancer and associated with patient prognosis (Rimkus et al. 2006).

Summary

SAMSN1 is a member of a novel gene family of putative adaptors and scaffold proteins containing SH3 and SAM domains. Recent studies demonstrated SAMSN1 is a component of immune response and is upregulated and functions in activation of adaptive immunity. SAMSN1 was suggested as a candidate tumor repressor. Future studies will continue to investigate the functions of SAMSN1 in different normal cells and tumor cells, to identify the pathways, partners and mechanisms involved in SAMSN1-mediated biological or pathologic consequences.

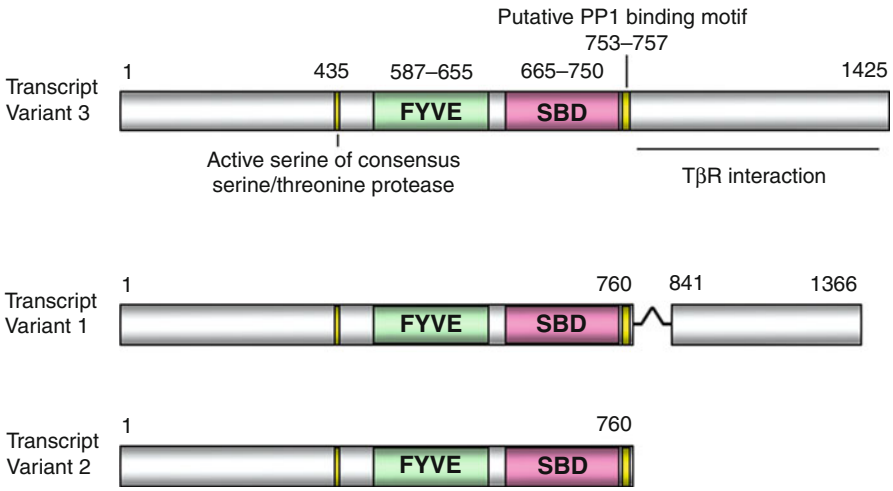
Historical Background

The adaptor protein SARA was first identified as a novel serine protease-like molecule in human brain (Meckelein et al. 1998), and then later characterized as an important regulator of TGF-β1 signal transduction. SARA interacts with both the type I and type II TGF-β1 receptors (TβRI and TβRII), and contains a Smad-binding domain (SBD) as well as a double zinc finger FYVE domain that localizes SARA to endosomal subcellular compartments (Tsukazaki et al. 1998). SARA also contains a region homologous to the active site of trypsin-like serine proteases (Meckelein et al. 1998) and a binding motif for the catalytic subunit of type 1 serine/threonine protein phosphatase (PP1c) (Bennett and Alphey 2002). Three alternatively spliced transcripts encoding distinct isoforms have been found for this gene (Fig. 1).

SARA in TGF-β1 Signaling

The TGF-β superfamily consists of TGF-β1, TGF-β2, TGF-β3, activins, and bone morphogenic proteins (BMP). These proteins are widely expressed in virtually all mammalian cell types, as are their downstream signaling mediators, the Smad proteins. TGF-β signaling is initiated when ligand-bound TGF-β type II receptor (TβRII) binds to, and phosphorylates, the TGF-β type I receptor (TβRI) (Roberts et al. 1990; Piek et al. 1999; Shi and Massague 2003). This phosphorylation, in the TβRI cytoplasmic GS region, leads to its activation and its ability to activate the receptor-regulated Smads (R-Smads), Smad2, and Smad3, by C-terminal serine phosphorylation. Once phosphorylated, the R-Smads form a heteromultimeric complex with the common mediator (Co)-Smad (Smad4) and accumulate in the nucleus to regulate transcriptional responses (Roberts et al. 1990; Piek et al. 1999; Shi and Massague 2003). The inhibitory Smads, Smad6 and Smad7, compete with the R-Smads for binding to the activated receptors (Shi and Massague 2003). R-Smads and Smad4 contain a Mad Homology (MH)-1 domain, which confers transcriptional activity, a linker region, and an MH2 domain involved in protein-protein interactions with other transcription factors and co-activators (Piek et al. 1999; Shi and Massague 2003). Figure 2 shows a basic diagram of the Smad signaling cascade induced by TGF-β1. However, this



SARA, Fig. 1 Putative domain structure of the three known variants of SARA. FYVE; zinc finger domain, named after the four cysteine-rich proteins: Fab 1 (yeast orthologue of PIKfyve), YOTB, Vac 1 (vesicle transport protein), and EEA1, in which it has been found. SBD; Smad-binding domain

oversimplified pathway is clearly insufficient to explain the plethora of outcomes induced by TGF-β1. Numerous proteins have been identified that promote Smad expression, stability, activation, and assembly into transcription-regulatory complexes (Bottinger and Bitzer 2002). Among these proteins, recent research has demonstrated important roles for adaptor proteins such as SARA that control the localization of Smads and TβRs, and the interaction of Smads with the receptor complex.

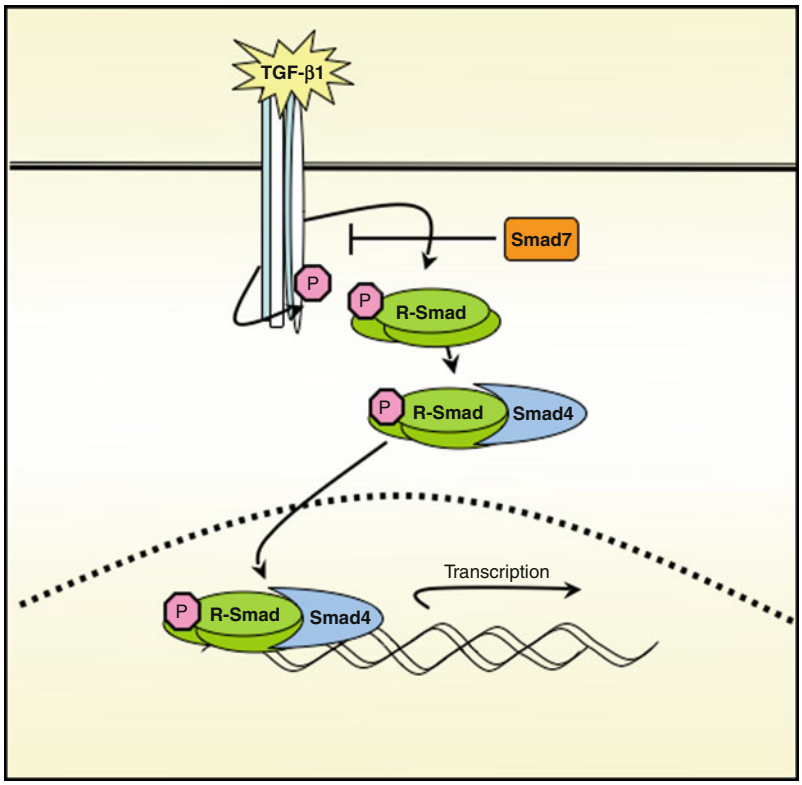
SARA was initially described as a recruitment factor, bringing R-Smads to the TβR complex for phosphorylation (Tsukazaki et al. 1998). In that study, SARA and Smad2 were described as being associated basally but separated upon TGF-β stimulation. However, a subsequent study found minimal basal association between SARA and Smad2, but a strong interaction after treatment with TGF-β (Runyan et al. 2005). SARA can associate basally with TβRI and TβRII (Tsukazaki et al. 1998). Therefore, it remains unclear whether SARA is predominantly localized with R-Smads or with TβRs in unstimulated cells.

The SBD of SARA can interact with the MH2 domain of either Smad2 or Smad3 (Tsukazaki et al. 1998) when over-expressed in cultured cell lines. However, examination of endogenous protein expression and interaction suggests that SARA preferentially binds Smad2 over Smad3 (Runyan et al. 2005). The ability of Smad3 to interact with SARA has been reported to be dispensable for Smad3 function (Goto et al. 2001; Runyan et al. 2009). In contrast, knockdown of SARA in HKC kidney proximal tubule cells results in a specific reduction in Smad2 expression, phosphorylation, nuclear translocation, and transcriptional activity (Runyan et al. 2009). In hepatic stellate cells, SARA expression is reduced during myofibroblastic differentiation and this reduced expression of SARA corresponds to a switch in predominant R-Smad activation by TGF-β from Smad2 to Smad3 (Liu et al. 2003).

In addition to promoting Smad2-dependent signaling, SARA may also function as a negative regulator of the TGF-β pathway. The *Drosophila melanogaster* homolog of SARA (Sara) binds the catalytic subunit of the type 1 serine/threonine protein phosphatase (PP1c), and mutations that disrupt this interaction result in hyper-phosphorylated type I receptor and inhibition of TGF-β-mediated signaling (Bennett and Alphey 2002). Later studies suggested that it was the Smad7-mediated antagonism of TβRI that was enhanced by the SARA PP1c interaction. Smad7 binds to the GADD34 regulatory subunit of the PP1 holoenzyme, which results in recruitment of the PP1c catalytic subunit to dephosphorylate the TβRI. This recruitment is enhanced by SARA interaction with PP1c (Shi 2004).

Endocytosis, SARA, and TGF-β1 Signaling

Tightly controlled localization of the TGF-β signaling components makes logistic sense as a modulator of the otherwise simple and linear Smad pathway. However, while roles for clathrin-mediated endocytosis (CME) as well as caveolar internalization have recently been proposed to impact the TGF-β pathway, receptor



SARA, Fig. 2 Basic TGF-β-Smad signaling pathway

trafficking in TGF-β-mediated Smad signaling is not completely understood.

CME initiates with formation of clathrin-coated vesicles via interaction of cytosolic proteins with components of the inner leaflet of the plasma membrane. Transmembrane receptors bind directly or indirectly to the heterotetrameric AP-2 adaptor complex which then interacts with the clathrin triskelion that polymerizes to form a basket-shaped lattice pulling the membrane into the cell. This invaginated clathrin-coated vesicle (CCV) is then internalized to the major sorting center of the cell, the early endosome. From the early endosome, internalized material can be transported back to the membrane through the recycling endosome, or routed to either the late endosome or to the trans-Golgi network. From either the late endosome (also referred to as a multi-vesicular body) or the trans-Golgi, internalized proteins may be redirected back to the early endosome, back to the membrane, or to the lysosome for degradation. These processes of endocytosis, trafficking, endosome fusion, and exocytosis (reviewed in (Mousavi et al. 2004; Miaczynska et al. 2004)) are controlled by diverse members of the Ras-like small G proteins called Rab GTPases. Like other GTPases, the Rab proteins cycle between an active, GTP-bound, and an inactive, GDP-bound state. Individual isoforms of the Rab proteins are localized to the surface of distinct, membrane-bound organelles. Rab4, Rab5, and Rab11 localize to early endosomes. However, Rab4 or Rab11 may also be found on the surface of perinuclear recycling endosomes. Rab7 and Rab9 localize to late endosomes and lysosomes, and Rab1 and Rab2 associate with vesicles mediating ER-to-Golgi transport (Seachrist and Ferguson 2003).

The FYVE domain in SARA directs its localization to Rab5-containing early endosomes. Within the early endosome, SARA interacts with Smad2 and the TβR complex. Other components that may be part of the SARA-containing endosome are the early endosome antigen 1 (EEA1), the cytoplasmic isoform of the promyelocytic leukemia tumor suppressor (cPML), and the hepatic growth factor-regulated tyrosine kinase substrate (Hrs).

EEA1 is a protein involved in the formation of the early endosome. cPML expression is induced by TGF-β1 and has been shown to be required for SARA association with Smad2 and for SARA and TβR accumulation in the early endosome (Lin et al. 2004).

Hrs is another FYVE domain-containing protein that regulates endosomal sorting and plays a critical role in the recycling and degradation of membrane receptors. Hrs binds to Smad2 and cooperates with SARA to stimulate activin-mediated signaling (Miura et al. 2000).

While the importance of internalization in dampening a signal through downregulation of receptors is well studied, endocytosis may also serve to propagate the signal, and this has led to the concept of a "signaling endosome" (Miaczynska et al. 2004; Benmerah 2004). The importance of endocytosis in TGF-β1 signaling has been described in numerous reports (Hayes et al. 2002; Penheiter et al. 2002; Runyan et al. 2005). Disruption of SARA endocytic localization through either expression of a mutant SARA lacking the FYVE domain (SARA/Δ1-664) (Tsukazaki et al. 1998) or inhibition of PI3P generation by wortmannin treatment (Itoh et al. 2002) causes a redistribution of SARA from punctate endocytic structures to the cytosol, and can prevent TGF-β1-mediated transcriptional responses.

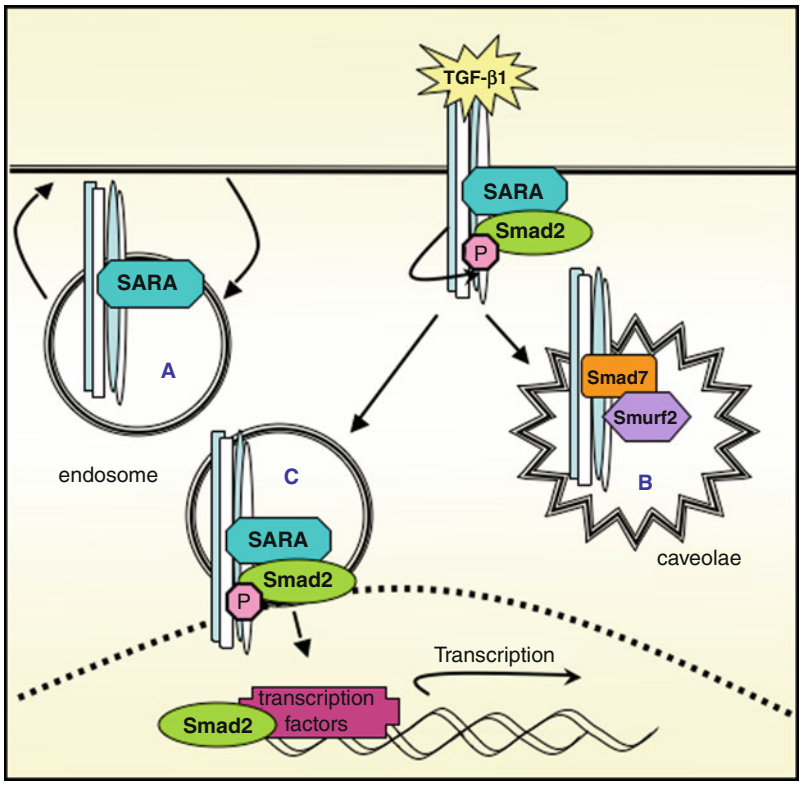
How the endosome specifically functions in TGF-β signaling is not known (Fig. 3). It may be that localization of the TβR to EEA1-positive, SARA-containing endosomes protects them from their alternative localization through the lipid raft-caveolar internalization pathway where they would interact with Smad7 and Smurf2 and be degraded (Di Guglielmo et al. 2003). Another possibility is that endosomal trafficking acts as a transport mechanism bringing the activated R-Smad in proximity of the nucleus. Smad2 can enter the nucleus through direct interaction with the nucleoporins CAN/Nup214 and Nup153, and these nucleoporins compete with SARA for the interaction with the hydrophobic corridor on the MH2 surface of Smad2 (Xu et al. 2002).

Putative Physiological Role of SARA

In developing tissues, morphogens can elicit concentration-dependent responses at very long ranges, and even small variations in their concentration can create very different effects. Because many signaling molecules are associated with intracellular membrane-bound compartments, these compartments, the signaling components, and their activation states need to be equally distributed between daughter cells during cell division. In the developing wing of *Drosophila melanogaster*, a specialized subset of Sara-endosomes, and the receptors therein, associate with the spindle machinery to segregate into the two daughter cells, thus allowing equal inheritance so that they retain the Dpp signaling levels of the mother cell (Bokel et al. 2006).

SARA has been reported to play a role in the signaling and remodeling events within the bone marrow niche where portions of the hematopoietic progenitor cells (HPC) membrane are actively endocytosed by osteoblasts and delivered to SARA-positive, signaling endosomes. In response to intercellular transfer, osteoblasts exhibit decreased Smad signaling and increased production of stromal-derived factor-1 (SDF-1), a chemokine responsible for HPC homing to bone marrow. Because TGF-β signaling can downregulate SDF-1, the transferred material within SARA-endosomes may sequester SARA away from its general cofactor function in Smad activation, allowing the osteoblast to produce more SDF-1 (Gillette et al. 2009).

SARA has also been reported to play a role in maintaining epithelial cell phenotype. During embryonic development, cells may initially have multiple characteristics but gradually differentiate into a more quiescent phenotype that has specialized functions. This process, known as mesenchymal-to-epithelial transition (MET), can be reversed in mature tissues in response to injury and attempted tissue repair in the process of epithelial-to-mesenchymal transition (EMT). Should such repair be inappropriate or misregulated, EMT can promote cancer progression and fibrosis. TGF-β is a well-established mediator of EMT, and at least in renal fibrosis, it may give rise to myofibroblast-like, matrix-producing cells. In a human kidney proximal tubule epithelial cell line, downregulation of SARA expression is a requirement for TGF-β-induced EMT. This depletion of SARA expression results in reduced Smad2 expression and activity via enhancement of Smad2 interaction with the ubiquitination factor Smurf2 (Runyan et al. 2009). Similar to EMT induced by TGF-β, SARA expression has been reported to decline during EMT induced by high glucose (Tang et al. 2010). The expression of SARA also declines during myofibroblast-like transition of hepatic stellate cells (Liu et al. 2003) and during progression of liver fibrosis (Tao et al. 2006). Therefore, SARA expression may be protective against fibrosis where EMT is a contributor.



SARA, Fig. 3 Possible roles for SARA and endocytosis in TGF-β signaling. (**a**) Through its ligand-independent binding to TβR, SARA may function to localize the TβRs to the endosome during constitutive receptor internalization and recycling. (**b**) Without CME, the receptor can be internalized into Smad7/Smurf2-containing caveolar compartments and be degraded. Therefore, SARA-mediated endosomal localization may protect the receptor from degradation. (**c**) After ligand binding and Smad2 recruitment, internalization of the TβR-SARA-Smad2 complex through CME may help transfer the active Smad through the cytosol to the nucleus

Other disease models suggest an increase in SARA expression. In asthma, damage to the bronchial epithelium results in release of TGF-β, which can suppress EGF-induced proliferation of epithelial cells, and higher levels of SARA expression are found when comparing epithelial cells from subjects with asthma to healthy controls (Semlali et al. 2008). Constitutive upregulation of SARA along with other components of the TGF-β signaling pathway has been found in rheumatoid arthritis compared to osteoarthritis synovial fibroblasts (Pohlers et al. 2007).

Summary

SARA is an adaptor protein, which interacts with TGF-β receptors and R-Smads and localizes to EEA1-containing, Rab5-positive early endosomes through clatherin-mediated endocytosis. While the precise role of SARA in TGF-β signaling is not fully characterized, it seems that SARA may preferentially modulate the Smad2-dependent response to TGF-β with little effect on the Smad3-mediated response. The importance of SARA's ability to localize to early endosomes has been demonstrated by a number of studies. However, the exact role of endocytosis in TGF-β signaling is not known. Although there are few studies linking SARA to a physiologic or disease process, it appears that SARA plays a negative role in fibrosis associated with its ability to suppress EMT and help maintain the intact epithelium.

Historical Background

Adapter proteins participate in intracellular signal transduction processes through physical interaction with catalytically active binding partners resulting in the formation of signaling complexes. Incorporation of adapter proteins into these complexes is mediated by modular binding domains contained in the adapter itself or in the respective binding partner(s). Through incorporation into complexes, adapter proteins modulate the activity of catalytically active proteins, directly or indirectly. In a subtractive cDNA library screen of activated human peripheral blood CD8 T cells, a novel adapter protein was identified that was named T cell specific adapter protein (TSAd) (Spurkland et al. 1998). TSAd is also known as Src-homology 2 (SH2) domain protein 2A (SH2D2A), based upon the presence of an SH2 domain in the center of the linear sequence. Subsequently, murine TSAd was identified as an interacting partner of the Src-family protein tyrosine kinase (PTK), LCK, and the Tec family protein tyrosine kinases, RLK and ITK, in yeast two-hybrid screening experiments (Choi et al. 1999; Rajagopal et al. 1999). Hence, TSAd/SH2D2A is also known as LCK-associated adapter protein (LAD) and RLK/ITK-binding protein (RIBP).

Structure

SH2D2A resembles a classical adapter protein that contains a central SH2 domain and a carboxyl region with a conserved proline-rich stretch and tyrosine residues that are present in consensus phosphorylation motifs (Lapinski et al. 2009). The SH2 domain of SH2D2A recognizes phosphorylated tyrosine residues contained in other signaling proteins, and, visa versa, SH2 domains of other signaling proteins recognize phosphorylated tyrosine residues in the SH2D2A carboxyl region. In addition, interaction of SH2D2A with signaling proteins can be mediated by SH3 domain binding to the SH2D2A carboxyl region proline-rich stretch. The amino-terminal region of SH2D2A has no discernible structure or function.

Expression

SH2D2A is most strongly expressed in the T cell lineage and in natural killer (NK) cells (Lapinski et al. 2009). In T cells, expression levels are increased following T cell activation. SH2D2A is expressed in CD4 and CD8 T cells and comparably in CD4 T

helper 1 and T helper 2 cell lines. In part, expression of SH2D2A in T cells is regulated by a cyclic adenosine monophosphate (cAMP) response element that is present in the SH2D2A promoter (Dai et al. 2004). Other than T and NK cells, SH2D2A expression has also been noted in B cells, epithelial cells, and vascular endothelial cells (Lapinski et al. 2009).

Interacting Partners

As noted above, SH2D2A interacts physically with LCK, RLK, and ITK. Furthermore, for LCK, physical interaction has been demonstrated in primary T cells between cell endogenous proteins (Marti et al. 2006). Interaction is thought to involve PTK phosphorylation of SH2D2A carboxyl region tyrosine residues that are then bound by the PTK SH2 domain. In addition, the LCK SH3 domain binds to the SH2D2A proline-rich stretch, thus constituting another mechanism of interaction.

Ligands of the SH2D2A domain that have been identified include linker of activated T cells (LAT), vascular endothelial growth factor receptor 2 (VEGFR2), and valosin-containing protein (VCP) (Lapinski et al. 2009; Marti and King 2005; Marti et al. 2001; Matsumoto et al. 2005). In the first two examples, the SH2 domain binds directly to phosphorylated tyrosine residues in the respective target proteins. In the case of VCP, however, tyrosine phosphorylation likely results in a conformational change, which exposes a distinct interaction site upon VCP for SH2D2A SH2 domain recognition.

Other signaling proteins that SH2D2A physically interacts with include Gβ protein subunits of heterotrimeric G proteins and the mitogen-activated protein 3 kinase, MEKK2 (Park et al. 2007; Sun et al. 2001). However, the molecular basis for interaction with these proteins has not been clearly defined.

SH2D2A Function

SH2D2A promotes activation of LCK at the outset of T cell antigen receptor (TCR) signal transduction in T cells (Marti et al. 2006). TCR recognition of ligand results in local aggregation of LCK at the plasma membrane. For those LCK molecules that preexist in an open primed conformation, aggregation leads to an increase in LCK kinase activity, consequent to LCK-mediated phosphorylation of a positive regulatory tyrosine residue present in the LCK kinase domain (Palacios and Weiss 2004). Increased LCK kinase activity then results in SH2D2A tyrosine phosphorylation and subsequent interaction of SH2D2A with the LCK SH2 and SH3 domains. These interactions are important since LCK SH2 domain binding to a phosphorylated negative-regulatory tyrosine residue, positioned carboxyl to the LCK kinase domain, and LCK SH3 domain binding to an LCK proline stretch, present in a linker region between the SH3 domain and kinase domain, act to constrain this PTK in an inactive conformation (Palacios and Weiss 2004). Therefore, in binding to LCK, SH2D2A disrupts these intramolecular inhibitory interactions. Consequently, additional LCK molecules are driven into open primed conformations whereupon they may become fully activated by phosphorylation upon the kinase domain positive-regulatory tyrosine residue. In turn, this will result in further SH2D2A phosphorylation, leading to further LCK activation and so on.

The importance of SH2D2A in the activation of LCK during the course of TCR signal transduction is shown by the finding that TCR-induced activation of LCK is impaired in T cells from SH2D2A-deficient mice (Marti et al. 2006). Consequently, all downstream signaling events in T cells including activation of the ZAP-70 PTK, activation of the Ras-MAPK pathway, calcium mobilization, and cytokine synthesis are reduced in magnitude in SH2D2A-deficient T cells.

T cell migration induced by the chemokines CXC12 and CCL5 is also SH2D2A-dependent (Park et al. 2007). Interestingly, the function of SH2D2A in this response again appears to relate to a required role for SH2D2A in the activation of LCK and ZAP-70 in the chemokine-induced signaling pathway downstream of heterotrimeric G proteins.

SH2D2A may also have a nuclear role in T cells (Marti and King 2005; Marti et al. 2001). This conclusion is based upon the finding that SH2D2A is actively transported to the nucleus in T cells via a mechanism that involves SH2 domain recognition of VCP. The exact function of SH2D2A in the cell nucleus is unknown.

Outside of the T cell compartment, expression of SH2D2A has been shown to be required for VEGFR2-induced migration of blood vascular endothelial cells in vitro and for blood vessel angiogenesis toward

tumors in vivo (Matsumoto et al. 2005). Physical interaction of SH2D2A with the VEGFR2 cytoplasmic domain is necessary for both of these responses. In epithelial cell lines, SH2D2A physical interaction with MEKK2 is required for activation of the ERK5 big MAPK induced by the epidermal growth factor (EGFR), osmotic and oxidative stress (Sun et al. 2001, 2003).

SH2D2A-Deficient Mouse Model

SH2D2A-deficient mice are viable and initially healthy (Rajagopal et al. 1999). T cell development proceeds normally, and in young adult animals, numbers and ratios of peripheral T cell subsets are similar to those observed in control mice. However, with increasing age, SH2D2A-deficient mice show signs of systemic lupus-like autoimmunity (Drappa et al. 2003; Marti et al. 2005). Disease is associated with splenomegaly, increased numbers of activated memory phenotype T cells in spleen and lymph nodes, production of autoantibodies against DNA and other nuclear targets, glomerulonephritis, and leukocytic infiltration into nonlymphoid organs. Furthermore, young SH2D2A-deficient mice are highly susceptible to experimentally induced lupus-like autoimmune disease. The likely cause of autoimmunity in SH2D2A-deficient mice is impaired apoptotic death of autoreactive peripheral T cells upon recognition of self antigens (Drappa et al. 2003). The molecular basis for this impaired death is uncertain but likely relates to impaired cytokine production by SH2D2A-deficient T cells.

Summary

SH2D2A is an SH2 domain-containing signaling adapter protein that is strongly expressed in T lymphocytes. SH2D2A functions at the beginning of the TCR signal transduction cascade by promoting activation of the LCK Src-family PTK through competitive inhibition of LCK intramolecular inhibitory interactions. In addition, roles for SH2D2A in T cell migration, VEGFR2 signal transduction in endothelial cells, and activation of the big MAPK signaling pathway in epithelial cells have been described. SH2D2A-deficient mice are susceptible to the development of systemic lupus-like autoimmune disease, thus illustrating the importance of SH2D2A as a regulator of T cell tolerance to self antigens.

Synonyms

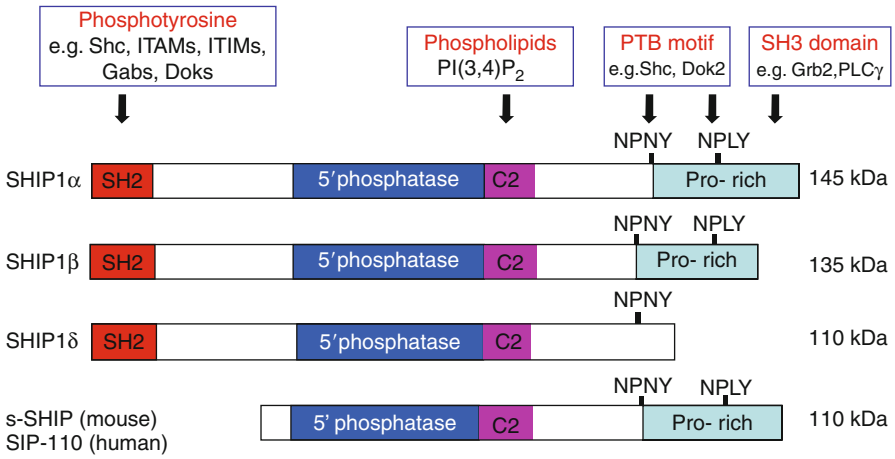
SHIP (Inositol polyphosphate-5-phosphatase, 145 kDa; Inpp5d; SH2 domain-containing inositol phosphatase)

Historical Background

SH2 domain-containing inositol phosphatase-1 (SHIP) was initially identified in 1994 as a tyrosine-phosphorylated protein after stimulation of blood cells by a broad number of cytokines and growth factors (Lioubin et al. 1994; Liu et al. 1994). It translocates to the plasma membrane after extracellular stimulation and hydrolyses the ▶ phosphoinositide 3-kinase (PI3K)-generated second messenger $PI(3,4,5)P_3$, to $PI(3,4)P_2$. As a result, SHIP is able to modulate $PI(3,4,5)P_3$-mediated signaling and hence the proliferation, differentiation, survival, activation, and migration of hematopoietic cells. The creation of germ-line $SHIP^{-/-}$ knockout mice in 1998 was instrumental in determining the role SHIP plays in the immune system (Helgason et al. 1998). Subsequent cell-restricted deletion in lymphoid and myeloid compartments some 10 years later, further advanced understanding of the intrinsic role of SHIP in a variety of immune cells (Leung et al. 2009).

Structure and Binding Partners of SHIP Family Members

SHIP is a 145 kDa protein encoded by the *INPP5D* gene on chromosome 2 (location 2q37.1) and is largely confined to hematopoietic cells. The protein is composed of 1,188 amino acids and possesses domains that mediate its interaction with other proteins on either side of its central catalytic domain. In addition to hydrolysing $PI(3,4,5)P_3$, SHIP can also dephosphorylate inositol-1,3,4,5-tetraphosphate, at least in vitro. SHIP possesses a centrally located catalytic domain responsible for the hydrolysis of the 5'-phosphate of the membrane phosphoinositide lipid $PI(3,4,5)P_3$, the major product of receptor-activated PI3K. A C2 domain adjacent to the catalytic domain has been identified and shown to be an allosteric- activating site when bound by SHIP's enzymatic product $PI(3,4)P_2$ (Hamilton et al. 2011). In addition, SHIP encodes multiple structural domains that facilitate protein–protein interactions and cellular re-localization upon receptor stimulation. The SH2 domain within SHIP interacts with proteins via the consensus amino acid sequence pY[S/Y][L/Y/M][L/M/I/V]. Through this SH2 domain, SHIP binds to the tyrosine phosphorylated forms of Shc, Doks, Gabs, CD150, platelet-endothelial cell adhesion molecule (PECAM), Cas, c-Cbl certain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) and some immunoreceptor tyrosine-based activation motifs (ITAMs). Recruitment of SHIP by the phosphorylated ITIM in the cytoplasmic domain of FcγRIIB was shown to inhibit recruitment of PH-domain-containing proteins and prevent extracellular calcium influx, overall reducing transcription activation, and cytokine release. The proline-rich region of SHIP enables interaction with proteins encoding SH3 domains, such as Grb2, Src, Lyn and phospholipase-Cγ and is essential for SHIP function (Harris et al. 2008). The two NPXY motifs in SHIP can become tyrosine phosphorylated and bind the phosphotyrosine-binding domain (PTB) motifs in Shc, Dok1, and Dok 2. These structural domains of SHIP are able to support the



SHIP, Fig. 1 *Schematic representation of the SHIP protein isoforms*. The protein interaction motifs are indicated, along with their binding partners. The SH2 domain allows SHIP to bind proteins (such as those indicated) which express the sequence phospho-Y(Y/S/T)L(M/L). The 5' phosphatase domain catalyzes the conversion of $PI(3,4,5)P_3$ to $PI(3,4)P_2$. The C2 domain has been identified as a binding domain of the SHIP product $PI(3,4)P_2$ which acts to increase the catalytic activity of SHIP. The NPXY motifs when phosphorylated provide binding sites for proteins which express phosphotyrosine binding domains. The proline-rich domain (PR) allows SHIP to interact with SH3 domain-containing proteins

re-localization of SHIP from the cytosol to the plasma membrane, where its catalytic activity regulates $PI(3,4,5)P_3$ accumulation. In addition, these structural features and binding motifs allow SHIP to serve a scaffolding role for the recruitment of other proteins to the plasma membrane, independent of catalytic function. The interaction of SHIP with other proteins can also indirectly abrogate PI3K signaling since SH2 domain-mediated interactions with ITAM-containing adaptor proteins has been demonstrated to dislodge or prevent further recruitment of PI3K via the p85 subunit (Peng et al. 2010).

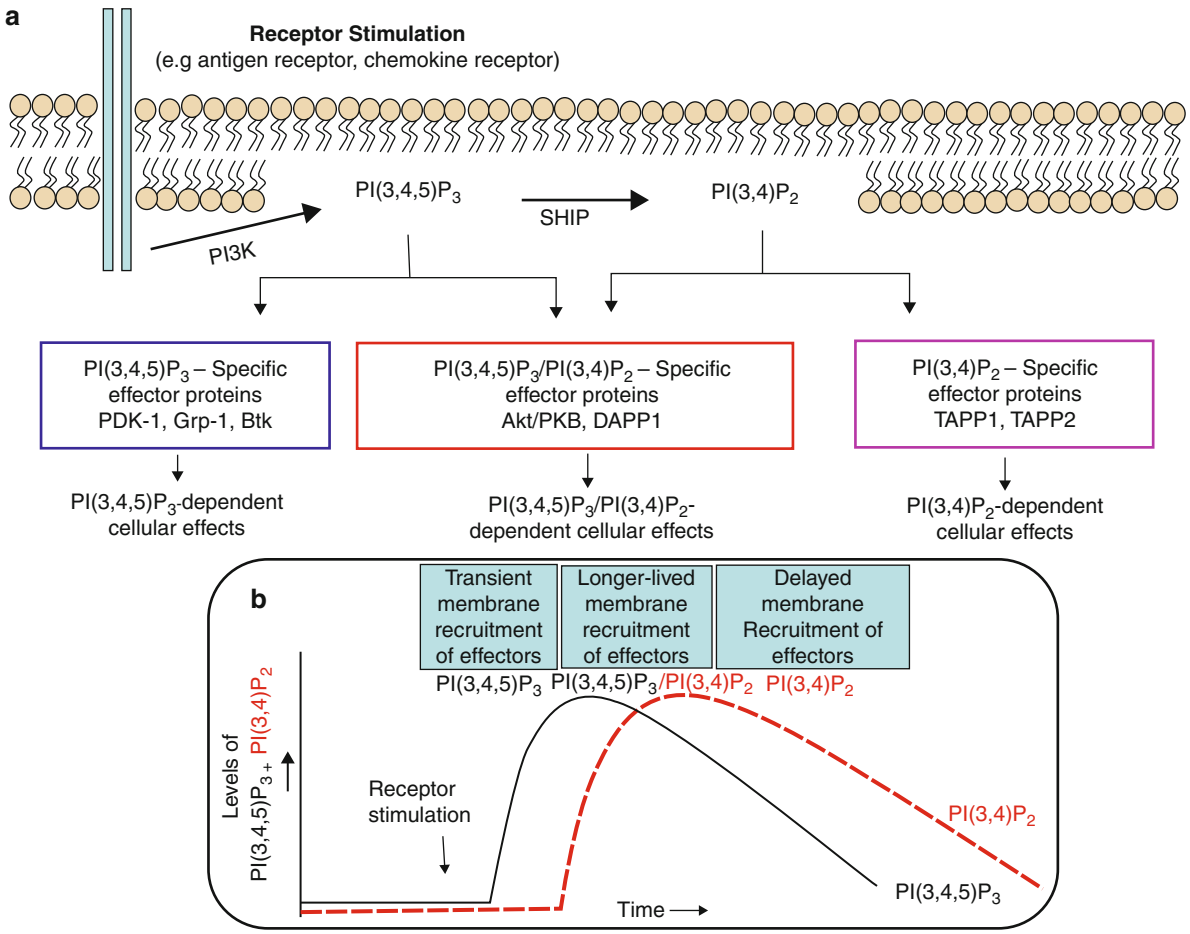
Splice Variants and Isoforms of SHIP

Multiple forms of SHIP have been reported with molecular weights of 145 (SHIPα),135 (SHIPβ), and 110 (SHIPδ) kDa (Fig. 1). In addition, other 130, 125, and 110 kDa forms of SHIP have been reported (Hamilton et al. 2011; Kerr 2011). The different forms of SHIP may arise from alternative mRNA splicing, protein degradation, or posttranslational modification such as phosphorylation. SHIP-2 is a 142 kDa protein that is highly homologous with the hematopoietic-specific SHIP, but is encoded by a different gene and exhibits distinct structural features as well as possibly having a broader phospholipid substrate specificity than SHIP, as it also hydrolyses $PI(4,5)P_2$ in vitro. SHIP-2 is expressed in both hematopoietic and non-hematopoietic tissues such as brain, skeletal muscle, heart, and to a lesser extent liver and kidney. The major role of SHIP-2 appears to be the negative regulation of insulin signaling in nonimmune cells (Ooms et al. 2009).

The different forms of SHIP exhibit different protein-binding profiles defined by the absence or presence of these distinct binding motifs that are described in more detail below (Fig. 1). For example, s-SHIP (expression of which is restricted to murine embryonic stem cells and primitive hematopoietic stem cells, but which is lost in lineage-committed hematopoietic cells) and its human homologue SIP-110, are truncated at the N-terminus and lack the SH2 domain which limits the repertoire of binding proteins available for interaction. For example, it cannot interact with Shc, but still interacts with Grb-2. Moreover, s-SHIP is mostly localized at the plasma membrane rather than the cytoplasm (Hamilton et al. 2011; Kerr 2011).

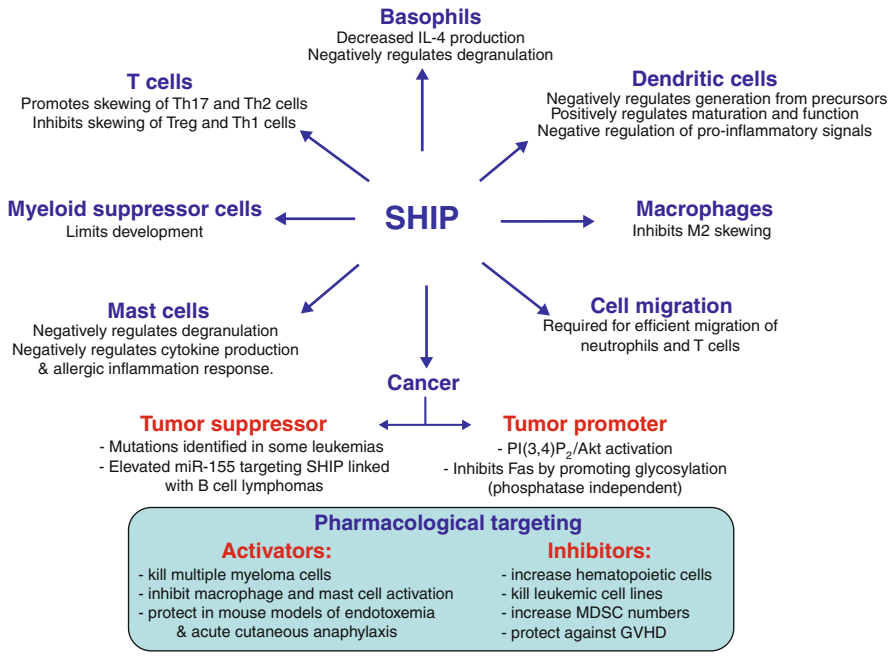
SHIP: A Checkpoint in PI3K-Dependent Signaling

The classical view of SHIP is that it acts to switch off PI3K-dependent signaling by degradation of $PI(3,4,5)P_3$ (Fig. 2). However, the metabolism of



SHIP, Fig. 2 *SHIP acts as a molecular "switch"*. SHIP catalyzes the conversion of the PI3K lipid product $PI(3,4,5)P_3$ to $PI(3,4)P_2$. Effector proteins which express PH domains are recruited and activated by these lipid second messengers at the cell surface membrane. PH-domains of proteins are able to discriminate between $PI(3,4,5)P_3$ and $PI(3,4)P_2$. Examples of proteins which bind only $PI(3,4,5)P_3$, both $PI(3,4,5)P_3$ and $PI(3,4)P_2$ or only $PI(3,4)P_2$ are shown (**a**). This diversity allows SHIP to both negatively regulate PI3K signaling and also to "switch" signal transduction pathways away from $PI(3,4,5)P_3$-dependent effectors toward $PI(3,4)P_2$-dependent effectors, in turn influencing kinetics and duration of recruitment of 3' phosphoinositide lipid binding proteins at the plasma membrane (depicted in **b**)

$PI(3,4,5)P_3$ by SHIP yields $PI(3,4)P_2$ which retains the phosphate grouping on the third position of the inositol ring and thus, may retain some signaling ability. Pleckstrin homology (PH) domains encoded in many proteins (e.g., Grp-1) bind exclusively to $PI(3,4,5)P_3$, whereas others such as that found in dual adaptor of phosphotyrosine and 3-phosphoinositides −1 (DAPP-1), can interact with both $PI(3,4,5)P_3$ and $PI(3,4)P_2$ (Lemmon and Ferguson 2000). In addition, the tandem PH domain-containing protein TAPP-1 encodes PH domains that show selectivity toward $PI(3,4)P_2$ (Harris et al. 2008). The ability of PH domain-containing proteins to distinguish between different 3'-phosphoinositide lipids suggests that SHIP can act as a switch to redirect PI3K-dependent signaling toward a set of distinct effectors that are temporally and functionally separate from $PI(3,4,5)P_3$-dependent events. Thus, SHIP may function to fine-tune phosphoinositide signaling, rather than terminate it (Fig. 2). In this regard, SHIP promotes recruitment of the GTPase Irgm1 to sites of phagocytosis in macrophages via generation of $PI(3,4)P_2$, a critical step in maturation of the phagosome and engulfment of bacteria. $PI(3,4,5)P_3$ and $PI(3,4)P_2$ appear sequentially following agonist stimulation in many cell types including T lymphocytes, but show temporal overlap. Some cell types, notably



SHIP, Fig. 3 *SHIP regulates immune cell functions and influences tumor development and growth*. SHIP plays a key role in the generation of lymphocyte and myeloid subsets and maintaining a balance between inflammatory and regulatory cells. Thus, modulation of SHIP offers potential for therapeutic intervention in a range of inflammatory and autoimmune diseases as well as in cancer and transplantation settings

B lymphocytes and platelets, exhibit sustained $PI(3,4)P_2$ production, lasting for up to 45–60 min poststimulation (Harris et al. 2008).

Role of SHIP in the Immune System: Maintaining a Balance between Inflammatory and Regulatory Cells

SHIP is expressed ubiquitously in differentiated cells of the hematopoietic system, in endothelial cells, hematopoietic stem cells (HSC), and embryonic stem (ES) cells. Both SHIP and s-SHIP have been implicated in the biology of pluripotent and adult stem cells. More recently, it has been shown to play a key role in the function of the bone marrow microenvironment (the stem cell niche) (Kerr 2008). Largely as a consequence of hematopoietic-specific expression, SHIP has been extensively studied for its regulatory role in B cells, T cells, macrophages and mast cells. SHIP was first recognized as an important component of the inhibitory signaling pathway triggered by the IgG receptor FcγRIIB in mast cells and B cells (Ono et al. 1996). Once recruited to the plasma membrane by signaling complexes, its catalytic activity depletes $PI(3,4,5)P_3$ and prevents membrane localization of some PH domain-containing effectors. SHIP has also been implicated in signaling pathways triggered by cytokine, chemokine, antigen, and IgG engagement in a variety of immune cells (Harris et al. 2008). Additionally, SHIP plays an important regulatory role in establishing endotoxin tolerance in macrophages as well as regulating leucocyte polarization during migratory responses to chemoattractants (Hamilton et al. 2011; Harris et al. 2008; Kerr 2011).

Genetic analysis of SHIP mutant mice has revealed a pivotal role for SHIP in a wide variety of differentiated hematopoietic cell types. SHIP has been shown to play a role in regulating the receptor repertoire and cytolytic function of Natural Killer (NK) cells, B lymphocyte development and antibody production, the myeloid cell response to bacterial mitogens, development of marginal zone macrophages, lymph node recruitment of dendritic cells, and mast cell degranulation (Fig. 3). The negative regulatory role for SHIP in the immune system is best illustrated by the phenotype of SHIP null mice which develop progressive myeloid hyperplasia and myeloid infiltration in the lungs that leads to respiratory failure

and to a dramatic decrease of life span. The myeloid hyper-proliferation is caused by the combination of two factors. First, the myeloid cells and their precursors are more sensitive to growth factors and second, these cells show a decreased sensitivity to pro-apoptotic stimuli (Helgason et al. 1998). Analysis of the SHIP null mice has also established that SHIP plays a critical role in homeostasis of myeloid and lymphoid effector and regulatory cells. For example, SHIP deficient mice exhibit more myeloid-derived suppresser cells (MDSCs) than their wild type counterparts. SHIP also plays a role in regulating the balance of M1 macrophages (implicated in the first inflammatory response) and M2 macrophages (implicated in inflammatory response termination, tissue repair, regeneration and remodeling). SHIP deficiency leads to increased macrophage skewing toward M2 macrophages. This indicates that $PI(3,4,5)P_3$ drives macrophage progenitors toward an M2 phenoype and that SHIP blocks this skewing (Hamilton et al. 2011; Kerr 2011). Moreover, SHIP is essential for normal Th17 cell development and this lipid phosphatase plays a key role in the reciprocal regulation of Tregs and Th17 cells (Hamilton et al. 2011; Kerr 2011). Because of abnormalities in secretion of cytokines observed in SHIP-deficient mice, the root cause of an abnormality in SHIP-deficient mice could also be due to extrinsic effects on that cell type. Thus, analysis of cell type specific deletion of SHIP in vivo is ultimately required before one can conclusively determine which SHIP-deficient cell type causes a specific phenotype in mice with a germline homozygous mutation of SHIP. This is best illustrated by analysis of mice carrying a T cell-specific deletion of SHIP, which uncovered a regulatory role for SHIP in controlling Th1/Th2 bias and cytotoxic responses as a result of its inhibitory effect on T-bet expression. Mice with a T cell-specific deletion of SHIP revealed that they do not skew efficiently to a Th2 phenotype and display Th1-dominant immune responses in vitro and in vivo (Leung et al. 2009). This is in contrast to evidence from germ line $SHIP^{-/-}$ mice, which indicates that SHIP can also repress Th2 skewing by inhibiting IL-4 production from basophils (Hamilton et al. 2011).

SHIP in Cancer and Other Diseases: Opportunities for New Therapies

The PI3K-dependent signaling pathway has a well-established role in regulating cell survival, proliferation and differentiation (Manning and Cantley 2007). As such, the levels of $PI(3,4,5)P_3$ are tightly regulated not only by SHIP but also by the 3' lipid phosphatase ▶ PTEN (Harris et al. 2008). The importance of these lipid phosphatases is underlined by the fact that PTEN is frequently lost in many leukemias and immortalized leukemic cell lines (Hollander et al. 2011). SHIP expression is also frequently lost, downregulated, or mutated in many cancer cells including acute myeloid leukemia (AML). MicroRNAs (miRNAs) are recently discovered regulators of gene expression that have a role in the regulation of hematopoiesis, the immune response and inflammation. MicroRNAs can repress protein expression through their ability to bind directly to the 3'UTRs of specific genes and prevent translation of the protein products. Scanning of the SHIP 3' UTR revealed perfect sequence complementarity with the seed sequence of miR-155. Elevated levels of miR-155 and consequent diminished SHIP expression have been linked to B cell lymphomas (Costinean et al. 2009). In addition, it has been reported that oncogenic proteins including BCR/Abl, and Tax (implicated in chronic myelogenous leukemia and adult T cell leukemia/lymphoma, respectively), induce SHIP downregulation by a variety of mechanisms (Kerr 2011). Consistent with its role as a tumor suppressor, SHIP restricts development of MDSCs and Tregs. Thus, SHIP deficiency leads to an expansion of MDSCs and Tregs and hence, suppression of T cell immune responses and so, this may be another mechanism for increased tumorigenesis if SHIP expression is reduced. However, the role of SHIP in leukemia seems more complex than initially thought, since there is evidence that SHIP can actually support cancer cell survival as a small molecule inhibitor of SHIP induces apoptosis of multiple myeloma cells (Brooks et al. 2010). This is consistent with its production of $PI(3,4)P_2$ which is known to facilitate Akt activation and hence cell proliferation, survival, and tumorigenesis (Manning and Cantley 2007). Others have shown that SHIP inhibits CD95/APO-1/Fas-induced apoptosis in T cells by promoting CD95 glycosylation independently of its phosphatase activity (Charlier et al. 2010).

HSC proliferation and numbers are increased in $SHIP^{-/-}$ mice. Despite expansion of the compartment, SHIP deficient HSCs exhibit reduced capacity for long-term repopulation and home inefficiently to bone marrow. The role of SHIP in the biology of both

HSC and the hematopoietic stem cell niche, suggests that it may be a useful target for treatment of bone marrow failure syndromes caused by viruses, radiation, chemotherapy, or malignancy. As already mentioned, MDSCs are a type of immunoregulatory cell that can repress allogeneic T cell responses. A common complication arising after bone marrow transplantation is Graft-versus-host disease (GVHD) which involves priming of allogeneic T cells. Remarkably, SHIP deficient mice express more myeloid suppressor cells than their WT counterparts and accept allogeneic bone marrow grafts with a reduced incidence of GVHD (Ghansah et al. 2004; Kerr 2008).

The key regulatory role of SHIP has been exploited by several opportunistic pathogens that target these phosphatases in order to evade immune detection. Thus, lymphocytes are particularly sensitive to the cytolethal distending toxin subunit B (CdtB), an immunotoxin produced by *Actinobacillus actinomycetemcomitans* that can hydrolyse $PI(3,4,5)P_3$ to $PI(3,4)P_2$. Exposure to CdtB leads to cell cycle arrest and death by apoptosis. The lipid phosphatase activity of CdtB may therefore result in reduced immune function, facilitating chronic infection with *Actinobacillus* and other enteropathogens that express Cdt proteins (Shenker et al. 2007). The measles virus evades destruction by the immune system at least in part, by targeting negative regulation of PI3K/Akt signaling. It induces expression of SIP-110 which depletes the cellular $PI(3,4,5)P_3$ pools, suggesting that the threshold for activation signals leading to induction of T cell proliferation is raised (Avota et al. 2006).

The role of SHIP in regulating the development and function of various hematopoietic cells and evidence linking SHIP to cancer and other diseases, has led to the search for small molecules that are able to modulate activity and which may be useful as drugs. Several compounds have now been reported and have been shown to exert an anti-inflammatory effect in in vitro and in vivo models (Harris et al. 2008). Moreover, these molecules have been sucessfully used to kill multiple myeloma cells in vitro indicating that SHIP agonists could be effective anticancer agents. Small molecule inhibitors of SHIP have also been reported which, consistent with observations from SHIP deleted mice, led to increased myeloid suppressor cells, reduced ability of peripheral lymphoid tissues to prime myeloid-associated responses, and protected against GVHD. SHIP inhibitors increased levels of granulocytes, red blood cells, neutrophils, and platelets in mice and could therefore, have application to improve blood cell number in patients with myelodysplastic syndrome or myelosuppressive infection. A SHIP inhibitor also triggered the apoptosis of human acute myeloid leukemia cell lines, consistent with SHIP being anti-apoptotic under some circumstances (Brooks et al. 2010).

Summary

SHIP is largely confined to hematopoietic cells and modulates PI3K/Akt dependent signaling by hydrolysing the PI3K-generated second messenger $PI(3,4,5)P_3$, to $PI(3,4)P_2$. As a consequence, SHIP is able to modulate $PI(3,4,5)P_3$-mediated signaling and hence the proliferation, differentiation, survival, activation, and migration of hematopoeitic cells. SHIP possesses a centrally located catalytic domain responsible for the hydrolysis of the 5'-phosphate of the membrane phosphoinositide lipid $PI(3,4,5)P_3$. In addition, SHIP possesses multiple structural domains that facilitate protein–protein interactions and cellular re-localization upon receptor stimulation. These structural features and binding motifs allow SHIP to serve a scaffolding role for the recruitment of other proteins to the plasma membrane. Indeed, SHIP has been shown to exert several functional effects independently of its catalytic function. The ability of PH domain-containing proteins to distinguish between different 3'-phosphoinositide lipids suggests that SHIP can act as a switch to redirect PI3K signaling toward $PI(3,4)P_2$-dependent effectors that are temporally and functionally separate from $PI(3,4,5)P_3$-dependent events. Thus, SHIP may function to fine-tune phosphoinositide signaling, rather than terminate it. SHIP can regulate a variety of signaling pathways related to cytokine, chemokine, antigen, and IgG engagement in both lymphocytes and myeloid cells. It plays a key role in the generation of lymphocyte and myeloid subsets and maintaining a balance between inflammatory and regulatory cells. Additionally, SHIP plays an important regulatory role in establishing endotoxin tolerance in macrophages, as well as regulating leucocyte polarization during migratory responses to chemoattractants. The expression of SHIP and/or its activity is often targeted by pathogens, whilst SHIP expression is lost, downregulated or

mutated in many cancer cells. Thus, modulation of SHIP offers potential for therapeutic intervention in a range of inflammatory and autoimmune diseases as well as in cancer and transplantation settings.

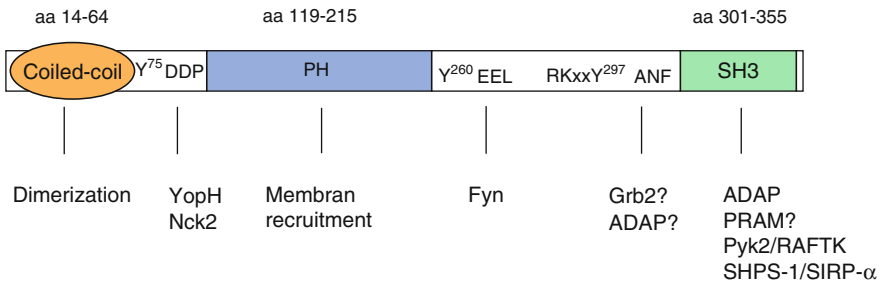
Historical Background

SKAP-HOM was originally described in 1998 as a protein homologous to the cytosolic adaptor protein SKAP55 (Marie-Cardine et al. 1998). Using the recombinant SH2 domain of the ▶ Src protein tyrosine kinase Fyn expressed as a GST fusion protein, SKAP55 as well as SKAP-HOM were purified from lysates of pervanadate-treated human T cells. Furthermore, it was demonstrated that SKAP-HOM acts as a substrate for the Src kinase Fyn and that it binds the adaptor molecule FYB/SLAP/▶ ADAP. At the same time, Liu et al. reported the identification and the molecular cloning of a protein termed SKAP55-R. Using the yeast two-hybrid system with FYB/SLAP/ADAP as bait, the SKAP55-related protein was identified (Liu et al. 1998). The murine homologue of human SKAP55-R was described in 2000 (Curtis et al. 2000). The authors reported that murine SKAP55-R plays a role in IL-6-induced myeloid cell differentiation and that overexpression of SKAP55-R inhibits growth of FDC-P1 myeloid cell line and primary hematopoietic progenitors. Independently, a retinoic acid-inducible protein was described, which is expressed during neuronal differentiation of mouse embryonal carcinoma cells. The protein, termed RA70, is highly homologous to SKAP55 and functions as an adaptor protein of the Src family kinases Fyn, Hck, and Lyn (Kouroku et al. 1998). Five years later, a novel adaptor protein, Pyk2/RAFTK-associated protein (PRAP), was identified using the yeast two-hybrid cloning system. PRAP specifically binds to Pyk2/RAFTK, thereby inhibiting Pyk2/RAFTK kinase activity. In this way, tyrosine phosphorylation of α-synuclein, a presynaptic protein that is involved in the pathogenesis of several neurodegenerative diseases is inhibited. Furthermore, PRAP was found to function as a substrate for Src family kinases such as Fyn (Takahashi et al. 2003).

Consistently, all researchers reported that unlike SKAP55, which is exclusively expressed in T cells, SKAP-HOM expression is ubiquitous.

Structural Organization

The cDNA of human SKAP-HOM encodes a 359 amino acid polypeptide which possesses a pleckstrin homology (PH) domain followed by a central region containing several tyrosine phosphorylation sites and a C-terminal SH3 domain. The tyrosine motif YEEL could serve as a putative binding site for the SH2 domain of Fyn. A second tyrosine motif YAN might represent a binding site for the SH2 domain of Grb2. SKAP-HOM shows the same overall structure as



SKAP-HOM, Fig. 1 Structure of SKAP-HOM and binding partners

SKAP55 except for an unique N-terminal coiled-coil domain, which is not present in SKAP55 (Fig. 1). The proteins show an overall 44% homology with the greatest conservation in the PH and the SH3 domains (Liu et al. 1998; Marie-Cardine et al. 1998). Given the size and the sequence similarity, it was hypothesized that SKAP55 and SKAP-HOM might originate from gene duplication. The chromosomal localization is chromosome 7 for human and chromosome 6 for the mouse gene, respectively. The identity in the amino acid sequence between mouse and human proteins is 91%.

Detailed structural and biochemical analysis including crystallization of the SKAP-HOM N-terminus revealed an unusual four-helix bundle dimerization domain. This dimerization domain mediates self-association and homodimerization in vivo. The isolated PH domain binds to phospholipids in vitro. The potential for allosteric inhibitory interactions between the dimerization domain and the PH domain suggests that SKAP-HOM exists in two states: a closed, docked state and an open free conformation capable of phosphoinositide binding. It was hypothesized that this phosphoinositide responsive molecular switch regulates subcellular targeting, thereby controlling SKAP-HOM function (Swanson et al. 2008).

SKAP55 binds to ADAP with high stoichiometry. In 2005, Huang and coworkers published the unexpected finding that ADAP-deficient Jurkat T cells also lack SKAP55 expression. It was shown that in the absence of ADAP, SKAP55 is rapidly proteolyzed and the half-life of the protein is decreased (Huang et al. 2005). This finding was further extended in ADAP-deficient mouse T cells where it was shown that both SKAP55 and SKAP-HOM are undetectable at protein level (Kliche et al. 2006). In contrast, SKAP-HOM-deficient T cells as well as SKAP55-deficient T cells show no changes in ADAP protein expression (Togni et al. 2005; Wang and Rudd 2008).

SKAP-HOM contains several modular interaction domains including a PH domain, a C-terminal SH3 domain, an N-terminal coiled-coil domain and multiple tyrosine phosphorylation sites (Y). The potential interaction partners are indicated below.

Binding Partners of SKAP-HOM

ADAP constitutively binds to SKAP55 or SKAP-HOM. The dominant binding occurs via the SKAP-HOM SH3 domain which binds to the proline rich-regions in ADAP (Liu et al. 1998; Marie-Cardine et al. 1998). A second interaction was described to occur between the ADAP helical SH3 domain and a non-canonical RKxxYxxY motif in SKAP55. Preliminary data indicated that this RKxxYxxY motif in SKAP-HOM also binds to the SH3 domain of ADAP (Wang and Rudd 2008).

PRAM-1 (PML-Retinoic acid receptor alpha regulated adaptor molecule-1) shares structural homologies with ADAP and is expressed early during myeloid differentiation and in mature granulocytes. Co-immunoprecipitation studies documented a constitutive association between PRAM-1 and SKAP-HOM. Although the interaction site was not characterized, PRAM-1 contains several proline-rich repeats corresponding to the SH3 recognition site (Moog-Lutz et al. 2001).

Another interaction partner of SKAP-HOM is the serine/threonine kinase ▶ *HPK1* (hematopoietic progenitor kinase 1) which constitutively associates with SKAP-HOM in mouse B cells. In addition, as shown for SKAP55 in T cells, SKAP-HOM interacts in B cells with *RIAM*, a Rap1 effector molecule involved in integrin activation (Königsberger et al. 2010).

In murine macrophages, SKAP-HOM has been reported to interact with *SHPS-1* (Src homology 2 domain-containing protein tyrosine phosphatase

substrate 1, also known as SIRP alpha), a transmembrane receptor of the immunoglobulin (Ig) superfamily. SHPS-1 functions as a scaffolding protein mediating the assembly of adhesion-regulated multi-protein complexes including SKAP-HOM, ADAP, Pyk2, and the tyrosine phosphatase SHP-1 (Timms et al. 1999).

Pathogenic species of *Yersinia* harbor a plasmid-encoded type III secretion system that translocates virulence-associated bacterial proteins into host cells. *YopH* (*Yersinia* outer protein H) is a highly active protein tyrosine kinase. When translocated into host cells, YopH disrupts focal adhesion complexes thereby causing detachment of infected cells and abrogation of the phagocytic process. It has been demonstrated that YopH dephosphorylates SKAP-HOM, ADAP, and Cas (Crk-associated substrate) in murine macrophages, thus interfering with adhesion-regulated signal transduction pathways (Fällman et al. 2002).The short peptide sequence of SKAP-HOM (DEYDDPF), located in the linker region between the dimerization domain and the PH domain, is recognized by the N-terminal substrate-binding domain of YopH. Based on this SKAP-HOM sequence, cyclic peptides have been designed to inhibit *Yersinia* infections (Leone et al. 2012).

Function of SKAP-HOM

SKAP-HOM seems to play a role during myelopoesis. When overexpressed in myeloid cells, SKAP-HOM inhibited proliferation without affecting differentiation (Bourette et al. 2005; Curtis et al. 2000). Furthermore, there is clear evidence that SKAP-HOM plays a role in adhesion events. In murine macrophages, the scaffolding protein SHPS-1 assembles an adhesion-regulated multi-protein complex including SKAP-HOM, ADAP, Pyk2, and the tyrosine phosphatase SHP-1. Timms et al. reported that SKAP-HOM is tyrosine phosphorylated in response to macrophage adhesion to fibronectin (Timms et al. 1999). Macrophages that lack SHP-1, display hyperphosphorylation and show increased adhesivness. In addition, Bourette et al. showed that macrophage colony-stimulating factor (M-CSF) induces tyrosine phosphorylation of SKAP-HOM in myeloid cells and its association with other proteins including actin (Bourette et al. 2005). Collectively, these data support the hypothesis that SKAP-HOM is involved in the regulation of actin dynamics in myeloid cells.

In T cells, ADAP and SKAP55 play an essential role in TCR-mediated inside-out signaling that is needed for LFA-1 clustering and conjugate formation between T cells and antigen-presenting cells (APC). Given the high homology, the question arises whether SKAP-HOM plays a redundant role in the same events. According to Wang and coworkers, SKAP-HOM failed to compensate for the loss of SKAP55 in LFA-1 clustering in T cells (Wang and Rudd 2008).

SKAP-HOM-deficient B cells show strongly reduced adhesion to fibronectin and ICAM-1 after BCR-stimulation, whereas B lymphocyte development and differentiation was normal (Togni et al. 2005). The signaling module regulating activation of B-cell integrins involves HPK1, SKAP-HOM, and RIAM. The loss of HPK1 induces enhanced integrin activity suggesting a negative regulatory role for this signaling complex. In conclusion, these data indicate that SKAP-HOM and SKAP55 may have similar but specialized functions in T and B cells (Königsberger et al. 2010).

In SKAP-HOM-deficient bone marrow-derived dendritic cells (BMDCs) the spontaneous motility is enhanced. By contrast, adhesion of mature BMDCs to fibronectin is reduced and antigen-dependent conjugate formation between SKAP-HOM-deficient DCs and T cells is delayed (Reinhold et al. 2009). Bone marrow-derived macrophages from SKAP-HOM-deficient mice exhibit abortive actin-rich ruffle formation (Swanson et al. 2008).

Overall, the results obtained from the characterization of the knockout mice (Table 1) confirm the role of SKAP-HOM in the regulation of integrin activation and adhesion in immune cells.

Only recently, new functions of SKAP-HOM outside the immune system were described. For example, heat shock factor *HSF4b* belongs to the transcriptional regulator family of heat shock proteins (Hsp). HSF4b is mainly expressed in lens epithelial cells and plays a major role in lens development. SKAP-HOM was identified as a novel target of HSF4b that associates with Nck2 and F-actin at membrane ruffles thereby regulating actin remodeling in lens cells (Zhou et al. 2011).

In an attempt to search for novel genes that are involved in pancreatic carcinogenesis, SKAP-HOM was the most frequently detected overexpressed gene in microdissections of pancreatic ductal adenocarcinoma specimen compared to reference samples. There was a significant correlation between DNA copy

number and mRNA expression level. This dysregulation of SKAP-HOM expression might be associated with the development of pancreatic cancer (Harada et al. 2008). Another study was performed to identify progression-associated metastasis genes in malignant melanoma. Functional assays were performed on a subset of 30 candidate genes including SKAP-HOM. siRNA-mediated knockdown of SKAP-HOM significantly inhibited invasion of melanoma cells in the Boyden Chamber assay (Kabbarah et al. 2010).

Summary

SKAP-HOM is a ubiquitously expressed cytosolic adaptor molecule. In immune cells, the molecular complex formed between SKAP-HOM, ADAP, and RIAM is involved in the regulation of inside-out signaling from immunoreceptors to integrins. To dissect the specialized function of SKAP-HOM and SKAP55 in T cells, an analysis of the respective knockout mice in parallel with a SKAP-HOM/SKAP55 double knockout mouse would be helpful. Further studies are needed to investigate the function of SKAP-HOM outside the immune system. The potential role of SKAP-HOM as a cancer-related gene seems to be of special interest. The knowledge of SKAP-HOM interaction partners and their protein-protein interaction domains might provide useful information for the design of synthetic inhibitors to modulate the invasive phenotype of tumor cells.

Slp (Synaptotagmin-Like Protein)

Mitsunori Fukuda
Laboratory of Membrane Trafficking Mechanisms, Department of Developmental Biology and Neurosciences, Graduate School of Life Sciences, Tohoku University, Sendai, Miyagi, Japan

Synonyms

Exophilin; Sytl (Syanptotagmin-Like)

Historical Background

Synaptotagmin-like proteins (Slps) were originally identified as synaptotagmin-related molecules containing two C2 calcium/phospholipid-binding motifs (named the C2A domain and the C2B domain) at their C terminus and no transmembrane domain at

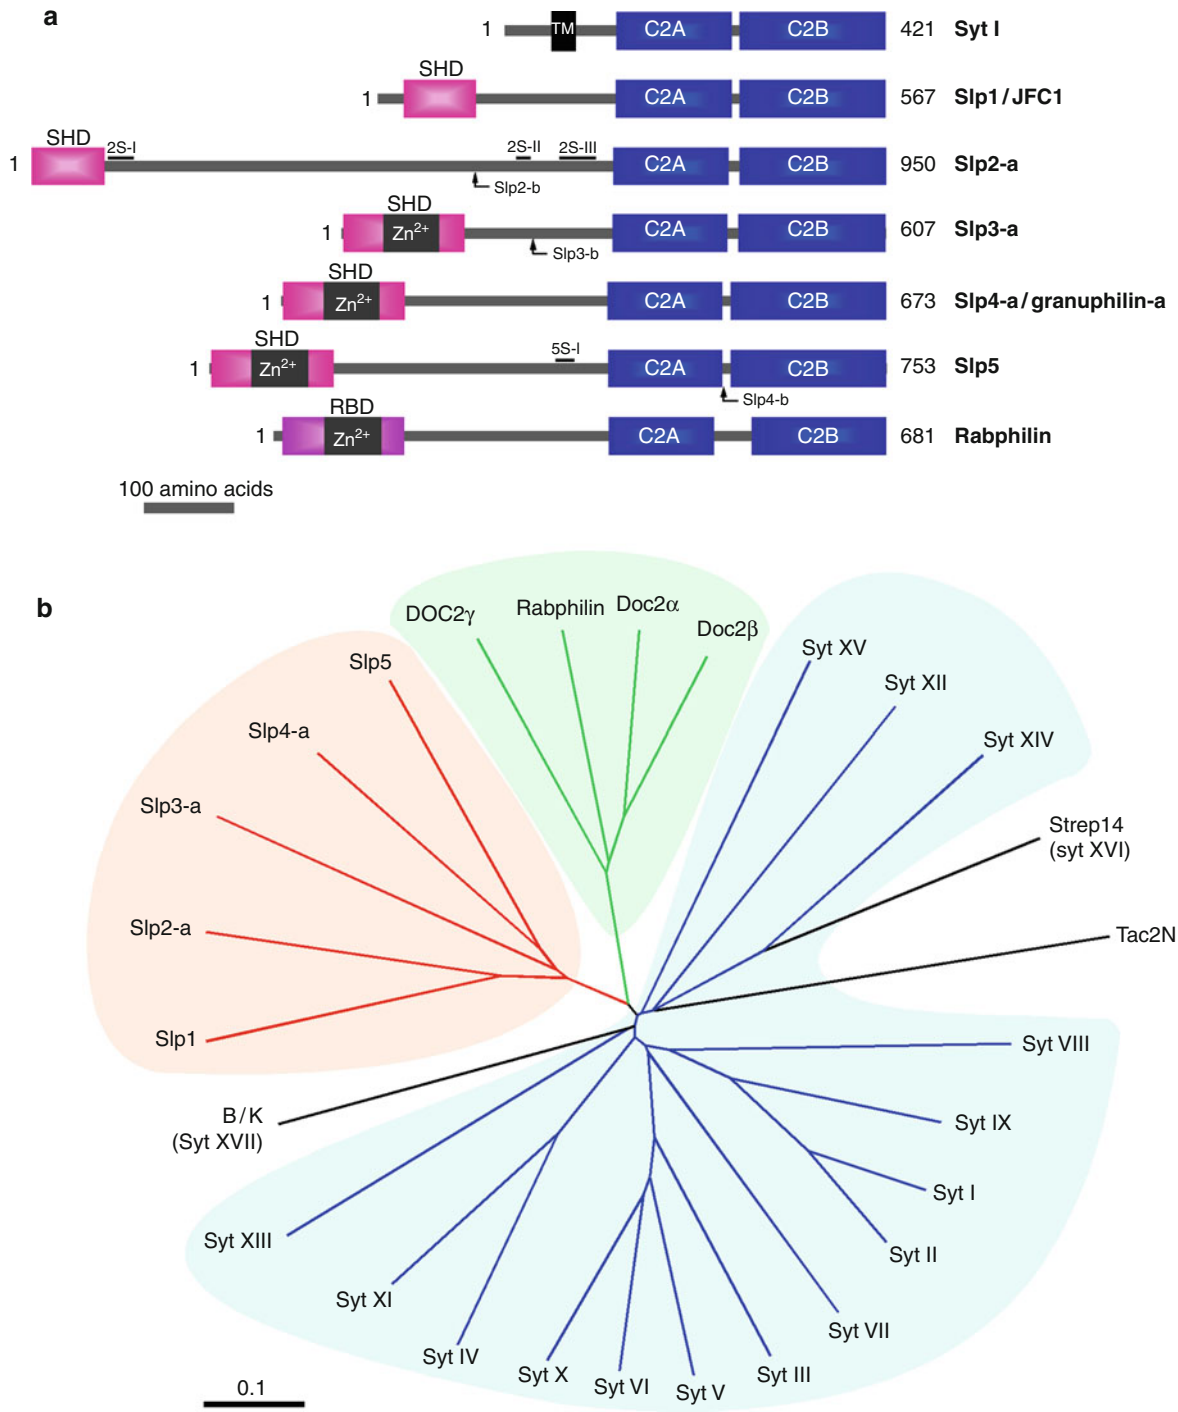
their N terminus (Fig. 1a), which suggested that they regulate certain intracellular membrane traffic events, the same as synaptotagmin I (Syt I) does in synaptic vesicle traffic (Fukuda and Mikoshiba 2001). The Slp family of proteins is now defined as a family of proteins, each of which contains an N-terminal conserved motif named the Slp homology domain (SHD) (Fig. 1a, magenta boxes) and C-terminal tandem C2 domains, although some members of the Slp family have several isoforms (e.g., Slp2-b, Slp3-b, and Slp4-b) that lack one of these domains because of alternative splicing (Fig. 1a, bars and arrows) (Fukuda et al. 2001). The Slp family is also recognized as the third group of C-terminal-type tandem C2 proteins that form a branch distinct from the synaptotagmin family and the rabphilin/Doc2 family in the phylogenetic tree (Fig. 1b). Slp family members appear to be conserved in all vertebrates, and five members of the Slp family (Slp1-5) have been reported in humans and mice (Wang et al. 1999; Fukuda and Mikoshiba 2001; McAdara Berkowitz et al. 2001; Kuroda et al. 2002b). Since mouse Slp mRNAs are differentially distributed in different tissues and at different developmental stages, Slp family members have been suggested to play a tissue-specific or cell-type-specific role in membrane traffic.

The common function of Slp family proteins was first revealed by biochemical analysis of the SHD, which has relatively weak amino acid sequence similarity to the Rab-binding domain of rabphilin, another type of C-terminal-type tandem C2 protein (Fig. 1a, bottom) (Fukuda et al. 2001). The results of an investigation of the ability of the SHD to bind all Rab isoforms clearly indicated that it serves as a specific effector domain for Rab27A and Rab27B (Kuroda et al. 2002a). The Rab27-binding SHD is also found in the N-terminal domain of another protein family, the Slac2 (Slp homologue lacking C2 domains) family, which consists of Slac2-a/melanophilin, Slac2-b, and Slac2-c/MyRIP (Fukuda 2008). Rab27 belongs to the Rab-type small GTPase family and functions as a molecular switch by cycling between two nucleotide-bound states, a GTP-bound active state and a GDP-bound inactive state. The GTP-bound form of Rab27 is recruited to specific membrane compartments, e.g., to melanosomes in melanocytes and to secretory vesicles in secretory cells, and interacts with its specific effector, namely, one of the members of the Slp family. The Rab27 effector function of the Slp family members in melanosome transport and secretory granule exocytosis has been revealed during the past decade, and the proposed function of each Slp is described below.

Slp1/JFC1

Slp1 was independently identified as JFC1, an NADPH oxidase- and phosphatidylinositol 3,4,5-trisphosphate (PIP_3)-binding protein (McAdara Berkowitz et al. 2001). In contrast to other SHDs, the SHD of Slp1 and Slp2-a lacks zinc finger motifs (Fig. 1a), but it still specifically recognizes Rab27 isoforms (Kuroda et al. 2002a). Mouse Slp1 protein is most abundantly expressed in the pancreas, especially in pancreatic acinar cells (Saegusa et al. 2008), and it is also expressed in other cell types, including neutrophils (Brzezinska et al. 2008), neurons (Arimura et al. 2009), platelets (Neumüller et al. 2009), and cytotoxic T lymphocytes (Holt et al. 2008). In neutrophils, Slp1 is co-localized with Rab27A on myeloperoxidase (MPO)-containing azurophilic granules, and knockdown of Slp1 by short hairpin RNA has been found to impair MPO secretion (Brzezinska et al. 2008). The Rab27A·Slp1 complex has been proposed to regulate the tethering and/or docking step of azurophilic granule exocytosis, possibly through interaction with PIP_3 in the plasma membrane. Similarly, Slp1 has been suggested to control other secretion events, including prostate-specific antigen secretion by human prostate carcinoma cells, dense granule exocytosis by platelets, and lytic granule exocytosis by cytotoxic T lymphocytes. Notably, Slp1 has also been found to form a complex with Rab27B·CRMP-2·TrkB·kinesin-1 and to mediate anterograde transport in axons (Arimura et al. 2009).

Despite the important roles of Slp1 at the cellular level, Slp1 knockout (KO) mice are viable, and no obvious abnormalities have been detected in their neurons or immune cells (Saegusa et al. 2008; Holt et al. 2008). The Slp1-deficiency in Slp1 KO mice may be compensated by a Slp1-related protein, Slp2-a. The only difference between wild-type and Slp1 KO mice that has been reported is a higher number of zymogen granules in the pancreatic acinar cells of fasted Slp1 KO mice (Saegusa et al. 2008).



Slp (Synaptotagmin-Like Protein), Fig. 1 (continued)

Slp2

Slp2-a is the largest member of the Slp family. A variety of Slp2 isoforms that have resulted from tissue/cell type-specific alternative splicing events have been reported in the literature (Fukuda et al. 2001; Holt et al. 2008) (Fig. 1a), but the physiological significance of the presence of multiple Slp2 isoforms remains unknown. The Slp2-a isoform contains an N-terminal SHD, whereas the Slp2-b and Slp2-c isoforms lack this domain. Mouse Slp2-a protein is most abundantly expressed in the stomach, especially in gastric surface mucous cells (Saegusa et al. 2006), and it is also expressed in other cell types, including melanocytes (Kuroda and Fukuda 2004), pancreatic α cells, and cytotoxic T lymphocytes (Holt et al. 2008). The well-known function of Slp2-a is to anchor melanosomes to the plasma membrane by simultaneously interacting with Rab27A on the melanosome via its SHD and with phosphatidylserine (PS) in the plasma membrane via its C2A domain (Kuroda and Fukuda 2004). Slp2-a also regulates the elongated cell shape of melanocytes by an unknown mechanism that is independent of Rab27A (Kuroda and Fukuda 2004). Slp2-a is also involved in the docking of mucus granules to the apical plasma membrane of the gastric surface mucous cells, because a smaller number of mucus granules and docking-defect have been observed in the gastric surface mucous cells of Slp2-a KO mice (Saegusa et al. 2006). An inhibitory role of Slp2-a in glucagon secretion has been proposed based on the results of an overexpression study, but the function of endogenous Slp2-a in pancreatic α cells is currently unknown.

Two possible links between human disease and Slp2-a have been reported. The first link is based on the fact that the Slp2-a protein level is dramatically reduced in the cytotoxic T lymphocytes of type II Griscelli syndrome patients (i.e., Rab27A-deficient) (Holt et al. 2008). Its reduction is presumably attributable to proteolysis, because Slp2-a contains multiple PEST sequences, which are potential signals for rapid protein degradation (Holt et al. 2008). However, cytotoxic T lymphocytes from Slp2-a KO mice exhibit normal killing activity (i.e., normal lytic granule exocytosis), suggesting that the Slp2-a-deficiency may be compensated by a Slp2-a-related protein, Slp1. The second link is based on the fact that dysferlin-deficiency has been shown to cause compensatory induction of Slp2-a (and also Rab27A) in limb girdle muscular dystrophy 2B (LGMD2B) muscles, and its induction may contribute to the onset of inflammation in patient muscles.

Slp3

Although Slp3 mRNA is expressed in mouse spleen, lung, kidney, and testis (Fukuda et al. 2001), almost nothing is known about the protein expression of Slp3. Two alternative splicing isoforms, Slp3-a and Slp3-b (Fig. 1a), have been reported, and the former form contains an N-terminal SHD with zinc finger domains. The results of an in vitro binding study indicated that the C2A domain of Slp3 and Slp5 functions as an atypical Ca^{2+}-dependent phospholipid-binding domain (Fukuda 2002), although key Glu/Asp residues responsible for Ca^{2+} binding of the C2 domain of Syt I and protein kinase C (PKC) are missing in the C2A domain of Slp3 and Slp5. Interestingly, expression of these Ca^{2+}-dependent-type Slps (i.e., Slp3-a and Slp5) in neuroendocrine PC12 cells strongly induced hormone secretion without changing the number of hormone granules docked at the plasma membrane (Fukuda 2003; Tsuboi and Fukuda 2006). By contrast, Ca^{2+}-independent-type Slps (i.e., Slp1, Slp2-a, and Slp4-a) had no effect or else had an inhibitory effect on hormone secretion by PC12 cells.

Slp (Synaptotagmin-Like Protein), Fig. 1 Structure of Slp family members. (**a**) Comparison of Slp family members with Syt I and rabphilin. Syt I, the Slp family members, and rapbphilin share the tandem C2 domains (i.e., the C2A domain and the C2B domain; *blue* boxes) at their C terminus, but their N-terminal structures differ. Syt I contains a single transmembrane domain (TM, black box), whereas the Slp family members contain a unique Slp homology domain (SHD, magenta boxes), also known as RBD27 (Rab-binding domain specific for Rab27 isoforms) (Fukuda et al. 2001; Kuroda et al. 2002a). The SHD of Slp3-5 is divided by zinc finger motifs (Zn^{2+}). Short bars (2 S-I, 2 S-II, 2 S-III, 5 S-I) and arrows (Slp2-b, Slp3-b, and Slp4-b) indicate the positions of alternative splicing sites. Amino acid numbers are given on both sides. (**b**) Molecular dendrogram of the mouse C-terminal-type tandem C2 proteins, including members of the synaptotagmin family (*blue* branch), the Slp family (*red* branch), and the rabphilin/Doc2 family (*green* branch). The dendrogram was drawn by using the ClustalW program set at the default parameters (available at http://clustalw.ddbj.nig.ac.jp/top-e.html)

Slp (Synaptotagmin-Like Protein), Table 1 Proposed functions and distribution of Slp family members

Name (gene ID)	Binding partners (binding site)	Proposed functions, distribution, and other features	KO mouse phenotypes
Slp1/JFC1 (mouse: 269589) (human: 84958)	CRMP-2 (N terminus) Rab27 (SHD) Rab8[a] PIP_3 (C2A) TrkB (C2A) Rap1GAP2 (C2A) NADPH oxidase	Control of prostate-specific antigen secretion by human prostate carcinoma cells Control of azurophilic granule exocytosis by neutrophils Control of TrkB transport in axons Control of dense granule secretion by platelets Control of amylase secretion by pancreatic acinar cells Possible involvement of lytic granule exocytosis by cytotoxic T lymphocytes Phosphorylation of Slp1 at serine 241 by Akt	Viable No apparent abnormalities in general appearance or behavior Increased zymogen granules in pancreatic acinar cells of the fasted Slp1 KO mice
Slp2 (mouse: 83671) (human: 54843)	Rab27 (SHD) PS (C2A)	Melanosome anchoring to the plasma membrane Control of basal mucus secretion by gastric surface mucous cells Control of glucagon secretion by pancreatic α cells Compensatory induction of Slp2-a in limb girdle muscular dystrophy 2B (LGMD2B) muscles Deficiency of Slp2-a protein in cytotoxic T lymphocytes from type II Griscelli syndrome patients	Viable No apparent abnormalities in general appearance or behavior Decreased basal mucus secretion by gastric surface mucous cells of Slp2-a KO mice
Slp3 (mouse: 83672) (human: 94120)	Rab27 (SHD) PS (C2A)[b]	Enhancement of hormone secretion by PC12 cells, when Slp3-a is overexpressed	None produced yet
Slp4/granuphilin (mouse: 27359) (human: 94121)	Rab3/8/27 (SHD) Munc18-1·syntaxin-1a (linker domain) Munc18-2·sytanxin-2/3 (linker domain)	Control of insulin secretion by pancreatic β cells Control of dense-core vesicle exocytosis by PC12 cells Control of amylase secretion by parotid acinar cells Control of pituitary hormone secretion by pituitary cells Control of exosome secretion by HeLa cells	Viable No apparent abnormalities in general appearance or behavior Very mild growth defect (~10% weight reduction) Increased insulin secretion
Slp5 (mouse: 236643) (human: 94122)	Rab27 (SHD) PS (C2A/C2B)[b]	Enhancement of hormone secretion by PC12 cells, when Slp5 is overexpressed Expression of Slp5 protein in pancreatic β cell lines	None produced yet

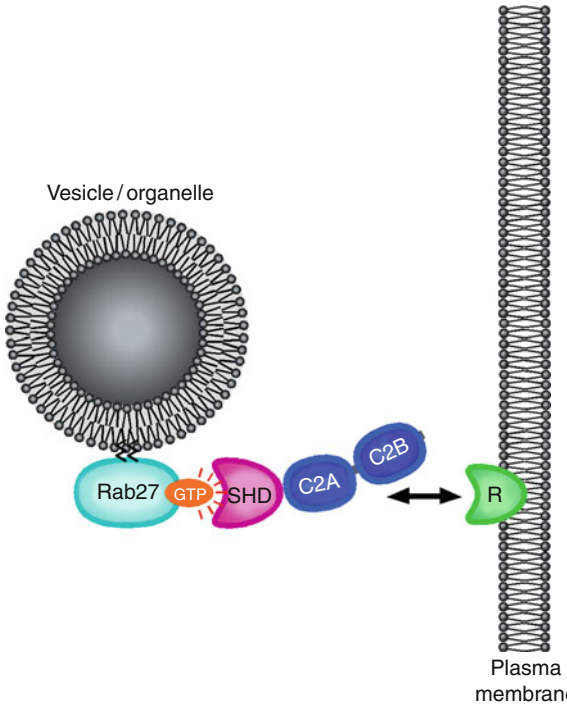
[a]Binding of Rab8 to Slp1 is a matter of controversy in the literature.
[b]The C2A domain of Slp3 and Slp5 exhibits Ca^{2+}-dependent phospholipid-binding activity.

Slp4/Granuphilin

Slp4/granuphilin was originally identified as a rabphilin-like protein associated with insulin granules in pancreatic β cells (Wang et al. 1999). Two alternative splicing isoforms, Slp4-a/granuphilin-a and Slp4-b/granuphilin-b, have been reported, and both of them contain an N-terminal SHD (Fig. 1a). However, no differences in the function of the two isoforms are unknown. Mouse Slp4-a protein is most abundantly expressed in the pancreas, especially in pancreatic β cells (Wang et al. 1999), and it is also expressed in other neuroendocrine cells (Tsuboi and Fukuda 2006), parotid acinar cells, and HeLa cells (Ostrowski et al. 2010). In contrast to other Slp family members, Slp4-a functions as a negative regulator of hormone secretion by neuroendocrine cells, including pancreatic β cells and PC12 cells (Wang et al. 1999; Fukuda 2003), although expression of Slp4-a promotes docking of hormone granules to the plasma membrane, possibly through interaction with Munc18-1·syntaxin-1a complex (Gomi et al. 2005; Tsuboi and Fukuda 2006; Tomas et al. 2008). Small interfering RNA-mediated

knockdown of endogenous Slp4-a or targeted disruption of *Slp4-a* gene actually caused increased hormone secretion despite decreasing the number of plasma membrane-docked hormone granules (Gomi et al. 2005; Tsuboi and Fukuda 2006). Therefore, granuphilin may be a potential therapeutic target for the treatment of type 2 diabetes.

In contrast to the negative role of Slp4-a in hormone secretion, positive roles of Slp4-a have been reported in other cell types. For example, Slp4-a is present on amylase-containing granules in parotid acinar cells together with Rab27A/B and forms a complex with Munc18-2·syntaxin-2/3. Disruption of the Slp4-a·Munc18-2·syntaxin-2/3 complex either by a GST-Slp4-a linker, which contains a Munc18-2-binding region, or antibody against the Slp4-a linker domain, attenuates isoproterenol-stimulated amylase release from streptolysin O-permeabilized parotid acinar cells. Slp4-a is also expressed in HeLa cells and contributes to exosome secretion through interaction with Rab27A.



Slp (Synaptotagmin-Like Protein), Fig. 2 Proposed function of Rab27·Slp complex in the transport of a Rab27-bearing vesicle/organelle. The Slp is recruited to a certain vesicle/organelle by direct binding of the SHD to GTP-Rab27 via an active GTP-Rab27 specifically localized there. The Slp also interacts with a certain receptor (R) in the plasma membrane, and the resulting Rab27·Slp complex mediates tethering, docking, and/or fusion of the transport vesicle/organelle. Thus, Slp family members function as a linker protein between Rab27 on a vesicle/organelle and protein/lipid in the plasma membrane (Fukuda 2008). Examples of "R" are syntaxin-1a/Munc18-1 for Slp4-a/granuphilin-a (Gomi et al. 2005; Tsuboi and Fukuda 2006; Tomas et al. 2008), PS for Slp2-a (Kuroda and Fukuda 2004), and PIP_3 for Slp1/JFC1

Slp5

Slp5 was identified as a protein closely related to Slp4-a, and the genes encoding both are located on the same X chromosome in humans, rats, and mice (Kuroda et al. 2002b). However, the biochemical properties of Slp4-a and Slp5 are clearly different in terms of Ca^{2+}-dependent phospholipid-binding activity and Munc18-1·syntaxin-1a–binding activity (Wang et al. 1999; Kuroda et al. 2002b; Fukuda 2003; Tsuboi and Fukuda 2006). Abundant expression of human Slp5 mRNA has been found in the placenta and liver, but its precise protein expression patterns remain to be determined. Although expression of Slp5 protein has been reported in some pancreatic β cell lines, its involvement in insulin secretion has never been investigated. As noted above in the section on Slp3, however, expression of Slp5 in neuroendocrine PC12 cells strongly induces hormone secretion without changing the number of hormone granules docked at the plasma membrane (Fukuda 2003; Tsuboi and Fukuda 2006).

Summary

The members of the Slp family of proteins are well-known Rab27 effectors that function in specific membrane traffic events (reviewed in Fukuda 2008) (summarized in Table 1). Although each member participates in a different type of membrane traffic event, we found a common molecular mechanism that underlies the Slp-mediated membrane traffic (Fig. 2). Since Slp family proteins are first recruited to the specific vesicle/organelle where the GTP-bound active form of Rab27 is present, and their C-terminal domain interacts with their specific receptor protein (R in Fig. 2) in the plasma membrane, members of the Slp family of proteins function as linkers between cargo (i.e., Rab27-containing vesicle/organelle) and target membrane and promote tethering/docking/fusion of the Rab27-containing vesicle/organelle to the target

membrane. Future determination of the detailed expression pattern of each Slp member and identification of more tissue/cell-type-specific binding partners of Slps, especially Slp3-a and Slp5, will be necessary to fully understand the molecular mechanism of Slp-mediated membrane traffic.

SLP-76

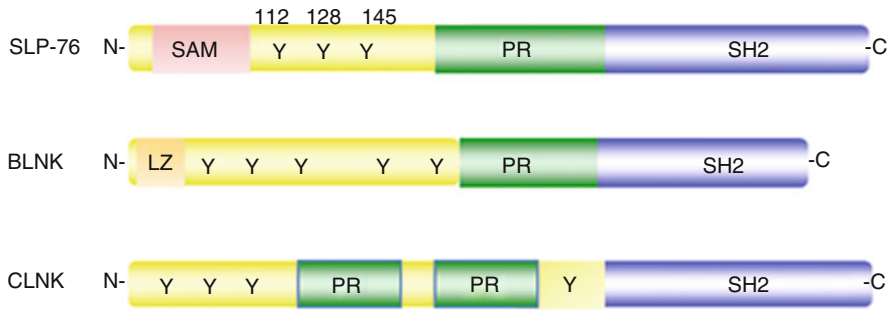
Jong Ran Lee
Department of Life Science, College of Natural Sciences, Ewha Womans University, Seoul, South Korea

Synonyms

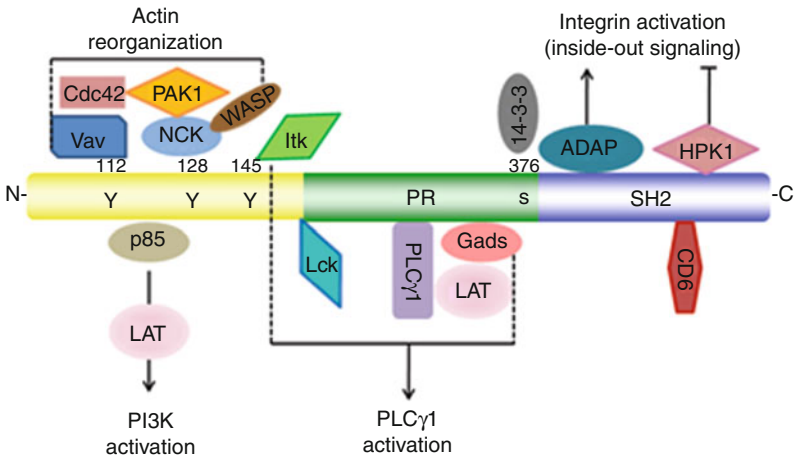
LCP2; Lymphocyte cytosolic protein 2; Src homology 2 (SH2) domain–containing leukocyte protein of 76 kDa

Historical Background

SLP-76 was first identified as a substrate of the protein tyrosine kinases that are activated by T-cell antigen



SLP-76, Fig. 1 Domain structures of SLP-76 adaptor family members. Domains found in the SLP-76 adaptor family members are schematically shown. *LZ* leucine-zipper motif domain, *SAM* sterile alpha motif domain, *SH2* Src homology 2 domain, *PR* proline-rich region. The amino acid position numbers are indicated in SLP-76



SLP-76, Fig. 2 Binding partners for functional domains of SLP-76. Binding partners for each domain structure of SLP-76 and the consequent functional outcomes are shown. *ADAP* adhesion- and degranulation-promoting adaptor protein, *Gads* Grb2-related adaptor proteins, *HPK1* hematopoietic progenitor kinase 1, *Itk* interleukin 2-inducible T-cell kinase, *LAT* linker for activation of T cells, *NCK* non-catalytic region of tyrosine kinase, *PAK1* p21-activated kinase 1, *PI3K* phosphatidylinositol 3-kinase, *PLC* phospholipase C, *WASP* Wiskott-Aldrich syndrome protein

receptors (TCRs) (Jackman et al. 1995). SLP-76, which functions as a signal transducer downstream of TCRs, is an adaptor protein that has three modular domains: an amino (N)-terminal acidic domain with three tyrosine (Y) phosphorylation motifs, a central proline-rich region, and a carboxy (C)-terminal SH2 domain (Fig. 1). Two other proteins, B-cell linker protein (BLNK/BASH/BCA/SLP-65) and cytokine-dependent hematopoietic cell linker (CLNK/MIST), constitute a family of SLP-76 adaptors, each expressed exclusively in hematopoietic cells. The three family members have only a moderate degree of sequence homology, but share a characteristic domain structure (Fig. 1). These SLP-76 family members are critical for nucleation of large signaling complexes in diverse hematopoietic cell types.

SLP-76 as a Scaffold for Signaling Complexes

Investigation into the three functional domains of SLP-76 has revealed how SLP-76 operates in TCR signaling. SLP-76 regulates T-cell function in various ways through its binding partners (Fig. 2).

The amino-terminal tyrosines of SLP-76 are essential for SLP-76 function. Three tyrosines at amino acids 112 (113 in humans), 128, and 145 become phosphorylated after TCR stimulation. Mutation of

tyrosine 112 and/or 128 abrogates the inducible association of SLP-76 with the guanine nucleotide exchange factor (GEF) ▶ Vav1 (Wu et al. 1996), the adaptor non-catalytic region of tyrosine kinase (NCK) (Wunderlich et al. 1999), and the p85 subunit of phosphatidylinositol 3-kinase (PI3K) (Shim et al. 2004). Mutation of tyrosine 145 results in the loss of binding to Tec family tyrosine kinase interleukin 2-inducible T-cell kinase (Itk) (Su et al. 1999). Recently, a sterile-α motif (SAM) was identified at amino acids 12–78 just proximal to the three tyrosines, but it is not currently known what interaction(s) the SAM domain of SLP-76 mediates.

The central proline-rich region of SLP-76 contains a characterized SH3-domain-binding motif (RxxK) that mediates constitutive interaction with Grb2-related adaptor proteins (Gads) (Berry et al. 2002). In addition to the Gads-binding site, the P1 domain at amino acids 157–223 was defined as a region necessary for the basal association of SLP-76 with phospholipase C-γ1 (PLCγ1) (Yablonski et al. 2001). However, the critical aspect of the P1 domain probably lies more in its role as a molecular spacer, preventing the premature recruitment of PLCγ1 to the cell membrane by associating with the transmembrane adaptor linker for activation of T cells (▶ LAT), rather than as a mediator of an essential protein/protein interaction (Gonen et al. 2005; Jung et al. 2010). The Src family kinase Lck also binds the proline-rich domain of SLP-76 (Sanzenbacher et al. 1999). Recently, serine 376 within the proline-rich region was shown to be phosphorylated by the serine-threonine kinase hematopoietic progenitor kinase 1 (HPK1), one of the binding partners of the SLP-76 SH2 domain. Phosphorylation at this site results in decreased TCR signal transduction (Shui et al. 2007), but the mechanism has yet to be defined.

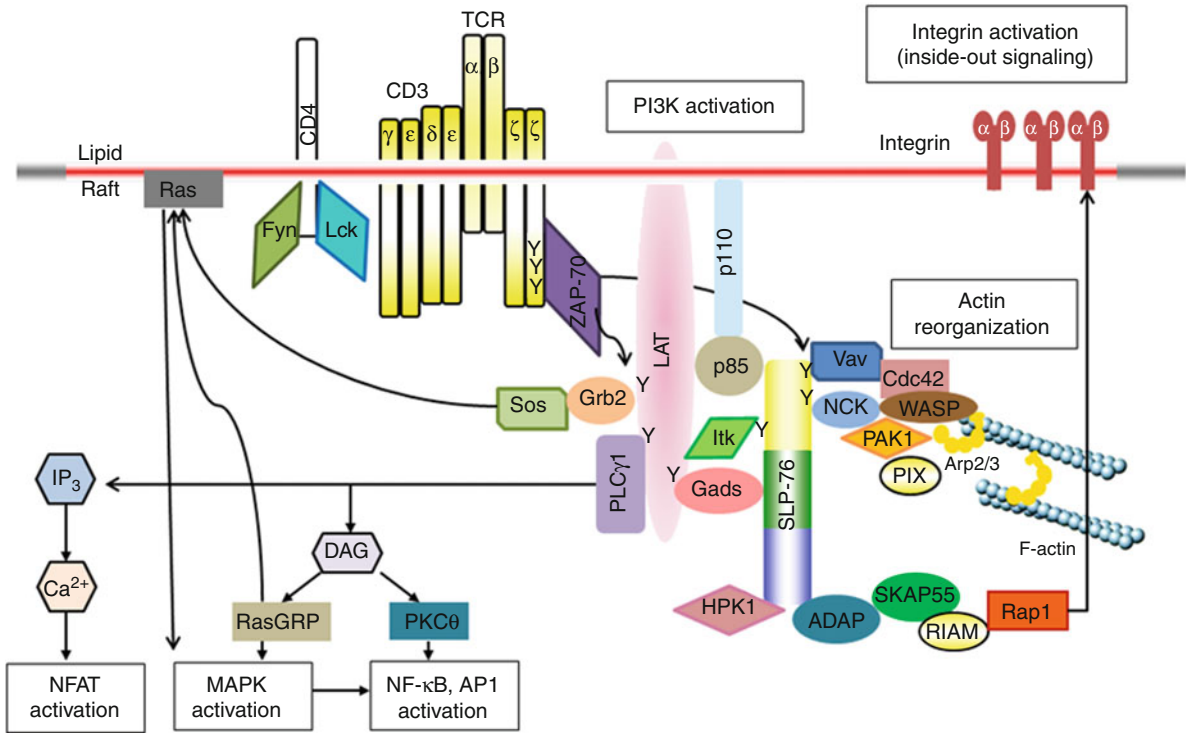
The carboxy-terminal SH2 domain of SLP-76 inducibly associates with adhesion- and degranulation-promoting adaptor protein (▶ ADAP) (Musci et al. 1997) and HPK1 (Sauer et al. 2001). The SLP-76 SH2 domain can also associate with the cytoplasmic tail of the T-cell surface receptor CD6 (Hassan et al. 2006).

Role of SLP-76 in TCR Signaling

TCR ligation results in activation of the Src family kinase Lck, which phosphorylates tyrosines in the immunoreceptor tyrosine–based activation motifs (ITAMs) present within the ▶ CD3 chains of the TCR complex. Phosphorylated ITAMs recruit the Syk family kinase ζ-chain-associated protein kinase of 70 kDa (▶ ZAP-70), leading to phosphorylation of SLP-76 and LAT, which is a critical step in the assembly of the signaling complex by the two adaptors. Phosphorylation of LAT indirectly recruits SLP-76 via Gads binding, and the two adaptors nucleate a multimolecular complex of several signaling proteins and transport this complex to the cell membrane, where LAT is constitutively localized within microdomains known as lipid rafts or glycolipid-enriched membrane domains (GEMs). For PLCγ1 enzyme activation, recruitment to the GEM and tyrosine phosphorylation is induced by binding to the phosphotyrosine of LAT via its SH2 domain, and SLP-76 recruitment to LAT via Gads is also required for this process (Yablonski et al. 1998). Thus, LAT, SLP-76, and Gads appear to constitute an integrated signaling unit that couples TCR-mediated activation of cytoplasmic protein kinases to PLCγ1 enzyme activation (Fig. 3).

The role of SLP-76 in TCR signaling was determined from overexpression studies in the Jurkat human leukemic T-cell line, demonstrating that SLP-76 is a positive regulator of TCR signaling. Complementary loss-of-function studies in SLP-76-deficient Jurkat cells known as J14 cells (Yablonski et al. 1998) revealed considerably reduced phosphorylation of PLCγ1, but not of ZAP-70, LAT, and Itk, showing that SLP-76 links proximal signaling molecules and downstream effectors. Thus, signaling events due to PLCγ1 activation, such as the generation of inositol-1, 4, 5-trisphosphate (IP_3) and diacylglycerol (DAG) and resulting intracellular calcium flux, the activation of protein kinase C (PKC) family members, and indirect activation of Ras through Ras guanyl-releasing protein (▶ RasGRP), are all reduced. Upregulation of a T-cell activation marker CD69, transcriptional activity of nuclear factor of activated T cells (▶ NFAT), and activator protein 1 (AP1) is significantly reduced with SLP-76 deficiency (Yablonski et al. 1998).

The SLP-76-binding partners Vav1 and NCK, which inducibly associate with the amino-terminal tyrosines of SLP-76 after TCR stimulation, regulate cytoskeletal organization via Cdc42 recruitment through p21-activated kinase 1 (PAK1) and Wiskott-Aldrich syndrome protein (WASP). This model of TCR-mediated cytoskeletal rearrangement implies that SLP-76 regulates actin polymerization in response to TCR stimulation by regulating colocalization of Vav1 with NCK (Zeng et al. 2003) (Fig. 3).



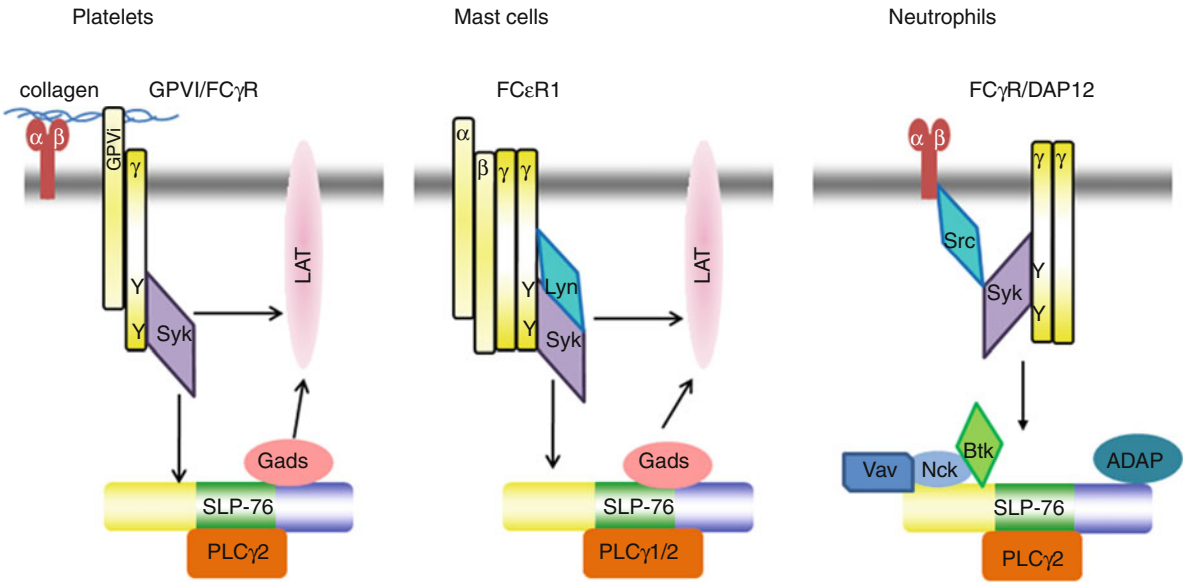
SLP-76, Fig. 3 Role of SLP-76 in T-cell function. SLP-76-mediated signaling pathways downstream of the T-cell receptor: cellular activation and inside-out signaling are shown. *AP1* activator protein 1, *DAG* diacylglycerol, *IP3* inositol-1, 4, 5-trisphosphate, *MAPK* mitogen-activated protein kinase, *NFAT* nuclear factor of activated T cells, *NF-κB* nuclear factor-κB, *PKC* protein kinase C, *Rap1* Ras-proximity-1, *RasGRP* Ras guanyl-releasing protein, *RIAM* Rap1-GTP-interacting adaptor molecule, *SKAP* Src kinase–associated phosphoprotein, *Sos* son of sevenless, *TCR* T-cell receptor

SLP-76 has been implicated in TCR-induced integrin activation, so-called "inside-out signaling" because of its association with ADAP through the SH2 domain. Mutational analysis of ADAP at sites of interaction with SLP-76 diminishes the ability of T cells to adhere to integrin-coated surfaces. The molecular mechanism of SLP-76-mediated inside-out signaling to integrins is thus likely ADAP dependent. Recently, direct involvement was shown for SLP-76 in membrane targeting and activation of the small GTPase Ras-proximity-1 (Rap1), which promotes clustering and affinity modulation of integrins for their full activation, although the domain requirements have not been identified (Horn et al. 2009) (Fig. 3).

SLP-76 Signaling in Other Receptor Systems

The amino-terminal tyrosine motifs of SLP-76 are the earliest phosphorylation substrates of Src and Syk family kinases and are activated by ligation of tyrosine kinase–associated receptors on a variety of hematopoietic cell types. This tyrosine phosphorylation of SLP-76 induces associations with SH2 domain–containing proteins. The central proline-rich sequences mediate constitutive interactions with SH3 domain–containing proteins, and the carboxy-terminal SH2 domain of SLP-76 induces phosphotyrosine-dependent interactions with additional binding partners. Consequently, the SLP-76 adaptor nucleates large signaling complexes and plays critical roles in a variety of tyrosine kinase–associated receptor signaling pathways in various hematopoietic cell types (Fig. 4).

SLP-76 expressed in platelets is phosphorylated after stimulation of the ITAM-bearing collagen receptor, glycoprotein (GP) VI. As in T cells, SLP-76 lies downstream of the Src and Syk family kinases but upstream of PLCγ activation. SLP-76 is also inducibly phosphorylated upon ligation of the platelet integrin αIIβB3, which is required for normal platelet



SLP-76, Fig. 4 Role of SLP-76 in signaling triggered by other surface receptors in hematopoietic cell types. SLP-76 signaling in other receptor systems that are associated with a variety of tyrosine kinases is shown

spreading on its ligand fibrinogen. Unlike TCR signaling, which depends critically on SLP-76 and LAT as well as the inducible interaction between these two adaptor proteins, collagen receptor and integrin signaling in platelets rely more on SLP-76 than on LAT for their function (Judd et al. 2002).

In addition to T cells and platelets, SLP-76 is expressed in multiple hematopoietic lineages including neutrophils, mast cells, macrophages, and natural killer (NK) cells (Jackman et al. 1995). The predominant ITAM-bearing receptors on these cells are Fc receptors (FcRs) including FcεRI in mast cells and FcγRs in other cell types. The signaling molecules that are both upstream and downstream of SLP-76 are similar among these receptors and across cell types. However, important differences exist in how SLP-76 coordinates signal transduction across different cell and receptor types.

Cross-linking of FcεRI, which constitutively interacts with the Src family kinase Lyn, with antigen-bound IgE induces activation and recruitment of Lyn and Syk. Consequently, tyrosine phosphorylation of SLP-76 and nucleation of a signaling complex similar to the one formed in T cells upon TCR activation occur. This complex includes LAT, Vav1, Btk, Gads, PLCγ1/2, and ADAP. SLP-76-deficient bone marrow–derived mast cells degranulate poorly and produce negligible amounts of the cytokine interleukin-6 and also show biochemical defects such as diminished calcium flux and phosphorylation of PLCγ2 (Pivniouk et al. 1999).

Upon FcγR stimulation in neutrophils, signals and effector functions are induced by activation of the Src family kinases Hck and Fgr, followed by Syk activation. These responses in neutrophils are synergistically augmented by cell adhesion. SLP-76-deficient neutrophils show reduced calcium flux and production of reactive oxygen species in response to FcγR stimulation and also fail to spread upon stimulation with integrins (Newbrough et al. 2003). These data suggest that SLP-76 is involved in both FcγR and integrin signaling in neutrophils.

In contrast to neutrophils, SLP-76-deficient macrophages respond normally to FcγR signals, leading to intact phagocytosis function and production of reactive oxygen species (Nichols et al. 2004). Similarly, SLP-76 appears dispensable for the FcγRIIIA-mediated killing function in NK cells (Peterson et al. 1999).

SLP-76-Deficient Mice and Defects in Multiple Lineages

The importance of SLP-76 as a regulator of signaling pathways for cellular function was highlighted by SLP-76-deficient mice. SLP-76-deficient mice present in Mendelian ratios in utero suffer perinatal mortality in more than 60% of the mice. SLP-76-deficient fetuses show

varying degrees of subcutaneous hemorrhage, and surviving mice have blood in the peritoneum (Clements et al. 1998). Adult SLP-76-deficient mice have very small thymi and lack peripheral T cells and lymph nodes. By contrast, normal numbers of macrophages and NK cells are seen in these mice (Clements et al. 1998).

SLP-76-deficient thymocytes are unable to induce allelic exclusion and β-selection due to the failure to transduce pre-TCR signals, resulting in a complete block of thymocyte development at the double-negative 3 stage (Clements et al. 1998). A possible role for SLP-76 in pre-B-cell receptor signaling at the pre-B-cell stage has been shown. Despite hemorrhage in the peritoneum in SLP-76-deficient mice, normal platelet development and normal bleeding times are observed (Clements et al. 1998). Loss of SLP-76 in platelets results in decreased PLCγ2 activation, aggregation, and degranulation in response to collagen as well as decreased spreading on fibrinogen. SLP-76-deficient neutrophils show defective responses to integrin stimulation, with a loss of reactive oxygen species production and failure to spread, as well as a reduced response to FcγR stimulation (Newbrough et al. 2003). SLP-76-deficient mice have a normal number and distribution of mast cells, but SLP-76 deficiency results in loss of mast cell–dependent responses: reduced degranulation, cytokine production, and consequent loss of passive systemic anaphylaxis (Pivniouk et al. 1999).

The abnormal subcutaneous hemorrhagic phenotype in SLP-76-deficient mice is due to a failure of separation of the lymphatic and blood vascular networks during development (Abtahian et al. 2003). SLP-76-deficient mice have chimeric vessels composed of lymphatic and blood endothelial cells, with blood-filled lymphatics sometimes observed. The exact role of SLP-76 for vascular development has yet to be determined.

Summary

SLP-76 was first cloned in 1995 as a substrate of the TCR-activated protein tyrosine kinases and a binding protein for Grb2. Since then, initial characterization of the role of SLP-76 in TCR signaling has documented SLP-76 as an adaptor protein containing multiple protein interaction domains, creating a molecular scaffold on which key signaling complexes are built. The adaptor protein SLP-76 is expressed in multiple lineages of hematopoietic cells including T cells, platelets, and neutrophils. The details of how SLP-76 functions were elucidated both in T cells and other hematopoietic lineages using cell lines and SLP-76-deficient mice. Besides having critical roles for signaling downstream of both immunoreceptors and integrins, SLP-76 may function as a regulator of additional cell surface receptor signals such as those in the vasculature. Insights from studies of how SLP-76 regulates immune cell development and coordinates signal transduction across different cell and receptor types will provide important information about how the immune system uses various strategies for optimal host defense. Based on these observations, potential therapeutic targets can be explored.

Synonyms

CIS (cytokine-inducible SH2-containing protein); JAB (Janus kinase binding protein); SSI (STAT-induced STAT inhibitor); TIP3 (Tec interacting protein-3 = SOCS1); (Nck-associated protein-4 = SOCS7)

Historical Background

Cytokines play an important role in the regulation of innate and adaptive immunity. In general, cytokines exert rapidly inducible but transient cellular responses. Whereas signal transduction by cytokines is nowadays known in molecular details, counteraction and termination by negative regulation has only recently begun to be understood. However, the integration of positive and negative signals is mandatory to ensure immunological homeostasis. Type I and II cytokine receptors (including receptors for interferons, interleukins, and hematopoietic growth factors) typically lack intrinsic kinase activity. Instead, cytokines that trigger those receptors activate receptor-associated cytoplasmic Janus kinases (JAKs) and signal transducer and activator of transcription (STAT) factors. The JAK/STAT signaling pathway regulates a variety of responses in immune cells, including development, activation, and differentiation. Negative regulation which terminates JAK/STAT signaling comprises internalization of cytokine receptors, secretion of decoy receptors that capture secreted cytokines, expression of constitutively activated regulators including PIAS (protein inhibitors of activated STAT) proteins, protein tyrosine phosphatases (PTP) such as SHP-1 (SH2-containing phosphatase 1), ▶ SHIP (SH2-containing inositol phosphatase), and protein modifications (ubiquitination and ISGylation) of signaling components. In 1995, CIS (cytokine-inducible SH2-containing protein) was discovered as the first member of the SOCS family during studies on the expression of immediate-early cytokine-induced genes (Yoshimura et al. 1995). In 1997, Suppressor of Cytokine Signaling (SOCS) proteins were subsequently identified independently by three groups as a protein family that regulates JAK/STAT signaling (Endo et al. 1997; Naka et al. 1997; Starr et al. 1997). Importantly, expression of SOCS proteins was induced by JAK/STAT signaling itself (explaining the synonyms STAT-induced STAT inhibitor, SSI and cytokine-inducible SH2-containing protein, CIS) and in turn SOCS proteins limited further signal transduction of this signaling pathway. Thus, SOCS proteins were identified and characterized as the first intracellular feedback inhibitors of type I and II cytokine receptors. They build up a negative regulatory pathway thereby limiting duration of JAK/STAT signaling. Since then, it has been discovered that the eight SOCS family members can be induced by a variety of cytokines that in turn are regulated in a (1) feedback inhibition mode. Moreover, it has turned out that beside this feedback loop SOCS proteins can also be induced by other immune receptors and signals, including Toll-like receptors, TNF receptor, T-cell receptors, cAMP, thereby regulating a cell's sensitivity towards subsequent cytokine stimulation, referred to as (2) crosstalk inhibition.

The SOCS Family

Based upon structural similarities, the SOCS family consists of eight members: SOCS1-7 and CIS (Alexander 2002; Alexander and Hilton 2003; Yoshimura et al. 2007). Since SOCS proteins are negative feedback inhibitors that are induced through JAK/STAT signaling, they contain STAT binding regions within their promoters. Hence, SOCS

expression is induced by activated STATs. However, SOCS proteins are pleiotropic, thus individual family members can be induced by and regulate different STAT signaling modules. SOCS genes have only few introns thus identifying them as rapidly inducible, immediate early genes. SOCS expression is regulated at the transcriptional level: Promoters bear STAT factor binding elements but also additional transcription factors drive SOCS expression (e.g., ▶ NF-κB, egr-1, IRF1). Moreover, SOCS protein expression is also controlled by translational mechanisms. Thus, SOCS proteins feature a short half-life time (approximately 1–4 h) ensuring timely and rapid regulation of transient cytokine responses. SOCS1 and SOCS3 abundance is determined by protein stability: ▶ Pim-1-induced phosphorylation stabilizes SOCS1 which in turn increases half-life time of the latter. Protein stability of SOCS3 is regulated through a specific 35-residue PEST sequence (Pro, Glu, Ser, Thr) that enhances its degradation. Additionally, the SOCS box is discussed to influence the stability of SOCS proteins. Structures for CIS in conjunction with Elongin B/C and SOCS3 together with a tyrosine-phosphorylated peptide from the IL-6 receptor have been solved.

Structure and Mode of Action

All SOCS proteins share the same principal domain structure (Fig. 1) with a SOCS box, a Src homology 2 (SH2) domain, and an optional kinase inhibitory region (KIR). The SOCS box domain is a 40 amino acid-comprising domain that can be found in the carboxy terminus of all SOCS family members. Additional proteins containing a SOCS box motif but not sharing the basic structure of SOCS1-7 and CIS (as defined by the SH2 domain) have also been assigned to the SOCS superfamily which includes more than 40 proteins united to four subfamilies depending on the motif located N-terminally of the SOCS box. These subfamilies contain ankyrin repeats, WD-40 repeats, SPRY domains, and small GTPases.

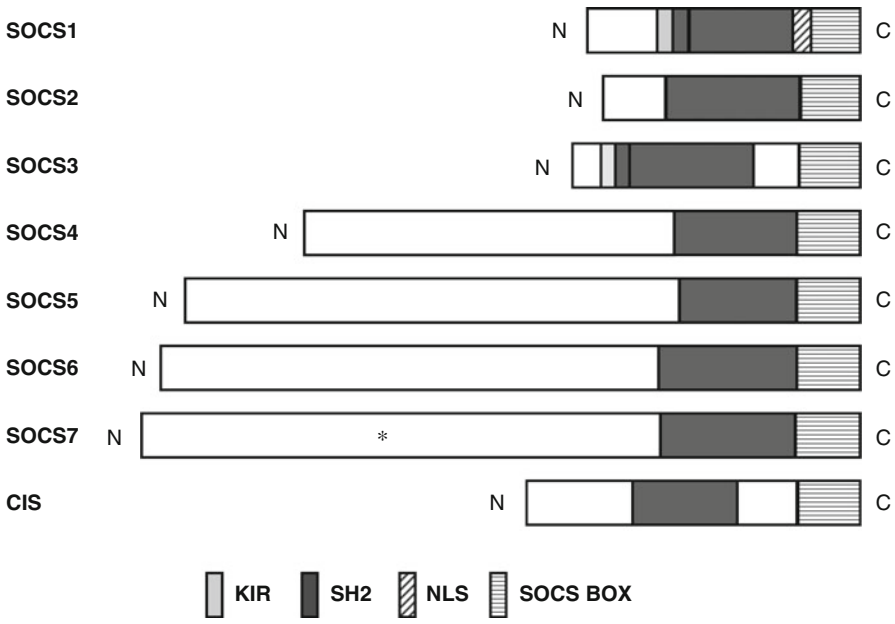
The SOCS box has been shown to operate as E3 ubiquitin ligase by interacting with Elongin B and C, cullin-5, and RING box 2 (Kile et al. 2002). In concert with two other enzymes of the ubiquitin system, E1 (ubiquitin-activating) and E2 (ubiquitin-conjugating), the E3 ubiquitin ligase induces ubiquitination of a specifically bound protein thus leading to the proteasomal degradation of the latter. SOCS proteins thus operate by inducing proteasomal decay of substrates which they bind by an additional N-terminal protein interaction domain, the SH2 domain. Inhibition of proteasomal degradation dampens the inhibitory effects of SOCS on cytokine signaling.

To access their substrates, SOCS1-7 and CIS bear a central SH2 domain which mediates binding to phosphorylated tyrosine residues within target proteins. SOCS1 binds to activated, phosphorylated Y1007 in JAK2 thereby inhibiting JAK2 signaling. It also interferes with JAK1-3 and Tyk2 activation. SOCS1 also binds to the type I and II IFN receptor chains IFNAR1 and IFNGR1. SOCS3 is also capable of binding to JAK2-pY1007 but with lower affinity as compared to SOCS1. Moreover, SOCS3, SOCS2, and CIS bind to phosphorylated residues exposed at cytoplasmic sites of various cytokine receptors. SOCS3 has a specific affinity to bind to gp130, thus inhibiting IL-6 and other gp130-dependent cytokines. In turn, STAT3 activity is controlled. Importantly, IL-10-induced STAT3 activity is not limited by SOCS3. SOCS3 inhibits JAK activity whereas CIS and SOCS2 do not interfere with JAKs but rather compete with STAT recruitment to the receptor. A consensus sequence to which the SH2 domain of SOCS3 binds has been identified as (S/A/V/Y/F)-hydrophopbic-(V/I/L)-hydrophobic-(H/V/I/Y).

Interestingly, the SH2 domain is also involved in binding proteins distinct from JAK/STAT, e.g., ▶ NF-κB p65, c-kit, insulin receptor, and tumor suppressor p53. Moreover, SOCS3 interferes also with ▶ MAP kinase activation by blocking the SHP2 binding site in gp130.

Additional small extended SH2 subdomains (ESS) N-terminal (SOCS1 and 3) of the SH2 domain essentially contribute to the binding of phosphorylated tyrosine residues. In case of SOCS1 and SOCS3 the SH2 domain mediates binding to substrates; however, inhibition of JAKs is achieved by a kinase inhibitory region (KIR) which is N-terminally attached to the SH2 domain and can only be found in SOCS1 and SOCS3. The KIR domain blocks the catalytic cleft of JAKs thereby contributing to termination of JAK/STAT signaling.

The further N-terminus is quite diverse among the SOCS family members and varies in length and sequence. In contrast to the specific function of SOCS proteins located at the cytoplasmic site of the



SOCS, Fig. 1 Domain structure of the eight SOCS family members. SOCS1 and SOCS3 bear an extended SH2 domain, as well as a KIR domain. SOCS1 contains a bipartite nuclear localization signal and SOCS7 possesses an ill-defined, central monopartite nuclear localization signal (*)

cytokine receptor, SOCS1 revealed an unexpected subcellular localization pattern with mainly nuclear occurrence. This was attributed to a specific sequence composed of two clusters of basic amino acid residues which function as classical bipartite nuclear localization signal (NLS) (Baetz et al. 2008). Furthermore, SOCS3 and 6 are found ubiquitously expressed throughout the whole cell by immunofluorescence and SOCS7 also has the capacity to translocate to the nucleus where it contributes in regulating the DNA damage response. The N-terminus of SOCS7 was shown to bear a basic region with homology to a classical monopartite NLS. The findings indicate that SOCS proteins might exert additional functions beyond inhibiting JAK/STAT signaling at the receptor level.

Physiological Functions of SOCS Proteins

SOCS proteins can be induced by a variety of cytokines and in turn show inhibitory effects on many different cytokines, hematopoietic growth factors, and further immunological stimuli within in vitro assays. However, generation of knockout or transgenic mice and subsequent analysis of the resulting phenotype have revealed important insights into the physiological importance of individual SOCS family members (Table 1) (Dalpke 2004).

$SOCS1^{-/-}$ mice succumb to perinatal death due to multiorgan inflammation. These mice reveal enhanced peripheral T cell (TC) and natural killer (NK) cell activation, macrophage organ infiltration, and fatty liver degeneration. Furthermore, thymus size is decreased and B lymphocytes undergo increased apoptosis. A major underlying dysregulation is undampened IFNγ signaling. Backcrossing to $Rag2^{-/-}$ or $IFN\gamma^{-/-}$ mice rescues $SOCS1^{-/-}$ mice from early death and the disease can be reinduced in $Rag2^{-/-}$ mice by transfer of hematopoietic $SOCS1^{-/-}$ cells confirming the importance of hyperactivated lymphocytes. Natural killer cell depletion reduces hepatotoxicity in $SOCS1^{-/-}$ mice. SOCS1/IFNγ double knockout mice show a delayed phenotype with polycystic kidneys, pneumonia, chronic skin ulcers, and granulomas in various organs. Moreover, the lethal phenotype can also be ameliorated by crossing $SOCS1^{-/-}$ mice with $STAT4^{-/-}$ or $STAT6^{-/-}$ mice, emphasizing that SOCS1 action is not limited to IFNγ signaling. Additionally, $SOCS1^{-/-}$ macrophages show higher proinflammatory protein production in response to Toll-like receptor (TLR) stimulation by lipopolysaccharide (LPS) indicating a role for SOCS1 in termination of TLR signal transduction. In dendritic cells, SOCS1 was required to suppress induction of autoimmune responses and to restrict breakdown of tolerance. Mice with isolated knockout of the SOCS box in

SOCS, Table 1 Functions of SOCS proteins as determined from genetic models

	Knockout phenotype	Transgene phenotype
SOCS1	Neonatal lethality, multiorgan inflammation, fatty liver degeneration, lymphocyte apoptosis, aberrant T-cell activation, increased IFNγ responsiveness, aberrant DC and B-cell activation, autoimmunity	Spontaneous T-cell activation, increase in $CD4^+$ T cells, decrease in γδ T cells, disturbed T-cell development
SOCS2	Gigantism, dysregulated growth hormone, and IGF-I signaling	Gigantism, dysregulated growth hormone signaling
SOCS3	Embryonic lethality with placental defects and aberrant erythropoiesis, increased hepatocarcinogenesis, prolonged and aberrant IL-6/STAT-3 signaling in macrophages	Embryonic lethality with anemia, increased T_H2 differentiation
SOCS4		
SOCS5	No abnormalities	Impaired T_H2 development, disturbed IL-4 signaling
SOCS6	Mild growth retardation	
SOCS7	Growth retardation, increased lethality postnatal due to hydrocephalus	
CIS	No obvious phenotype	IL-2/STAT-5 signaling defects, lactation failure, reduced numbers of NK, NKT cells, reduced body weight

SOCS1 have been generated and also show an amelioration of the acute lethal phenotype with a delayed onset of the multi-inflammatory disease of SOCS1 knockouts.

$SOCS2^{-/-}$ mice exhibit augmented growth which is supposed to occur due to altered growth hormone and insulin-like growth factor I signaling. Interestingly, SOCS2 transgenic mice also show increased growth. SOCS2 is also necessary to mediate the anti-inflammatory effects of lipoxin A4 in dendritic cells.

$SOCS3^{-/-}$ mice are embryonic lethal, presumably due to placenta defects and increased LIF receptor sensitivity. They also show defects in erythropoiesis, but $SOCS3^{-/-}$ fetal liver stem cells can reconstitute erythropoiesis when transferred into lethally irradiated adults. SOCS3 deficiency in macrophages shows altered IL-6 signaling: On the one hand, IL-6 signal transduction is not limited anymore resulting in prolonged STAT3 activity with IL-10-like effects. On the other hand, in SOCS3 deficient macrophages IL-6 adopts IFN-like activities due to unchecked STAT1 activity. SOCS3 is also crucially involved in the regulation leptin and G-CSF signaling.

SOCS5 transgenic mice show diminished T_H2 differentiation due to constrained IL4 signaling. $SOCS6^{-/-}$ and $SOCS7^{-/-}$ mice are smaller than wild-type littermates, the latter showing increased lethality due to hydrocephalus development. Both SOCS6 and SOCS7 regulate insulin receptor signaling. However, SOCS4-7 mice are less studied so far. $CIS^{-/-}$ mice do not show a distinct phenotype, but CIS transgenic mice have defects in lactation, a disturbed IL2/STAT5 signaling and reduced numbers of γδ T cells, natural killer cells, and natural killer T cells.

SOCS proteins also act as tumor suppressors (Rottapel et al. 2002): SOCS1 is involved in the early stage of tumor development by limiting inflammation and tissue damage whereas SOCS3 terminates STAT3-mediated proliferation and tissue remodeling. SOCS1 expression is lost in many tumors. Especially in liver fibrosis and hepatocellular carcinomas, the SOCS1 promoter is hypermethylated resulting in decreased SOCS1 expression, enhanced inflammation, and tumorigenesis. Likewise, SOCS1 was downregulated by hepatitis C virus core protein. SOCS1 has also been discovered as essential activator of the p53 tumor suppressor thus impeding with tumor development. Besides, SOCS1 has been identified to degrade HPV (human papillomavirus) E7 oncogene thus blocking the proliferation of infected cells. The SOCS3 gene was hypermethylated in lung cancer with restoration of SOCS3 expression resulting in STAT3 inhibition and concomitant growth inhibition.

Finally, SOCS proteins are also involved in chronic inflammatory diseases. SOCS3 is elevated in human ulcerative colitis and regulates STAT3 activity in an animal model of inflammatory bowel disease. SOCS1 is also involved in suppression of experimental colitis. Patients with allergic contact dermatitis and psoriasis have dysregulated SOCS1-3 expression and SOCS3 can also be found elevated in rheumatoid arthritis. Also hematopoietic malignancies and loss of

therapeutic IFN responsiveness might be associated with SOCS expression. The question remains to be solved whether disturbed SOCS expression is a consequence of altered cytokine networks or, at least in some conditions, might cause and contribute directly to pathogenesis of those diseases. Nevertheless, those observations implicate that SOCS manipulation is a promising approach to alter cytokine signaling.

Further Functions of SOCS within the Immune System

To address the role of SOCS within the immune system, regulation of both, innate and adaptive immunity, has been studied experimentally (Dalpke et al. 2008; Yoshimura 2009). SOCS1 has been shown to affect TLR responses, with increased secretion of proinflammatory cytokines once SOCS1 is missing. SOCS1 and 3 are also strongly induced by TLR triggering thus limiting the action of subsequent cytokine receptor triggering. Thus, SOCS1 limited GM-CSF (granulocyte–monocyte-colony-stimulating factor) and IL-4-mediated differentiation of $CD14^+$ monocytes to dendritic cells. SOCS1 also is important for STAT6 to STAT1 switching during dendritic cell maturation. Further experiments show that SOCS1 encounters activated NF-κB within the nucleus and inhibits its action as transcription factor via ubiquitination and subsequent degradation of the NF-κB subunit p65. Also, TLR-induced SOCS1 inhibits paracrine signal amplification by type I IFN and this circuit is mainly responsible for increased LPS sensitivity of $SOCS1^{-/-}$ mice because $SOCS1^{-/-}/Tyk2^{-/-}$ mice which lack type I IFN signaling had no increased LPS sensitivity anymore. Furthermore, single reports claim interaction of SOCS1 with the TLR2/4 adaptor protein ▶ Mal through interaction with Bruton's tyrosine kinase and with IRAKs as well as inhibition of TLR-induced JAK activity. In turn, $SOCS1^{-/-}$ mice exhibit lack of endotoxin tolerance. SOCS1 is therefore involved in regulating innate immune responses; however, the distinct outcome of its action seems to be dependent on the respective gene analyzed. SOCS1 deficiency also leads to hyperactivated dendritic cells that supported autoimmune responses.

Concerning adaptive immunity, SOCS proteins play an important role in the differentiation of T-cell subsets. On the one hand, SOCS1 is upregulated during T-cell development in the thymus and $SOCS1^{-/-}$ mice show a defect in the development of single positive thymocytes with a bias toward $CD8^+$ T cells. On the other hand, SOCS proteins are induced during cytokine-mediated T helper (T_H) development which in turn is regulated by SOCS proteins.

T_H1 cells preferentially develop in an IL-12 environment: They have high levels of SOCS1 and SOCS5 which suppresses IL-4 induced STAT6 activation directing T cells into T_H2 development. In contrast, T_H2 cells mainly develop in a "non-IL-12" environment and express GATA-3 as transcription factor due to IL-4-mediated STAT6 activation. T_H2 cells possess high levels of SOCS3 suppressing IL-12 signaling and thus inhibiting T-bet induction and T_H1 differentiation. Indeed, patients with T_H2-shifted diseases like asthma and atopic dermatitis show a correlation between SOCS3 levels and T cell-mediated disease activity. T_H17 cells for which IL-6, IL-21, and IL-23 with subsequent activation of STAT3 are important are also affected by SOCS3. Since SOCS3 blocks STAT3 action it has been identified as negative regulator of T_H17 differentiation. SOCS1 and 3 have also been implicated to play a role in development of regulatory T cells (Treg). Treg cells are $CD4^+$ cells defined by high expression of CD25 and the transcription factor FOXP3. Expression of FOXP3 induces microRNA (miRNA) 155 which targets SOCS1. This miRNA-mediated SOCS1 downregulation enhances IL-2/STAT5 signaling which in turn increases the number of Treg cells. Furthermore, miRNA-155 has also been shown to target SOCS1 which is used by the host's immune system upon viral infection to positively regulate type I IFN signaling.

The role of SOCS proteins as negative regulators of the immune system is confirmed by pathogenic microbes that misuse cell intrinsic negative regulation circuits to evade immune recognition. Murid herpesvirus-4 (MuHV-4) encodes for a SOCS box motif containing protein (ORF73) that targets NF-κB for ubiquitination and proteasomal degradation thereby inhibiting NF-κB activity. Other viruses have evolved SOCS-dependent mechanisms to escape host immune system: HIV-1 Tat protein is a key regulator of viral replication; however, it additionally induces SOCS2 which in turn interferes with JAK/STAT signaling thus supporting virus replication. Likewise, RSV surface proteins G and F induce

SOCS1 expression. For HSV-1 direct effects on the SOCS1 promoter, followed by increased SOCS1, have been shown. Not only viruses but also parasites take advantage of the SOCS negative regulatory system: *Toxoplasma gondii* replicates in macrophages and induces SOCS1, 3 and CIS which deactivate JAK/STAT signaling. *Leishmania major* infection was associated with lower pathogenicity in SOCS1-deficient cells, though at the cost of detrimental effects due to uncontrolled cytokine signaling. Also, intracellular mycobacteria are reported to interfere with macrophage activation by IFNγ through SOCS1 and −3 induction. Furthermore, SOCS3 induction by hepatitis C virus might be a mean to circumvent antiviral activities of type I interferons.

Besides JAK/STAT regulation, SOCS proteins show further effects in a variety of additional signaling pathways: Thus SOCS1 has been reported to regulate the insulin receptor, TNF receptor, and Toll-like receptors; SOCS3 in vitro also inhibits insulin receptor, IL1R, and CXCR4 signaling to name a few. Although the molecular details are not known it seems probable that the function of SOCS proteins is not restricted to the inhibition of classical type I and II cytokine receptors.

Future Directions

SOCS proteins have been shown to be involved in a variety of cellular processes and could therefore present a potential target for the treatment of inflammatory diseases. To confirm the function of specific domains of SOCS and to imitate SOCS expression, SOCS mimetics have been produced. SOCS mimetics comprise peptides corresponding to functional domains coupled to protein translocation domains facilitating cell penetration. A peptide that resembles the KIR region has been described to mimic the inhibitory effects of SOCS on JAK activity. Treatment of mice with SOCS mimetics prevented vaccinia virus transcription and replication. Regarding the role of SOCS1 in regulating NF-κB signaling, there is evidence that SOCS1 administration limits the TNF production in synovial fluid macrophages isolated from patients suffering from rheumatoid arthritis. Similarly, delivery of recombinant whole proteins has been proposed. Other techniques to control SOCS expression include siRNA or miRNA approaches which will lead to a downregulation of the respective protein.

Summary

SOCS proteins comprise a family of eight proteins (CIS, SOCS1-7) that have first been identified as intracellular negative regulators of JAK/STAT signaling upon type I and II cytokine receptor stimulation. Therefore, SOCS proteins contain an extended SH2 domain which allows them to bind to tyrosine-phosphorylated cytokine receptors or Janus kinases. Through a kinase inhibitory region (SOCS1 and 3) as well as a SOCS box domain which targets substrates for proteasomal degradation SOCS proteins limit signal transduction. However, the activity of SOCS exceeds the control of JAK/STAT signal transduction: SOCS proteins are also involved in the termination of NF-κB responses, negatively influence insulin signaling and function as tumor suppressors. Depending on the cytokine milieu, SOCS proteins shape the immune system by influencing macrophages, dendritic cells, and lymphocyte differentiation. Evidence for crucial roles of individual SOCS proteins within the immune system comes from mice with targeted disruption of SOCS genes that show major deregulated cytokine pathways. Since SOCS proteins are essential modulators of immunity, precise understanding of their defined mode of action could be beneficial to develop new therapeutic strategies to combat inflammatory and autoimmune diseases as well as cancer.

Somatostatin Receptor

Barbara Mariniello
Endocrinology Unit, Department of Medical and Surgical Sciences, University of Padua, Padua, Italy

Synonyms

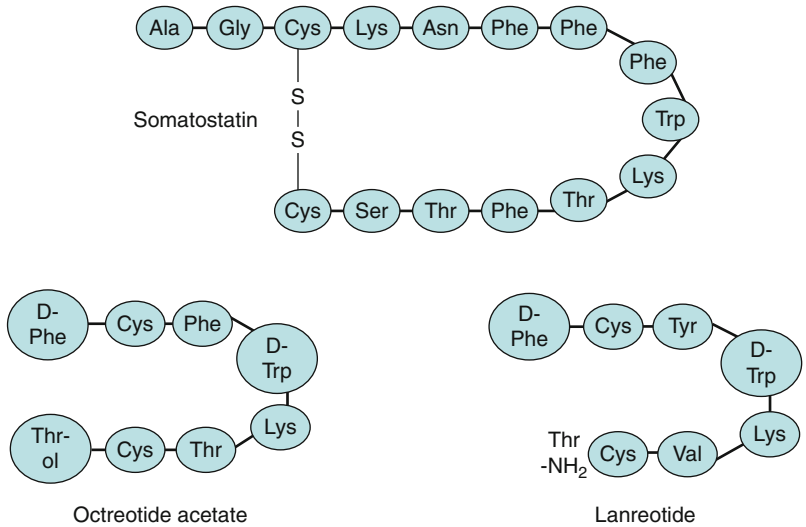
SSTR

Historical Background

Somatostatin (SST) is a cyclopeptide that was first identified in the hypothalamus inhibiting GH secretion and immediately after in pancreatic islets inhibiting the insulin secretion in vitro, but it is produced also throughout the central and peripheral nervous system and in most major peripheral organs as endocrine pancreas, thyroid, adrenals, spleen, submandibular glands, gut, liver, kidneys, prostate, and placenta (Reisine and Bell 1995). SST is initially synthesized as a large precursor molecule, preprosomatostatin that undergoes tissue-specific enzymatic degradation generating two bioactive products: SST-14, identified in hypothalamus, and SST-28 that corresponds to somatostatin with a NH_2-terminal extension of 14 amino acids. Nutrients (glucose, amino acids, lipids), neurotransmitters, neuropeptides (glucagons, growth hormone releasing hormone, bombesin), hormones (insulin, glucocorticoids) and cytokines (interleukin-1, interleukin-6, transforming growth factor-β, tumor necrosis factor-α, insulin-like growth factor, leptin, interferon-γ, etc.), and several intracellular mediators including cyclic AMP, cyclic GMP, Ca2+, and nitric oxide, all influence the transcription and/or secretion of SST. The two peptides act through the inhibition of endocrine and exocrine secretion, inhibition of intestinal motility, absorption of nutrients and ions, vascular contractility, and immune cell functions. Moreover, they have a role in neurotransmission and cognitive functions, and they have antiproliferative effects acting on cell secretion, proliferation, and differentiation. SST can also inhibit angiogenesis in vitro and in vivo inhibiting the production of vascular endothelial growth factor and platelet-derived growth factor (Öberg et al. 2010).

Somatostatin Analogues

SST, which takes effect through high-affinity plasma membrane five SST receptors ($SSTR_{1–5}$) (see below), has limited clinical use due to its short half-life (<3 min) but the identification of stable SST analogues with a longer half-life has raised new hopes for the treatment of tumors (Fig. 1). Octreotide, the first SST analogue available commercially, contains three substituted amino acids (D-Phe, LThr [ol], D-Trp) that make it resistant to metabolic degradation with a longer half-life (2 h). It is an SSTR2-preferring agonist with a moderate affinity for SSTR3 and SSTR5. Lanreotide is a second analogue with a similar binding profile of octreotide. Furthermore, radiolabeled SST analogues are used as diagnostic tools for the detection of endocrine tumors, as well as for the therapy. A novel multiligand SST analogue, a cyclohexapeptide named pasireotide, has a 20–30, 5, and 40–100 times higher binding affinity than octreotide and lanreotide for the receptors SSTR1, SSTR3, and SSTR5, respectively (Bruns et al. 2002). The very favorable 24 h elimination half-life of pasireotide makes this novel compound suitable for clinical application. Interestingly, pasireotide modulates SST receptor trafficking and leads to the formation of unstable SSTR2 complex with beta-arrestin that dissociate at or near the plasma membrane.



Somatostatin Receptor, Fig. 1 Chemical structure of SST-14 and SST analogues

Consequently, SSTR2 are recycled faster to the plasma membrane after endocytosis in cells treated with pasireotide than in those treated with octreotide. This finding suggests that a longer-lasting functional response could be achieved with pasireotide (Cescato et al. 2010).

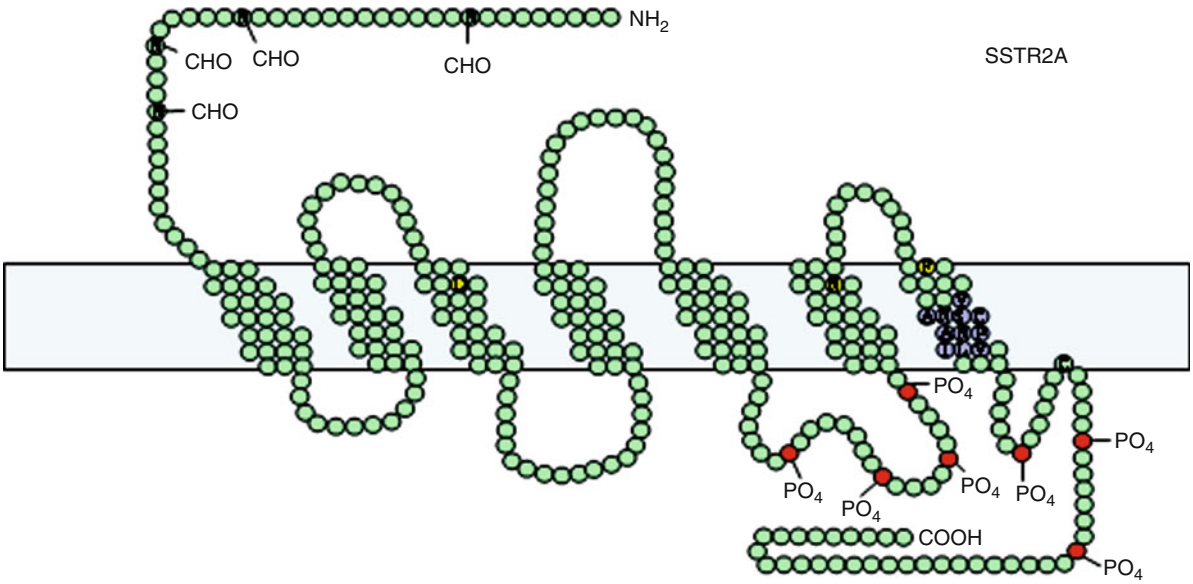
Somatostatin Receptors

SSTRs were first described in the pituitary GH4C1 cell line. Studies using a variety of techniques such as membrane binding analyses, in vivo and in vitro autoradiography, covalent cross-linking, and purification of a solubilized receptor showed SSTR expression in various densities in brain, gut, pituitary, endocrine and exocrine pancreas, adrenals, thyroid, kidneys, and immune cells. SSTRs have also been identified in a large variety of human cancers including pituitary adenomas, islet tumors, carcinoids, adenocarcinomas of the breast, prostate, ovary, kidney and colon origin, lymphomas, as well as astrocytomas, neuroblastomas, and medulloblastomas. Analyses of SSTR mRNAs demonstrate that various human tumors from neuroendocrine and gastroenteropancreatic origin, brain tumors, pheochromocytomas, medullary thyroid carcinomas, prostate, lung, and breast cancers express various SSTR mRNA, each tumor expressing more than one subtype and SSTR2 being the most frequently expressed (Benali et al. 2000).

Photoaffinity labeling and purification studies have provided evidence for the existence of several SSTR proteins of 32–85 kDa that are expressed in a tissue-specific manner and some that exhibit selective agonism for SST-14 or SST-28 (Patel 1999). The $SSTR_{1\text{-}5}$, identified in the early 1990s (Yamada et al. 1992), are codified by five genes that segregate on five different chromosomes: 14q13, 17q24, 22q13.1, 20p11.2, and 16p13.3. Genes for SSTR1, 3, 4, and 5 lack classical introns, the SSTR2 gene displays a cryptic intron at the 3′ end of the coding segment, which determine two spliced variants, a long (SSTR2A) form and a short (SSTR2B) form. The 2A and 2B variants differ only in the length of the cytoplasmic tail. There are thus six putative SSTR subtypes of closely related size that present a high degree of sequence identity (39–57%), with seven α helical transmembrane domains (TM) typical of G-protein-coupled receptors (GPCR) (Fig. 2). The sequence differences reside in the extracellular and intracellular domains and are probably responsible for their signaling specificity. SST binding induces a conformational change in the receptor that results in activation of an associated heterotrimeric G protein complex leading to exchange of GTP for GDP on the α-subunit. The GTP bound form of the free α-subunit and β/γ complex interact with the specific cellular effector pathways (Patel 1999). These receptors differ in their signaling pathways and cellular and tissue distribution, which are crucial factors determining tissue response to SST and SSTR agonists.

Intracellular Pathways Coupled to SSTRs

Using recombinant SSTR expressed in various eukaryote cells, the intracellular signaling pathways coupled to SSTRs have been extensively studied; they are complex and vary among receptor, cell, and organ types.



Somatostatin Receptor, Fig. 2 Model for the orientation of the SST receptors in the plasma membrane. The four potential sites for N-linked glycosylation, indicated by "CHO," in the extracellular NH_2-terminal domain are noted. PO_4 are the putative sites for phosphorylation by protein kinase A, protein kinase C, and casein kinase in the extracellular COOH-terminal domain, shown by the closed red circles. The YANSCANPI/VLY sequence, shown by the closed *blue circles*, in the VIIth TM is highly conserved in all SSTRs. The cysteine residue 12 amino acids downstream from the VIIth TM is conserved in SSTR1,2,4,5 and may be the site of a potential palmitoyl membrane anchor. Residues Asp^{122}, Asn^{276}, and Phe^{294}, shown by the closed *yellow circles*, in TMs III, VI, and VII, respectively, have been proposed to form part of a ligand-binding pocket for octreotide

The complexity arises not only from the large number of SSTR subtypes and range of cell types that express them, but also because each receptor subtype is coupled to multiple intracellular transduction pathways (Table 1 and Fig. 3).

All five SSTRs are functionally coupled to inhibition of adenylate cyclase and cAMP production that is the first pathway implicated. In neuronal and neuroendocrine cells, SST and analogues also regulate several subsets of K+ channels causing hyperpolarization of the plasma membrane and leading to decreased Ca2+ influx through voltage-gated Ca2+ channels and consequently to a reduction in intracellular Ca2+. Moreover, a third pathway affected by SST and analogues is represented by the activation of a number of protein phosphatases including serine/threonine phosphatases, tyrosine phosphatases, and a Ca2 + -dependent phosphatase. Somatostatins inhibit proliferation directly by regulating tyrosine kinase, tyrosine phosphatase, nitric oxide synthase, cyclic guanosine 3′, 5′ cyclic monophosphate-dependent protein kinase, and RAS/extracellular signal-regulated kinase signaling pathways. The regulation of these pathways varies according to SSTR subtype and the cell environment. All five receptors stimulate phospholipase C and increase Ca2+ mobilization via both pertussis toxin–sensitive and pertussis toxin–insensitive G protein.

In vitro data and biodistribution studies in animals have shown that SST and agonists induce internalization of SSTR2, SSTR3, and also SSTR5 with a consequent desensitization and attenuated receptor relating signaling. This is a crucial feedback mechanism that prevents persistent stimulation by the agonist. Agonist-induced internalization is rapid; almost all SSTR2 moved from the cell membrane to endosome-like cellular structures within the cytoplasm. Agonist binding to SSTR5 induces mobilization of intracellular stores of the receptor to the cell membrane and then internalization of membrane SSTR5 following ligand binding (Öberg et al. 2010).

Biological Effects of Somatostatin Receptors

Because the same cell expresses multiple receptor subtypes and the coupling of SSTRs to similar transduction pathways, it can be assumed that the SSTR subtypes may act in concert (Table 2). In the cell, the

Somatostatin Receptor, Table 1 G-protein-coupled signal transduction: characteristics of SSTR subtypes

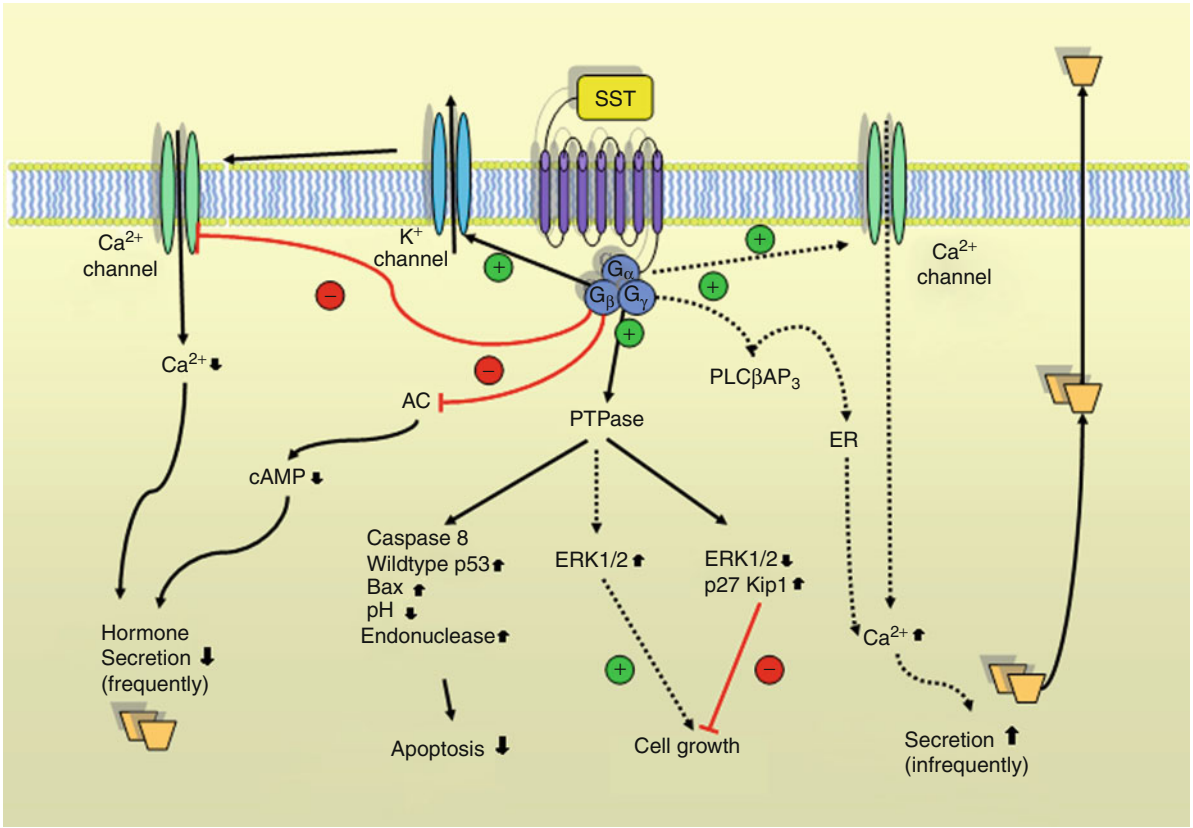
blockade of secretion by SST is mediated through inhibition of Ca2+ and to a reduction of cAMP production. In the pituitary, SSTR2, SSTR5, and SSTR1 are involved in inhibiting growth hormone release. In the pancreas, SSTR2 mediates inhibition of glucagon release, whereas SSTR5 is a negative regulator of insulin secretion. SSTR2 also mediates insulin secretion in human pancreas. The high expression of SSTR1 in human pancreatic islet cells suggests that it may also be involved in regulating insulin release. SSTR5 is involved in the inhibition of pancreatic exocrine secretion. In the stomach, SSTR2 contributes to the inhibition of histamine and gastrin release and the inhibition of gastric acid secretion. SSTR1 and SSTR2 mediate the inhibition of intestinal ionic secretion. In human neuroendocrine gut tumor cells, SST and octreotide inhibit L-type voltage-dependent calcium channels with the same amplitude suggesting that at least SSTR2 and SST5R may be involved in the inhibition of Ca2+ influx and thereby inhibition of tumor-produced neurotransmitters and hormone. SSTR3 could be involved in the stimulation of gastric and intestinal smooth muscle cell contraction and SSTR5 in the inhibition of colonic muscle cell contraction (Benali et al. 2000).

SST analogues are also thought to inhibit cell proliferation by inducing apoptosis, which may be mediated through the SSTR2 and SSTR3. When SSTR3 is transfected into previously SST-free cell lines, addition of octreotide causes the upregulation of the tumor suppressor protein ▶ p53, which subsequently induces apoptosis. Furthermore, in athymic mouse and in hamster models, SSTR2 re-expression caused dramatic decrease in tumor growth and inhibition of primary tumor growth without metastatic progression, respectively.

Homo- and Heterodimerization of SST and Dopamine (DA) Receptors

Membrane SSTRs exist in the basal state as a monomeric species, but activation by ligand induces SSTR dimerization (Rocheville et al. 2000a), both homo- and heterodimerization with other members of the SSTR family, and dimerization alters the functional properties of the receptor such as ligand binding affinity and agonist-induced receptor internalization and upregulation. Both homo- and heterooligomeric receptors are occupied by two ligand molecules. Evidences show that monomeric, homooligomeric, and heterooligomeric receptor species occur in the same cell cotransfected with two SSTRs, and that oligomerization of SSTRs is regulated by ligand binding by a selective process that is restricted to some (SSTR5) but not other (SSTR1) subtypes. SSTR5 formed heterodimers with SSTR1 but not with SSTR4 suggesting that heterodimerization is



Somatostatin Receptor, Fig. 3 Intracellular signaling pathways coupled to SSTRs, leading to changes in hormone secretion, apoptosis, and cell growth. *AC* adenylyl cyclase, *ER* endoplasmic reticulum, *ERK* extracellular signal-regulated kinase, *Gα*, *Gβ*, *Gγ* G protein subunit, *IP3* inositol triphosphate, *PLC* phospholipase C, *PTPase* phosphotyrosine phosphatase

a specific process that is restricted to some but not all receptor subtype combinations (Patel et al. 2002).

SST and DA are two major neurotransmitter systems that share a number of structural and functional characteristics. SSTR and DA receptor (DR) families share about 30% sequence homology, are colocalized in neuronal subgroups, and SST is involved in modulating DA-mediated control of motor activity. DA, like SST, acts through its own family of five GPCRs (D1R to D5R). D2R and SSTR5 associate on the plasma membrane and the SSTR5-D2R heterooligomer displays enhanced signaling when simultaneously activated by both SST and DA ligands (Rocheville et al. 2000b). Hetero-oligomerization defines a new level of functional diversity in endogenous GPCR signaling, and should constitute novel unrecognized drug targets for combinations of agonists or antagonists.

Effect of SST Analogues on Various Tumors

SSTR2 and SSTR5 are the most important subtypes in inhibiting hormonal secretions in functioning gastrointestinal neuroendocrine tumors (GI-NETs) due to their wide-ranging effects; it is thought the dual inhibition of both subtypes may have an increased inhibitory effect (Öberg et al. 2010). The two subtypes may also mediate antiproliferative effects. Patients with NETs receiving SSTR2-preferring analogues such as octreotide and lanreotide may experience a loss of response. It has led to interest in new, multi-receptor ligand SST analogues that could be as effective and well tolerated in patients who experience an escape from response. Pasireotide may fulfill this role due to its high affinity for SSTR1–3 and SSTR5. Preliminary data are promising, with effective control of diarrhea and flushing observed in NET patients refractory or resistant to octreotide.

Somatostatin Receptor, Table 2 Biological effect of each SSTR

Induction of apoptosis		+	+		

The SSTRs are also demonstrated expressed in neuroblastoma, therefore the treatment with SST analogues or radiolabeled SST could represent a new therapeutic possibility in patients with neuroblastoma where high-dose chemotherapy, irradiation, and autologous stem cell transplantation have failed (Georgantzi et al. 2010).

The finding of SSTRs ubiquitously distributed in normal kidney and IgA nephropathy suggests that the increased expression of these receptors might be the potential pathogenesis of inflammatory renal disease (Bhandari et al. 2008).

SST system, through SSTR1 and SSTR2, exerts mainly an immunosuppressive effect in human macrophages and may, therefore, represent a therapeutic window that can be exploited for the development of new strategies in pharmacological therapy of inflammation (Armani et al. 2007).

One of the organs in which SST has an important inhibitory effect on hormone secretion is the anterior pituitary gland (Hofland et al. 2010). SSTRs have a predominant inhibitory role of growth hormone secretion, although the secretion of other pituitary hormones, e.g., prolactin, thyroid stimulating hormone, and adrenocorticotropic hormone is regulated by SST as well. Also DRs, in particular the D2R, have an important regulatory role in the PRL secretion. Pituitary tumors express both SST and/or D2 receptors. The SSTR subtype, as well as the co-expression of SSTR and D2R, has significant impact on the possibility to treat patients with pituitary tumors with SST analogues and DA agonists to control hormonal hypersecretion and tumor growth. Pasireotide is also a promising pituitary-directed medical therapy for patients with persistent or recurrent Cushing's disease after unsuccessful surgery, in patients awaiting the effects of pituitary radiation or in inoperable patients (Arnaldi and Boscaro 2010).

Moreover, pasireotide affects cell growth, apoptosis, and catecholamine levels in pheochromocytoma (Pasquali et al. 2008). Finally, a markedly reduced cortisol and aldosterone secretion by pasireotide was also evident in human adrenocortical cell line (H295R) and in primary adrenocortical cultures that strongly expressed SSTR5 and SSTR2 (Mariniello et al. 2010).

However, with the availability of newer SST analogues such as pasireotide, the determination of differential expression of various SSTR subtypes and an assessment of heterogeneity of such expression in larger series of primary and metastatic tumors is clinically relevant. Furthermore, SSTR subtype expression should be correlated with the pattern of clinical response of such patients to SST analogue therapies.

Summary

SST and all five receptor subtypes were ubiquitously distributed in many organs and in a large variety of

human cancers. Synthetic derivatives of SST have similar activity to native SST but with a longer half-life, they lack the key enzyme cleavage sites and are more stable than native SST. The analogues, such as octreotide, lanreotide, and the multiple SSTR ligand, pasireotide, are currently in preclinical evaluation or in early clinical trials. There is evidence for a number of direct and indirect mechanisms by which SST analogues can exert antitumor effects. Direct antitumor activities, mediated through SSTRs expressed in tumor cells, include blockade of autocrine/paracrine growth-promoting hormone and growth factor production, inhibition of growth factor-mediated mitogenic signals, and induction of apoptosis. Indirect antitumor effects, that do not require the presence of SSTRs in tumor cells, include inhibition of growth-promoting hormone and growth factor secretion, and antiangiogenic actions. Therefore, not only the receptor profiles but also the cell types, as well as the dimerization, are responsible for the final effect of a given ligand. These elements open new perspectives for the use of the new chimeric compounds in human tumors.

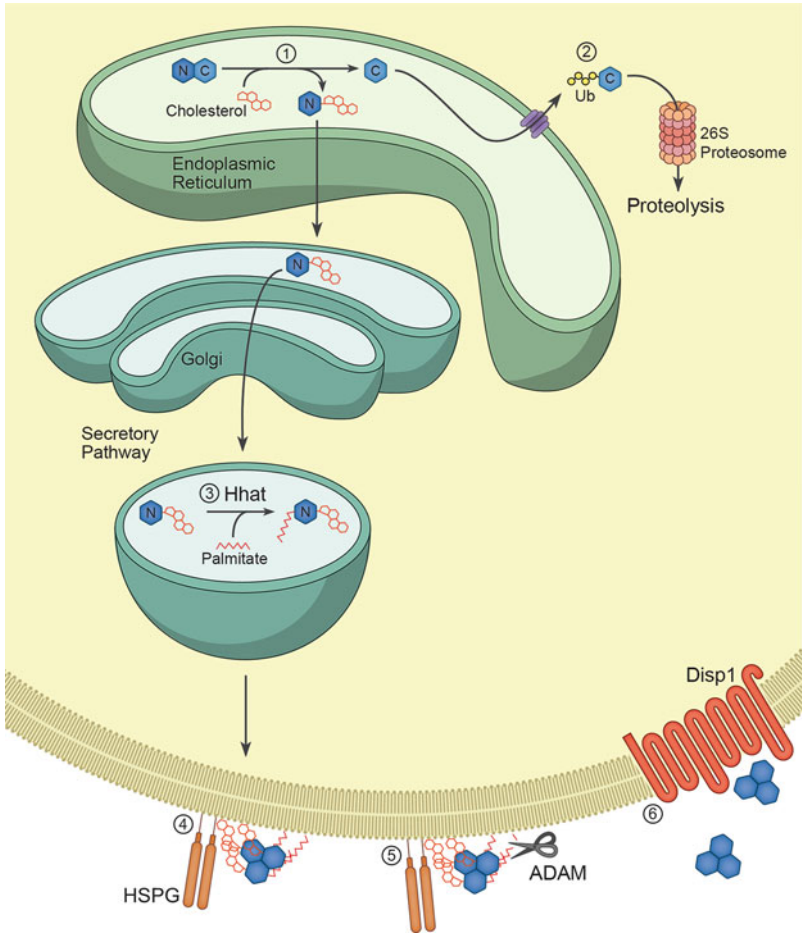
Sonic Hedgehog (Shh)

Kaitlyn Ryan and Chin Chiang
Department of Cell and Developmental Biology, Vanderbilt University Medical Center, Nashville, TN, USA

Historical Background

The Hedgehog (Hh) family of secreted proteins plays an essential role in metazoan development, and defects in the Hh pathway lead to congenital abnormalities such as holoprosencephaly and certain forms of cancer. The importance of *Hh* during embryogenesis was first discovered in a genetic screen for mutations disrupting larval patterning in *Drosophila melanogaster* by Nusslein-Volhard and Wieschaus in



Sonic Hedgehog (Shh), Fig. 1 Shh processing and release. Shh is synthesized as a 45 kDa precursor in the endoplasmic reticulum. (*1*) An autocatalytic cleavage event results in the formation of C- and N-terminal fragments. The cholesterol-modified N-terminal fragment enters the secretory pathway and ultimately serves as the mature signaling ligand, whereas (*2*) the C-terminal fragment is degraded via ER-associated degradation (ERAD). (*3*) Hh acyltransferase (Hhat) catalyzes the covalent attachment of palmitate to the N-terminus of the N-terminal fragment. Dually lipidated Shh is targeted to the cell membrane where (*4*) Heparan sulfate proteoglycans (HSPG) facilitate the formation of Shh multimers. Multimeric Shh is secreted via (*5*) A disintegrase and metalloproteases (ADAM) and the (*6*) 12-pass transmembrane protein Dispatched1 (Disp1)

1980 (Varjosalo and Taipale 2008). Unlike *Drosophila*, which harbors a single *Hh* gene, the mammalian genome encodes three *Hh* ligands: *Dessert Hedgehog* (*Dhh*), *Indian Hedgehog* (*Ihh*), and *Sonic Hedgehog* (*Shh*), all of which activate the vertebrate Hh pathway in a similar manner. *Shh* is the most widely expressed of these ligands, and much of what is known about vertebrate Hh signaling stems from studies on Shh. Though similar in many ways to the *Drosophila* Hh pathway, several features of vertebrate Hh signaling make it unique. Perhaps the most striking divergence is in the role that the primary cilium, a vestigial organelle that is largely absent in flies, plays in vertebrate Hh signaling. Over the past two decades considerable process has been made in understanding vertebrate Hh signaling and Shh in particular. Nonetheless, why the primary cilium plays such a central role in the vertebrate pathway is one of several unanswered questions requiring further inquiry and exploration. Thus, in addition to summarizing the current understanding of Shh signaling, this entry will also introduce unanswered questions and remaining areas of ambiguity.

Sonic Hedgehog Processing and Release

Hedgehog proteins undergo a unique series of post-translational processing steps that result in the covalent attachment of two lipid moieties: cholesterol at the C-terminus and palmitate at the N-terminus. Shown in Fig. 1, Shh is synthesized as a 45 kD precursor molecule in the endoplasmic reticulum. Following removal of its signal sequence, Shh undergoes a cholesterol-dependent autocatalytic cleavage, generating two peptides roughly equal in size (Varjosalo and Taipale 2008). The C-terminal fragment has no known signaling function and undergoes ER-associated degradation (ERAD), a process that requires the ubiquitin

ligase Hrd1 and its partner Sel1 as well as the ATPase p97 (Chen et al. 2011). The N-terminal fragment ultimately gives rise to the dually lipidated mature signaling molecule. A cholesterol moiety is added to its C-terminus during the aforementioned cleavage event, and Hh acyltransferase (Hhat) catalyzes the attachment of a palmitate moiety at the N-terminus (Varjosalo and Taipale 2008). Dually lipidated Shh is targeted to the cell surface through the secretory pathway.

While the process of cholesterol and palmitate attachment to Shh is relatively well-defined, the functional significance of these modifications is more complex. One of the key features of Shh is its ability to signal over long distances, and cholesterol was originally thought to promote such long-range signaling (Lewis et al. 2001). However, initial studies relied upon a mouse model in which Shh expression was severely impaired, and additional studies showed that cholesterol restricts, rather than promotes, the spread of Shh (Li et al. 2006). By contrast, palmitoylation appears to primarily affect the potency of Shh, as mouse mutants producing a non-palmitoylated form of Shh have significantly reduced levels of Shh pathway activity (Chen et al. 2004). Recent studies in vitro indicate that the palmitate moiety promotes the formation of active Shh oligomers by facilitating the cleavage of N-terminal peptides that otherwise obstruct important receptor binding sites in multimeric Shh (Ohlig et al. 2011). This cleavage is mediated by A disintegrase and metalloproteases (ADAMs), which remove the palmitate moiety and adjacent amino acids before Shh is released (Ohlig et al. 2011). In the absence of palmitoylation, either due to loss of Hhat or to mutations in the N-terminal cysteine residue where palmitate attaches, this cleavage cannot occur and the resulting multimer is far less potent. Cholesterol also plays an essential role in multimer formation, as Shh lacking cholesterol (ShhN) is secreted solely as monomers (Guerrero and Chiang 2007). Cholesterol may promote multimer formation by tethering Shh to the plasma membrane, allowing negatively charged heparan sulfate proteoglycans (HSPG) to bind positively charged residues in the Cardin Wientraub (CW) motif and cluster Shh on the membrane (Dierker et al. 2009). Taken together, these data provide insight into why Shh receives such unusual posttranslational modifications in order to properly function.

The covalent attachment of cholesterol and palmitate render Shh membrane-tethered, and the release of lipid-modified Shh into the extracellular environment requires the activity of the 12-pass transmembrane protein Dispatched1. Mouse *Disp1* mutants die around embryonic day 9.5 with severe defects in the Shh pathway, indicating that *Disp1* plays an essential role in vertebrate Hh signaling (Caspary et al. 2002; Kawakami et al. 2002; Ma et al. 2002). Cells lacking *Disp1* synthesize and process Shh normally, but are unable to secrete the mature ligand. Instead, Shh accumulates on the plasma membrane of *Disp1*$^{-/-}$ cells, able to signal to neighboring cells but unable to signal distally (Ingham et al. 2011). In addition to Disp1, recent in vitro work suggests that ADAMs may also facilitate Shh secretion by cleaving both lipid moieties, rendering the secreted form of Shh unlipidated (Dierker et al. 2009; Ohlig et al. 2011). Nonetheless, the importance of ADAM-mediated cleavage in vivo has not been shown, nor has whether ADAMs interact and cooperate with Disp1 to facilitate Shh secretion. Addressing these two questions will help complete the story of how Shh is released from producing cells.

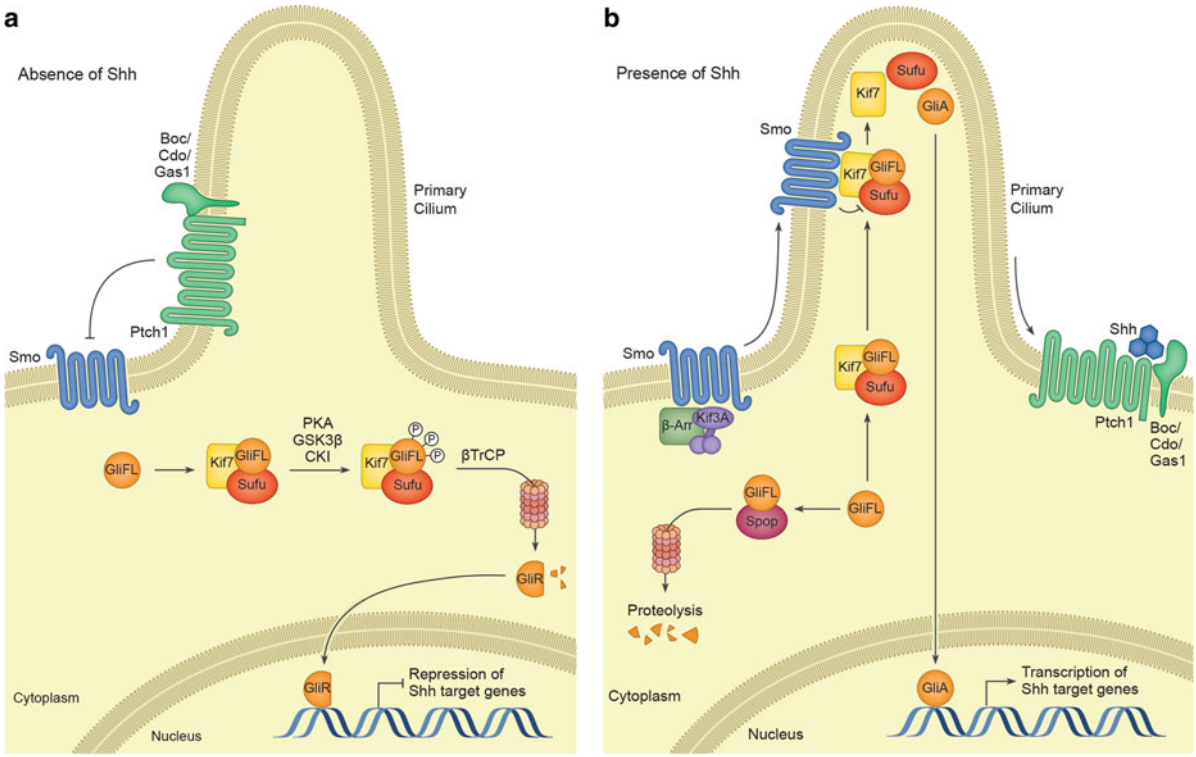
Cytosolic Sonic Hedgehog Signaling

Overview

The core components of *Drosophila* Hh signaling are conserved in vertebrates. Shh-producing cells secrete Shh, which binds Patched1 (Ptch1), a 12-pass transmembrane protein that serves as the Shh receptor. Binding of Shh to Ptch1 relieves Ptch1-mediated inhibition of the signal transducer Smoothened (Smo), and Smo activates the zinc finger transcription factors Gli2 and Gli3, which translocate into the nucleus and promote the transcription of Shh target genes. In the absence of Shh, these transcription factors are partially processed into N-terminal transcriptional repressors that suppress the transcription of Shh targets. Thus, the relative abundance of transcriptional activators and inhibitors ultimately regulates the transcription of Shh target genes.

The Primary Cilium

Although many aspects of *Drosophila* Hh signaling are conserved in vertebrates, vertebrate Hh signaling depends upon the primary cilium. Primary cilia are slim, microtubule-based nonmotile structures projecting



Sonic Hedgehog (Shh), Fig. 2 Cytosolic Shh signaling. (**a**) In the absence of ligand, Ptch1 localizes to the cilium and inhibits Smo. Sufu-Gli-Kif7 complexes are phosphorylated by PKA, GSK3β and CKI, enabling their recognition by the E3 Ubiquitin ligase β-TrCP and resulting in the proteolytic processing of C-terminal peptides. The resulting of N-terminal transcriptional repressors (GliR) repress the transcription of Shh target genes. (**b**) In the presence of Shh ligand, Shh binds Ptch1-co-receptor complexes, causing them to exit the cilium. No longer inhibited by Ptch1, Smo enters the cilium by lateral transport. Activated Smo recruits and dissociates Sufu-Gli-Kif7 complexes, and additional modifications lead to the formation of transcriptional activators (GliA), which enter the nucleus and promote the transcription of Shh target genes. Spop competes with Sufu for binding to full-length Gli molecules and promotes the proteolytic degradation of Gli-FL

from the cell surface of nearly all vertebrate cell types. The assembly and maintenance of primary cilia requires intraflagellar transport (IFT) proteins, and several members of the IFT family are essential for proper Shh signaling (Goetz and Anderson 2010). Mutations in components of the IFT-B complex, which mediates the anterograde transport of molecules from the base of the cilium to the tip, lead to a complete loss of Shh signaling. By contrast, mutations in members of the IFT-A complex, which controls retrograde transport, lead to unkempt Shh pathway activation (Goetz and Anderson 2010). Nonetheless, it not currently known whether IFT-A and -B complexes interact directly with Shh pathway components to control their localization and activity or if, instead, these complexes facilitate Shh signaling simply by maintaining proper cilia architecture. Indeed, recent genetic studies suggest that the primary cilium may function primarily as a scaffold for Shh signaling, arguing against a direct role for IFT proteins in the movement of Shh pathway components (Ocbina et al. 2011).

Cytosolic Shh Signaling in the Absence of Ligand

Shown in Fig. 2a, in the absence of Shh ligand, Ptch1 localizes to the cilium and inhibits the seven-pass transmembrane protein Smoothened (Wilson and Chuang 2010). The precise details of this inhibition are not well understood, but may involve the transport of small molecules that maintain Smo in an inactive conformation, a possibility that is supported by the fact that Smo is susceptible to inhibition and activation by small molecules (Ingham et al. 2011). In its inactive conformation, Smo is unable to inhibit the partial proteolytic processing of the zinc finger

transcription factors Gli2 and Gli3 from their full-length form into N-terminal repressors. Gli2 and Gli3 processing is facilitated by Suppressor of Fused (Sufu), which promotes the phosphorylation of Gli2 and Gli3 by Protein Kinase A (PKA), Casein Kinase I (CKI), and Glycogen Synthase Kinase β (GSK3β) (Humke et al. 2010; Tukachinsky et al. 2010). The Kinesin 4 family member Kif7 may also facilitate this phosphorylation. Phosphorylated Gli2 and Gli3 are recognized by the E3 ubiquitin ligase β-TrCP, leading to the proteolytic degradation of C-terminal peptides and the formation of Gli2 and Gli3 transcriptional repressors (Gli2R and Gli3R) (Wilson and Chuang 2010). Because Gli3 is more efficiently processed than Gli2, Gli3R serves as the principle repressor of Shh signaling. These transcriptional repressors translocate into the nucleus where they suppress the transcription of Shh target genes.

While Sufu has a relatively minor role in *Drosophila*, it is indispensible for proper Shh signaling in vertebrates (Ingham et al. 2011). *Sufu*$^{-/-}$ mice die around embryonic day 9.5, displaying aberrant Shh pathway activation and dramatically reduced levels of both full length and repressor forms of Gli, supporting a model wherein Sufu stabilizes full-length Gli and assists in GliR formation (Tukachinsky et al. 2010). Recent studies indicate that the Cul3 adaptor Speckle-type POZ protein (Spop) promotes the degradation of full-length Gli2 and Gli3 and competes with Sufu for binding of these molecules (Wang et al. 2010). Accordingly, genetic ablation of *Spop* from *Sufu*$^{-/-}$ cells partially rescues full-length Gli2 and Gli3 protein levels.

In addition to Sufu, the kinesin Kif7 also promotes the processing of full-length Gli and may form a complex with Gli and Sufu (Endoh-Yamagami et al. 2009; Wilson and Chuang 2010). Mice lacking functional *Kif7* have reduced levels of Gli3R, increased levels of full-length Gli2, and exhibit features of aberrant Shh pathway activation such as polydactyl (Cheung et al. 2009; Endoh-Yamagami et al. 2009; Liem et al. 2009). Thus, much as its *Drosophila* homolog Cos2, Kif7 may serve as a scaffolding molecule for GliR production in the vertebrate Hh pathway (Wilson and Chuang 2010). However, unlike Cos2, Kif7 has a functional motor domain, and mutations in this domain impair the ability of Kif7 to promote GliR formation (Liem et al. 2009). Nonetheless, whether Kif7's motor function influences the trafficking of Shh pathway components remains unclear, as does the precise role of Kif7 in Shh signaling.

Cytosolic Shh Signaling in the Presence of Ligand

Shown in Fig. 2b, activation of the Shh pathway results in both inhibition of Gli repressor formation and induction of Gli activator formation, ultimately leading to the transcription of Shh target genes. In the presence of Shh ligand, Shh binds Ptch1, relieving Ptch1-mediated inhibition of Smo. Smo levels increase on the plasma membrane, and Smo moves into the cilium where it promotes the disassembly of Sufu-Gli-Kif7 complexes and inhibits the proteolytic processing of Gli2 and Gli3 into their repressor forms (Milenkovic et al. 2009; Tukachinsky et al. 2010; Humke et al. 2010). Full-length Gli2 and Gil3 acquire additional poorly characterized modifications that convert them to their activator forms (Gli2A and Gli3A). Whereas Gli3 acts primarily as a transcriptional repressor, Gli2 acts primarily as a transcriptional activator. In the presence of Shh, Kif7, Smo, and Gli are enriched in the cilium tip, which may serve the location of GliA formation. Activated Gli2 induces the expression of *Gli1*, which acts solely as an activator of Shh signaling. In addition to inducing the transcription of genes involved in proliferation and differentiation, Gli1 and Gli2 promote the transcription of *Ptch1*, which inhibits further pathway activation in the absence of additional ligand.

Co-receptors

Three membrane-associated co-receptors – Growth arrest-specific 1 (Gas1), CAM-related/downregulated by oncogenes (Cdo), and Brother of Cdo (Boc) – facilitate Shh reception and positively regulate the pathway (Beachy et al. 2010). While removal of any one of these molecules leads to a modest, tissue-specific reduction in Shh pathway activity, loss of all three co-receptors completely abolishes Shh signaling, indicating that *Cdo*, *Boc*, and *Gas1* are indispensible for vertebrate Hh signaling (Allen et al. 2011; Izzi et al. 2011). These molecules likely form distinct receptor complexes with Ptch1 and enable proper Shh binding (Izzi et al. 2011). In contrast to these positive regulators of Shh signaling, Hedgehog interacting protein (Hhip) functions as a decoy receptor and serves as a negative regulator of the pathway (Beachy et al. 2010). Whereas the expression of *Cdo*, *Boc*, and *Gas1*

are downregulated in the presence of Shh, the expression of *Hhip* is upregulated, thus providing a means of tempering pathway activity.

Shh Signaling in Development and Disease

Shh functions as a morphogen, mitogen, and survival factor to regulate the development and patterning of many tissues in the vertebrate embryo. In the embryonic neural tube, for instance, floor plate-derived Shh promotes the proliferation, survival, and specification of neural progenitors. Similarly, Shh arising from the zone of proliferation (ZPA), a Shh-producing center in the posterior region of the limb bud, regulates digit specification in the embryonic limb (Jiang and Hui 2008). In the developing foregut, endoderm-derived Shh provides instructional cues to the surrounding mesoderm, resulting in proper development of both the gastrointestinal tract and lung (McMahon et al. 2003). In some tissues, the importance of Shh persists even after birth. For example, during the late embryonic and early postnatal stages, Purkinje cell-derived Shh is essential for granule cell precursor proliferation in the developing cerebellum (Jiang and Hui 2008). In the adult, Shh is required for the maintenance of stem cell populations both in the brain and the epithelium (Jiang and Hui 2008). Defects in Shh signaling have been linked to numerous congenital abnormalities, including holoprosencephaly, polydactyl, and tracheal-esophageal fistula, underscoring the importance of the pathway for normal development (McMahon et al. 2003).

Whereas loss of Shh signaling leads to congenital abnormalities, increased pathway activity has been linked to certain forms of cancer. Somatic mutations in *Ptch1*, the Shh receptor and a potent inhibitor of the pathway, are observed in nearly all cases of basal cell carcinoma (BCC), a common but rarely metastatic form of skin cancer (Barakat et al. 2010). Similarly, inactivating mutations in *Ptch1* or activating mutations in *Smo* are observed in a subset of medulloblastomas (MB), a malignant tumor of the cerebellum and the most common pediatric brain tumor (Jiang and Hui 2008). Additionally, aberrant Shh pathway activity may contribute to rhabdomyosarcoma (RMS), a pediatric cancer thought to arise from skeletal muscle progenitors (Barakat et al. 2010). While aberrant pathway activation underlies BCC, MB, and RMS, other cancers such as pancreatic ductal adenocarcinoma exhibit paracrine Shh signaling, whereby tumor cells secrete Shh into the surrounding stroma and influence the tumor microenvironment (Yauch et al. 2008). Given the role of Shh signaling in oncogenesis, it is unsurprisingly that efforts have been made to target the pathway pharmacologically. Many of these agents have recently entered phase II and III clinical trials, and the efficacy of Shh inhibitors will become apparent in years to come (Ng and Curran 2011).

Summary

The most widely expressed of the three Hh ligands in mammals, Sonic Hedgehog is essential for proper embryonic development and patterning. Over the past 20 years, significant progress has been made in understanding the production, release, and downstream signaling of Shh ligands. Nonetheless, several fundamental questions regarding the pathway remain unanswered. First, a detailed understanding of how Disp1 and ADAMs mediate the secretion of multimeric Shh remains elusive. Second, the process by which Ptch1 inhibits and regulates the subcellular localization of Smo is not yet known, nor is the process by which Sufu-Gli complexes are dissociated by activated Smo. Finally, and perhaps most perplexing, is the question of how, and why, the primary cilium plays such an essential role in vertebrate Hh signal transduction. Answering these questions will not only provide insight into vertebrate development, but may inform the treatment of Hedgehog-driven tumors.

Sphingenine-1-Phosphate

► Sphingosine-1-Phosphate

Sphingosine-1-Phosphate

Ashok Kumar and Julie D. Saba
Center for Cancer Research, Children's Hospital Oakland Research Institute, Oakland, CA, USA

Synonyms

D-*erythro*-sphingosine-1-phosphate; Long-chain base phosphate; S1P; Sphingenine-1-phosphate; Sphingosine-1-phosphoric acid

Historical Background

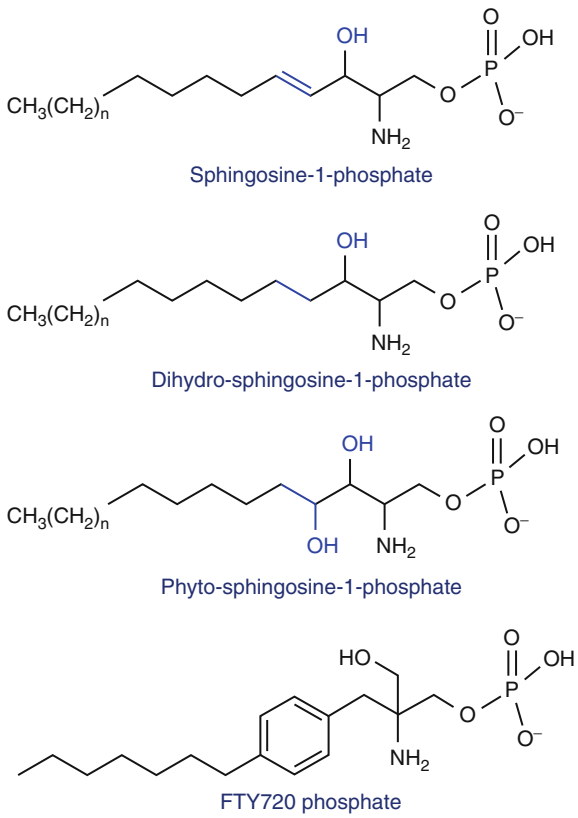
Sphingosine-1-phosphate (S1P) is a naturally occurring bioactive sphingolipid metabolite. Sphingolipids

are essential structural constituents of the plasma membrane of all eukaryotic organisms and are also produced by some bacteria. Sphingolipids are highly enriched along with cholesterol in microdomains or lipid rafts. In response to a wide range of stressful stimuli, membrane sphingomyelin and to lesser extent other complex sphingolipids are rapidly metabolized to the bioactive sphingolipid intermediate, *ceramide* and subsequently to sphingosine (Hannun and Obeid 2008). Phosphorylation of sphingosine by two *sphingosine kinases* results in the formation of S1P. S1P has emerged as a potent signaling molecule that regulates diverse cellular processes including cell proliferation, survival, differentiation, and migration (Spiegel and Milstien 2003). S1P plays a critical role in several physiological processes, including lymphocyte trafficking, vascular development, and inflammation. S1P exerts its biological actions both in cell-extrinsic and cell-intrinsic manner. S1P acts as ligand for five G-protein coupled receptors (GPCRs) known as S1P receptors 1-5 ($S1P_{1\text{-}5}$). S1P also acts as an intracellular second messenger. In 2002, it was discovered that the phosphorylated form of FTY720, an immunosuppressive compound, is an analog of S1P and binds to four out of five S1P receptors (Mandala et al. 2002). Subsequent to this discovery, intense research by many groups has provided a comprehensive understanding the role of S1P signaling in lymphocyte development, immune cell migration, and inflammation (Rivera et al. 2008; Spiegel and Milstien 2011). In addition to its role in immune cell trafficking and signaling, S1P functions as an oncogenic lipid that promotes tumor growth and progression. S1P plays a critical role in the regulation of many essential biological and developmental processes (Fyrst and Saba 2010). Not surprisingly, both the deficiency of S1P as well as its excessive accumulation are involved in pathological conditions including cancer, vascular abnormalities, inflammation, and autoimmune diseases and are likely to be linked to human congenital defects. Conversely, targeting the S1P signaling pathways and S1P metabolism appears promising as a therapeutic strategy for a number of human diseases.

Sphingosine, which comprises the backbone of most mammalian sphingolipids, was named in 1884 by JLW Thudichum after the Greek mythological creature, the sphinx, because of its enigmatic nature. One century later, the biological effects of sphingosine and its metabolite S1P are beginning to be elucidated. In the early 1990s, Sarah Spiegel's research group discovered that S1P regulates cell growth and stimulates DNA synthesis in response to platelet-derived growth factor (PDGF) (Olivera and Spiegel 1993). Further, they demonstrated that S1P suppresses ceramide-mediated apoptosis and thus proposed the concept of a sphingolipid rheostat (Cuvillier et al. 1996; Spiegel and Milstien 2003). In this model, the balance between intracellular ceramide/sphingosine and S1P levels influences whether cells exposed to stressful conditions will undergo growth arrest/apoptosis or proliferate and survive. Initially, it was proposed that S1P, like ceramide, mediates all its functions by acting as an intracellular second messenger. In the late 1990s, Timothy Hla and Sarah Spiegel discovered that S1P is a natural agonist for the *Endothelial Differentiation Gene-1* (EDG1), renamed S1P receptor 1 ($S1P_1$) (Lee et al. 1998). It is now well established that in higher eukaryotes, S1P exerts many of its actions by binding to its five cognate GPCRs (S1P receptors; $S1P_{1\text{-}5}$), thereby triggering intracellular signaling pathways through which it regulates a diverse array of biological processes such as angiogenesis, vascular integrity, cardiac development, and lymphocyte trafficking (Hla and Brinkmann 2011).

Structure, Biosynthesis, and Metabolism

Structure: S1P is synthesized by phosphorylation of its precursor sphingolipid, sphingosine. All sphingolipids contain a sphingoid or long-chain base (LCB) backbone. The term sphingoid base refers to a group of related compounds that contain two hydroxyl groups at the C1 and C3 positions, and an amino group at the C2 position (Chen et al. 2010). The most prevalent of sphingoid bases are sphinganine [(2 S,3R)-2-aminooctadece-1,3-diol] and sphingenine [(2 S,3R,4E)-2-aminooctadec-4-ene- 1,3-diol]. In mammalian cells, the most common sphingoid base is (2 S,3R,4E)-2-aminooctadec-4-ene-1,3-diol, which is also called *D-erythro*-sphingosine or just sphingosine. Other sphingoid bases vary in alkyl chain length and branching, the number and position of double bonds, the presence of additional hydroxyl groups, and other features (Chen et al. 2010). In fungi and plants, *D-ribo-phyto-sphingosine* (phyto-sphingosine) is predominant, and it carries an additional hydroxyl group at C4. *D-erythro-dihydrosphingosine* (dihydrosphingosine or sphinganine) is also detectable



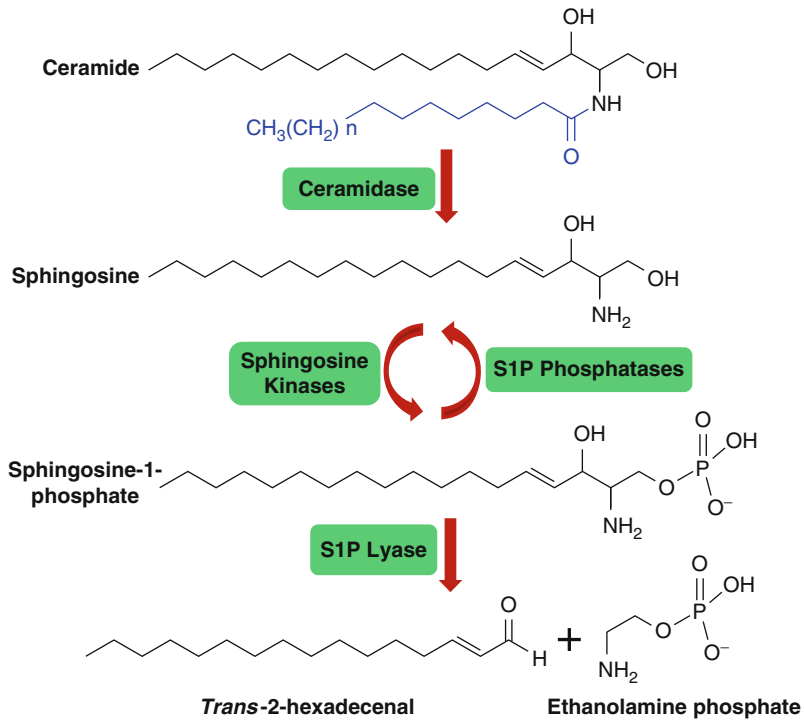
Sphingosine-1-Phosphate, Fig. 1 *Structure of natural and synthetic long-chain base* (*LCB*) *phosphates*. Sphingosine-1-phosphate and dihydro-sphingosine-1-phosphate are major long-chain base phosphates found in yeast, nematodes, flies, and mammals, whereas phyto-sphingosine-1-phosphate is abundant in fungi and plants. LCB phosphates vary in chain length among the species, with mammals carrying C18 chain length. (n = 3–7). FTY720 phosphate is a synthetic analog of S1P

in most organisms. Sphingoid bases vary in chain length among species, with mammals carrying primarily C18; yeast, C16, C18, and C20; fly, C14 and C16; and nematode, C17. Some species, such as nematodes, contain unusual branch chain sphingoid bases. Unless otherwise stated, S1P biosynthesis, metabolism, and functions have been referred to the mammalian S1P.

Biosynthesis and Metabolism: Two highly homologous sphingosine kinases, known as sphingosine kinase 1 (SphK1) and sphingosine kinase 2 (SphK2) catalyze the phosphorylation of the hydroxyl group (1-OH) of sphingosine to form S1P (Fig. 1) (Spiegel and Milstien 2003). Both SphK1 and SphK2 phosphorylate sphingosine and dihydrosphingosine, whereas SphK2 exhibits broader substrate specificity and can also phosphorylate phyto-sphingosine and FTY720 (a synthetic drug structurally related to sphingosine). Sphingosine and other LCBs are produced mainly by two pathways: *de novo* sphingolipid biosynthesis or by breakdown of ceramide. In *de novo* biosynthesis, the first step is the condensation of L-serine and palmitoyl-CoA through the action of serine palmitoyltransferase to form 3-ketodihydrosphingosine, which is then reduced to dihydrosphingosine. In yeast, hydroxylation at the C4 position of dihydrosphingosine by the hydroxylase Sur2p yields the predominant yeast LCB, phyto-sphingosine. However, sphingosine cannot be synthesized by the *de novo* pathway and is generated instead via the deacylation of ceramide catalyzed by ceramidase (salvage pathway).

S1P levels in the tissues and plasma are tightly regulated. SphK1 is the primary enzyme responsible for S1P generation and is mainly localized in the cytosol. Activation of SphK1 is regulated by many factors such as its intracellular localization, epigenetic or post-translational modification. SphK1 can be activated by wide variety of growth factors including PDGF, vascular endothelial growth factor, epidermal growth factor, hepatocyte growth factor and tumor necrosis factor-α (TNF-α) (Pitson 2011). Upon stimulation by growth factors, cytokines, and lipopolysaccharide, SphK1 translocates to the plasma membrane. SphK1 generated S1P has been implicated in many pathophysiological conditions including vascular permeability, angiogenesis and inflammation. Compared to SphK1, much less is known about the regulation and function of SphK2. SphK2 is localized in mitochondria, nucleus, and endoplasmic reticulum and regulates apoptosis and gene expression.

Circulating and tissue S1P levels are also regulated by its catabolism. There are six enzymes known to catabolize S1P and which play a role in maintaining S1P levels in the tissues (Fig. 2). The first enzyme is S1P lyase, which degrades S1P irreversibly to ethanolamine phosphate and a long-chain aldehyde (*trans*-2-hexadecenal) (Kumar and Saba 2009). S1P phosphatase-1 and -2 remove the phosphate group reversibly from S1P and convert it back to sphingosine. These three enzymes are localized in the endoplasmic reticulum and are highly selective for S1P and LCB phosphate substrates. Additionally, there are three plasma membrane-bound phosphatases known as lipid phosphate phosphatases 1, 2, and 3 (LPP1-3) that can dephosphorylate a broad range of lipid



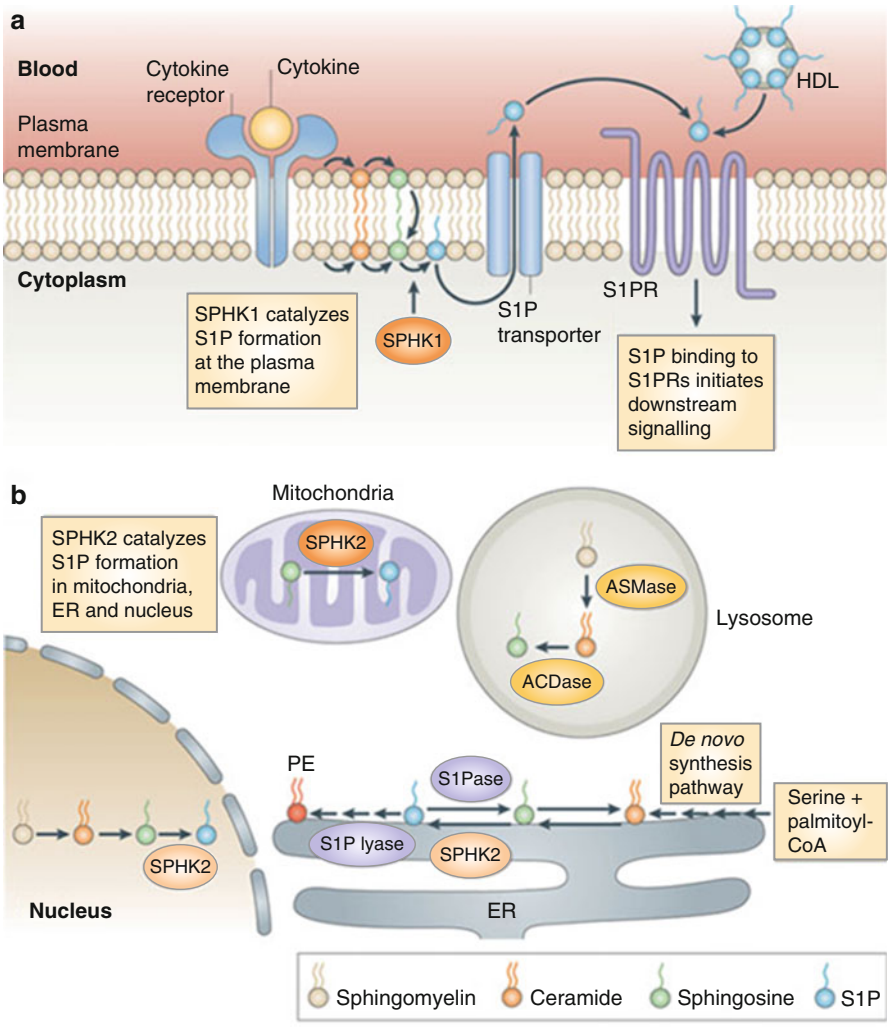
Sphingosine-1-Phosphate, Fig. 2 *Sphingosine-1-Phosphate* (*S1P*) *metabolic pathway in mammalian cells.* S1P is generated by the conversion of ceramide to sphingosine by the enzyme ceramidase and the subsequent phosphorylation of sphingosine to S1P, which is catalyzed by two sphingosine kinases. S1P can be dephosphorylated back to sphingosine in a reversible reaction catalyzed by S1P phosphatases or lipid phosphate phosphates. This sphingosine can be reused in the salvage pathway. S1P can also be irreversible degraded by the enzyme S1P lyase forming a long-chain aldehyde (*trans*-2-hexadecenal) and ethanolamine phosphate. Several molecular species of ceramide are found in mammals based on fatty acid chain length (n = 4–16)

phosphate substrates including S1P, ceramide-1-phosphate, lysophosphatidic acid, and phosphatidic acid (Pyne and Pyne 2010).

Occurrence, Source, and Transport

S1P is generated by most cell types in mammals. In blood, S1P concentrations vary between 0.2 and 1.0 μM. In lymph, S1P is present in the hundred-nanomolar range and is produced by radiation-resistant cells of non-hematopoietic origin, presumably lymphatic endothelial cells. Erythrocytes and platelets are rich sources of S1P, as both of these cell types are exposed to circulating sphingosine, contain sphingosine kinase activity, and lack most of the S1P degrading enzymes. Vascular endothelium and mast cells also secrete S1P. In blood, S1P remains bound to albumin and lipoproteins, most notably high-density lipoproteins (HDL). Albumin-bound S1P and free S1P are susceptible to degradation, whereas HDL-bound S1P is more stable. HDL likely facilitates the delivery of S1P to its receptors (Rivera et al. 2008).

Many cells that produce S1P also export it, thereby allowing S1P to bind and activate the S1P receptors present on neighboring cells (paracrine action) or the same cell (autocrine action). The latter mechanism is also known as "Inside-Out Signaling" (Fig. 3). S1P is an amphiphilic molecule that requires facilitated export from cells. The ATP-binding cassette (ABC) family of transporters has been shown to be involved in the export of S1P from the cells. Mast cells and platelets secrete S1P in a stimulus-dependent manner and require the activity of ABCC1 and ABCA-like transporters, respectively. On the contrary, erythrocytes and endothelial cells export S1P constitutively in a stimulus-independent manner. Erythrocytes mediate S1P export through the ABCA1 transporter protein.



Sphingosine-1-Phosphate, Fig. 3 *Mechanism of action of S1P*. In response to cytokine or other stimuli, S1P is synthesized by phosphorylation of sphingosine by sphingosine kinase 1 (SPHK1) at the plasma membrane (**a**) and by SPHK2 at the endoplasmic reticulum (ER), mitochondria and nucleus (**b**). At the ER, S1P is irreversibly degraded by S1P lyase or dephosphorylated to sphingosine by an S1P phosphatase (S1Pase). S1P produced at the plasma membrane in response to stimuli is released by specific transporters and regulates cellular functions by binding to specific S1P receptors (S1PRs) and initiating downstream signaling pathways. S1P produced in the mitochondria and nucleus by SPHK2 has direct intracellular targets, and S1P generated by SPHK1 at the plasma membrane can also function intracellularly. In the blood, S1P is produced mainly by erythrocytes (although platelets, endothelium, and other cellular sources also contribute to S1P levels under various conditions), is bound to albumin and high-density lipoprotein (HDL), and can activate S1PRs. ACDase, acid ceramidase; ASMase, acid sphingomyelinase (Reprinted by permission from Macmillan Publishers Ltd: Nature Immunology, Spiegel and Milstien 11:403, copyright (2011))

Recently, a novel S1P transporter *Spns2* was discovered in zebrafish. Mutations in *Spns2* caused the cardiac bifida phenotype that resembled that of the S1P receptor zebrafish mutant, thus revealing the two genes to be operating in the same pathway (Kawahara et al. 2009). The human orthologue of *Spns2* has also been shown to export S1P and other phosphorylated LCBs including FTY720 from the cells.

Mechanism of Action

With the discovery of EDG1 as a high-affinity receptor for S1P, it became evident that an important biological function of S1P is to act as a natural ligand for the EDG GPCR family of receptors, now referred to as S1P receptors (Lee et al. 1998). To date, five S1P receptors EDG1/$S1P_1$, EDG5/$S1P_2$, EDG3/$S1P_3$, EDG6/$S1P_4$, and EDG8/$S1P_5$ that bind to S1P and dihydro-S1P have been identified in vertebrates (Hla and Brinkmann 2011). In mammalian cells, S1P receptors are ubiquitous, but their expression patterns vary among the different tissues. Each S1P receptor couples to different heterotrimeric G-proteins. For example, $S1P_1$ and $S1P_4$ couple mainly to G_i; $S1P_2$ and $S1P_3$ activate G_i, G_q, and $G_{12/13}$; and $S1P_5$ binds to G_i and $G_{12/13}$. After coupling to G-proteins, these receptors either activate or inhibit downstream signaling pathways including extracellular signal-regulated kinase, c-Jun N-terminal Kinase, phosphatidylinositol 3-kinase, phospholipase C, Rac, Rho, cyclic AMP, and phospholipase D (Spiegel and Milstien 2003). The functional response of each cell to S1P varies depending on S1P receptor expression and intracellular signaling configuration. By activating these receptors, S1P regulates diverse biological processes including vascular development, angiogenesis, and immunity. To date, S1P receptors have not been identified in invertebrates, leading to the current opinion that these receptors evolved with the coelomates.

S1P regulates many biological processes including cell survival, DNA damage repair, calcium mobilization, and stress response by acting as an intracellular second messenger. Many studies conducted in lower organisms such as yeast, flies, slime molds, nematodes, and plants that lack identifiable S1P receptors revealed that S1P regulates important developmental processes through direct intracellular signaling. In fact, S1P has a universal signaling role in calcium mobilization in yeast, plants, and mammals. However, the question of how S1P mediates its intracellular signaling effects remained unanswered, and specific intracellular targets of S1P remained elusive. Recently, several direct intracellular S1P targets have been identified. For examples, S1P directly binds to histone deacetylase (HDAC)-1 and -2, TNF receptor-associated factor 2 (TRAF2), p21-activated protein kinase 1 and prohibitin 2. Whether these or other intracellular interactions are responsible for the function of S1P in simple metazoans remains to be determined.

S1P in Health and Disease

S1P in immunity: In a landmark study by Mandala and colleagues, it was shown that FTY720, an immunosuppressive agent is an analog of sphingosine and after phosphorylation in vivo it (phosphorylated compound of FTY720) binds to four of five S1P receptors and induces lymphopenia (Mandala et al. 2002). A plethora of immunological investigations have now revealed the major impact of S1P signaling on the mammalian immune system. S1P signaling through its receptors was found to regulate the trafficking and migration of many bone marrow–derived immune cells including T and B lymphocytes, natural killer (NK) T cells, dendritic cells, macrophages, neutrophils, mast cells, and hematopoietic progenitors cells (Rivera et al. 2008; Spiegel and Milstien 2011). Pharmacological and genetic approaches combined with sophisticated in vivo imaging of immune cells have provided novel insights regarding the role of $S1P_1$ signaling in mature lymphocyte egress from the thymus and secondary lymph nodes in to the circulation. Due to high levels of plasma and lymph S1P and low S1P levels in lymphoid tissues, an S1P gradient exists between plasma and lymphoid organs. Mature thymocytes expressing high levels of $S1P_1$ sense the gradient and migrate toward the blood stream. Inhibition or genetic deficiency of S1P catabolizing enzymes, such as S1P lyase or lipid phosphate phosphatase 2 raises thymic S1P levels, disrupting the S1P gradient and resulting in blockade of exit of mature thymocytes, thereby producing lymphopenia (Schwab et al. 2005). In addition to its role in leukocyte migration, S1P signaling contributes to T lymphocyte differentiation, allergy, inflammation, endothelial barrier integrity in anaphylactic shock, and other immune functions.

S1P in cell survival and cell death: The metabolic balance between ceramide, sphingosine, and S1P plays an important role in determining cell fate. In general, ceramide and sphingosine accumulation result in growth arrest and/or induce cell death, whereas S1P has a mitogenic function and inhibits apoptosis. S1P inhibits ceramide-induced apoptosis in many cell types (Cuvillier et al. 1996; Spiegel and Milstien 2011). Moreover, overexpression of SphK1 inhibits apoptosis and induces chemoresistance, whereas overexpression of S1P lyase which depletes intracellular S1P promotes apoptosis in response to DNA damaging agents and ionizing radiation (Min et al. 2004; Kumar et al. 2011).

S1P increases the expression of anti-apoptotic proteins Bcl-2 and Mcl1 and downregulates pro-apoptotic Bcl-2 family proteins Bad and Bax. In vivo, S1P protects small intestine from radiation-induced endothelial apoptosis and it also prevents radiation-induced cell death in germ cells (Morita et al. 2000; Bonnaud et al. 2010). However, the rheostat model has recently been challenged due to some interesting findings. For example, under certain conditions, S1P can induce autophagy, similar to ceramide. However, the cellular outcome of S1P-induced autophagy is different than the ceramide-induced autophagy, because S1P-induced autophagy promotes cell survival whereas ceramide-induced autophagy leads to cell death (Pyne and Pyne 2010). There is also evidence that S1P pools generated by SphK1 versus SphK2 have opposite effects on cellular growth and apoptosis. While SphK1 generates S1P, which promotes cell growth and rescues cells from ceramide-induced apoptosis, overexpression of SphK2 suppresses growth and enhances cell death (Pyne and Pyne 2010; Pitson 2011).

S1P in cardiovascular system: S1P signaling through endothelial $S1P_1$ is required for vascular maturation during development, as dramatically illustrated by the embryonic lethality of $S1P_1$ knockout mice (Lee et al. 1998; Hla and Brinkmann 2011). S1P signaling also contributes to cardiac development, angiogenesis, HDL-mediated effects, and regulation of vascular tone and permeability. S1P enhances survival in cardiomyocytes during hypoxia, and both SphK1 and SphK2 appear to contribute to ischemic preconditioning, a mechanism by which brief exposure to minor ischemic episodes affords cardioprotection against larger ischemic events. Deficiency of SphK1 or S1P receptors $S1P_2$/$S1P_3$ exacerbates infarction size in cardiac ischemia-reperfusion model in mice. In contrast, S1P lyase deficiency in mice or inhibition of its enzymatic activity by a pharmacological agent enhances recovery from cardiac ischemia-reperfusion. In addition to the direct effects of S1P in the heart, there is increasing evidence that some of the protective effects of HDL against atherosclerosis and heart disease are mediated through S1P (Fyrst and Saba 2010).

S1P in cancer: Through its roles in regulating cell death pathways, proliferation, migration, and angiogenesis, S1P signaling has a significant impact on the processes of carcinogenesis, cancer progression, and drug and radiation resistance patterns. Many components of S1P signaling pathways including sphingosine kinases, S1P lyase, and S1P receptors have been mechanistically linked with cancer cell aggressiveness, invasion, metastasis, and chemoresistance. SphK1 is overexpressed in various types of human cancers including prostate, gastric, breast, lung, colon cancer, glioma, and non-Hodgkin's lymphoma (Pyne and Pyne 2010). Further, overexpression of SphK1 in mouse fibroblast induces transformation through a Ras-dependent pathway, demonstrating that SphK 1 is an oncogene. Elevation of SphK1 expression in cancers is often associated with clinical grade of tumors and chemoresistance. Inhibition of SphK1 enzyme activity or genetic knockdown blocks tumor progression in many types of cancers and induces apoptosis and autophagy (Pyne and Pyne 2010). On the contrary, S1P lyase expression is downregulated in melanomas, colon and ovarian cancer and may act as a tumor suppressor gene (Kumar and Saba 2009). S1P promotes tumor invasion, neovascularization, and metastasis by activating its cognate receptors. However, no consistent pattern of S1P receptor gene expression has been associated with clinical tumor grade. Notably, mice lacking $S1P_2$ develop diffuse large B-cell lymphoma, and several mutations have been reported in $S1P_2$ gene in diffuse large B-cell lymphoma patients.

Therapeutic targeting of S1P signaling pathways: Due to the central involvement of S1P signaling in immunity and tumorigenesis, substantial activity in the pharmaceutical industry has developed around the goals of targeting S1P (the monoclonal antibodies developed by LPath), S1P receptors (S1PR-specific agonist and antagonist compounds generated by many research groups), sphingosine kinase (inhibitors), and S1P lyase (inhibitors) for therapeutic purposes. Notably, FTY720, a synthetic analogue of sphingosine, has been approved by the US Federal Drug Administration in relapsing multiple sclerosis patients. S1P-specific monoclonal antibody (ASONEP; LPath, Inc.) which reduces tumor progression in various mouse models of cancer has been approved for Phase 1 clinical trial in cancer. LX2931 (Lexicon Inc.), an oral S1P lyase inhibitor is in Phase II clinical trial for use in rheumatoid arthritis. Several sphingosine kinase inhibitors are being tested in mouse models for cancer, inflammation and sepsis. As more potent and selective agents become available, their evaluation in pre-clinical models and clinical trials will reveal the true potential of targeting S1P signaling for therapeutic purposes.

Summary

S1P signaling regulates myriad biological functions, and each year new targets are being identified. In fact, over the last two decades, S1P has become one of the most highly investigated signaling lipids. Although the S1P signaling field has advanced tremendously, some important questions remained unanswered. For example, the exact role of S1P in regulating diverse physiological functions in lower eukaryotes in the absence of identifiable S1P receptors is still an enigma. Direct intracellular binding of S1P to TRAF2 and HDAC has been shown recently. However, it is highly likely that additional intracellular targets remain to be discovered. FTY720 has been approved for clinical use in relapsing multiple sclerosis patients, providing the first major impact of the S1P pathway on medical care. Whether FTY720 will be efficacious and safe in other conditions such as chronic inflammatory demyelinating neuropathy, which is the peripheral counterpart to multiple sclerosis, in other autoimmune diseases, or in other conditions such as regenerative diseases, radioprotection, and cancer are still outstanding questions. While it seems that FTY720's main function is by receptor downregulation, there is evidence that agonism of S1P receptors contributes to some of its beneficial effects. It is hoped that other S1P receptor agonists/antagonists will be useful in various clinical contexts. As biological and physiological research continues to reveal the functions of S1P signaling, the clinical contexts in which S1P signaling can be targeted for patient benefit will also likely expand.

Synonyms

Sex determining region on the Y chromosome; Testis determining factor; TDF

Historical Background

Mammalian sex determination occurs during a short period in embryonic development, with SRY (Sex determining Region on the Y chromosome) playing a key role. In the 1940s, Jost et al. demonstrated that a testis is necessary for development of the male phenotype in mammals, as implied by the fact that castrated rabbits of either chromosomal sex developed as females (Jost et al. 1973). Karyotypes of patients with Turner Syndrome (45, X) and Klinefelter syndrome (47, XXY) demonstrated that sex is chromosomally controlled, and that the Y chromosome, in particular, determines male development regardless of X chromosome number (Vilain and McCabe 1998). Based on these observations, it was hypothesized that a dominant inducer of testis formation, the so-called testis determination factor (TDF), was located on the Y chromosome and encoded a gene or genes specifying the male phenotype; in the absence of this TDF, a female phenotype ensued (Vilain and McCabe 1998).

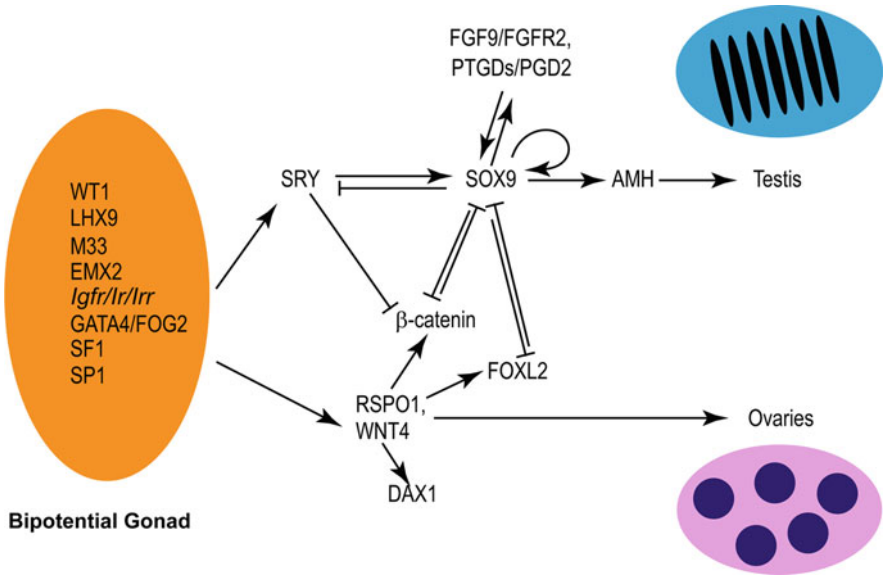
In 1990, the master gene on the Y chromosome, *Sry*, was isolated by positional cloning and identified as the TDF (Polanco and Koopman 2007). In the genome of true hermaphrodites and XX males, the small fragment of the Y chromosome that had translocated to the X chromosome was found to encode *Sry*, where XX mice transgenic for *Sry* developed as males with normal testes and testicular cords, implying that *Sry* was the only Y-encoded gene necessary for testis formation and the resulting male phenotype (Harley et al. 2003).

In mammalian males, SRY acts on the undifferentiated genital ridge as a switch to initiate the development of a testis, instead of an ovary, from the genital primordium; driving cells to a Sertoli (i.e., male) rather than a granulosa (female) fate (Sekido and Lovell-Badge 2009). *Sry* transcripts are expressed for a brief period during gonadal development in mice, consistent with SRY's role being that of initiating, rather than maintaining testis differentiation through triggering a complex cascade of events leading to testicular development (see Fig. 1) (Sekido and Lovell-Badge 2009).

Expression of SRY During Development

In mammals, the gonad initially develops in a nonspecific manner, and is morphogenically identical in XX and XY mouse embryos until *Sry* expression, which occurs between 10.5 and 12.5 days (d) post coitum (pc) (Sekido and Lovell-Badge 2009). At 11.5 dpc, sex-specific differences become apparent, with the differentiation of the supporting lineage into Sertoli cells and alignment into testis cord and presumptive seminiferous tubules. In the absence of SRY, the ovary forms via a default pathway 2–3 days later in female embryos forming granulosa or theca cells. After 12.5 dpc, SRY is detectable only at very low levels in the mouse (Polanco and Koopman 2007).

In humans, the gonadal ridge forms around day 33 of gestation, with *Sry* detectable in XY embryos at day 41, peaking at day 44 when the testis cords are visible. By 52 days gestation, the germ cells are surrounded by Sertoli cells, which continue to express *Sry* at low levels (Harley et al. 2003). In contrast to in the mouse, the *Sry* transcript is expressed widely in the human embryo, including in the brain and continues to be transcribed even in human adult testis, consistent



Sry, Fig. 1 *Signaling pathways in sex determination*. Development of the gonads is highly regulated through complex signaling and antagonistic interactions between the two sex determining pathways, with SRY as the key initiator of male sex determination and *Sox9* expression to favor testis development. *Arrow-headed lines* indicate positive upregulation and *bar-headed lines* indicated repressive influences. with roles additional to those in sex determination, such as spermatogenesis (Harley et al. 2003).

Little is known of how *Sry* expression is regulated, with the transcription factors WT1 (Wilm's tumor suppressor gene 1) and SF1 (Steroidogenic factor 1) playing key roles (see Fig. 1) (Polanco and Koopman 2007). Mutations in either can result in sex reversal and gonadal dysgenesis, with SF1 able to bind and transactivate the human and porcine *Sry* promoter in vitro. Two isoforms of WT1 have been found to play key roles in testis development, −KTS and +KTS, which exclude or include the amino acid sequence lysine-threonine-serine in the zinc finger nucleic acid binding domain, respectively. The −KTS isoform regulates *Sf1* expression, with evidence that it can also bind and transactivate the human and porcine *Sry* promoter. Intriguingly, the +KTS isoform shows higher affinity for RNA than DNA, and has been proposed to be involved in enhancing *Sry* translation and/or stabilizing the *Sry* mRNA (Polanco and Koopman 2007). Lhx9 (LIM-homeobox gene 9) and a polycomb group protein M33 are also involved in regulating *Sry* expression, with both being able to upregulate *Sf1* expression (Piprek 2009). CITED1 [CBP(CREB-binding protein)/p300-interacting transactivator with ED-rich tail 2], a non-DNA binding transcriptional cofactor, may also act with SF1 and WT1 to increase *Sry* expression (Buaas et al. 2009).

The transcription factor GATA-4, along with its cofactor FOG2 can also upregulate *Sry* expression, with synergism between GATA-4 and the +KTS isoform of WT1 resulting in strong transactivation of the porcine and mouse *Sry* promoter (Piprek 2009). The transcription factor SP1 (specificity protein 1) may also activate *Sry* expression, with mutations affecting its binding to the *Sry* promoter associated with human XY sex reversal (Polanco and Koopman 2007). The insulin receptor, insulin-related receptor, and the insulin-like growth factors are also implicated in testis development, with sex reversal resulting from a triple

null mutation in mice (Sekido and Lovell-Badge 2009). A transcription factor, EMX2 (empty spiracles homeobox 2), is also believed to play a role in testis development, although little is known of the mechanism (Piprek 2009).

The expression of *Sry* in the embryonic gonad appears to occur as a dynamic wave, originating from the center of the gonads and diffusing out toward the anterior and posterior poles between 10.5 and 12.5 dpc in mice (Polanco and Koopman 2007). SRY positive cells are detectable at 12 tail somites (ts; ~11.0 dpc), by 18 ts (~11.5 dpc) one third of cells express SOX9 [SRY-related HMG (high mobility group)-box 9], half of which are SRY positive, and by 25 ts (~12.0 dpc) 50% of cells show SOX9 expression, with 90% of all cells being SRY negative (Oh and Lau 2006). Recent studies indicate that SRY has a critical time window of 6 h to trigger *Sox9* upregulation and induce testis differentiation (Hiramatsu et al. 2009). Once *Sox9* is expressed, *Sry* expression is switched off through a negative feedback mechanism either through the actions of SOX9, since *Sry* expression is higher in gonads with low levels of *Sox9*, or through *Sry* itself, where mice carrying weak *Sry* alleles have prolonged *Sry* expression, presumably as a result of delayed *Sox9* expression (Sekido and Lovell-Badge 2009).

Genetic studies of the variants of Y chromosome present on the C57BL/6 J (B6) mouse strain, as well as transgenic mice, indicate that threshold levels of *Sry* are required to be expressed at critical times during male sex development, with reduced levels and delayed expression of *Sry* resulting in aberrant testis development (Sekido and Lovell-Badge 2009; Polanco and Koopman 2007). These results indicate that *Sry* must act during a critical time window to appropriately activate *Sox9* and must be expressed before the ovarian pathway is engaged for testis development to proceed (Polanco and Koopman 2007).

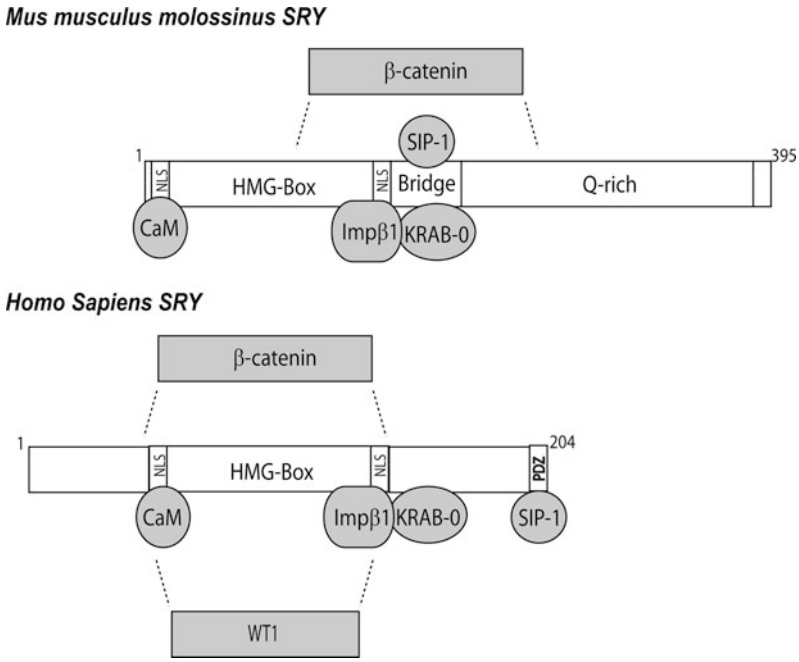
Targets of SRY in the Cell

A property of the family of SOX DNA-binding proteins is the ability to bind to the consensus DNA sequence AACAAT, with SRY having the highest affinity for the (A/T)AACAA(T/A) sequence, being able to bind DNA specifically and inducing strong bending of specific target DNAs (Polanco and Koopman 2007). The 204 amino acid human SRY is encoded as a single exon, which can be divided into three regions; a central 79 amino acid HMG-box domain that confers DNA binding, flanked by the N- and C-terminal domains (Polanco and Koopman 2007). Significantly for SRY's role in the nucleus, the HMG-box domain is flanked by two basic sequences that have been shown to be functional as nuclear localization signals (NLSs) (see Fig. 2) (Kaur and Jans 2011). In mouse (*Mus musculus molossinus*), SRY contains a large C-terminal glutamine-rich region, separated from the HMG-box by a "bridge domain" (see Fig. 2) (Sekido and Lovell-Badge 2009). This C-terminal region is absent in the subspecies *M.m. domesticus*, however, consistent with the idea that the HMG region is the key domain for SRY function (Harley et al. 2003).

There is essentially no sequence conservation outside of the HMG domain of SRY between different mammalian and reptile species, signifying its rapid divergence through evolution (Harley et al. 2003). The SRY HMG domain shows >70% amino acid sequence similarity for the SRY sequences from human, mouse, rabbit, wallaby, marsupial mouse, and sheep (Harley et al. 2003). The nuclear magnetic resonance structure of the HMG domain of SRY in complex with DNA has been determined, showing three α-helices forming an L shape. Through binding the minor groove of DNA, SRY can induce a large conformational change involving DNA helix unwinding, minor groove expansion, and DNA bending. These events collectively represent a molecular switch, allowing interactions between proteins bound at distant sites on the DNA to modulate transcription (Harley et al. 2003).

The N-terminal domain of SRY has also been shown to play an important role in DNA binding, with phosphorylation, by cAMP-dependent protein kinase (PKA), of serine residues at the N-terminal enhancing binding in the case of hSRY to DNA. Intriguingly, impaired PKA phosphorylation due to the R30I mutation of the PKA recognition site ($RRSSS^{33}$) reduces DNA binding activity, resulting in XY sex reversal (Assumpcao et al. 2002). Recent data also indicates the importance of the C-terminal domain of SRY in contributing to DNA binding in vitro (Sanchez-Moreno et al. 2009).

Timing of *Sry* expression is clearly crucial for testis development, as is the appropriate cellular environment provided by the Sertoli cells through provision



Sry, Fig. 2 *Functional Domains of SRY*. Schematic diagram of the domain structures for the *Mus musculus molossinus* and *Homo sapiens* SRY proteins. *Dotted lines* denote regions within SRY mediating interactions with the indicated binding partners. Key: *CaM* calmodulin, *HMG* High mobility group, *Impβ1* Importin β1, *KRAB-O* Kruppel-associated box only, *NLS* nuclear localization signal, *PDZ* Protein–protein interacting domain, *Q-rich* Glutamine-rich, *SIP*-1, SRY interacting protein 1, *WT1* Wilm's tumor gene 1

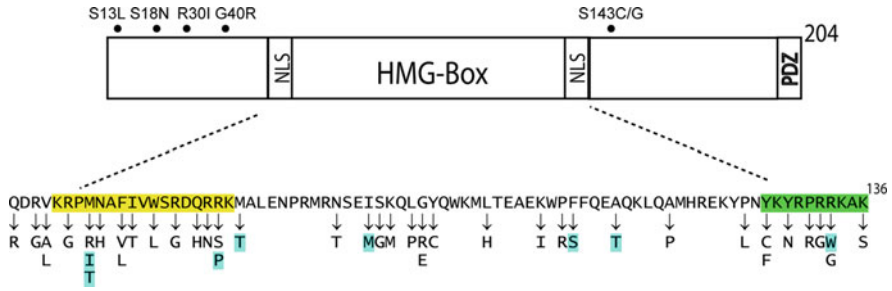
of cofactors, posttranslational modification, subcellular localization, and access to target DNA (Oh and Lau 2006). Although DNA binding, through the HMG domain, appears to be critical for sex determination, several proteins have also been identified to interact with SRY (see Fig. 2). The SRY-Interacting Protein 1 (SIP-1/NHERF-2), for example, may perhaps be involved in the modulation of SRY transcriptional activity, interacting through its protein–protein interacting (PDZ) domain, with the Thr-Lys-Leu (KTL) motif in hSRY's C-terminus, and the bridge domain in mSRY (Sekido and Lovell-Badge 2009).

KRAB-O (Kruppel-associated box only) has also been found to interact with SRY (see Fig. 2) through the bridge domain of mSRY and a domain adjacent to the hSRY HMG-box (aa 138–155) (Oh and Lau 2006). KRAB-O is believed to be involved in modulating SRY transcriptional activity, where it interacts directly with the KRAB-association protein 1 (KAP1) and indirectly with heterochromatin protein 1 (HP1), which acts as a transcriptional repressor (Oh and Lau 2006). Intriguingly, reduced expression of *Sox9* is observed in KRAB-O knockout mouse models, although no effects are evident in terms of testis development (Oh and Lau 2006).

Wilm's tumor gene (WT1; see also above) is also essential for testis development, with mutations such as R394W and D369N impairing the interaction of WT1 with SRY (see Fig. 2) and resulting in reduced transactivation, leading to Denys-Drash syndrome (DDS), which is characterized by Wilm's tumor, pseudohermaphroditism, and neuropathy (Matsuzawa-Watanabe et al. 2003). Other proteins that interact with SRY include PARP1 (poly(ADP-ribose) polymerase 1), which upon binding SRY's HMG domain is thought to interfere with SRY's DNA binding activity (Li et al. 2006).

SRY and Sex Reversal

That, as a general rule, XY embryos become males and XX embryos become females does not hold true for sex-reversed individuals where the normal process of sexual differentiation has been altered. Since gonadal differentiation in most mammals cannot be induced by environmental variations or external manipulations, these must arise from genetic abnormalities. XX female-to-male sex reversal is a rare event, observed in 1:20,000 newborns, with 80% of cases due to *Sry* translocation. However, XY male-to-female sex reversal occurs at a frequency of 1:3,000 in newborns (Sarafoglou and Ostrer 2000), although only 15% of all cases can be attributed to mutations within *Sry*,



Sry, Fig. 3 *Sex-reversing mutations in human SRY cluster in the HMG-box domain.* Sex reversing point mutations are denoted by *arrows*, with the amino acid substitution indicated. Few point mutations are located outside the HMG-box domain, indicated by the *circles* above the N- and C-terminal domains. The N-terminal "CaM-NLS" (*yellow*) and the C-terminal "β-NLS" (*green*) are indicated, with mutations highlighted in *blue* having no significant affects on SRY's abilities to bind/bend DNA

consistent with the idea that a number of other key genes are involved in sex determination, such as *Sox9*, *Sf1*, and *Wt1*.

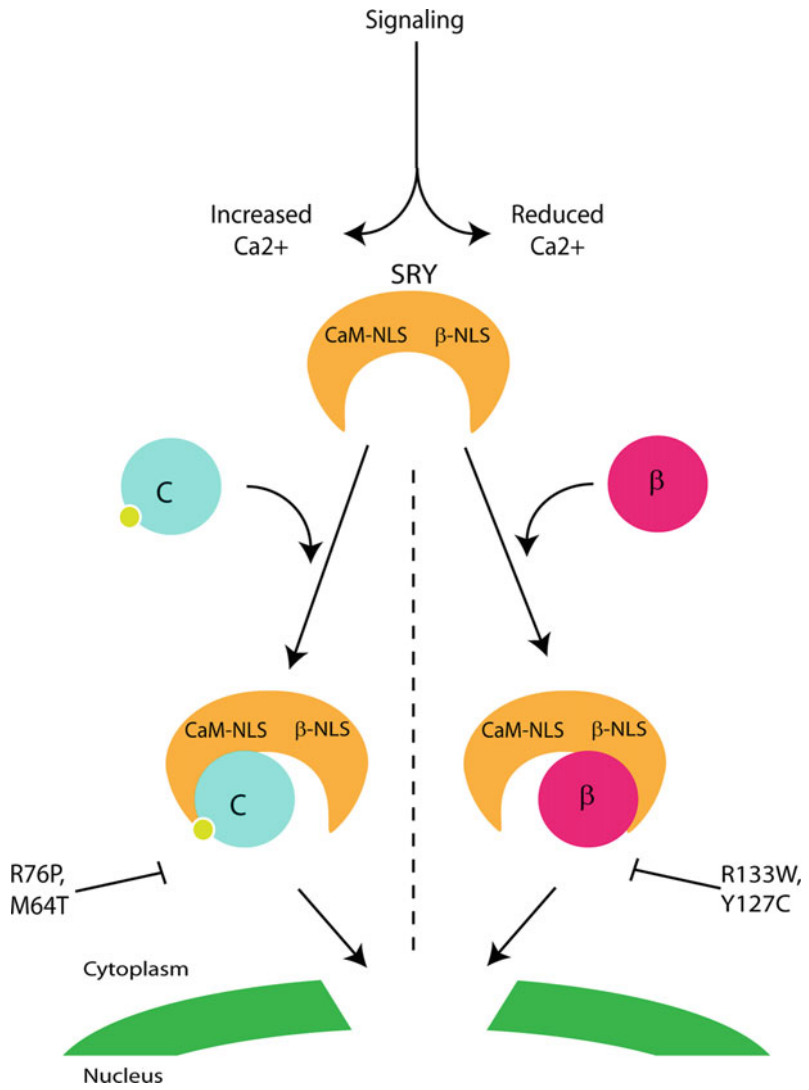
Almost all patients with SRY mutations show pure or complete gonadal dysgenesis (CGD), lacking testicular development with well-developed Mullerian structures and streak gonads in place of normal ovaries (Sarafoglou and Ostrer 2000). XY sex reversal patients develop as normal females with female internal and external genitalia, but are sterile, lack ovarian function, and present clinically with primary amenorrhea (Sarafoglou and Ostrer 2000). About 50% of XY female sex reversal cases show gonadoblastomas, additional to CGD, necessitating surgical removal of gonadal tissues (Mitchell and Harley 2002). The majority of SRY sex-reversing mutations occur de novo, thus affecting only one individual in the family (Mitchell and Harley 2002). However, mutations in the HMG domain have also been described in fathers of XY females. In these so-called familial cases, it is thought that genetic background compensates for the mutation in the father, but not in the affected individual (Mitchell and Harley 2002).

Sex reversing mutations in h*Sry*, including frameshift, nonsense or missense mutations, are largely clustered in the central region of the HMG domain, consistent with the idea that the DNA binding motif plays an essential role in vivo. Of the approximately 50 known *Sry* missense mutations (see Fig. 3), 4 mutations are found in the N-terminal domain (S3L, S18N, R30I, and G40R), with 2 more recently characterized mutations localized to the C-terminal region (S143C and S143G), highlighting the importance of these domains in sex determination (Assumpcao et al. 2002; Sanchez-Moreno et al. 2009). All other SRY missense mutations reside within the HMG-box, indicating that mutations that impair interaction between SRY and its DNA targets or protein-binding partners result in sex reversal. Importantly, a number of sex reversing mutations (e.g. R76P, R133W) do not impair DNA binding or bending significantly, but appear to affect nuclear accumulation specifically (Kaur et al. 2010).

Nuclear Entry of SRY

SRY gains access to the nucleus through the arginine-rich N-terminal (^{61}KRPMNAFIVWSRDQRRK) CaM- and C-terminal (^{126}KYRPRRKAK) β-NLSs at either end of the HMG domain (Kaur and Jans 2011). Nuclear import of SRY via its β-NLS is mediated by Impβ1/RanGTP transport factors of the importin (Imp) superfamily which mediate translocation of the cargo through the nuclear pore complex for subsequent release into the nucleus (see Fig. 4) (Kaur and Jans 2011). Interestingly, Impβ1 binding and nuclear accumulation has been reported to be enhanced by acetylation at residue K136, by the histone acetyl transferase p300, while deacetylation by histone deacetylase 3 (HDAC3) induces relocation of SRY from the nucleus to the cytoplasm (Thevenet et al. 2004).

Nuclear import via the CaM-NLS is mediated in an unconventional manner through direct interaction with the calcium-binding protein calmodulin (CaM), in a Ca^{2+}-dependent and Ran-independent manner (see Fig. 4) (Kaur and Jans 2011); precisely how CaM mediates nuclear import is not known but it seems



Sry, Fig. 4 *Schematic representation of SRY's dual nuclear import pathways; Ca^{2+} as a switch*. SRY possesses dual NLSs; the CaM-NLS mediates nuclear import through interaction with CaM (C) in Ca^{2+}-bound state (*green circle*) and the β-NLS, which mediates nuclear import through binding Impβ1 (β); both CaM and Impβ1 bind SRY in a mutually exclusive manner, presumably through a simple masking mechanism. Cellular signals that increase intracellular Ca^{2+} levels facilitate nuclear import through the CaM-NLS by enabling CaM to bind to SRY, as well as hindering transport through the β-NLS. Under non-stimulated conditions (low intracellular Ca^{2+}), CaM is unable to bind to the CaM-NLS, allowing Impβ1 to bind to the β-NLS to mediate nuclear import. Sex-reversing mutations that specifically inhibit CaM or Impβ1 binding, and hence nuclear import in the presence or absence of elevated intracellular Ca^{2+}, respectively, are delineated (single letter code); all evidence suggests that both NLS-dependent nuclear import pathways are required for male sex determination, so that optimal SRY nuclear import can occur under conditions of both high and low intracellular Ca^{2+}

reasonable to suggest that CaM is an adaptor binding SRY to another molecule that then transports SRY through the nuclear pore. Intriguingly, changes in intracellular Ca^{2+} concentrations may also play a role in modulating nuclear accumulation of SRY through switching between the nuclear import mechanisms, with impaired nuclear import via the β-NLS pathway observed in the presence of increasing Ca^{2+} concentrations (Kaur and Jans 2011). What is clear, however, is that both NLSs are essential for SRY's role in sex determination, since mutations in the β-NLS (R133W) and CaM-NLS (M64T and R76P) that do not affect

DNA binding/bending but result in reduced binding to Impβ1 and CaM, respectively, result in sex reversal (Kaur et al. 2010).

Targets of SRY Action

SRY clearly can act as a transcriptional activator, with *Sox9* being a strong candidate as a direct target of SRY. *Sox9* is strongly upregulated soon after *Sry* expression, with *Sry* positive cells becoming *Sox9* positive cells as well in mouse testis (Sekido and Lovell-Badge 2009). More recently, transgenic mice studies have demonstrated that SRY, acting synergistically with SF1, can induce the upregulation of *Sox9* transcription through a testicular specific enhancer of *Sox9* core (TESCO) situated 14 kb upstream of the *Sox9*'s start codon, with SF1 and SRY found to directly bind multiple elements within TES in vivo (Sekido and Lovell-Badge 2009). Consistent with the idea that *Sox9* is a key target of SRY action, a number of studies indicate that SOX9 can replace SRY function (Sekido and Lovell-Badge 2009). Sex reversal resulting from mutations in *Sox9* has also been described in XY campomelic dysplasia (CD) patients (Sekido and Lovell-Badge 2009).

Recent evidence suggests that SRY mediates testis development by repressing Wnt/β-catenin signaling (see Fig. 1), which is stimulated by a small secreted factor, R-spondin 1 (RSPO1; see Fig. 1). RSPO1 synergizes with Wnt4 to activate ovarian development in XX females, where mutations in *Rspo1* have been found to result in female-to-male sex reversal (Lau and Li 2009). SRY's role appears to be through binding to β-catenin via the HMG-box in the case of hSRY, and the HMG-box and Q-rich domains in the case of mSRY (see Fig. 2) (Sekido and Lovell-Badge 2009). SRY inhibits Wnt/β-catenin signaling in the nucleus at the level of β-catenin, possibly through inducing degradation of β-catenin upon SRY binding, or interfering with β-catenin's ability to transactivate target genes, thus, acting to repress ovarian differentiation and thereby promote male sex development (Lau and Li 2009).

Summary

SRY plays a key role in mammalian sex determination with mutations in *Sry* resulting in sex reversal. Since its discovery several decades ago, slow progress has been made in determining the mechanisms of SRY function. Lack of experimental systems, especially in humans, has limited the study of sex determination to the mouse, with further limitations due to the brief period of expression of *Sry* in a small number of embryonic cells. It is clear however, that upregulation of SOX9 by SRY is a key event in mediating male sex differentiation, with emerging evidence implicating a role for SRY in repressing ovarian development through Wnt/β-catenin. Significantly, the dual nuclear import mechanisms of SRY play a key role in male sex determination, with mutations therein resulting in impaired SRY targeting to the nucleus and sex reversal. Intriguingly, calcium plays a role in switching between the two import mechanisms of SRY to enable efficient SRY nuclear accumulation to be maintained under various physiological conditions. A key to understanding the development of the male sex will be in unraveling the regulation of *Sry* expression in early gonadal development, the dynamic movements of SRY within the cell during its brief period of expression, and the interplay of key sex determining proteins leading to repressed ovarian function and favored testis development.

Historical Background

Steroid hormones have profound effects on physiology and behavior. Most of these biological effects of steroid hormones are mediated through their respective receptors, which are members of the steroid/nuclear receptor superfamily of transcriptional activators. These receptors can act in a classic genomic mechanism by interacting directly with DNA to alter transcription or at the membrane to rapidly activate cytoplasmic signaling pathways (Tetel and Lange 2009). In the classic genomic mechanism of action, nuclear receptor coregulators act to enhance (coactivators) or repress (corepressors) the transcriptional activity of these receptors. While over 300 coactivators have been identified to function in receptor transcription, the role of these coactivators in a wide range of human diseases is becoming better understood (Lonard et al. 2010). This review will focus on the function of the steroid receptor coactivator family as signaling molecules in physiology and behavior and in human disease.

p160 Steroid Receptor Coactivator Family

The steroid receptor coactivator (SRC) family of p160 proteins consists of SRC-1 (NcoA-1), SRC-2 (GRIP1/TIF2/NCoA-2), and SRC-3 (AIB1/TRAM-1/ACTR/RAC3/pCIP). The SRC family and the other nuclear receptor coactivators share a common set of characteristics. The SRC family of coactivators physically interacts with steroid receptors, including receptors for androgens (AR), estrogens (ER), progestins (PR), and glucocorticoids (GR), in a ligand-dependent manner (Johnson and O'Malley 2011). The SRCs physically associate with agonist-bound receptors through centrally located multiple LXXLL motifs (L, leucine; X, any amino acid) that make up nuclear receptor (NR) boxes. The SRCs, as well as other coactivators, do not bind DNA and thus differentiate them from traditional transcription factors. The C-terminus of the SRCs contains two activation domains (AD-1 and AD-2). The N-terminus contains a third activation domain (AD-3) and a bHLH-PAS motif (basic helix loop helix-Per Arnt Sims), which is the most conserved domain within this family of proteins. The activation domains interact with secondary coactivators known as co-coactivators. These co-coactivators act as bridging molecules between the receptor and the general transcription machinery and modify chromatin within the promoter and enhancer regions by histone acetylation and methylation (Johnson and O'Malley 2011).

p160 SRC Family in Physiology

SRC-1

In addition to what is known about the molecular mechanisms of the SRCs from in vitro studies, more is being learned about their role in hormone action in vivo. SRC-1 knockout mice, while fertile, have decreased responsiveness in progestin target tissues (Xu et al. 1998), partial resistance to thyroid hormone (Weiss et al. 1999), and delayed development of cerebellar Purkinje cells (Nishihara et al. 2003). Interestingly, in these mice SRC-2 is up-regulated in steroid-sensitive tissues, including brain and testes, suggesting that increased expression of SRC-2 compensates for the loss of SRC-1 (Xu et al. 1998).

SRC-2

Studies of SRC-2 knockout mice reveal that this coactivator is important in fertility and ductal branching in mammary gland (Fernandez-Valdivia et al. 2007). Disruption of SRC-2 expression in uterine PR-positive cells of $PR^{Cre/+}SRC\text{-}2^{flox/flox}$ mice led to an early block in embryo implantation (Fernandez-Valdivia et al. 2007). Furthermore, removal of SRC-1 in $PR^{Cre/+}SRC\text{-}2^{flox/flox}$ uteri caused a block in decidualization, suggesting that both SRC-1 and SRC-2 are required for complete PR-dependent decidualization. In addition, SRC-2 is important for PR action in mammary gland as demonstrated by the lack of significant branching and alveolar morphogenesis in the $PR^{Cre/+}SRC\text{-}2^{flox/flox}$ mammary gland (Fernandez-Valdivia et al. 2007). Microarray analysis of uteri from SRC-2 null mice reveals that SRC-2 is involved in the ability of progesterone to repress specific genes involved in a variety of functions, including cell cycle and immunity (Jeong et al. 2007).

SRC-3

Female SRC-3 null mice, while fertile, have delayed puberty and longer estrous cycles, ovulate fewer eggs, and have impaired mammary gland development (Han et al. 2006). Studies in SRC-3 null mice reveal that this coactivator is critical for normal PR-dependent mammary gland development and function (Han et al. 2006). Interestingly, gonadotropin-releasing hormone (GnRH) can activate PR-dependent transcription of a reporter gene in a pituitary cell line (An et al. 2006). Knockdown of SRC-3 by siRNA abolishes this effect, suggesting that SRC-3 is required for this GnRH-induced activation of PR (An et al. 2006).

p160 SRC Family in Metabolism and Adipogenesis

SRC-1

All three members of the p160 family of coactivators are involved in metabolic homeostasis and adipogenesis, which increases risk for clinical conditions including cardiovascular disease and diabetes. SRC-1 is critical in maintaining energy balance by regulating both energy intake and expenditure (Louet and O'Malley 2007). In support, SRC-1 knockout mice have decreased energy expenditure and a reduced thermogenic capacity and are, thus, prone to obesity. One proposed mechanism for SRC-1 in metabolism is through its interactions with PPARγ coactivator-1α (PGC-1α), a protein important in the control of mitochondrial biogenesis and oxidative phosphorylation (Louet and O'Malley 2007).

SRC-2

In contrast to SRC-1, SRC-2 knockout mice are leaner compared with wild type mice and have an increase in adaptive thermogenesis (Chopra et al. 2008). It appears that the absence of SRC-2 increases the interaction of SRC-1 with PGC-1α, enhancing thermogenic activity. Thus, it has been proposed that the ratio of SRC-1 and SRC-2 plays a role in maintaining the balance of energy expenditure and adipogenesis through controlling the metabolic activity of PGC-1α. In the liver, SRC-2 acts as a coactivator for the nuclear receptor RORα in the regulation of hepatic G6Pase, an important regulator of glucose production. Ablation of SRC-2 in mice leads to phenotypes of Von Gierke's disease, an inherited glycogen storage disease (Chopra et al. 2008).

SRC-3

SRC-3 knockout mice have lower body fat content compared with wild type animals (Louet and O'Malley 2007). SRC-3 controls the transcription of PPARγ2, important for adipocyte differentiation through enhancing the CAAT enhancer binding protein-β (Chopra et al. 2008). In support, adipocyte

differentiation and adipogenesis were impaired in both mouse embryonic fibroblasts from cells isolated from SRC-3 knockout mice and a knockdown of SRC-3 in 3T3-L1 adipocyte cells (Chopra et al. 2008). However, a knockdown of SRC-1 and SRC-2 had little effect on adipocyte differentiation. Taken together, these studies suggest that all three members of the p160 family of coactivators play an important role in energy homeostasis and adipogenesis.

SRC Family Functions in Brain and Behavior

A variety of recent studies indicate that two of the p160 SRC family members, SRC-1 and SRC-2, are important for hormone action in brain and the regulation of behavior (Tetel et al. 2009).

SRC-1 is expressed at high levels in the hypothalamus, cortex, and hippocampus of rodents (Tetel et al. 2009). Moreover, SRC-1 is expressed in the majority of estradiol-induced PR cells in regions involved in metabolism and female reproduction, including the ventromedial nucleus of the hypothalamus (VMN), medial preoptic area, and arcuate nucleus in rodents (Tognoni et al. 2011). Furthermore, SRC-1 interacts with steroid receptors; recent studies reveal that SRC-1 from brain physically associates with ER and PR in a receptor subtype- and brain region-specific manner (Molenda-Figueira et al. 2008). SRC-1 is critical for normal development of hormone-dependent sexual differentiation of the brain and adult sexual behavior (Auger et al. 2000). In the adult brain, SRC-1 functions in the VMN to modulate ER-mediated transactivation of the behaviorally relevant PR gene (Molenda et al. 2002). In addition, SRC-1 functions in distinct ER- and PR-dependent aspects of female sexual behavior (Molenda-Figueira et al. 2006). Interestingly, reduction of SRC-1 expression in brain by antisense altered PR function and reduced PR-dependent proceptivity (behavior by the female to solicit interaction by the male), but not PR-dependent receptivity (Molenda-Figueira et al. 2006). These findings suggest that reduction of SRC-1 by antisense disrupted the activity of PR signaling pathway(s) that influence(s) proceptivity, while alternate PR signaling pathways, that regulate PR-dependent receptivity, remained intact and functional.

SRC-2 is coexpressed with PR and ERα in rodent hypothalamus and physically associates with these receptors in a hormone-dependent manner (Yore et al. 2010; Tognoni et al. 2011). In further support of a role for SRC-2 in hormone action in brain, SRC-2 functions in estradiol-induction of hypothalamic PR and female sexual behavior in mice and rats (Apostolakis et al. 2002). Interestingly, in contrast to the other members of the SRC family, *SRC-3* is only sparsely expressed in the hypothalamus and does not appear to modulate the expression of reproductive behavior (Apostolakis et al. 2002).

p160 SRC Family in Breast and Prostate Cancer

SRC-1

SRC-1 has been found to be elevated in breast tumors and a strong predictor of breast cancer recurrence and hormone-independent tumors. In vitro studies demonstrate that SRC-1 promotes cancer metastasis through the estrogenic pathway. MCF-7 breast cancer cells over-expressed with SRC-1 have increased expression of estrogen-induced genes and enhanced estrogen-induced cell growth. However, MCF-7 cells treated with antisense against SRC-1 show a decrease in cell proliferation and invasion, as well as a lower level of SDF-1α, a protein that controls cell proliferation through autocrine and paracrine mechanisms (Xu et al. 2009). These findings suggest that SRC-1 increases breast cancer cell proliferation through regulating the SDF-1α pathway.

SRC-1 promotes estrogen-independent breast cancer metastasis through the integrin α5 (ITGA5) signaling pathway. In ER-negative tumors, SRC-1 expression is positively correlated with ITGA5, an important molecule involved in mediating cell adhesion and migration (Qin et al. 2011). In further support of SRC-1 promoting cancer proliferation through an estrogen-independent pathway, ITGA5 promoter activity is enhanced by SRC-1.

In prostate cancer, SRC-1 is correlated with increased tumor aggressiveness and promotes cell proliferation by enhancing AR activation and function (Agoulnik et al. 2006). The phosphorylation of SRC-1 by mitogen-activated protein kinase (MAPK) leads to an increase in AR activity (Suzuki et al. 2003). Reduction of SRC-1 in AR-positive cell lines, but not in AR-negative cell lines, resulted in

decreased tumor proliferation, suggesting the major effect of SRC-1 is through the androgenic pathway.

SRC-2

The role of SRC-2 in oncogenesis remains controversial. While one study reported a correlation of SRC-2 with cyclin D1 in ERα-positive breast tumors, another study found no changes in SRC-2 levels (Xu et al. 2009). However, the over-expression of SRC-2 in MCF-7 breast cancer cells led to a decrease in cell proliferation and invasion and a reduction in the expression of ERα target genes. In prostate cancer, SRC-2 expression correlates with recurrence of the disease. The down-regulation of SRC-2 by antisense reduced expression of AR-induced genes and decreased cell proliferation in both AR-dependent and AR-independent prostate cancer cell lines (Agoulnik et al. 2006).

SRC-3

SRC-3 (aka amplified in breast cancer-1, AIB1) is highly over-expressed in breast cancer and is correlated with ER and PR expression and tumor size (Anzick et al. 1997; Bautista et al. 1998). SRC-3 expression is also correlated with poor clinical prognosis. Breast cancer cells transfected with SRC-3 had enhanced estrogen-dependent transcription, suggesting that SRC-3 promotes tumorigenesis through an estrogenic pathway (Lanz et al. 2010). Several mechanisms have been proposed on how SRC-3 acts to promote cancer growth. SRC-3 regulates E2F1-mediated cell cycle progression and GRB-2 associated binding protein2, which activates the AKT/▶ mTOR pathway and increases cancer growth. SRC-3 has also been shown to activate epidermal growth factor receptor EGFR and ERBB2, resulting in the hyperactivation of Akt and MAPK which contributes to cancer proliferation, growth, and migration (Yan et al. 2008). In further support, Akt signaling is down-regulated in SRC-3 knockout mice. In another study, SRC-3 increased PEA3 and AP-mediated matrix metalloproteinase expression which promote breast and prostate tumor cell metastasis (Yan et al. 2008).

In prostate cancer, SRC-3 is correlated with both tumor stage and poor clinical prognosis (Culig et al. 2004). SRC-3 is involved in the androgenic pathway by acting as a coactivator for AR. However, SRC-3 is also involved in androgen-independent cancer proliferation as the down-regulation of SRC-3 in androgen-insensitive prostate cancer cells also leads to a decrease in proliferation (Zou et al. 2006).

Summary

The p160 family of nuclear receptor coactivators has a critical role in modulating steroid receptor action and thus the appropriate cellular response to steroids. A variety of studies indicate that these coactivators are essential in physiology, including metabolism and adipogenesis. In addition, this family of coactivators functions in brain to regulate important aspects of steroid action and the regulation of behavior. Thus, it is no surprise that alteration of the function of these molecules can contribute to steroid-responsive cancers, such as breast and prostate cancer, in profound ways. The findings reviewed above indicate that each of these members of the p160 family of coactivators can mediate distinct signaling pathways of steroid receptors. Therefore, understanding the recruitment of different coactivator complexes to the promoter, which is likely to be cell- and tissue-specific, will be critical for understanding how hormones regulate complex physiological and behavioral events, as well as hormone-dependent diseases.

Acknowledgments Studies contributed by the author's laboratory were supported by grants from National Science Foundation IBN 0080818 and National Institutes of Health R01 DK61935 (MJT).

Synonyms

PTPN5

Historical Background

Protein tyrosine phosphatases (PTPs) play a significant role in diverse signaling mechanisms ranging from cellular differentiation to synaptic plasticity (Paul and Lombroso 2003; Tonks 2006). *ST*riatal-*E*nriched protein tyrosine *P*hosphatase (STEP) is a brain-specific protein tyrosine phosphatase belonging to the non-receptor tyrosine phosphatase family. Although enriched in the striatum, it is also localized to neurons in the cortex, hippocampus, and related brain regions (Boulanger et al. 1995). Interestingly, it is absent in cerebellum, where a highly related PTP, PTP-STEP-like is present (Watanabe et al. 1998). STEP exists as two major isoforms, named after their mobility in SDS-PAGE and designated $STEP_{61}$ and $STEP_{46}$. These isoforms are produced by alternative splicing of a single *STEP* (*Ptpn5*) gene (Bult et al. 1997). Since its discovery 20 years ago (Lombroso et al. 1991), a series of studies have established a role for STEP in opposing the development of synaptic strengthening in neurons. This occurs through STEP-mediated tyrosine (Tyr) dephosphorylation and inactivation of a number of key signaling molecules and receptors that are required for normal synaptic function (Braithwaite et al. 2006). As will be discussed at length below, disruption of STEP function is implicated in several neuropsychiatric disorders due to this critical regulatory function at synapses.

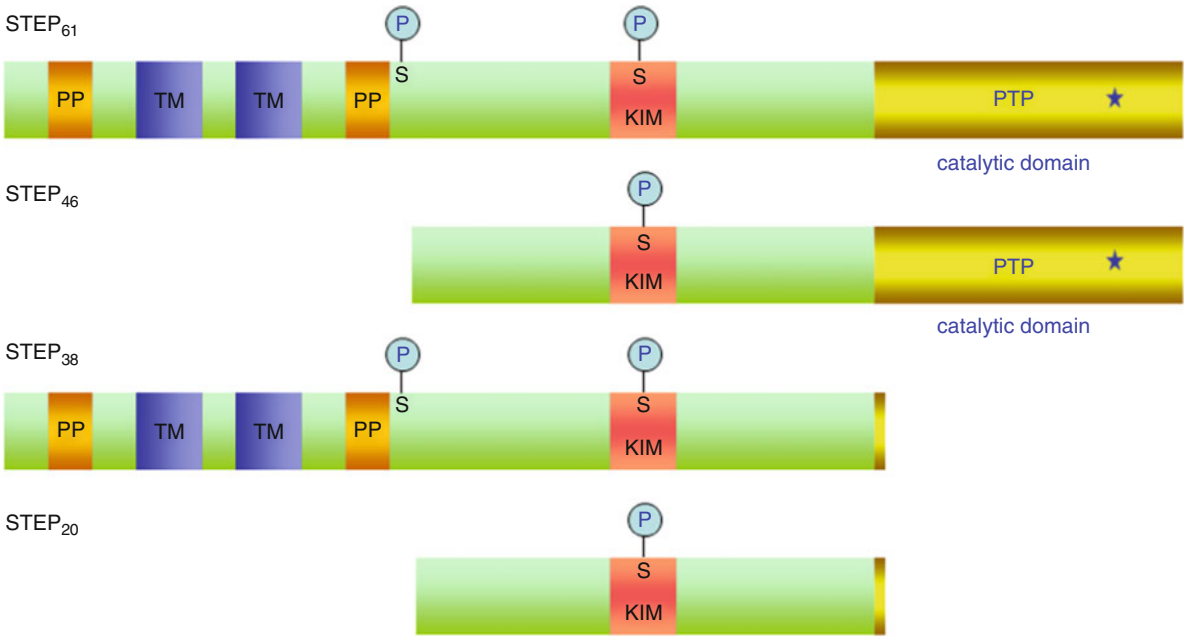
Domain Structure

Like other PTPs, STEP has a highly conserved catalytic domain ([I/V]HCxAGxxR[S/T]G) within the ~280 amino acid phosphatase domain that is present at its C-terminal region. In addition to the catalytic domain, various amino acid motifs exist that are responsible for the interaction of STEP isoforms with diverse signaling proteins (Fig. 1). Both $STEP_{61}$ and $STEP_{46}$ contain a regulatory kinase-interacting motif (KIM) that is required for the interaction of STEP with its substrates that include Fyn tyrosine kinase and two members of the mitogen-activated protein kinase family (MAPK), ERK (extracellular-regulated kinase) and p38 MAPKs (Pulido et al. 1998; Nguyen et al. 2002; Poddar et al. 2010). The KIM domain in STEP has a serine phosphorylation site for protein kinase A (PKA), and phosphorylation of this site sterically prevents the interaction of STEP with its substrates (Paul et al. 2000).

$STEP_{61}$ has an additional 172 amino acids at its N-terminus that consists of two hydrophobic domains, two polyproline-rich regions and PEST sequences. The hydrophobic domains in $STEP_{61}$ are responsible for targeting it to membrane compartments, including the endoplasmic reticulum and postsynaptic density (PSD) (Lombroso et al. 1993; Boulanger et al. 1995; Oyama et al. 1995). One of the polyproline-rich domains is necessary for the interaction of $STEP_{61}$ with its substrate Fyn (Nguyen et al. 2002). The PEST sequences in $STEP_{61}$ serve as potential signals for proteolytic cleavage sites under certain physiological conditions (Nguyen et al. 1999). Two additional isoforms of STEP are reported ($STEP_{38}$ and $STEP_{20}$), which are produced by alternative splicing and lack a catalytic domain (Sharma et al. 1995). The exact functions of these isoforms are not known, but they may act as dominant-negative isoforms to protect STEP substrates from dephosphorylation while trafficking within neurons and future studies are needed to address the role of these family members.

Regulation of STEP

STEP activity is modulated by phosphorylation, local translation, proteolytic cleavage, ubiquitination, and oligomerization (Fig. 2). Alterations in STEP activity



Striatal-Enriched Protein Tyrosine Phosphatase (STEP), Fig. 1 *Domain structure of STEP*. Alternative splicing of STEP gene produces four STEP isoforms, $STEP_{61}$, $STEP_{46}$, $STEP_{38}$, and $STEP_{20}$. $STEP_{61}$ contains two transmembrane (TM) domains and two polyproline-rich sequences (PP) in the N-terminal 172 region, whereas $STEP_{46}$ lacks this region. Both $STEP_{46}$ and $STEP_{61}$ share the binding site for ERK, the kinase-interacting motif (KIM), and the PTP catalytic domain, which contains an 11-amino-acid catalytic site (*asterisks*). $STEP_{61}$ has two serine residues that are phosphorylated by PKA (S), whereas $STEP_{46}$ contains one PKA site, within the KIM domain. $STEP_{38}$ and $STEP_{20}$ are catalytically inactive, due to the absence of PTP domain and possibly function as dominant-negative variants toward active STEP

by these mechanisms have a significant impact on normal synaptic function as well as various disease states, and these are discussed next.

Phosphorylation

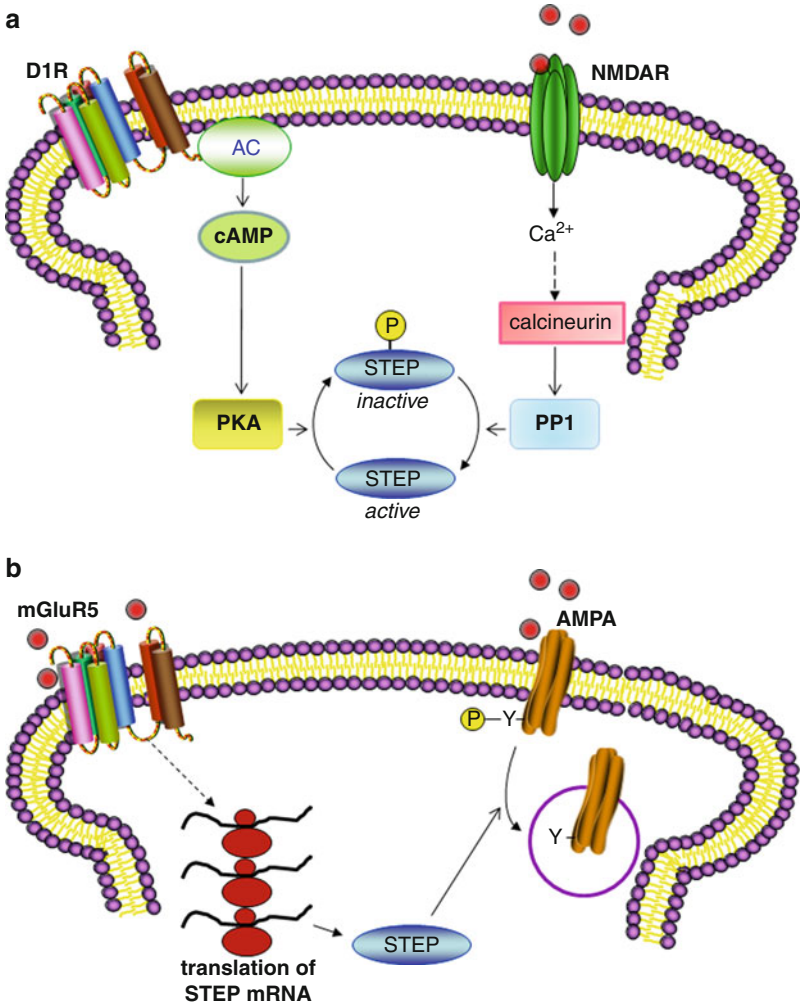
Phosphorylation is an important posttranslational modification that regulates numerous intracellular signaling pathways. Both $STEP_{61}$ and $STEP_{46}$ are phosphorylated by protein kinase A (PKA). Dopamine (DA)-mediated D1 receptor (D1R) stimulation leads to activation of adenyl cyclase and increases in intracellular cAMP levels and PKA activity. PKA phosphorylates both $STEP_{61}$ and $STEP_{46}$ at a conserved serine residue within the KIM domain (ser^{49} in $STEP_{46}$ equivalent to ser^{221} in $STEP_{61}$). $STEP_{61}$ is also phosphorylated by PKA at an additional site (ser^{160}) in its unique N-terminal domain (Paul et al. 2000). Phosphorylation of the serine residue within the KIM domain renders STEP inactive in terms of its ability to bind to its substrates. Additional studies have also shown that psychostimulants such as amphetamine inactivate STEP by promoting a DA/D1R/cAMP/PKA-mediated phosphorylation of this residue, as well as inhibiting dephosphorylation of STEP by PP1 through the PKA activation of ▶ DARPP-32 (Valjent et al. 2005).

In contrast, glutamate-mediated stimulation of GluN2B-containing *N*-methyl-D-aspartate receptors (NMDARs), subsequent influx of Ca^{2+}, and activation of the calcium-dependent phosphatase calcineurin (PP2B) lead to dephosphorylation of the serine residue within the KIM domain. Dephosphorylation of this residue allows STEP to bind to its substrate (Paul et al. 2003; Paul and Connor 2010). Beta-amyloid (Aβ), the peptide implicated in Alzheimer's disease (AD), has also been shown to modulate the activity of STEP through calcineurin/PP1-mediated dephosphorylation of this residue. Active STEP, in turn, leads to tyrosine dephosphorylation and subsequent internalization of functional NMDARs (Snyder et al. 2005). Impairment of NMDA receptor trafficking plays a role in the pathogenesis of AD and suggests

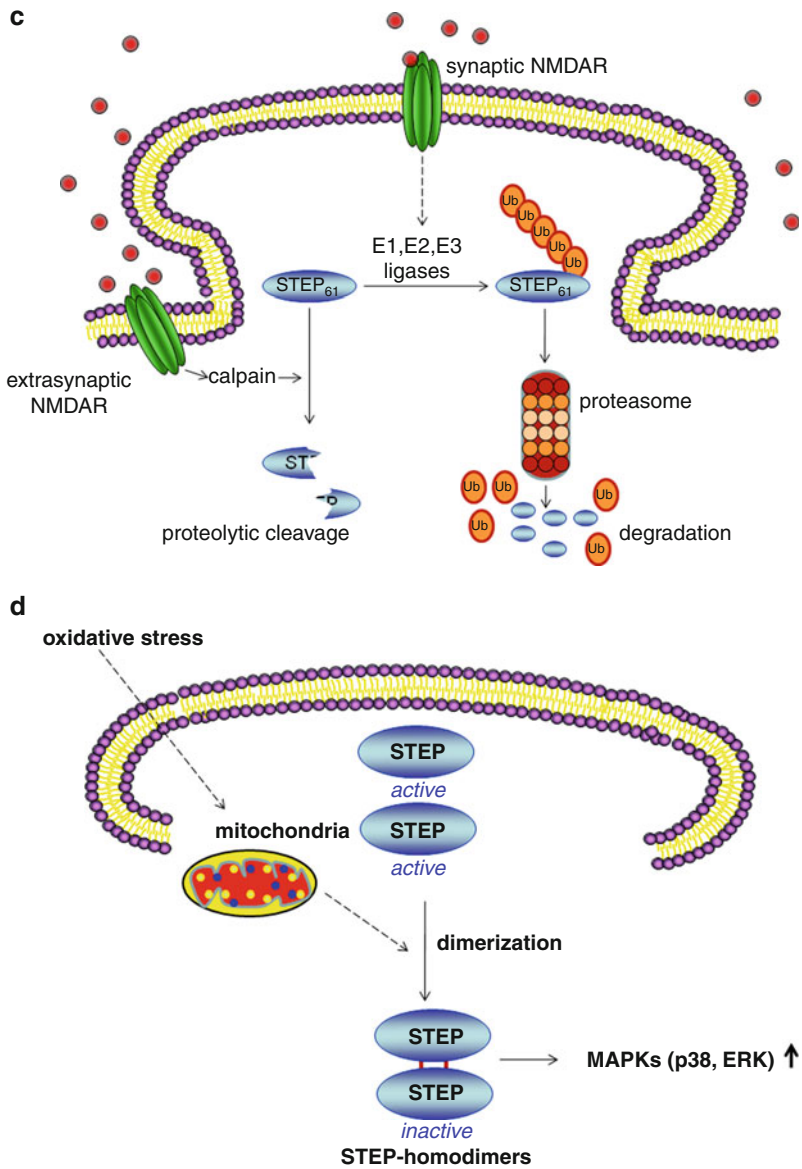
a role of STEP in AD-related dementia (Kurup et al. 2010a). The role of phosphorylation of ser^{160} in $STEP_{61}$ remains unknown, although its proximity to a PEST sequence suggests that it may play a role in the degradation of $STEP_{61}$ through either ubiquitination or proteolysis, as will be discussed further below.

Local Translation

Local translation is a process by which specific mRNA transcripts are translated at distant dendritic sites upon synaptic activity (Wang et al. 2010). This mechanism helps to remodel spines to either strengthen or weaken synaptic connections, depending on incoming synaptic stimuli. For local translation to occur, mRNA transcripts are transported along dendrites and kept in a repressed state by inhibitory RNA-binding proteins. Upon synaptic stimuli, the repression is removed and the message is translated. STEP mRNA is present in synaptoneurosomal fractions and is translated upon group I metabotropic glutamate receptor 5 (mGluR5) stimulation (Zhang et al. 2008). mGluR signaling is involved in long-term depression (LTD) and mGluR-dependent translation has been implicated in several disorders including fragile X syndrome (Waung and Huber 2009). STEP translation regulates AMPAR trafficking during mGluR-dependent LTD. In STEP knock out (KO) cultures, mGluR stimulation with the agonist DHPG failed to induce AMPAR endocytosis. Moreover, at baseline, STEP KO mice show increased surface AMPARs subunits (GluA1 and GluA2)



Striatal-Enriched Protein Tyrosine Phosphatase (STEP), Fig. 2 (continued)



Striatal-Enriched Protein Tyrosine Phosphatase (STEP), Fig. 2 *Regulation of STEP at synapse*. (**a**) *Phosphorylation*: Dopamine receptor (D1) stimulation leads to activation of PKA by adenyl cyclase/cAMP pathway, which results in phosphorylation of a regulatory serine within the KIM domain, resulting in inactivation of STEP. Glutamate stimulation reverses the KIM domain phosphorylation of STEP by activating the phosphatase calcineurin/PP1 pathway through NMDAR calcium influx. Thus, STEP is activated by a PKA/PP2B/PP1-mediated mechanism. (**b**) *Local translation*: mGluR5 activation by the agonist (DHPG) leads to local translation of STEP mRNA. STEP dephosphorylates a regulatory tyrosine residue (s) of the GluA2 subunit of AMPA receptor that results in increased internalization of AMPA receptor subunits from the neuronal surface. (**c**) *Ubiquitin-proteasome system (UPS) and proteolytic cleavage*: Synaptic NMDAR activation recruits ubiquitin enzymes and addition of ubiquitin molecules to $STEP_{61}$, which eventually leads to degradation of $STEP_{61}$ by the proteasome. Stimulation of extrasynaptic NMDARs activate calpain, which proteolytically cleaves STEP within the KIM domain to form a lower molecular weight $STEP_{33}$ isoform that is unable to bind to STEP substrates. (**d**) *Oligomerization*: Oxidative stress induced by H_2O_2 inactivates $STEP_{61}$ catalytic activity by homodimerization. This results in increased activation of MAPK signaling molecules, such as p38 and ERK

(Zhang et al. 2008). These studies suggest that local translation of STEP is required for AMPAR internalization during mGluR-dependent LTD. There are several potential Tyr residues at the carboxy-terminus of GluA2, but whether STEP directly dephosphorylates one or more of these residues to induce endocytosis of GluA1/GluA2 receptor complexes is under investigation.

Ubiquitination

Ubiquitination and subsequent degradation of cellular proteins by the ubiquitin-proteasome system (UPS) plays a role in the development of synaptic plasticity (Yi and Ehlers 2007). Local degradation of proteins at the synapse increases the efficacy of synaptic signaling in specific regions of the spine and permits spine remodeling (Haas and Broadie 2008). The degradation of STEP is differentially regulated by synaptic and extrasynaptic NMDARs (Xu et al. 2009). Synaptic and extrasynaptic NMDARs are differentially localized in the neuron (Goebel-Goody et al. 2009), and activate distinct signaling pathways (Hardingham and Bading 2003). Synaptic NMDAR stimulation preferentially activates pERK signaling and promotes neuronal survival pathways, whereas stimulation of extrasynaptic NMDARs activates p-p38 signaling and initiates the cell-death pathways (Hardingham et al. 2002). The UPS degrades STEP after synaptic NMDAR stimulation, whereas STEP is proteolytically cleaved by calpain after extrasynaptic stimulation. In both cases, STEP is removed from synaptic sites and is no longer able to dephosphorylate its substrates (Xu et al. 2009).

In primary neuronal cultures, proteasome inhibitor treatment results in an increase of $STEP_{61}$ levels (Kurup et al. 2010a). The increase in $STEP_{61}$ is insensitive to transcription or translation inhibitors. Moreover, accumulation of STEP-ubiquitin conjugates is observed in $STEP_{61}$-transfected HEK cells, as well as in mouse brain tissues. In several different AD mouse models, $STEP_{61}$ levels are elevated due to inhibition of the proteasome system by beta-amyloid oligomers. This results in the accumulation of active $STEP_{61}$, which subsequently reduces surface NMDAR levels (Kurup et al. 2010a). More details on the role of STEP in Alzheimer's disease are presented in a separate section below. In summary, UPS-mediated degradation regulates many proteins involved in synaptic plasticity, including STEP, and this process is dysregulated in various CNS disorders.

Proteolytic Cleavage

Proteolytic cleavage is another mechanism by which signaling proteins are either activated or inactivated during synaptic signaling (Bingol and Sheng 2011). Exposure to high levels of glutamate leads to overactivation of NMDARs primarily at extrasynaptic sites and influx of Ca^{2+}, which activates a number of proteases including calpain (Doshi and Lynch 2009). Calpain is a Ca^{2+}-dependent cysteine protease that cleaves $STEP_{61}$ to release a lower MW isoform $STEP_{33}$ during excitotoxic conditions. Cleavage occurs within the KIM domain to produce $STEP_{33}$, which no longer has an intact substrate-binding site, and can no longer associate with STEP substrates (Xu et al. 2009).

Recent studies have shed light on how extrasynaptic NMDAR stimulation can couple to neuronal cell-death pathways through a STEP-regulated activation of the MAPK family member, p38. STEP dephosphorylates a tyrosine residue in the activation loop of p38 and thereby blocks p38-mediated signaling (Poddar et al. 2010). Calpain cleavage of $STEP_{61}$ produces the truncated isoform $STEP_{33}$ that no longer inactivates p38, and results in sustained activation of p38 and cell-death pathways. Blocking STEP cleavage by a competition peptide corresponding to the calpain cleavage site protected cortical cultures from glutamate-mediated excitotoxicity, as well as cortical slices from neuronal death after oxygen-glucose deprivation (Xu et al. 2009). In summary, this study addresses the mechanisms by which STEP exerts a neuroprotective role or promotes cell-death pathways depending on the type of NMDAR stimulation that occurs.

Oligomerization

Dimerization is a well-known regulatory mechanism for transmembrane proteins that includes tyrosine phosphatases (den Hertog et al. 2008). A recent study showed that homo dimerization of $STEP_{61}$ is readily detectable under basal condition in hippocampus, cortex, as well as cultured neurons (Deb et al. 2011). Dimerization of $STEP_{61}$ involves intermolecular disulfide bond formation between two cysteine residues

present in the hydrophobic region at the N-terminus and involves a domain that is not conserved among tyrosine phosphatases. Oxidative stress leads to increase in dimerization and higher order oligomer formation of $STEP_{61}$ resulting in reduced phosphatase activity. $STEP_{46}$ does not form dimers under basal condition, but does following oxidative stress, resulting in subsequent loss of activity. The precise implication of oxidative stress–induced oligomerization of STEP in neurons is not well understood. However, a concomitant increase in the phosphorylation of ERK MAPK, a physiological substrate of STEP, was observed in neurons treated with hydrogen peroxide, suggesting the inability of oligomerized STEP to inactivate it. Consistent with these findings, several studies have suggested a role of ERK and p38 MAPKs in oxidative stress–induced neurodegeneration (Choi et al. 2004; Stanciu et al. 2000). Taken together, these findings suggest that inactivation of STEP through oligomerization could play a role in the initiation of neuronal degeneration by promoting chronic activation of ERK and p38 MAPK that eventually leads to activation of pro-apoptotic pathways.

STEP Substrates

Mitogen-Activated Protein Kinases (MAPKs)

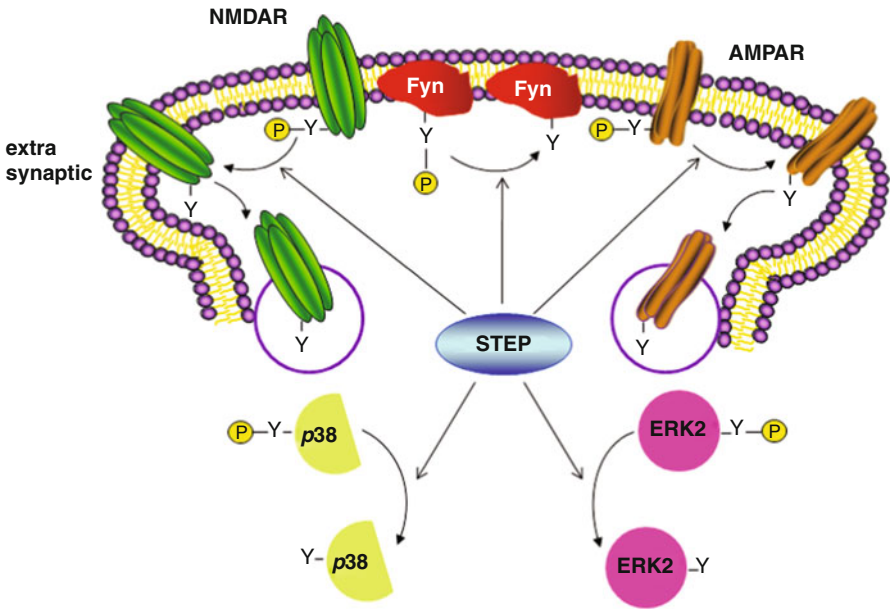
MAPKs play an important role in transducing extracellular signals to intracellular targets (Keshet and Seger 2010). ERK1/2 and p38 are members of the MAPK family and are phosphorylated and activated by their respective MEKs in cells. MEK is a dual specificity kinase that phosphorylates at tyrosine and threonine/serine residues. ERK1/2 are widely expressed protein kinases whose functions include the development of synaptic plasticity, regulation of transcription and translation, and the consolidation of long-term memory (Sweatt 2001). Many different stimuli, including growth factors and ligands for heterotrimeric G protein–coupled receptors, activate the ERK1/2 pro-survival pathways, while p38 MAPK responds to stress stimuli and its activation initiates cell-death pathways.

ERK1/2: ERK1 and ERK2 are substrates of STEP (Paul et al. 2003; Munoz et al. 2003). Most of the studies on STEP and ERK were carried out with ERK2 isoform, so the contribution focuses on this isoform. Activated ERK2 strengthens synaptic plasticity by promoting local translation of proteins, initiating gene transcription, neurotransmitter release, and spine reorganization (Sweatt 2001). Both $STEP_{61}$ and $STEP_{46}$ dephosphorylate a regulatory tyrosine residue (Tyr^{204}) in ERK2, thereby inactivating it. Thus, STEP regulates the duration of ERK2 signaling in neurons (Paul et al. 2003). STEP interacts with ERK through its KIM domain, and PKA phosphorylation of STEP prevents this interaction and prolongs ERK activity in neurons. In STEP KO brain tissues (e.g., striatum, hippocampus, amygdala), activated pERK1/2 levels are significantly increased. In comparison to wild-type neuronal cultures, STEP KO neuronal cultures show exaggerated activation of active ERK after group I metabotrophic glutamate receptor (mGluR) stimulation with DHPG (Venkitaramani et al. 2009).

Activated ERK2 is required for memory consolidation. The inactivation of ERK2 opposes this process and a role for STEP was demonstrated in Pavlovian fear conditioning learning in rats (Paul et al. 2007). Infusion of a substrate-trapping mutant of STEP, which binds to ERK2 and does not release it, blocked translocation of ERK2 to the nucleus and prevented consolidation of fear conditioning learning. These results support a role of STEP in normally opposing long-term memory formation.

Recent studies have indicated that subunits of NMDARs can differentially regulate ERK2 activation. The activation of NMDARs leads to a rapid influx of calcium and transient activation of ERK initially, which is dependent on GluN2A-containing receptors. In contrast, delayed calcium influx through GluN2B-containing receptors results in inactivation of ERK2 through activation of the calcineurin/PP1 pathway and dephosphorylation of STEP (Paul and Connor 2010).

p38: Both $STEP_{46}$ and $STEP_{61}$ isoforms bind p38 and inactivate it. The contribution of STEP in p38-mediated cell death was discussed above. In summary, glutamate stress or physiological stress induced by oxygen-glucose deprivation induces p38 activation. This is due in part to calpain-mediated cleavage of STEP to its lower MW inactive isoform $STEP_{33}$, which no longer dephosphorylates p38 and results in activation of cell-death pathways (Xu et al. 2009). Taken together with the earlier ERK studies, these findings point to the important role of STEP in regulating MAPKs in the development of both synaptic plasticity as well as activation of neuronal cell-death pathways.



Striatal-Enriched Protein Tyrosine Phosphatase (STEP), Fig. 3 *STEP substrates*. Active STEP dephosphorylates critical tyrosine residues in its substrates (Tyr^{182} of p38, Tyr^{204} of ERK) to inactivate them. Active Fyn phosphorylates Tyr^{1472} residue in GluN2B and facilitates the exocytosis of NMDARs to the neuronal surfaces. STEP dephosphorylates Tyr^{420} of Fyn and inactivates it, thereby opposing surface expression of NMDARs. STEP also directly dephosphorylates Tyr^{1472} residue of the GluN2B subunit to internalize surface GluA1/GluA2B. STEP also dephosphorylates unidentified tyrosine residue(s) in the GluA2 subunit of AMPARs that promotes internalization of surface AMPAR

NMDARs

Glutamate receptors are required for the development of synaptic plasticity and consolidation of long-term memories (Peng et al. 2011). NMDARs are ligand-gated ionotrophic channels, and are named for the selective agonist that binds to NMDARs but not to other glutamate receptors. A unique property of the NMDAR is its voltage-dependent activation, a result of ion channel block by extracellular Mg^{2+} ions. The NMDARs forms a heterotetramer between two GluN1 and two GluN2 subunits (Paoletti and Neyton 2007). The surface expression of NMDARs is regulated by various kinases and phosphatases during long-term potentiation (LTP). LTP-inducing stimuli promote trafficking of GluN1/GluN2B complexes to neuronal surfaces (Grosshans et al. 2002) and activate a number of proteins required for synaptic strengthening.

Dysregulation of NMDAR trafficking is found in several neuropsychiatric diseases, including Alzheimer's disease and schizophrenia (Lau and Zukin 2007). STEP directly binds to GluN1 subunit of the NMDAR complex and inhibits high-frequency stimulation (HFS)-LTP (Pelkey et al. 2002). Moreover, trafficking of GluN1/GluN2B complex to neuronal surfaces is regulated by STEP (Snyder et al. 2005; Braithwaite et al. 2006; Zhang et al. 2010). STEP directly dephosphorylates Tyr^{1472} (Y^{1472}) in the GluN2B subunit, leading eventually to clathrin-mediated internalization of GluN1/GluN2B (Roche et al. 2001; Snyder et al. 2005; Braithwaite et al. 2006).

Fyn

Fyn is a member of the Src family of non-receptor tyrosine kinases. Fyn phosphorylates tyrosine residues on multiple targets to initiate several signaling pathways. Fyn is activated by auto-phosphorylation of its tyrosine residue (Y^{420}) to generate a binding site that recruits other signaling molecules. Conversely, $STEP_{61}$ inactivates Fyn by binding to it via the proline-rich domain present in $STEP_{61}$ and by dephosphorylating Tyr^{420} (Nguyen et al. 2002). Fyn regulates NMDAR trafficking by directly phosphorylating Tyr (Y^{1472}) on the GluN2B subunit (Nakazawa et al. 2001; Dunah et al. 2004). STEP thereby opposes the surface expression of GluN2B-containing NMDARs in two ways: by decreasing Fyn-mediated phosphorylation of Tyr^{1472} and by

directly dephosphorylating the GluN2B subunit at Y^{1472} (Braithwaite et al. 2006; Baum et al. 2010). See Fig. 3 for list of STEP substrates.

STEP Knockout Mice

The current model of STEP function is that it opposes synaptic strengthening and memory consolidation by inactivating a number of synaptic proteins. A prediction of this hypothesis would therefore be that loss of STEP might facilitate learning and memory in certain cognitive tasks. STEP KO mice were generated using a target vector to replace 1.3 kb genomic region containing the phosphatase domain with the neomycin gene in ES cells by homologous recombination (Venkitaramani et al. 2009). STEP KO mice are viable, fertile, and with no obvious phenotypic abnormalities, suggesting that STEP is not essential for embryonic or postnatal survival. Biochemically, STEP KO progeny show no expression of STEP, but have increased tyrosine phosphorylation of STEP substrates. STEP KOs have increased synaptosomal membrane expression of glutamate receptors, including both NMDARs (Zhang et al. 2010) and AMPARs (Zhang et al. 2008), confirming the critical role STEP plays in the regulation of glutamate receptor trafficking.

Recent studies with STEP KO mice have clarified the role of STEP on hippocampal-dependent learning and memory (Venkitaramani et al. 2011). When subjected to the Morris water maze and radial arm maze, STEP KO mice show enhanced cognitive flexibility and fewer working memory errors than wild-type (WT) littermates. STEP KO mice show improved performance in these tasks, correlating with enhanced tyrosine phosphorylation of ERK1/2, the GluN2B subunit of the NMDAR, as well as increased phosphorylation of the transcription factors CREB and Elk-1 downstream of ERK1/2 activation (Venkitaramani et al. 2011). These findings suggest a role for STEP in negatively regulating hippocampal-dependent memory.

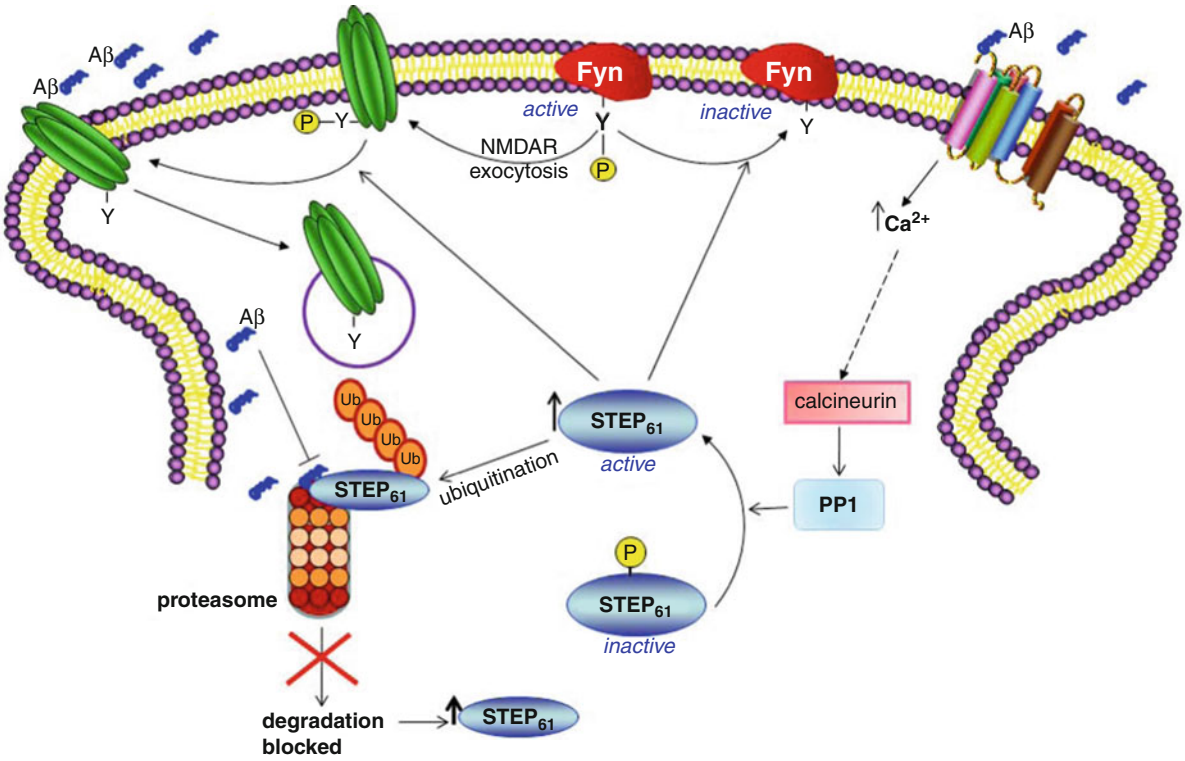
Diseases

Alzheimer's Disease

Alzheimer's is the most common neurodegenerative disorder associated with loss of memory and other cognitive symptoms. A hallmark of AD is the accumulation of beta-amyloid (Aβ) peptide in brains, a process that has been implicated in the progression of the disease (Selkoe 2002). Aβ peptides are formed from amyloid precursor protein (APP) by the sequential cleavage of β- and γ-secreteases (Turner et al. 2003). APP overexpressing transgenic mouse models mimic some, but not all, of the biochemical and behavioral defects observed in AD (Elder et al. 2010). These models have been used in efforts to uncover the molecular basis and pathophysiology of AD.

STEP has recently been shown to play a role in the etiology of AD. STEP levels are elevated in the brains of human AD as well as in several mouse AD models (Chin et al. 2005; Kurup et al. 2010a). Elevated STEP levels were associated with increased internalization of surface NMDARs (Snyder et al. 2005; Kurup et al. 2010a) and AMPARs (Zhang et al., submitted). An earlier study found that Aβ leads to activation of STEP through a calcineurin/PP1-mediated dephosphorylation of STEP. Aβ directly bound to α7 nicotinic acetylcholine receptor (α7nAChR) on neuronal surface, leading to calcium influx and activation of calcineurin and PP1. This pathway dephosphorylates STEP at the regulatory KIM domain serine residue and activates STEP. STEP is now able to dephosphorylate its substrates. STEP dephosphorylates Y^{1472} of GluN2B and causes internalization of GluN1/GluN2B receptor complexes. This study also showed the effect of Aβ was blocked by transducing a dominant-negative STEP, which competes for endogenous STEP binding to GluN2B. This model was confirmed using STEP KO neuronal cultures in which Aβ failed to induce NMDAR endocytosis, and internalization was rescued after the addition of membrane-permeable active STEP protein back into the cultures prior to Aβ treatment (Kurup et al. 2010b).

A recent study established a second mechanism by which STEP levels are elevated in AD (Kurup et al. 2010a). STEP is normally degraded by the ubiquitin proteasomal system (UPS). In human AD brains, proteasomal activity is decreased and associates with an accumulation of ubiquitin-immunoreactive inclusion bodies (Lam et al. 2000; Mori et al. 1987). Aβ peptide inhibits proteasome activity, which leads to the accumulation of numerous proteins normally degraded by the UPS. Treatment of cortical cultures with Aβ-enriched medium (7PA2-conditioned medium) results in an increase in $STEP_{61}$ levels, which is insensitive to translational or transcriptional inhibitors. $STEP_{61}$ and $STEP_{61}$ ubiquitin conjugates are increased upon Aβ



Striatal-Enriched Protein Tyrosine Phosphatase (STEP), Fig. 4 *Regulation of STEP in Alzheimer's disease*. STEP levels and activity are regulated by amyloid beta (Aβ) peptide. Aβ binds to the α7 nicotinic acetylcholine receptor (α7nAChR), which results in calcium influx and activation of calcineurin and PP1. This pathway dephosphorylates STEP at the regulatory KIM domain serine residue and activates STEP. Active STEP then dephosphorylates GluN2B at Tyr^{1472} and causes the internalization of GluN1/GluN2B receptor complexes from neuronal surfaces. In addition, STEP inactivates Fyn and blocks exocytosis of NMDARs to the neuronal surface. Aβ peptide also inhibits proteasome activity to block normal degradation of STEP. This leads to an increase in active STEP levels in the presence of Aβ and internalization of NMDA receptors. Thus, Aβ surface expression of NMDARs by two parallel pathways that involve STEP

treatment, suggesting that there is a blockade in proteasomal degradation and clearance of ubiquitinated proteins. These observations were confirmed in an AD mouse model (Tg2576 mouse), which show progressive increases in $STEP_{61}$ levels and $STEP_{61}$-ubiquitin conjugates in the cortex over the first year of life that correlates with an increase in Aβ levels and a decrease in surface glutamate receptor levels. Taken together, these studies indicate that Aβ regulates STEP through two pathways (Fig. 4): (1) by favoring calcineurin/PP1-mediated dephosphorylation and activation of STEP, and (2) by blocking the proteasome-mediated degradation of $STEP_{61}$, thereby accumulating active $STEP_{61}$.

The aforementioned studies demonstrate a role for $STEP_{61}$ in AD and suggest that genetic reduction of STEP might rescue the cognitive defects in AD mouse models. This hypothesis was tested by crossing a well-established AD model (triple transgenic mice; 3xTg-AD) with STEP KO mice to obtain progeny with elevated Aβ levels but null for STEP (double mutant; DM). Characterization of DM mice using several behavioral tests indicates significantly improved cognitive performance in spatial and nonspatial hippocampal-dependent memory tasks compared to 3xTg-AD. These behavioral improvements in DM mice are associated with increase in surface levels of NMDAR subunits (GluN1/GluN2B), increase in active ERK (pERK) and active Fyn (pY^{420} Fyn) (Zhang et al. 2010). As discussed earlier, both ERK and Fyn are STEP substrates. ERK mediates synaptic strengthening in part via regulating gene expression and local translation, while Fyn directly phosphorylates GluN2B at Y^{1472} and promotes increased surface expression of NMDARs. Thus, loss of STEP restores cognitive function in the 3xTg-AD mouse model by increasing tyrosine phosphorylation of its substrates and by favoring glutamate receptor surface expression.

Status Epileptics

Status epilepticus (SE) is a severe condition consisting of a prolonged seizure. SE often leads to long-lasting changes in hippocampal synaptic physiology that results in the development of temporal lobe epilepsy. A prominent feature of SE is the reduction of GABAergic hippocampal interneurons. A recent study demonstrates that STEP is highly expressed in hilar somatostatin-sensitive interneurons. Moreover, the abundance of STEP in these neurons renders them more vulnerable to SE-induced cell death by opposing ERK/MAPK activation. Activation of the ERK/MAPK cascade leads to expression of neuroprotective factors, whereas high expression of STEP in these interneurons suppresses ERK/MAPK-mediated neuroprotective responses. Accordingly, blocking calcineurin/PP1-mediated activation of STEP using the calcineurin inhibitor (FK506) rescues cell death in the pilicarpine-induced SE model (Choi et al. 2007). These findings suggest that a reduction of STEP in these interneurons might increase their resistance to pilicarpine-induced SE. A follow-up study extended these findings in the STEP KO model. STEP KO mice display a higher seizure threshold for the development of pilicarpine-induced SE compared to WT littermates (Briggs et al. 2011). This inherent property is due to increased excitation of inhibitory hilar neurons and reduced excitation of dentate gyrus granular cells. Enhanced inhibitory input to granule cell neurons in STEP KOs compared to WT increases their resistance to the development of seizures. These data suggest that targeted inhibition of STEP in hilar interneurons region may prove beneficial for the treatment of seizure disorders.

Summary

STEP is a non-receptor tyrosine phosphatase uniquely expressed in the brain. It plays a significant role in synaptic plasticity by regulating MAPK signaling and glutamate receptor trafficking. Several STEP substrates have been identified that include ERK1/2, p38, Fyn, and GluN2B. STEP dephosphorylates these substrates and thereby opposes the development of synaptic plasticity and the consolidation of long-term memories. STEP activity is regulated by PKA-mediated KIM domain phosphorylation, local translation, degradation by the ubiquitin-proteasome system, and by proteolytic cleavage. Excessive STEP levels and activity is implicated in a number of disorders, including Alzheimer's disease. STEP levels are increased in AD mouse models and human AD patients. Genetically reducing STEP levels in an AD mouse model rescues the biochemical and cognitive deficits associated with AD. In addition, recent studies on STEP show a potential role in epilepsy. Overall, these studies suggest that small molecule inhibitors of STEP might have therapeutic potential for the treatment of these disorders.

CD87; PLAUR; uPA Receptor; uPAR; Urokinase-type plasminogen activator receptor

Historical Background

The receptor (uPAR) for the urokinase-type plasminogen activator (uPA) was firstly identified in 1985 on the surface of monocyte-like cells but only in 1990 uPAR protein was purified and cDNA cloned and sequenced. The first role proposed for uPAR was the focusing of the uPA proteolytic activity on the cell membrane, thus allowing cell migration through the extracellular matrix (ECM), without affecting the general architecture of the tissue. Since then, a large body of evidence clearly showed various roles for uPAR, independent of uPA enzymatic activity. In fact, uPAR is able to transduce proliferation, differentiation, adhesion, and migration signals into the cells, despite the absence of a transmembrane region and a cytosolic tail. However, the ability of uPAR to focus uPA activity on the cell membrane attributed to this specific receptor a key role in the plasminogen activation system.

Plasminogen is a plasma zymogen; the cleavage at the Arg_{561}-Val_{562} bond converts the single polypeptide chain plasminogen into plasmin, that consists of two polypeptide chains held together by a disulfide bond. Plasminogen can associate to fibrin via lysine-binding sites located in the noncatalytic region. In fact, the primary in vivo function of plasminogen/plasmin is to regulate fibrinolysis, i.e., the process wherein the fibrin clot, end product of the coagulation process, is degraded. However, plasminogen/plasmin ability to bind low-affinity cellular receptors and to degrade extracellular matrix (ECM) proteins indicated a crucial role for plasmin in other processes involving protein degradation, in particular in cell migration, an important event occurring in various physiologic and pathologic processes, such as embryogenesis, wound healing, angiogenesis, and tumor cell dissemination (Castellino and Ploplis 2005).

Plasminogen can be activated by different proteases, but its specific physiologic activators are the tissue-type (tPA) and the urokinase-type (uPA) plasminogen activators. Both serine-proteases are secreted as single chains and are activated by a single cleavage, that yields two chains held together by a disulfide bond.

tPA is mainly involved in fibrinolysis since it binds fibrin with high affinity. The assembly of fibrinolytic components, plasminogen and tPA, at the surface of fibrin results in efficient fibrin degradation (Rijken and Lijnen 2009). uPA, which lacks fibrin-binding sites but

is able to bind cellular receptors, is instead mainly involved in processes including cell migration and tissue invasion, such as inflammation, angiogenesis, and tumor invasion (Irigoyen et al. 1999).

The plasminogen activation system represents a very efficient proteolytic machinery, thus its activity must be strictly regulated. The primary plasmin inhibitor is the alfa2-antiplasmin; the most efficient inhibitor of plasminogen activators (PAs) is the type-1 inhibitor (PAI-1) (Balsara and Ploplis 2008). The other specific PA inhibitor is the type-2 inhibitor (PAI-2); its lower inhibitory efficiency, as compared to PAI-1, and the intracellular detection of PAI-2 nonglycosylated forms suggested a regulatory role for PAI-2 in the activity of enzymes other than uPA (Medcalf and Stasinopoulos 2005).

Plasminogen, tPA, and uPA can bind cellular receptors. Binding to cellular receptors represents another crucial regulatory step, since focusing enzymes and substrates on the cell surface strongly enhances the proteolytic cascade. Plasminogen binds in a lysine- and/or carbohydrate-dependent manner to the cell surface, with low affinity but high capacity. Cell-bound plasmin is protected from its natural inhibitors, since both receptors and inhibitors utilize plasminogen/plasmin C-terminal lysines. Different cellular binding sites for tPA have been described.

uPA binds a specific high-affinity cell-anchored receptor, the urokinase-type plasminogen activator receptor (uPAR), which, in the last decades, has been largely characterized in its expression, structure, and function.

uPAR Expression

The human uPAR gene is located on the long arm of chromosome 19 (19q13) and contains seven exons and six introns extending over 23 kb of genomic DNA. This region lacks TATA and CAAT boxes and contains GC-rich sequences and consensus elements for SP1, AP1, AP2, NF-k B, and the Kruppel-like transcription factor, which have been reported to drive uPAR transcription.

uPAR expression can be regulated also at a posttranscriptional level. In fact, several sequence elements regulating uPAR mRNA decay have been identified throughout the transcript. These sequences are present both in the coding and in the 3′ untranslated region (UTR) of the uPAR transcript and are able to bind proteins that promote stability or degradation of uPAR mRNA. Interestingly, uPA regulates the expression of its receptor both at transcriptional and posttranscriptional levels (Nagamine et al. 2005).

uPAR is expressed constitutively in many cell lines; however, its expression in culture is inducible by several factors as phorbol esters or various growth factors. In vivo, uPAR is moderately expressed in various tissues including lungs, kidneys, spleen, vessels, uterus, bladder, thymus, heart, liver, and testis. uPAR expression can be strongly up-regulated in organs undergoing extensive tissue remodeling, as in gestational tissues during embryo implantation and placental development or in keratinocytes during epidermal wound healing. Stress, injury, and inflammation also induce uPAR expression. In blood, the expression of uPAR is strongly increased upon activation of neutrophils, monocytes, and T cells (Smith and Marshall 2010). Up-regulation of uPAR expression has been also reported in peripheral CD33+ myeloid and CD14 + monocytic cells, following granulocyte-colony-stimulating factor (G-CSF)-induced mobilization of CD34+ hematopoietic stem cells (Ragno and Blasi 2008).

A wide variety of human and mouse cancers overexpress uPAR. uPAR-deficient mice show phenotypes consistent with these observations and not always coincident with phenotypes of uPA-deficient mice, strongly suggesting additional proteolysis-independent in vivo role of uPAR.

uPAR Structure

uPAR is synthesized as a single polypeptide chain of 313 amino acid residues, with a 21-residues signal peptide. Posttranslational cleavage and removal of the last 30 C-terminal residues allow the attachment of a glycosyl-phosphatidyl-inositol (GPI) tail to Gly 283 that anchors the receptor to the cell surface. Mature uPAR consists of three homologous domains of approximately 90 amino acids (D1, D2 and D3, from the N-terminus), belonging to the Ly-6/uPAR/alfa-neurotoxin protein domain family. By virtue of its GPI-tail, uPAR partitions preferentially to lipid rafts, cholesterol-rich microdomains of cell membrane, which represent anchoring platforms for specific cell-signaling mediators.

The crystal structure of a uPAR soluble form bound to an antagonist peptide has been solved, thus confirming that uPAR consists of three domains with a typical three-finger fold, each domain containing three adjacent loops rich in beta-pleated sheets and a small C-terminal loop. The three domains of uPAR form an almost globular receptor with a breach between D1 and D3, thus generating a central cavity where the ligand peptide is located. The top of the cavity is quite large and progressively narrows toward the bottom. The peptide establishes multiple contacts with the walls of the cavity; D1 plays a predominant role in this ligand interaction by providing half of the binding interface. uPAR exhibits a large outer surface that harbors the interdomain linker regions and the five possible N-linked glycosylation sites. This model suggests that uPA is embedded in the central cavity and that the large outer receptor surface is available to bind additional ligands (Kjaergaard et al. 2008).

The three domains of the GPI-anchored uPAR are joined by linker sequences. The D1-D2 linker region is particularly exposed to proteolysis and can be cleaved by several enzymes, including plasmin and uPA itself. The cleavage can occur at different sites in the D1-D2 linker region and may disrupt or not a specific sequence (SRSRY), corresponding to amino acids 88–92, involved in cell migration. In both cases, the cleavage generates truncated forms of GPI-uPAR, lacking D1 (D2-D3 uPAR), which have been detected on the surface of different cell lines and in normal and cancer tissues.

Both full-length and cleaved uPAR can be shed, thus generating soluble uPAR forms (suPAR and D2-D3 suPAR, respectively) identified in biological fluids, both in vitro and in vivo. The shedding can be due to the activity of glycosyl-phosphatidyl-inositol specific phospholipase C or D, or to a juxtamembrane proteolytic cleavage of uPAR. D2-D3 suPAR can also be generated by proteolytic cleavage of full-length suPAR mediated by metalloproteases, cathepsin G or elastase (Montuori et al. 2005).

uPAR Interactors

uPAR Extracellular Ligands

uPAR was firstly identified as the cellular receptor for the urokinase-type plasminogen activator (uPA). uPA is secreted as a 54 kDa single-chain pro-enzyme that can be converted, likely following binding to uPAR, into the two-chain active form by a single cleavage at Lys_{158}-Ile_{159}. The N-terminal A chain or its amino terminal fragment (ATF, residues 1–135) binds uPAR with high affinity and specificity. The C-terminal B chain contains the serine-protease domain and is unable to bind the receptor (Carriero et al. 2009).

uPA binds the N-terminal uPAR domain 1 (D1), even though the full-length uPAR is required for an efficient uPA binding. uPA binding to GPI-anchored uPAR allows the cell to focus uPA proteolytic activity, which activates cell-bound or free plasminogen into plasmin. Plasmin promotes ECM degradation directly, by degrading ECM components, including fibrinogen, fibronectin, and vitronectin, and indirectly, by activating several metalloproteases.

In spite of its name, uPAR acts also as a receptor for other extracellular molecules, such as vitronectin (VN), an ECM component, and the cleaved form of high molecular mass kininogen (HKa). The functional epitope on uPAR that is responsible for its interaction with the full-length, extended form of vitronectin is formed by three residues in domain I (Trp(32), Arg (58), and Ile(63)) and two residues located in the flexible linker peptide connecting uPAR domains I and II (Arg(91) and Tyr(92)). uPA positively regulates VN binding to uPAR, likely by inducing formation of uPAR dimers that exhibit a higher affinity for VN as compared to the monomers. HKa, unlike uPA, inhibits uPAR-mediated cell adhesion to VN, likely because it binds and blocks the VN-binding site in uPAR. Furthermore, the type-1 plasminogen activator inhibitor (PAI-1) competes with uPAR in the binding to VN because they bind overlapping regions on VN located in the N-terminal somatomedin B (SMB) domain, close to the integrin-binding site. uPAR expression confers to the cell the ability to adhere to VN, thus it is a non-integrinic VN receptor (Madsen and Sidenius 2008).

uPA and VN can be bound only by full-length uPAR, both in the cell-anchored and in the soluble form, even if, in the latter case, with less efficiency; the cleaved forms of uPAR are unable to bind both uPA and VN (Montuori et al. 2005).

Cell Surface uPAR Interactors

Cell surface uPAR interactors encompass a long list of proteins. The structural basis of these interactions is still poorly understood; however, much evidence

demonstrates that the physical/functional interaction of uPAR with these proteins is essential for its non-proteolytic functions. uPAR functionally interacts with receptor tyrosine kinases, as the epidermal growth factor receptor (EGFR) and the platelet-derived growth factor receptor (PDGFR)-beta, various integrins, caveolin, the receptors for bacterial formylated peptides (fMLP receptors, fMLP-Rs), the collagen receptor uPARAP/Endo180, and receptors of the low-density lipoprotein receptor family including the LDL receptor-related protein (LRP) and LRP1B. In addition, uPAR has been shown to associate with the cation-independent Mannose 6-phosphate/insulin-like growth factor-II receptor that has been implicated in the targeting of uPAR to lysosomes. As a consequence of some of these interactions, uPAR activates intracellular signaling molecules involved in cell proliferation, survival, differentiation, adhesion, and migration. In fact, uPAR lacks a transmembrane region and a cytosolic tail, thus it could not transduce signals inside the cell unless it associates to signaling partners; the best candidates to this role seem to be integrins and fMLP receptors (Blasi and Sidenius 2010).

uPAR and Integrins

uPAR co-capping with the β2 integrin Mac-1 was firstly demonstrated in resting neutrophils; subsequently, the presence of uPAR and β2 integrins was identified in large receptor complexes that included signaling molecules. Fluorescence resonance energy transfer analysis (FRET), immunolocalization, and co-immunoprecipitation have identified uPAR in complex with several integrin families, such as β1, β2, β3, and β5. uPAR-binding sites have been identified on α- and β1-integrin chains. α3β1 integrin associates with uPAR via a surface loop within the α3 β-propeller, outside the ligand-binding region; cell treatment with a 17 mer α3β1 integrin peptide (peptide α 325) or Ala mutations within the uPAR-interacting loop of α3 (H245A) chain abolishes uPAR co-immunoprecipitation with α3β1 integrin and impairs uPA-uPAR-dependent signals. A uPAR-binding site has also been identified in a β1-chain loop (residues 224–232) of α5β1 integrin; this loop is very close to the β-propeller of α5 chain in the energy-minimized model of the integrin structure. The synthetic peptide corresponding to the uPAR-binding site of β1 or a β1 chain Ser227Ala point mutation abrogates functional uPAR effects on α5β1 integrin.

Subsequently, also putative integrin-binding sites on uPAR have been identified in the uPAR domains 2 and 3. The peptide covering the interaction site in D2 abolishes uPAR co-immunoprecipitation with αvβ3 and α5β1 integrins, activates αvβ3 integrin-dependent signaling pathways, and stimulates cell migration, whereas peptide D2A-Ala, generated by mutating two glutamic acids into two alanines, lacks chemotactic activity, and, in addition, inhibits VN-, FN-, and CG-dependent cell migration. The peptide covering D3 interaction site binds purified α5β1 integrin; substituting a single amino acid in this peptide or in full-length soluble uPAR impairs binding of the purified integrin. uPAR binding to integrins requires the full-length receptor, as in the case of uPAR binding to uPA and VN (Tang and Wei 2008).

Interestingly, uPA may bind simultaneously both uPAR and integrins. In fact, uPA interacts with uPAR through its growth factor-like domain (GFD) in the amino terminal fragment (ATF), whereas it recognizes Mac-1 and β1 integrins through the kringle domain and the αvβ5 integrin through the "connecting peptide" (residues 132–158). Mac-1 also is able to bind at the same time uPA and uPAR, through its I and non-I domains, respectively (Carriero et al. 2009; Tang and Wei 2008).

uPAR–integrin interactions seem to exert opposite effects, depending on the cell type examined. In fact, the first evidence of uPAR interaction with β1 integrins was reported in uPAR-transfected HEK-293 cells, in which uPAR and integrins form stable complexes that inhibit cell adhesion to fibronectin (FN) and, in parallel, increase RGD-independent uPAR-mediated cell adhesion to VN. By contrast, uPAR activates α5β1 integrin in human epidermoid carcinoma HEp-3 cells.

uPAR and fMLP Receptors

fMLP (fMet-Leu-Phe) is a formylated peptide of bacterial origin that stimulates chemotaxis by activating seven transmembrane domain receptors coupled to G-proteins. Three fMLP receptors (fMLP-R) have been identified and cloned: the high-affinity *N*-formyl-peptide receptor (FPR) and its homologues FPR-like 1 (FPRL1) and FPR-like2 (FPRL2). FPR is a high-affinity receptor for fMLP. FPRL1 has a much lower affinity for fMLP, whereas it is efficiently activated by several different molecules, such as lipoxin A_4, serum amyloid A, the prion peptide $PrP_{106\text{-}126}$, HIV-1 envelope peptides, the Helicobacter Pylori Hp(2–20)

peptide, and various synthetic peptides. FPRL2 shows a high homology with the other two fMLP receptors but does not bind fMLP and shares some ligands with FPRL1, as Hp(2–20) and synthetic peptides. fMLP-Rs were firstly identified in leukocytes, and subsequently in several different cell types, including epithelial cells (Le et al. 2002).

Full-length GPI-anchored uPAR functionally interacts with fMLP-Rs through a specific SRSRY sequence (residues 88–92) in the D1-D2 linker region; in fact, uPAR expression is required for fMLP-dependent migration in monocytes and HEK-293 epithelial cells and, conversely, fMLP-R expression is required in cell migration induced by uPA or its amino terminal fragment (ATF).

Interaction of uPAR with fMLP-Rs was originally demonstrated by showing that the soluble cleaved form of uPAR (D2-D3 suPAR), or its derived peptides containing the SRSRY sequence (residues 88–92), bind and activate FPRL1 in monocyte-like cells, thus inducing their migration. Interestingly, D2-D3 suPAR does not induce calcium mobilization, unlike fMLP and other FPRL1 ligands. Subsequently, D2-D3 suPAR capability to induce cell migration through activation of all members of the fMLP-R family has been shown in various cell types. Unlike full-length GPI-anchored uPAR, full-length soluble uPAR does not bind fMLP receptors, even though it is able to interact with integrins and VN (Ragno 2006).

uPAR as Signal Transducer

A large body of evidence clearly shows that uPAR is able to activate intracellular signaling leading to cellular responses such as cell adhesion, migration, differentiation, proliferation, and survival. uPAR-dependent signaling can be activated by uPA (independently of its proteolytic activity), VN, and by uPAR overexpression itself. Many signaling partners have been proposed for uPAR, which lacks a transmembrane region and a cytosolic tail; however, the most important transmembrane receptors associated with uPAR signaling seem to belong to the integrin and fMLP-R families.

Even if a direct and physical uPAR interaction with integrins has been questioned, many studies show that uPAR signaling requires integrin cooperation. uPAR-β1 and uPAR-αv integrin interactions have been often associated with the activation of FAK/src signaling, leading to increased activities of Rac1 and/or ERK1/2.

The first uPAR–integrin interaction to be described involved the β2 integrin Mac-1, which is expressed primarily in leukocytes, where it regulates migration, differentiation, and phagocytosis. uPAR association with Mac-1 improves Mac-1 binding to fibrinogen; up-regulation and/or engagement of Mac-1 enhance uPAR-dependent adhesion to VN in monocytes. Signaling promoted by the uPAR-Mac-1 interaction seems to involve Src family kinases. A crucial role for uPAR in regulating β2 integrin activity has also been suggested in vivo; in fact, the β2 integrin-dependent recruitment of leukocytes to inflamed peritoneum and of neutrophils to the lung in response to *P. aeruginosa* pneumonia infection is significantly reduced in uPAR-deficient mice (Smith and Marshall 2010).

In normal microvascular endothelial cells (MVECs), full-size uPAR is connected with the actin cytoskeleton via the alphaM- and alphaX-subunits of β2 integrins. In systemic sclerosis (SSc), MVECs angiogenesis is blocked by uPAR cleavage; in fact, uPAR cleavage induces uPAR uncoupling from β2 integrins, impairing the activation of Rac and Cdc42 and the integrin-delivered signals to the actin cytoskeleton (Margheri et al. 2006).

One of the first reports on uPAR involvement in cell-signaling described a uPAR-dependent mechanism in which, in tumorigenic cells, high uPAR levels activated α5β1 integrin, thus promoting its binding to fibronectin and the assembly of integrin-bound fibronectin into insoluble structures during fibronectin fibrillogenesis. α5β1-dependent signaling induced a strong and persistent ERK1/2 activation, which promoted cell proliferation. By contrast, cells expressing low uPAR levels showed p38 MAPK activation, which inhibited ERK1/2 activation. In vivo, tumor cells with low ERKs/p38 activity ratio rapidly arrested in G_0–G_1 and remained viable but dormant for a prolonged period of time (Aguirre-Ghiso et al. 2003). Subsequently, several reports have shown that signaling events downstream of uPAR-β1 integrin interactions promote FAK phosphorylation and ERK1/2 activation. Src also co-immunoprecipitates with uPAR-β1 integrin complexes and is activated by uPAR signaling through both α5β1 and α3β1 integrins (fibronectin and laminin receptors, respectively). ERK1/2 and Src activation induced by uPAR-β1 integrin mediates cell adhesion, migration, invasion of ECM, proliferation,

epithelial-mesenchymal transition (EMT), and, in addition, increase in the expression of uPA and metalloproteases, suggesting that uPAR signaling through β1 integrins can contribute to invasion also by increasing pericellular proteolysis (Smith and Marshall 2010).

αv- integrins have also been strongly implicated in uPAR signaling. Both uPAR and αv integrins bind vitronectin, uPAR recognizing the SMB domain and αv integrins the Arg-Gly-Asp sequence of vitronectin. The uPAR-av integrin interaction has an important role in signaling for cell migration. The functional effects of uPAR-αv integrin association were studied in fibrosarcoma and breast carcinoma cell lines, both of which exhibit uPA-dependent physical association between uPAR and αvβ5. uPA promoted cellular migration via a uPAR/αvβ5-dependent signaling cascade in which Ras, ERKs, and myosin light chain kinase (MLCK) serve as essential downstream effectors. In uPAR-transfected cells, uPAR signaling through αv-β3 integrin may activate Src, leading to phosphorylation of ▶ p130Cas and subsequent binding of CRK; the p130Cas–CRK complex recruits DOCK1 for Rac activation. Further, uPAR is required to activate αvβ3 integrin in podocytes, promoting cell motility and activation of the small GTPases Cdc42 and Rac1. Blocking αvβ3 integrin reduces podocyte motility in vitro and lowers proteinuria in mice; thus uPAR seems to play a physiologic role in the regulation of kidney permeability. Also, in some cells, uPAR signaling promotes the cell surface expression of αvβ3 integrin (Smith and Marshall 2010).

Different forms of uPAR are present on the cell surface: full-length uPAR and cleaved uPAR forms (D2-D3 uPAR), lacking the D1 domain and exposing or not a specific SRSRY sequence (residues 88–92), which is able to functionally interact with fMLP-Rs. uPAR and D2-D3 uPAR appear to mediate different signaling pathways. A report on fibroblast-to-myofibroblast differentiation showed that fibroblasts express increased amounts of full-length cell surface uPAR as compared to myofibroblasts, which have increased expression of D2-D3 uPAR. uPAR cleavage seems to be required to induce fibroblast transition to myofibroblast, since inhibition of uPAR cleavage prevents myofibroblast differentiation (Ragno 2006).

uPAR can be shed from the cell surface. However, the soluble receptor is able to activate cell-signaling pathways in uPAR negative cells and can still activate β2 and β1 integrins, thus inducing leukocyte adhesion to endothelium or ERK1/2 activation in Hep3 carcinoma cells (Montuori et al. 2005).

The soluble form of D2-D3 uPAR (D2-D3 suPAR), or its derived peptides containing the SRSRY sequence, bind and activate fMLP-Rs, stimulating cell migration. Thus, D2-D3 suPAR can be considered as a ligand for fMLP receptors and is also able to activate cell-signaling pathways. Indeed, the SRSRY peptide increases uPAR-αvβ5 association and stimulates PKC activity and ERK phosphorylation (Gargiulo et al. 2005).

uPAR can also cross-talk with growth factor receptors, such as EGFR and PDGFR-beta. Indeed, uPA binding to uPAR can initiate a cell-signaling pathway that is mediated by EGFR, and, conversely, uPAR-dependent cell-signaling may prime cells to proliferate in response to EGF.

uPAR cross-talk with the platelet-derived growth factor receptor (PDGFR)-beta has been reported in human vascular smooth muscle cells (VSMC), in which uPA induces uPAR association with PDGFR-beta, thus stimulating its phosphorylation. uPAR-PDGFR-beta association is required for uPA-induced migratory and proliferative downstream signals. However, unlike the association to EGFR, uPA strongly inhibits PDGF-induced migration (Ragno 2006).

Recently, the cross-talk between uPAR and CXCR4, the receptor for the stromal-derived factor 1 chemokine, has been reported; uPAR expression regulates CXCR4 activity on specific extracellular matrix components by a mechanism involving fMLP-Rs and αv integrins (Montuori et al. 2010).

Summary

The urokinase receptor (uPAR) was firstly identified in 1985 on the surface of monocyte-like cells. It is moderately expressed in various tissues and its expression can be strongly up-regulated in organs undergoing extensive tissue remodeling. Stress, injury, and inflammation induce uPAR expression; a wide variety of human and mouse cancers also overexpress uPAR.

uPAR is a GPI-anchored protein that binds with high affinity the serine-protease urokinase-type plasminogen activator (uPA), thus regulating cell membrane–associated proteolytic activity and, hence, increasing cell ability to move and migrate through barriers.

uPAR mobility along the cell membrane, due to its GPI-tail, and its structure, recently solved, strongly suggest that uPAR is a molecule prone to interact with other cell surface molecules. In fact, over the years, a large body of evidence clearly showed that uPAR is capable of multiple interactions and, likely by virtue of these interactions, it is able to activate intracellular signaling, leading to cellular responses such as cell adhesion, migration, differentiation, proliferation, and survival. The majority of reports is focused on its likely interaction with integrins, which has been questioned in the last years, even though a crucial role of integrins in uPAR signaling activities is generally accepted. Other possible uPAR signaling partners could be the receptors for the fMLP formylated peptide (fMLP-Rs). In this case also, there are no reports on a direct interaction of cell membrane uPAR with fMLP-R; however, a direct binding between the cleaved form of soluble uPAR has been demonstrated in the past on monocyte-like cells. Thus, at present, the mechanism enabling uPAR to signal is still unclear and represents a very intriguing area of research; elucidation of these mechanisms could shed light on the real meaning and importance of uPAR in the various biologic and pathologic processes in which it is overexpressed and involved.

Historical Background

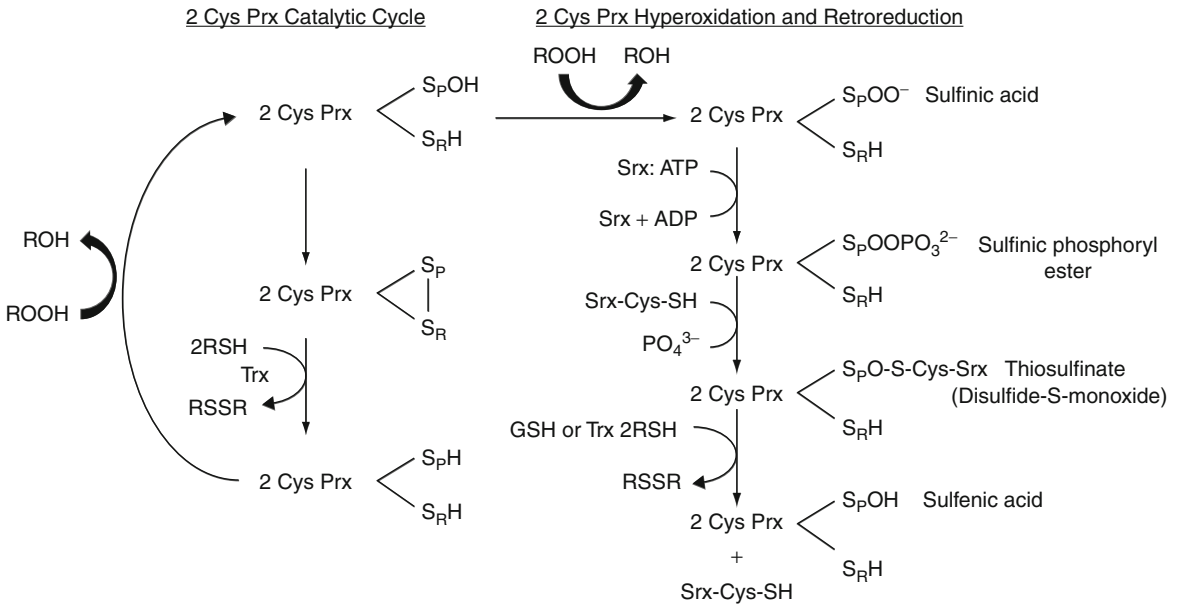
Redox homeostasis is critical for normal cellular function, and cellular redox imbalance is associated with a number of human pathologies including cardiovascular disease and cancer (Circu and Aw 2010). Reactive oxygen species (ROS) include the superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals ($^{\cdot}OH$). ROS can oxidatively damage cellular constituents such as DNA, protein, and unsaturated lipids. Traditionally ROS were considered to be solely deleterious, but it has recently become apparent that evolution harnessed the labile nature of ROS for beneficial purposes (Circu and Aw 2010). Cells are exposed to ROS arising from both exogenous and endogenous sources. Environmental sources of ROS include ionizing radiation and certain drugs and toxins. The first endogenous source of ROS to be recognized is electrons leaking prematurely from mitochondrial electron transport chain complexes I and III that reduce molecular oxygen to superoxide anion. In addition, NADPH oxidases present in macrophages and neutrophils produce large bursts of superoxide anions in order to kill bacteria. Although NADPH oxidases were originally thought to be specific to immune cells, more recent work demonstrates NADPH oxidase isoforms are ubiquitously expressed (Brown and Griendling 2009). These NADPH oxidases are transiently activated in response to ligand binding to some peptide growth factor receptors, cytokine receptors, and G protein-coupled receptors (GPCRs). The superoxide produced is rapidly converted to hydrogen peroxide by spontaneous dismutation or by the activity of superoxide dismutase enzymes, and the hydrogen peroxide thus produced acts as a second messenger in cellular signaling pathways. Although low levels of hydrogen peroxide promote cell growth, high levels cause cellular damage and result in cell death. Consequently, controlling the cellular level of ROS is of critical importance.

Oxidative stress ensues when the level of ROS exceeds the antioxidant capacity of the cell, and cells possess a host of antioxidant enzymes and small molecule antioxidants that function to maintain redox homeostasis (Circu and Aw 2010). The enzymatic antioxidant defense system is composed of several enzyme families including superoxide dismutase, which catalyzes the dismutation of superoxide to hydrogen peroxide, and glutathione peroxidase, catalase, and peroxiredoxins, which reduce hydrogen peroxide to water. The sulfur of cysteine residues can exist in a number of chemical forms including thiol (S-H), thiolate anion (S^-), disulfide (S-S), sulfenic acid (S-OH), sulfinic acid ($S\text{-}O_2H$), and sulfonic acid (SO_3H). This versatility of sulfur chemistry is of paramount importance for maintaining redox homeostasis and redox signaling. The tripeptide glutathione (GSH) comprising glutamate-glycine-cysteine is present at millimolar concentrations in cells, and GSH is the primary cellular small molecule antioxidant (Townsend et al. 2003). GSH is in equilibrium with GSH disulfide (GSSG) in cells, and the ratio of reduced (GSH) to oxidized (GSSG) glutathione is indicative of the level of oxidative

stress. The intracellular environment is reducing and the GSH to GSSG ratio is typically 100:1, but during oxidative stress this ratio can be reduced to 10:1 or even less. In addition to acting as the primary small molecule antioxidant, the formation of mixed disulfides between proteins and GSH (P-S-S-G) – i.e., protein glutathionylation – is a mechanism to prevent the oxidation of cysteine residues to sulfinic and sulfonic states that may inactivate proteins or target them for degradation. The posttranslational glutathionylation modification of proteins is also involved in cell signaling (Townsend et al. 2003). The pKa of a typical cysteine residue is ~8.5 so most cysteine residues exist as sulfhydryls in the reducing environment of the cytosol. However, some cysteine residues have much lower pKa values, due to the presence of neighboring positively charged residues such as lysine and arginine that stabilize the thiolate anion. The thiolate anion is much more readily oxidized by ROS than sulfhydryls. Thus, when cells are exposed to oxidative stress, low pKa cysteine residues in proteins are readily oxidized to cysteine sulfenic acids. These cysteine sulfenic acids can condense with the free sulfhydryls of other cysteine residues to form disulfides including mixed disulfides with glutathione or can further be oxidized to sulfinic or sulfonic acids. Thus, through their ability to modify cysteine residues, ROS act as signaling molecules by altering protein structure and function. For example, one mechanism whereby hydrogen peroxide can act as a second messenger involves the oxidative inactivation of phosphatases, the catalytic cysteine of which exists as a thiolate anion. Redox regulation of protein cysteine residues is known to regulate the structure and function of a number of proteins including peroxiredoxins, actin, and some protein tyrosine phosphatases (Circu and Aw 2010).

Peroxiredoxins and the Identification of Sulfiredoxin

Peroxiredoxins (Prxs) are a ubiquitous and abundantly expressed family of enzymes found in both prokaryotes and eukaryotes that catalyze the reduction of hydrogen peroxide and organic hydroperoxides to water and alcohol, respectively. In addition to their role as antioxidant enzymes, some eukaryotic Prxs are involved in cell signaling (reviewed in Hall et al. 2009). Mammals have six Prxs that are divided into three subgroups based on the presence of conserved cysteine residues and reaction mechanisms. All mammalian Prx isoforms have a conserved N-terminal cysteine residue designated the peroxidatic cysteine, and the most abundant subgroup of Prxs, the typical 2-Cys Prxs (PrxI-IV), also has a conserved C-terminal cysteine residue designated the resolving cysteine. Atypical 2-Cys Prxs (Prx V) have a second non-conserved cysteine whereas 1-Cys Prxs (Prx VI) only have the conserved N-terminal cysteine residue. Typical 2-Cys Prxs function as homodimers, and during enzymatic reduction of hydrogen peroxide the peroxidatic cysteine of Prx is oxidized to sulfenic acid (C–S–OH; Fig. 1). This peroxidatic cysteine sulfenic acid residue then condenses with the free sulfhydryl of the resolving cysteine of the other subunit of the dimer to form an intermolecular disulfide bond. The thiols are reconstituted by thioredoxin (Trx) using reducing equivalents derived from NADPH, thus completing the catalytic cycle. Before disulfide formation between the peroxidatic and resolving cysteines can occur, the peroxidatic cysteine sulfenic acid can be hyperoxidized to cysteine sulfinic acid (C–S–O_2H) by a second H_2O_2 molecule. Cysteine sulfinic acids cannot be reduced by cellular thiols such as Trx or GSH and their presence results in inactivation of the enzyme (Yang et al. 2002). Interestingly, eukaryotic 2-Cys Prxs are much more susceptible to hyperoxidative inactivation than their prokaryotic homologs. The crystal structure of human Prx II revealed that the peroxidatic cysteine sulfenic acid is located more than 12 Å away from the free sulfhydryl of the resolving cysteine requiring a conformational change for disulfide bond formation to occur. In addition, sequence analysis revealed that eukaryotic Prxs have two unique structural features, an additional C-terminal α helix (α7) with a conserved YF motif and a separate GGLG motif located near the peroxidatic cysteine. These structural features render the peroxidatic cysteine of eukaryotic Prxs susceptible to hyperoxidation to cysteine sulfinic acid (Jonsson and Lowther 2007; Hall et al. 2009). The sulfinic acid modification of the peroxidatic cysteine was initially thought to result in irreversible inactivation of the enzyme, but careful analyses of the fate of hyperoxidized Prxs subsequently revealed that the sulfinic acid modification of Prx is actually reversible (Woo et al. 2003), begging the question of which enzyme is responsible for this sulfinic acid reductase activity.



Sulfiredoxin, Fig. 1 The 2 Cys Prx catalytic cycle and reaction scheme for the retroreduction of sulfinic 2-Cys Prx by Srx. In the 2 Cys Prx catalytic cycle, the peroxidatic cysteine (S_P) is oxidized by peroxide (ROOH) forming a sulfenic acid (S_POH). The peroxidatic cysteine sulfenic acid condenses with the resolving cysteine (S_R) to form an intermolecular disulfide. Reduced 2 Cys Prx is reconstituted by thioredoxin (Trx). The peroxidatic cysteine sulfenic acid can be hyperoxidized by a second peroxide molecule to form a peroxidatic cysteine sulfinic acid. Srx with ATP bound catalyzes the formation of the sulfinic phosphoryl ester intermediate in the first step of the retroreduction reaction. In the second step, the catalytic cysteine of Srx attacks the Prx phosphoryl ester forming a thiosulfinate intermediate. Subsequent reduction occurs by glutathione (GSH) thiol-disulfide exchange reactions or is catalyzed by Trx

In 2003, Toledano and coworkers identified sulfiredoxin (Srx) in the yeast *S. cerevisiae* based on the observations that its expression was markedly induced by hydrogen peroxide exposure and that deletion of Srx reduced tolerance to hydrogen peroxide (Biteau et al. 2003). Srx was shown to associate with Tsa1 (yeast Prx) in cells by co-immunoprecipitation, and in vitro experiments demonstrated Mg^{2+} and ATP-dependent reduction of the sulfinic acid form of yeast Prx by purified Srx. Soon thereafter, Rhee and colleagues identified mammalian orthologs of yeast Srx in mice, rats, and humans (Chang et al. 2004). Using antibodies specific to the sulfinic form of 2-Cys Prxs, mammalian Srx was also demonstrated to have sulfinic acid reductase activity toward Prxs. The reduction of hyperoxidized 2-Cys Prxs by Srx was found to be a slow process (k_{cat} = 0.18/min) that required ATP hydrolysis, and both GSH and Trx were identified as potential electron donors as their K_m values were in the physiological range and similar V_{max} values were obtained with both reductants (Chang et al. 2004).

Mechanism of Action of Sulfiredoxin

Based on the observations that the reaction requires ATP hydrolysis, Mg^{2+} and the conserved cysteine of sulfiredoxin forming a transient disulfide with yeast Prx, the mechanism of sulfinic acid reductase activity by Srx was originally proposed to involve activation of Prx sulfinic acid by phosphorylation followed by a thiol-mediated reduction step involving the conserved Cys residue of Srx (Biteau et al. 2003). An alternate reaction scheme has been proposed whereby the initial step is attack of Srx Cys^{99} on the γ phosphate of ATP generating an Srx thiophosphate intermediate that is then attacked by the Prx sulfinic acid generating the same Prx sulfinic phosphoryl ester intermediate proposed in the original scheme (Jeong et al. 2006). In addition, this alternate scheme suggests that the thioltransferase is provided not by Srx but by GSH. Although some experimental evidence has been interpreted to support the alternate scheme (for review see Jonsson and Lowther 2007), the preponderance of evidence suggests that the original scheme whereby Srx acts as both

a phosphotransferase and a thioltransferase is correct. Thus, ATP bound Srx catalyzes the phosphorylation of Prx sulfinic acid forming a sulfinic phosphoryl ester intermediate (Fig. 1). This enables the sulfhydryl group of the catalytic cysteine of Srx to attack the peroxidatic cysteine phosphoryl ester forming a thiosulfinate (disulfide mono-oxide) intermediate that is reduced by thiols such as GSH to Prx sulfenic acid and Srx mixed disulfide. Several lines of evidence support this model. The crystal structure of human Srx in complex with ADP and a model of Srx:ATP based on this structure shows that the γ phosphate of ATP is near Srx Cys^{99} but does not directly interact with the Srx Cys^{99} residue (Jonsson et al. 2005). Superimposition of this Srx:ATP model onto the crystal structure of human Srx in complex with PrxI revealed that unfolding of the PrxI peroxidatic cysteine sulfinic acid would place the peroxidatic cysteine sulfinic acid near ATP and that the oxygen atom of the peroxidatic cysteine sulfinic acid is positioned for inline attack on the γ phosphate of ATP while Srx Cys^{99} is not positioned properly (Jonsson et al. 2008a). Studies with mutant Prx that cannot complete the reaction because the peroxidatic Cys is mutated to Asp also support sulfinic acid phosphorylation as the first step in the reaction (Jonsson et al. 2009). Finally, using chemical quenching and mass spectrometry a thiosulfinate intermediate between Srx and Prx was observed (Jonsson et al. 2008b). In sum, it appears the reaction mechanism proceeds as originally proposed whereby Srx acts first to properly position ATP for attack by the Prx peroxidatic cysteine sulfinic acid and then the Srx catalytic cysteine attacks the sulfinic acid phosphoryl ester to create a Prx-Srx thiosulfinate intermediate that can be reduced by GSH or Trx. At the present time it is unclear if the physiological reductant is GSH or Trx. If GSH is the reductant of the Prx-Srx thiosulfinate, a Prx cysteine sulfenic acid and an Srx mixed disulfide (glutathionylated Srx) would result. Reduced Srx could be regenerated after further reduction of glutathionylated Srx with additional GSH or other cellular thiols.

Sulfiredoxin as a Deglutathionylating Enzyme

In addition to its activity as a cysteine sulfinic acid reductase specific to 2-Cys Prxs, two recent studies demonstrate that Srx is capable of reversing glutathionylation of proteins (Findlay et al. 2006; Park et al. 2009). This observation has important implications for cell signaling because, as noted above, glutathionylation of protein cysteine residues is a posttranslational modification that affects protein structure and function. The anticancer prodrug PABA/NO is a potent inducer of glutathionylation of a number of proteins. Human embryonic kidney (HEK293) cells transfected with Srx exhibit a decrease in protein glutathionylation following PABA/NO treatment compared with control cells (Findlay et al. 2006). Further, actin and protein tyrosine phosphate 1B (PTP1B) were identified in vitro as specific targets of Srx deglutathionylation activity and these interactions were confirmed with in vivo studies (Findlay et al. 2006). Importantly, it was shown that glutathionylation of PTP1B inhibits its enzymatic activity and that deglutathionylation of PTP1B by Srx restored the phosphatase activity of PTP1B (Findlay et al. 2006). Another recent study demonstrates that 2-Cys Prxs are glutathionylated and that Srx is capable of reversing this modification (Park et al. 2009). Specifically, human Prx I has four cysteine residues – Cys^{52}, Cys^{71}, Cys^{83}, and Cys^{173} – and in vitro studies show Cys^{52}, Cys^{83}, and Cys^{173} can be glutathionylated. Using Cys mutants it was demonstrated that deglutathionylation of Cys^{83} and Cys^{173} is preferentially catalyzed by Srx whereas deglutathionylation of Cys^{52} is preferentially catalyzed by glutaredoxin. Thus, Srx impacts redox signaling pathways by both regulating hydrogen peroxide levels through reactivation of hyperoxidized Prxs and by reversing glutathionylation.

Regulation of Sulfiredoxin Expression

As mentioned Srx was originally identified, in part, through the observation that its expression is induced by hydrogen peroxide in yeast. More recent work shows that Srx transcription is induced by a variety of signaling pathways in mammals (Soriano et al. 2009). Several studies demonstrate mammalian Srx is a target of the activator protein-1 (AP-1) complex. The AP-1 complex is formed by transcription factors of the Jun and Fos families that bind as homo- and hetero-dimers to AP-1 response elements in promoters of target genes to activate transcription. An investigation of rodent pancreatic β cells stimulated with elevated glucose and cAMP first identified Srx as a target of the AP-1 complex (Glauser et al. 2007). AP-1 induction of Srx expression was also observed in studies of rat neurons (Papadia et al. 2008).

In this study (Papadia et al. 2008), synaptic activity acting through NMDA receptor signaling activated transcription of genes involved in intrinsic antioxidant defenses, and two active AP-1 response elements were identified in the rat Srx promoter. Although both of these AP-1 sites are conserved in most mammals, the distal site is not present in the primate lineage. Knockdown of Srx expression increased the sensitivity of neurons to oxidative stress (Papadia et al. 2008). Another group utilized the tumor promoter TPA (12-*O*-tetradecanoylphorbol-13-acetate) that activates AP-1 and TAM67, a dominant negative form of c-Jun, to show that Srx is an AP-1 target in mouse epidermal JB6 cells (Wei et al. 2008). Srx expression was found to be necessary for anchorage-independent growth of JB6 cells, and several human skin malignancies demonstrated elevated Srx protein levels (Wei et al. 2008).

Srx expression is also regulated by Nuclear factor erythroid 2–related factor (▶ Nrf2). Nrf2 is a transcription factor that binds as hetero-dimers with members of the Maf protein family to Antioxidant Response Elements (AREs) in target genes whose products are involved in protecting cells from oxidative stress. In the basal state, Nrf2 is targeted for degradation by Kelch-like ECH associated protein (Keap1). Oxidative stress and chemopreventive agents such as D3T (3 H 1,2 dithiole-3-thione) inhibit Keap1 and lead to the accumulation of Nrf2 resulting in increased expression of ARE-containing Nrf2 target genes. In studies of neurons over-expressing Nrf2 and by using the Nrf2 activator D3T it was demonstrated that Srx expression in rat neurons is induced by Nrf2, and an ARE was identified in the Srx promoter (Soriano et al. 2008). Another study showed that exposure of lung epithelial cells to cigarette smoke induced Srx through Nrf2 and an ARE in the Srx promoter (Singh et al. 2009). The ARE in the Srx promoter identified in this latter study (Singh et al. 2009) is in a different orientation and slightly different position relative to the first identified ARE (Papadia et al. 2008). In addition, the proximal AP-1 response element described above is located within the first identified ARE (reviewed in Soriano et al. 2009). Interestingly, both chemopreventative agents such as D3T and sulforaphanes and tumor-promoting phorbol esters can induce Srx expression. While Srx is demonstrated to protect against oxidative stress in neurons and in the lung, Srx expression is associated with transformation in skin cells. Moreover, Srx over-expression triggers altered expression and phosphorylation of cell cycle regulators p21, p27, and ▶ p53 and stabilizes the phosphatase ▶ PTEN (Lei et al. 2008). Perhaps equally importantly, Srx interacted directly with, and enhanced the activity of, phosphatase PTP1B. In turn, this promoted Src kinase activity by dephosphorylating its inhibitory tyrosine residue (Tyr^{530}). Also, Srx expression was stimulated by cell exposure to certain growth factors. Together, these data suggest a role for Srx in controlling the phosphorylation status of key regulatory kinases through effects upon phosphatase activity with an ultimate impact on pathways that influence cell proliferation (Lei et al. 2008).

Summary

Due to their involvement in cell signaling and their ability to damage cellular components, ROS levels must be tightly regulated. Cells have evolved a number of enzyme systems to guard against oxidative stress, and the Prx family of antioxidant enzymes is especially abundant and ubiquitously expressed. Hyperoxidized Prxs form higher order structures that function as chaperones to protect client proteins from oxidative damage during oxidative stress. Current understanding of the protective role played by GSH, Prxs, and other enzyme systems in protecting cells against oxidative insults is relatively advanced. Current understanding of the role of Prxs in hydrogen peroxide-mediated cell signaling in normal physiology and development, however, is somewhat limited. Much current research is focused on extending our knowledge of ROS-mediated signaling in normal physiology and on the role dysregulated ROS plays in the etiology and progression of diseases. Due to its ability to reactivate Prxs that have been hyperoxidized, Srx plays an important role in both the protective aspects and signaling aspects of Prx function. In addition, the recent realization that Srx possesses deglutathionylating activity is an interesting development that expands the functional implications of the homeostatic redox properties of this protein.

Synonyms

BAF; BRG1; BRM; hBRM; PBAF RSC; SMARCA; SWI/SNF

Historical Background

There are several large multi-subunit complexes that couple ATP hydrolysis with regulation of the chromatin landscape and are referred to as ATP-dependent chromatin remodelers. These complexes are primarily divided into four major classes based on the domain organization of their catalytic subunit. In this entry we focus on one of those major classes called the SWI/SNF subfamily. The SWI/SNF subfamily of chromatin remodelers are well conserved throughout all eukaryotes and typically the catalytic subunit has at least four signature motifs that are the ATPase, bromo,

AT-hook, and HSA domains. The ATPase domain has sequence homology with the two lobes of such ATP-dependent DNA translocases like RecA and Rad54. The DNA translocation activity of SWI/SNF is essential for these complexes to move nucleosomes along DNA. The bromo domain binds to acetylated lysines in histone tails which may modulate the activity of the remodeler. While the A/T hook domain in other complexes is used to bind to DNA, the role of the A/T hook in SWI/SNF is not well understood. The HSA domain is not unique to SWI/SNF complexes, but is found in other chromatin remodelers and is generally used to recruit actin or actin-related proteins (Arp) to the catalytic subunit. The Arps have been shown to stimulate the catalytic activity and to be an important part of a core complex. The subunit composition of SWI/SNF subfamily members ranges from 12 to 17 subunits and can be quite varied in humans. In yeast and Drosophila there are two SWI/SNF complexes present, while in humans the number is significantly higher. The two yeast complexes called SWI/SNF and RSC have different catalytic subunits, but share the same two Arps (Arp7 and 9). In Drosophila there is only one catalytic subunit called Brahma or Brm which is assembled into two different complexes that differ primarily by a subunit which contains multiple bromo domains and is called polybromo. In yeast the RSC complex also differs from SWI/SNF in that besides the catalytic subunit there are seven bromodomains spread throughout three different subunits. Human SWI/SNF in some ways is a combination of both yeast and Drosophila. There are two catalytic subunits in humans called BRG1 and hBRM, like yeast SWI/SNF, which are assembled into distinct complexes. However, like Drosophila, in humans there is also an ortholog of the polybromo subunit called BAF180 that is assembled with BRG1 or hBRM. In addition there are different forms of several of the other subunits which are respectively assembled into different SWI/SNF complexes which add to the diversity of human SWI/SNF. Many of the human SWI/SNF complexes are tissue or developmentally specific which lends itself well to the many different combinations of SWI/SNF that can be formed using different subunits. In this entry we focus on the various roles of SWI/SNF in regulating processes that involve DNA. Much of this work has come from studies in yeast where the functional role of SWI/SNF can more readily be studied.

Involvement in Transcription

Chromatin dynamics for transcription regulation involve the intricate interplay of ATP-dependent chromatin remodelers, ATP-independent histone modifiers, and trans-acting activator/coactivator or repressor/corepressor proteins. However, the temporal control of these factors presents a chicken-and-egg situation. Some promoters may be initially remodeled by chromatin remodelers to create accessible sites for activator binding which in turn can recruit other factors promoting transcription. In other promoters, activator proteins can first bind to promoter regions and recruit chromatin remodelers. Alternatively, activators may recruit histone modifiers like histone acetyl transferases (HATs) that put on active acetyl marks that are in turn recognized by remodeler subunits bearing special "modification-identifying" domains. In some other cases, activators may initially bind to exposed low-affinity sites, recruit remodelers which in turn expose more high-affinity sites. Repressors may function similarly, except that they interact with remodelers that evenly space nucleosomes to form a repressive chromatin structure. The repressed state of chromatin can also be achieved by recruitment of histone deacetylases (HDACs). Besides a normal recruitment establishment and maintenance function, activator/repressor proteins might directly modify the catalytic activities of the remodeler complexes.

Genome-wide gene expression studies with budding yeast SWI/SNF mutants Δ*swi2* and Δ*swi1* showed that they affected ~6% of genes in *Saccharomyces cerevisiae* (Sudarsanam et al. 2000). In *Schizosaccharomyces Pombe*, however, Δ*snf2* and Δ*snf5* mutants showed that they affected 2.6% of the genome but a different set of genes compared to *S. cerevisiae* (Monahan et al. 2008). In budding yeast, about 50% of the affected genes were downregulated in the mutants suggesting that SWI/SNF is involved equally in transcription activation and repression. Δ*swi2* and Δ*swi1* affected an overlapping set of genes suggesting they function as a complex. Given the spatial location of genes that were affected, it was evident that SWI/SNF affects individual promoters rather than chromosomal domains. More direct evidence of SWI/SNF's role in transcription activation was provided by biochemical studies on individual promoters like *SUC2, PHO5, PHO8, ARG1, RNR3, SNZ1* and *INO1* among others (Ford et al. 2007; Ransom et al. 2009; Tomar et al. 2009; Kim et al. 2005).

Chromatin immunoprecipitation (ChIP) studies provided evidence of the direct binding of SWI/SNF to these promoters. Swi2, Snf5, and Swi1 were shown to directly interact with acidic activators like Gcn4, Hap4, and Gal4 that help in targeting of the complex to promoters (Neely et al. 2002). In humans, BRG/BRM complex can associate with type I and type II nuclear receptors such as glucocorticoid receptor (GR), estrogen receptor (ER), androgen receptor (AR), retinoic acid receptor (RAR), vitamin D3 receptor (VDR), or peroxisome proliferator-activated receptor γ (PPARγ) in a ligand-dependent or independent manner to activate hormone responsive genes(Hsiao et al. 2003). Nuclease sensitivity assays, primer extension, UV cross-linking, and indirect end labeling showed SWI/SNF dependent nucleosome repositioning concomitant with transcript appearance at several genes.

The direct role of SWI/SNF in repression of yeast genes has been less well characterized. *SER3* a serine biosynthesis gene was initially implicated as a target of SWI/SNF mediated repression (Martens and Winston 2003). However, it was later found to be an indirect effect of an intergenic transcript from an adjacent *SRG1* promoter (Martens and Winston 2003). SWI/SNF has also been shown to interact with Hir1/Hir2 repressors, but this interaction activates transcription at the *HTA1-HTB1* genes (Prochasson et al. 2005). SWI/SNF represses heat shock genes under heat stress but its effect is less pronounced (Shivaswamy and Iyer 2008). In *S. pombe*, Snf22 physically associates with $fip1^+$, $frp1^+$, and $str3^+$ promoters and mediates the repression of hexose transport and iron transport genes (Monahan et al. 2008).

In humans, involvement of BRG/BRM complexes in repression is more studied and has important implications in tumor suppression. Knock-down, deletion, or mutations in BRG1, Brm, or hSNF5/Ini1 components produce malignancy (Medina and Sanchez-Cespedes 2008). BRG1/Brm is recruited by tumor suppressors such as prohibitin and retinoblastoma (Rb) protein to mediate repression of E2F-responsive genes (Wang et al. 2004; Lorch et al. 2001). BRG1 forms a repressor complex with Rb to inhibit ▶ cyclin A, D1, and E (Giacinti and Giordano 2006; Zhang et al. 2000). BRG1 represses the expression of *c-fos* proto-oncogene in an Rb-dependent but E2F or GR independent manner (Simpson et al. 1993). BRG1 and Brm associate with Rb to repress ribonucleotide reductase, thymidylate synthase, and dihydrofolate reductase genes by the recruitment of histone deacetylase mSin3B (Gunawardena et al. 2007).

In addition to tumor-suppressor interaction, BRG1 also associates with several corepressor complexes. Interaction with CoREST recruits BRG1 to neuronal genes to assist in REST mediated repression in conjunction with other deacetylases (Battaglioli et al. 2002). BRG1 components were also shown to interact with NCoR corepressor complex (Underhill et al. 2000). Recently, BRG1 was shown to directly interact with HP1α suggesting the involvement of SWI/SNF components in heterochromatin formation (Lavigne et al. 2009; Nielsen et al. 2002).

RSC conditional mutants affected 12% of the yeast genome in contrast to 6% in case of SWI/SNF. Rsc4 bromodomain conditional mutants downregulated 47–111 genes and upregulated 123–194 genes suggesting an important role of RSC in transcription activation and repression respectively. Another *rsc4*-Δ4 mutant (four amino acids from the C-terminus deleted) downregulated 168 genes but upregulated 338 (Kasten et al. 2004; Soutourina et al. 2006). Microarray on Δ*rsc30* showed RSC's role in ribosomal gene repression (Angus-Hill et al. 2001). In support, *rsc4-2* bromodomain mutant affected a large number of ribosomal and histone genes (Kasten et al. 2004). More direct evidence of RSC involvement in transcription activation comes from DNaseI accessibility data suggesting a repressive chromatin structure at *DUT1* and *SMX3* genes (Soutourina et al. 2006). Direct evidence of RSC-mediated repression of *CHA1* was shown by nucleosome positioning in indirect labeling experiments suggesting an open chromatin structure (Moreira and Holmberg 1999). At the *HTA1-HTB1* genes, RSC plays an antagonistic role to SWI/SNF by repressing transcription even though both chromatin remodeling complexes are recruited by the same Hir1/Hir2 repressor (Prochasson et al. 2005; Ng et al. 2002).

Unlike SWI/SNF which affects only polII genes, loss of RSC reduces transcription from polI, polII, and polIII genes as shown by genome-wide Sth1 localization and nucleosome occupancy studies (Ng et al. 2002; Parnell et al. 2008). This could partly be due to the association of Rsc4 with Rpb5, a subunit shared by all three RNA polymerases (Soutourina et al. 2006). Importantly, loss of Sth1 increases nucleosome density at polIII promoters (particularly tRNA genes) while polII promoters show more subtle single nucleosome changes that include gain or movement. This study has

important implications on promoter-specific activity of RSC – nucleosome eviction at polIII vs. sliding at polII (Ng et al. 2002).

Several subunits of the SWI/SNF complex in yeast show genetic interactions with proteins involved in transcription elongation. Prominent among these, Swp29 genetically interacts with TFIIS elongation factor while Swi2, Snf5, and Snf6 with Spt16, a subunit of the elongation complex FACT (Shogren-Knaak et al. 2006; Malone et al. 1991). Drosophila Brahma, Moira, and Osa suppress the rough eye phenotype of *asf1* mutants and physically interact with ASF1, another elongation factor implicated in redeposition of histones in the coding regions of genes (Moshkin et al. 2002). Human Brm is found in *CD44* coding regions where it regulates alternate splicing (Batsche et al. 2006). Similarly, BRG1 is associated with *HSP70* promoter and coding regions following heat shock (Corey et al. 2003). Several yeast SWI/SNF subunits are also localized to coding regions of inducible genes such as *GAL1*/*GAL10, HSP82, HSP104, MET2* and *MET6* under conditions of active transcription, traveling with the elongating RNA polymerase(Schwabish and Struhl 2007). The RSC complex is recruited to acetylated nucleosomal templates and helps in elongation by promoting the passage of stalled PolII. PolII passage through chromatin involves loss of a H2A/H2B dimer forming hexasomes. Complexes promoting dimer loss like SWI/SNF and RSC therefore promote polII passage during elongation. However, in an in vitro transcription assay, RSC was more potent than SWI/SNF in promoting polII passage across nucleosomal barriers (Carey et al. 2006). It has been proposed that ATP-dependent chromatin remodelers may also interact with histone chaperones to facilitate polII passage (Park and Luger 2008).

Transcription memory is the ability of daughter cells to remember the transcription activity of certain genes in the mother. This promotes the efficient "switching on" or "switching off" of genes in the daughter to quickly establish a "mother-like transcription status." In this regard, histone modifications (particularly methylation) of promoter regions have been shown to play a role in recruiting transcription factors that activate or repress transcription (Francis et al. 2004). Recently, SWI/SNF has been implicated as being involved in establishing transcription memory of *GAL1* genes in daughter cells. Daughter cells show fast kinetics of galactose reinduction following up to 4 h of repression with glucose. Normally, cells that have never been exposed to galactose take ~20 min to induce the *GAL1* gene peaking at 1 h. Daughter cells however take <10 min and are able to show this fast kinetics for one round of cell division suggesting epigenetic memory is transient. Transcriptional memory was not dependent on histone modifications, but an ISWI deletion in a Δ*swi2* background reinforced the fast reinduction kinetics. This suggested that SWI/SNF establishes transcriptional memory at *GAL1* by antagonizing ISWI action (Kundu et al. 2007).

SWI/SNF and Histone Acetylation Coordinate to Control Chromatin Structure and Function

Current studies indicate that chromatin is dynamic rather than a passive structural scaffold. The chromatin modification enzymes incorporate post-translational modifications on the histone proteins to create docking sites for specific chromatin associated proteins containing specialized domains. Some of these modifications are temporary while others may persist through cell divisions to confer stable epigenetic memory. This principle of histone marking by covalent modifications forms the basis of a "histone code" (Strahl and Allis 2000).

The yeast SWI/SNF and RSC complexes contain one or several bromodomain(s), which are also found in HAT complexes like SAGA and the general transcription factor $TAF_{II}250$ (Jacobson et al. 2000). Bromodomains are 110 residue protein motifs that specifically interact with acetylated lysine residues in histones as well as in non-histone proteins (Dhalluin et al. 1999). While, SWI/SNF possesses a single bromodomain motif residing in the Swi2/Snf2 subunit, 8 out of the 15 bromodomains in yeast are found in RSC. The ATPase motor subunit, Sth1, has only one bromodomain right at its C-terminus much like Swi2/Snf2. The Rsc1, Rsc2, and Rsc4 subunits each have two bromodomains (Kasten et al. 2004; Cairns et al. 1999). The two bromodomains in RSC4 are essential for cell viability and are located adjacent to each other to form the Rsc4 tandem bromodomain. The eighth bromodomain of RSC resides in its RSC10 subunit.

The presence of bromodomain(s) in RSC and SWI/SNF suggests that recognition of histone acetylation

might play a major role in chromatin targeting and/or in their chromatin remodeling function. The single bromodomain in Swi2/Snf2 is dispensable for SWI/SNF activity and has little or no phenotypic effect upon its own deletion (Hassan et al. 2002). Likewise, the bromodomain in Gcn5, the catalytic subunit of SAGA and ADA HAT complexes, also does not play a significant role as is evident from the modest phenotypes observed in Gcn5 bromodomain deletion mutants (Hassan et al. 2002). The bromodomain in Sth1, on the other hand, is required for wild-type function, and deletion mutants lacking different portions of the Sth1 bromodomain are thermosensitive and arrest with highly elongated buds (Du et al. 1998). However, in combination with Gcn5 bromodomain deletion or Tra1 (a targeting subunit in SAGA) *ts* mutation bromodomain deleted SWI/SNF showed strong phenotypes including a synthetic growth defect on raffinose suggesting complimentary functions of SAGA and SWI/SNF in vivo (Hassan et al. 2002). These results are indeed consistent with other evidence for a functional interplay between histone acetylation and SWI/SNF. For example, prior remodeling by SWI/SNF is required for the recruitment of Gcn5 during late mitosis when chromatin is condensed (Krebs et al. 2000); conversely, the Gcn5 bromodomain is required to stabilize SWI/SNF on promoter nucleosomes (Syntichaki et al. 2000). Studies of several promoters induced during differentiation and development revealed that SWI/SNF and SAGA complexes do function jointly, but the temporal order of these complexes can vary. For instance in the case of *yeast* HO gene, expression that occurs at the end of mitosis absolutely required SWI/SNF action for Gcn5 recruitment while activation of the human interferon beta promoter involves a very different order of events wherein histone acetylation by Gcn5 is followed by SWI/SNF recruitment (Cosma et al. 1999; Agalioti et al. 2002). Transactivation by RAR/RXR heterodimers is found to require histone acetylation prior to SWI/SNF action (Dilworth et al. 2000). Similarly, at the PHO8 promoter histone acetylation is a prerequisite for nucleosome remodeling by SWI/SNF (Reinke et al. 2001). The human α1 antitrypsin promoter is unique in the sense that PIC or preinitiation complex assembly occurs long before transcription activation by hBrm and two HAT complexes CBP and P/CAF are recruited simultaneously after PIC assembly (Soutoglou and Talianidis 2002).

Analogous to SWI/SNF, a series of elaborate genetic experiments established cooperativity between RSC and SAGA complexes. Deletions of SAGA encoding genes like *spt20*Δ (believed to abolish all SAGA function), *gcn5*Δ (required for SAGA's histone acetyl transferase activity), and *spt3*Δ (required for a HAT independent activity of SAGA) when combined with *rsc1*Δ or *rsc2*Δ mutations produced the same pattern of synthetic phenotypes as observed with Gcn5 and Swi2/Snf2 double bromodomain deletion mutants (Cairns et al. 1999). Genetic evidence for a functional link between RSC and histone acetylation was further provided when RSC4's tandem bromodomain *ts* mutation in combination with Gcn5 deletion or with histone H3K14 mutation turned out to be lethal suggesting that histone H3K14 acetylation is critical for Rsc4 function (Kasten et al. 2004).

Recently, using immobilized nucleosome arrays containing a block of four Gal4 binding sites it is shown that prior acetylation of the array with SAGA and NuA4 HAT complexes does not enhance SWI/SNF binding per se, but does allow retention of the SWI/SNF complex even after dissociation of the Gal4-VP16 activator that recruited SWI/SNF to the acetylated nucleosomal arrays. In a subsequent publication, they showed that retention of SWI/SNF on acetylated chromatin templates following removal of the transcription activator required the Swi2/Snf2 bromodomain. They validated the role of Swi2/Snf2 bromodomain in anchoring SWI/SNF to target loci in vivo by showing that the Swi2/Snf2 bromodomain contributes to SWI/SNF occupancy at the *SUC2* promoter (Hassan et al. 2002). In addition to histone tail acetylation, H3-K56 acetylation in the structured globular region of the core histone has been also shown to facilitate SWI/SNF recruitment most likely via the disruption of histone-DNA interactions near the entry-exit site of the nucleosome (Xu et al. 2005). An independent experiment by Carey et al. demonstrated that SAGA acetylated nucleosomes also stimulate binding of RSC under in vitro conditions (Carey et al. 2006).

Targeting of chromatin regulators to particular locations in the genome occurs either through interactions with sequence-specific DNA binding transcription factors or by using specialized protein motifs or domains that recognize specific post-translational modifications on histone tails. While, not yet demonstrated in vitro, since histone acetylation stabilizes SWI/SNF binding to nucleosomes, in principle

SWI/SNF could be recruited to chromatin via bromodomain dependent interaction with acetylated histone tails (Carey et al. 2006; Hassan et al. 2001, 2002). Particularly in the case of RSC based on the preponderance of bromodomains contained within its subunits one might envision that the multiple bromodomains might cumulatively increase the affinity for acetylated histone tails and provide efficient targeting of RSC to its substrates. Alternatively, the individual bromodomains within the RSC complex might not be redundant but may interact with different targets, acetylated histones and non-histone proteins, to localize RSC to different nuclear compartments or to regulate its remodeling activity. This may also explain why some of the bromodomains in RSC are essential and others are not. Further supporting the notion that the bromodomains in RSC have distinct binding partners, a recent finding showed that while one (BD#2) of the two essential tandem bromodomains in RSC4 is involved in histone H3-K14 acetylation recognition, the other (BD#1) participates in the auto-regulation of RSC activity by specifically interacting with acetylated Rsc4-K25 (VanDemark et al. 2007). This mechanism might have evolved to regulate the residence time of RSC at sites of remodeling which is critical for RSC to cater to the needs of ~700 physiological targets in the yeast genome. That individual bromodomains within the RSC complex might not be redundant but could have special functional features is further exemplified by the fact that only one of the two bromodomains (BD#2) of RSC1 and RSC2 is essential for cell viability (Cairns et al. 1999).

Does acetylation induced stabilization of SWI/SNF binding only facilitate recruitment of these complexes or such stabilization also contributes to their catalytic activity is another relevant question that has begun to be addressed recently. Biochemical data from Hassan et al. and Chandy et al. showing the requirement of the Swi2/Snf2 bromodomain for octamer transfer and remodeling of SAGA acetylated nucleosomes suggest that histone acetylation can affect the functional activity of SWI/SNF complexes by acting as binding epitopes for recruitment (Hassan et al. 2006). Thus in vivo we see that Pho5 and co-regulated Pho8 gene activation requires transient acetylation of promoter nucleosomes by SAGA and only the nucleosomes acetylated by SAGA become marked for displacement by SWI/SNF (Reinke and Horz 2003; Barbaric et al. 2003). Additional evidence in supporting that histone acetylation affects chromatin remodeling function of SWI/SNF complexes is provided by Ferreira et al. who demonstrated that RSC catalyzed remodeling is enhanced several fold upon histone H3 tail acetylation via lowering of K_m for acetylated nucleosomes (Ferreira et al. 2007).

Involvement in Double Strand Break Repair and Genome Stability

The maintenance of a stable and unaltered genome is crucial to cell survival and faithful propagation of genetic information to its progeny. Genome stability is threatened by numerous exogenous (ionizing radiation, radiomimetic agents) and endogenous (recombination, transposition, mating type switching, chromosome segregation) factors that introduce mutations and chromosomal rearrangements. A cell bearing an unstable genome is prone to growth arrest, premature ageing, apoptosis, and even malignant transformation. Instability is initiated among others by double strand breaks (DSBs) which are by far the most deleterious outcomes of genome-damaging agents (Paques and Haber 1999). Suppressors of DSBs include a class of *trans* acting factors that encompass replication, repair, and checkpoint proteins. A new addition to this class of factors has been ATP-dependent chromatin remodelers like INO80, SWR1, RSC, and SWI/SNF (van Attikum et al. 2007; Chai et al. 2005). SWI/SNF and RSC mutants (*Δsnf2, Δsnf5, sth1, sfh1*) show sensitivity to DNA damaging agents like hydroxyurea, bleomycin, MMS, and γ-irradiation (Chai et al. 2005; Koyama et al. 2002; Bennett et al. 2001). A more direct role has been established by their recruitment to DSBs by ChIP analysis albeit with different kinetics. RSC is bound to induced DSBs at the *MAT* locus in a localized region (0.2 Kb surrounding the break) within 10 min whereas SWI/SNF is recruited by 40 min with increased binding for over 4 h suggesting a role late in the repair process (Chai et al. 2005).

Cells have adopted two highly regulated damage repair pathways to counter DSBs. The homologous recombination repair (HRR) pathway makes use of long stretches of homologous regions of the sister chromatids that act as templates for faithful replication. Nonhomologous end joining (NHEJ) is more error-prone and joins together the broken ends of DNA by recognizing microhomologies of 1–5 bp. An investigation into the repair pathway affected in

SWI/SNF mutants revealed that they were able to rejoin cut plasmids through NHEJ but were unable to perform HRR. HRR proceeds via five steps: (1) 5′-3′ resection, (2) strand invasion, (3) new DNA synthesis, (4) unwinding from template and annealing, and (5) ligation (Peterson and Cote 2004). In SWI/SNF mutants, specifically the strand invasion step during homology search was affected and mutants decreased Rad51 and Rad52 association at *HMLα* (homologous donor template for *MAT* locus repair) (Chai et al. 2005). Given the remodeling and nucleosome displacement properties of SWI/SNF, it can be speculated that SWI/SNF plays a late but essential role in remodeling the homologous donor template region for efficient synapsis during HRR.

In contrast to SWI/SNF, RSC has been speculated to have roles in both NHEJ and HRR. RSC recruitment to DSBs has been shown to be dependent on yKu70, Mre11, and Rsc30 subunit. In addition, pull-down assays and two-hybrid studies indicate Rsc1 and Rsc2 physically interact with yKu80 and Mre11 (Shim et al. 2005). The yKu70/80 heterodimer is the central component of NHEJ recognizing DNA ends and recruiting other NHEJ factors. Mre11 is a component of the MRX/MRN (Mre11, Rad50, Xrs2/Mre11, Rad50, Nbs1) trimeric complex that is one of the key sensors of damaged DNA. It exhibits 3′ to 5′ exonuclease and endonuclease activities that are stimulated in presence of Rad50 and aid in 3′ end resection during NHEJ and HRR. A Δ*rsc30*Δ*rad52* and Δ*rsc8*Δ*rad52* double mutant showed enhanced hypersensitivity to DNA damaging agents suggesting that these RSC subunits affect a pathway other than that affected by Rad52 (Shim et al. 2005). Rad52 is an essential component in HRR and acts as a cofactor for Rad51 recombinase helping it to overcome competition from Replication Protein A (RPA) to bring about efficient strand exchange. Thus Rsc30 and Rsc8 are required for NHEJ. In contrast to *RSC30* and *RSC8*; *STH1*, *SFH1*, *RSC1*, and *RSC2* mutants are all able to perform NHEJ as efficiently as WT but not HR suggesting differential requirement of RSC subunits in the two modes of DSBR (Chai et al. 2005). Despite its early recruitment to DSB sites, a Δrsc2 mutant is unable to perform the final ligation step in HRR pointing to an early and late role of RSC in DSBR (Chai et al. 2005).

Chromosomal segregation during mitosis and meiosis is yet another cellular event that maintains genomic integrity and stability. From the S phase to anaphase, sister chromatids are held together at the centromeres and arms by a four-subunit cohesin complex comprising two SCC (Sister Chromatid Cohesion) proteins Mcd1/Scc1 and Scc3 and two SMC (Structural Maintenance of Chromosomes) proteins Smc1 and Smc3. Cohesion at centromeres and chromosomal arms is temporally regulated and recently the RSC complex has been implicated in cohesin loading. RSC association with cohesin in the arms is cell-cycle regulated while its association at the centromere is constitutive (Huang et al. 2004). However, *STH1* and *RSC2* mutants impair RSC recruitment specifically at the arms and result in their precocious separation. There are two alternative models proposed to explain the role of RSC in chromosomal arm cohesion. One model suggests RSC-mediated cohesin loading is coordinated with DNA replication. In support, factors involved in replication, Ctf7/Eco1, Ctf18, and Ctf8, interact genetically with RSC (Baetz et al. 2004). In another model, chromosomal arm cohesin loading is coupled to DNA repair and recombination. Cohesin has been found to be involved in post-replicative repair and two subunits Smc1 and Smc3 are components of recombination and repair complex RC1 (Huang and Laurent 2004). It is postulated that RSC remodels chromatin at chromosomal arms and recruits cohesin to maintain sister chromatid cohesion. These sister chromatids on one hand serve as templates for proper recombination and repair events and on the other allow for processive DNA replication by assuming ring structures.

Involvement of RSC and SWI/SNF in Cell Cycle Control, Differentiation, and Development

The temporal sequence of events that takes place in a eukaryotic cell before it undergoes replication to form two daughter cells together comprises the cell cycle or cell-division cycle. A typical cell cycle can be divided into two brief periods: interphase and mitotic or M phase. The interphase can be again divided into three sub-phases: gap1 or G1, synthesis or S, and gap2 or G2 phases while the mitotic M phase can be subdivided into prophase, metaphase, anaphase, and telophase.

As cell cycle controls DNA synthesis and cell proliferation, so the progression of cell cycle is highly regulated with specific checkpoints at particular points in the cell cycle like at the G1/S and G2/M transition points guarded by cyclins and cyclin dependent

kinases (CDKs) to monitor the progress of cell cycle. In budding yeast, the genes regulating cell cycle progression have been studied using temperature sensitive lethal mutants (*cdc* mutants) whose growth is arrested at specific points of the cell cycle at the restrictive temperature (Hartwell et al. 1974). These studies generated substantial evidence for an interconnection between chromatin remodeling and cell division cycle progression. Two such elegant genetic studies conducted in budding yeast demonstrated the requirement of two key subunits of RSC, Sth1 and Sfh1, for cell cycle progression through mitosis. Tsuchiya et al. showed that when Sth1, the Swi2/Snf2 counterpart in RSC, is depleted cells undergo an arrest and accumulate at the large bud stage with a single nucleus containing DNA of G2/M phase (Tsuchiya et al. 1992). Consistent with these results a temperature sensitive mutation in Sfh1, the Snf5 paralog in yeast, was found to induce cell cycle arrest at the G2/M phase (Cao et al. 1997). Both of these studies suggested a functional link between cell cycle control and RSC. Subsequent genetic studies conducted to investigate the actual role that RSC plays in cell cycle regulation isolated a temperature sensitive Sth1 mutant with impaired chromatin structure surrounding the centromeres (Tsuchiya et al. 1998). These results provide the molecular basis of the link between RSC and cell cycle control. The defective chromatin organization in absence of a functional RSC complex around centromeres might be abolishing kinetochore function which ultimately results in cell cycle arrest at G2/M transition. The yeast SWI/SNF complex on the other hand plays no role in the progression of cell division cycle through mitosis. In the contrary, SWI/SNF is required to efficiently exit from mitosis by mediating the expression of some late mitotic genes (Krebs et al. 2000). However, in flies, depletion of BAP (Brahma/BRM associated protein) complex, the *Drosophila* SWI/SNF complex, via RNAi mediated knockdown of its OSA subunit resulted in G2 to M arrest while cells lacking the RSC homolog PBAP (polybromo-containing BAP) complex showed no cell cycle defects (Moshkin et al. 2007). The *Drosophila* BAP complex regulates cell cycle progression by controlling the expression of STRING/► CDC25 which is required for entry into mitosis. This apparent contradiction from *yeast* to *flies* suggests for a functional shift in the course of evolution. In humans, both hBRM and BRG1 (BRM related gene 1) complexes participate in the regulation of cell cycle control by interacting with retinoblastoma proteins (Dunaief et al. 1994). These observations once more reinforces the notion that functional differences between yeast SWI/SNF complexes cannot be directly translated to higher eukaryotes.

The RSC complex also stimulates expression of early meiotic genes and sporulation and thereby facilitates developmental processes in budding yeast (Yukawa et al. 1999). There are numerous examples of involvement of the human SWI/SNF complexes in various developmental programs, such as muscle, heart, blood, skeletal, neuron, adipocite, liver, and T-cell development. The SWI/SNF class of chromatin remodeling complexes has instructive and reprogramming roles during development. Of particular importance are the findings that in vertebrates SWI/SNF complexes are combinatorially assembled for maintaining pluripotency and multipotency. Studies of the mammalian SWI/SNF complex, BAF (Brahma associated factor) indicate that a progressive change in its subunit composition underlies the transition from pluripotent embryonic stem cells (ESCs) to multipotent neuronal progenitors to post-mitotic differentiated neurons during nervous system development (Lessard et al. 2007). Mouse ESCs express a BRG1 containing esBAF complex which also contains BAF155 but not BAF170 (Ho et al. 2009). The esBAF complex is crucial for maintaining pluripotency and self-renewal of mouse ESCs (Ho et al. 2009). As ESCs differentiate into neuronal progenitors, the esBAF complex undergoes dynamic subunit exchanges incorporating BRM and BAF60C and eliminating BAF60B to form the neuronal-progenitor specific BAF (npBAF) complex (Lessard et al. 2007; Ho et al. 2009). BRG1 in npBAF complex ensures self-renewal of the neuronal progenitors and their differentiation into committed neurons (Lessard et al. 2007). The BAF45A subunit in npBAF induces proliferation of neuronal progenitors past their normal mitotic exit point (Lessard et al. 2007). As neuronal progenitors exit from mitosis, the BAF45A and BAF53A subunits in the npBAF complex are replaced by BAF45B and BAF53B subunits to form the neuron-specific BAF (nBAF) complex (Lessard et al. 2007). More recently, it has been shown that BAF45A depletion in post-mitotic neurons is microRNA (miR-9* and miR-124) mediated (Yoo et al. 2009). The nBAF complex is essential for post-mitotic neuronal function including activity-dependent dendritic outgrowth by

interacting with CREST, a Ca^{2+} responsive dendritic regulator (Peterson et al. 2007).

The tissue specific BAF complexes have been also reported to play a role in cardiac fate determination during heart development in vertebrates (Lickert et al. 2004). BAF60C which is selectively expressed in regions of the mouse embryo that gives rise to a heart is required for heart morphogenesis, differentiation of cardiac and skeletal muscle cells (Lickert et al. 2004) and more importantly when injected into the non-cardiogenic regions of the developing embryo BAF60C in coordination with transcription factors GATA4 and TBX5 induces the development of beating cardiomycetes from non-cardiogenic mesoderm (Lickert et al. 2004). These data suggest the existence of a BAF60C containing specialized cBAF complex although till date such a cardiogenic complex could not be isolated. On the other hand, the highly homologous polybromo or BAF180 containing BAF (PBAF) complex which is expressed in the epicardium plays roles in mediating coronary development and cardiac chamber maturation (Huang et al. 2008).

The role of BAF complexes is also implicated in T-cell development in the thymus. However, there is no report of any specialized BAF complexes in the thymocytes. During T-cell differentiation two co-receptors of the T-cell antigen receptor, CD4 and CD8, are differentially expressed. *Cd4* is developmentally repressed by a distantly located silencer ~2 kb from the transcription start site of *Cd4* (Sawada et al. 1994). At an early stage of development BAF complex binds to the distant silencer element via BRG1 and BAF57 and recruits a transcription factor RUNX1 which mediates *Cd4* gene silencing (Wan et al. 2009). This data also suggests fundamental mechanistic differences between yeast SWI/SNF and mammalian BAF complexes as the former is known to regulate its target genes by binding to promoters. In mice, BRG1 is again required at a later stage to activate *Cd4* expression indicating that BAF complexes can both activate and repress the same gene depending on the developmental context (Dey et al. 2003).

Although it remains poorly understood, BRG1 and BAF complexes might also be required for skeletal muscle differentiation as a dominant negative allele of *Brg1* or RNAi mediated depletion of BAF60C appears to be detrimental for myogenic transcription factor (MYOD1 and MEF2D) action (Lickert et al. 2004; de la Serna et al. 2001).

Summary

Clearly, there are many ways that the SWI/SNF chromatin remodelers are involved in regulation of transcription, replication, recombination, and DNA repair. It is also evident that with the large number of SWI/SNF complexes that they are not particularly redundant in terms of function, but rather have very specialized roles in the cell. While much can be learned about the fundamental mechanistic properties of SWI/SNF by studying one form of these complexes in such organisms like yeast, it seems likely that there will be differences in their mode of operation which will be context dependent. Differences between various SWI/SNF complexes will be reflected in part how they are differentially recruited to specific genomic regions, but aside from this the data suggest that they will also probably remodel nucleosomes in distinctive ways. So far progress has been made on cataloging the SWI/SNF complexes involved in different developmental pathways, but still there is no data to indicate how the presence or absence of a particular subunit could alter the mode of remodeling that occurs.

Historical Background

Plekhg5 first emerged as a partial cDNA clone KIAA0720 in the HUGE (Human Unidentified Gene-Encoded) database of large proteins analyzed by the Kazusa Human cDNA Project in Japan (http://www.kazusa.or.jp/huge). It was initially characterized as a RhoA-specific GEF and a potential oncogen named GEF720 (de Toledo et al. 2003). Independently, the rat cDNA of the same protein (named Tech) was characterized also as a RhoA-specific GEF that was highly expressed in cortical and hippocampal neurons (Marx et al. 2005). Two full-length cDNA clones of the mouse ortholog were identified as splice variants (named Syx1 and Syx2) and characterized as participants in cell motility (Liu and Horowitz 2006).

Splice Variants and Domain Structure

The majority of the known splice-variants of Plekhg5 are produced by the initiation of transcription at alternate 5′ start codons (http://www.uniprot.org/uniprot/O94827). These five transcripts code for variants ranging in length from 930 to 1083 residues. Interestingly, the sixth variant is generated by 3′ splicing, very close to the stop codon. The shorter splice variant lacks the two 3′ codons. The absence of the two carboxy-terminus residues in the shorter splice variant removes the PDZ-binding motif and abolishes binding to the PDZ adaptor proteins synectin (Liu and Horowitz 2006) and Mupp1/Patj (Ernkvist et al. 2009). The expression level of the shorter splice variant is negligible in most cell types, except in lines of glioblastoma multiforme, where it reached close to 10% of the expression level of the longer splice variant (Liu and Horowitz 2006). The absence of the PDZ-binding domain resulted in a diffuse rather than targeted distribution of the overexpressed shorter splice variant. RhoA activity in these cells was similarly diffuse and higher than the basal RhoA activity in cells expressing the longer splice variant.

Plekhg5 conforms to the canonical Dbl structure, where a Dbl homology (DH) domain, which is the site of catalytic activity, is flanked by a pleckstrin homology (PH) domain (Fig. 1). Similar to numerous Rho GEFs (Garcia-Mata and Burridge 2007), the C-terminus of the long splice variant of Plekhg5 (Syx1) consists of a PDZ-binding motif. This motif is absent in the shorter splice variant Syx2 (Liu and Horowitz 2006).

Major Sites of Expression and Subcellular Location

Northern blots of mouse tissue showed that plekhg5 is expressed primarily in the brain and to a lesser extent in the heart (de Toledo et al. 2003). More recent Northern blotting pinpointed the expression of plekhg5 in the brain to the hippocampus and cortex (Marx et al. 2005). Quantitative PCR showed that the highest expression level in the human nervous system was in the peripheral nerves (Maystadt et al. 2007). Gene array studies reported a more widely distributed expression of human plekhg5, with similar expression

SYX/PLEKHG5, A Rhoa Guanine Exchange Factor Involved in Cell Migration and Angiogenesis, Fig. 1 Domain structure of Syx. *DH* dbl homology, *PH* pleckstrin homology, *PDZ* postsynaptic density 95, disk large, zona occludens-1. Numbers denote amino acid positions in the mouse protein

levels in the brain, heart, skeletal muscle, lung, kidney, liver, pancreas, and the prostate (Yanai et al. 2005).

Plekhg5 was observed in three main cellular compartments. Plekhg5 is present in the cytoplasm, associated with endocytic vesicles and with angiomotin, primarily but not exclusively in the perinuclear region. Plekgh5 collocated with Rab13, suggesting it traffics together with tight junction proteins (Wu et al. 2011). It was also observed at tight junctions where it collocated with ZO1, and in the leading edge of endothelial cells.

Function

Plekhg5 (pleckstrin homology domain containing family with Rho GEF domain 5) is a member of the Dbl Rho GEFs. Plekhg5 conforms to the canonic Dbl structure, that is, a Dbl homology (DH) domain that catalyzes GDP removal from Rho GTPases, followed by a pleckstrin homology (PH) domain. The PH domain is commonly involved in GEF auto-regulation and targeting. The carboxy-terminus of Plekhg5 (SEV*) conforms to the consensus sequence of neuronal nitric oxide synthase (nNOS) class 1 PDZ-binding motifs. Plekhg5 is widely expressed and highly conserved in vertebrates, but is not expressed in *Drosophila melanogaster* and in the nematode *Caenorhabditis elegans*. Among vertebrates, it is expressed in the zebrafish (XM_001923778.1, 75% homology), chicken (XP_423692.2, partial sequence, 92% homology), mouse (AY605057.1, 86% homology), rat (AY499658.1, 87% homology), cow (XM_867846.3, 90% homology), horse (XP_001915300.1, 90% homology), dog (XM_536728.2, 91% homology), and chimpanzee (XP_514339, 85% homology). Plekhg5 was characterized as RhoA-specific versus RhoB, RhoC, RhoG, Rac1-3, and Cdc42 (de Toledo et al. 2003). The RhoA-specificity was confirmed in an independent study (Marx et al. 2005).

In vitro studies showed that Plekhg5 is essential in endothelial cell migration and tube formation (Liu and Horowitz 2006). Knockdown of the zebrafish *plekhg5* ortholog resulted in growth arrest of the intersegmental vessels and alteration of the morphology of the tip cells of these vessels (Garnaas et al. 2008). Instead of a tapered end that projected long filopodia, the tip cells in the knockdown zebrafish had a round end from which a dense array of thin filopodia protruded in all directions. The loss of filopodia directionality suggests that the growth arrest of the intersegmental vessels was caused, at least in part, by a guidance defect. The *plekhg5*$^{-/-}$ mouse was viable and fertile, but had a subtle angiogenic defect of a similar nature to the phenotype of the zebrafish *plekhg5* knockdown – sparseness of arterioles and capillaries. Probably because of reduced perfusion, the pumping function of the *plekhg5*$^{-/-}$ heart was significantly lower than the wild-type heart. Further in vitro studies showed that *plekhg5* silencing in endothelial cells was accompanied by loss of the ZO1 scaffold protein from tight junctions, and an increase in monolayer permeability (unpublished data). Accordingly, electron microscopy showed that tight junctions in the *plekhg5*$^{-/-}$ coronary capillaries were missing or not fully formed. In vitro studies showed that *plekhg5* silencing in endothelial cells was accompanied by loss of the ZO1 scaffold protein from tight junctions, and an increase in monolayer permeability (unpublished data).

High throughput screening of genes that activate nuclear factor κ B (NFκB) signaling identified *plekhg5* among a group of 299 genes (Matsuda et al. 2003). In agreement, in vitro studies with epithelial cells found that overexpression of *plekhg5*-produced a tenfold increase in NFκB activity (Maystadt et al. 2007). A point mutation (F703S) in the PH domain of human *plekhg5* was found to be a marker of a previously uncharacterized autosomal recessive lower motor neuron disease prevalent in a large inbred family from sub-Saharan Africa (Maystadt et al. 2007; Maystadt et al. 2006). Further studies revealed that overexpressed mutant *plekhg5* in murine motor neuronal cells (but not in human epithelial cells) formed large cytoplasmic aggregates (Maystadt et al. 2007). Conceivably, and similar to other degenerative diseases of the nervous system, the aggregation of the mutant Plekhg5 could have damaged the motor neurons in the affected individuals (Ross and Poirier 2005).

At this point, no nervous system defects were reported in the *plekhg5*$^{-/-}$ mouse.

Relatively little is known on Plekhg5 regulation. Truncation of the first 248 amino-terminal residues together with the carboxy-terminal region immediately downstream of the PH domain conferred constitutive activity on Plekgh5 (Marx et al. 2005). Since both the amino and carboxy-terminus regions were truncated, it is not yet possible to determine if auto-regulation requires one or both regions. No Plekgh5 phosphorylation sites have been reported yet.

The phenotype of the zebrafish *plekhg5* knockdown has been described above. The loss of filopodia directionality suggests that the growth arrest of intersegmental vessels was caused, at least in part, by a guidance defect. The *Plekhg5*$^{-/-}$ mouse was viable and fertile, but had an angiogenic defect consisting of sparseness of arterioles and capillaries. Probably because of reduced perfusion, the pumping function of the *plekhg5*$^{-/-}$ heart was significantly lower than that of the wild-type heart. Further in vitro studies showed that *plekhg5* silencing in endothelial cells was accompanied by loss of the ZO1 scaffold protein from tight junctions and an increase in monolayer permeability (unpublished observations).

Interactions with Ligands and Other Proteins

Plekhg5 binds RhoA (Marx et al. 2005), in agreement with its specificity for RhoA as an effector. A recent study reported that Plekhg5 binds Rnd3 (alternatively named RhoE), a constitutively active GTPase of intrinsically low GTP hydrolysis rate (Goh and Manser 2010). Rnd3 is thought to act as a RhoA antagonist by activating the GTPase activating protein p190 RhoGAP (Wennerberg et al. 2003). Rnd3 expressed endogenously in mouse embryonic stem cells binds to a 70 amino acid-long domain in the N-terminus region of Plekhg5 that bears similarity to the Raf1 Ras-binding domain (Goh and Manser 2010).

Two PDZ adaptor proteins are known to bind the carboxy-terminus of Plekhg5: synectin (Liu and Horowitz 2006) and Mupp1 (Ernkvist et al. 2009; Estevez et al. 2008) as well as the Mupp1 paralog Patj (Ernkvist et al. 2009). The binding site of Plekhg5 to Mupp1 is either the 10th or 13th PDZ domain, or both (Estevez et al. 2008), whereas Plekhg5 binds to the 10th PDZ domain of Patj (Ernkvist et al. 2009). Both Mupp1 and Patj bind angiomotin, which couples Plekhg5 to members of the Par-6/Par-3 apico-basal polarity complex (Ernkvist et al. 2009; Wells et al. 2006). This angiomotin-associated complex includes the Cdc42-specific GTPase-activating protein Rich1, and the scaffold protein Pals1. In turn, Pals1 and Patj link angiomotin and Plekhg5 to the Crumbs complex. Hence, Plekhg5 is member of a large signaling complex involved in maintaining cell polarity and tight junctions.

Summary

Syx/Plekhg5 is a ubiquitously expressed RhoA guanine exchange factor whose functions are known only partially. Despite its high expression level in the brain, its specific neural function is not fully understood. While the highest site of expression appears to be in cortical and hippocampal neurons of the central nervous system, a point mutation in human PLEKHG5 results in an autosomal recessive lower motor neuron disease. In contrast, animal models suggest that one of the primary functions of Syx/Plekhg5 is in angiogenesis.

Historical Background

The major microtubule organizing center in animal cells is the centrosome which consists of a pair of centrioles surrounded by the pericentriolar matrix. In interphase cells, centrosomes nucleate and organize the microtubule cytoskeleton and are usually maintained at the cell center in close association with the nucleus (Bettencourt-Dias and Glover 2007). This association constitutes a primordial axis of cytoplasmic compartments organization and organelle positioning (e.g., ER and Golgi apparatus). Centrosomes are also involved in mitotic spindle formation, and an aberrant centrosome number has been linked to multipolar spindles and to cancer cells. In the last years, the ability of centrosomes to become basal bodies and assemble cilia emerged also as a critical role (Bettencourt-Dias and Glover 2007). Cilia are now established as having important roles as movement

TBCCD1, Fig. 1 Schematic representation of the functional domains of TBCC domain containing proteins: TBCC, TBCCD1, and RP2. These three proteins share the TBCC and CARP domains

generating and sensory organeles being essential for embryonic development. Critically, cilia malfunction has been associated with abnormal left-right asymmetry, polycystic disease, obesity, neuropathies, blindness, and other ciliopathies (Nigg and Raff 2009).

Proteomic studies have been revealing an increasing number of centrosomal proteins, making it clear that many of them have unknown roles in the cell and can be translocated to different compartments during the cell cycle or in response to environmental cues (Nigg and Raff 2009; Andersen et al. 2003; Keller et al. 2005). This shows that centrosomes concentrate and probably regulate the interactions and the intracellular distribution of a variety of proteins contributing to the establishing of networks of different pathways.

One example of a group of proteins that have been recently localized at the centrosome is the one that comprises several components of the via that promotes the maturation of tubulin heterodimers, the building blocks of microtubules, as well as their regulatory and related proteins. These proteins being critical for the assembly of tubulin heterodimers competent to polymerize and controlling heterodimer quality and degradation (Lopez-Fanarraga et al. 2001) are central factors in regulating microtubule assembly and dynamics. As far as these proteins have been studied in vivo in different biological models, their ability to play other functions, not always related to their role in the tubulin folding pathway, started to emerge. For example, the recently described centrosomal protein TBCCD1 is a protein related, through its functional domains, to the tubulin cofactor C, one of the least studied components of the tubulin folding pathway, that plays a role in centrosome positioning and centrioles' interplay (Feldman and Marshall 2009; Gonçalves et al. 2010).

The Centrosomal/Basal Bodies Localization of TBCCD1

Recently, a new protein related to TBCC (tubulin cofactor C) and RP2 (retinitis pigmentosa 2), called TBCCD1 (TBCC-domain containing 1), was described both in *Chlamydomonas reinhardtii* and human cells (Feldman and Marshall 2009; Gonçalves et al. 2010). These three proteins share two conserved functional domains: TBCC and CARP (Fig. 1). The CARP domain is also described in CAP proteins which regulate actin polymerization. TBCC, together with tubulin cofactor D, acts as β-tubulin GTPase activating proteins (GAP) in the via that leads to mature tubulin heterodimers (Fontalba et al. 1993; Tian et al. 1999). In vitro, RP2 can also act as a GAP for tubulin, but it does not substitute for TBCC in the tubulin-folding pathway. Nevertheless, a functional overlap was further shown by the capacity of RP2 to partially complement the *CIN2* (*tbcc* homologous gene) deletion in budding yeast (Bartolini et al. 2002). RP2 was also shown to bind to and be a GAP for the ADP-ribosylation factor-like 3 (Arl3), a member of the ADP-ribosylation factor family of small GTPases that is highly conserved in eukaryotes, and plays important roles in the regulation of microtubule-dependent

processes. Human Arl3 localizes at centrosomes, midzones, midbodies, and cilia (Veltel et al. 2008; Zhou et al. 2006) and, in the mouse, its knockout causes ciliary problems like: abnormal development of renal, hepatic, and pancreatic epithelial tubule structures, and photoreceptor degeneration (Schrick et al. 2006). It was also shown that Arl3 is necessary for flagellum biogenesis in *Leishmania* (Cuvillier et al. 2000).

RP2 mutations are implicated in the Retinitis Pigmentosa pathology characterized by a progressive photoreceptor cell degeneration leading to the loss of peripheral vision and eventually to blindness. In fact, 15–20% of the cases of Retinitis Pigmentosa result from mutations in the *rp2* gene (Schwahn et al. 1998). The GAP activity of RP2 and *TBCC* relies on the TBCC domain, and many of the RP2 mutations involved in this pathology occur in this domain (Schwahn et al. 1998). For example, this activity is abolished if RP2 is mutated in the only arginine residue conserved between RP2 (Arg-118) and TBCC (Arg-262) and that also abolishes TBCC's GAP activity (Veltel et al. 2008). Human and *Chlamydomonas* TBCCD1 proteins do not contain this critical arginine residue, suggesting that its TBCC domain lost the GAP activity. This hypothesis is supported by the observation that human TBCCD1 is unable to rescue the phenotypes of *CIN2* deletion in yeast (Gonçalves et al. 2010).

Studies of the subcellular localization of TBCCD1 in human cells show that it is localized in the centrosome throughout the cell cycle being also detected in the spindle midzone and in the midbody at the end of cell division (Fig. 2A). TBCCD1 was also found in the basal bodies of primary and motile cilia. Interestingly, *Chlamydomonas* TBCCD1 also localizes at centrioles/basal bodies and in rhyzoplasts, structures that connect them to each other and to the nucleus (Fig. 2B) (Feldman and Marshall 2009).

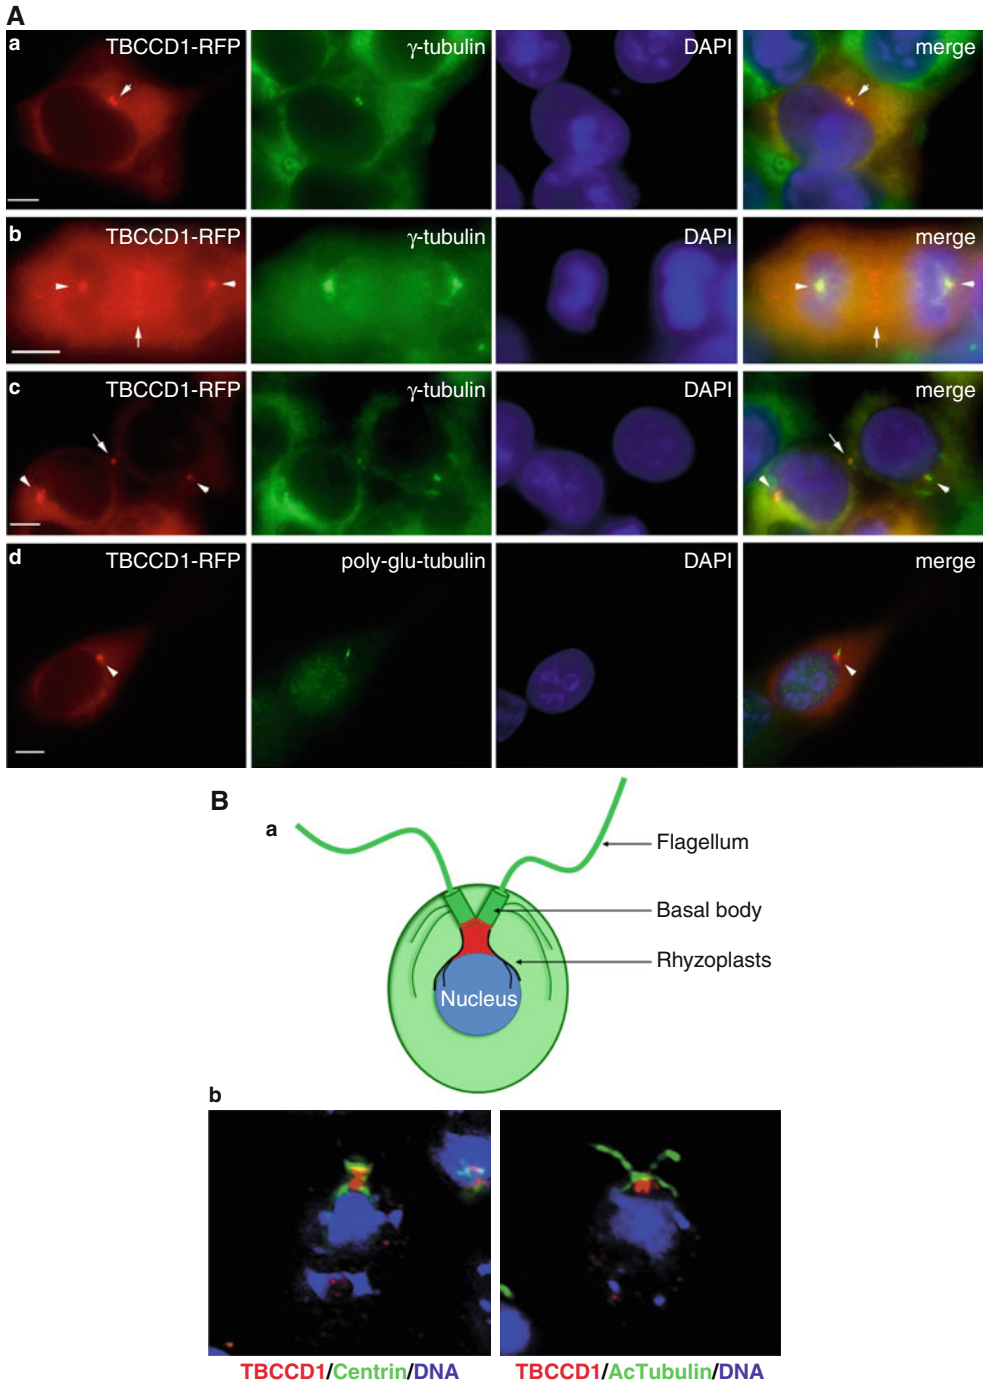
TBCCD1: The Nucleus–Centrosome Connection

TBCCD1 silencing by RNAi in human RPE-1 cells caused a remarkable separation of the centrosome from the nucleus being the former often located at the cell periphery (Gonçalves et al. 2010). Similarly, in *Chlamydomonas*, TBCCD1 loss of function by an insertion disrupting the *TBCCD1* gene caused centriole positioning defects, which leads to the assembly of the mitotic spindle with incorrect orientation (Feldman and Marshall 2009).

In the last years, the importance of the nucleus–centrosome connection has been recognized not only for the intracellular organization of the cytoplasm but also has a key factor implicated, for example, in directed cell migration, adhesion and polarity, crucial events in development and cancer. This connection is dynamic and able to be remodeled in response to several signals, like those involved in cell differentiation (e.g., differentiating neurons). However, the mechanisms underlying the dynamic nucleus–centrosome connection are far from being understood. In this context, TBCCD1 being required for centrosome positioning and correct mitotic spindle orientation is an emerging key factor in the nucleus–centrosome interplay and in the centrosome activities that depend on it. Supporting this view are the observations that in human cells silenced for TBCCD1, the centrosome mispositioning is accompanied by a dramatic disorganization of Golgi apparatus and a G1 cell cycle delay. Moreover, TBCCD1-depleted cells are larger, less efficient in primary cilia assembly, and their migration is slower in wound-healing assays.

Elegant experiments growing mammalian cells in patterned surfaces have shown that geometrical constraints imposed by the substratum play a crucial role in centrosome positioning and cytoplasmic organization (Pouthas et al. 2008). However, this is not the sole responsible factor since microtubules and forces exerted on them by actomyosin and dynein are also critical (Burakov et al. 2003). The existence of a physical link between the centrosome and the nuclear envelope is supported by a variety of data being proteins that are able to bind it to nuclear envelope, such as Zyg-12, Emerin, and Samp1, implicated in it (Malone et al. 2003; Salpingidou et al. 2007; Buch et al. 2009). This interaction seems to be regulated by a group of distinct kinases like the p160ROCK Rho associated and the Polo/Greatwall (Gwl) mitotic kinases (Chevrier et al. 2002; Archambault et al. 2007).

In *Chlamydomonas*, the absence of TBCCD1 can lead to aberrant numbers of centrioles and flagella. TBCCD1 mutant cells (*asq2*) can have up to seven flagella which show that the protein is not essential for the formation of these structures. Additionally, the increased number of centrioles suggests that, in *Chlamydomonas*, TBCCD1 could have a regulatory role in de novo centriole assembly pathway (Feldman



TBCCD1, Fig. 2 *Subcellular localization of TBCCD in human cells and Chlamydomonas*. (**A**) *HEK-293T* Cells were transfected with a plasmid containing TBCCD1-RFP and immunostained using antibodies against γ-tubulin (**a**, **b**, and **c**), or polyglutamylated tubulin (**d**). Arrowheads point to TBCCD1-RFP at centrosomes. Arrows indicate spindle midzone (**b**), midbody (**c**) and basal body (**d**). (**Ba**) Schematic representation of the TBCCD1 localization in *Chlamydomonas*. TBCCD1 cellular localization is showed in red in the region between the rhyzoplasts, structures that are responsible for the connection between the basal bodies and the nucleus. (**Bb**) In wild-type cells, TBCCD1 localizes to the region between the rhizoplasts and to the centrioles (Reproduced from Feldman and Marshall, 2009 with permission)

and Marshall 2009). This phenotype has not been detected in human cells depleted in TBCCD1 which may be related to remaining levels of TBCCD1 in these cells that impair the appearance of more dramatic effects.

Marshal and coworkers (Feldman and Marshall 2009) have also showed that the linkage between centrioles in *asq2* mutant cells has been affected. Interestingly, in moving RPE-1 centrin-GFP knockdown cells analyzed by time-lapse microscopy, the centrioles are less dynamic that in control cells. In fact, in control-moving cells, the centrioles present a dynamic behavior in which they temporarily distance slightly from each other, suggesting that TBCCD1 is also involved in centriole–centriole interaction.

Summary and Perspectives

Both characterizations of TBCCD1 in human cells and *Chlamydomonas* show that TBCCD1 is a centrosomal/basal body protein conserved throughout evolution that is involved in the correct positioning of these organelles in the cell and affecting the activities depending on it.

The roles of TBCCD1 only now started to be revealed, and much more investigation is required to clarify its functions. In the immediate, it would be important to understand if this protein establishes a physical link to the nucleus or, alternatively, if it regulates this interaction. Therefore, the clarification if TBCCD1 presents or not a GAP activity associated to the identification of its partners would be a decisive step to clarify this question.

Historical Background

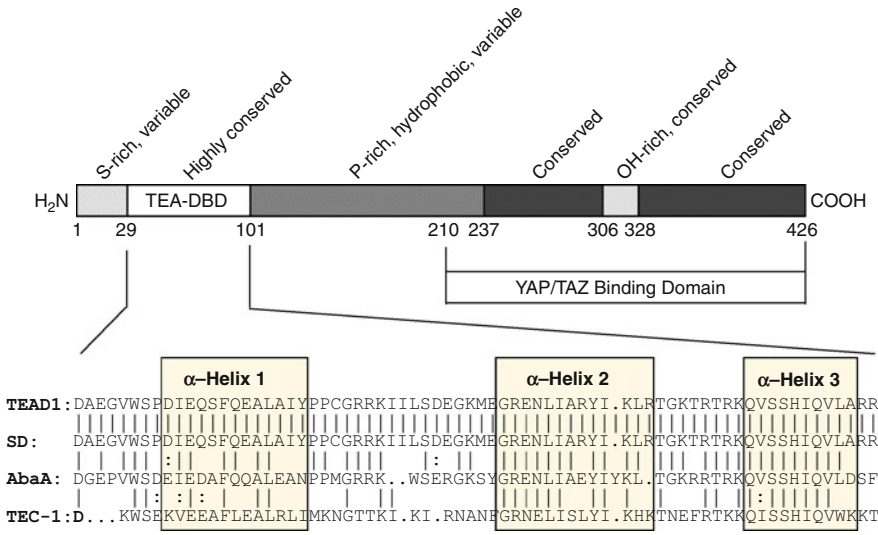
In vertebrates, the TEAD family of transcription factors is comprised of four members that contain a highly conserved (99–100%) DNA-binding domain, designated the TEA/ATTS domain (Burglin 1991) (Fig. 1). This highly conserved domain is comprised of three α helical domains and is not confined to vertebrates, but is also found in transcription factors from multiple organisms, including the TEAD1 homologs AbaA (*Aspergillus nidulans*), TEC1 (*Saccharomyces cerevisiae*), and scalloped (sd, *Drosophila melanogaster*). Thus TEAD family members represent primordial transcription factors, emphasizing their very early evolutionary origins and central importance in regulating gene expression and essential developmental functions. TEAD1 was originally cloned as a transcriptional enhancer factor (TEF) that was involved in mediating the activity of the Simian virus 40 (SV40) enhancer (Xiao et al. 1991). Subsequent studies revealed that TEAD family members bind to the MCAT motif, 5′-CATTCCT-3′, that is found in the promoter–enhancer regions of cardiac, smooth, and skeletal muscle-specific genes (reviewed in Yoshida 2008). In addition, TEAD family members have been found to be involved in the regulation of a diverse array of genes, including the human papilloma virus (HPV) E6 and E7 oncogenes, and human chorionic somatomammotropin, Foxa2, and PAX3 genes (reviewed in Eberhardt et al. 1996; Jacquemin and Davidson 1997; Kaneko and DePamphilis 1998; and Walker et al. 1991). Most knowledge of TEAD regulation of gene expression is derived from studies of muscle-specific genes.

TEAD genes play critical roles in mammalian development as demonstrated by knockout of the TEAD1 and TEAD4 genes, both of which lead to embryonic lethal phenotypes (Chen et al. 1994; Yagi et al. 2007). In addition, dual knockout of TEAD1 and TEAD2 results in embryonic lethality with severe growth defects and morphological abnormalities (Sawada et al. 2008), emphasizing the diverse critical roles TEAD family members play in mammalian development.

TEAD1

The human *TEAD1* gene is located on chromosome 11p15.4. TEAD1, the prototypical member of the TEA/ATTS transcription factor family, is widely expressed in multiple tissues, including skeletal muscle, pancreas, placenta, lung, and heart. TEAD3 and TEAD4 share a similar tissue distribution, suggesting that these proteins have partially redundant functional roles. TEAD1 regulates the expression of several muscle-specific genes, including cardiac troponin T, β-myosin heavy chain, smooth muscle α-actin, skeletal α-actin, and the α1-adrenergic receptor gene in cardiac myocytes (reviewed in Yoshida 2008). In addition, the expression of myocardin, the transcriptional co-activator of serum response factor (SRF), is regulated by an enhancer that is mediated by the combined actions of TEAD1, Mef2, and Foxo transcription factors. TEAD1 is required specifically for myocardin enhancer activation in neural-crest-derived smooth muscle cells and dorsal aorta. TEAD1 represses expression of the gene encoding involucrin in keratinocyte terminal differentiation and regulates early gene expression in mouse embryogenesis. TEAD1 has been implicated in the control of a placental enhancer/silencer driving the expression of the placental lactogens in syncytiotrophoblasts and inhibiting the expression of these genes in pituitary somatolactotrophs (reviewed in Eberhardt et al. 1996; Jacquemin and Davidson 1997; and Walker et al. 1991).

The most compelling evidence for TEAD1 involvement in cardiac development comes from studies of TEAD1 knockout mice, resulting in multiple cardiac defects and embryonic lethality (Chen et al. 1994). The mutant embryos exhibited enlarged pericardial cavity, bradycardia, a dilated fourth brain ventricle, and lethality at days e11.5–12.5. Heart development in the mutant embryos was extensive, indicating that TEAD1 was not required for initiation of heart development, but exhibited a very thin ventricular wall and reduced trabeculation. Transcription of several muscle-specific genes believed to be TEF-1 targets appeared to be normal, suggesting that many of these genes may be regulated by the other TEAD family members. The defect in cardiogenesis has been attributed to diminished transcription of one or several cardiac-specific genes that may be more specifically regulated by TEAD1.



Tead, Fig. 1 Schematic structure of TEAD family members showing the domains with enriched amino acids, serine (S), proline (P), hydrophobic, and hydroxylated (OH) and their relative degree of conservation. The N-terminal serine-rich domain is frequently phosphorylated, providing a mechanism for modulation of TEAD activity. The amino acid sequences of the highly conserved TEA DNA-binding domains (DBD) of TEAD1, AbaA (*Aspergillus nidulans*), TEC1 (*Saccharomyces cerevisiae*), and scalloped (SD, *Drosophila melanogaster*) and the α-helical regions are shown. The YAP/TAZ binding domain is indicated. The x-ray crystal structure of the YAP-TEAD4 complex indicates that the N-terminal region of YAP is folded into two short helices interspersed with a loop containing the PXXΦP motif and the C-terminal domain of TEAD4 has an immunoglobulin-like fold (Chen et al. 2010). The TEAD4-YAP binding is mediated chiefly by the two α-helices on the N-terminus of YAP. Numbers indicate amino acid positions for TEAD1 and are very similar for the other TEAD family members

TEAD2

The human *TEAD2* gene is located on chromosome 19q13.3. The tissue-specific expression pattern of TEAD2 is unique, since it is essentially absent from adult tissues. TEAD2 is expressed during the first 7 days of embryonic development in selected embryonic tissues, including the cerebellum, testis, tail bud, and distal portion of the forelimb and hindlimb buds. TEAD2 is involved in mouse early embryo development and has been implicated along with Ets-1 in the regulation of CTP:phosphocholine cytidylyltransferase activity. Mouse TEAD2 has also been shown to be a regulator of Pax3, a transcription factor that is essential for premigratory neural-crest cells that give rise to the peripheral nervous system, melanocytes, and certain vascular smooth muscle cells. TEAD2 has also been shown to be important in effective muscle regeneration, where it acts in conjunction with MyoD and Fgfr4.

TEAD2 and TEAD1 have been shown to exhibit partially overlapping and redundant functions and are critical for normal development (Sawada et al. 2008). While mice lacking TEAD2 appear to be normal, knock out of both TEAD1 and TEAD2 genes results in an embryonic lethal phenotype at E9.5. Embryos exhibited reduced cell proliferation and increased apoptosis along with multiple severe growth defects and morphological abnormalities, including absence of a closed neural tube, notochord, and somites.

TEAD3

The human *TEAD3* gene is located on chromosome 6p21.2. TEAD3 is expressed primarily in the heart and placenta. TEAD3 binds to the chorionic somatomammotropin gene enhancer and positively regulates hCS gene expression in human and murine placental cells (reviewed in Eberhardt et al. 1996; Jacquemin and Davidson 1997; and Walker et al. 1991). TEAD3 has also been implicated in the regulation of the gene encoding 3β-hydroxysteroid dehydrogenase/isomerase in the placenta. In the heart TEAD3, along with TEAD4, is involved in regulating the expression of muscle-specific genes and is involved in mediating the α1-adrenergic response in cardiac myocytes.

TEAD4

The human *TEAD4* gene is located on chromosome 12p13.2-p13.3. TEAD4 is expressed primarily in cardiac and skeletal muscle, where the protein activates muscle-specific genes through interactions with the muscle-specific MCAT response element. Genes regulated by TEAD4 include cardiac α-myosin heavy chain, skeletal muscle α -actin, and the S100B gene. TEAD4 seems to have a unique function in mediating the α1-adrenergic response in hypertrophic cardiac myocytes. The α1-adrenergic activation of TEAD4 appears to require phosphorylation at Ser 322. TEAD4 has also been implicated in the regulation of vascular endothelial growth factor (VEGF) in the ischemic heart and hypoxic endothelial cells.

Knock out of the mouse TEAD4 gene in mice results in a preimplantation lethal phenotype (Yagi et al. 2007). Specification of mammalian cell lineages begins shortly after fertilization with formation of a blastocyst comprised of trophectoderm and inner cell mass (ICM), giving rise to the placenta and embryo, respectively. TEAD4(−/−) embryos lack expression of trophectoderm-specific genes, including Cdx2, and lack trophoblast stem cells, trophectoderm, or blastocoel cavities with resultant inability to implant into the uterine endometrium. However, conditional knock out of TEAD4 embryos after implantation results in complete development, demonstrating that TEAD4 is the earliest gene required for specification of the trophectoderm lineage.

Co-regulatory Molecules Involved in TEAD Function

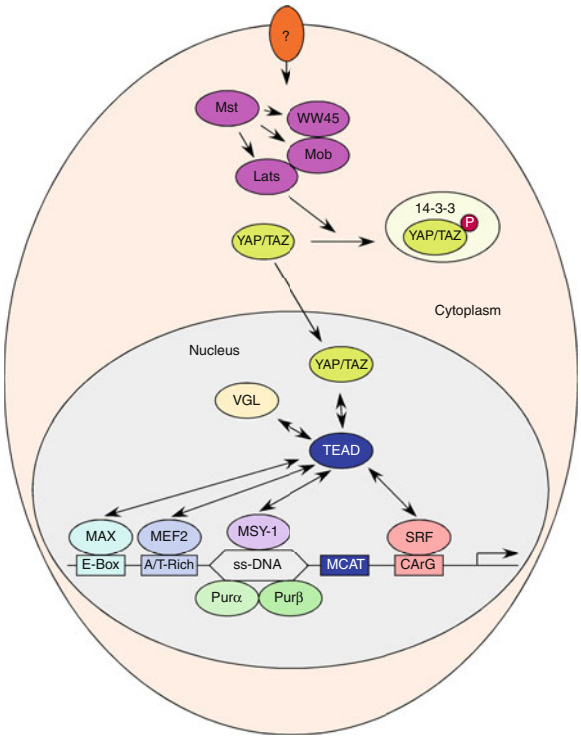
Like most transcription factors, the TEAD family interacts with a number of co-activator molecules that are essential for TEAD function. Two well-studied interactions include the vestigial and Yki/Yap/Taz family of proteins (Fig. 2). In Drosophila, the TEAD1 homolog Scalloped (Sd) interacts with Vestigial (Vg) to form a complex that binds DNA through the TEA/ATTS DNA-binding domain of Sd. The Sd–Vg complex is a critical regulator of wing development. In humans, there is a family of vestigial-related (Vgl) gene products, which interact with TEAD1. Vgl-2 (VITO-1), a member of the SID or scalloped interaction domain-containing gene products, interacts with TEAD1 and is associated with differentiation during embryonic skeletal myogenesis. Vgl-4, a novel member of the vestigial-like family of transcription cofactors, regulates α1-adrenergic activation of gene expression in cardiac myocytes.

Recent studies have implicated the Hippo signaling pathway in the control of organ size and tumorigenesis in both Drosophila and mammals (reviewed in Zhao et al. 2008). The Hippo pathway modulates the nuclear localization of the paralogous Yki/YAP/TAZ transcription co-activators that interact directly with the TEAD family transcription factors. In mammalian cells, the Hippo pathway kinase cascade phosphorylates YAP and TAZ, which prevents their nuclear localization via an interaction with the 14-3-3 protein. All TEAD family members have been shown to bind YAP65, a powerful transcriptional co-activator. It has been suggested that YAP65 regulates TEAD-dependent transcription in response to mitogenic signals.

Several other proteins have been shown to interact with TEAD family members that are important in modulating TEAD function. TEAD1 interacts with poly(ADP-ribose) (PARP) polymerase and this interaction has been proposed to provide muscle-specific gene expression in cardiac myocytes. PARP is thought to be an auxiliary protein required for TEAD1 transcriptional function. TEAD1 interacts with the basic helix–loop–helix zipper protein Max. Max is thought to cooperate with TEAD1 to regulate expression of the gene encoding α-myosin heavy chain. Multiprotein complexes of TEAD1, Max, and PARP have been proposed to be involved in gene expression in slow muscle fibers. TEAD1 binds to the TATA-binding protein (TBP), resulting in the loss of the ability of TBP to bind to the TATA box, and may be partly responsible for TEAD1 transrepressor activity. TEAD1 has been shown to bind the SV40 large T antigen. TEAD1 interacts with SRF and Mef2 in cardiomyocytes. TEAD1 and TEAD2 have been shown to interact with ▶ SRC1 and all members of the p160 family including SRC1, TIF2, and ▶ RAC3, and all of these factors are able to potentiate transcription from a TEF response element in vitro.

Summary

The TEAD family of transcription factors evolved very early and plays critical roles in the regulation of gene



Tead, Fig. 2 Schematic diagram of known components of regulation of TEAD activity and interaction with other transcriptional control elements in the regulation of mammalian gene expression. Within the nucleus, TEAD family members interact with a number of transcription factors indicated by *double-headed arrows*. The indicated pathways emphasize the regulation of muscle-specific genes (Yoshida 2008). Not all interactions are implied to occur simultaneously. Localization of YAP/TAZ within the nucleus is mediated by members of the Hippo intracellular kinase signaling cascade (Zhao et al. 2008). Members of the Hippo pathway in mammals include the hippo (Hpo) homolog Mst (Mst1/2, or STK4/STK3), the Sav homolog WW45, the Mats homolog Mob, the Wts homolog Lats (Lats1/2), and the yorkie (Yki) homologs YAP and TAZ

expression in yeast, flies, plants, and mammals. TEAD function is critical for mammalian development, including cardiac, trophoblast, neural tube, notochord, and somite development. TEAD family members regulate the expression of a large variety of genes including viral, muscle-specific, and developmentally important genes such as Cdx2 and Pax3. Considerable insight into the mechanisms by which TEAD family members regulate gene expression has been obtained, including the interaction of a large number of other transcription factors and/or co-regulators, such as Max, Mef2, SRF, YAP/TAZ, and Vgl. Future studies are anticipated to uncover many additional developmental and regulatory pathways that are mediated by TEAD family members. In addition, increasing detail will be added at the molecular level to our understanding of the discrete mechanisms by which TEAD family members regulate gene expression.

Acknowledgments I wish to extend my apologies to the many authors whose contributions could not be cited due to space limitations. Where possible I have cited review articles to allow readers access to the literature. In addition, the readers may access additional information and references on TEAD via the Nature-UCSD signaling gateway: http://www.signaling-gateway.org/.

The 5-HT_3 Receptor

Sarah C. R. Lummis
Department of Biochemistry, University of Cambridge, Cambridge, UK

Synonyms

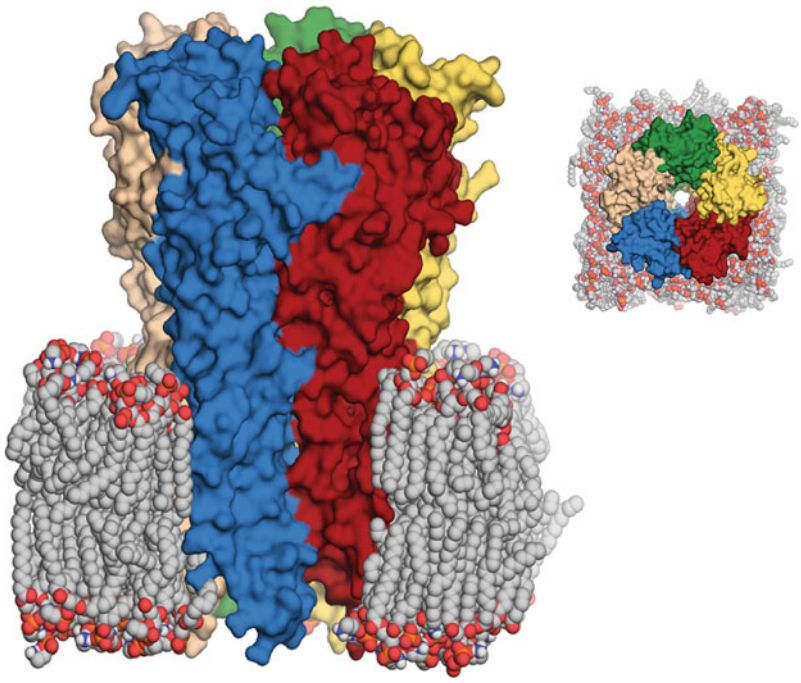
5-HT; 5-Hydroxytryptamine; Serotonin

Historical Background

5-Hydroxytryptamine (5-HT), also known as serotonin, was initially identified as a potent vasoconstrictor present in blood serum (Rapport et al. 1947). It is now clear 5-HT has a multitude of functions including activation or inhibition of muscle, exocrine and endocrine glands, central and peripheral neurons, and cells of the hematopoietic and immune systems. 5-HT receptors were initially subdivided into D and M subtypes, based on their sensitivity to dibenyline or morphine (Gaddum and Picarelli 1957). Currently, 5-HT receptors are divided into seven major families ($5\text{-}HT_{1\text{-}7}$) based on transduction and structural characteristics. All are G-protein-coupled receptors, except for the $5\text{-}HT_3$ receptor which is a ligand-gated ion channel (LGIC), and indeed, it is this receptor which is the original M receptor.

Introduction

The $5\text{-}HT_3$ receptor is a cation-selective member of the Cys-loop family of LGIC. The receptors are located primarily in the central and peripheral nervous systems and in reasonable quantities in the gastrointestinal tract and the immune system. They are also found in lower amounts in many other tissues, suggesting a possible physiological importance in many body regions. Structural details of the $5\text{-}HT_3$ receptor at the molecular level are unresolved, but a wealth of evidence shows that it is closely related to the nACh receptor



The 5-HT$_3$ Receptor, Fig. 1 The 5-HT$_3$ receptor. Homology model based on the structure of GluCl (Hibbs and Gouaux 2011) showing the 5-subunit configuration of this protein. These subunits surround the ion pore (see *inset*, image from above). The extracellular domain contains the ligand binding site which is predominantly β-sheet; the transmembrane domain is mostly α–helical and contains the pore. There is also an intracellular domain whose structure was not determined for GluCl

(see Thompson et al. 2010; Reeves and Lummis 2002 for reviews). Consequently, the 5-HT$_3$ receptor is well represented by cryo-electron microscope images of the nACh receptor and by crystal structures of the acetylcholine binding protein (AChBP), the GluCl receptor, and the bacterial Cys-loop receptor homologues GLIC and ELIC (Brejc et al. 2001; Hilf and Dutzler 2008, 2009; Bocquet et al. 2009; Hibbs and Gouaux 2011). It consists of a large, mostly β-sheet structured, extracellular domain, an α-helical transmembrane domain, and a relatively unstructured intracellular domain. Activation by 5-HT and other agonists opens an integral cation-selective channel. The receptor is inhibited by 5-HT$_3$ receptor-selective antagonists, some of which are useful therapeutic agents, and is also modulated by a wide range of substances, including alcohols, steroids, and anesthetics.

Receptor Heterogeneity

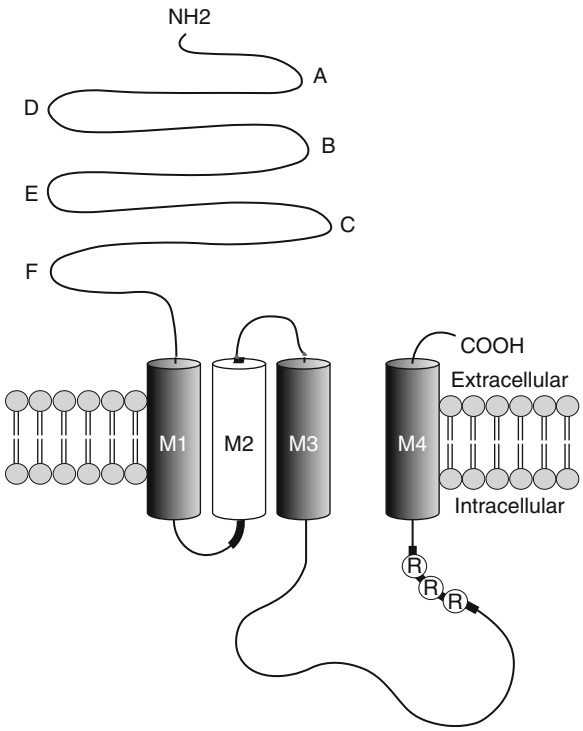
The functional receptor is a pentamer (Fig. 1), and five 5-HT$_3$ receptor subunits have been identified (5-HT3A-E). Only the A subunit can form functional homomeric receptors, while subunits B–E function only as heteromeric receptors in combination with the A subunit (Davies et al. 1999; Niesler et al. 2003). Homomeric 5-HT$_3$A and heteromeric 5-HT$_3$AB receptors have been extensively characterized. 5-HT$_3$AB receptors have an increased single channel conductance, reduced Ca^{2+} permeability, faster kinetics, increased EC$_{50}$s, and decreased Hill slope. There are also some differences in the potency of noncompetitive antagonists. Data from functional expression of 5-HT3A with either 5-HT3C, D, or E subunits suggest their characteristics are similar to those of homomeric 5-HT$_3$A receptors, but there may be some differences in expression levels (Holbrook et al. 2009; Niesler et al. 2007).

The Receptor Binding Site

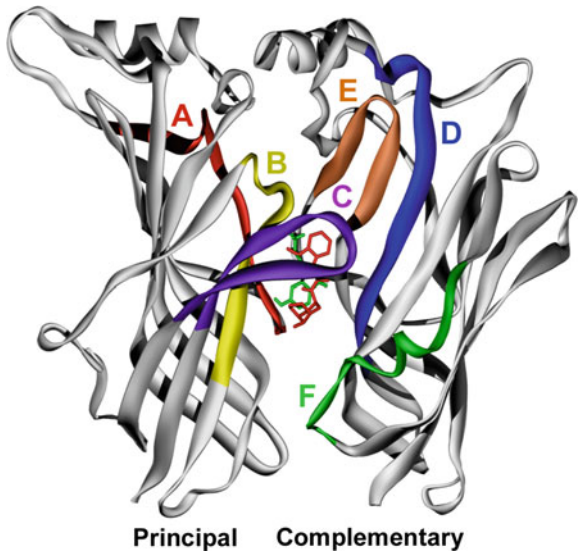
The five subunits surround a central ion-conducting pore (Fig. 1). The extracellular N-terminal region contains the ligand binding site, which lies at the interface of two adjacent subunits and is formed by three loops (A-C) from the "principal" subunit and three β-strands (D–F) from the adjacent or "complementary" subunit (Figs. 2 and 3). A number of studies have identified key residues that are involved in both agonist and antagonist binding (Fig. 4). A comprehensive review of the 5-HT$_3$ ligand binding site can be found in Thompson and Lummis (2006).

The Receptor Transmembrane Domain

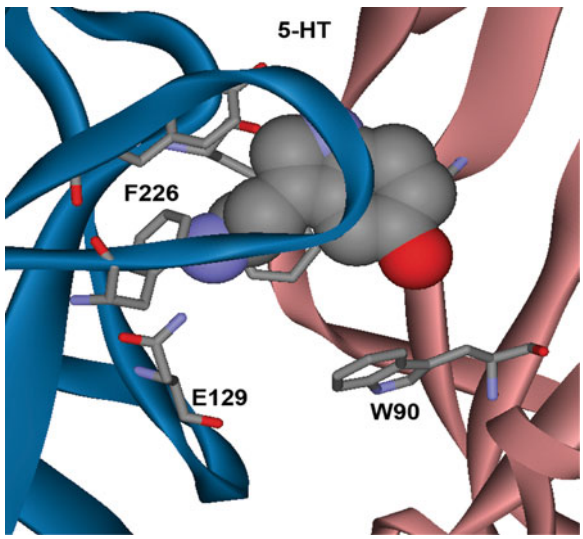
The transmembrane region contains four membrane spanning α-helices (M1–M4) and a short



The 5-HT$_3$ Receptor, Fig. 2 A 5-HT$_3$ receptor subunit. Cartoon representation of a subunit showing the binding loops A–F, the four transmembrane spanning segments and the intracellular domain which contain three functionally important arginine (R) residues



The 5-HT$_3$ Receptor, Fig. 3 The 5-HT$_3$ receptor binding site. Model based on AChBP. The binding site is located between two adjacent subunits and constituted from three loops (A–C) from the principle subunit and three loops (D–F) from the complementary subunit. 5-HT and granisetron are shown docked in the binding pocket



The 5-HT$_3$ Receptor, Fig. 4 5-HT in the binding site. Model showing 5-HT docked into the binding site and several residues known to be important in ligand binding

C-terminus. M2 from each subunit lines the pore and contains regions responsible for channel gating and ion selectivity. In 5-HT$_3$ receptors, this pore is predominantly sodium and potassium selective, and its opening results in a rapidly activating and then desensitizing inward current. The intracellular domain is formed by a loop of residues (~110) between M3 and M4. The structure of this domain remains uncertain, but functionally it has a role in channel conductance and receptor modulation. Homomeric 5-HT$_3$ receptors composed of A subunits alone form functional channels with a conductance that is so small (sub-pS) that it cannot be resolved directly. Although the B subunit cannot form homomeric channels, it can be combined with A subunits to generate functional heteromeric receptors that display a much larger conductance (9–17 pS); this difference is the consequence of three arginine residues that lie within an α-helix in the M3–M4 loop (Fig. 2) (Kelley et al. 2003). The intracellular domain is also known to modulate 5-HT$_3$ receptor function as a result of posttranslational modifications.

Therapeutics

5-HT_3 receptor antagonists are in use clinically, primarily for controlling chemotherapy and radiotherapy-induced nausea and vomiting and in postoperative nausea and vomiting. Alosetron is an effective symptomatic treatment for irritable bowel syndrome. In addition, studies have revealed a diversity of potential disease targets that might be amenable to alleviation by 5-HT_3 receptor selective compounds; these include addiction, pruritis, emesis, fibromyalgia, migraine, rheumatic diseases, and neurological phenomena such as anxiety, psychosis, nociception, and cognitive function (Thompson and Lummis 2007).

Summary

The 5-HT_3 receptor is the only 5-HT receptor that is a ligand-gated ion channel. It is a member of the Cys-loop family of neurotransmitter-gated ion channels, which also includes nACh, glycine, and GABA A receptors. It is a pentamer, and five subunits (A–E) can contribute to a functional receptor, as long as A subunits are present. The large extracellular domain contains the neurotransmitter binding site which is located between two adjacent subunits. The transmembrane pore is lined by α-helices, and the intracellular domain has a role in channel conductance and receptor modulation. A range of diseases may be amenable to treatment with 5-HT_3 receptor antagonists; currently, such compounds are in clinical use as antiemetics and to treat irritable bowel syndrome.

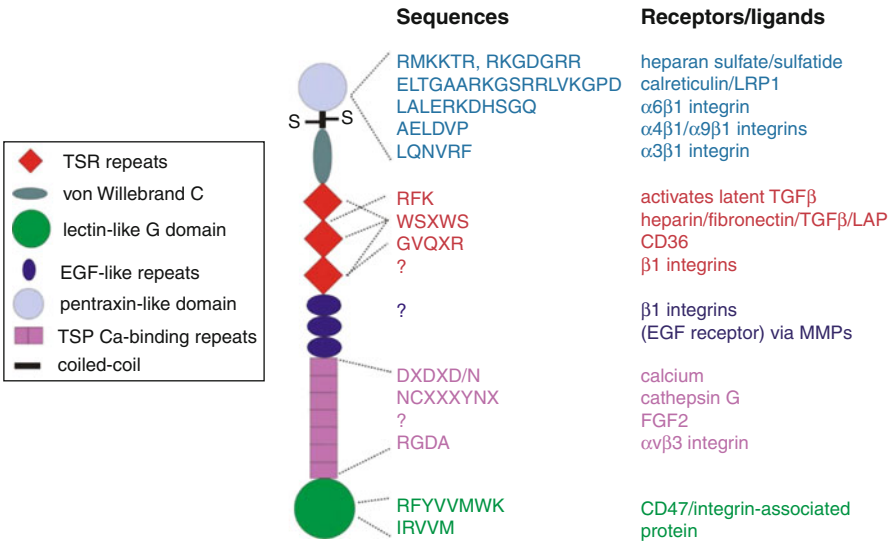
Glycoprotein G; THBS1; Thrombospondin; TSP1

Historical Background

Thrombospondin-1 (TSP1) was first characterized in 1971 by Baenziger et al. as a glycoprotein released from the α-granules of platelets in response to treatment with thrombin (Roberts and Lau 2011). This large protein consists of three 150 kDa disulfide-linked subunits and is highly conserved among vertebrate species (Carlson et al. 2008). Multi-sequence analysis has generated a phylogenetic tree for the evolution of modern TSPs (Bentley and Adams 2010). Duplication of the gene encoding a primordial TSP that is currently found in insects initiated the evolution of two subfamilies containing five members in modern vertebrates (Bentley and Adams 2010). The central feature of all TSPs is the presence of a carboxy-terminal signature domain containing EGF-like modules and seven TSP-type Ca-binding repeats, which wrap around the C-terminal lectin-like globular domain. This domain is about 650 amino acids long and is the most conserved region between the TSPs (Carlson et al. 2008). TSP1 and TSP2 belong to the first subfamily and are trimeric proteins that contain an N-terminal globular domain that binds heparin, followed by a coiled-coil motif that mediates trimer formation, a von Willebrand factor type C domain, three type 1 repeats (TSRs), followed by the signature domain (Carlson et al. 2008) (Fig. 1). Although they share only 25% sequence identify, the N-terminal domains of both TSP1 and TSP2 bind to heparan sulfate proteoglycans, low-density lipoprotein receptor-related protein (LRP1), and α4β1 and α6β1 integrins. However, only TSP1 binds to α3β1 integrin via this domain. The second group is composed of TSP3–5, which are pentameric proteins that are most abundant in bone and cartilage extracellular matrix (Carlson et al. 2008; Roberts and Lau 2011). The members of this subgroup lack a von Willebrand factor type C domain and type 1 repeats and contain four copies of the type 2 EGF repeats (Carlson et al. 2008; Roberts and Lau 2011). Gene deletion studies in mice have demonstrated little redundancy between the functions of each family member, indicating that each TSP has specific roles in vertebrates (Roberts and Lau 2011).

Function

In certain contexts, TSP1 mediates cell-to-cell and cell-to-matrix interactions, but its major physiological functions involve modulation of signaling by other extracellular factors and direct signaling through its cell surface receptors (Fig. 2). Stable proteolytic fragments of TSP1 were used in early studies to uncover activities of several regions of the molecule. The amino-terminal heparin-binding domain interacts with proteins in the extracellular matrix and on the cell surface. This unit contains binding sites for heparin, sulfated glycolipids, α3β1, α4β1, α6β1, and α9β1 integrins, calreticulin, and LRP1 (Carlson et al. 2008). The von Willebrand factor C module, also termed the pro-collagen module, has been implicated in the anti-angiogenic effects of TSP1, but this needs confirmation by mutagenesis. The TSRs mediate interactions with β1 integrins, fibronectin, the latency-associated protein of TGFβ, and the scavenger receptor CD36. The latter interaction mediates an anti-angiogenic activity of TSP1, and binding to latency-associated protein causes activation of latent TGFβ. The three epidermal growth factor-like (EGF) modules indirectly activate the EGF receptor and contain additional β1 integrin-binding sites. The calcium-binding modules when ligated by calcium wrap around the C-terminal lectin-like (or G) module of TSP1, binds fibroblast growth factor, and the last of these contains a RGD integrin-binding motif (Carlson et al. 2008). The C-terminal G module interacts with the other major receptor for TSP1, ▶ CD47, and mediates a second major anti-angiogenic activity of TSP1 as well as its modulation of vascular smooth muscle tone and inhibition of T-cell activation (Frazier et al. 2010).

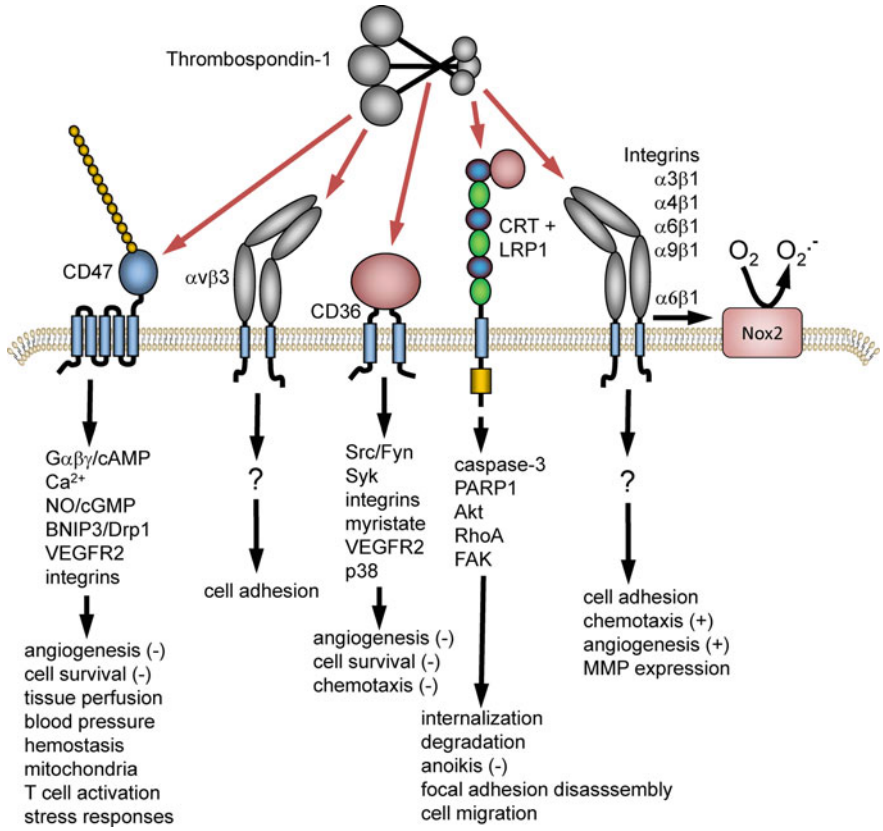


Thrombospondin-1, Fig. 1 Schematic representation of the structure and functional sequences of TSP1. TSP1 is a ~450 kDa trimeric glycoprotein composed of three identical 150 kDa polypeptide chains linked by disulfide bonds. Each subunit of TSP1 contains the following structural elements: an N-terminal globular domain, an α-helical region that forms a parallel homotrimeric coiled coil, a von Willebrand factor type C module, three TSP type 1 (TSR) repeats, and the TSP "signature" domain, which consists of three epidermal growth factor (EGF)-like TSP type 2 repeats, seven calcium-binding type 3 repeats (the last of which contains an RGD integrin-binding sequence), and a COOH-terminal domain. Known receptors and ligands are mapped to their respective binding domains in TSP1 and to specific recognition sequences where known

Expression and Regulation

TSP1 is produced by many cell types upon stimulation by cytokines, growth factors, and stress (Isenberg et al. 2009). TSP1 is expressed during early embryogenesis particularly on the cells surface of embryonic cells (Bornstein et al. 1990). Treatment of with antibodies inhibited blastocyst outgrowth, suggesting a role of TSP1 during early development. In normal adults, the expression of TSP1 is low but detectable in muscle cells, bone marrow cells, among others (Isenberg et al. 2009). TSP1 expression is regulated at the level of transcription, mRNA stability, translation, and post-translational modification. Posttranslational modifications have been demonstrated in several domains of this protein and may be important for some TSP1 functions (Roberts and Lau 2011). Expression of TSP1 is elicited by stress, injury, and inflammatory responses (Lopez-Dee et al. 2011). During the acute phase of inflammation, TSP is transiently expressed, and multiple factors seem to modulate the release of TSP1 during this process. TSP1 is strongly expressed in neutrophils, inducing an intense chemotactic response to injured tissues (Lopez-Dee et al. 2011). Ischemia/reperfusion injury results in a marked elevation of expression of TSP1 and is associated with an increase in cell death (Isenberg et al. 2008, 2009).

Tissue levels of TSP1 also tend to increase during aging and are associated with the onset of chronic diseases such as atherosclerosis, Alzheimer's, and type II diabetes (Roberts and Lau 2011). Consistent with the latter clinical finding, TSP1 is regulated by glucose. Transcription of TSP1 is activated by the hexosamine pathway of glucose catabolism (Roberts and Lau 2011). Specific inhibitors of glutamine:fructose 6-phosphate amidotransferase (GFAT), an enzyme controlling the hexosamine pathway, as well as direct inhibitors of protein glycosylation, efficiently inhibited glucose-stimulated TSP1 transcription (Roberts and Lau 2011). Hyperglycemia increases TSP1 transcription in kidney mesangial cells by the stimulation of USF2 protein accumulation this is negatively regulated by an increase in cGMP. Moreover, the regulation of USF2 is mediated by an angiotensin II–dependent mechanism, indicating that expression of TSP is also regulated by the rennin angiotensin system (Visavadiya et al. 2011). TSP1 levels were elevated in adipocytes of rats fed a high fat diet to induce obesity and insulin



Thrombospondin-1, Fig. 2 Signaling functions of TSP1 receptors. TSP1 has over eight known receptors. TSP1 interacts with several integrins (α3β1, α4β1, α6β1, and α9β1) that mediate cell adhesion, migration, and the pro-angiogenic activity of the N-terminal domain. TSP1 signaling through α6β1 in activated macrophages activates the NADPH oxidase Nox2 to produce superoxide (O_2^-). The N-terminal domain of TSP1 also modulates endothelial cell focal adhesions and vascular permeability by engaging calreticulin (CRT) and low density lipoprotein receptor-related protein (LRP1). The central type 1 repeats of TSP1 inhibit angiogenesis by stimulating apoptosis and inhibiting chemotaxis of microvascular endothelial cells through engaging the receptor CD36. CD36 is a class B scavenger receptor and fatty acid translocase. TSP1 inhibits uptake of myristate via CD36. CD47 is a high affinity cell surface receptor for the C-terminal domain of TSP1. CD47 is ubiquitously expressed and also plays an important role in the regulation of cell survival, stress responses, systemic blood pressure, and immune regulation. TSP1 binding to CD47 modulates intracellular calcium, heterotrimeric G protein, and cyclic nucleotide signaling in various cell types

resistance. Expression of TSP1 was increased in adipocytes treated in vitro with high glucose, indicating that TSP1 expression and secretion is modulated by glucose and in models of insulin resistance in vivo and in vitro. Levels of ATP are also responsible for secretion and expression of TSP1 from dendritic cells. This may be regulated by the increase in cAMP, but other mechanisms may be involved (Roberts and Lau 2011). Uptake by receptors is also important for the regulation of extracellular TSP1 levels. The uptake is mediated by the amino terminus of TSP1 binding to heparan sulfate proteoglycans and LRP1/calreticulin (Roberts and Lau 2011).

Expression of TSP1 is also altered in malignant cells (Isenberg et al. 2009). For a majority of cancers, expression of TSP1 decreases with tumor progression. Expression of TSP1 is generally higher in the early stages, and its reduction over time is implicated in the angiogenic switch and precedes the increase expression of VEGF-A (Isenberg et al. 2009). However, not all cancer types follow this pattern, and higher circulating levels of TSP1 were reported in patients with malignant colorectal carcinoma even though levels in the tumor cells are decreased (Isenberg et al. 2009; Lopez-Dee et al. 2011). Several oncogenes and tumor suppressor genes regulate the transcription or

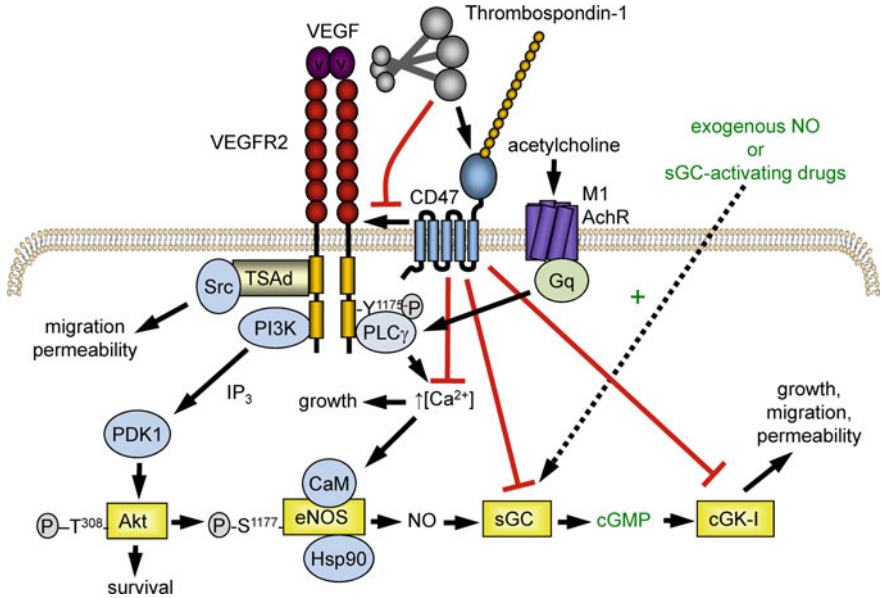
translation of TSP1 including N-Ras, K-Ras, R-Ras, ▶ Myc, ▶ p53, p73, nm23, U19/EAF2, and WT1 (Isenberg et al. 2009; Su et al. 2010). TSP1 is also subject to silencing by hypermethylation in some cancers.

Physiology

To study the physiological role of TSP1, Lawler et al. generated TSP1 deficient mice using homologous recombination to disrupt the mouse gene (Roberts and Lau 2011). Despite its expression in embryonic tissue, TSP1 null mice are viable, fertile and do not show gross abnormalities (Lopez-Dee et al. 2011; Roberts and Lau 2011). A reduction in reproductive fitness is associated with altered ovarian follicle morphology and with a deficiency in clearing VEGF by internalizing LRP1 (Roberts and Lau 2011). The original colony of null mice showed in some cases lordotic curvature of the spine and chronic lung inflammation, the latter associated with regulation of latent TGFβ activation. However, rederived TSP1 null mice in C57Bl/6 background do not exhibit this phenotype (Roberts and Lau 2011). Investigators have noticed that TSP1 null mice are leaner than their wild-type counterparts, which is consistent with their increased mitochondrial density and may result from its regulation of mitochondrial biogenesis by modulation of the cGMP and cAMP pathways (Frazier et al. 2011). Although TSP1 was originally isolated from and is highly expressed in the α-granules of platelets, the *tsp1* null mice showed no defects in aggregation of washed platelets. However, subsequent studies showed that TSP1 plays a role in platelet function by regulated activity of von Willebrand factor by inhibiting its proteolytic cleavage of ADAM13 (Roberts and Lau 2011). TSP1 also inhibits soluble ▶ guanylate cyclase and cGMP-dependent protein kinase activation in platelets. In the presence of physiological levels of NO or its physiological precursor arginine, TSP1 is necessary for thrombin-induced platelet aggregation, and this activity is mediated through its receptors ▶ CD47 and CD36 (Isenberg et al. 2009; Frazier et al. 2010).

The first physiological function identified for TSP1 was inhibition of angiogenesis (Isenberg et al. 2009; Lopez-Dee et al. 2011). TSP1 inhibits the growth and migration of endothelial cells and induces apoptosis. TSP1 blocks endothelial cell growth and migration stimulated by pro-angiogenic factors such as fibroblast growth factor-2 (▶ FGF2) and VEGF in vitro and in vivo (Isenberg et al. 2009). Anti-angiogenic activities are mediated by two TSP1 receptors: CD36 and ▶ CD47 (Fig. 2). TSP1 binding to CD36 on endothelial cells alters ▶ Src and Fyn kinase activities, with downstream effects on Akt, p38 MAPK, and Syk (Kazerounian et al. 2011) (Fig. 2). TSP1 binding to CD47 alters heterotrimeric G protein activation, calcium, cGMP, and cAMP signaling in vascular cells (Bauer et al. 2010; Frazier et al. 2010; Yao et al. 2011). TSP1 was recently discovered to potently inhibit VEGF receptor-2 (VEGFR2) signaling through engaging its receptor ▶ CD47 in endothelial cells, which is dissociated from its constitutive association with VEGFR2 (Kaur et al. 2010). Pro-angiogenic activity of TSP1 has also been reported, which is mediated by the N-terminal domain interacting with α3β1, α4β1, and α9β1 integrins (Fig. 2).

One of main functions of TSP1 is the regulation of nitric oxide (NO) signaling (Fig. 3). NO is a bioactive gas that serves as a signaling molecule with several physiological functions. NO is the endothelium derived relaxing factor that controls arterial smooth muscle tone by relaxing vascular smooth muscle cells (VSMC). NO diffuses rapidly through tissue and binds to its most responsive target soluble guanylate cyclase to stimulate the production of cGMP, which in VSMC triggers their relaxation (Isenberg et al. 2009). Endogenous TSP1 functions as a tonic antagonist of NO and signaling in endothelial cells, VSMC, and platelets. The inhibition of NO signaling by TSP1 is mediated primarily by ▶ CD47 and under some conditions by CD36. TSP1 type 1 repeats and synthetic peptides derived from this domain engage CD36, which blocks its ability to uptake myristate required for translocation of ▶ Src kinases to the plasma membrane (Isenberg et al. 2009). TSP1 blocks myristate-stimulated cGMP synthesis in an endothelial NO synthase (eNOS)-dependent manner. This mechanism is associated with the inhibition by TSP1 of angiogenesis and the regulation of endothelial cell chemotaxis. Binding of CD36 is sufficient for the inhibition of NO/cGMP signaling but it is not necessary since TSP1 strongly inhibits NO/cGMP signaling in cells that lack CD36. The C-terminal domain of TSP1 binds ▶ CD47, and this unit or peptides derived from it potently and redundantly inhibit NO/cGMP signaling at the level of eNOS, soluble guanylate cyclase, and



Thrombospondin-1, Fig. 3 TSP1 inhibition of NO/cGMP signaling through CD47. Binding of TSP1 signals via CD47 to inhibit NO-mediated activation of soluble guanylate cyclase (sGC) in endothelial cells, VSMC, and platelets and cGMP-mediated activation of cGMP-dependent protein kinase (cGK-I) in platelets. TSP1 interaction with CD47 directly inhibits VEGFR2 signaling in endothelial cells by displacing CD47 from its constitutive complex with VEGFR2. TSP1 also inhibits vasodilation mediated by acetylcholine by limiting the duration of calcium flux stimulated by acetylcholine in endothelial cells, which activates endothelial nitric oxide synthase (eNOS) via calmodulin (CaM)

cGMP-dependent protein kinase. Notably, TSP1 also inhibits activation of soluble guanylate cyclase by heme-dependent and heme-independent pharmacological activators (Miller et al. 2010). Thus, these drugs may not be effective for overcoming deficiencies in NO/cGMP signaling in pathological conditions where TSP1 expression is elevated. The expression of ▶ CD47 is also essential for CD36-mediated inhibition of NO signaling. Moreover, a 100-fold lower concentration of TSP1 is sufficient to inhibit NO signaling in vascular cells through ▶ CD47 when compared to CD36 (Isenberg et al. 2009). TSP1 and ▶ CD47 null mice, but not CD36 null mice, show elevated cGMP levels in vascular cells and muscle tissue.

The regulation of NO by TSP1 has many physiological repercussions especially in the vascular system. TSP1 null mice are hypersensitive to vasorelaxation induced by NO donors. Furthermore, TSP1 null mice exhibit decreased central pulse pressure and lower blood pressure than their wild-type counterparts, and these mice have exaggerated hypotensive responses to anesthetics and vasorelaxants (Bauer et al. 2010). TSP1 also inhibits the acetylcholine-mediated activation of eNOS in the endothelium through ▶ CD47. TSP1 inhibits eNOS activation through the inhibition of calcium signaling and serine-1177 phosphorylation of eNOS. Intravenous treatment with TSP1 and ▶ CD47 antibodies acutely increases blood pressure (Bauer et al. 2010). Therefore, TSP1 regulation of NO has vasopressor functions that regulate systemic blood pressure. NO also plays an important role in mediating angiogenic signaling stimulated by VEGF, and TSP1 inhibits angiogenesis in part by inhibiting cGMP synthesis stimulated by VEGF. NO is also an important inhibitor of platelet activation, and TSP1 promotes platelet activation by blocking this activity of NO.

High NO levels can reduce fixed ischemic and ischemia/reperfusion injuries by improving blood flow and limiting an inflammatory response. Expression of TSP1 is strongly induced during reperfusion of ischemic cardiac muscle, kidney, and liver tissues in mouse, rat, and porcine I/R injury models (Isenberg et al. 2009). Pretreatment and posttreatment of these injuries decreases I/R injury. This indicates that TSP1

levels are also important in the regulation of tissue perfusion during stress situations.

Inflammation is another important physiological response regulated by TSP1. TSP1 plays important roles in regulating innate and adaptive immunity through its effects on monocytes, macrophages, dendritic cells, T cells, and NK cells. TSP1 is released during acute inflammation and can exert both proinflammatory activities in several cell types. This duality can be explained in part by differential regulation of CD36 by peroxisome proliferator-activated receptor (PPAR) and TGFβ (Lopez-Dee et al. 2011). PPAR expression elicits potent anti-inflammatory responses however in the absence of PPAR in leukocytes causes the increased secretion of TSP1 and stimulates chemotaxis of these cells along with neutrophils (Lopez-Dee et al. 2011). On the other hand, it is well known that TSP1 causes activation of latent TGFβ by releasing or changing the conformation of its latency-associated protein (Lopez-Dee et al. 2011). TGFβ negatively regulates CD36 which can limit the recruitment of macrophages (Lopez-Dee et al. 2011). Moreover, its interaction with ▶ CD47 is also essential for the recruitment of polymorphonuclear cells. However, in a model of retinal injury TSP1 limited the migration of microglial cells (Roberts and Lau 2011). Levels of TSP1 regulate migration of phagocytic cells such as macrophages and neutrophils to areas of injury, lack of TSP1 in model of wound healing wound closure was delayed due to lack of macrophages to the wound, however lack of TSP1 was also found to be protective in liver ischemic injuries (Isenberg et al. 2009). TSP1 also regulates the activation of macrophages, and M1 differentiated macrophages are increased in tumors that overexpress TSP1 (Isenberg et al. 2009). Furthermore, TSP1 acutely induces superoxide production via NADPH oxidase-2 in macrophages via its binding to α6β1 integrin (Isenberg et al. 2009).

TSP1 is also a potent regulator of T cells. TSP1 stimulates T-cell adhesion, matrix metalloproteinase expression, and migration via α4β1 integrin. Interaction of TSP1 with ▶ CD47 inhibits ▶ CD3-dependent T-cell activation and regulates differentiation of CD4+ CD25+ T cells. Inhibition of T cell receptor signaling by TSP1 requires a proteoglycan isoform of ▶ CD47 (Kaur et al. 2011).

TSP1 as a Therapeutic Target

The diverse physiological effects of TSP1 make it an attractive therapeutic target. Since the discovery of the anti-angiogenic properties of this molecule, research has focused on the use of TSP1 analogs as anticancer treatments. ABT-510 is a synthetic nonapeptide derived from the TSR repeats of TSP that interacts with CD36. Preclinical data indicates that ABT-510 inhibits VEGF and ▶ FGF2 signaling and limits endothelial cell migration, proliferation, tube formation and neovascularization, and induces endothelial and tumor cell apoptosis (Isenberg et al. 2009). ABT-510 inhibits tumor growth in mouse xenograft models. However, ABT-510 therapy did not demonstrate clear clinical efficacy in a clinical trial of patients with stage IV melanoma. Further dose escalation or combination with cytotoxic therapy may be more effective therapeutically (Markovic et al. 2007). However, ABT-510 is well tolerated and was studied in combination with other chemotherapies (Nabors et al. 2010).

Blockade of TSP1 signaling through ▶ CD47 may also be beneficial in certain pathologies. Blockade of TSP1 or CD47 results in improved recovery from ischemia and I/R injuries in several animal models (Isenberg et al. 2009). Blocking TSP1 also overcomes the deleterious effects of aging on survival of ischemic stress in a mouse model. Moreover, lack of TSP1 in combination with radiation enhanced tumor growth delay in a syngeneic melanoma model. Blockade of TSP1/CD47 signaling in wild-type mice simultaneously protected muscle and bone marrow tissue from radiation while markedly reducing tumor growth (Maxhimer et al. 2009).

Summary

TSP1 is a multifunctional signaling protein that engages at least eight distinct signaling receptors on endothelial cells and subsets of these receptors on other cell types. Studies in mice lacking TSP1 and several of its receptors have identified physiological functions for TSP1 in regulating platelet hemostasis, angiogenesis, mitochondrial homeostasis, local and systemic regulation of blood flow, and innate and adaptive immunity. Elevated TSP1 expression contributes to the pathogenesis of acute injuries and several chronic diseases of

aging. Conversely, loss of TSP1 expression in some cancers promotes tumor angiogenesis and impairs innate antitumor immunity. Agents targeting specific TSP1 receptors have shown benefit in treating these diseases in animal models and early clinical trials, and further study of the signaling mechanisms regulated by TSP1 could lead to development of additional therapeutics for these conditions.

Introduction

The translation initiation process is mediated by a series of partial reactions each of which requires the participation of a large number of protein factors collectively called eukaryotic (translation) initiation factors (eIFs). The process leads to the assembly of an 80S ribosome-bound initiator Met-tRNA$_i$ at the start AUG codon of an mRNA that is active in peptidyl transfer. According to the currently accepted view of translation initiation, the first step is the binding of the initiator Met-tRNA$_i$ to the heterotrimeric GTP-binding initiation factor eIF2 to form the Met-tRNA$_i$•eIF2•GTP ternary complex. The ternary complex then binds to the 40S ribosomal subunit containing bound initiation factor eIF3, a process that requires two other initiation factors eIF1 and eIF1A. This interaction leads to the formation of a 43S preinitiation complex (40S•eIF3•eIF1•eIF1A•Met-tRNA$_i$•eIF2•GTP) which is then recruited to the 5′-capped end of the mRNA via protein-protein interaction between the cap-bound initiation factor eIF4F and eIF3 bound to the 43S preinitiation complex. The resulting 43S complex then binds two RNA-helicases eIF4A and eIF4B and scans the mRNA in a 5′ → 3′ direction until it is positioned at the initiating codon (usually an AUG codon) by base-pairing interaction between the AUG codon and the anticodon of Met-tRNA$_i$ to form the 48S initiation complex (mRNA•40S•eIF3•eIF1•eIF1A•Met-tRNA$_i$eIF2•GTP). Concomitant with the formation of the 48S initiation complex, eIF1 is released from its binding site in the 48S complex. Subsequently, another initiation factor eIF5 interacts with eIF2 in the 48S initiation complex, and acting as a GTPase activating protein (GAP), activates the intrinsic GTPase activity of eIF2 to promote the hydrolysis of bound GTP. Hydrolysis of GTP leads to the immediate release of P_i and eventually of inactive eIF2•GDP (and other bound factors) during eIF5B-mediated joining of the 60 ribosomal subunit to the 48S ribosomal complex to form an 80S initiation complex (80S•Met-tRNA$_i$•mRNA) that is competent to form the first peptide bond during the elongation phase of protein synthesis. (For a review, see Pestova et al. 2007; Hinnebusch et al. 2007; Sonenberg and Hinnebusch 2009; Lorsch and Dever 2010).

Historical Background

Isolation and Initial Characterization of eIF5

Initiation factor eIF5 was one among the seven distinct eIFs that were originally isolated in many laboratories from a variety of eukaryotic sources including rabbit reticulocyte lysates on the basis of its ability to stimulate in vitro translation of globin mRNA in a partially purified reconstituted system. The purified protein was shown to be a monomeric protein of apparent M_r = 150,000–170,000 (For a review, see Maitra et al. 1982 and references therein). Functional characterization of eIF5 in the translation initiation assay showed that eIF5 did not play a role in the in vitro formation of the 48S initiation complex. However, the protein was essential for the subsequent joining of the 60S ribosomal subunit to the 48S complex to form a functional 80S initiation complex. It was further shown that prior to or concomitant with the subunit joining reaction, eIF5 promoted the hydrolysis of GTP bound to eIF2 in the 48S initiation complex. Hydrolysis of GTP was shown to be a prerequisite for the joining of the 60S ribosomal subunit to the 48S complex to form the active 80S initiation complex (reviewed by Maitra et al. 1982). However, later, using a more direct and a specific assay that measured the ability of eIF5 to mediate the joining of the 60S ribosomal subunit to a preformed 48S initiation complex formed with an AUG trinucleotide in lieu of an entire mRNA, a new activity of about 50 kDa was isolated from calf liver extracts and rabbit reticulocyte lysates that migrated on SDS-polyacrylamide-gels with an apparent M_r of 58,000 (reviewed by Das and Maitra 2001).

Subsequently, a similar activity was purified from the yeast *Saccharomyees cerevisiae* as a protein of about 45 kDa that migrated in SDS-polyacrylamide-gels as a protein of about 54,000–56,000 (Das and Maitra 2001).

This anomaly in molecular size of eIF5 was resolved when later work (Pestova et al. 2000) showed that the higher molecular weight polypeptide detected in earlier eIF5 preparations reported by others is another distinct initiation factor, designated eIF5B, that is required along with eIF5 for the joining of the 60S ribosomal subunit to the 48S initiation complex formed with a natural mRNA as the template. However, eIF5B has no role to play in the hydrolysis of GTP bound to eIF2 in the 48S initiation complex formed either with AUG or a natural mRNA as a template.

Biochemical characterization of the 50 kDa protein, designated as eIF5, showed that eIF5 promotes the hydrolysis of GTP only when the nucleotide is bound as a Met-tRNA$_i$•eIF2•GTP ternary complex on the 40S ribosomal subunit. eIF5 fails to promote hydrolysis of either free GTP or GTP bound to eIF2 as a ternary complex. The reaction is unaffected by the presence of 60S ribosomal subunits, indicating that GTP hydrolysis reaction precedes the joining of the 60S ribosomal subunit to the 40S complex. Finally, following eIF5-promoted GTP hydrolysis, even though P_i is released almost instantaneously from the 40S ribosomes, eIF2•GDP complex formed remains initially bound to the ribosomal complex and can be released by prolonged incubation at 37°C or by sucrose gradient centrifugation (Raychaudhuri and Maitra 1986).

Molecular Genetic Characterization eIF5

To show that the 50 kDa protein functions as a canonical translation initiation factor essential for translation of mRNAs in vivo, both the mammalian cDNA and the single copy essential yeast gene *TIF5* encoding eIF5 were cloned and expressed in *Escherichia coli* (For a review see, Das and Maitra 2001). In each case, the purified recombinant mammalian protein (calculated molecular mass 48,926) or the yeast protein (calculated molecular mass 45,436) mimics eIF5 isolated from natural sources in molecular size, in specific activity, and in its ability to promote the hydrolysis of GTP bound to eIF2 in the 48S initiation complex. Additionally, to understand the function of eIF5 in vivo in yeast cells, a conditional mutant yeast strain in which a functional but a rapidly degradable form of eIF5 fusion protein was synthesized from the glucose repressible *GAL* promoter was constructed. Depletion of eIF5 from this mutant yeast strain resulted in inhibition of cell growth and the rate of in vivo protein synthesis. Analysis of the polysome profiles of eIF5-depleted cells showed greatly diminished polysomes with simultaneous increase in the pool of free 80S ribosomes and free 60S and 40S ribosomal subunits. Such a polysome/ribosome profile is characteristic of cells lacking an essential translation initiation factor. Furthermore, lysates of cells depleted of eIF5 were inactive in translation of both total yeast poly(A)$^+$ and luciferase mRNAs in vitro. Addition of 45-kDa purified yeast eIF5 restored translation in these cell lysates. Similar observation was also made when a thermosensitive mutant yeast strain was used. These results show that the *TIF5* gene product, a protein of 45,346 Da, is indeed an initiation factor required for initiation of protein synthesis. Additionally, mammalian eIF5 can functionally substitute for yeast eIF5 in maintaining yeast cell viability and growth, indicating that the mechanism of eIF5-promoted GTP hydrolysis is conserved from yeast to mammals.

eIF5 Is Not a GTPase Protein, but Rather Functions as a GTPase Activating Protein (GAP)

GTP-binding domains, G1-G4, are characteristic of members of the GTPase superfamily. An important feature of these proteins is that they not only bind GTP but also possesses an intrinsic GTPase activity, which is often stimulated by their interaction with an effector molecule that acts as a GTPase activating protein (GAP). Both mammalian and yeast eIF5 contain imperfect G1-G4 domains. The presence of imperfections in the G1-G4 domains of eIF5 explains why eIF5, by itself, does not bind or hydrolyze free GTP (Das and Maitra 2001). In contrast, the heterotrimeric eIF2 binds GTP and its γ subunit contains the conserved GTP-binding domains (G1-G4) (Hinnebusch et al. 2007; Lorsch and Dever 2010). Since interaction of eIF5 with Met-tRNA•eIF2•GTP bound in the 48S initiation complex is necessary for hydrolysis of GTP, the question arises whether eIF5 functions as a specific

GAP to eIF2-GTPase (reviewed by Das and Maitra 2001; Hinnebusch et al. 2007; Pestova et al. 2007).

Binding studies show that eIF5 forms a complex with eIF2, the GTP-binding protein, by specifically interacting with the eIF2β subunit (Das et al. 1997; Asano et al. 1999). It was further demonstrated that the N-terminal lysine-rich region of eIF2β (designated K-boxes 1, 2, and 3) is involved in binding the C-terminal region of eIF5 containing a glutamic acid-rich bipartite motif (amino acids 345-347 and 384-386) (Asano et al.; 1999; Das and Maitra 2000). Mutational analysis showed that yeast eIF5 mutants E346A, E347A and E384A, E385A exhibited a marked decrease in binding to eIF2, and were also severely defective in eIF5-mediated hydrolysis of GTP bound to the 48S initiation complex (Das and Maitra 2000). These mutant eIF5 proteins were also defective in stimulating translation in eIF5-depleted yeast cell-free translation extracts, indicating that the eIF5•eIF2 interaction is essential for eIF5 function in vitro and in vivo.

eIF5 also binds to the γ subunit of eIF2. In fact, it has been demonstrated the amino terminal domain (NTD) of yeast eIF5 (residues 1-279) is as active as full-length eIF5 in activating the intrinsic GTPase activity of eIF2 (Hinnebusch et al. 2007). This observation led to the hypothesis that interaction between eIF2β and eIF5 does not activate the intrinsic GTPase eIF2γ, rather it may merely serve to recruit eIF5 to eIF2 in the 48S ribosomal complex. However, mutational studies in the γ and β subunits of yeast eIF5 are also consistent with an alternative hypothesis that eIF5-eIF2β interaction derepresses the GTPase activity of eIF2γ (reviewed by Pestova et al. 2007).

Further deletion analysis studies showed that an invariant arginine residue at position 15 at the N-terminal end of eIF5 is also essential for its GTP hydrolysis-promoting activity (Das et al. 2001; Paulin et al. 2001. This property of eIF5 is reminiscent of typical GAPs like RasGAPs and RhoGAPs that contain "arginine finger" motifs consisting of an invariant arginine residue at the N-terminus of their catalytic domains that is necessary for their GTPase-stimulating activity, in addition to motifs required for interacting with their respective G proteins. In typical GAPs, a secondary arginine residue stabilizes the finger loop carrying the primary arginine residue (reviewed by Das and Maitra 2001). In analogy with RasGAP and RhoGAP, it appears that either Lys33 or Lys55, or both in rat eIF5 constitute the "secondary" element required for eIF5 GAP function. (Das et al. 2001; Paulin et al. 2001).

However, it should be emphasized that while interactions between eIF5 and eIF2β and eIF5 and eIF2γ are necessary for activation of GTPase activity of eIF2γ, these interactions alone are not sufficient since binding of eIF2 as a Met-tRNA$_i$•eIF2•GTP ternary complex to the 40S ribosomal subunit is essential for the GAP activity of eIF5 toward eIF2. Therefore, it has been postulated that the 40S ribosomal subunit also interacts with eIF2γ and stabilizes the switch regions of eIF2γ, which is required for the GTPase activity of eIF2 (Das and Maitra 2001; Das et al. 2001). In summary, during translation initiation, the γ subunit of eIF2 which contains the consensus GTP-binding domains G1-G4, is the presumed GTPase, while eIF5 and the 40S ribosome act as GAPs. It should be noted that as a GAP for eIF2, eIF5 increases the rate of GTP hydrolysis in the ribosomal preinitiation complex by over six orders of magnitude (Algire et al. 2005).

Role of eIF5 in AUG Start Codon Selection and the Link Between eIF5-Promoted GTP Hydrolysis and AUG Selection

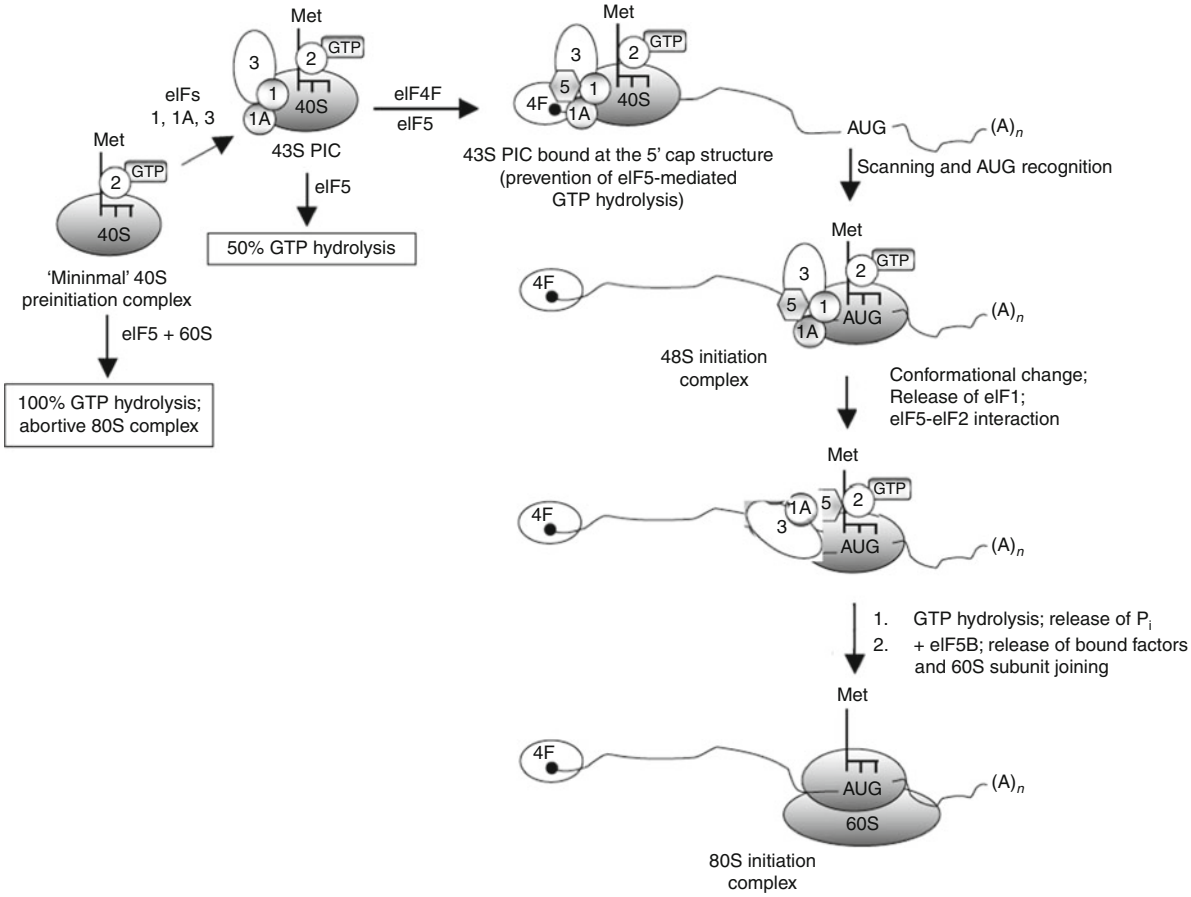
In eukaryotes, translation is known to be initiated almost exclusively from AUG codons. This is in sharp contrast to prokaryotes where non-AUG codons such as UUG or GUG codons also serve as efficient sites for translation initiation from about 10% of mRNAs. To understand the mechanism by which the stringency of start site selection in eukaryotes is maintained, a series of elegant yeast genetic experiments was carried out by Donahue and his colleagues (Huang et al. 1997; Donahue 2000). It was shown that translation can be initiated from a UUG codon only in the presence of complementary suppressor mutations in several initiation factors – eIF1, α, β, and γ subunits of eIF2, and eIF5. The identification, in this screen of eIF2, a GTP-binding initiation factor, and eIF5, a protein known to be a GAP, indicated that a defect in GTP binding/hydrolysis may be the cause for the breakdown in the fidelity of translation start site selection. Indeed, subsequent biochemical assays (Huang et al. 1997) demonstrated that in each of the *Sui* mutants, either an elevated level of GTP hydrolysis by eIF2 or an aberrant dissociation of Met-tRNA$_i$

releases bound initiation factors from the 43S preinitiation complex prematurely and leaves the initiator Met-tRNA at the P site of the 40S subunit. This allows the translation machinery to initiate from a UUG codon. These data suggest that in eukaryotes, in order to ensure translation fidelity, hydrolysis of GTP must be suppressed during scanning of the mRNA by the 43S preinitiation complex. It can only occur when the 43S preinitiation complex has selected the initiation AUG codon and that the process of AUG selection and eIF5-promoted GTP hydrolysis is likely to be coupled. Since all the components required for GTP hydrolysis, namely eIF2, eIF5, and 40 ribosome, are present in the 43S preinitiation complex, there must exist a mechanism by which premature GTP hydrolysis and therefore aberrant initiation is prevented prior to AUG selection. The possibility exists that the coupling of eIF5-promoted GTP hydrolysis to the AUG selection process may be modulated by other initiation factors bound in the 43S preinitiation complex.

Biochemical support for the role of multiple initiation factors in AUG selection stemmed from a variety of protein-protein interaction studies. It was observed that in addition to its interaction with eIF2, eIF5 also interacts with eIF3, eIF4G, and eIF1 (reviewed by Hinnebusch et al. 2007; Pestova et al. 2007). While the N-terminal domain of eIF5 interacts with the G-domain of eIF2γ, the C-terminal domain of eIF5 interacts with the K-boxes of eIF2β, as well as with eIF1, eIF3, and eIF4G. Additionally, work in the yeast *S. cerevisiae* has shown that eIF5 is a component of the multifactorial protein complex consisting of eIF2, eIF3, eIF1, and stoichiometric amount of Met-tRNA$_i$. (Asano et al. 2000) that may be important for coordinating eIF5-promoted GTP hydrolysis to the AUG selection process. In fact, eIF5 was found to be associated with the 43S preinitiation complex bound to eIF4F at the 5′-cap structure of mRNA (Majumdar and Maitra 2005). It may, thus, be possible that the eIF5•eIF2 interaction, which is essential for GTP hydrolysis, is physically blocked in the 43S preinitiation complex prior to AUG selection via protein-protein interactions involving one or more bound initiation factors, and this block is released once AUG is selected by the ribosomal complex.

Subsequent in vitro biochemical studies on eIF5-mediated GTP hydrolysis demonstrated that addition of eIF5 to the 43S preinitiation complex containing bound ternary complex, as well as bound initiation factors eIF1, eIF1A, and eIF3 did not result in complete inhibition of hydrolysis of the GTP bound to the 43S preinitiation complex (Majumdar and Maitra 2005). However, near-complete abolition of GTP hydrolysis was observed when eIF4F protein (containing a bound 5′ mRNA cap structural analog) was added to the 43S preinitiation complex containing bound eIF1, eIF1A, and eIF3 (Majumdar and Maitra 2005). Similar results were obtained when the 43S preinitiation complex was positioned at the 5′-capped end of an mRNA via binding to eIF4F (Majumdar and Maitra 2005). Surprisingly, although both cap analog-bound eIF4F as well as eIF4F free of the cap analog-bound the 43S preinitiation complex with comparable efficiency, eIF4F could exert its effect on eIF5-promoted GTP hydrolysis only when it was bound to the cap analog. Taken together, these results indicate that the specific cap-bound conformation of the eIF4F protein was, perhaps, required to fully block eIF5-promoted GTP hydrolysis in the 43S preinitiation complex. Since, eIF5 was found to be stably associated with 43S preinitiation complex as well, it strongly favors the hypothesis that eIF5 was completely prevented from interacting with eIF2 in the 43S preinitiation complex in the presence of the other bound initiation factors, eIF1, eIF1A, eIF3, and eIF4F and as a result aberrant GTP hydrolysis (i.e., GTP hydrolysis prior to positioning of the 43S preinitiation complex at the AUG start codon) was prevented under these conditions.

However, when the 43S preinitiation complex was allowed to scan the 5′-UTR (in presence of additional factors required for scanning – eIF4A, -4B, and ATP) to reach the start AUG codon, there was a complete restoration of eIF5-promoted GTP hydrolysis. Under these conditions, toe-printing analysis revealed the 40S ribosomal complex to be positioned at the AUG codon of the mRNA (Majumdar and Maitra 2005). It has been demonstrated that codon-anticodon base-pairing between the initiator Met-tRNA$_i$ and the AUG codon of an mRNA leads to a marked conformational change in the 48S complex resulting in the release of bound eIF1 and possibly reorientation of the bound factors within the complex (Nanda et al. 2009). As a result, eIF5 may then be able to interact with eIF2, which triggers the GAP activity of eIF5 resulting in the hydrolysis of GTP bound in the 48S initiation complex. Support for this model came from determination of structures of N-terminal and C-terminal domains of



TIF5 (eIF5), Fig. 1 Schematic representation for the role of eIF5 in AUG start codon selection and the link between eIF5-promoted GTP hydrolysis and AUG selection. By virtue of its ability to interact with multiple eIFs (eIF1, eIF1A, eIF3, and eIF4F), eIF5 can bind to the 43S preinitiation complex bound to eIF4F at the 5′-cap structure. However, bound eIF5 is prevented from interacting with the 40S-bound eIF2•GTP due to the presence of other bound initiation factors. In particular, due to the structural similarity between eIF1 and the NTD of eIF5, this domain of eIF5 that must interact with the GTP-binding domain of eIF2γ to act as a GAP for eIF2 and is excluded from the eIF1 binding site in the 43S preinitiation complex (PIC) (Lorsch and Dever 2010), preventing premature GTP hydrolysis prior to AUG selection. Positioning of the 43S PIC at the AUG start codon causes a conformational change of the 48S initiation complex that releases eIF1 from the 40S ribosome and allowing the NTD of eIF5 to occupy the eIF1 binding site in the PIC. eIF5 can now interact with eIF2 thereby leading to GTP hydrolysis. Although shown bound to the 5′-cap structure, whether eIF4F remains bound to the cap or is a component of the scanning 43S ribosomal complex is not yet clear (Adapted from Majumdar and Maitra 2005)

eIF5 (Pestova et al. 2007; Lorsch and Dever 2010). It has been observed that the N-terminal domain of eIF5 is structurally similar to eIF1 (Conte et al. 2006). This finding along with the observation that eIF5 and eIF1 antagonizes each other's binding to the 43S preinitiation complex (Nanda et al. 2009) has suggested a model (Nanda et al. 2009) in which eIF1 is bound in the scanning 43S complex in competition with the NTD of eIF5 thus preventing interaction between the NTD of eIF5 and eIF2. Release of eIF1 upon start codon recognition of the 43S complex may allow eIF5 to move to the eIF1 binding site in the preinitiation complex and allow interaction with eIF1A as well as with eIF2 to trigger its GAP activity leading to GTP hydrolysis and Pi release. At any rate, it is clear that the process of AUG selection is intimately connected to the hydrolysis of bound GTP in the 48S initiation complex. The overall sequence of events in the link between AUG section and GTP hydrolysis is summarized in Fig. 1.

Summary

eIF5, a single-subunit protein of about 49 kDa in mammals and 45 kDa in the yeast *Saccharomyces cerevisiae*, in conjunction with GTP and other translation initiation factors, plays an essential role in initiation of protein synthesis in eukaryotic cells. Following scanning of the 5′-UTR of an mRNA by 43S ribosomal preinitiation complex (40S•eIF3•mRNA•Met-tRNA•eIF2•GTP•eIF1•eIF1A) and positioning of the preinitiation complex at the AUG start codon of the mRNA to form the 48S initiation complex, eIF5 interacts with eIF2 bound as a Met-$tRNA_i$•eIF2•GTP ternary complex in the ribosomal complex to promote the hydrolysis of bound GTP. Hydrolysis of GTP is a stringent prerequisite for the eventual release of eIF2•GDP and other bound initiation factors during eIF5B-mediated joining of the 60 ribosomal subunit to the 48S complex to form the functional 80S initiation complex. Extensive biochemical studies have shown that eIF5 physically interacts with eIF2 and acts a GTPase-activating protein (GAP) for eIF2, increasing the intrinsic GTPase activity of eIF2 by over six orders of magnitude. Additionally, recent genetic, biochemical, structural analysis of eIF5 and other initiation factors have provided compelling evidence that eIF5, by virtue of its interaction with other initiation factors, is also an essential component of the scanning 43S ribosomal complex and plays an important role in the stringency of the start codon selection. Specific single-site mutation of eIF5 has been shown to alter the ability of the scanning 43S preinitiation complex to utilize UUG codons as start sites in addition to AUG codons. Thus, in addition to its function as a constitutive GAP for eIF2, the initiative factor eIF5, in conjunction with other initiation factors in the ribosomal scanning complex, plays a direct role in start codon selection.

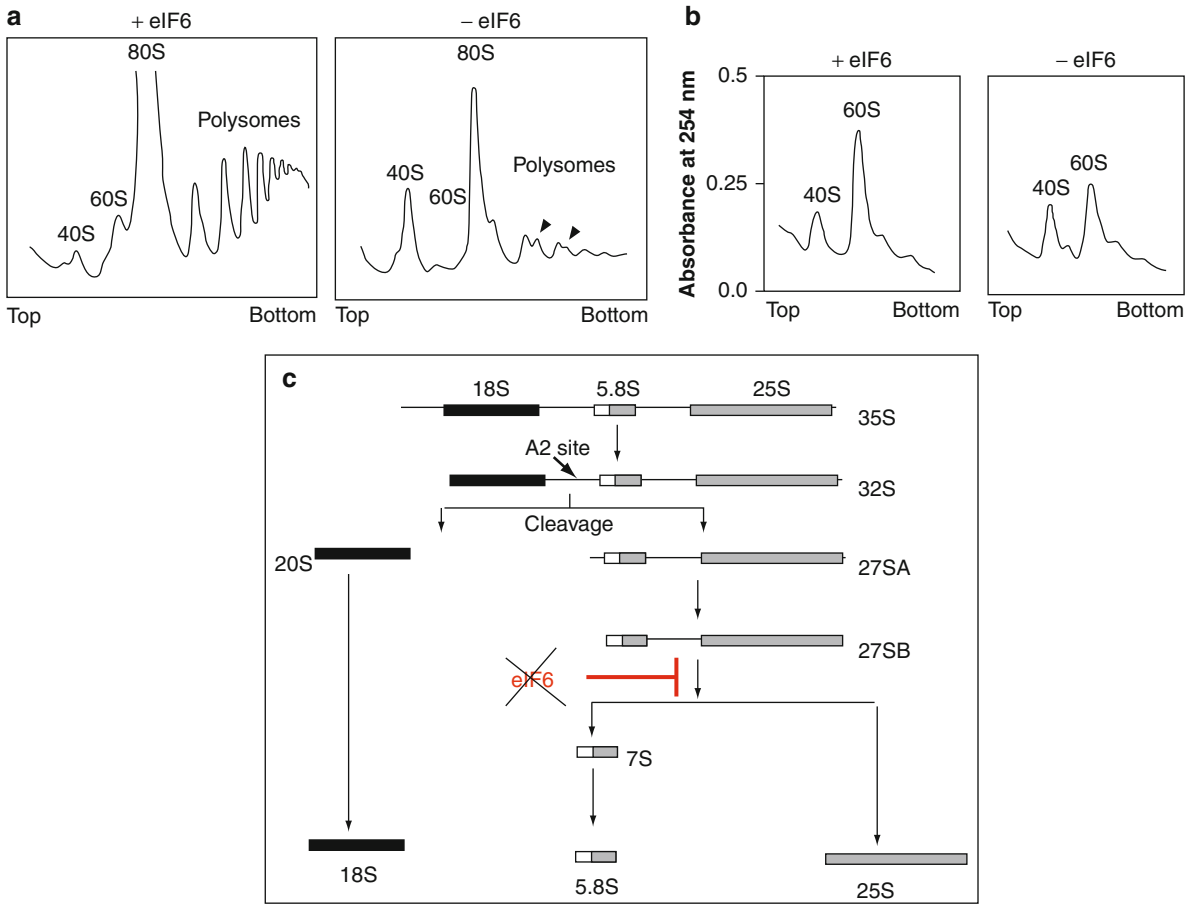
Historical Background

(a) *Isolation and initial characterization of eIF6* – Eukaryotic initiation factor 6 (eIF6), a monomeric protein of about 26.5 kDa, was originally isolated from the postribosomal supernatant of both wheat germ (Russel and Spremulli 1979) and mammalian cell extracts (Valenzuela et al. 1982) based on an in vitro assay that measured the ability of the protein to bind specifically to the 60S ribosomal subunit and to prevent the association of the 60S subunit to the 40S ribosomal subunit to form the 80S ribosomes. Because, the assembly of the 80S initiation complex during initiation of protein synthesis requires a cellular pool of free 40S and 60S ribosomal subunits, eIF6 was thought to play a direct role in the provision of free ribosomal subunits required for initiation of protein synthesis. The protein was therefore classified as a eukaryotic translation initiation factor (eIF), although its function in translation was poorly characterized. Notably, it was shown that eIF6-bound 60S ribosomal subunit is incapable of joining the 40S (48S) initiation complex to form the 80S initiation complex (Valenzuela et al. 1982). It should be noted that recent cryo-electron microscopic studies reveal that eIF6 and the 40S ribosomal subunit share a common binding region on the 60S subunit and cannot bind simultaneously. Thus the ribosomal subunit anti-association activity of eIF6 is due to its ability to physically block intersubunit bridge formation (Gartmann et al. 2010).

(b) *Functional characterization of eIF6* using m*olecular genetic analysis in yeast*: To facilitate further characterization of eIF6, first a human cDNA (Si et al. 1997) and then the single-copy essential *Saccharomyces cerevisiae* gene (Si and Maitra 1999; Sanvito et al. 1999) encoding functionally active eIF6, each of 245 amino acids (calculated M_r,26,558 for human eIF6 and 25,550 for yeast eIF6) were cloned and expressed in *Escherichia coli*. The two proteins are 72% identical. A molecular genetic analysis in yeast was therefore used by investigators to elucidate the cellular function of eIF6 (Si and Maitra 1999; Sanvito et al. 1999). Using a mutant yeast strain having a conditional eIF6 expression system, these investigators showed that depletion of eIF6 from this mutant strain resulted in inhibition of both cell growth and rate of in vivo protein synthesis. Analysis of the polysome profiles of wild-type and eIF6-depleted cells showed that eIF6-depletion caused a marked reduction in the number of polyribosomes compared with that in wild-type cells (Fig. 1a). However, in contrast to cells depleted of an essential initiation factor, where a reduction in the size of polyribosomes is always accompanied by a marked increase in the number of 80S ribosomes and both free 40S and 60S ribosomal subunits, the decrease in polyribosome content in eIF6-depleted cells is accompanied by a decrease (not increase) in the number of both 80S and 60S ribosomes and concomitant accumulation of half-mer polyribosomes (representing stalled 43S initiation complexes at the 5'-UTR and at the AUG



TIF6 (eIF6), Fig. 1 (**a**) Analysis of the polyribosome profile of eIF6-depleted mutant yeast cells. Lysates of wild-type (wt) and eIF6-depleted mutant yeast cells were subjected to 7–47% (wt/vol) sucrose gradient centrifugation and the A_{254} profile of the gradient fractions was analyzed in a UV-absorbance monitor. The positions of free 40S, 60S, 80S ribosomes, polyribosomes, and half-mer polyribosomes are indicated. Details of the procedures are in the reference, Si and Maitra (1999). (**b**), eIF6 depletion results in a decrease in 60S ribosomal subunits. Total ribosome isolated from wild-type and eIF6-depleted cells were dissociated into 40S and 60S ribosomal subunits, and sedimented through 15–40% sucrose gradient and ribosome profiles were determined. (The figures in panels (**a**) and (**b**) are reproduced with permission from Si and Maitra 1999). Copyright 1999, the American Society of Microbiology. (**c**) Schematic representation of the organization and processing sites of 35S pre-rRNA. The 35S precursor RNA contains the sequences for 18S, 25S, and 5.8S rRNAs that are separated by transcribed spacer regions that are removed at various processing steps. The major cleavage sites, the endonucleolytic and exonucleolytic processing steps, processing intermediates, and pathways leading to mature rRNAs are indicated. The processing step that is blocked by eIF6 depletion is also shown (adapted from the reference Basu et al. 2001)

codon of mRNAs awaiting association with 60S ribosomal subunits). Direct determination of total 40S and 60S subunit content of eIF6-depleted cells confirmed that there was a selective reduction of total 60S with respect to total 40S ribosomal subunits, causing a stoichiometric imbalance in the 60S/40S subunit ratio (Fig. 1b) resulting in the formation of half-mer polysomes. These results, along with the observation that lysates of yeast cells lacking eIF6 remained active in translation of mRNA in vitro (Si and Maitra 1999), led to the conclusion that eIF6 does not function as a canonical translation initiation factor for global protein synthesis. Additionally, it was shown that the stability of mature 60S ribosomal particles, synthesized in yeast cells in the presence of eIF6, was not significantly affected following removal of eIF6 from these cells (Basu et al. 2001). Rather evidence

clearly indicated that in eIF6-depleted cells, the reduction of 60S ribosomal subunits is due to severe inhibition in the biogenesis of 60S ribosomal subunits. To understand how depletion of eIF6 affects 60S ribosome biogenesis, it is necessary to review very briefly the salient features of ribosome biogenesis.

eIF6 is Essential for the Biogenesis of 60S Ribosomal Subunits

Ribosome biogenesis (reviewed in Kressler et al. 2010; Venema and Tollervey 1999) is a highly conserved process from yeast to mammals and occurs primarily in the nucleolus, where four ribosomal rRNAs (25S in yeast or 28S in mammals), 18S, 5.8S, and 5S are formed, modified co-transcriptionally by pseudouridylation and methylation, and processed during their assembly with 78 (in yeast) and 79 (in mammals) ribosomal proteins into mature 40S and 60S ribosomal subunits. In yeast, where the process has been best characterized, the 18S rRNA of the 40S subunit and the 25S (28S in mammals) and 5.8S rRNAs of the 60S subunit are transcribed in the nucleolus from the rDNA transcription unit by RNA polymerase I as a single large precursor RNA known as the 35S pre-RNA in yeast and 45S pre-rRNA in mammals. The fourth rRNA 5S, also a constituent of the 60S subunit, is transcribed independently from 5S DNA by RNA polymerase III. Immediately following the synthesis of the 35S pre-rRNA, many ribosomal proteins (mostly of the 40S subunits) as well as a large number of transacting nonribosomal proteins and small nucleolar RNPs (SnoRNPs) associate with the 35S pre-rRNA to form the 90S ribonucleoprotein (RNP) particle. Association of the transacting nonribosomal proteins as well as snoRNAs with the preribosomal RNP particles are required for accurate pre-RNA processing, pre-rRNA modification, and ribosome assembly. The 35S pre-rRNA present in the 90S RNP then undergoes a sequence of ordered exonucleolytic trimming and endonucleolytic cleavage reactions (see Fig. 1c) giving rise to several intermediate RNP particles of decreasing size in the nucleus and eventually to a mature 40S ribosomal subunit containing 18S rRNA and a mature 60S ribosomal subunit containing 5.8S and 25S rRNAs. As shown in Fig. 1c, the very first endonucleolytic cleavage at the A_2 site results in the formation of pre-40S (43S) and pre-60S (66S) particles. Each precursor particle then follows an independent pathway for subsequent biogenesis in the nucleolus and nucleoplasm, nuclear export and final maturation in the cytoplasm. It should be noted that not all transacting assembly proteins associate simultaneously with the 90S or intermediate pre-40S and pre-60S RNP particles. Rather, these proteins associate with preribosomal RNP particles at different steps of the processing reactions. As the biogenesis and maturation of the pre-60S and pre-40S particles proceed first in nucleolus and then in the nucleoplasm, most of the bound transacting proteins (not the ribosomal proteins) are sequentially released along the biogenesis pathway and recycled in the nucleolus for new rounds of biogenesis. The pre-40S and pre-60S particles that emerge from the nuclear pore complex to the cytoplasm contain only a few bound transacting proteins (reviewed in Kressler et al. 2010; Panse and Johnson 2010). These bound proteins are released in sequence from the preribosomal particles in the cytoplasm to form translation-competent mature ribosomal subunits.

eIF6 is one of the essential 60S ribosomal assembly proteins that associates with the pre-60S ribosomal particles in the nucleolus and is required for the subsequent maturation of the 60S ribosomal particles. In eIF6-depleted cells, while the 20S precursor RNA present in the pre-40S particles is processed to 18S rRNA quite efficiently, most of the 27S pre-rRNA present in the pre-60S particles is degraded without forming 25S and 5.8S rRNAs (Basu et al. 2001). Specifically, depletion of eIF6 blocks the processing of the intermediate 27SB pre-rRNA to 7S and 25.5S pre-rRNAs that are the precursors of 5.8S and 25S mature rRNAs, respectively (Basu et al. 2001 and Fig. 1C). Thus, eIF6 is necessary for the formation of 60S ribosomal subunits because it is necessary for the formation of 25S and 5.8S rRNAs, constituents of the 60S ribosomal subunit.

eIF6 (Tif6p) is Phosphorylated In Vitro and In Vivo in Mammalian and Yeast Cells

In earlier studies (Basu et al. 2003; Ray et al. 2008), it was observed that in both mammalian and yeast cells, eIF6 (Tif6p) is phosphorylated at Ser-174 (major site) and Ser-175 (minor site) by the nuclear isoform of CK1 (CK1α or δ in mammals and Hrr25p in yeast). In yeast

cells, these are the only sites that are phosphorylated in vivo. Mutation of Ser-174 alone to alanine abolishes phosphorylation of yeast eIF6 by >75% while mutation of both Ser-174 and Ser-175 to alanine or depletion of Hrr25 from yeast cells causes total abolition of eIF6 phosphorylation. More importantly, failure to phosphorylate eIF6 in vivo either by depletion of Hrr25p from yeast cells or alanine replacement of Ser-174 and Ser-175 of Tif6p inhibited efficient processing of preribosomal RNA to form the mature 25S and 5.8S rRNAs and thus 60S ribosome biogenesis in yeast (Ray et al. 2008). Conversely, mutation of Ser-174 alone to alanine abolishes yeast cell growth and viability. Taken together, these results suggest that phosphorylation of Tif6p at Ser-174 and Ser-175 plays an important regulatory role in the function of Tif6p. However, the molecular basis of phosphorylation of eIF6 (Tif6p), is not apparent from these studies.

Nuclear Export of eIF6 (Tif6p) Bound to the pre-60S Ribosomal Particles and its Subsequent Release

Although the nascent pre-60S particles are mostly assembled in the nucleolus and to a lesser extent in the nucleoplasm, they are exported out of the nucleus to the cytoplasm where final maturation of the pre-60S ribosomal particles occurs to form the mature translationally competent 60S ribosomal subunits. Most of the transacting protein factors that associate with the preribosomal particles during their nucleolar assembly are released in the nucleus prior to the export of the pre-60S particles in the cytoplasm. However, a small number of protein factors including eIF6 (Tif6p) remain bound as the pre-60S particles exit the nucleus and enter the cytoplasm. The cytoplasmic ribosomal maturation pathway involves sequential and ordered release of these bound protein factors by the action of specific energy-consuming cytoplasmic ATPases or GTPases, each of which associates with the preribosomal particles to affect the release of a specific bound factor. In addition, some critical ribosomal proteins are also added at this stage to the 60S particles to make functional 60S ribosomes. The released factors are recycled back to the nucleus for another round of pre-60S ribosome assembly and export. In the ordered release of the bound factors, Tif6p and the nuclear export adapter Nmd3 are the last proteins to be released. Following their release, the pre-60S particles become mature 60 ribosomal subunits and competent to participate in translation.

Mechanism of Release of eIF6 (Tif6p) from the pre-60S Particles

In earlier studies it was reported that in mammalian cells, release of eIF6 from the pre-60S particles is triggered by phosphorylation of eIF6 at Ser-235 by protein kinase C (PKC) and RACK1 (receptor for activated kinase C) (Ceci et al. 2003). However, molecular genetic analysis in yeast cells provided compelling evidence that two cytoplasmic proteins – the GTPase elongation factor-like 1 (Efl1p) (Becam et al. 2001; Senger et al. 2001) and Sdo1, the yeast ortholog of highly conserved mammalian Shwachman–Bodian–Diamond Syndrome (SBDS) protein that is mutated in the inherited bone marrow failure and predisposition to leukemia disorder – genetically interact with the pre-60S particles containing bound eIF6 in the cytoplasm, and act cooperatively to facilitate the release of eIF6 from the pre-60S particles (Menne et al. 2007).

In yeast cells, deletion of either *EFL1* or *SDO1* confers a very slow growth phenotype. It was also observed that while in wild-type yeast cells, eIF6 (Tif6p) localized predominantly to the nucleolus, there was a large accumulation of Tif6p bound to the pre-60S particles in the cytoplasm of *efl1*Δ and *sdo1*Δ cells. Importantly, multiple gain of function *TIF6* alleles (having a missense mutation in *TIF6)* that rescued the growth defect of either *sdo1*Δ or *efl1*Δ cells also restored both the nuclear export defect and nucleolar localization of Tif6p. Biochemical analysis showed that in contrast to wild-type Tif6p, which binds to 60S ribosomal subunits with a relatively high affinity, mutant eIF6 in the suppressor strains has a much reduced affinity for 60S subunits and can thus bypass the requirement of Sdo1 and Efl1p for eIF6 release (Menne et al. 2007).

Direct biochemical evidence in support of the requirement of SDO1 and EFL1 in the release of eIF6 from the pre-60S particles came from the recent elegant work of Finch et al. (2011) using a

reconstituted in vitro system. These investigators isolated stalled pre-60S ribosomal particles containing bound eIF6 from *sbds*-deleted mouse liver. Incubation of these eIF6-bound pre-60S particles with purified recombinant human SBDS and EFL1 proteins resulted in the release of eIF6 from the pre-60S particles. This reaction requires GTP binding to EFL1 and subsequent energy of hydrolysis of GTP coupled to eIF6 release. EFL1 alone has a low intrinsic GTPase activity which is markedly stimulated by the addition of purified mature mammalian 60S ribosomal subunits (Senger et al. 2001). Addition of SBDS stimulated further 60S-dependent GTP hydrolysis by EFL1 (Finch et al. 2011). However, despite its 60S ribosome-dependent GTPase activity, EFL1 alone in the absence of SBDS is unable to promote the release of eIF6 from the 60S-found. eIF6 complex although GTP hydrolysis still occurs under these conditions. Further mechanistic studies showed that the essential role of SBDS is to tightly couple the activation of EFL1-mediated GTP hydrolysis on the 60S ribosome to eIF6 release. A conserved lysine residue at position 151 of SBDS, which is mutated in SDS disorder, is required for cooperativity with EFL1 and is essential for this coupling process.

Taken together, these observations of Menne et al. (2007) and Finch et al. (2011) provide compelling evidence that the mechanism of eIF6 release from the pre-60S particles in the cytoplasm during the final maturation of 60S ribosomal subunits is highly conserved between yeast and mammals and involves cooperative interaction of SBDS and EFL1 in mediating the GTP hydrolysis-dependent release of eIF6 from the pre-60S particles. In contrast to the report of Ceci et al. (2003), there was no evidence for the requirement of phosphorylation of eIF6 at Ser-235 for its release.

Recycling of eIF6: Opposing Action of Casein Kinase 1 and Calcineurin Phosphatase in Nucleo-Cytoplasmic Shuttling of eIF6

After eIF6 is released from the pre-60 particles, it must be imported back to the nucleus for continued 60S ribosome biogenesis. eIF6 does not appear to have a nuclear localization signal (NLS) or a nuclear export signal (NES). However, as mentioned before, both the yeast and mammalian eIF6 are phosphorylated by the nuclear isoform of CK1 at Ser-174 and Ser-175 and phosphorylation of eIF6 plays an important physiological role in its function in yeast cells. Additionally, examination of the highly conserved amino acid sequence of eIF6 surrounding the CK1 phosphorylation sites at Ser-174 and Ser-175 shows that in all nucleated species examined so far, the protein also possesses a sequence motif LQVP that is known to be a binding motif for the Ca^{2+}-regulated protein phosphatase calcineurin as shown below (reviewed in Biswas et al. 2011).

^{168}E D Q D E L**S S** L L Q V P L V^{182}	Human

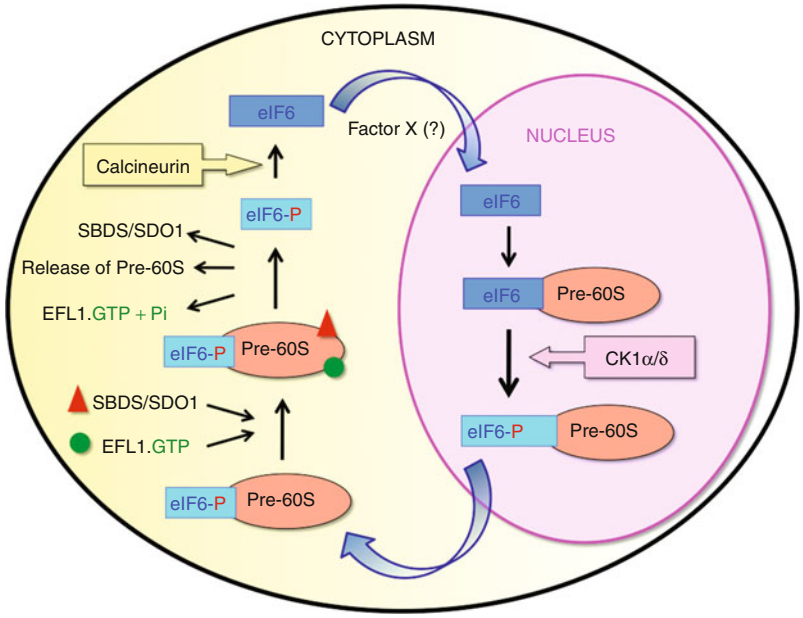
Q D Q D E L**S S** L L Q V P L V	*Drosophila melanogaster*
D E L E F LK S LF K V E Y I	*Methanococcus jannaschii*

The presence of a biologically important CK1 phosphorylation site and a calcineurin docking motif in nucleated species gave rise to the hypothesis that the nuclear entry and export of eIF6 might be regulated by CK1 phosphorylation and dephosphorylation by calcineurin as was described for NFAT family of transcription factors in vertebrates and a stress-responsive transcription factor, Crz1p, in yeast (reviewed in Biswas et al. (2011)).

In a recent report, Biswas et al. (2011) presented several lines of evidence which suggest that eIF6 shuttles back and forth between the nucleus and the cytoplasm of mammalian cells. This process is dependent on phosphorylation and dephosphorylation of eIF6 at Ser-174 and Ser-175 mediated by CK1 and the Ca^{2+}/calmodulin-dependent protein phosphatase calcineurin, respectively. Using COS7 cells, it was shown that the nuclear export of eIF6, bound to the pre-60S particles, requires phosphorylation of Ser-174 and Ser-175. Failure to phosphorylate at these sites either by mutation of the serine residues to alanine or treatment of cells with a CK1 inhibitor causes a significant fraction (>90%) of eIF6 to be retained in the nucleus. These observations also suggest that it is the phosphorylated form of eIF6 that is exported to the cytoplasm and is presumably released from the pre-60S particles. For nuclear import of eIF6, the protein phosphatase



TIF6 (eIF6), Fig. 2 Schematic representation of the functional pathway of eIF6 in 60S ribosome biogenesis. In the nucleolus, eIF6 associates with the pre-60S particles along with >100 transacting protein factors and is essential for pre-60S ribosome assembly and pre-rRNA processing. eIF6 remains associated with the pre-60S particles during pre-60S maturation in the nucleoplasm as well as during the nuclear export of the pre-60S particles. Nuclear export of eIF6 bound to the pre-60S particles requires phosphorylation of eIF6 at Ser-174 and Ser-175 by the nuclear isoform of CK1. In the cytoplasm, during the final maturation process, two cytoplasmic proteins SBDS/Sdo1 and EFL1/Efl1p interact with the pre-60S particles and catalyze the release of eIF6 coupled to GTP hydrolysis by EFL1. The released eIF6 that is presumably in the phosphorylated form then interacts with Ca^{2+}/calmodulin-regulated protein phosphatase calcineurin and the dephosphorylated form of eIF6, either by itself or by interaction with another as yet unidentified protein factor X containing the NLS signal, is imported to the nucleolus to participate in another round of 60S ribosome biogenesis

calcineurin, following its activation by Ca^{2+}, associates with eIF6 that is presumed to be in the phosphorylated form, and appears to play an essential role in eIF6 nuclear import as the localization of eIF6 changes from cytosolic to nuclear subsequent to calcineurin activation in vivo. This event is blocked by the immunosuppressive drug cyclosporin A, that is known to be a specific calcineurin inhibitor suggesting that the dephosphorylated form of eIF6 is imported to the nucleus. At present, it is not known whether nuclear import of dephosphorylated eIF6 requires its association with any cofactor (providing the NLS signal) or eIF6 can enter the nucleus by itself due to its low molecular weight. Additionally, nuclear import and export of eIF6 occur even in the presence of a potent protein synthesis inhibitor cycloheximide and is therefore a reflection of dynamics of import and export of preexisting eIF6 molecules rather than de novo new eIF6 synthesis. The release of eIF6 from the pre-60S particles and its recycling to the nucleus are summarized schematically in Fig. 2.

Summary

eIF6, a highly conserved protein from yeast to mammals, binds to the 60S ribosomal subunit and functions as a ribosomal subunit anti-association factor by preventing premature association with the 40S ribosomal subunit. Molecular genetic analysis in yeast has provided compelling evidence that eIF6 is not a canonical translation initiation factor. Rather, it is essential for 60S ribosome biogenesis and assembly. Specifically, eIF6 associates with the pre-60S particles in the nucleolus along with many other transacting protein factors and is essential for 60S ribosome assembly and pre-rRNA processing to form the mature

rRNAs, constituents of the 60S ribosomal particle. Association of eIF6 with the pre-60S particles is also required for the export of the assembled pre-60S particles from the nucleus to the cytoplasm where the release of eIF6 occurs. Nuclear export of the pre-60S particles containing bound eIF6 requires phosphorylation of eIF6 at Ser-174 and Ser-175 by the nuclear isoform of CK1. In the cytoplasm, during the final maturation of the pre-60S particles, two cytoplasmic proteins SBDS/Sdo1 and EFL1/Efl1p interact with the pre-60S particles and catalyze the release of eIF6 coupled to hydrolysis of GTP by EFL1. The released eIF6 that is presumably in the phosphorylated form then interacts with Ca^{2+}/calinodulin-dependent protein phosphatase calcineurin and the dephosphorylated form of eIF6 is imported to the nucleus to participate in another round of 60S ribosome assembly and biogenesis. These observations suggest eIF6 plays an important regulatory role in 60S ribosome biogenesis in eukaryotic cells.

Concluding Remarks

Since the original isolation of eIF6 as a ribosomal subunit anti-association factor, it is now clear that this activity of eIF6 is not utilized to generate free 40S and 60S ribosomal subunits required for initiation of protein synthesis. Rather, association of eIF6 with the pre-60S particles in the nucleolus prevents their premature interaction with the pre-40S particles both in the nucleus and cytoplasm. eIF6 is released only when all other bound factors dissociate from the pre-60 particle leading to the formation of mature 60S ribosomal subunit. Secondly, the essential requirement of SBDS (along with the GTPase EFL1) in the release of eIF6 from the pre-60S particles underscores the importance of this protein in 60S ribosome biogenesis. Mutation of the SBDS gene has been shown to be associated in the inherited leukemia predisposition disorder Shwachman–Diamond syndrome (SDS). Some of the disease-causing mutant proteins are unable to catalyze the release of eIF6 from the pre-60S particles causing defects in 60S ribosome maturation and biogenesis. Thus, SDS has been defined as a "ribosomopathy" by Finch et al. (2011). Finally, the requirement of Ca^{2+}-activated calcineurin phosphatase in the nuclear import of eIF6 could provide a means by which changes in intracellular Ca^{2+} levels could modulate nuclear import of eIF6, and consequently, nucleolar 60S ribosome biogenesis. Clearly, a detailed molecular investigation of these steps is necessary to understand various quality control mechanisms in the pathway of ribosome biogenesis.

Historical Background

Overproduction of the cytokine profile (cytokine tsunami or storm) can be caused by both infectious and non-infectious diseases. During this process, inflammatory responses are activated either to provide a protective mechanism or to damage tissues when excessively produced cytokines attempt to overwhelm the cause of their production. This system is activated whenever there is a foreign invasion of the body. Foreign invasion is attributed to microbial associated molecules known as Pathogen Associated Molecular Patterns (PAMPS), which activate our immune system through Pattern Recognition Receptors (PRRs) present in the body fluids, cell membranes, and cytoplasm. PRRs not only identify PAMPs, but also molecules released from damaged cells known as Damage Associated Molecular Patterns (DAMPs). There is a great deal of evidence that DAMPs such as products of necrosis or breakdown components of extracellular matrix are originated or produced by the host species (Yang et al. 2010; Schaefer 2010), even though this would seem to contradict the original belief that the immune system only responded to non-self compounds.

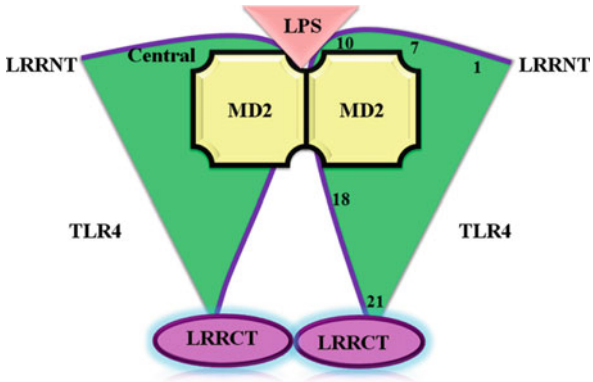
One group of transmembrane PRRs located on the cell membranes and endosomes are known as Toll-like Receptors (TLRs). TLRs are involved in the primary response against invaders, connecting the innate and adaptive immune responses. Recently, three major classes of PRRs were identified in addition to TLRs, C-type lectin receptors (CLR), retinoic acid-inducible gene (RIG)-1-like receptors (RLR), and nucleotide-binding oligomerization domain protein-1- like receptors (NLR). These systems augment the response of TLRs to invading agents. Originally, the activation of any of the aforementioned receptors was thought to be associated with the production of pleotrophic inflammatory cytokines such as TNF, IL-1b, and IL-6. However, type I IFNs are also produced by TLR activation and these compounds enable the cells to resist viral infection, leading to acquired immune responses as well as hematopoietic stem cell production and turnover (Beutler 2009; Kawai and Akira 2009).

Prima facie TLRs were reported in *Drosophila melanogaster* as Toll1 receptor in 1985 (Hansson and Edfeldt 2005). In this fly, Toll gene performs nonimmune functions such as establishing dorsoventral polarity, synaptogenesis, and axon path finding during embryogenesis (Anderson et al. 1985; Halfon et al. 1995; Rose et al. 1997). TLRs are Type I transmembrane glycoproteins that are characterized by the presence of Leucine Rich Repeats (LRRs) and TIR (Toll/Interleukin 1 Receptor) domains. To date, 10 TLRs have been identified in humans, while 13 have been identified in mice. Various TLRs bind with different PAMPs located in the outer wall of microbes or within their cytoplasm. Among the PAMPs, bacterial lipopolysaccharide (LPS) binds with TLR4, while lipopeptides are recognized by TLR2 in conjunction with TLR1 and TLR6, triacylated lipopeptides are bound by TLR1/2 heterodimers, diacylated lipopeptides interact with TLR2 and TLR6, ▶ TLR5 interacts with flagellin, dsRNA binds with TLR3, ssRNA interacts with TLR7 and TLR8, and ▶ TLR9 binds with unmethylated CpG islands. Innate immunity through the TLR system is known to be very important for vaccine design (Hashiguchi et al. 2010). In this entry, we discuss TLR4, its structure and associated receptors, signaling pathways, and the mechanism by which it is activated.

TLR4 Structural Features with MD2

The TLR4 gene, which is also known as Lps; Ly87; Ran/M1; and Rasl2-8, is located in chromosome 4 in mice and chromosome 9 in humans. TLR4 belongs to the LRR family and is composed of an N-terminal, central, and C-terminal domain. TLRs are characterized by two conserved regions, the extracellular leucine rich region (LRR) and the cytoplasmic Toll/IL-1 receptor (TIR) domain. The LRR, which is involved in recognition of the ligand, is composed of 19–25 tandem repeats of 24–29 amino acids folded in strands and helices that are linked by loops. TLR4 is composed of a 608 residue extracellular domain (Medzhitov et al. 1997) and is highly polymorphic when compared with the transmembrane and cytosolic domains (Schmitt et al. 2002; Gay and Gangloff 2007). The TIR domain, which shares homology with the interleukin 1 receptor (IL-1R), modulates protein–protein interactions between the TLRs and the adaptor proteins involved in the signal transduction cascade (O'Neill and Bowie 2007). The TIR domain, which provides a scaffold for the recruitment of MyD88 (myeloid differentiation primary response gene 88), is composed of three highly conserved motifs known as Box-1, Box-2, and Box-3 (Xu et al. 2000). In these three boxes, Box-2

forms loops known as BB loops by connecting β-strands and α-helixes. These loops are indispensable for signaling, as a single point mutation in proline residue (P712H) render C3H/HeJ mice hyporesponsive to LPS (Poltorak et al. 1998). Ligand induced dimerization is one of the hallmarks of TLR4 activation as it is the first line of regulation. CD14, MD2, and TLR4, which are receptosomes, are very important for ligand (LPS) recognition by TLR4. The role of CD14 is to enhance LPS binding to MD2, whereas MD2 is indispensable in the formation of stable receptor-ligand complexes. Interaction between TLR4 and MD2 is mediated in the concave surface at the amino-terminal region of TLR4, especially Glu (24) and Pro (34) and central domains that are critical for MD2 binding (Nishitani et al. 2005) (Fig. 1). Following ligand binding, the TIR domain initiates downstream signaling events starting with adaptor proteins. After recognition of LPS complexes and signaling, the TLR4, MD2, CD14, and LPS complex is ubiquitinated and sorted to late endosomes/lysosomes (dynamin and clathrin dependent mechanism) for degradation, after which the antigens are presented to $CD4^{+}$T cells and signaling is terminated.



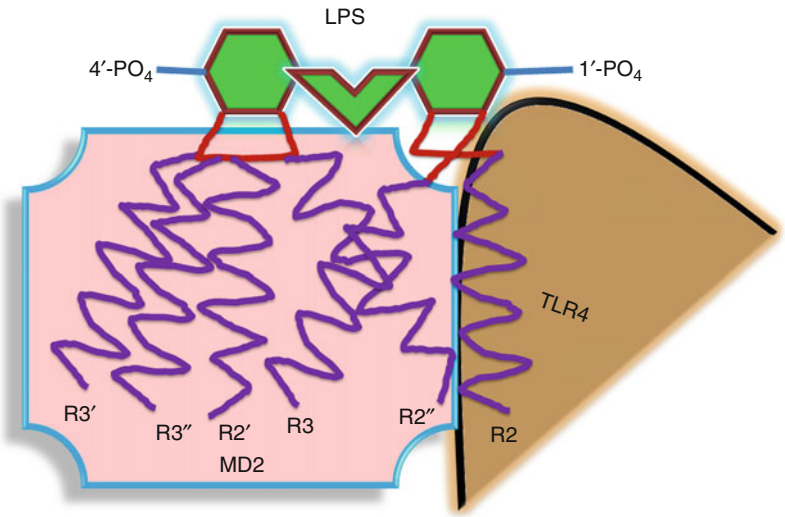
TLR4, Toll-Like Receptor 4, Fig. 1 Diagrammatic representation of the structure of the TLR4-MD2-LPS complex. TLR4 is composed of outer extracellular domain and intracellular domain known as TIR domain. Outer structure is formed of leucine rich repeats and divided as N-terminal, central, and C-terminal domains. MD2 binds with the amino and central domains. After ligand binding and dimerization of TLR4, carboxy terminals fuse together to conduct signaling

Single Nucleotide Polymorphisms of TLR4

Several studies of mice and humans have demonstrated an increased susceptibility to various infections when TLR genes display mutations. Single nucleotide polymorphisms (SNPs) have been reported in various TLR genes, such as TLR2, ▶ TLR4, TLR5, TLR6, TLR9, and TLR10, which are associated with increased disease susceptibility (Schroder and Schumann 2005). TLR4 is unable to function when it shows single nucleotide polymorphisms in its expression on Asp299Gly and Thr399IIe, and is unresponsive to LPS (Douville et al. 2010). TLR4 SNPs (single nucleotide polymorphisms) have been investigated in an extent way. It shows two nonsynonymous SNPs, an A/G transition at SNP rs4986790 that causes the substitution of aspartic acid by glycine at amino acid position 299 (Asp299Gly), and a C/T transition at SNP rs4986791 that causes the substitution of threonine by isoleucine at amino acid position 399 (Thr399Ile). These two SNPs occur in serious infections in HIV-1 infected patients with a history of nadir CD4 cell count of <100 cells/cubic mm (Papadopoulos et al. 2010). Such SNPs also display extensive damage to the system during infections with various diseases and in response to various conditions such as Gram-negative bacteria, septic shock, endotoxemia, disseminated candidiasis, invasive aspergillosis, respiratory syncytial virus infection, meningeal disease, bacterial vaginosis, premature birth, brucellosis, coronary heart disease, asthma, hematogenous osteomyelitis, and *Plasmodium falciparum* infections.

Binding of LPS with MD2 and TLR4

LPS, a TLR4 agonist, is used in several adjuvants that have been shown to be highly effective in both experimental and clinical settings (Thompson et al. 2005; Przetak et al. 2003; Kundi 2007; Baldridge et al. 2004). When LPS interacts with MD2, five of the six lipid chains of LPS are buried deeply in the hydrophobic pocket in MD2, whereas the remaining chain interacts with the conserved phenylalanine in the TLR4 receptor through a hydrophobic interaction (Fig. 2) (Park et al. 2009; Liu et al. 2008; Jin et al. 2007). Park et al. (2009) determined the crystal structure of TLR4-MD2, which helped explain its binding mechanisms. When this complex binds, it provides an "M"- shaped architecture. TLR4 consists of LRRNT (leucine rich repeats N-terminal), central, and LRRCT (leucine rich repeat

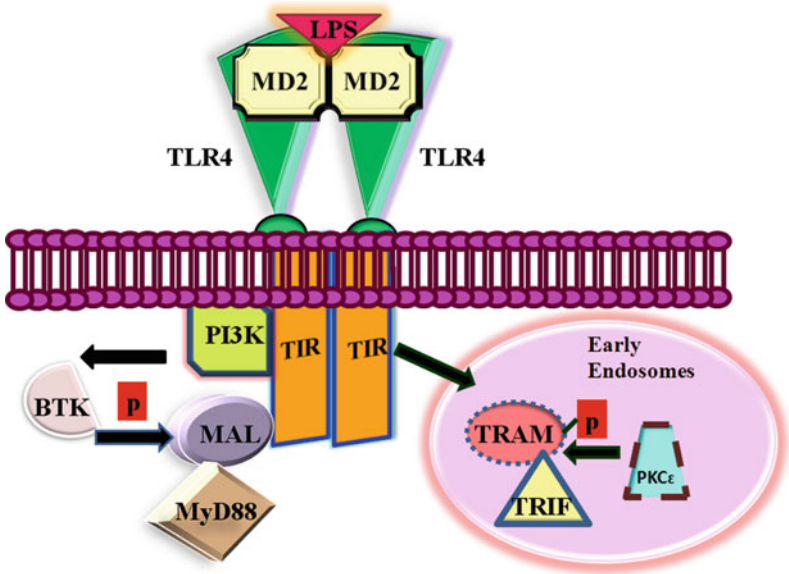


TLR4, Toll-Like Receptor 4, Fig. 2 Binding region of LPS with TLR4 and MD2. Schematically shown is the structure of TLR4-MD2-LPS complex. The receptosomes form an "M" shaped structure. Five acyl chains of LPS named R3′, R3″, R2′, R3, and R2″ form hydrophobic interaction with MD2 and bound in deep interior pockets whereas one chain R2 is exposed to bind with TLR4

C-terminal) domains. MD2 binds with the amino and central domains through their two antiparallel beta-sheets, which forms hydrophobic interactions with LPS. LPS is composed of lipids as well as carbohydrates, the former being referred as endotoxin and the latter being composed of O-antigens. For LPS, it is necessary to have six lipid acyl chains (R3′, R3″, R2′, R3, R2″, and R2) and two phosphate groups to elicit its endotoxic effects. Five of the six acyl chains (R3′, R3″, R2′, R3, R2″) are buried deeply in MD2, whereas the remaining chain (R2) is exposed to the surface to bind with TLR4. The two phosphate groups, 4′-PO_4 and 1′-PO_4, are critical for LPS induced dimer formation, where they form ionic interactions with positively charged amino acids such as lysine and arginine. In addition, the binding of LPS to MD2 causes notable changes in Phe^{126}, which forms the hydrophilic interaction that is critical for MD2 and TLR4 receptor stabilization as well as activation. Eritoran (or E5564, a lipid A antagonist) is a synthetic molecule produced from non-pathogenic *Rhodobactor sphaeroids* (Mullarkey et al. 2003). The crystal structure of TLR4-MD2 complex bound with Eritoran has recently been described, which has shed light into how Eritoran makes its connection with the large hydrophobic internal pocket in MD2 without binding to TLR4 (Kim et al. 2007). Further, in vitro studies have shown that Eritoran blocks the production of cytokines and downregulates intracellular generation of proinflammatory cytokines (Mullarkey et al. 2003; Czeslick et al. 2006). Moreover, there is pharmacological evidence that the drug must be administered every 12 h for its optimum response (Rossignol et al. 2008). Due to its action as an antagonist, Eritoran blocks signaling and subsequent ▶ NF-κB activation. Elucidation of the action of agonists or antagonists on TLR receptors permits design of new therapeutic interventions.

Signaling Components Associated with TLR4

Bruton's tyrosine kinase (BTK) is a TIR-domain-binding protein that participates in NF-κB activation during TLR4 signaling (Fig. 3). BTK binds with Box-1 and Box-2 of the TIR domain and phosphorylates ▶ MAL (MyD88-adaptor-like) at its tyrosine residue. TLR4 interacts directly with Nox4 (NAD(P)H oxidase 4), which is a protein related to gp91phox (Nox2) of phagocytic cells. This binding is involved in the production of ROS and NF-κB activation during LPS induced activation. TLR4 also binds with high mobility group box 1 (HMG1). This binding is mediated by a B-box within one of the two DNA-binding regions in the HMG1 protein. Specifically, HMG1-induced cytokine production through TLR4 stimulation requires the presence of cysteine in position 106 within the HMG1 (Yang et al. 2010). Another key kinase involved in TLR signaling is the p85 subunit of phosphoinositide 3-kinase (PI3K), which binds through its SHC (Src homology 2 domain containing) domain to the phosphotyrosine residue. There are two putative ▶ PI3K binding sites, Tyr674 and Tyr630 in TLR4, and PI3K is



TLR4, Toll-Like Receptor 4, Fig. 3 Signaling components associated with TLR4. TLR4-mediated signaling is identified as MyD88-dependent and independent. MyD88-independent signaling is mediated by TRAM and TRIF. TRIF signaling occurs in early endosomes where it gets phosphorylated by PKCε. PI3K and BTK are also involved in MAL and MyD88-dependent signaling

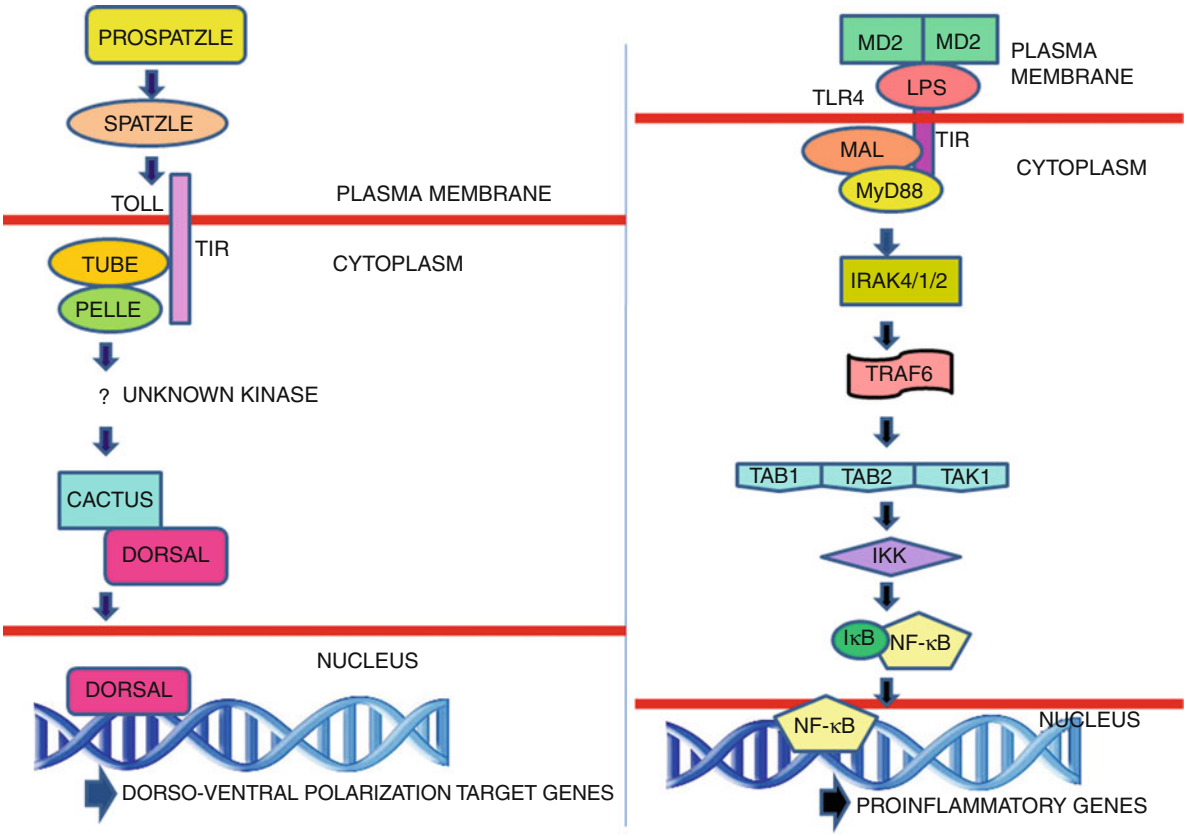
involved in the phosphorylation of TLR2 and TLR3 phosphotyrosine residues as well. ▶ TRAM (TRIF-related adaptor molecule) is phosphorylated by PKCε at its serine-16 residue when stimulated with LPS, which attenuates the response of *Irf3* (Interferon regulatory factor 3) and *Ccl5* (Chemokine (C-C) motif ligand 5). TRAM is trafficked to early endosomes, where it binds with ▶ TRIF (TIR-domain-containing adapter-inducing interferon-β).

Comparison of Toll (*Drosophila*) Signaling with TLR4 Signaling

As discussed earlier, Toll was first identified in *Drosophila* as a protein that mediates dorsoventral polarity during embryonic development (Fig. 4). However, in 1996, Jules A. Hoffman showed that Toll is involved in defense against fungal infection in *Drosophila* (Lemaitre et al. 1996). At the same time, another group searching for LPS-binding protein found a similar structural sequence of Toll in the human genome that resembled the IL1 receptor extracellular domain (Gay and Keith 1991). Thereafter, Janeway group showed that a receptor similar to TLR induced the expression of certain genes involved in adaptive immunity when stimulated with artificial antibodies (Medzhitov et al. 1997). Finally, Poltorak et al. (1998) discovered the current TLR4 and its association with LPS for immune responses. The *Drosophila* genome is composed of nine TLR genes. In *Drosophila*, Toll-1 is maternally transmitted. Spatzle, which is generated from prospatzle during positional signaling in the ventral region of embryo, binds with Toll-1. In turn, Toll-1 recruits and activates ▶ MyD88 homologue Pelle and Tube. Pelle, which is a serine/threonine kinase, phosphorylates itself and Tube as well. The subsequent signaling by an unknown kinase activates cactus (a homologue of IκB proteins) and releases Dorsal (a homologue of NF-κB), which in turn translocates to the nucleus to turn on genes associated with dorsoventral polarity (similar to TLR signaling leading to proinflammatory responses).

Signaling Pathways of TLR4

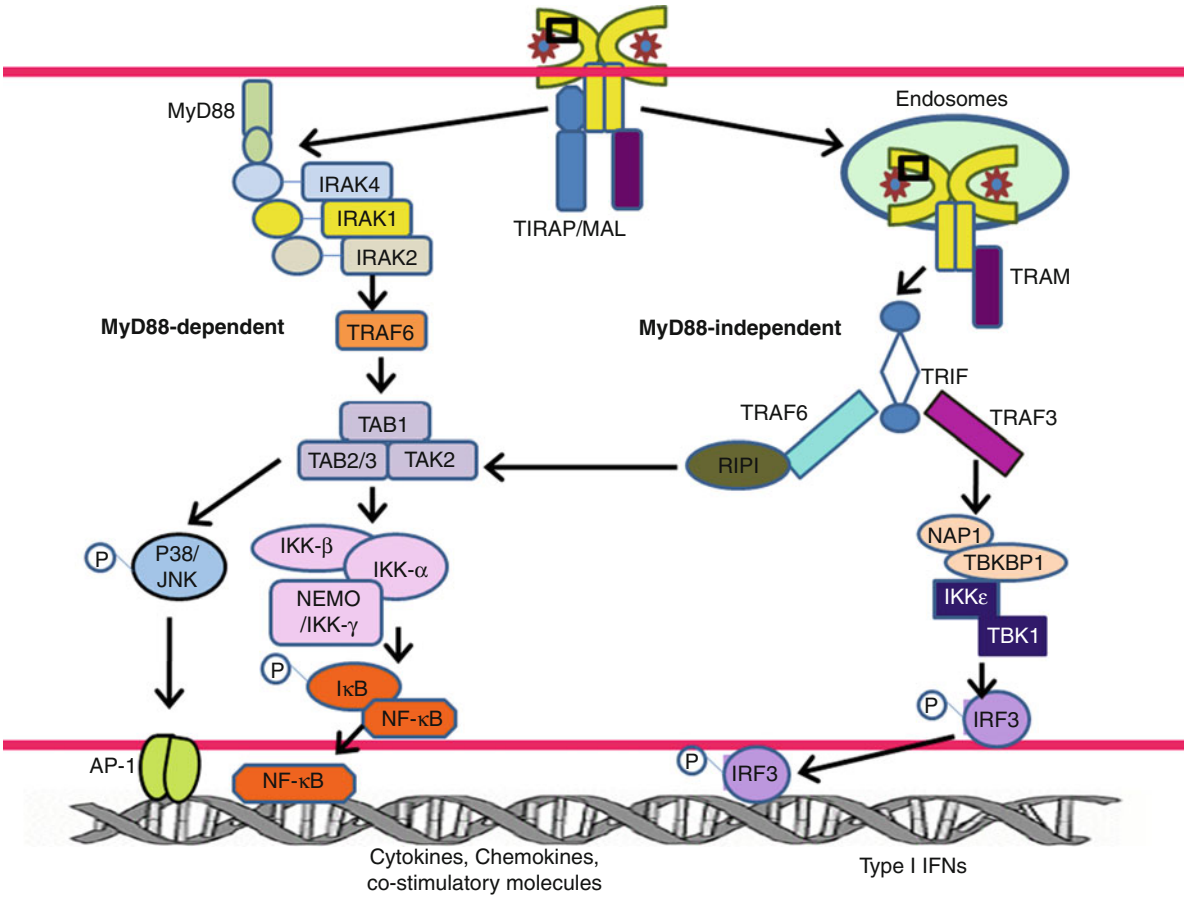
After ligation of the TLR ligands, TLRs dimerize and transmit signals throughout the cell, which leads to the activation of various signaling mechanisms and causes the transcriptional upregulation of distinct genes depending on the cell type and the nature of the stimuli. TLRs use five TIR-domain-containing adaptors, MyD88, Toll/IL-1 receptor (TIR)-domain-containing adaptor inducing interferon-β signal adaptor protein (TRIF also known as TICAM-1), ▶ TIRAP (TIR-domain-containing adaptor protein)/Mal, TRIF-related adaptor molecule (TRAM), and Sterile-alpha and Armadillo motif-containing protein (SARM). These adaptors brace the lacunae between the receptor and



TLR4, Toll-Like Receptor 4, Fig. 4 Comparison of Toll of *Drosophila* with human TLR4. Toll4 resembles Toll of *Drosophila melanogaster*. Both the receptors look alike in their extracellular domains as well as intracellular domains. Toll mediated signaling through cactus and dorsal gives rise to the genes involved in dorsoventral polarization. TLR4 mediated signaling through IκB and NF-κB leads to the robust induction of the genes involved in proinflammatory responses, which connects between innate and adaptive immunity

signaling molecules to elicit biological responses, which are essential for innate immunity.

TLR signaling is classified into two distinct pathways based on the use of MyD88 (widely used receptor) and TRIF. Among various TLR receptors, TLR4 signaling is unique in that it signals via two different pathways, the MyD88-dependent pathway, which is dependent on the MyD88 adaptor, and the MyD88-independent pathway, which depends on TRIF (Fig. 5). The first pathway is crucial for the rapid production of the proinflammatory cytokines IL-6 and ▶ TNF-α. Even though the MyD88-dependent signaling is very important for most infections, it is not involved in resisting the secondary lethal challenge caused by influenza virus (Seo et al. 2010). MyD88 deficient mice display increased risk for obesity associated diabetes (Hosoi et al. 2010). MyD88 is composed of an N-terminal death domain (DD) separated from the C-terminal TIR domain by a short linker region. MyD88-TIR is composed of three sites that are related to conserved boxes 1–3 of the domain and is important for the LPS/TLR4 pathway (Ohnishi et al. 2009). Two of these sites are located at opposite surfaces of the molecule and mediate direct interaction with Mal-TIR. Several knockout studies have provided evidence that MyD88 is essential for various TLR-responses, with the exception of TLR3 (Kawai et al. 1999; Adachi et al. 1998; Schnare et al. 2000). In general, MyD88 serves as a signaling adaptor by communicating signals to downstream kinases. In contrast, MAL acts as a sorting or connecting adaptor that only promotes interaction between MyD88 and TLR4. MyD88 interacts with IL-1R associated kinase (IRAK4) through its N-terminal DD, after which IRAK4 activates other family members such as IRAK1 and IRAK2. Recent studies have identified



TLR4, Toll-Like Receptor 4, Fig. 5 Signaling of TLR4. TLR4 uses four adaptor proteins such as MyD88, TRIF, TRAM, and MAL. Based on the usage of MyD88, TLR4 signaling is classified as MyD88-dependent or independent pathway. Both the pathways use TRAF6. MyD88-dependent pathway activates MAP kinases and IKK leading to NF-κB and AP1 nuclear translocation, thus causing proinflammatory cytokine production. PKCε phosphorylates TRAM, which in turn activates TRIF. TRIF activates both TRAF6 and TRAF3. TRAF6 leads to MAPK and IKK activation through RIP1. TRAF3 leads to IRF3/7 nuclear translocation through TBK1 and IKKε. The translocated IRF complex causes the expression of type I IFNs

critical residues in MyD88 DD as being important for its interaction with IRAK family members, as the substitution of these residues impaired propagation of downstream signaling responses (Loiarro et al. 2009). The activated IRAKs dissociate from MyD88 and interact with TRAF6, an E3 ubiquitin protein ligase. TRAF6 recruits another E2 ubiquitin-conjugating enzyme complex composed of Ubc13 and Uev1A, which catalyze the formation of conjugated lysine 63-linked polyubiquitin chain on TRAF6 itself as well as the formation of unconjugated free polyubiquitin chain (Xia et al. 2009). This macromolecular complex ultimately impinges on TGF-β-activated kinase 1 (TAK1), TAK1-binding protein 1 (TAB1), and TAB2/3. TAB3 is activated by free polyubiquitin chain and phosphorylates IKK complex composed of IKK-α, IKK-β, and NF-κB essential modulator (NEMO). These activated complexes phosphorylate IκB-α, an NF-κB inhibitory protein, followed by freeing NF-κB in the cytoplasm. This freed NF-κB translocates to the nucleus, where it binds with κB sequences to activate various cytokines, chemokines, and costimulatory molecules. Other notable kinases activated by this signaling mechanism and p38 and JNK, which belong to the MAP kinase family and lead to activation of the AP-1 family of transcription factors that further add to the expression of cytokine genes (Kawai and Akira 2006). The ultimate goal of this pathway is to activate the underlying signaling mechanisms/cascades that use NF-κB as a central

vigilance controller and concomitant activation of AP-1 to turn the pleiotropic genes involved in many physiological (cell process and cell proliferation) and inflammatory response on and off.

In the MyD88-independent pathway, TLR4 makes use of TRIF. The presence of well conserved TIR domain and several TRAF6-binding regions makes TRIF the unique adaptor for signal transduction (Yamamoto et al. 2003) as it activates both IRF3/7 and NF-κB (Fitzgerald et al. 2003). However, because TLR4-TRIF is unable to act alone, this recruits TRAM, and it is myristoylated at N-terminus to be associated with plasma membrane and requires PKCε phosphorylation for its activation (Rowe et al. 2006; McGettrick et al. 2006). TRIF-dependent pathway activates TRAF3, and it is important to activate two IKK related kinases, IKKε and TBK1. Various proteins interact with IKKε and TBK1, such as TBK-binding protein 1 (TBKBP1) and NAK-associated protein 1 (NAP1). This complex phosphorylates IRF3/7 at its C-terminus initiating type I IFN production. In addition, TLR4 has recently been shown to recognize not only PAMPS, but also the viral molecules that bind indirectly with viral activated DAMPs following infection with H5N1 avian influenza virus, thus modulating its effects (Imai et al. 2008).

Summary

Toll was first identified in *Drosophila melanogaster* as a gene that controls dorsoventral polarity. Further, continuous investigations by various research groups to identify the receptor responsible for binding of LPS in mammalian cells revealed that a gene very similar to the IL1 receptor extracellular domain had a sequence similar to that of *Drosophila melanogaster* Toll-1, which was named TLR. LPS is captured by LPS-binding protein and presented to the MD2-CD14 and TLR4 complex. Since MD2 lacks an intracellular signaling domain, it presents LPS to TLR4 for further action. Of the six acyl chains of LPS, five chains bind in the deep pocket of MD2 through hydrophobic interactions, while the remaining chain is exposed to the surface to bind with TLR4. The two phosphate groups of LPS aid in the formation of receptor dimer. The signaling responses of TLR4 to LPS are divided into MyD88-dependent and independent events, in which the former uses MyD88 as adaptor and occurs in the cytoplasm and the latter uses TRIF as the major adaptor for signaling mechanisms and occurs in the early endosomes. The gene expression mediated by TLR4 connects innate and adaptive immune responses, which form the first line of defense against microbes. The binding of LPS to TLR4 is determined by the crystal structure, but little research has been conducted to investigate the binding mechanism of various other ligands, such as taxol and heat shock proteins. Dimerization and underlying signaling mechanisms have been elucidated by the identification of crystal structures of TLR1-TLR2, TLR3, and TLR4. Such identification is indispensable for all other TLR families; hence, additional research should be conducted in that area. Overall, TLR4 is a key elicitor of immune responses that is also involved in various types of physiological and pathological events. Post-translational modifications, ubiquitination mechanisms such as mono and linear ubiquitinations, and phosphorylation events make it more arduous to delineate the signaling networks; however, elucidation of the TLR4 structure, extracellular and intracellular binding mechanisms, and signaling events indicate that it is a promising candidate for therapeutics related to various immune-related disorders.

Introduction

An infected host can quickly recognize an invading pathogen via germ-line-encoded pattern recognition receptors (PRRs) that detect microbe-associated molecular patterns (MAMPs) commonly expressed by many pathogens. Recognition of MAMPs by their corresponding receptor allows the host to initiate a rapid inflammatory response that can limit initial pathogen replication (Janeway and Medzhitov 2002). At least four different groups of PRRs have been described with varying cellular location and ligand specificity. Toll-like receptors (TLRs) and C-type lectin receptors (CLRs) are membrane-associated, while RIG-I-like receptors (RLRs) and NOD-like receptors (NLRs) are found in the cytosol. Among the 13 known TLRs, only TLR5 and TLR11 exclusively recognize protein microbial ligands (Kawai and Akira 2010). TLR5 detects flagellin, a protein MAMP that is highly conserved and expressed by both gram-negative and gram-positive bacteria (Hayashi et al. 2001).

Monomeric flagellin is the major subunit of bacterial flagella, which is a whiplike structure that helps bacteria to resist intestinal peristalsis and establish productive infection. Polymerized flagellin forms the majority of the flagellar structure and is therefore one of the most abundant proteins expressed by flagellated bacteria. Furthermore, *Salmonella sp.* is known to secrete monomeric flagellin in response to lyso phosphatidylcholine, a product of intestinal epithelial cells (Subramanian and Qadri 2006). Thus, flagellin represents a major bacterial product, especially within the intestine. After recognition of flagellin, TLR5 forms a homodimer and induces proinflammatory signaling through the recruitment of adaptor molecules. Induction of proinflammatory genes by TLR5 detection of flagellin leads to recruitment of immune cells to the site of infection, thereby allowing the host to contain initial infection.

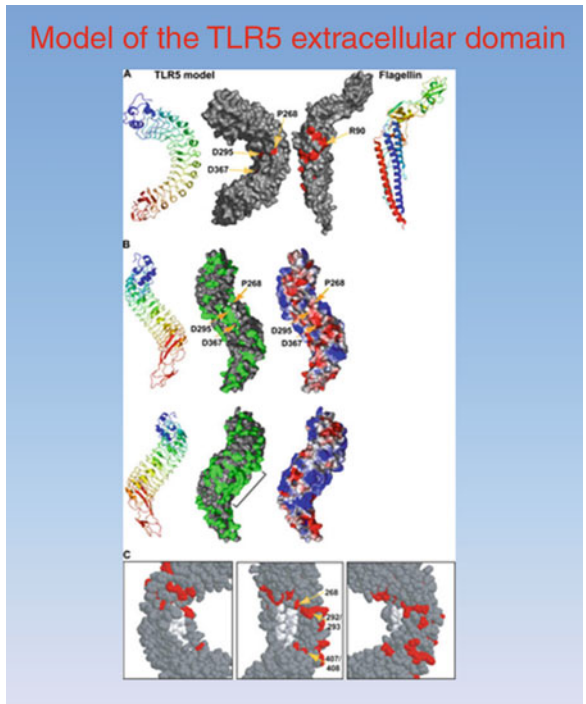
Background

In 1997, Rock et al. cloned and characterized human TLR5 and mapped this gene to chromosome 1. The corresponding TLR5 gene in mouse was reported 2 years later by Sebastiani et al. (Rock et al. 1998; Sebastiani et al. 2000). Murine TLR5 gene bears 81% homology to human TLR5 gene and around 40% homology to other TLR gene sequences (Sebastiani et al. 2000). In 2001, Hayashi et al. reported that bacterial flagellin is a ligand for TLR5 and requires ▶ Myd88 to produce inflammatory cytokines in response to flagellin stimulation (Hayashi et al. 2001). Further studies on TLR5 demonstrated that it is able to modulate adaptive immune response by inducing the expression of co-stimulatory molecules on antigen-presenting cells and secretion of immunomodulatory cytokines such as IL-12 (Iwasaki and Medzhitov 2004). Because of these stimulatory properties, TLR5 has been shown to function as an effective adjuvant (Mcsorley et al. 2002).

Structure of TLR5 and Flagellin

TLR5 is a type I transmembrane glycoprotein composed of 858 amino acids (aa) in humans and 859 aa in mice with a large extracellular domain, a transmembrane domain, and intracellular domain (Andersen-Nissen et al. 2007). The extracellular domain contains leucine-rich repeats (LRRs) at the N-terminal region and forms a horseshoe-shaped 3D solenoid structure (Werling et al. 2009). This region consists of a conserved sequence, LxxLxxLxxNxxL (where L is a leucine and x is any amino acid). The crystal structure of TLR5 has not yet been solved, but mathematical modeling by the Aderem laboratory (Fig. 1) has provided critical information about the structure of the extracellular domain (Andersen-Nissen et al. 2007). The binding site for flagellin was mapped to the highly conserved lateral concave region that forms the central core (174–401) of the solenoidal structure encoded by multiple LRRs within the extracellular domain of TLR5 (Andersen-Nissen et al. 2007). This concave region consists of β-sheets which provide stability to the solenoid and also allows a large surface area for flagellin binding. Three residues in the concave region of TLR5 molecule, P268, D295, and D367, take part in the direct interaction with flagellin molecules (Andersen-Nissen et al. 2007). Alterations in the amino acid (aa) composition of TLR5 within this region between different hosts result in differential ability of the receptor to recognize flagellin (Fig. 1) (Andersen-Nissen et al. 2007). It is not yet clear whether flagellin monomers bind to a single TLR5 receptor, which then dimerizes with another flagellin-bound TLR5 molecule like other cell surface receptors, or if flagellin binds to already dimerized TLR5 molecule leading to conformational change in the receptor to initiate the signaling program (Andersen-Nissen et al. 2007).

The N- and C-terminal regions of flagellin together form a hydrophobic core that brings the ends of the molecule together and allows binding to the extracellular domain of TLR5 (Smith et al. 2003). These amino acids are located in the highly conserved D1 domain of the flagellin protein and cluster on the convex surface that contacts adjacent flagellin monomers in the flagellar protofilament (Smith et al. 2003). Thus, mutation of individual residues within this TLR5 recognition site significantly reduced or completely abolished bacterial motility (Andersen-Nissen et al. 2007), suggesting that evolving functional flagellin that can evade TLR5 detection requires a complex series of mutations. The TLR5 recognition site on flagellin is therefore conserved among a wide variety of flagellated bacteria,



TLR5, Fig. 1 Model of the TLR5 extracellular domain. (**a**) Ribbon representations (*far left* and *far right*) and molecular surface representations (*middle left* and *middle right*) of the best model of the TLR5 ectodomain (*left*) and the structure of flagellin (PDB lucu; *right*). The ribbon is colored sequentially from the N-terminus (*blue*) to the C-terminus (*red*). Amino acids important for flagellin recognition are shown on the TLR5 model in red. Amino acids on flagellin previously determined to be important for TLR5 recognition are shown in red on the flagellin structure. (**b**) Ribbon representations (*left*) and molecular surface representations (*middle* and *right*) of the best model of the TLR5 ectodomain, oriented ~90° to the view in (**a**). Views 180° apart are shown in the top and bottom rows. The ribbon is colored sequentially from the N-terminus (*blue*) to the C-terminus. Molecular surface representations are colored by conservation (*center*: residues ≥90% similar among TLR5 sequences are *green*) or by electrostatic potential (*right*: positive, *blue*; negative, *red*). The conserved concavity and lateral patch regions are indicated with a dotted white oval and bracket, respectively. Positions of residues important for flagellin recognition are indicated with *arrows*. (**c**) Space-filling representation of the TLR5 model. Residues of the conserved concavity (*white*) and residues that differ between human and mouse TLR5 in the central 228-amino-acid region, as well as 407 and 408 (*red*), are highlighted. Amino acids surrounding the concavity that were mutated are indicated with *arrows*

although there are select bacterial species that possess unique flagellin molecules able to evade TLR5 recognition (Andersen-Nissen et al. 2007).

Distribution of TLR5 in Mammals

TLR5 has been reported to be expressed exclusively on the surface of the human epithelial cells present in the airway, spleen, lung, liver, intestine, kidney, and urogenital tract (Nishimura and Naito 2005; Ochiel et al. 2010). In the airway epithelium, Zhang et al. demonstrated the importance of TLR5 during *Pseudomonas aeruginosa* infection by showing that an aflagellate mutant of Pseudomonas was poorly controlled in host lungs due to a deficient inflammatory response (Zhang et al. 2005). A similar protective role for TLR5 has also been reported for pneumococcal lung infection (Munoz et al. 2010).

In the murine intestine, TLR5 expression has been reported to be confined to the basolateral surface within the ileum and colon and on apical surface of the follicle-associated epithelium (FAE) (Bogunovic et al. 2007; Gewirtz et al. 2001). TLR5 expression in the intestine is thought to be important for the detection of intestinal pathogens, but may also be important in maintaining intestinal homeostasis via recognition of intestinal flora. Indeed, an imbalance in the detection of intestinal microbiota via TLR5 has been reported to cause intestinal inflammation (Vijay-Kumar et al. 2008).

Although flagellin recognition by TLR5 can activate splenic dendritic cells (Mcsorley et al. 2002), the expression of TLR5 by conventional dendritic cells is somewhat controversial (Salazar-Gonzalez and McSorley 2005). While human dendritic cells can be activated by flagellin in vitro (Means et al. 2003), there are conflicting accounts of murine dendritic cell activation via TLR5 (Means et al. 2003; Salazar-Gonzalez et al. 2007; Didierlaurent et al. 2004). A report by Uematsu et al. has suggested that murine TLR5 expression may be limited to dendritic cells from the intestinal lamina propria (Uematsu and Akira 2009). However, TLR5-specific effects have been detected using purified murine splenic dendritic cells in vitro (Letran et al. 2011a), although it should be noted that this primarily involved an effect of TLR5 on antigen presentation to CD4 T cells, rather than innate immune activation.

TLR5 Signaling

Recognition of flagellin by TLR5 activates a signaling cascade that leads to the activation of nuclear factor kappa B (NF-kB) (Kawai and Akira 2010). As noted above, the binding site for flagellin is found on the LRR within the extracellular domain of TLR5. It is thought that this binding induces conformational change in the intracellular domain that allows homodimerization and initiation of downstream signaling (Hayashi et al. 2001; Mizel et al. 2003). TLR5 is also able to form a heterodimer with TLR4, and this heterodimerization induced nitric oxide production in COS-1 cells (Mizel et al. 2003). Activation of both homo- and heterodimers mobilizes NF-kB and induces tumor necrosis factor alpha production (Moors et al. 2001). Upon ligand binding, TLR5 uses myeloid differentiation factor 88 (▶ Myd88) and IL-1 receptor-associated kinase 4 (IRAK4) to activate a series of molecules that includes the key intermediate TNF receptor–associated factor 6 (TRAF6) (Kawai and Akira 2010). TLR5 signaling has mostly been thought to be ▶ Myd88-dependent (Kawai and Akira 2010), but recent evidence is emerging that it can also function in a Myd88-independent manner (Letran et al. 2011a, b; Kawai and Akira 2011).

Myd88-Dependent Pathway

After TLR5 dimerization, ▶ Myd88 is recruited to the C-terminus of the conserved cytoplasmic TIR domain. ▶ Myd88 has a bipartite structure composed of an amino-terminal death domain and a carboxyl-terminal TIR domain with a short intervening linker segment (McGettrick and O'Neill 2004). It is able to recruit IRAK 4 through the interaction of death domains in the N-terminus of ▶ Myd88 and IRAK4 to form a DD complex (Lin et al. 2010). This ▶ Myd88 and IRAK4 complex further recruits IRAK4 downstream partners IRAK2 or IRAK1 and forms a complex termed "the myddosome" (Lin et al. 2010).

The IRAK complex allows phosphorylation of Ser/Thr molecules within the C-terminus of IRAK molecules leading to activation (Lin et al. 2010). After activation, IRAK1 and IRAK2 can dissociate from the complex and interact with TRAF6, an E3 ubiquitin ligase which polyubiquitinates and activates the transforming growth factor β-activated kinase

TAK1/TAB1/TAB2/TAB3 complex (Kawai and Akira 2010). This activated TAK1 complex causes phosphorylation and activation of the IKK complex consisting of IKK-α IKK-β, and IKK-γ/NEMO (Kawai and Akira 2010). The IkB complex is strongly associated with NF-kB in the cytosol and upon phosphorylation undergoes degradation by the proteasome pathway, allowing free NF-kB to translocate to the nucleus and induce transcription of proinflammatory genes (Kawai and Akira 2010). TAK1 also simultaneously activates the MAP kinase pathway, by directly interacting with MEKK, p38, and JNK, which results in phosphorylation and activation of NF-kB and AP-1 transcription factors (Kawai and Akira 2011). NF-kB and AP-1 control inflammatory responses by inducing proinflammatory cytokines and increase expression of co-stimulatory molecules on antigen-presenting cells (Iwasaki and Medzhitov 2004). A schematic pathway of the factors involved in TLR5 signaling is presented in Fig. 2.

Myd88-Independent Functions of TLR5

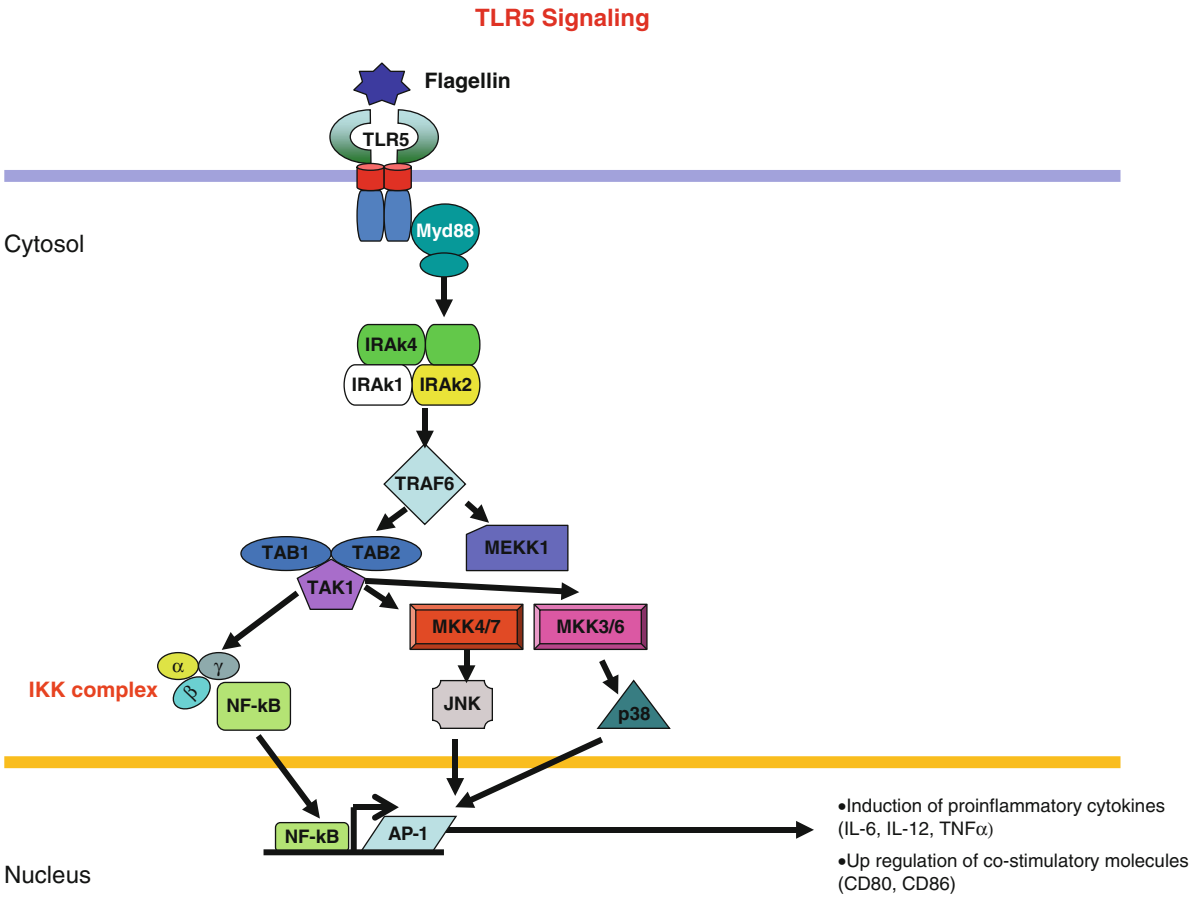
Other TLRs such as TLR3 and TLR4 can signal independently of ▶ Myd88 using the adaptor molecule TRIF, which can also efficiently activate NF-kB (Kawai and Akira 2011). Although TLR5 does not signal through TRIF (Choi et al. 2010), TLR5 signaling can be inhibited by TRIF via a proteolytic effect that requires the extracellular domain of TLR5 and the C-terminus region of TRIF (Choi et al. 2010). A direct interaction of TRIF with the extracellular domain of TLR5 is not thought to occur, but rather requires the activity of caspases (Choi et al. 2010). Activation of caspases on the proteolytic breakdown of TLR9 has also been described during maturation (Choi et al. 2010). Further insight into the mechanism of action of caspases on TLR5 induced by TRIF should increase understanding of the cross talk between TRIF and TLR5 and may also help illuminate that nature of Myd88-independent signaling.

Recent data also suggest that TLR5 can play a major role in promoting the antigen presentation of flagellin epitopes to CD4 T cells (Letran et al. 2011a, b; Kawai and Akira 2011). Intriguingly, this effect seems to be independent of Myd88 and TRIF (Letran et al. 2011a). A Myd88-independent function of TLR5 was demonstrated to promote humoral and adaptive immune responses to flagellin immunization and suggest that TLR5 might function as an endocytic receptor in similar fashion to C-type lectin receptors (Letran et al. 2011a). It is not yet clear what molecules are involved downstream to TLR5 to promote this biological effect. It seems possible that signaling molecules present in other endocytic receptor pathways could be involved, or that molecules promoting autophagy could direct endocytosed flagellin to the lysosome complex (Fig. 3). Further understanding of Myd88-independent functions of TLR5 is required and may be beneficial in understanding the targeting of flagellin during inflammatory bowel disease (Lodes et al. 2004).

Pathologies Associated with TLR5 Signaling

The intestine harbors a large and diverse microbiological community, and the host immune system has developed mechanisms to prevent inappropriate responses to these organisms (Santaolalla et al. 2011). Given that the intestine harbors flagellated bacteria, TLR5-expressing intestinal epithelial cells, and dendritic cells, the role of TLR5 signaling in intestinal immunity is likely to be of some importance. As noted above, there is evidence that TLR5 is tightly associated with the basolateral surface of epithelial cells, suggesting that recognition of flagellin might only occur after penetration of the epithelial layer by a pathogen (Gewirtz et al. 2001). However, this would also mean that any perturbation in the epithelial layer could give rise to a massive inflammatory response against commensal organisms (Vijay-Kumar et al. 2008). It is possible that this process plays a role in the initiation or progression of inflammatory bowel disease.

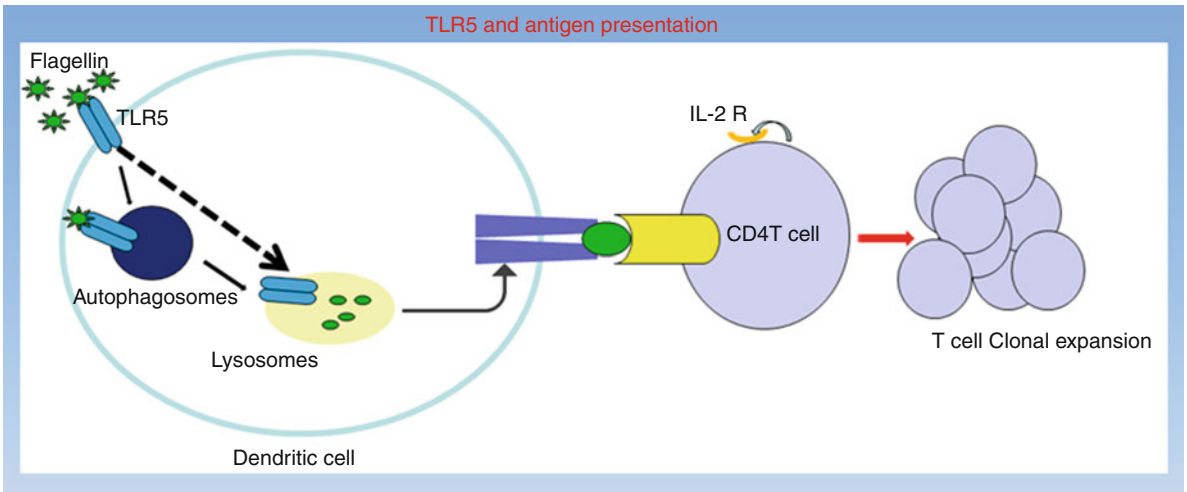
In contrast, several studies have described an important role for TLRs in promoting intestinal homeostasis and wound healing (Rakoff-Nahoum et al. 2004). Indeed, TLR signaling has been shown to promote epithelial cell proliferation, IgA production, maintenance of tight junctions, and antimicrobial peptide expression, thus maintaining a healthy epithelial barrier (Santaolalla et al. 2011). Indeed, studies by the Gewirtz laboratory point to an important role for TLR5 signaling in maintaining intestinal homeostasis (Vijay-Kumar et al. 2008). TLR5-deficient mice displayed no resistance to the development of intestinal inflammation, and conversely, a proportion of these



TLR5, Fig. 2 TLR5 signaling pathway. Flagellin recognition by the extracellular domain of TLR5 leads to the recruitment of adaptor molecule Myd88 to the TIR domain to initiate the signaling cascade. Myd88 forms a complex with IRAK4 and IRAK1/2 called as "myddosome" that allows the phosphorylation of the IRAK molecules. IRAK1/2 upon phosphorylation interacts with E3 ubiquitin ligase and TRAF6 which then polyubiquitinates TAK1 and activates MEK kinases to activate downstream molecules MAPK, p38, and JNK. TAK1 subsequently phosphorylates IKK complex, resulting in the release of NF-kB. TRAF6 signaling leads to the activation of NF-kB and AP-1 transcription factor which then induces the transcription of proinflammatory genes and upregulates co-stimulatory molecules

mice develop spontaneous colitis manifested by rectal prolapse, splenomegaly, anemia, and enlarged mesenteric and sublingual lymph nodes (Vijay-Kumar et al. 2010). However, this phenotype is not consistently observed, and the same line housed in other animal facilities did not develop intestinal inflammation (Letran et al. 2011b). It therefore seems likely that specific bacterial flora underlie the reported susceptibility of TLR5-deficient mice to the development of colitis.

There are natural polymorphisms in human TLR5 that allow analysis of this receptor in human disease (Hawn et al. 2003). Four single-nucleotide polymorphisms (SNPs) have been identified (Hawn et al. 2003). The TLR5-stop SNP (cytosine$_{1174}$ – thymidine transition converting Arg$_{392}$ to a stop codon) causes loss of the signaling TIR domain, thus abolishing TLR5 activity (Hawn et al. 2003). Approximately 10% of the world's population across a variety of ethnicities carries the TLR5-stop as heterozygotes and have a 75% reduction in TLR5 function (Hawn et al. 2005). Although TLR5-stop homozygotes have not been reported to be associated with health problems, heterozygous carriage of TLR5-stop increases the likelihood of developing clinical disease upon exposure to *Legionella* (Hawn et al. 2003), but not *Salmonella typhi* (Dunstan et al. 2005), perhaps suggesting that TLR5 is more important in protection



TLR5, Fig. 3 TLR5-mediated antigen presentation. Recognition of flagellin by TLR5 on dendritic cell promotes its uptake and presentation independent of ▶ Myd88

against pathogens that colonize mucosal surfaces than against those that breech mucosal surfaces to cause systemic disease. The TLR5-stop polymorphism, but not other TLR5 alleles, is associated with protection from developing SLE, and the protection was most pronounced in individuals who are seronegative for anti-dsDNA autoantibodies (Hawn et al. 2005). Further analysis of this cohort of patients should allow greater understanding of the role of TLR5 in humans.

Sepsis is a systemic inflammatory disorder caused by excessive inflammation induced by the activation of innate immune receptors. It is one of the leading causes of mortality in surgical intensive care units. Hemodynamic studies have shown that septic shock induced by TLR5 signaling results in hypotension-associated cardiac failure and multiple organ dysfunctions (Liaudet et al. 2002). Thus, targeting flagellin/TLR5 axis could help in preventing the debilitating effects of septic shock.

Conclusion

TLR5 is an important receptor that can direct innate and adaptive immune responses to flagellated bacterial pathogens. The role of TLR5 in the development of inflammatory disorders of the intestine requires further investigation, but available data suggest that this receptor may be important for maintaining gut homeostasis. Although the downstream signaling pathways through ▶ Myd88 are well described, the role of TLR5 in antigen presentation is Myd88-independent and requires greater analysis to uncover whether this represents a novel signaling pathway.

TMEM85 (Transmembrane Protein 85)

Cell proliferation-inducing gene 17; Proliferation-inducing gene 17

Historical Background

Prior to 2008, there were no publications on the TMEM85 gene or protein. The GenBank and Entrez Gene databases described TMEM85 as an evolutionary conserved transmembrane domain containing protein (DUF1077 superfamily motif) found in all eukaryotes examined (TMEM85-gene). In the yeast *Saccharomyces cerevisiae*, the TMEM85 orthologue is called *YGL231c*. In 2003, it was reported that yeast cells lacking *YGL231c* showed an increased sensitivity to the toxic effects of ectopically expressed Parkinson's disease associated gene α-synuclein (Willingham et al. 2003). Finally, the analysis of a GFP tagged genomic copy of *YGL231c* suggests that the protein is a resident of the endoplasmic reticulum (ER) (YGL231c-gene).

TMEM85, an Anti-apoptotic Gene

By screening a human heart cDNA expression library in yeast cell undergoing apoptosis due to the ectopic expression of a cDNA encoding the pro-apoptotic Bax protein, Ring et al. (2008) identified human TMEM85 as a Bax suppressor. Bax is the pro-apoptotic member of the ▶ Bcl-2 family of proteins. Such yeast-based screens have been useful in identifying a variety of different anti-apoptotic sequences (Greenwood and Ludovico 2010). For example, the ceramide utilizing sphingomyelin synthase was originally identified in such a screen.

Ectopic expression of TMEM85 also protected yeast from the apoptotic inducing effects of Reactive Oxygen Species (ROS). This suggests that TMEM85 is not simply a Bax suppressor but an anti-apoptotic gene. Overexpression of the yeast TMEM85 orthologue also protected yeast cells from apoptotic inducing stress (Ring et al. 2008).

TMEM85 Structure and Function

Human TMEM85 is a complex alternatively spliced gene that is reported to produce four different transcripts and proteins (Ring et al. 2008). The predicted proteins range in size from 183, 149, 97, and 66 residues. The largest protein is predicted to contain two transmembrane domains and it likely corresponds to the yeast 190 residue *YGL231c* ortholog. The 149 residue TMEM85 variant (v2) is identical to the 183 residue protein at its N-terminal but it contains a unique C-terminal region and a single transmembrane domain. It represents the sequence identified as having anti-apoptotic properties. The other variant proteins are predicted to be soluble proteins.

There are other discernable functional sequences present within the TMEM85 proteins. Thus the structure provides no insight to what its function could be in the ER or how it may function as an anti-apoptotic protein (UniProt page). Although many anti-apoptotic proteins, such as heat shock proteins and Bcl-2, belong to large family of proteins many others are unique or small groups of proteins, such as heme oxygenase 1, whose anti-apoptotic effects cannot be readily deciphered from their sequence. This lack of functional information is somewhat surprising considering that TMEM85 is highly conserved and is present in species from yeast to man ranging all way from worms to plants. There are a large number of web sites that have compiled the TMEM85 sequences from different species (http://omabrowser.org/cgi-bin/gateway.pl?f=DisplayEntry&p1=0061323).

One interesting study, using a two hybrid screen, identified TMEM85 as protein that interacts with protein prestin (Zheng et al. 2009). Prestin is a component of the outer hair cells (OHC) that are housed in the organ of Corti and play a mechanosensing role important for hearing. Knockout mouse models of prestin clearly show that they play an important role in the process of hearing. The fact that TMEM85 is highly conserved and is present in unicellular organisms like yeast suggest that it must play a fundamental role in the cell, while its potential interaction with more specialized proteins like preston suggests that TMEM85 may also have multiple functions in protozoans.

TMEM85 Expression

Very little is currently published regarding the expression or regulation of the mammalian TMEM85 gene. RT-PCR analysis of the RNA isolated from a variety of tissues suggests that all four transcripts are expressed in the heart while variant 1 and 4 are commonly observed in most tissues (Ring et al. 2008). A few other reports that have studied global gene expression patterns have identified TMEM85 expression to be increased in the Caudate Nucleus of Parkinson's patients as well as being more highly expressed in the brain white matter compared to the spinal cord (Bossers et al. 2009; Yan et al. 2009).

Function of the TMEM85 Orthologue in Yeast

Nothing else is known about mammalian TMEM85, so further clues as to the potential function of TMEM85 may be obtained from a recent study in yeast that carried out a global analysis to identify proteins that are required for protein folding in the ER (Jonikas et al. 2009). Of interest, the yeast orthologue of TMEM85, *YGL231c*, was identified as being part of tight multiprotein transmembrane complex of six poorly characterized proteins. Although the function of the complex was not determined, all six members were renamed as EMC1 to 6 proteins (*YGL231c* is *EMC4p*) to reflect that they are part of an ER membrane protein complex that is likely to have a functional significance. Cells lacking the complex show increased accumulation of misfolded ER proteins. Given that misfolded proteins leads to ER stress and to the induction of apoptosis, the proposed function of the EMC complex is in line with the reported anti-apoptotic function of TMEM85.

Summary

Human TMEM85 represents a complex alternatively spliced gene that encodes highly conserved transmembrane domain proteins of largely unknown function. TMEM85 was identified as a protein with anti-apoptotic properties in a screen of yeast cells ectopically expressing a pro-apoptotic mammalian Bax sequence. Analysis of the yeast ortholog of TMEM85, *YGL231c*, suggests that it is a protein that resides in the endoplasmic reticulum (ER). Further analysis suggests that *YGL231c* forms a tight complex with five other also largely functionally uncharacterized proteins. *YGL231c* was renamed *ECM4* to reflect the fact that it is found in this ER membrane protein complex. The proposed role of the ECM complex in regulating folding of ER proteins is consistent with the reported anti-apoptotic function of human TMEM85. A significant amount of work is still required in order to understand the role of TMEM85.

Historical Background

The innate immune system of mammals is equipped with various kinds of cells, such as macrophages and dendritic cells (DCs), which provides the first line of defense to the host in recognizing various kinds of pathogens. These cells have developed different classes of protein based receptors for recognizing numerous kinds of pathogen associated molecular patterns (PAMPs) (Miggin and O'Neill 2006). These different classes of pathogen recognition receptors (PRRs) includes, *Membrane bound PRRs* such as Toll-like receptors (TLRs), Receptor kinases, Mannose receptors and *Cytoplasmic PRRs* such as Nucleotide oligomerization domain (NOD) receptors, the Retinoic acid inducible gene I (RIG-I)-like receptor (RLR) family, and the recently described AIM2 and DAI cytosolic DNA receptors. All these receptor proteins play a crucial role in "danger" recognition and induction of the innate immune responses against a variety of bacterial and viral infections at the cytoplasmic, endosomal, intercellular, and extracellular level (Kumar et al. 2009; Siednienko et al. 2011)

To date, ten human TLRs have been identified and equivalent forms of many of these have been found in other mammalian species (Kumar et al. 2009). Each member of the TLR family recognizes different kinds of PAMPs. For example, TLR1 in combination with TLR2 or TLR6 recognizes triacyl lipopeptides and diacyl lipopeptides, respectively. TLR4 recognizes lipopolysaccharide (LPS) from gram-negative bacteria and TLR5 recognizes flagellin from bacterial flagellum. In contrast to the above-mentioned plasma-membrane-localized TLRs, the so-called antiviral TLRs, TLR3, TLR7/8, and TLR9 are located on endocytic vesicles, and recognize double-stranded (ds)RNA and single-stranded (ss)RNA, respectively, whereas, murine TLR11 recognizes uropathogenic *Escherichia coli* (Kumar et al. 2009).

After recognition of PAMPs, activation of TLRs is initiated by the formation of multi-protein complexes containing the TLR and the recruitment of proximal cytoplasmic Toll/IL-1 receptor (TIR) domain-containing adaptor proteins. To date, four activating TLR adaptor proteins have been identified, namely, Myeloid differentiation factor 88 (▶ MyD88), ▶ MyD88 adaptor-like (Mal) (also known as TIR domain containing adaptor protein (TIRAP)), TIR domain-containing adaptor inducing interferon (IFN)-beta (TRIF) (also known as TICAM-1) and TRIF-related adaptor molecule (TRAM). In addition, an inhibitory TLR adaptor protein called sterile alpha and TIR motif-containing protein (SARM) has also been identified (Vercammen et al. 2008). Upon recruitment of the activationary adaptor proteins to the TLRs via TIR domain interactions, a series of TLR signaling cascades are elicited which culminates in the production of proinflammatory cytokines such as tumor necrosis factor α (TNF-α), interleukin (IL)-6, IL-1β, and IL-12. In addition, activation of TLR3, -7, -8, and -9 induces the production of antiviral type I interferons (IFN-β and IFN-α). Moreover, TLRs induce DC maturation, which is essential for the activation of pathogen-specific adaptive immune responses (Miggin and O'Neill 2006; Kumar et al. 2009).

In spite of various similarities between all TLRs in terms of signal transduction pathways and the production of proinflammatory cytokines, there is rigid specificity with respect to their adaptor usage (Miggin and O'Neill 2006; Kumar et al. 2009). ▶ MyD88 is the common downstream adaptor that is recruited by all TLRs except TLR3 and leads to activation of nuclear factor (NF)-κB. Mal is required for signaling by TLR4 and TLR2 (Miggin and O'Neill 2006; Kenny et al. 2009). TRIF mediates TLR3 and TLR4 signaling and induces the activation of transcription factors IRF3 and IRF7 which leads to the expression of Type I IFNs. Finally TRAM regulates TLR4 signaling exclusively acting as a bridging adaptor to recruit TRIF to the TLR4 complex (Kumar et al. 2009).

In recent years, researchers have gained a more in depth understanding of the signaling pathways that are modulated upon TLR engagement. This essay focuses on *Toll-like receptor 3*, a key molecule that recognizes viral double-stranded (ds) RNA originating from dsRNA viruses such as reovirus. TLR3 also recognizes dsRNA produced during the replication of single-stranded (ss) RNA viruses, such as West Nile virus (WNV), respiratory syncytial virus (RSV), and encephalomyocarditis virus (EMCV). In addition, TLR3 also recognizes a synthetic analogue of dsRNA known as polyriboinosinic:polyribocytidylic acid (poly(I:C)) (Kumar et al. 2009). Herein, *Toll-like receptor 3* will be described in terms of its structure, expression, subcellular localization, and its ligands. In addition, the signaling pathways that are activated by TLR3 and its curtailment by various molecules thus limiting proinflammatory cytokines and Type I IFN

production will also be described. Also, major perspective applications of *Toll-like receptor 3* in the context of antiviral and cancer immunotherapies will also be described.

Properties of TLR3

Discovery of the first human Toll-like receptor by Nomura and colleagues in 1994 (Nomura et al. 1994) has paved the way for a breakthrough in Immunobiology. Since then, a family of ten human TLRs with detailed crystal structures has been identified and they have been proved to be pivotal elements in the human innate immune system.

Structure of TLR3

Human TLR3 consists of an extracellular domain containing 23 leucine-rich repeats (LRRs), N- and C-terminal flanking regions, a transmembrane domain, and an intracellular TIR domain (Bell et al. 2006). Analysis of the TLR3-ectodomain (ECD) revealed that the LRRs form a large horseshoe shaped structure which has an inner diameter of approximately 42 Å, an outer diameter of 90 Å, and a thickness of 35 Å. The TLR3-ECD is highly glycosylated with 15 predicted N-glycosylation sites, while the lateral surface is completely carbohydrate free and offers a large surface area for interaction with other molecules. It has been demonstrated that amino acid residues H539 and N541 located on the glycosylation-free lateral surface of the LRR domain of TLR3 are critical for ligand binding (Bell et al. 2006). TLR3-ECD bind as dimeric units to dsRNA oligonucleotides of at least 45 bp in length, the minimal length required for the transduction of signal through the receptor (Botos et al. 2009). A LRR-deletion study on TLR3 has shown that the C-terminal LRRs control receptor signaling and dimerization; the intermolecular contacts between the C-terminal domains of two TLR3-ECD stabilize the dimer and position the C-terminal residues closely, which is considered to be essential for signal transduction across plasma membrane in intact TLR3 molecules (Botos et al. 2009).

Expression and Subcellular Localization of TLR3

The expression and subcellular localization of TLR3 is regulated in a cell-type specific manner and is modulated by the activation status of the cell. TLR3 expression has been detected in immune cells including macrophages, DCs, γδ T cells, NK cells, T cells, and mast cells (Siednienko and Miggin 2009; Gauzzi et al. 2010). TLR3 expression has also been detected in nonimmune cells, including fibroblasts, epithelial cells, keratinocytes, glial cells, and neuronal cells (Gauzzi et al. 2010; Siednienko et al. 2010).

Unlike the other viral RNA sensor proteins whose localization is exclusively cytoplasmic, TLR3 has been found localized intracellularly within endosomal vesicles and also localized at the cell surfaces (Siednienko et al. 2010). For example, in DCs, TLR3 is predominantly detected in the intracellular endocytic vesicles (Siednienko et al. 2010). In contrast, while fibroblasts and epithelial cells express intracellular TLR3, its expression predominates on the cell surface. Likewise, peritoneal and bone marrow-derived murine mast cells express TLR3 both in the cytoplasm and on the cell surface. In keratinocytes, high levels of intra-cytoplasmic TLR3 expression and low levels of surface TLR3 are detected (Gauzzi et al. 2010). Interestingly, Arg740 and Val741 are involved in the intracellular localization and expression of TLR3 in humans, while in murine TLR3, no crucial structural motif residues have been identified to date (Funami et al. 2004). The expression of TLR3 in both DCs and macrophages is upregulated by viral infection and exogenous addition of poly(I:C) or type I IFN (Gauzzi et al. 2010; Siednienko et al. 2010).

Ligands and its Delivery to TLR3

The primary ligand for TLR3 is dsRNA. As previously stated, TLR3 senses dsRNA viruses such as reovirus and dsRNA produced during the replication of ssRNA viruses, such as WNV, RSV, and EMCV. In addition to dsRNA from viral origin, endogenous dsRNA released from dying cells also activates TLR3 (Gauzzi et al. 2010). Interestingly, poly(I:C) in a cell-associated form is reported to be more efficient in triggering TLR3 than soluble dsRNA, suggesting that dsRNA derived from dying cells is a more potent and physiologically relevant TLR3 ligand than dsRNA from live cells (Gauzzi et al. 2010). In the laboratory, the stable synthetic dsRNA analogue, poly(I:C) is extensively used as an artificial activator of TLR3. It must be noted that beyond TLR3, dsRNA is also recognized by several other cytosolic sensors, such as protein kinase R, 20–50-oligoadenylate synthetases, and the more recently identified RLR RNA helicases, RIG-I and melanoma

differentiation-associated gene5 (Mda5) (Gauzzi et al. 2010). In certain cell types, TLR3 is predominantly expressed intracellularly, thus the TLR3 ligand is transfected into the cells with cationic lipososmes such as lipofectin and DOTAP and these ligand-liposomes complexes are believed to be delivered to the endosome to activate TLR3 (Gauzzi et al. 2010). It has been found that TLR3 provides several sites to accommodate ligand binding depending on the glycosylation status of the extracellular domain and the structural characteristics of the ligand (example: modification and ligand length). Notably, TLR3 signaling has been shown to be more potently induced by longer duplex length of poly(I:C) rather than shorter ones (de Bouteiller et al. 2005).

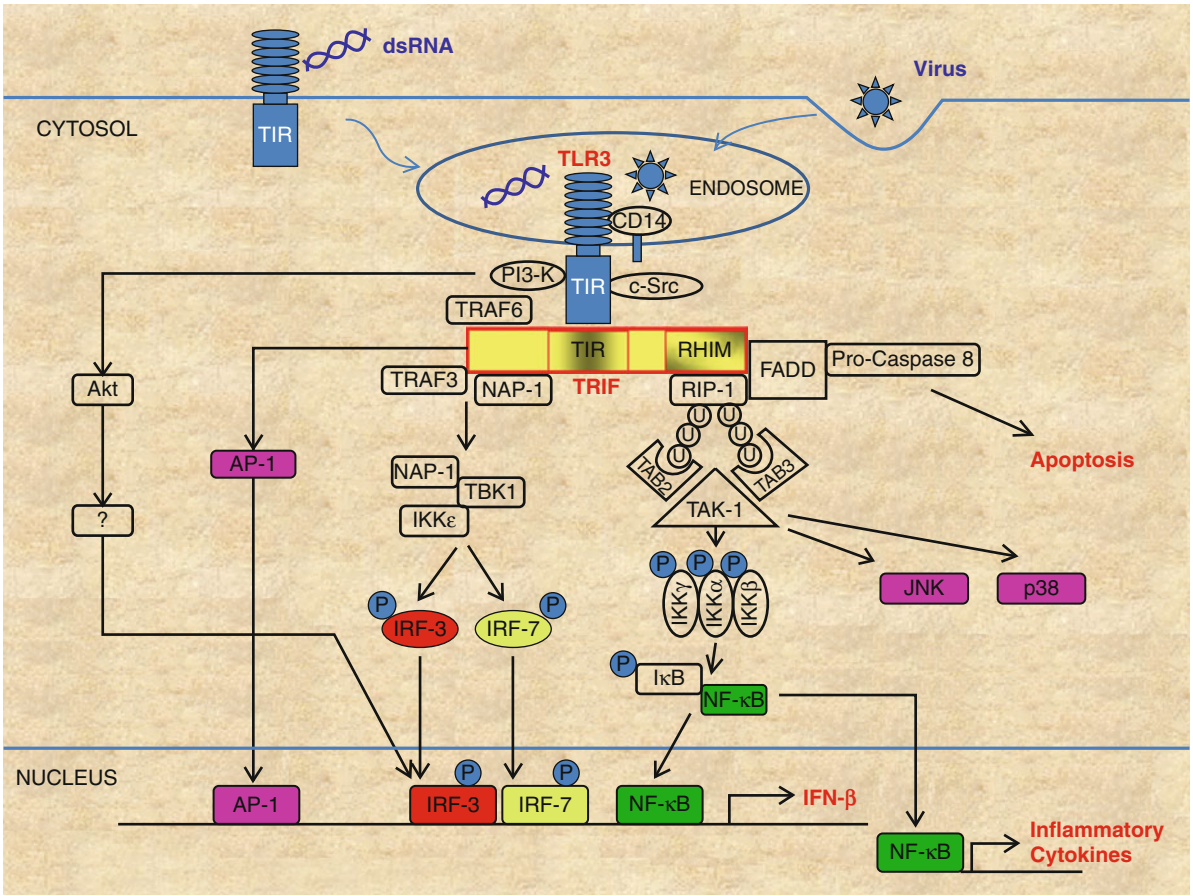
Regarding the delivery mechanism of dsRNA to the TLR3 containing endocytic vesicle, it has been demonstrated that CD14 directly binds to extracellular poly(I:C) and enhances dsRNA-mediated TLR3 activation (Gauzzi et al. 2010) by direct internalization and co-localization of CD14 with TLR3 which then facilitates the transfer of the dsRNA to the intracellular TLR3 (Gauzzi et al. 2010). Supporting this concept is the fact that intracellular co-localization of TLR3 and CD14 in multiple compartments, including the endoplasmic reticulum and the Golgi apparatus has been demonstrated (Gauzzi et al. 2010). Interestingly, human DCs, which do not express CD14 and do not express TLR3 on their surface, produce type I IFN and IL-12p70 in response to exogenously added dsRNA and antibodies against TLR3 do not inhibit dsRNA-induced IFN-β production by DCs (Gauzzi et al. 2010). This suggests that the extracellular dsRNA must be internalized via a putative uptake receptor (e.g., clathrin-mediated endocytosis) or by the uptake of the apoptotic bodies derived from virally infected cells containing viral dsRNA in order to activate intracellularly localized TLR3. Thus, the dsRNA may originate from many sources including dying cells, apoptotic bodies, and viruses and the mechanisms that facilitate association of the dsRNA with TLR3 largely depends on the cell type and concomitant subcellular distribution of TLR3.

Signaling Pathway

TRIF-Mediated TLR3 Signaling

The transduction of TLR3 signaling is mediated by the TIR domain-containing adaptor protein, TRIF, which binds to the intracellular TIR domain of TLR3 (Fig. 1) leading to the activation of various transcription factors such as interferon regulatory factor (IRF) 3, ▶ NF-κB, and activator protein (AP)-1, and concomitant induction of inflammatory cytokines, type I IFN, DC maturation, and activation of the adaptive immune system. The mechanisms by which TRIF activates ▶ NF-κB and IRF3 have been analyzed extensively and research have shown that mice deficient in TRIF display impaired responses to dsRNA (Kumar et al. 2009; Siednienko et al. 2010), indicating the indispensible role played by TRIF in TLR3 signaling.

Regarding TRIF, the proline-rich N-terminal domain of TRIF mediates IRF3 activation by facilitating the phosphorylation of IRF3 at critical residues via a number of auxiliary molecules. NAK-associated protein 1 (NAP-1) forms part of the active kinase complex for IRF3 and facilitates the association of TRIF with TANK-binding kinase 1 (TBK1; also called NAK or T2K) and IκB kinase related kinase ε (IKKε; also called IKKι) (Gauzzi et al. 2010). TBK1 and IKKε also interact with TANK (TRAF family member-associated ▶ NF-κB activator) which also facilitates the activation of IRF3 (Kumar et al. 2009). Furthermore, TNF receptor-associated factor 3 (TRAF3) plays a crucial role in TLR3 signaling as various independent studies show that TRAF3 forms a complex with NAP-1 and TRIF and TRAF3-deficient mice exhibit impaired IFN-β in response to poly(I:C) (Fig. 1) (Oganesyan et al. 2006). It must be noted that TRAF3 and NAP-1 are also critical adaptor proteins in RIG-I/Mda5-mediated IRF3 activation (Oganesyan et al. 2006). TRAF6 also interacts with TRIF, though its role in IFN-β production is largely non-critical (Yamamoto and Takeda 2010). The RNA helicase, DEAD box protein 3 (DDX3) has also been shown to play a role in TLR3 signaling (Schröder et al. 2008). Upon TKB1/IKKε-mediated phosphorylation and homo/heterodimerization of IRF3/7, the complex subsequently translocates into the nucleus and binds to the IFN-β enhanceosome (Schröder et al. 2010) and IFN-stimulated response elements (ISREs) to induce the transcription of responsive genes including the Type I IFN-β and CCL5 genes (Siednienko et al. 2011) (Fig. 1). Thus, TRAF3, NAP-1, TBK1/IKKε, and the N-terminal region of TRIF play an important role in TLR3-mediated IRF3/7 activation (Oganesyan et al. 2006).



Toll-Like Receptor 3, Fig. 1 TLR3 signaling pathway

While the N-terminal region of TRIF mediates IRF3/7 activation, the leucine-rich C-terminal region of TRIF is involved in ▶ NF-κB activation via receptor-interacting protein 1 (RIP1) (Fig. 1). RIP1 interacts with TRIF through the RIP homolytic interaction motif (RHIM) domain of TRIF, followed by polyubiquitination (U) of RIP1, which recruits the ubiquitin receptor protein transforming growth factor β-activating kinase (TAK) binding proteins 2 and 3 (TAB2 & TAB3) and TAK1 to form a TAK1 complex (Fig. 1) (Gauzzi et al. 2010; Yamamoto and Takeda 2010). TAK1 then phosphorylates IKKα and IKKβ, which consequently phosphorylates the ▶ NF-κB inhibitor IκB, concomitantly leading to its degradation and nuclear translocation of ▶ NF-κB and induced expression of IFN-β (Fig. 1) (Gauzzi et al. 2010). TAK1 also activates two other classes of kinase, JNK and p38 and these activate the transcription factor, AP-1 (Jin et al. 2010). In addition, another protein, TRAF6 also mediates ▶ NF-κB activation, though this involves binding of TRAF6 to the N-terminal region of TRIF (Fig. 1). Studies have suggested that the participation of TRAF6 in TRIF-mediated ▶ NF-κB induction is cell-type specific as TRAF6 is essential for ▶ NF-κB activation in mouse embryonic fibroblasts, whereas poly(I:C) induced ▶ NF-κB activation is not impaired in TRAF6 deficient macrophages (Gauzzi et al. 2010; Sasai et al. 2010). The TAK1 complex also activates the mitogen-activated protein kinases (MAPKs) including *c-jun* N-terminal kinase, p38, and extracellular signal related kinase (ERK) to control mRNA expression and the stability of mRNA for inflammatory genes by mediating phosphorylation of the AP-1 transcription family proteins (Yamamoto and Takeda 2010).

Of all the TLR adaptor proteins, TRIF is the only adaptor that is able to engage mammalian cell death signaling pathways whereby TRIF interacts with

Fas-associated cell death domain (FADD) through RIP1 and activates procaspase-8 to initiate cell apoptosis (Vercammen et al. 2008; Jin et al. 2010); this is an important host defense mechanism for limiting the spread of viral infection. Moreover, TRIF also plays a role in TLR3 induced proliferative responses in B cells (Vercammen et al. 2008).

PI3K and c-src in TLR3 Signaling

While the TIR domain of TLR3 serves to recruit the adaptor molecule, TRIF, additional molecules are also capable of interacting with TLR3 and modulating its signaling. For example, studies have shown that phosphatidylinositol 3-kinase (PI3K) is capable of interacting with phosphorylated tyrosine residues Tyr^{759} and Tyr^{858} located within the TIR domain of TLR3. This interaction serves to activate the TLR3 pathway toward IRF3 and concomitant induction of IFN-stimulated genes while impairing ▶ NF-κB-dependent proinflammatory signaling (Fig. 1) (Vercammen et al. 2008). Another tyrosine kinase molecule known as c-Src has also been shown to interact with endosomally localized TLR3 and has been shown to play a crucial role in dsRNA-mediated TLR3 signaling (Vercammen et al. 2008).

In summary, TLR3 is distributed on the cell surface and the endosome in a cell-type-dependent manner. The adaptor protein TRIF is localized in the cytoplasm. Upon stimulation of TLR3 with synthetic dsRNA or upon recognition of an invading virus, TRIF is recruited to the endosomal/cell surface TLR3 via TIR domain interactions and thereafter moves away from the receptor to speckle-like structures that also include downstream signaling molecules. The interaction of TRIF with RIP1 results in polyubiquitination (U) of RIP1 and its binding to the ubiquitin receptors TAB2 and TAB3 which activates TAK1. Activated TAK1 induces phosphorylation of IKKα and IKKβ leading to phosphorylation and degradation of IκB and release and translocation of NF-κB to the nucleus. TAK1 also activates two other classes of kinase, JNK and p38 and these activate the transcription factor, AP-1. Also, TRIF activates TBK1 and IKKε through NAP1 and this results in phosphorylation and nuclear translocation of IRF3 and IRF7 resulting in IFN-β production. TRAF3 also binds with the TBK1/IKKε complex inducing IRF3 activation. PI3K is also recruited to the TIR domain of TLR3 and activates kinase Akt for full phosphorylation and activation of IRF3 in the nucleus. Tyrosine kinase c-Src also plays a role in TLR3 signaling. TRIF interacts with FADD through RIP1 and activates procaspase-8 to initiate cell apoptosis. Many of the mechanisms by which TLR3/TRIF is activated and transmits signals remain largely unknown. Phosphorylation and activation of the various transcription factors such as IRF3, IRF7, NF-κB, and AP-1 molecules leads to IFN-β and proinflammatory cytokine production and consequent DC maturation and complete activation of the innate and adaptive immune system.

Negative Regulation of TLR3 Signaling

Excessive or sustained activation of TLR3 signaling, leading to elevated levels of proinflammatory cytokines and IFN-β is potentially harmful or even fatal for the host cell. Clinically, this may present as systemic inflammatory response syndromes such as inflammation-associated myopathies, WNV-driven CNS inflammation and viral or autoimmune liver diseases. Given this, the body has evolved several mechanisms for modulating and curtailing TLR3-mediated cellular responses. For example, protein inhibitor of activated signal transducers and activators of transcription (PIASy), TRAF1, and TRAF4 have been shown to inhibit TLR3 ligand induced activation of IRF3 and ▶ NF-κB (Vercammen et al. 2008). Interestingly, PI3K has been shown to inhibit TLR3-mediated ▶ NF-κB activation while activating IRF3. Similarly, another kinase known as RIP3 has been shown to inhibit TLR3 induced ▶ NF-κB activation by competing with RIP1 for TRIF binding (Vercammen et al. 2008). In contrast, suppressor of IKKε (SIKE) has been shown to inhibit TLR3-mediated IRF3 activation, without affecting ▶ NF-κB activation (Vercammen et al. 2008).

The TLR adaptors Mal and ▶ MyD88 were not thought to be involved in TLR3 signaling until a recent study demonstrated that ▶ MyD88 negatively regulates TLR3/TRIF-induced corneal inflammation through a mechanism involving JNK phosphorylation, but not p38, IRF3, or ▶ NF-κB (Johnson et al. 2008; Siednienko et al. 2011). ▶ MyD88 has also been shown to inhibit TLR3-dependent phosphorylation of IRF3 and thus curtail TLR3-mediated IFN-β and RANTES production (Siednienko et al. 2011). ▶ MyD88 also inhibits TLR3-dependent IL-6 induction, but not IκB degradation nor p38 activation in murine macrophages (Kenny et al. 2009). The TLR adaptor Mal has also been shown to inhibit TLR3-dependent IFN-β production through

a mechanism distinct from ▶ MyD88 whereby Mal inhibits TLR3 ligand-mediated IRF7 activation (Siednienko et al. 2010). Mal has also been shown to inhibit TLR3-dependent IL-6 induction (Kenny et al. 2009). In addition, the fifth TLR adaptor protein, SARM which contains a sterile α-(SAM) and a HEAT/armadillo (ARM) motif has been shown to inhibit TLR3 signaling. While SARM does not induce IRF3 or ▶ NF-κB activation itself, it inhibits TRIF-mediated TLR3 signaling (Carty et al. 2006) with both the TIR and SAM domains proving vital for SARM functionality.

Thus, it is clear that TLR3 inhibitory molecules have the ability to curtail global TLR3 signaling and/or to inhibit a specific pathway on the TLR3 signaling cascade in a cell-type specific manner. These molecules may serve to alter the balance between ▶ NF-κB and IRF3/7 following TLR3 activation, thus providing an immune response that it tailored to a specific cell-type/ligand/biological milieu. Moreover, the vast array of molecules and mechanisms that have evolved to curtail TLR3 signaling highlights the importance of TLR3 immunomodulation.

Therapeutic Manipulation of TLR3

Once microbes breach the physical barriers of the body such as skin or the intestinal tract mucosa, they are recognized by TLRs which activates the innate immune cell response.

Antiviral Function

It is well established that dsRNA-induced activation of TLR3 instigates a series of signaling cascade events which leads to the induction of *IFN-β* gene transcription and the production of antiviral IFN-β, IL-12, and various inflammatory cytokines (Vercammen et al. 2008; Gauzzi et al. 2010). Thus, TLR3 plays a key role in antiviral immune responses.

TLR3 is involved in the sensing of dsRNA derived from reovirus (Vercammen et al. 2008). TLR3 also recognizes dsRNA produced during the replication of many viruses including single-stranded (ss)RNA viruses, such as WNV, RSV and EMCV (Vercammen et al. 2008). It must be noted that TLR3 is dispensable for the detection of certain viruses (Vercammen et al. 2008). Regarding the therapeutic value of TLR3 manipulation, it has been shown that activation of TLR3 using poly(I:C) inhibits human immunodeficiency virus (HIV) infection by increasing the expression of Type I IFN antiviral factors thus restricting HIV expression and replication (Zhou et al. 2010). Also, poly(I:C) has proven beneficial as a mucosal adjuvant for an influenza virus vaccine in a murine infection model (Vercammen et al. 2008). Interestingly, another TLR3 agonist, Poly(I:C_{12}U), has been shown to have antiviral activity against hepatitis B virus, several flaviviruses, coxsackie B_3 virus, and Punta Toro virus. Given that excessive TLR3 signaling that is associated with many viral based infections, the use of TLR3 antagonists to curtail excessive TLR3 signaling would also be of therapeutic value.

Antitumor Effect

TLR agonists have the capacity to prime and shape adaptive immunity and so have aroused significant interest in the development of cancer immunotherapies (Cheng and Xu 2010). Regarding TLR3, its activation by dsRNA induces dual antitumoral activity, either an anticancer immune response or apoptosis of the cancer cells via TLR3 which is expressed by the cancer cell (Jin et al. 2010); these two modes of action work synergistically against cancer. Given that cancer cells are malignantly transformed cells of the host, they express antigens that are either not expressed or only expressed in trace amounts by the healthy host and so are referred to as tumor associated antigens (TAAs). Thus, induction of TLR3-mediated apoptosis of the cancer cells presents the immune system with a new repertoire of TAAs in a TLR3 activation context that is favorable to the development of long-term anticancer immune responses (Jin et al. 2010). In addition, activation of TLR3 using agonists leads to production of type I IFN and other inflammatory mediators, which aid in the phenotypic and functional maturation of DCs. For example, immunization with the melanoma peptide trp2 and adjuvants consisting of cationic liposomes complexed with TLR3/9 agonists has been shown to control the growth of established B16 melanoma tumors in a therapeutic tumor vaccine model (Vercammen et al. 2008). Despite increased expression of TLR3 on many tumors and the immunostimulatory and protective properties of dsRNA, many questions remain to be answered regarding TLR3 in the context of its antitumor activity.

Summary

Much information has come to light in the last decade providing a convincing picture of the important, yet complex, interplay between TLR3, the TLR adaptor proteins, the signaling pathways and the role of TLR3 in antiviral and antitumor therapies. It must be noted that although it is clear that several viruses stimulate TLR3-dependent signaling, the importance of TLR3 signaling in the antiviral immune response is not definitive. For example, an absence of TLR3 does not affect the outcome of a viral infection in some instances; this may be attributed to redundancy with other dsRNA sensors, such as the RLRs, RIG-I, and Mda5. Another complication in understanding TLR3 functionality is the absence of a physiological ligand for TLR3. Most studies use poly(I:C), a synthetic agonist, but the identity of the viral RNA sequences that actually activate TLR3 are poorly understood. Moreover, the potential of endogenous RNA (e.g., from dying cells) to mediate TLR3 signaling requires further study. Regarding the cellular localization of TLR3, it is important to consider that the subcellular localization of TLR3 may affect subcellular signaling events. Lastly, to fulfill the therapeutic potential of TLR3, studies must be performed to further elucidate the signaling pathways and proteins that can positively and/or negatively regulate TLR3 signaling. These molecules could potentially be used to modulate inappropriate TLR3 signaling in a number of clinical contexts and to develop enhanced vaccine adjuvant therapy against tumor and viral infectious diseases.

TLR9

Historical Background

Toll receptors are transmembrane proteins that are evolutionarily conserved. These receptors were first recognized in *Drosophila*, as an essential molecule for embryogenic patterning (Anderson 2000).

Activation of these receptors in *Drosophila* initiates an intracellular kinase cascade that produces a translocation of transcription factors from cytoplasm to nucleus. These factors activate a variety of inflammatory mediators and cytokines, initiating an immune response (Imler and Hoffmann 2000).

Considering these facts, some researchers began a search for toll-related proteins in humans. In 1997, they identified the first human homologue, initially termed "human toll" and subsequently termed ▶ TLR4 (Medzhitov et al. 1997). After this, more toll-like receptors were discovered, as TLR1, TLR2, TLR3, ▶ TLR5, and TLR6.

In 2000, Du et al. examined the human genomic sequence database in an effort to identify novel TLRs (Du et al. 2000). He found more three TLRs, which were designated TLR7, TLR8, and TLR9. Two of these TLRs are X-linked and lie in close opposition to one another at Xp22. A third is located at human chromosome 3p21.3.

Structure

Molecular Cloning and Sequence Analysis of TLR9

All the information about structure of TLR9 was well described by Chuang et al. (Chuang and Ulevitch 2000). TLR9 exhibit features of type I transmembrane proteins. Type I proteins are single pass molecules anchored to the lipid membrane with a stop-transfer anchor sequence and have their N-terminal domains targeted to the endoplasmic reticulum lumen during synthesis.

TLR9 contains two hydrophobic regions: (1) a transmembrane domain, and (2) a signal peptide at the amino-terminus. The transmembrane regions separate TLR9 into two domains: an extracellular domain with more than 800 amino acid residues and a cytoplasmic domain with around 200 amino acid residues. External domain contains copies of leucine-rich repeats, more than found in other TLRs. Following the leucine-rich repeats-flanking region, there is a sequence of about 60 amino acid containing cysteine residues, which are conserved in all TLRs. This conserved area can be found in other proteins such as platelet glycoprotein IX and 1b-alpha (Hickey et al. 1989). The cytoplasmic domains of TLR9 share sequence homology with other members of human TLR family, although there is some variation within these regions.

Tissue Distribution of TLR9

Toll-like receptors can be found in different tissues. In contrast to all of the other TLRs, the TLR9 was initially found in immune-cell-rich tissue, including spleen, lymph node, bone marrow, and peripheral blood leukocytes. However, the TLR9 can also be found in the skin and endothelial cells (Tuon et al. 2010a, b).

Activation of TLR9

Some TLRs recognize protein and lipid structures found in microorganisms. However, toll-like receptor 3, 7, 8, and 9 recognize nucleic acid fragments from microorganisms. TLR3 respond to specific double-stranded RNA segments, TLR9 respond to DNA-specific oligonucleotides-bearing unmethylated CpG base pairs (CpG motifs), and TLR7 and TLR8 recognize specific single-stranded RNA segments (Barton et al. 2006).

The TLR9 can recognize CpG motifs which can be found in many bacterial and viral genomes (Gangloff and Gay 2008). After the recognition of the CpG motifs, several intracellular enzymatic reactions occur and the translocation of NF-kB to the nucleous induces the production of cytokines, initiating the innate immune response.

The role of TLR9 in CpG motifs detection was suggested by the observation that the activation of CpG-induced responses requires components of TLR signaling pathways, including ▶ MyD88 and ▶ TRAF6 (Hacker et al. 2000; Schnare et al. 2000). TLR9 was identified as a receptor by demonstrating that responses to CpG DNA are abrogated in mice lacking TLR9 (Hemmi et al. 2000). Furthermore, sensitivity to CpG DNA can be reconstituted by expression of TLR9, without the co-expression of CD14 (Bauer et al. 2001).

Unlike other TLRs, the TLR9 is localized in intracellular compartments such as the endosome and lysosome (Fig. 1). Thus, to stimulate an innate immune response the non-self nucleic acid must be internalized by phagocytosis. This occurs in macrophages, dendritic cell, as well as endothelial cells. Endosomal acidification is prerequisite for the activation of the signaling pathway mediated by CpG DNA. This data suggests that generation of the CpG DNA signal takes place inside the endosome (Hacker et al. 1999). Binding of DNA containing unmethylated CpG motifs to TLR9 causes a conformational shift in the receptor, which is thought to result in recruitment of the adapter protein MyD88. All TLRs share the same signaling molecule, the MyD88, attached in the cytoplasmatic portion of the receptors. After the activation, MyD88 recruits the serine/threonine kinase IRAK (IL-1 associated protein kinase). IRAK is phosphorylated and dissociated from the receptor complex and associates with TRAF6 (TNF receptor–activated factor 6). This process results in the activation of three pathways: JNK, MAPK, and NF-κB. NF-κB attaches to DNA in the promoter region of target genes as a dimmer, inducing the synthesis of several cytokines.

Although NF-kB is known to function as an activator of transcription, its role in the differential transcription of cytokines is less well defined. Some interactions between NF-kB and other activated transcription factors are important for determining the transcription rates of cytokine genes. NF-kB may also produce preferential binding, which could favor the production of certain cytokines. For example, cooperative binding with the transcription factor NF–IL-6 (a variance of NF-kB) is required for the transcriptional activation of IL-8 and IL-6 (Baeuerle and Baltimore 1996). In addition, NF-kB may have direct protein–protein interactions with other transcription factors, such as the glucocorticoid receptor, that alter the ability of NF-kB to bind to DNA.

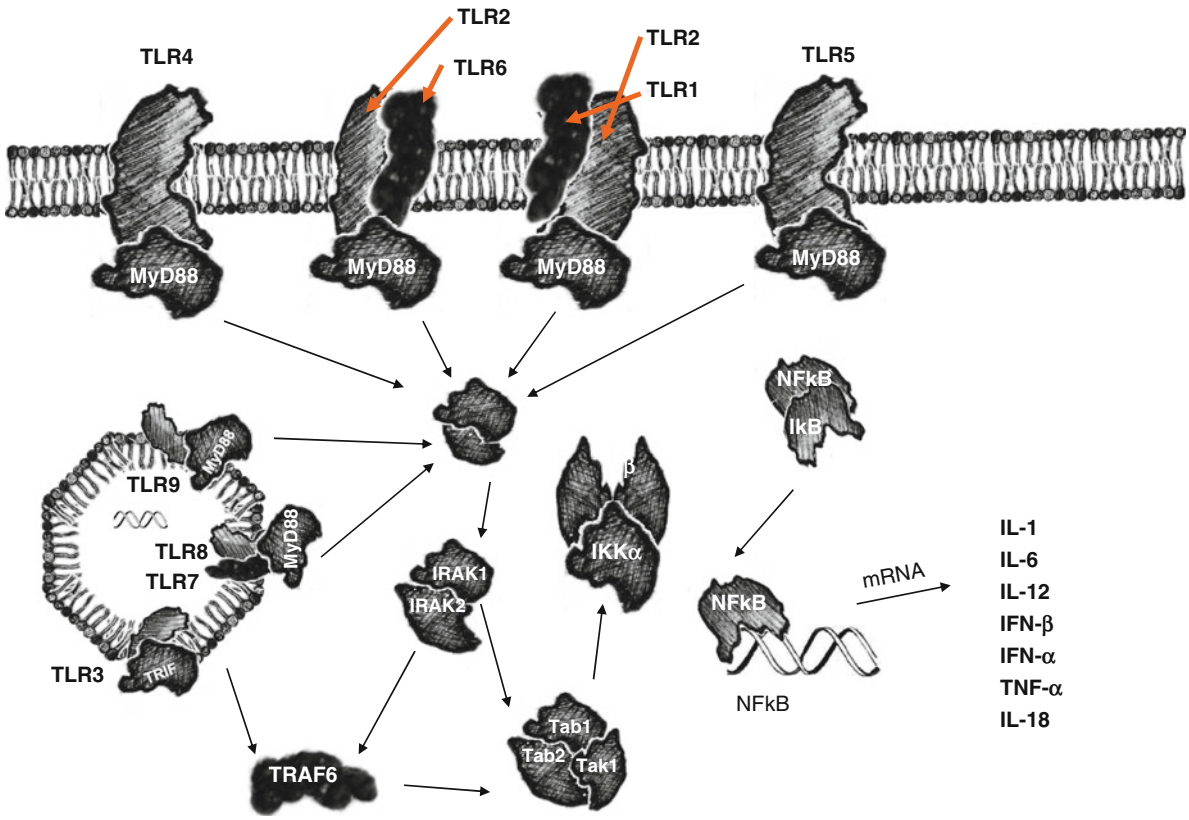
The activation of TLR9 is associated with the expression of IL-1, IL-8, TNF-alpha, IFN-gamma, CD80 and CD86.

Application

TLR9 agonists are currently in clinical trials for use in lung cancer, as antiviral therapy, as adjuvants, and as immune modulators in asthma and allergies. TLR9 antagonists, such as the antimalarial drug chloroquine, have been used since the 1950s to treat immune-mediated inflammatory disorders such as rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. However, the use of antimalarials is limited due to the side effects or suboptimal efficacy (Sun et al. 2007).

Cancer

TLR9 agonists have shown activity against several neoplasms. Phase I and II clinical trials have indicated that these agents have antitumor activity as single agents and enhance the development of antitumor T-cell responses when used as therapeutic vaccine adjuvants. The efficacy of these anticancer agents is being tested in several tumor types (Krieg 2008). The activation of the innate response has direct antitumor effects and the enhanced presentation of the tumor antigen in a Th1-like cytokine and can promote an better antitumor immune response.



Toll-Like Receptor 9, Fig. 1 Toll-like receptors in the human cell – The TLR9 is shown in endosome as well as TLR7, TLR8, and TLR3. All toll-like receptors are linked with MyD88, except TLR3. After the activation, MyD88 recruits the IRAK4. IRAK is phosphorylated and dissociated from the receptor complex and associates with TRAF6. This process results in the activation of NF-κB which attaches to DNA in the promoter region of target genes inducing the synthesis of some cytokines

Synthetic oligodeoxynucleotide (ODN) agonists for TLR9 are currently in development for the treatment of cancer. Because the phosphodiester bond of native DNA is rapidly degraded by endonucleases, these investigational CpG ODNs use a nuclease-resistant phosphorothioate backbone that improves the half-life in the body. These agonists have been tested in cervical carcinoma, sarcoma, breast cancer, chronic lymphocytic leukemia, lymphomas, lung and renal cancer, and glioblastoma.

Although the results are encouraging evidence of the potential clinical benefits of TLR9 activation, the greatest improvement in patient outcomes is likely to result from the use of this approach in combination with other therapies that work in a synergistic manner. However, two phase III trials of PF-3512676 administered concurrently with chemotherapy for patients with lung cancer have reported a lack of incremental efficacy.

Autoimmune Disorders

The exacerbation of inflammatory response by TLRs cytokine increases the production of antibodies, and several studies have been done to evaluate this overexpression of cytokines as a cause of autoimmune disorders.

Murine studies of lupus have examined whether CpG ODN would induce or flare lupus. These studies have shown increase in anti-DNA antibodies, proteinuria, and glomerulonephritis. Treatment with CpG ODN also exacerbated disease in mice, perhaps because of a more sustained immune stimulatory effect (Krieg and Vollmer 2007).

There are controversial findings of the role of TLR9 in central nervous system autoimmune disorders, including multiple sclerosis. CpG ODN accelerated the development of multiple sclerosis. Furthermore, TLR9 −/− and MyD88 −/− mice were resistant and partially resistant to multiple sclerosis development,

respectively. These findings suggest an association of TLR9 with autoimmune disorders in central nervous system. Nevertheless, in some in vivo models, TLR9 activation has decreased the severity of multiple sclerosis, once mice injected with CpG ODN starting 4 days before multiple sclerosis model induction had a marked reduction in the subsequent disease severity, compared with mice treated with a control ODN (Krieg and Vollmer 2007).

Several investigators have examined the effects of CpG DNA on experimental models of arthritis. Because disease in these models results from Th1-mediated inflammation, TLR9 stimulation would be expected to aggravate the disease process. When injected into joints, CpG ODNs induce a transient self-limited inflammatory arthritis with a peak severity at 3 days, followed by resolution. However, systemic injection of CpG does sensitize the mouse, resulting in an exaggerated arthritis when the mice are subsequently given an intra-articular injection of a low dose of CpG DNA.

TLR9 activation on intestinal epithelial cells suppresses gut inflammation, in contrast to the immune stimulatory effects in immune cells. Mice genetically deficient in TLR9 are susceptible to acute colitis. TLR9 activation promotes the development of T regulatory cells that protect against gut inflammation. These studies suggest that in this anatomic region, TLR9 activation has a constitutive role in preventing inflammation.

Recent evidence has suggested that selective, specific antagonists for TLR9 might be beneficial in certain diseases, such as lupus. Thus, the use of suppressive ODN or novel small molecule TLR inhibitors with a larger safety window and differentiated selectivity may potentially have significant clinical utility.

Infectious Diseases

Therapeutic treatment with TLR9 agonists might protect against intracellular microorganisms. Studies in mice have demonstrated that the innate immune defenses activated by CpG ODNs can protect against a wide range of viral, bacterial, and even some parasitic pathogens (Krieg 2007). The adjuvant therapy increases the pro-inflammatory cytokine synthesis, improving the antigen presentation, macrophage activation, and adequate Th1-like adaptive immune response. Animal models have been shown efficacy in chronic viral infection as hepatitis C and B, and mycobacterial infection by *M. tuberculosis*.

However, the major application of TLR9 agonist is related with the gold standard vaccine adjuvant, capable of inducing powerful antigen-specific antibody and Th1 cellular immune responses. This strong adjuvant activity results from synergy between TLR9 and B-cell receptor, inhibition of B-cell apoptosis, enhanced IgG class switch DNA recombination, and dendritic cell maturation and differentiation, resulting in enhanced activation of Th1 cells and strong cytotoxic T lymphocyte generation.

In humans, CpG ODNs have been used as adjuvants in controlled randomized trials for hepatitis B vaccination, anthrax vaccine, and influenza vaccine.

Summary

In summary, TLR9 exhibit structural features shared by all the other TLRs. TLR9 activate NF-kappaB through the same signal transduction pathway used by other TLRs. TLR9 activation induces powerful Th1-like innate and adaptive immune responses and is emerging as a promising therapeutic approach in several disease fields. TLR9 agonists can provide a temporary protection against diverse pathogen and have become a powerful vaccine adjuvant, inducing faster and stronger humoral and cellular immune responses. However, the cause of some autoimmune disorders has been attributed to TLR9 stimulus or, at least, worse the clinical evolution of autoimmune diseases.

Historical Background

Toll-like receptors (TLRs) play a critical role in innate immunity by providing a frontline defense mechanism against invading pathogens such as bacteria, fungi and viruses. They accomplish this by recognising evolutionarily conserved pathogen-associated molecular patterns (PAMPs) which are unique to pathogens are allow the host immune system to distinguish non-self from self. For example, TLR2 and TLR4 recognise bacterial cell wall components such as lipopeptides and lipopolysaccharide (LPS) respectively, whereas TLR3 and TLR9 recognise signature viral and bacterial nucleotide sequences (Miggin and O'Neill 2006). TLRs are also activated by sterile inflammatory mediators known as danger-associated molecular patterns

(DAMPs), for example hyaluronan - an extracellular matrix fragment (Chen and Nunez 2010).

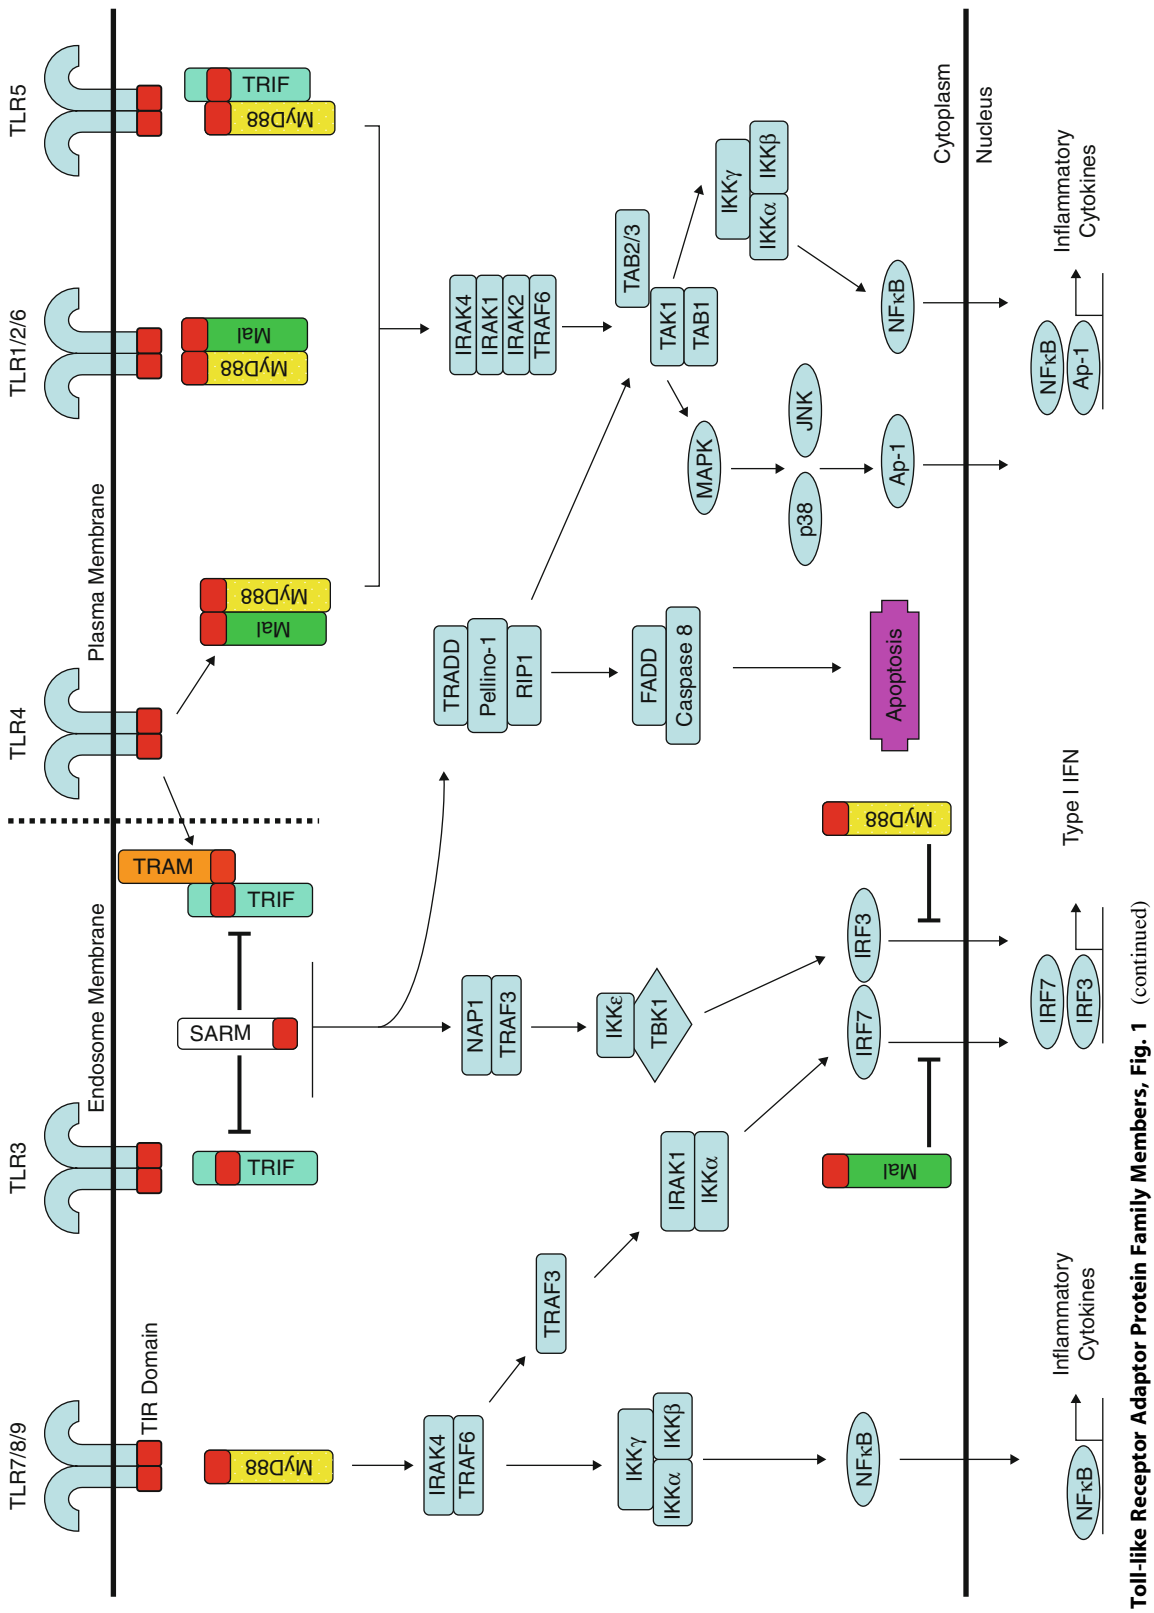
The existence of the TLRs, their adaptor proteins, as well as their functionality in the context of innate immunity commenced in 1998 and was proceeded by rapid advancements in the field thereafter. This concurred with the revival of the idea that the innate immune system and its role in inflammation were the central pivot upon which the early immune response is dictated. Each member of the TLR family senses different PAMPs and DAMPs which leads to the activation of TLR signaling, the downstream dissemination of which involves recruitment of appropriate TLR adaptor proteins to the TLR complex. The TLR adaptor proteins then couple to downstream protein kinases that ultimately lead to the activation of transcription factors such as nuclear factor-κB (▶ NF-κB) and members of the interferon (IFN)-regulatory factor (IRF) family.

A critical domain common to all five of the TLR adaptors as well as to the TLRs themselves is the Toll/interleukin-1 (IL-1) receptor (TIR) domain. This is located on the intracellular portion of all TLRs and allows binding to the reciprocal TIR domain on the adaptor's exposed surface. The IL-1 receptor also contains a TIR domain hence the existence of the TLR/IL-1R superfamily (Miggin and O'Neill 2006). Despite the TLRs having somewhat similar signal transduction pathways, there is specificity with regard to their adaptor usage (Akira and Takeda 2004) (Fig. 1). There are four *activating* TLR adaptor proteins myeloid differentiation factor 88 (MyD88), MyD88 adaptor-like (Mal); also known as Toll-IL-1 adaptor protein (TIRAP), TIR-domain-containing adaptor inducing IFN-β (TRIF; also known as TICAM-1) and TRIF-related adaptor molecule (TRAM; also known as TICAM-2 and TIRP). Despite the TLRs having somewhat similar signal transduction pathways, there is specificity with regard to their adaptor usage (Akira and Takeda 2004). MyD88 is the common downstream adaptor that is recruited by all TLRs, except TLR3 (Kawai and Akira 2006). Mal is required for TLR4, and to a lesser extent, TLR2 signaling (Yamamoto et al. 2002; Kenny et al. 2009). TRIF mediates TLR3 and TLR4 signaling (Fitzgerald et al. 2003). Finally, TRAM mediates TLR4 signaling exclusively (Fitzgerald et al. 2003) acting as a bridging adaptor to recruit TRIF to the TLR4 complex. In addition, an *inhibitory* TLR adaptor protein called sterile alpha and TIR motif-containing protein (SARM) has also been identified (Carty et al. 2006) which negatively regulates TRIF mediated signaling. TLR4 is the only TLR whose activation utilises all five TLR adaptor proteins and as a result, its signalling is split into two broad categories according to their dependency on MyD88. The 'MyD88-dependent' pathway utilises Mal and MyD88 and is responsible for early stage inflammation. It is used by TLR2/4/7/8 and TLR9. The 'MyD88 independent' pathway uses TRAM and TRIF to activate anti-viral and late-stage inflammatory responses and is used by TLR3 and TLR4. Thus, the function of the adaptor proteins is to provide specificity to TLR signalling in order to tailor the resulting cytokine profile to best defend against the infectious agent.

To summarise, TLR engagement in response to a PAMP or DAMP instigates the recruitment of the relevant TLR adaptor protein(s) which provides a docking platform for downstream effector signaling molecules. This culminates in the production of pro-inflammatory cytokines, chemokines, and antiviral type I IFNs (IFN-β and IFN-α) which serve to trigger an inflammatory and/or antiviral immune response to limit the infectious agent. The remainder of the chapter will provide a more detailed discussion of the functionality of each of the TLR adaptors.

MyD88

As previously stated, ▶ MyD88 is the common downstream adaptor that is recruited by all TLRs, except TLR3. MyD88 was first identified in 1990 as a protein that was induced during the terminal differentiation of $M1D^{+}$ myeloid precursors in response to IL-6 (O'Neill and Bowie 2007). Early studies indicated that ▶ MyD88 was a TLR adaptor molecule that functioned to recruit IL-1R-associated protein kinase (IRAK-1) to the interleukin-1 receptor (IL-1R) complex following IL-1 stimulation which resulted in the activation of ▶ NF-κB. Human ▶ MyD88 is 296 amino acids in length and contains three domains: a N-terminal death domain which enables interactions with the IRAKs, an interdomain, and a C-terminal TIR domain which facilitates homotypic interaction with other



Toll-like Receptor Adaptor Protein Family Members, Fig. 1 (continued)

TIR-containing proteins (Jenkins and Mansell 2010). In 1998, MyD88 was also implicated in TLR signaling (Medzhitov et al. 1998). In contrast to the other TLR adaptor proteins, ▶ MyD88 also mediates signaling through the IL-1 receptor. Further elaboration on ▶ MyD88 and its role in TLR signaling can be found within this encyclopedia as a separate entry.

Mal

Mal, the second TLR adaptor to be identified, was simultaneously discovered by two independent labs in 2001 (Fitzgerald et al. 2001; Horng et al. 2001). Having observed late stage ▶ NF-κB and Jun N-terminal kinase (JNK) activation in MyD88-deficient mice, Fitzgerald and colleagues (Fitzgerald et al. 2001) speculated that another, as yet unidentified TIR-domain-containing adaptor protein was mediating this effect. High-throughput sequencing of a human DC EST cDNA library identified Mal – a TIR-domain-containing protein, 235 amino acids in length, that was capable of activating ▶ NF-κB (via IRAK2) and JNK as well as extracellular signal-regulated kinase (ERK) -1 and -2. Mal was shown to homodimerize and heterodimerize with ▶ MyD88. It was also shown that a dominant-negative form of Mal inhibited TLR4 (but not IL-1R or IL-18R) mediated ▶ NF-κB activation (Fitzgerald et al. 2001; Horng et al. 2001). It is generally accepted that Mal acts a bridging adaptor between MyD88 and TLR4/2.

Mal Localization

Mal is localized primarily to the plasma membrane, although Mal-positive, actin-negative vesicles can be found throughout the cell (Kagan and Medzhitov 2006). Mal is concentrated at the leading edge of murine embryonic fibroblasts (MEFs). In macrophages, Mal is localized to discrete regions of the plasma membrane called membrane ruffles which are biochemically similar to the leading edge of fibroblasts (Kagan and Medzhitov 2006).

Mal interacts with the TIR domain of TLR2 and TLR4. This association is facilitated by the phosphatidylinositol 4,5-bisphosphate (PIP_2)-binding domain contained within the N-terminal region of Mal (Kagan and Medzhitov 2006). This allows Mal to target to PIP_2-rich regions of the plasma membrane which contain high levels of TLR2 and TLR4, thus facilitating their association with Mal (O'Neill and Bowie 2007). Notably, Mal is not involved in the recruitment of MyD88 to other compartments, including endosomal compartments devoid of PIP_2 (Kagan and Medzhitov 2006). Further, in Mal/MyD88 double-deficient cells, transfection of a mutant construct which incorporates a PIP_2 binding site to the C-terminus of MyD88 directs MyD88 to the plasma membrane and restores lipopolysaccharide (LPS) signaling *via* TLR4 (Kagan and Medzhitov 2006).

Surface charge distribution models of Mal, MyD88, and TLR4 have shown that the TIR domains of TLR4 and MyD88 are electropositive – and would thus be expected to repel each other under normal circumstances. However, the TIR domain of Mal is electronegative which would facilitate binding of TLR4 to MyD88 in order to transduce TLR4 signaling (O'Neill and Bowie 2007). Moreover, molecular docking experiments have suggested that Mal binds to a homodimer of TLR4 and that Mal actually competes with TRAM for TLR4 binding (Nunez Miguel et al. 2007).

Toll-like Receptor Adaptor Protein Family Members, Fig. 1 *Role of TLR adaptors in TLR signaling pathways.* MyD88 is the central adaptor in TLR signaling, capable of transducing signals mediated by all TLRs except TLR3. MyD88 does however negatively regulate TLR3-induced IRF3 activation. Regarding TLR1/2, TLR2/6, TLR4, and TLR5 signaling, MyD88 interacts with the TLR though their TIR domains (red). IRAK4 is then recruited to the complex which in turn recruits IRAK1 and/or IRAK2 via death domain (DD) interactions. TRAF6 is then recruited to activate TAK1, leading to subsequent activation of MAPK and ▶ NF-κB. In the case of TLR7/8/9 signaling, the MyD88 complex can also recruit TRAF3 which activates IRF7. TRIF is the sole adaptor involved in TLR3 signaling and recruits NAP1 and TRAF3 to activate the noncanonical IKKs, TBK1, and IKKε. These in turn phosphorylate IRF3 and IRF7 causing their translocation into the nucleus where they bind to the type I IFN (IFN-α and IFN-β) gene promoter. TRIF is also required to mediate maximal TLR5-induced ▶ NF-κB and MAPK activation by binding directly to TLR5. As part of a suspected negative feedback loop, TRIF can also mediate caspase-dependent TLR5 degradation. Mal acts as a bridge to allow TLR4 and to a lesser extent TLR2, to signal via the MyD88 pathway. Mal also negatively regulates TLR3-mediated IRF7 activation. TRAM, like Mal, is another bridging adaptor and links TLR4 to the TRIF pathway. The Mal:MyD88 and TRAM:TRIF complexes facilitate bifurcation of the TLR4 pathway to allow for the synthesis of both inflammatory cytokines and type I IFN, respectively. The fifth adaptor SARM interacts with TRIF and impairs TRIF signaling

Mal and TLR4 Signaling

Ligand engagement of TLR4, e.g., binding of LPS via MD-2 and CD14, causes TLR4 dimerization and nonexclusive interaction with Mal. Docking experiments have predicted that the Mal (and TRAM) interaction surfaces on the TLR4 dimer interface are at either side of the structure rather than at the top, a region that would be sterically hindered by the membrane (Nunez Miguel et al. 2007). The TLR4 dimer:Mal complex provides a platform allowing MyD88 to bind which then facilitates the recruitment of IRAK1 and IRAK4. Tumor necrosis factor (TNF)-receptor-associated factor 6 (TRAF6) is subsequently recruited and activated via an oligomerisation/auto-ubquitination event. Activated TRAF6 then recruits transforming growth factor activated kinase 1 (TAK1) and TAK1 binding protein 2 (TAB2). This complex interacts with the inhibitor of ▶ NF-κB kinase (IKK) complex, which consists of IKKα, IKKβ, and IKKγ (also known as NEMO), leading to the activation of ▶ NF-κB and subsequent activation of ▶ NF-κB-dependent genes, including the pro-inflammatory cytokines IL-1,IL-6, and TNFα (Moynagh 2008).

Mal and TLR2 Signaling

The role of Mal in TLR2 signaling is complicated by the fact that TLR2 can heterodimerize with both TLR1 and TLR6 to recognize tri- and diacylated lipopeptides, respectively. Overexpression studies have shown that Mal interacts with TLR1 and TLR2, but not TLR6 (Kenny et al. 2009). Although Mal was originally suspected to be essential for TLR2 signaling (Horng et al. 2002), more recent studies have shown that Mal plays a lesser role here when compared to TLR4 (Kenny et al. 2009). Specifically, whilst Mal is required for TLR2 signaling when exposed to low levels of *Salmonella typhimurium*, Mal is redundant at high concentrations of ligand or in response to high levels of *S. typhimurium* (Kenny et al. 2009). This suggests that the physiological role of Mal in the context of TLR2 signaling is to prime or amplify low strength bacterial signals.

Modulators of Mal Functionality

Additional levels of specificity and control are added to TLR signaling by virtue of the fact that the TLR adaptors themselves are subject to a myriad of regulatory mechanisms. Mal contains a proline, glutamic acid, serine, and threonine (PEST) domain, located at amino acids 32–72 in human Mal. PEST domains are found in short-lived proteins which undergo phosphorylation, polyubiquitination of lysine residues, and subsequent degradation via the 26S proteasome. The presence of a PEST domain in Mal would therefore suggest that it may be a target for degradation. Interestingly, suppressor of cytokine signaling 1 (SOCS-1), has been shown to inhibit LPS signaling by ubiquitinating Mal and thus targeting it for proteosomal degradation (O'Neill and Bowie 2007). The ubiquitination of Mal is facilitated by Bruton's tyrosine kinase (Btk) – a protein which is the case of Mal, performs two important functions. Specifically, Btk induces tyrosine phosphorylation of Mal, thus potentiating TLR2/4-driven ▶ NF-κB signaling. However, the same phosphorylation event provides a platform for the aforementioned SOCS-1 mediated ubquitination/degradation of Mal – thus serving to limit the over-activation of the inflammatory immune response (O'Neill and Bowie 2007). IRAK1 and IRAK4 have also been shown to phosphorylate Mal, thereby facilitating its TLR4-ligand-mediated ubiquitination and degradation; IRAK1 and IRAK4 inhibitors blocked this effect (Dunne et al. 2010). Mal has also been shown to interact with caspase-1, with cleavage of Mal by caspase-1 being required to modulate Mal functionality (Miggin et al. 2007; Ulrichts et al. 2010).

A number of studies have been carried out on a variant of Mal that contains a leucine at position 180 instead of a serine (O'Neill and Bowie 2007; Jenkins and Mansell 2010). It has been reported that Mal Ser180Leu does not associate with TLR2 and confers a protective phenotype in malaria and tuberculosis by inhibiting the inflammatory response (O'Neill and Bowie 2007). Other groups dispute this claim (Jenkins and Mansell 2010). Overall, the studies to date indicate an association between heterozygosity at Mal Ser180Leu and protection against multiple infections.

TRIF

Initially, Mal was thought to mediate the MyD88-independent pathway following TLR4 engagement, leading to IRF3 activation and delayed/late activation of ▶ NF-κB. However, given that Mal was instead shown to act as a bridging adaptor in the

MyD88-dependent pathway which was activated following TLR4/2 engagement, it remained unclear how TLR4 might mediate IFN-β induction (O'Neill and Bowie 2007).

In 2003, a third TLR adaptor, TRIF, was identified by two separate groups, by one employing database screening to identify novel TIR-domain containing proteins with the other employing a yeast two-hybrid screen using TLR3 as a bait (O'Neill and Bowie 2007). It was found that overexpression of TRIF, 712 amino acids in length, leads to the induction of the IFN-β promoter. In TRIF-deficient mice, whilst impaired TLR3 and TLR4 ligand induced IRF3 activation and concomitant IFN-β induction was observed, TLR2, TLR7 and TLR9 signaling was unaffected (O'Neill and Bowie 2007). Notably, TLR4 ligand induced ▶ NF-κB activation is completely abolished in cells deficient in both MyD88 and TRIF, indicating that TRIF is essential for "MyD88-independent" TLR4 signaling (Jenkins and Mansell 2010). Further, a germline mutation in mice termed Lps2 confirmed the role of TRIF in mediating "MyD88-independent" signaling (Jenkins and Mansell 2010).

TRIF Localization

TRIF is expressed at low levels in most tissues and cells and is diffusely localized in the cytoplasm of resting cells (Tatematsu et al. 2010). When endosomal TLR3 is activated by double strand (ds) RNA, TRIF transiently colocalizes with TLR3 and then dissociates from the receptor forming speckled structures that colocalize with downstream signaling molecules (Tatematsu et al. 2010). Upon stimulation of TLR4 with LPS, TRIF is activated by endosomal TRAM, which associates with the internalized TLR4 complex (Tatematsu et al. 2010). Thus, TRIF is indirectly recruited to TLR4 via TRAM. Also, overexpression of TRIF leads to homo-oligomerization through the TIR domain and the C-terminus, forming a complex called the TRIF signalosome (Jenkins and Mansell 2010; Tatematsu et al. 2010).

TRIF and TLR3/4 Signaling

TRIF, like Mal, has consensus TRAF6-binding motifs in the N-terminal region as well as a TIR domain (O'Neill and Bowie 2007). TRIF also has a TRAF2-binding site in the N-terminal region (Tatematsu et al. 2010) and a C-terminal receptor-interacting protein (RIP) homotypic interaction motif (RHIM) domain (O'Neill and Bowie 2007). The TIR domain of TRIF is essential for binding to the TIR domain of TLR3 and to TRAM. All of these domains serve to facilitate TRIF-mediated signaling, with each domain playing a distinct role therein.

The N-terminal region of TRIF participates in IRF3/7 activation by recruiting the IRF3-activating kinases, TANK-binding kinase 1 (TBK1), and inhibitor of ▶ NF-κB kinase ε (IKKε, also known as IKKι). NAK-associated protein 1 (NAP-1) forms part of the active kinase complex for IRF3 and serves to facilitate the association of TRIF with TBK1 and IKKε (Gauzzi et al. 2010). Upon TBK1/IKKε-mediated phosphorylation and homo/heterodimerization of the IRF3/7 complex, translocation of the phosphorylated IRF complex to the nucleus occurs. Here, it binds to both the IFN-β enhanceosome (Siednienko et al. 2010) and the IFN-stimulated response elements (ISREs) to induce the transcription of responsive genes including the type I IFN and CCL5 genes (Siednienko et al. 2011) (Fig. 1). TNF receptor-associated factor 3 (TRAF3) plays a crucial role in TLR3 signaling as various independent studies show that TRAF3 forms a complex with NAP-1 and TRIF (Fig. 1) (O'Neill and Bowie 2007).

Two separate ▶ NF-κB activation pathways bifurcate from TRIF, and these map to distinct sites at the N- and C-termini. The binding motifs in the N-terminal region of TRIF serve to recruit TRAF6 although its role in TRIF signaling remains controversial (O'Neill and Bowie 2007). Studies suggest that the participation of TRAF6 in TRIF-mediated ▶ NF-κB induction is cell type specific as TRAF6 is essential for ▶ NF-κB activation in mouse embryonic fibroblasts (MEFs), whereas poly(I:C), a TLR3 ligand, induced ▶ NF-κB activation is not impaired in TRAF6-deficient macrophages (Gauzzi et al. 2010; Sasai et al. 2010). There is a separate route to ▶ NF-κB activation involving the RHIM domain of TRIF whereby TRIF facilitates the recruitment of both RIP1 and RIP3 through this domain. Adding credence to the importance of RIP1 and RIP3 in TRIF signaling is the fact that poly(I:C)-induced ▶ NF-κB activation is completely blocked in RIP-1-deficient MEFs. In contrast, RIP3 has been shown to negatively regulate the TRIF–RIP1–▶ NF-κB pathway. Studies are ongoing to further define the role of RIP1 and RIP3 in TLR signaling (O'Neill and Bowie 2007).

TRIF also mediates the induction of apoptosis through TLR3 and TLR4. This is facilitated by direct recruitment of RIP1 to the C-terminal RHIM domain of TRIF, and involves activation of a complex containing TRADD, FADD, and caspase-8 (O'Neill and Bowie 2007). This apoptotic pathway is believed to be responsible for bacterial-induced apoptosis of infected macrophages, bacterial-induced DC apoptosis and DC maturation (O'Neill and Bowie 2007; Jenkins and Mansell 2010).

TRIF and TLR5 Signaling

Although it was thought that TRIF mediated TLR3 and TLR4 signaling only, a number of recent studies have shown that TRIF also plays an important role in TLR5 signaling. Stimulation of human colonic epithelial cells with the TLR5 ligand flagellin, allows TLR5 and TRIF, but not TRAM, to interact and mediate TLR5-induced ▶ NF-κB and mitogen-activated protein kinase (MAPK) activation in intestinal epithelial cells (IEC) (Rhee 2011). TRIF-deficient IECs stimulated with flagellin exhibit decreased inflammatory cytokine expression when compared to their wild-type counterparts (Rhee 2011). Furthermore, TRIF-deficient mice are resistant to flagellin-mediated exacerbation of colonic inflammation and dextran sulfate sodium–induced experimental colitis. Moreover, studies have shown that TRIF-induced caspase activity causes the degradation of TLR5 (Rhee 2011) indicating that TRIF can participate in the proteolytic modification of TLR functionality at the posttranslational level. These recent findings therefore suggest that TRIF plays an important role in regulating host-microbial communication *via* TLR5 in the gut epithelium.

TRIF and Cytosolic dsRNA Detection

A further role for TRIF in innate immune signaling, independent of the TLRs, has recently been identified whereby TRIF appears to be an essential component of a novel dsRNA sensing pathway in DCs (Zhang et al. 2011). More specifically, the RNA helicases DDX1, DDX21, and DHX36 form a complex which enables the sequestration of cytosolic dsRNA which is then followed by binding to TRIF and subsequent induction of type I IFN and inflammatory cytokine responses. It has been shown that DDX1 binds dsRNA via its helicase A domain and that DHX36 and DDX21 bind to TRIF via their HA2-DUF and PRK domains, respectively. The resulting complex triggers the innate antiviral response (Zhang et al. 2011).

Negative Regulation of TRIF

Numerous strategies exist to curtail TRIF signaling, either directly, or via inhibition of downstream signaling molecules. In terms of direct inhibition of TRIF, a number of molecules have been identified. For example, the inhibitory TLR adaptor protein SARM contains a TIR domain and serves to inhibit TRIF-mediated signaling. SARM has been shown to interact with TRIF and both the TIR and SAM domains of SARM are vital for SARM's functionality in this regard. While the exact mechanism of inhibition has not been elucidated, it is suspected that SARM and TRIF interact via their TIR domains, thus preventing the binding of downstream molecules such as RIP1. Alternatively, the SAM domain of SARM may facilitate recruitment of an, as yet unidentified, inhibitory molecule (Carty et al. 2006; Jenkins and Mansell 2010).

Consistent with a role for TRIF in restricting viral replication through type I IFN induction, at least two viruses have been shown to contain proteins that antagonize TRIF. The vaccinia virus (VACV) encoded proteins, A46R and A52R, differentially affect TRIF signaling. More specifically, A46R interacts directly with TRIF and inhibits TRIF mediated TLR3 signaling. Notably, A46R also interacts with the other TLR adaptors and also inhibits TLR4 signaling. In contrast, A52R acts downstream of the TLR adaptors by targeting TRAF6 and IRAK2 (O'Neill and Bowie 2007). Hepatitis C (HCV) virus contains a serine protease NS3-4A that causes the proteolysis of TRIF. The cleavage of TRIF by NS3-4A inhibits both ▶ NF-κB and IRF3 activation by TLR3, thus disabling the innate immune response to the virus (Jenkins and Mansell 2010). The above examples illustrate the importance of TRIF in mediating the anti-viral signalling pathway such that specific inhibition by VACV and HCV confers an advantage to the viruses in vivo.

TRAM

In 2003, the fourth TIR-domain-containing adaptor, TRAM, 235 amino acids in length, was identified following a bioinformatic search of the human genome database (Jenkins and Mansell 2010). It was initially

thought that TRAM was involved in both TLR and IL-1R mediated ▶ NF-κB activation, but not IFN-β induction (Bin et al. 2003). Subsequently, a definitive description of TRAM showed that it interacts with TLR4 and TRIF to regulate TLR4-mediated IRF3 and IRF7 activation (Fitzgerald et al. 2003). TRAM-deficient cells have impaired TLR4-mediated cytokine production and B cell activation, as was observed with TRIF, thus supporting the notion that in the case of TLR4, both the "MyD88-dependent" and "MyD88-independent" pathways are integral for maximal production of pro-inflammatory cytokines. It is now accepted that TRAM acts as bridging adaptor between TLR4 and TRIF in the "MyD88-independent" pathway (Jenkins and Mansell 2010).

TRAM Localization and Involvement in TLR4 Signaling

TRAM exclusively mediates TLR4 signaling. It activates the "MyD88-independent" pathway by facilitating the association of TRIF with TLR4 - similar to the way in which Mal links TLR4 and MyD88. To date, it serves no other known role in TLR signaling. Regarding localization, the N-terminal region of TRAM undergoes constitutive myristoylation, thus facilitating its association with the plasma membrane (Jenkins and Mansell 2010). Moreover, mutation of the myristoylation motif in TRAM abolishes its ability to signal (O'Neill and Bowie 2007).

A distinct requirement for TRAM signaling to occur is the phosphorylation of TRAM on serine 16 by protein kinase Cε (PKCε) (Jenkins and Mansell 2010). TRAM has also been shown to contain a bipartite sorting signal that modulates its trafficking between the plasma membrane and the endosomes. In fact, TRAM must be delivered to the endosomes in a complex with TLR4 to facilitate the activation of IRF3 (Jenkins and Mansell 2010). Thus, activation of TLR4 sequentially induces two signaling pathways from two different cellular locations. The "MyD88-dependent" pathway is induced from the plasma membrane, whereas the "MyD88-independent" pathway is induced from endosomes. Further, these findings suggest that the ability of TLRs to induce an IFN response is dependent on their intracellular localization (Jenkins and Mansell 2010).

Negative Regulation of TRAM

VACV is capable of modulating TRAM functionality. Specifically, an 11-aa-long peptide derived from A46R (termed viral inhibitor peptide of TLR4, or VIPER) has been shown to interact with TRAM (and Mal), thus inhibiting TLR4 signaling. It has been postulated that masking of the critical binding sites on Mal and TRAM specifically inhibits TLR4 signaling (Lysakova-Devine et al. 2010). Also, a splice variant of TRAM, termed TRAM adaptor with GOLD domain (TAG), has been shown to competitively bind TRAM and displace TRIF during LPS-mediated signaling, leading to decreases in RANTES cytokine production without affecting ▶ NF-κB activation (Palsson-McDermott et al. 2009).

SARM

SARM was initially identified in 2001 as a human gene encoding an orthologue of a *Drosophila melanogaster* protein. Structurally, SARM is 690 amino acids in length and contains two sterile alpha motifs (SAM) domains as well as a HEAT/Armadillo repeat motif (ARM) domain (O'Neill and Bowie 2007). Both the SAM and ARM domains are known to be involved in the formation of protein complexes. It was initially shown that the *Caenorhabditis elegans* SARM homologue, TIR1, was important in the efficient immune response against fungal and bacterial infection (O'Neill and Bowie 2007). However, in human cells, it was also shown that unlike the other TIR-domain adaptors, overexpression of SARM failed to induce ▶ NF-κB or activate IRF3-dependent reporter genes and in fact inhibited their activation and expression. (Carty et al. 2006). Human SARM was identified as a negative regulator of TRIF mediated signalling and was therefore the first TIR-domain-containing adaptor shown to be involved in the negative regulation of TLR signaling (Carty et al. 2006). In contrast, a later study showed that macrophages from SARM knockout mice responded normally to TLR3, TLR4, and TLR9 ligands, suggesting that mouse SARM has a redundant role in regulating macrophage responses to these TLR ligands (Jenkins and Mansell 2010). Further research must be undertaken to definitively assign a role for SARM in TLR signaling.

SARM and TLR3/4 Signaling

Although disputed, it appears that in humans, SARM inhibits TRIF-mediated TLR3 and TLR4 signaling by selectively targeting TRIF. In unstimulated cells,

SARM and TRIF are weak interactors, but stimulation with LPS or poly(I:C) induces SARM protein expression and enhances the interaction between SARM and TRIF (Carty et al. 2006). SARM overexpression serves to inhibit TRIF-dependent, but not MyD88- or Mal-dependent, ▶ NF-κB activation. SARM also inhibits poly(I:C)-mediated CCL5 and IFN-β promoter activity. The exact mechanism utilized by SARM to impair TRIF functionality requires further investigation, however it is speculated that SARM may use its TIR domain to bind TRIF and use its SAM domains to recruit an as-yet-unidentified inhibitor. Alternatively, SARM may competitively block the ability of TRIF to directly interact with downstream signal transducers such as TBK1, RIP1, and TRAF6.

Negative Regulation of TLR Signaling by TLR Adaptors

A number of recent studies have highlighted the role of the TLR adaptors themselves in the curtailment of TLR signaling. For example, MyD88 has been shown to negatively regulate TLR3-TRIF-induced corneal inflammation through a mechanism involving JNK phosphorylation, but not p38, IRF3, or ▶ NF-κB (Johnson et al. 2008) and to inhibit TLR3-dependent IL-6 induction (Kenny et al. 2009). MyD88 has also been shown to inhibit TLR3-dependent phosphorylation of IRF3 and thus curtail TLR3-mediated IFN-β and RANTES production (Siednienko et al. 2011). Furthermore, Mal has been shown to inhibit TLR3-dependent IFN-β production through a mechanism that is distinct from MyD88 whereby Mal inhibits TLR3 ligand–mediated IRF7 activation (Siednienko et al. 2010). Mal has also been shown to inhibit TLR3-dependent IL-6 induction (Kenny et al. 2009). As already stated, SARM has been shown to inhibit TRIF-dependent TLR3 and TLR4 signaling (Carty et al. 2006).

Summary

The TLR adaptor proteins are integral modulators of TLR signaling, and consequentially, of innate and adaptive immunity. The specificity of their usage, combined with their broad downstream effects on both autocrine and paracrine immune signaling, highlights them as potential targets for therapeutic immunomodulation (O'Neill et al. 2009).

Many recent advances have been made towards a greater understanding of how TLR adaptors function in the context of innate immunity. It is evident that the TLRs and their adaptor molecules have evolved to respond appropriately to a pathogenic challenge while at the same time, retaining the ability to limit their excessive activation which could otherwise cause detrimental or deleterious damage to the host system. Indeed, many intricate mechanisms by which TLR signaling may be regulated, including adaptor sequestration, differential adaptor utilization, protein degradation, and compartmentalization, have been identified (Akira and Takeda 2010).

While TLR adaptor functionality in the context of signal initiation is well described, the mechanisms that serve to negatively regulate or control them are poorly understood. Evidence suggests that the adaptors may require tight regulation to control the immune response and thus prevent chronic inflammation. Adding credence to this hypothesis is the fact that the TLR adaptors have been shown to bifurcate between activationary and inhibitory roles in TLR signaling as seen with Mal and MyD88. Further study is therefore required to expand on the current understanding of the role played by the TLR adaptors under normal physiological conditions and whether perturbations occur during chronic inflammatory diseases.

Historical Background and Overview

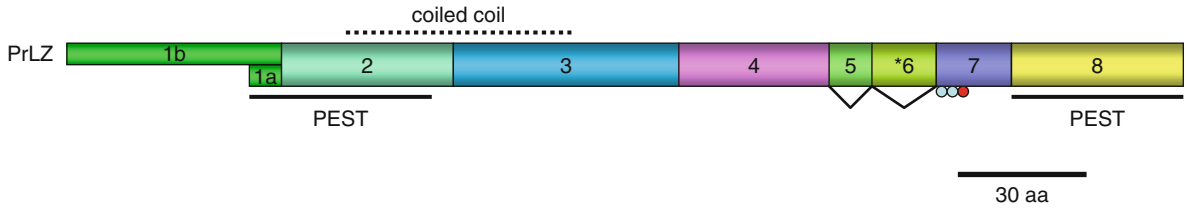
Mammalian *TPD52* sequences were first reported in the mid-1990s, through a number of independent approaches. Two early reports identified *TPD52* sequences through their increased expression in human cancer tissue or cell lines, relative to either nonmalignant tissues or fibroblast cell lines. Orthologous sequences from other species were identified as proteins phosphorylated in response to increased intracellular calcium, or as a retroviral target gene. Early reports also highlighted the existence of paralogous sequences in human and mouse, and *TPD52* is now known to be part of a four-member mammalian gene family. While TPD52-like sequences are well conserved both within and between species, they show little homology with those of other proteins.

Human TPD52 isoforms are approximately 200 residues in length, and represent largely hydrophilic peptides that lack predictors of catalytic activity. The sequences feature a coiled-coil motif of approximately 50 amino acids, and N- and C-terminally located PEST sequences, which have been linked with regulating protein stability (Fig. 1). A number of alternatively spliced *TPD52* transcripts have been either isolated or predicted. Notably, the use of an alternate gene promoter results in the inclusion of an alternate first exon, which produces a longer N-terminal domain (Fig. 1), and such isoforms have been termed PrLZ (prostate leucine zipper) or PC-1 (human prostate and colon-1). A number of internal exons may also be alternatively spliced, including an exon that encodes a putative 14-3-3 binding site (Fig. 1). Most alternative splicing events are not predicted to change protein molecular weights significantly, or to alter isoform detection through the use of C-terminally targeted TPD52 antisera. *TPD52* transcripts are also characterized by long 3'-untranslated regions, thus alternative splicing of small exons might not produce obvious changes to transcript length. Many expression microarray, Northern and Western blot analyses may have thus examined a number of TPD52 transcripts or isoforms simultaneously. For this reason, the term TPD52 will be used generically in this chapter, and isoform-specific identifiers will only be used when discussing functions proposed to be isoform specific. This chapter will also focus upon literature published from 2008, and references to other articles can be found in previous reviews (Boutros et al. 2004; Shehata et al. 2008).

Expression in Normal and Neoplastic Tissues

TPD52 is a predominantly cytoplasmic protein that is partitioned between soluble and insoluble cellular protein fractions, although a nuclear subcellular localization for TPD52 has been reported in some cell types. TPD52 is broadly expressed within normal tissues, with higher expression levels noted within epithelial tissues and mature B cells. While TPD52 expression is characteristic of differentiated cell types, TPD52 expression is also significantly increased in neoplastic tissues relative to corresponding normal tissues.

TPD52 protein is overexpressed in the majority of breast carcinoma samples, and present at increased copy number in a proportion of these cases. While TPD52 appears to be broadly overexpressed within breast carcinoma subtypes, TPD52 overexpression may be enriched in ERBB2-associated breast tumors (Natrajan et al. 2010). TPD52 overexpression has also been repeatedly identified in prostate cancer, with recent studies continuing to confirm this finding (Ummanni et al. 2008). TPD52 protein expression and gene copy number have been reported to be significantly increased in both primary and metastatic prostate cancer, and high TPD52 expression has also been detected in high-grade prostatic intraepithelial neoplasias. Multiple TPD52 isoforms have been



TPD52 (Tumor Protein D52), Fig. 1 Exon and domain organization of TPD52 isoforms. Sequence regions encoded by each exon are numbered and colored individually. The coiled-coil motif is shown as a broken line above the box diagram, whereas the PEST motifs are shown by solid lines below the diagram. Alternatively spliced exons are shown in shades of *green* (electronic version only), these being exons 1a, 1b, 5, and 6. Exon 1b encodes the longer N-terminal region characteristic of PrLZ isoforms, as indicated. Exons 5 and 6 are alternatively spliced in a cassette fashion, as indicated by diagonal lines below the sequence representation. Exon 6 encodes a putative 14-3-3 binding site, indicated by an asterisk. Examples of phosphorylation sites predicted by proteomics studies are shown as *blue* circles (electronic version, light grey in print version), and the confirmed phosphorylation site at Ser136 is shown by a *red* circle (electronic version, dark grey in print version). Note that these sites cluster after the insertion site of exons 5 and/or 6. The scale bar indicates 30 amino acid residues

shown to be overexpressed in prostate cancer, notably the alternative isoform PrLZ which derives from the use of an alternative first *TPD52* exon (Fig. 1). A number of studies have now associated increased TPD52 expression or copy number with poor patient survival in breast and other cancers. However, whereas TPD52 is also overexpressed in the majority of ovarian carcinomas, increased TPD52 expression is associated with significantly improved patient prognosis (Byrne et al. 2010). Understanding the nature of this paradox may highlight different cellular functions for TPD52 in different cancer types.

In addition to solid tumors, TPD52 overexpression has been reported in a number of different hematological malignancies, including multiple myeloma, where *TPD52* may represent an amplification target. Viral integrations within or upstream of *TPD52* genes have been identified in animal models of lymphomagenesis. Recently, increased *TPD52* copy number was reported in human cell lines of both solid and hematopoetic tumor origin, and viral integration sites were noted upstream of the *Tpd52* gene in lymphomas induced by the murine leukemia virus (Mattison et al. 2010).

Immunotherapeutic Targeting

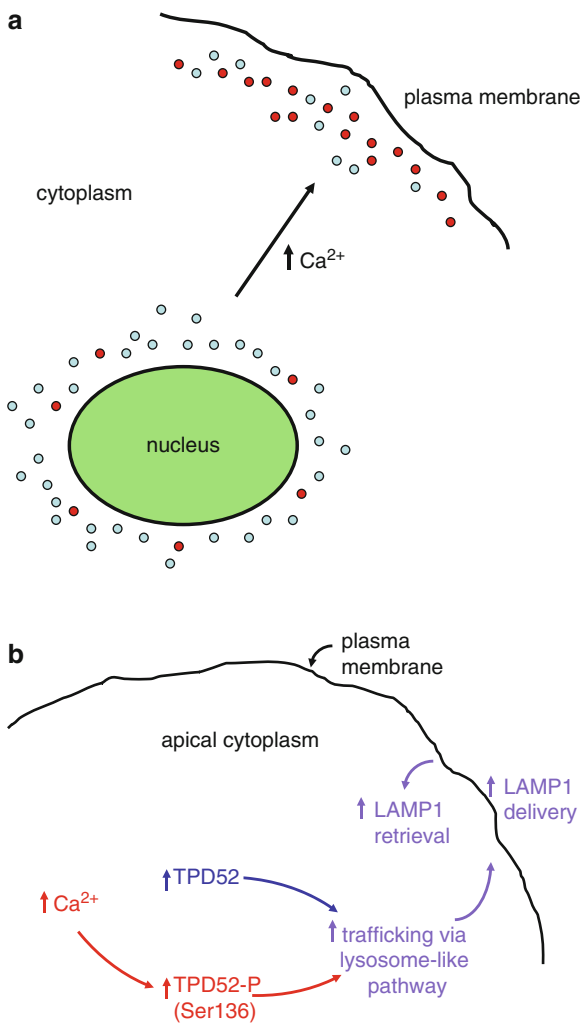
Widespread TPD52 overexpression in different cancer types, combined with the identification of TPD52 as a breast tumor antigen, suggests that TPD52 overexpression in cancer cells may produce immune responses that could be harnessed for cancer therapy. As a consequence, TPD52 overexpression has been targeted in different preclinical models using a number of vaccination strategies. The first such study employed recombinant glutathione S-transferase-TPD52 as a protein vaccine, and assessed the capacity of vaccinated animals to reject challenges of mKSA kidney tumor or 3T3.mD52 fibroblastic cells that endogenously or exogenously express *Tpd52*, respectively (Payton et al. 2008). A significant proportion of animals that had been immunized with a recombinant TPD52 protein vaccine rejected mKSA or 3T3.mD52 tumor challenges, and produced tumor-specific cytotoxic T lymphocyte responses (Payton et al. 2008). The same group then compared their previous recombinant TPD52 vaccine with a *TPD52* cDNA vaccine, in terms of rejection of subcutaneous TRAMP-C1 tumor cell challenges (Lewis et al. 2009). The DNA-based vaccine proved superior, in that immunized mice remained tumor-free for longer. Survivors of the initial tumor challenge rejected a second tumor challenge, and cytokine secretion patterns indicated that a T(H)1-type cellular immune response was involved in producing this tumor protection (Lewis et al. 2009). An independent group has employed overlapping synthetic peptides covering the TPD52 sequence to vaccinate inbred and outbred mice, which elicited specific CD8(+) and CD4(+) T-cell responses (Mirshahidi et al. 2009).

When TPD52-vaccinated BALB/c mice were then challenged with mouse breast carcinoma cells expressing endogenous TPD52, vaccinated animals showed significantly improved survival relative to unvaccinated controls (Mirshahidi et al. 2009). Notably, in all three studies, TPD52 vaccination was not accompanied by evidence of autoimmunity (Payton et al. 2008; Lewis et al. 2009; Mirshahidi et al. 2009), and thus TPD52-based vaccination may be a safe therapeutic strategy to test in human patients.

Cellular Functions

TPD52 expression has been associated with apparently opposing cellular functions typical of differentiated and cancer cells, respectively. On one hand, TPD52 positively regulates exocytosis, a physiological function of differentiated cell types, whereas TPD52 expression also promotes cell proliferation, anchorage-independent growth, and tissue invasion. A challenge for future research will be to determine whether the same or different molecular functions underpin these divergent cellular effects.

Numerous studies have linked TPD52 with exocytosis in different cell types. TPD52 orthologs were identified through being phosphorylated in response to secretory stimuli of gastric parietal and pancreatic acinar cells. Introduction of recombinant TPD52 protein into rat pancreatic acinar cells stimulated the secretion of amylase, and treatment of different cell types with secretagogue produces rapid translocation of TPD52 from supranuclear to subapical cytoplasmic compartments (Fig. 2a). However, the accumulation of TPD52 below the plasma membrane did not correspond with increased TPD52 being detected in membrane fractions (Thomas et al. 2010). TPD52 was found to promote lysosomal-associated membrane protein 1 (LAMP1) trafficking within a lysosome-like secretory pathway, and TPD52 overexpression could also enhance LAMP1 endocytosis (Thomas et al. 2010) (Fig. 2b). TPD52 has been previously found to co-localize with early endosomal markers, and has been reported in close proximity to structures resembling early endosomes in rat pancreatic acinar cells. Co-localization studies also suggest that TPD52 may be associated with endocytic compartments beyond that of the early endosome (Thomas et al. 2010).



TPD52 (Tumor Protein D52), Fig. 2 Diagrammatic representations of (**a**) the consequences of increased intracellular calcium in terms of TPD52 phosphorylation at Ser136 and subcellular localization, and (**b**) TPD52's role in LAMP1 trafficking via a lysosomal-like secretory pathway in cultured cells (from Thomas et al. 2010). (**a**) Increased intracellular calcium produces TPD52 translocation from the perinuclear and/or apical cytoplasm toward the plasma membrane, and increased TPD52 phosphorylation at Ser136. *Red* and *blue* circles (electronic version, dark and light circles in print version) represent TPD52 phosphorylated or not at Ser136, respectively. (**b**) Increased TPD52 expression and/or its calcium-dependent phosphorylation at Ser136 enhanced LAMP1 trafficking to the cell surface and retrieval. TPD52 was found to promote LAMP1 trafficking within a lysosome-like secretory pathway, and TPD52 expression also enhanced LAMP1 endocytosis. *Purple* text highlights functions which may be regulated by both increased TPD52 levels (shown in *blue*) and increased intracellular calcium and/or TPD52 phosphorylated at Ser136 (shown in *red*) Coloured text is visible in electronic version only

Cell line studies show that ectopic TPD52 expression in fibroblasts results in a transformed, metastatic phenotype, and increased PrLZ levels in prostate cancer cell lines further enhance proliferation and tumorigenicity. Increased PrLZ expression in LnCaP cells was shown to increase invasive but not migratory capacity using transwell assays, and was associated with increased cellular MMP-2 levels (Li et al. 2009). Similarly, while TPD52 knockdown reduced both migration and invasion by carcinogen-transformed bronchial epithelial cells, the effects on cellular invasion were more pronounced (Zhao et al. 2010). However, reduction in TPD52 levels also produces significant levels of apoptotic cell death in some cell lines, and so reported effects of TPD52 knockdown upon cellular migration and invasion may be indirect.

Phosphorylation

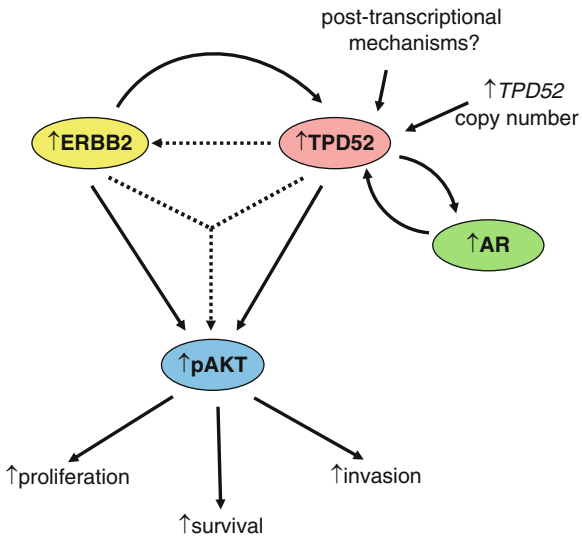
The identification of rabbit and rat TPD52 orthologs as phosphoproteins underscores the likely importance of protein phosphorylation in regulating their functions. Numerous studies indicate that TPD52 proteins from different species are phosphorylated on serine residues, and that phosphorylation occurs in response to increased intracellular calcium (Fig. 2a). Calmodulin kinase II or casein kinase II were both postulated as kinases responsible for TPD52 phosphorylation, with a calmodulin kinase II-like enzyme seeming the most likely candidate. Chew et al. (2008) identified rapid phosphorylation of TPD52 residue Ser136 (Fig. 1) in response to increased intracellular calcium, and presented evidence that the responsible kinase is a previously uncharacterized calmodulin kinase II isoform. The rapid phosphorylation of Ser136 in both HEK293 cells and mouse gastric glands was postulated to be related to exocytosis, which occurs over a similar time frame Chew et al. (2008). The identity of Ser136 as a key phosphorylation site was confirmed by Thomas et al. (2010), and accumulation of TPD52 at the plasma membrane in response to increased intracellular calcium was dependent upon Ser136 phosphorylation (Thomas et al. 2010) (Fig. 2b). Expression of a Ser136Ala TPD52 mutant also enhanced LAMP1 trafficking to the cell surface, but was not responsive to increased intracellular calcium (Thomas et al. 2010).

Signalling Functions and Binding Partners

TPD52 expression has been reproducibly associated with increased cell proliferation, and this may underpin reported associations between increased TPD52 expression in cancer, and poor patient prognosis. Numerous studies have now reported that *TPD52* transcripts are hormone inducible in breast and prostate cancer cell lines, although only isoforms produced from the alternative (*PrLZ* or *PC-1*) promoter may be hormonally regulated (Dutertre et al. 2010). Increased PrLZ expression has been previously associated with an androgen-resistant phenotype in prostate cancer cells. More recently, increased PrLZ expression in LnCaP cells was reported to increase the levels of the androgen receptor (AR) and secretion of prostate-specific antigen (Li et al. 2009). Increased TPD52 expression could contribute to an autocrine loop whereby androgen induces TPD52 expression and activity, which in turn increases AR expression (Fig. 3). In this way, increased TPD52 expression could contribute to the development of androgen resistance in prostate cancer.

A number of independent studies report positive associations between TPD52 expression and that of the receptor tyrosine kinase ERBB2 (Whiteaker et al. 2007; Natrajan et al. 2010) (Fig. 3). Accordingly, a meta-analysis of gene expression studies examining ERBB2-positive breast cancers and cell lines identified increased *TPD52* expression (Kourtidis et al. 2010). Subsequent TPD52 knockdown was associated with reduced viability of breast cancer cell lines, although these effects were not confined to ERBB2-positive cell lines (Kourtidis et al. 2010). A positive association between ERBB2 and TPD52 expression suggests that co-expression of these molecules may be more favorable than the expression of either independently (Fig. 3). That increased TPD52 levels may contribute to increased signalling downstream of ERBB2 is supported by PrLZ overexpression in LnCaP cells having been associated with increased Akt phosphorylation (Fig. 3) on Ser473 (Ummanni et al. 2008), and Thr308, as well as phosphorylation of the downstream targets GSK-3β and Raf.

How TPD52 might exert signalling functions at the molecular level is poorly understood. The primary sequence of TPD52 is largely uninformative in terms of predicting protein function, and protein partners identified to date (such as MAL2, and other



TPD52 (Tumor Protein D52), Fig. 3 Possible relationship between ERBB2, androgen receptor (AR), and TPD52 expression in cancer cells. Findings supported by the literature are shown by solid arrows, whereas proposed relationships are shown using broken arrows. Increased ERBB2 and TPD52 expression have been independently linked with increased Akt signalling. The positive relationship between ERBB2 and TPD52 expression identified through gene expression and proteomic studies is also shown. Concurrently increased ERBB2 and TPD52 expression suggests that these proteins might cooperatively increase Akt signalling, and its downstream effects. TPD52 could also regulate ERBB2 function through endocytotic mechanisms, although this is yet to be demonstrated. In addition, TPD52 expression is hormone responsive, and further elevated by other mechanisms such as gene amplification. Elevated TPD52 expression may also feed back to increase AR expression (Li et al. 2009), potentially creating an autocrine loop which contributes toward the development of androgen independence in prostate cancer

TPD52-like proteins) have undefined signalling functions themselves. TPD52 is known to associate with annexin VI, a negative regulator of EGFR signalling. Interactions between TPD52 and annexin VI have been shown to be calcium dependent, and as increased intracellular calcium also increases TPD52 phosphorylation at Ser136 Chew et al. (2008; Thomas et al. 2010), annexin VI might also bind TPD52 when phosphorylated at Ser136. While it is also tempting to speculate that TPD52 potentiates growth factor receptor signaling by negatively regulating annexin VI, such a mechanism might have more physiological than pathological relevance, as annexin VI expression may be reduced or lost in cancer cells.

While the molecular mechanism is currently unclear, a reasonable working hypothesis might be that TPD52 influences growth factor receptor signalling by modulating endocytosis (Fig. 3). Endocytosis is widely recognized as a mechanism by which receptor-mediated signalling may either be enhanced (by reducing the uptake of receptor–ligand complexes from the cell membrane, and/or promoting their recycling), or attenuated (by enhancing receptor–ligand degradation).

Summary

Despite being first identified over 15 years ago, the signalling functions of TPD52 remain largely elusive. Its expression is characteristic of both differentiated cell types and malignant cancer cells, and this may reflect different functions which predominate in physiological as opposed to pathological settings. Similarly, the differing clinical significance of TPD52 overexpression in different cancer types may reflect multiple functions for TPD52 proteins which may be selected under particular conditions. TPD52 appears to regulate both exo- and endocytosis, possibly by regulating a common function within these pathways, such as vesicle docking or fusion. That TPD52 overexpression plays a key role in tumorigenesis is evidenced by its representing an amplification target in tumors of diverse cellular origins, and a viral integration site in models of leukemia and lymphoma. To date, few studies have directly interrogated the signaling functions of this protein. More such studies will undoubtedly shed valuable light on the mechanisms by which increased TPD52 expression contributes to cellular transformation and tumor progression.

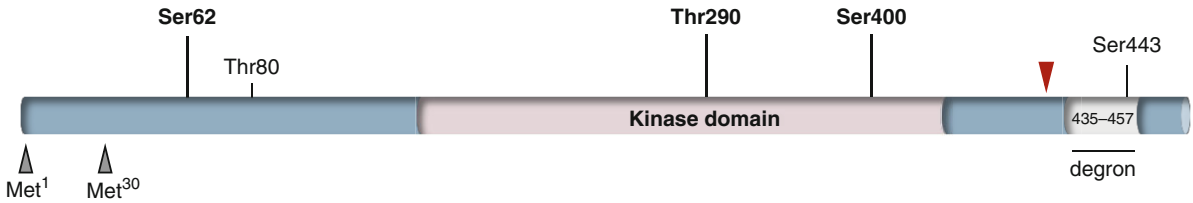
Historical Background

The *Tpl2* gene, also known as Cot and MAP3K8 (Vougioukalaki et al. 2011), was independently discovered by three research teams in the early 1990s. Cot (Cancer Ozaka Thyroid) was initially described by Miyoshi et al. as a putative human proto-oncogene found to have a rearranged 3′ end in the last coding exon (Miyoshi et al. 1991). The rat homologue of Cot, named *Tumor progression locus* (Tpl2) was identified by Tsichlis et al. as a proto-oncogene that is activated by provirus integration in Moloney murine leukemia (MoMuLV) virus-induced T-cell lymphomas (Patriotis et al. 1993). In mice, the *Tpl2* gene locus is also targeted by provirus insertion in mouse mammary tumor virus (MMTV)-associated mammary carcinomas (Erny et al. 1996). In both cases, provirus insertion occurs in the last intron of the gene and gives rise to a carboxy-terminally truncated protein with transforming capacity. In 1993, the normal *cot* gene was cloned and found to encode for an ORF of 467 aa that generates two protein isoforms of 58 and 52 kDa (Fig. 1) through the utilization of alternative translation initiation sites at methionine 1 and methionine 30 (Aoki et al. 1993). The homology of Tpl2 serine/threonine kinase domain to that of *Saccharomyces*



TPL2, Fig. 1 *Tpl2 primary structure and phosphorylation sites.* The normal *Tpl2* gene locus encodes two different cytoplasmic proteins (58 and 52 kDa) through the utilization of alternative translation initiation sites at methionine 1 and methionine 30. The catalytic domain of Tpl2 kinase activity is located in the center of the protein, bordered by the N-terminus and C-terminus. Several phosphorylation sites of Tpl2 have been identified within its kinase domain, including Thr^{290} and Ser^{400}. Both Thr^{290} and Ser^{400} phosphorylations are necessary but not sufficient for Tpl2 activation and occur prior to its dissociation from NF-κB1/ABIN2 complex. Ser^{62} becomes autophosphorylated and has been proposed to contribute to maximal Tpl2 activation. The C-terminus carries a reported "degron" sequence (aa 435–457) that targets Tpl2 for proteasomal degradation. NF-κB1 binds to and masks "degron" thus regulating Tpl2 stability and activity. C-terminal truncations that occur as a result of provirus insertion in MoMuLV-induced T-cell lymphomas and MMTV-induced mammary adenocarcinomas in rats (*red* arrowhead, aa 424) also remove the "degron" sequence, increasing the stability of Tpl2. The function of N-terminal region is still largely unknown

cerevisae gene product STE11 which is a mitogen-activated protein kinase kinase kinase (MAP3K) was the first indication that Tpl2 may act as a MAP3K.

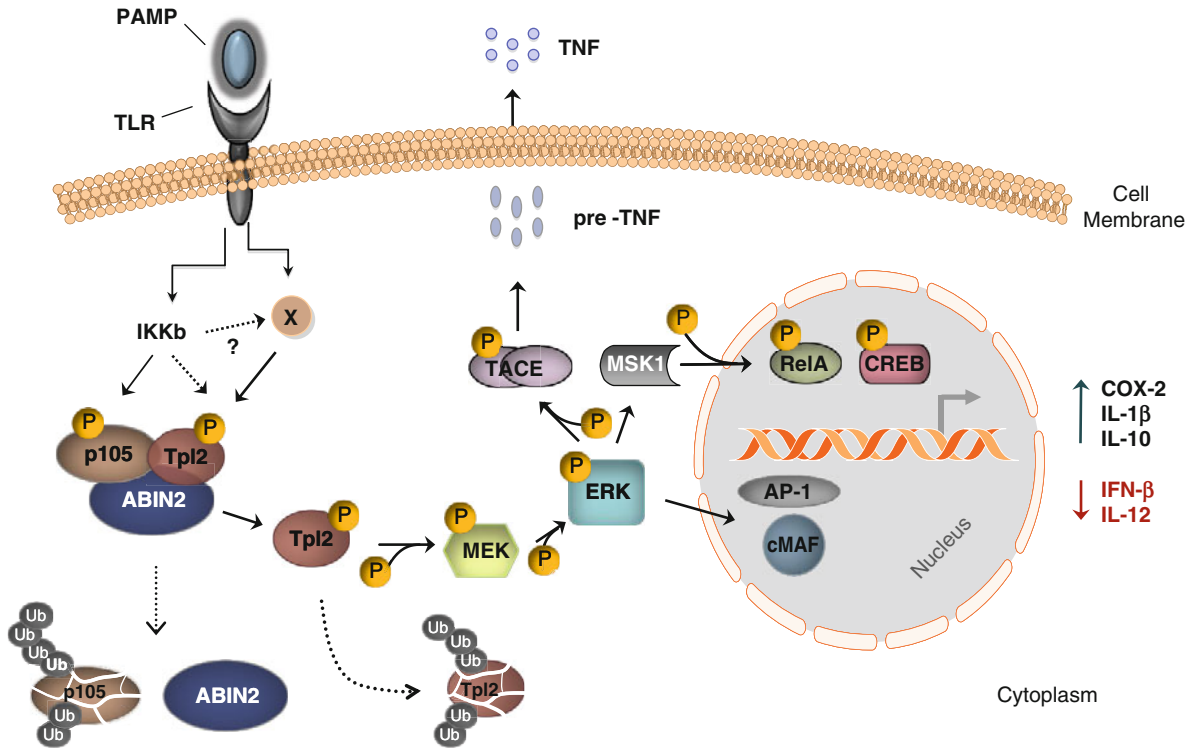
Tpl2 Signal Transduction

When overexpressed, Tpl2 activates several mitogen-activated protein kinases (MAPKs), including the extracellular-signal-regulated kinase (ERK1/2) which is its predominant target, c-Jun N-terminal kinase (JNK), and to a lesser extent p38 and ERK5 by directly phosphorylating their upstream kinases MKK4, MKK6, and MEK5, respectively (Ceci et al. 1997; Salmeron et al. 1996; Chiariello et al. 2000). Overexpression of Tpl2 also results in the transduction of ▶ NF-κB, AP-1 and ▶ NF-AT activation signals potentiating TCR-mediated transcriptional responses (Gomez-Casero et al. 2007; Lin et al. 1999; Tsatsanis et al. 1998a; Tsatsanis et al. 1998b) and in the regulation of the transcription factors c-fos and p53 (Fig. 2) (Choi et al. 2008; Khanal et al. 2009).

In comparison to wild-type Tpl2, expression of the oncogenic C-terminus-deleted Tpl2 associates with elevated catalytic activity and signaling capacity (Ceci et al. 1997). Three mechanisms have been proposed to explain this phenomenon. First, the truncated protein lacks an amino acid sequence called "degron" (aa 435-457) that targets wild-type Tpl2 for proteasomal degradation (Fig. 1) (Gandara et al. 2003). Second, the deletion has been suggested to abolish the intermolecular interaction between the C-terminal tail and the kinase domain of Tpl2, thus increasing its catalytic activity (Ceci et al. 1997). Finally, the C-terminus of Tpl2 is important for the efficient interaction with other proteins that regulate its stability and kinase activity such as the p50 ▶ NF-κB precursor NF-κB1/p105, which functions to sequester Tpl2 from its substrates (Beinke et al. 2003; Waterfield et al. 2003).

Studies in $Tpl2^{-/-}$ mice suggest that Tpl2 has an important physiological role in ERK signaling downstream of a plethora of receptors involved in innate and adaptive immunity including TLRs, CD40, TNF, and IL1 receptors (Banerjee et al. 2008; Das et al. 2005; Dumitru et al. 2000; Eliopoulos et al. 2003; Stafford et al. 2006). In addition to ERK, Tpl2 has been shown to contribute to JNK activation in TNF-stimulated fibroblasts and to be required for ▶ NF-κB transactivation by mediating the Msk1-dependent phosphorylation of the RelA (p65) ▶ NF-κB subunit at Ser^{276} (Das et al. 2005).

The precise molecular mechanisms which regulate Tpl2 activity are not fully defined. In steady state conditions, the entire pool of Tpl2 associates with p105 NF-κB1 (Beinke et al. 2003; Belich et al. 1999). Through this molecular interaction, NF-κB1 stabilizes Tpl2 by masking the "degron" sequence but also inhibits its kinase activity by preventing access to ▶ MEK1, the ERK kinase. The signal-induced phosphorylation of NF-κB1 at Ser^{927} and Ser^{932} by IKKβ leads to NF-κB1 degradation and release of Tpl2 from the complex. Liberated Tpl2 is active toward MEK1 but unstable and consequently undergoes rapid degradation via the proteasome, thus restricting prolonged activation of



TPL2, Fig. 2 *Intracellular signaling cascade involved in Tpl2 activation downstream of Toll-like receptors* (*TLRs*). The main cell signaling events involved in Tpl2 activation from ligation of TLRs by certain pathogen-associated molecular patterns (PAMPs) to translocation and/or activation of key transcription factors. At steady state, Tpl2 associates with the cytoplasmic NF-κB inhibitory protein p105 and ABIN-2. The p105-Tpl2 complex is functionally inactive and its activation involves signal-induced (PAMP) p105 degradation and the dissociation of Tpl2 from the complex. The signal-induced Tpl2 activation requires IKKβ, which phosphorylates p105 at Ser^{927} and Ser^{932} and triggers its proteolysis. Tpl2 is phosphorylated at Thr^{290} and Ser^{400} by as yet unknown kinase(s) (labeled as X) or through autophosphorylation at Ser^{62} while in complex with NF-κB1. Both Thr^{290} and Ser^{400} phosphorylations take place prior to Tpl2 dissociation from NF-κB1/ABIN2. Liberated Tpl2 is active toward MEK1 but unstable and consequently undergoes rapid degradation via the proteasome, restricting prolonged activation of MEK/ERK signaling. MEK phosphorylation of ERK results in activation of various transcription factors that may force the transcription of inflammation-related genes. ERK also mediates the phosphorylation of other kinases, such as Msk1, which contributes to the activation of the transcription factors RelA (p65 NF-κB) and CREB by phosphorylation at Ser^{276} and Ser^{133}, respectively. In addition, ERK is responsible for the post-transcriptional regulation of TNF synthesis. Pro-inflammatory cytokines, such as TNF and IL-1β, activate Tpl2 also through the IKKβ-mediated signals

ERK signaling (Waterfield et al. 2003). The A20 binding inhibitor of NFκB-2 (ABIN-2) is also important for stabilizing Tpl2 but is not required for its activation (Fig. 2) (Beinke et al. 2003; Papoutsopoulou et al. 2006).

Tpl2 is subject to phosphorylation at multiple sites including Thr^{290}, Ser^{400}, and Ser^{62} (Fig. 1) (Cho et al. 2005; Robinson et al. 2007; Stafford et al. 2006). Phosphorylations at Thr^{290} and Ser^{400} are stimulus-induced and are necessary although not sufficient for Tpl2 activation (Cho et al. 2005; Robinson et al. 2007). Both Thr^{290} and Ser^{400} phosphorylations take place prior to the dissociation of the catalytic subunit from NF-κB1/ABIN2. The phosphorylation at Thr^{290} is required for its release from p105 NF-κB1 and has been proposed to be mediated by IKKβ-dependent signals (Cho et al. 2005) or that it is an autophosphorylation event (Mieulet et al. 2010; Rousseau et al. 2008). The phosphorylation of Ser^{400} is believed to contribute to kinase activation through the induction of a conformational change which releases the inhibitory intermolecular interaction between the C-terminal tail and the kinase domain of Tpl2 (Robinson et al. 2007). Ser^{62} becomes autophosphorylated following IL-1 stimulation and has been proposed to contribute to maximal Tpl2 activation (Stafford et al. 2006).

The Functional Role of Tpl2 Kinase in Inflammation and Immunity

The establishment of Tpl2 knockout mice (Dumitru et al. 2000) allowed the analysis of the physiological role of Tpl2 kinase in inflammatory and immune responses. Tpl2-deficient mice were found to be resistant to LPS-induced endotoxic shock because of a defect in ERK activation, resulting in lower TNF-α and COX-2/prostaglandin E2 production by macrophages (Dumitru et al. 2000; Eliopoulos et al. 2002). Tpl2-deficient mice have also been studied in the context of an inflammatory bowel disease (IBD) mouse model ($TNF^{\Delta ARE}$). These mice exhibited attenuated progression of the disease, ablated TNFα-induced ERK activation in macrophages and low numbers of memory $CD4^+$ and peripheral $CD8^+$ lymphocytes showing that Tpl2 kinase regulates the lymphocytic response during progression of IBD (Kontoyiannis et al. 2002). Furthermore, Tpl2 kinase is a critical regulator of acute pancreatitis. In this case, non-myeloid expression of Tpl2 regulates pancreatic inflammation by mediating pro-inflammatory signals and the generation of neutrophil chemoattracting factors (MCP-1, MIP-2, and IL-6). The impact of Tpl2 was also shown in ligature-induced periodontitis (Ohnishi et al. 2010). Tpl2 is involved in the induction of RANKL, TNFα, COX-2, prostaglandin E2, and IL-1β and is essential for the progression of alveolar bone loss and osteoglastogenesis in periodontal tissue during experimental periodontitis (Ohnishi et al. 2010). In addition, Tpl2 kinase regulates obesity-associated metabolic dysfunction as Tpl2-defective mice exhibited improved insulin sensitivity with enhanced glucose uptake in skeletal muscle and increased suppression of glucose and lipid output in liver (Jager et al. 2009).

However, in certain disease models Tpl2 deficiency exacerbates the inflammatory response. Thus, in a mouse model of allergen (ovalbumin)-induced inflammation, $Tpl2^{-/-}$ mice produce considerably higher levels of both OVA-specific and total IgE than $Tpl2^{+/+}$ mice. It was proposed that the upregulation of IgE is correlated with increased secretion of Th2 cytokines such as IL-4 and IL-5 and decreased secretion of IFN-γ by $Tpl2^{-/-}$ T cells exposed to ovalbumin (Watford et al. 2010). The shift toward Th2 polarization of the T cell response to OVA in $Tpl2^{-/-}$ mice is in agreement with studies showing that the defense of Tpl2 knockout mice to *Toxoplama gondii* is impaired because of a T cell autonomous Th2 shift of the T cell response (Watford et al. 2008). Moreover, *Sugimoto* et al. showed that bone marrow–derived DCs from $Tpl2^{-/-}$ mice produce significantly more IL-12 in response to CpG-DNA than those from WT mice and showed Th1-skewed antigen-specific immune responses upon *Leishmania major* infection in vivo (Sugimoto et al. 2004).

Tpl2 may also participate in adaptive immune responses. Thus, it is required for the transduction of ERK activation signals initiated by CD40 engagement and contributes to IgE synthesis in response to IL-4 and anti-CD40 mAb stimulation in B lymphocytes (Eliopoulos et al. 2003). Several published reports suggest that Tpl2 also plays an important role in T cell activation and interleukin-2 production by inducing the transcription of related genes (Tsatsanis et al. 1998a, b).

The Impact of Tpl2 Kinase in Cancer

Early studies identified Tpl2 as a proto-oncogene activated by C-terminal truncation in mouse and rat. Indeed, transgenic mice expressing the truncated Tpl2 under the control of a T-cell-specific promoter develop T cell lymphoblastic lymphomas by the age of 3 months whereas expression of wild-type Tpl2 has no effect (Ceci et al. 1997). However, the role of Tpl2 in human malignancy remains enigmatic (Vougioukalaki et al. 2011). Elevated Tpl2 expression has been reported in human breast cancer, large granular lymphocyte proliferative disorders, natural killer (NK) cell lymphocytosis, gastric colon adenocarcinomas, Epstein-Barr virus (EBV)-related nasopharyngeal carcinoma, Hodgkin's disease, and other virus-related malignancies. Furthermore, increased expression and catalytic activity of Tpl2 promotes androgen depletion-independent (ADI) prostate cancer growth through the activation of the MEK/ERK signaling pathway and ▶ NF-κB (Jeong et al. 2011). In contrast, other studies suggest that Tpl2 may function as an inhibitor of tumor growth in certain cancer types. $Tpl2^{-/-}$ mice bred onto an MHC Class I-restricted T-cell antigen receptor transgenic (TCR2C) background develop $CD8^+$ T-cell lymphomas because of a defect in ERK-dependent CTLA4 induction that renders $CD8^+$ T lymphocytes to hyperproliferate in response to TCR signals. Thus, Tpl2 is required for full activation of ERK in response to TCR signals

(Tsatsanis et al. 20088). Moreover, Tpl2$^{-/-}$ mice exhibit a significantly higher incidence of tumors as well as increased signs of inflammation in chemically induced skin carcinogenesis model (Decicco-Skinner et al. 2011). In line with these findings, human melanomas carrying activating B-Raf mutations express reduced level of Tpl2 and Tpl2 copy number gains associate with resistance to Raf inhibitors (Johannessen et al. 2010). Therefore, Tpl2 may positively or negatively impact on oncogenesis depending on cell/organ type.

Summary

Tpl2 is a serine/threonine protein kinase with an obligatory role in the transduction of Toll-like receptor, death receptor, and G-protein–coupled receptor-mediated ERK MAPK signaling. Tpl2 catalytic activity and stability are closely intertwined and regulated through the interaction of Tpl2 with p105 NF-κB1 and ABIN2. The phosphorylation of Tpl2 is mainly dependent on its association with NF-κB1 and the presence of active IKKβ, an obligatory component of the canonical ▶ NF-κB pathway. The generation of Tpl2 knockout mice has contributed considerably to the delineation of the physiological role of Tpl2 in innate and adaptive immune responses. These studies have demonstrated both positive and negative effects of Tpl2 in inflammatory pathologies and tumorigenesis and warrant further analyses of the molecular mechanisms that govern its regulation and function.

TRAF6

Maréne Landström[1,2] and Reshma Sundar[1]
[1]Department of Medical Biosciences, Department of Pathology, Umeå University, Umeå, Sweden
[2]Ludwig Institute for Cancer Research, Uppsala University, Uppsala, Sweden

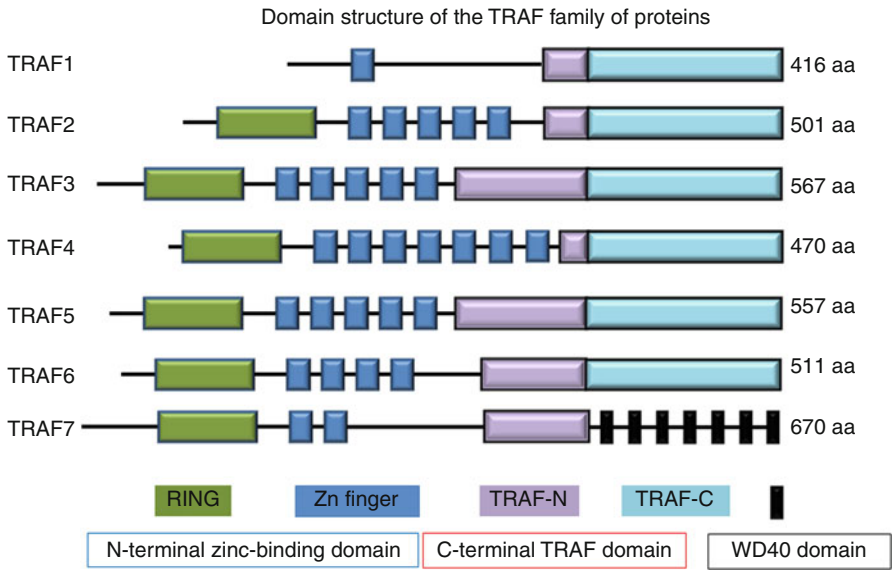
Synonyms

E3 ubiquitin-protein ligase, tumor necrosis factor receptor-associated factor 6 (TRAF6); Interleukin-1 signal transducer; Location chromosome 11p12; MGC:3310; RING finger protein 85 (RNF85)

Historical Background

TRAF Family

Tumor necrosis factor receptor-associated factors 1 and 2 (TRAFs) were initially identified as adaptor proteins that associate with the type-2 tumor necrosis factor



TRAF6, Fig. 1 Domain structures found in members of the tumor necrosis factor receptor-associated factors (TRAFs) family. TRAF1 lack the Really Interesting New Gene (RING) domain which possess ubiquitin ligase activity, while other domains found in TRAF1-TRAF7 are conserved with the exception of the C-terminal TRAF domain. In contrast, TRAF7 harbors seven WD40 domains in its C-terminal part

(TNF) receptor (TNF-R2) (Cao et al. 1996; Ishida et al. 1996; Rothe et al. 1994). The TRAF family members play important roles in the signal transduction cascades that regulate inflammatory responses via nuclear factor kappa-light-chain-enhancer of activated B cells (▶ NF-κB) and mitogen-activated protein kinases (MAPKs) that are initiated by activated cell surface receptors, such as TNF-R, interleukin 1 receptor (IL-1R), and Toll-like receptors (TLRs). The TRAFs have different cellular and physiological functions despite of their conserved C-terminal domain found in TRAF1-6 (Fig. 1). Unlike the other TRAFs, TRAF7 possesses several WD40 repeats in its C-terminal domain (Bouwmeester et al. 2004; Bradley and Pober 2001; Darnay et al. 2007; Xu et al. 2004). The TRAFs are genetically conserved in mammals (Arch et al. 1998), *Dictyostelium discoideum* (Regnier et al. 1995), *Caenorhabditis elegans* (Wajant et al. 1998), and *Drosophila* (Liu et al. 1999; Zapata et al. 2000).

In addition to inflammatory responses, TRAFs proteins regulate cell proliferation and survival. TRAF family members share a stretch of conserved sequence at their C-terminal domains known as the TRAF domain (Rothe et al. 1994). The TRAF domain is divided into a highly conserved carboxyl terminal region (C-domain), the TRAF-C sub-domain, and the coiled-coil amino terminal region and the TRAF-N sub-domain (Inoue et al. 2000). The TRAF domain mediates homo- and hetero-dimerization of TRAF family members, although TRAF4 shows a poor ability to associate with the other family members. The TRAF domain confers also direct or indirect interaction with the intracellular domain of cell surface receptors and signal transducers (Cheng et al. 1995; Kaufman and Choi 1999).

All TRAFs, except TRAF1 contain an amino terminal RING finger motif, in addition to the TRAF domain (Hsu et al. 1996). TRAF4 contains seven zinc finger domains while TRAF2, TRAF3, TRAF5, and TRAF6 have fewer zinc finger domains.

TRAF6

TRAF6 (Gene accession number of TRAF6 NM_004620, http://www.ncbi.nlm.nih.gov/gene/7189) was first identified independently as an adaptor protein, important for ▶ NF-κB activation, initiated by IL-1 and ▶ CD40. It was initially isolated using yeast two hybrid systems, using an EST expression library (Cao et al. 1996; Ishida et al. 1996). TRAF6 is a cytosolic protein although it is predominantly present in membrane bound cellular compartments (Dadgostar and Cheng 2000). TRAF6 contains a C3HC3D-type Really Interesting New Gene (RING) finger followed by five zinc finger regions in its N-terminus (Inoue et al. 2000). TRAF6 plays a specific role in innate and adaptive immune response apart from other diverse range of physiological processes (Naito et al. 1999) and (Lomaga et al. 1999) TRAF6 exists in a trimeric form at very high

concentrations. TRAF6 null mice have an abnormal phenotype of defective bone formation and die at early age (Lomaga et al. 1999; Naito et al. 1999)

TRAF6 functions as an E3 ubiquitin ligase that interact with the E2 conjugating enzyme Msm2, which consists of Ubc13 and Uev1A to synthesize lysine-63 linked polyubiquitin (Deng et al. 2000; Wang et al. 2001). The enzymatic activity of TRAF6 is promoted by its oligomerization and autoubiquitination on Lys124, which has been reported to be the key ubiquitin lysine acceptor site on TRAF6 (Bhoj and Chen 2009; Lamothe et al. 2007). Previously, it has been reported that TRAF6 interacts with tumor members of the TNFR family such as ▶ CD40 and RANK, IL-1R/Toll-like receptors (TLR) family members (Muzio et al. 1997; Suzuki et al. 2002; Wesche et al. 1999). Recent studies have demonstrated that TRAF6 also binds to the type I transforming growth factor β (TGFβ) receptor (TβRI) (Sorrentino et al. 2008).

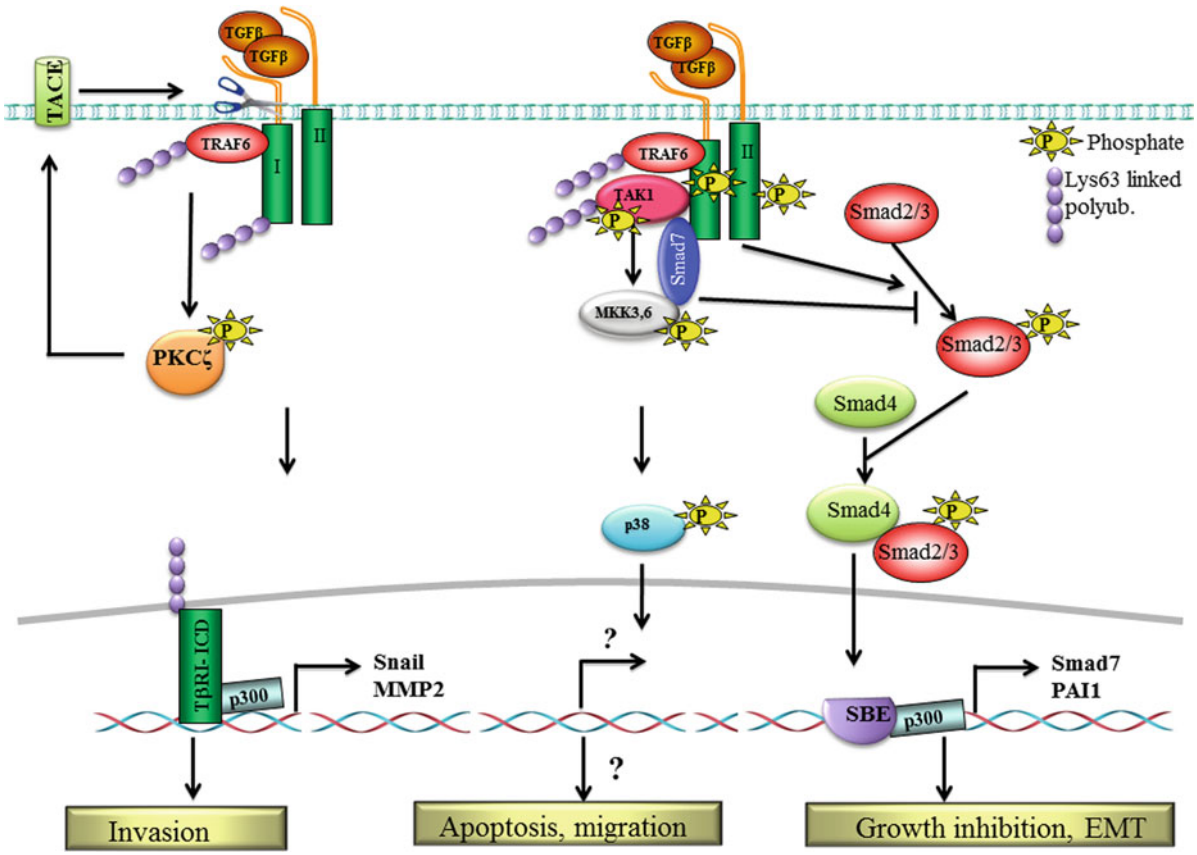
Role of TRAF6 for Smad-Independent TGFβ Signaling

TGFβ is a multifunctional cytokine involved in many critical cellular functions, such as growth arrest, differentiation, and apoptosis, which is a crucial event during embryogenesis, angiogenesis, and epithelial-mesenchymal transition (EMT) (Heldin et al. 2009; Heldin and Moustakas 2011; Massague 2008). TGFβ receptors are transmembrane serine/threonine kinase cell surface glycoproteins, which are expressed ubiquitously. TβRI is a 53 kDa protein and has a high specificity to bind to the TβRII to form a hetero-tetrameric complex. The TGFβ ligand initially binds to the TβRII, this enhances the affinity between TβRII and TβRI and thereby TβRII phosphorylates TβRI at the unique GS domain, which is located in the start of its kinase domain (Groppe et al. 2008; Wrana et al. 1994; Yamashita et al. 1994). When the receptor complex is activated, Smad-dependent and Smad-independent pathways are activated (Heldin and Moustakas 2011; Mu et al. 2011b) (Fig. 2).

TGFβ is known to transduce signals through Smad proteins as well as non-Smad mediators, like extracellular signal-regulated kinases (ERKs), the small GTPases Rho, Rac, Cdc42, c-Jun N-terminal kinases (JNKs), and mitogen-activated protein kinase (MAPK) (Derynck and Zhang 2003; Landstrom 2010; Mu et al. 2011a).(Yamaguchi et al. 1995) originally showed that transforming growth factor-β activated kinase-1 (TAK1), a member of mitogen-activated protein kinase kinase kinase (MAPKKK) family, functions as a mediator in a signaling pathway of TGFβ superfamily members. TAK1 regulates various cellular responses like cell survival through activation of JNK, p38 MAPK and inflammatory responses via IκB kinase (IKK) pathways (Adhikari et al. 2007; Landstrom 2010; Thakur et al. 2009). TAK1 is also crucial for the activation of LKB1 serine/threonine kinase which in turn control cell metabolism, growth, and polarity (Adhikari et al. 2007; Landstrom 2010; Mu et al. 2011a; Shaw 2009; Thakur et al. 2009).

Later, Sorrentino et al. 2008 and Yamashita et al. 2008 reported that TRAF6 is crucial for the activation of downstream targets p38 MAPK pathway in TGFβ signaling cascade, through its enzymatic activity as an E3 ligase. Sorrentino et al. showed that TRAF6 constitutively binds to conserved consensus motif (basic residue-X-P-X-E-X-X-aromatic/acidic acid) TGF-β type 1 receptor (TβR1) and this interaction leads to the autoubiquitination of TRAF6, in response to TGFβ-stimulation of cells which in turn causes Lys63-linked polyubiquitination of TAK1 at Lys-34 (Sorrentino et al. 2008). The kinase activity of TAK1 might be inhibited by N-terminal part of TAK1 itself (Yamaguchi et al. 1995); therefore, it is possible that this cascade of events then leads to the activation of TAK1 either due to a conformational change to open up its structure or recruitment of the TAK1 binding proteins 2 and 3 (TAB2 and 3) (Landstrom 2010; Sorrentino et al. 2008). Kim et al. (2009) reported that TGFβ-induced autoubiquitination of TAK1 recruits the adaptor molecule TAB1.

Recently, Mu et al. (2011b) showed a novel TRAF6-dependent pathway by which TGFβ mediates its oncogenic effects. TRAF6 binds to TβRI via conserved consensus site and upon TGFβ-induced autoubiquitination and activation, TRAF6 causes Lys63-linked polyubiquitination of TβRI. In cancer cells, TβRI undergoes cleavage by TNF-alpha converting enzyme (TACE) in a PKCζ-dependent manner and the intracellular domain (ICD) of cleaved TβRI translocate to the nucleus where it associates with the transcriptional regulator p300 and the snail promoter (Fig. 2). The association of TβRI ICD to p300 and the snail promoter enhances tumor invasion by induction of pro-invasive genes such as *snail* and *MMP2*. The negative regulation of TGFβ signaling



TRAF6, Fig. 2 TGFβ-induced Lys63-linked polyubiquitination and subsequent activation of the ubiquitin ligase TRAF6 causes PKCζ-dependent activation of TNF-alpha converting enzyme (TACE) which results generation of an intracellular fragment of the type I TGFβ receptor (TβRI-ICD) which enters the nucleus where it associates with components of the transcriptional complex, such as p300 and promotes expression of the pro-invasive genes *Snail* and *MMP2*. TRAF6 associates via a conserved consensus site in the TβRI to promote noncanonical and Smad-independent pathways, to cause Lys63-linked polyubiquitination and activation of the TAK1-MKK3/6-p38 MAPK pathway. In contrast, TRAF6 is not required for canonical TGFβ-induced activation of the Smad-signaling pathway, where the activated Smad-complex binds to Smad-binding elements (SBE) in their specific target genes, such as Smad7. Epithelial to mesenchymal transition (EMT) is regulated by the canonical TGFβ-induced Smad-pathway

due to the ectodomain shedding of TβRI by TACE was previously reported by Liu et al. (2009). Their report suggests that the TACE-mediated ectodomain shedding of TβRI also results in reduced TGFβ-mediated growth inhibition and EMT.

Summary

TRAF6 is an important enzyme causing Lys-linked polyubiquitination of its substrates to promote proinflammatory responses downstream of members of the TNF-R, IL-1R and TLR families. Recently, TRAF6 was also identified to be a crucial regulatory enzyme for Lys63-linked activations of TAK1 and TACE-dependent cleavage of TβRI. The identification of TRAF6 as a key regulator of TGFβ-induced tumor invasion will hopefully help to design novel inhibitors to prevent tumorigenic effects.

TRAIL Receptor 1/2 (Death Receptor 4/5, DR4/5)

Eun-Sil Sung and Yong-Sung Kim
Department of Molecular Science and Technology, Ajou University, Yeongtong-Gu, Suwon, South Korea

Synonyms

TRAIL-R1 (tumor necrosis factor-related apoptosis-inducing ligand receptor 1); TRAIL-R2 (tumor necrosis factor-related apoptosis-inducing ligand receptor 2)

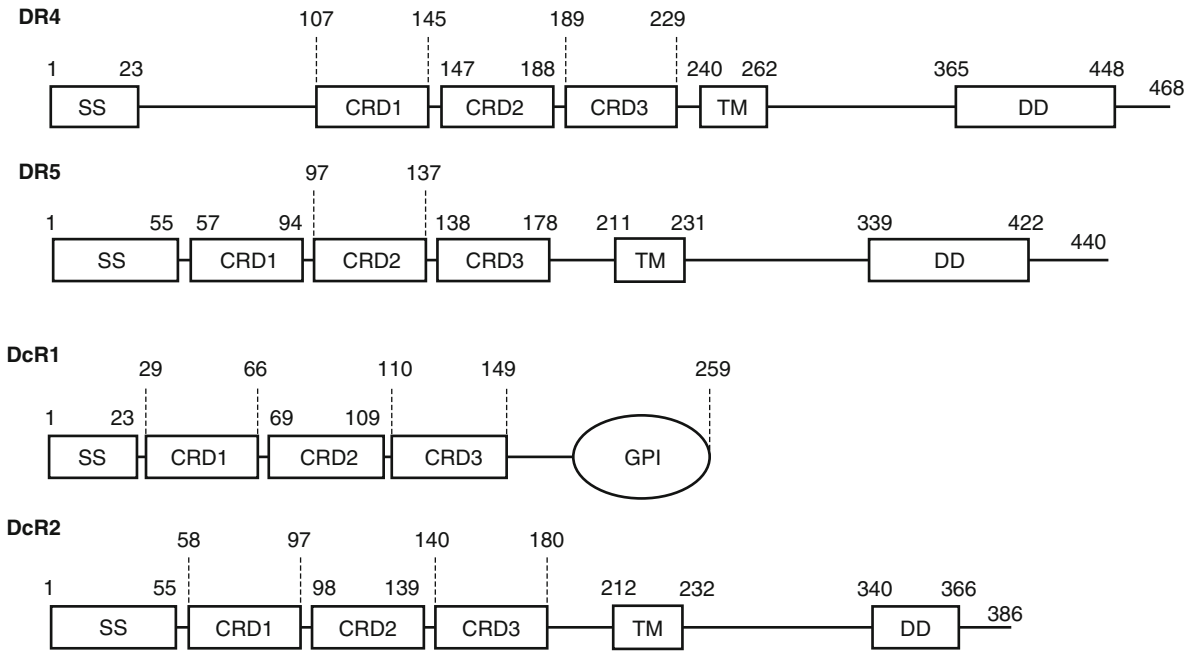
Historical Background

The *tumor necrosis factor* (*TNF*)-related apoptosis inducing ligand (TRAIL, *Apo2L*) identified in the middle of 1990s (Pitti et al. 1996; Wiley et al. 1995) was given its name due to its ability of inducing apoptosis and its high homology to other TNF member ligands. Then, its first receptor, death receptor 4 (DR4, TRAIL-R1), was identified by searching an EST database for sequences related to the *TNF receptor*-1 (*TNFR*1) death domain (DD) (Pan et al. 1997b). Thereafter, by virtue of its sequence homology to the DR4 DD, death receptor 5 (DR5, TRAIL-R2) was also cloned independently by two groups (MacFarlane et al. 1997; Walczak et al. 1997). Both DR4 and DR5 are belonging to members of the *TNF receptor superfamily (TNFRSF)*. However, unlikely with TNFRSF receptors containing the intracellular DD, such as TNFR1 and *CD95*, DR4 and DR5 are capable of transmitting tumor cell-selective apoptosis signaling upon activation by ligation with the cognate ligand of TRAIL (Ashkenazi 2008; Johnstone et al. 2008). DR4 and DR5 share a sequence identity of 58%, and their fucntions are largely redundant. However, recent studies with the receptor-specific monoclonal antibodies (mAbs) and TRAIL mutants have shown that some tumor cells undergo apoptotic cell death through signaling by either pro-apoptotic DR4 or DR5, but not both (Sung et al. 2009).

The two additional membrane receptors, decoy receptor 1 (DcR1/TRAIL-R3/TNFRSF10C/TRID) and decoy receptor 2 (DcR2/TRAIL-R4/TNFRSF10D/TRUNDD), were also identified by sequence homology search with the extracellular domain of DR4 and DR5 (MacFarlane et al. 1997; Marsters et al. 1997; Pan et al. 1997a). DcR1 completely lacks the intracellular DD and is anchored to the membrane via a glycophosphatidyl inositol (GPI) tail, whereas DcR2 is a type I transmembrane protein, but contains a truncated DD (Marsters et al. 1997). Due to the lack of functional DD, the two decoy receptors are not capable of inducing apoptosis. However, they may protect cells against TRAIL-mediated apoptosis by competing with DR4 and DR5 for binding to the ligand (Ashkenazi 2008; Johnstone et al. 2008). In addition to these four cell-surface expressed receptors, a soluble receptor called osteoprotegerin (OPG) was identified to bind to TRAIL with low affinity (Emery et al. 1998).

Structural Features of DR4 and DR5

DR4 and DR5 are single pass type I membrane proteins. The primary structural features of DR4



TRAIL Receptor 1/2 (Death Receptor 4/5, DR4/5), Fig. 1 Schematic representation of the primary structure of membrane-bound TRAIL receptors, DR4, DR5, DcR1, and DcR2 proteins. The secretion signal sequence (SS), cysteine-rich domain (CRD), transmembrane domain (TM) and intracellular death domain (DD) were highlighted in box. Numbers designate amino acids based on the following NCBI reference sequence: DR4 (NP_003835), DR5 (NP_003833), DcR1 (NP_003832), and DcR2 (NP_003831)

(468 residues) and DR5 (440 residues) include a secretion signal, three cysteine-rich domains (CRDs) in the extracellular regions, a transmembrane domain and a death domain in the intracellular regions (Fig. 1). CRD, present from 1 to 6 in all TNFSF receptors in the extracellular regions, is defined by six highly conserved cysteines that form three intrachain disulfide bridges. Both DR4 and DR5 have one partial CRD1 with only one cysteine bond and two complete CRDs, CRD2 and CRD3, with the three cysteine bonds (Cha et al. 2000). Interestingly, DR5 can be expressed in two alternatively spliced isoforms, DR5A/TRICK2A (short) and DR5B/TRICK2B (long): the short isoform of DR5A lacks 29 amino acids by missing the extracellular residues between 185 and 213 of the canonical long isoform of DR5B (Screaton et al. 1997). However, DR5A and DR5B have not shown any functional differences among each other. Secondary structural analysis of the extracellular domain of DR4 and DR5 showed ~15% β-sheet and ~85% unordered secondary structure.

Like the other four TNFRSF receptors containing the DD, the intracellular part of DR4 and DR5 contains an ~80 amino acid long, conserved domain called the DD (MacFarlane et al. 1997; Pan et al. 1997b; Walczak et al. 1997). This structural motif is essential for interaction with a key adaptor protein that is required for transmission of the death signal. Determination of the solution structure of the intracellular DDs of Fas, FADD, and TNFR1 DD by NMR spectroscopy has shown that the DD shares a common secondary structural feature, consisting of six antiparallel amphipathic α-helices packed into a globular structure, despite of low sequence homology below 30% (Fig. 2). Thus the DDs of DR4 and DR5 share less than 30% identity with those of other TNFRSF receptors (Fig. 2), which may be responsible for their different specificity in intracellar signaling through distinct protein–protein interactions. However, the DD of DR4 shares ~63% identity with that of DR5 (Fig. 2), indicative of their redundant functions.

The extracellular domain DR5 protein forms a compact 3:3 complex with TRAIL, where TRAIL forms a central homotrimer around which three DR5 molecules snuggled into long crevices between pairs of

TRAIL Receptor 1/2 (Death Receptor 4/5, DR4/5), Fig. 2 Sequence alignment (**a**) and sequence homology in percentage (**b**) of the intracellular death domain (DD) of the six TNFRSF receptors. The following NCBI reference sequence was used in the analysis : DR4 (NP_003835), DR5 (NP_003833), TNFR1 (NP_001056), Fas (CD95) (NP_000034), DR3 (NP_003781), DR6 (NP_055267). The multiple sequence alignment form and results found in UniProtKB/Swiss-Prot

monomers of the homotrimeric ligand (Cha et al. 2000). There has been no report yet about tertiary structures of DR4 alone or in complex with TRAIL.

Cell and Tissue Expression of DR4 and DR5

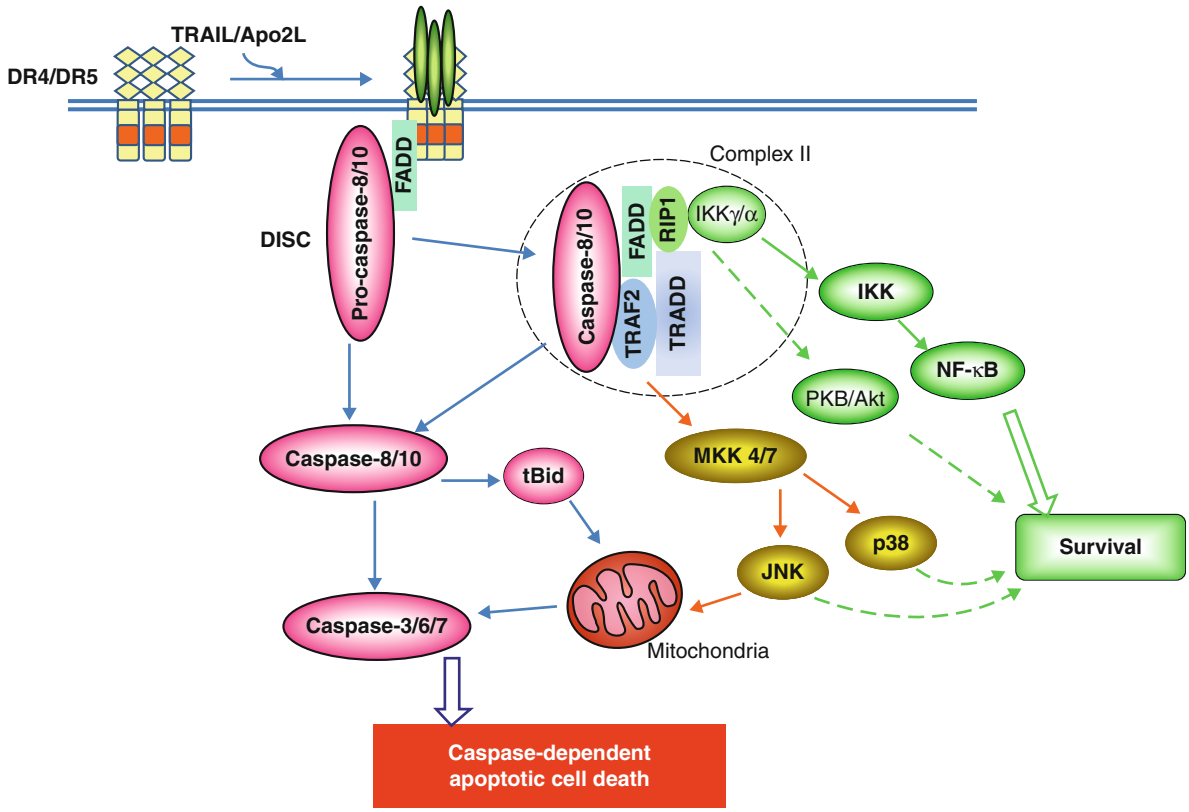
Cellular surface expression of DR4 and DR5 has been reported for a broad spectrum of cancer lines and/or primary tumor cells isolated from tissues, including lung, blood, skin, bone, breast, ovary, thyroid, and the brain (Fox et al. 2010; Johnstone et al. 2008). Weak, but detectable DR4 and/or DR5 expression has been identified by flow cytometry on the surface of normal cell types, including hepatocytes, keratinocytes, astrocytes, and osteoblasts (Fox et al. 2010; Johnstone et al. 2008). Noticeably, however, there has been no definite correlation between expression levels of DR4 and/or DR5 at both the mRNA and protein level, and the susceptibility to apoptosis by the agonist treatments (Ashkenazi 2008; Fox et al. 2010; Johnstone et al. 2008). Although most tumor cells co-express DR4 and DR5 to some degree, DR5 is expressed more widely by both tumor cells and normal tissue than DR4 (Johnstone et al. 2008). A specific physiological role for either DR4 or DR5 has yet to be defined, although the existence of two death receptors for the same ligand might suggest an essential role in tissue homeostasis.

DR4- and DR5-Mediated Signaling

TRAIL has been highlighted as a tumor selective molecule that transmits death signal via ligation to the pro-apoptotic receptors, DR4 and DR5 (Ashkenazi et al. 1999). When stimulated by either TRAIL or agonistic mAbs, DR4 and/or DR5 can mediate apoptotic cell death in most of TRAIL-sensitive cancer cells dominantly through the sequential activation of caspases (Fig. 3) (Ashkenazi 2008; Johnstone et al. 2008). Depending on the external stimuli and specific cell types, however, DR4 and/or DR5 can also transduce multiple cellular signaling pathways in a caspase-dependent or caspase-independent manner, involved in cell survival, differentiation, and death (Figs. 3 and 4) (Pennarun et al. 2010).

Caspase-Dependent Apoptosis Signaling

Binding of trimeric or multimeric TRAIL to the pro-apoptotic receptors results in the receptor clustering to activate the intracellular DD and recruit Fas-associated death domain (FADD) and then the initiator caspases, caspase-8 and/or −10, similarly to what occurs when Fas (CD95) is activated (reviewed in (Gonzalvez and Ashkenazi 2010). This primary signaling complex, consisting of ligand, receptor, FADD, and apical caspase(s), is called the death-inducing signaling complex (DISC) (Gonzalvez and Ashkenazi 2010). Activated caspase-8/10 by the DISC formation triggers



TRAIL Receptor 1/2 (Death Receptor 4/5, DR4/5), Fig. 3 The major signaling pathways of DR4 and DR5. DR4 and DR5 upon activation by the cognate ligand TRAIL multimerize and undergo some conformational change to activate their intracellular death domain to form the primary signaling complex DISC by recruiting FADD and caspase-8 and/or -10. The secondary signaling complex II can be formed, the components of which vary depending on the specific conditions, as described in detail in the text. The primary and secondary signaling complex mainly activate the initiator caspases, caspase-8 and/or -10, which subsequently activate the effector caspases, such as caspase-3, -6, and -7 via the extrinsic and intrinsic pathway, leading to the typical apoptosis. Beside activating caspases, TRAIL may stimulate intracellular kinase cascades such as NF-κB, JNK, p38 MAPK, and PKB/Akt pathways, the final outcomes of which vary depending on the cellular context and specific conditions

the extrinsic pathway by directly activating the downstream effector caspases, such as caspase-3, -6, and -7, which in turn cleave many cellular substrates to exert apoptosis (Fig. 3). The extrinsic pathway can be amplified by cross-talk with the intrinsic pathway, the link of which is Bid cleavage by activated caspase-8 (Ashkenazi 2008; Johnstone et al. 2008). Cleaved Bid (tBid) induces oligomerisation of pro-apoptotic Bax and/or Bak, leading to the release of cytochrome c and Smac/Diablo from mitochondria into cytoplasm and activation of caspase-9 (Ashkenazi 2008; Johnstone et al. 2008). The mitochondrial pathway eventually activates the effector caspases to execute apoptotic cell death. In some cells (designated Type I cells), caspase-8 activation is sufficient to activate the effector caspases to execute apoptosis via the extrinsic pathway, whereas, in other cells (designated Type II cells), amplification of the extrinsic pathway through the intrinsic (mitochondrial) pathway is needed to commit the cells to apoptotic cell death (Pennarun et al. 2010; Sung et al. 2009).

Activation of the initiator caspase-8/10 at DISC can be inhibited, subsequently decreasing the apoptosis signaling through the extrinsic and/or intrinsic pathways. The anti-apoptotic protein of cellular FLICE-inhibitory protein (c-FLIP) can also be recruited to the DISC to replace caspase-8, forming inactive DISC to inhibit the following downstream signaling. Furthermore, DcR1 and DcR2 might form ineffective DISC via heteromeric complex formation with DR4

and/DR5, leading to blocking the following apoptosis signaling (Fox et al. 2010; Pennarun et al. 2010).

In addition to the cognate ligand of recombinant TRAIL, a number of agonistic monoclonal antibodies (mAbs) have been developed by targeting DR4 or DR5, which also induce cell death in various types of tumors in vitro and in vivo (reviewed in Ashkenazi 2008; Fox et al. 2010; Johnstone et al. 2008). More recently, alternative protein scaffold based on human Kringle domain (Lee et al. 2010) and peptides (Pavet et al. 2010) isolated against DR4 or DR5 have been reported to specifically bind to activate DR4 and/or DR5, leading to tumor cell-selective apoptotic cell death. Some of them are now under various phases of clinical trials (Fox et al. 2010; Johnstone et al. 2008). The cell death mechanism of most agonistic mAbs against DR4 or DR5 has been reported to be similar to that of TRAIL, inducing caspase-dependent apoptotic cell death through forming the canonical DISC in the intracellular domain of DR4 and/or DR5 (Ashkenazi 2008).

The receptor-specific agonistic mAb studies demonstrated that, while various solid tumors were more sensitive to DR5-mediated apoptosis than DR4-induced apoptosis, primary chronic lymphocytic leukemia (CLL) cells underwent apoptotic cell death almost exclusively through DR4, not DR5 (MacFarlane et al. 2005), indicative of distinct functions of DR4 and DR5 depending on the specific type.

Kinase Activation Signaling

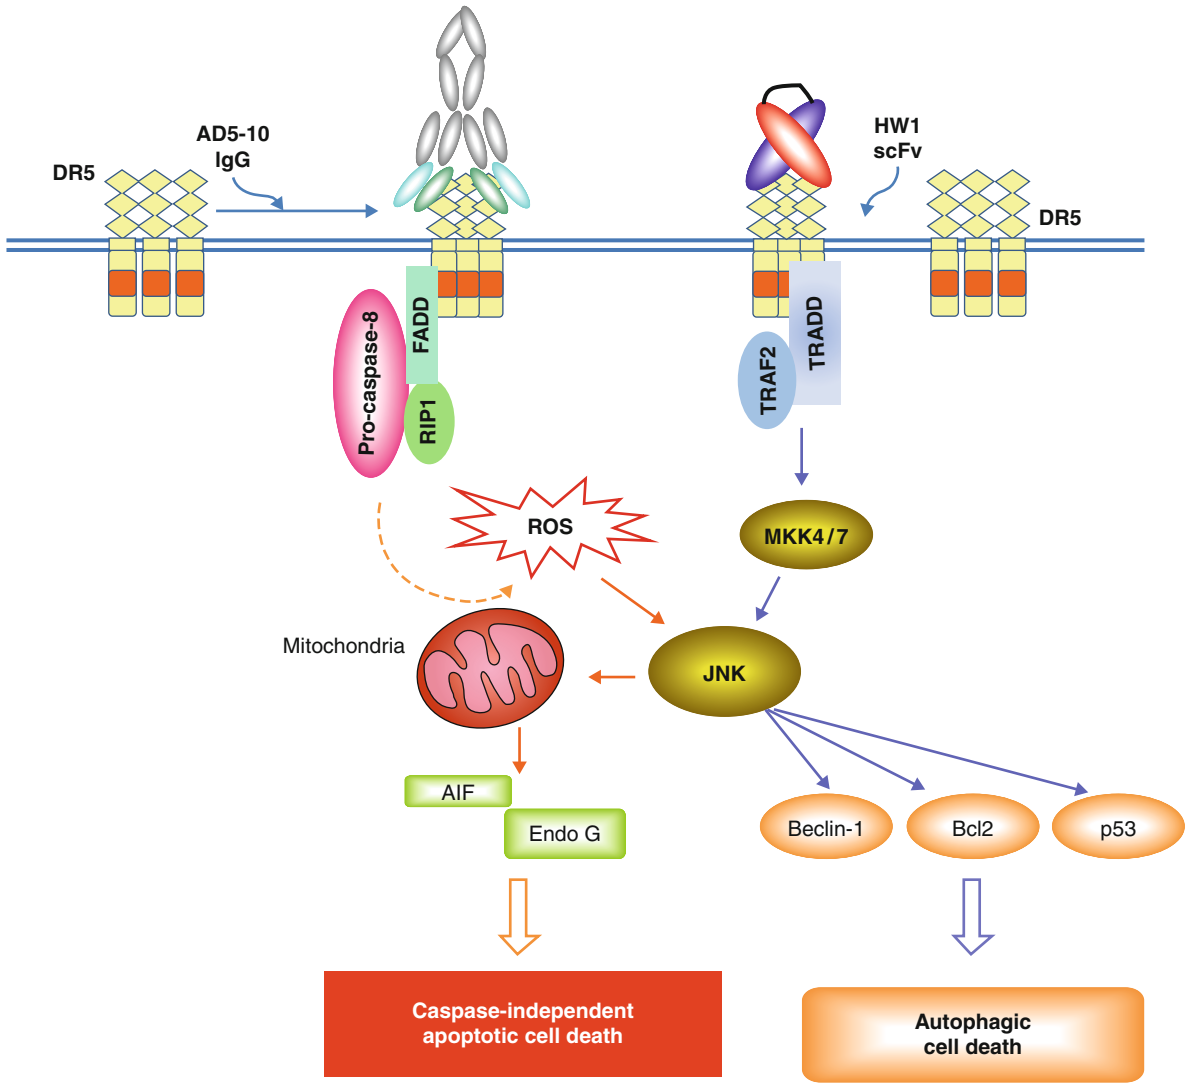
In addition to caspase activation by forming the canonical DISC, TRAIL stimulation of DR4 and/or DR5 can activate several kinase pathways, including nuclear factor (NF)-κB (NF-κB), c-Jun N-terminal kinase (JNK), and p38 mitogen-activated protein kinase (MAPK), either by forming a secondary signaling complex in the downstream of DISC or by forming different signaling complex at the intracellular domain (Gonzalvez and Ashkenazi 2010; Pennarun et al. 2010).

Mühlenbeck et al. (2000) showed that TRAIL stimulation can lead to JNK activation, which occurs in a cell type-specific manner. TRAIL-induced JNK activation was dependent on caspase activation in HeLa cells, whereas it was not in Kym-1 cells, indicative of the two independent pathways leading to JNK activation. Further, JNK activation was independent of FADD in HeLa cells, suggesting another adaptor molecule to DR4/DR5 might be involved in the JNK activation. The group also showed that DR4 and DR5 have different capabilities for stimulating the JNK pathway: DR4 can signal NF-κB activation and apoptosis, whereas DR5 can signal NF-κB activation, apoptosis, and JNK activation (Muhlenbeck et al. 2000). However, detailed studies to analyze the molecular components involved in the signaling pathway had not been done.

Lin et al. (2000) had shown that RIP1 was essential for TRAIL-induced NF-κB and JNK activation, but not required for the apoptosis. Askenazi group (Varfolomeev et al. 2005) had shown in detail that TRAIL stimulation in HT1080 human fibrosarcoma cells leads to activations of kinase pathways by promoting the association of a secondary signaling complex II at the downstream of the primary DISC assembly (Fig. 3). The signaling complex II retained the DISC components FADD and caspase-8, but recruited several additional factors, such as Receptor interacting protein 1 (RIP1), TNF receptor-associated factor 2 (TRAF2), and I-κB kinase subunit gamma (IKKγ/NEMO). TRAIL stimulation of JNK and p38 further depended on receptor interacting protein 1 (RIP1) and TRAF2, whereas the inhibitor of κB kinase (IKK) activation required IKKγ/NEMO. More recently, Jin and El-Deiry (2006) showed that TRAIL can induce formation of a complex II containing FADD, RIP, IKKα, and caspase-8 and -10, leading to activation of caspase-8. Thus they showed that TRADD and caspase-10 can be recruited to the signaling complex II.

Secchiero et al. (2003) also showed that TRAIL could activate the protein kinase B (PKB/Akt) and extracellular signal-regulated kinase 1//2 (ERK1/2), without NF-κB, p38 and JNK activations in primary human umbilical vein endothelial cells (HUVECs) and aortic endothelial cells, thereby promoting the cell survival. However, the detailed molecular mechanisms are not completely understood.

Ohtsuka et al. (2003) also reported that, using agonistic anti-DR4 2E12 and anti-DR5 TRA-8 mAbs, both DR4 and DR5 have a capability to activate JNK and p38, which was mediated by MAPK kinase 4 (MKK4). The JNK/p38 signaling activated the mitochondrial apoptosis pathways, leading to caspase-dependent apoptotic cell death of breast MDA-MB-231 cell lines. However, they did not examine the signaling complex recruited to each receptor after mAb



TRAIL Receptor 1/2 (Death Receptor 4/5, DR4/5), Fig. 4 A noncanonical signaling of DR5 triggered by the agonistic antibodies. Recent studies with anti-DR5 agonistic antibodies have shown that the intracellular domain of DR5 has more potential to provide a platform for the formation of multiprotein signaling complexes, which initiating JNK-activation dependent apoptosis and autophagy. For example, mouse anti-DR5 AD5-10 mAb induced apoptotic cell death in Jurkat cells via ROS generation, sustained JNK activation, loss of mitochondrial membrane potential, and Endo G release from mitochondria to the cytosol. A human anti-DR5 scFv, HW1, activated JNK via forming a signaling complex composed of TRADD and TRAF2 at the intracellular domain of DR5 and sequentially upregulated Beclin-1 expression and induced the phosphorylation of Bcl-2 and p53, leading to DR5-mediated autophagic cell death

stimulation. Sah et al. (2003) reported that JNK activation is required for sensitization of prostate PC3 cells to TRAIL-induced apoptosis by translation inhibitors in cells that are otherwise TRAIL-resistant.

Zheng group (Chen et al. 2009) showed that, while TRAIL induces only caspase-dependent cell death, an anti-DR5 agonistic mAb, AD5-10, induces both caspase-dependent and caspase-independent cell death in Jurkat cells. AD5-10-mediated stimulation of DR5 generated reactive oxygen species (ROS) accumulation, which subsequently evoked sustained activation of JNK, loss of mitochondrial membrane potential, and release of apoptosis-inducing factor (AIF) and endonuclease G (Endo G) from mitochondria into the cytosol and then nucleus in Jurkat cells (Fig. 4) (Chen et al. 2009). Immunoprecipitation

experiments showed that AD5-10 induced assembly of DISCs containing DR5, FADD, caspase-8, and RIP in wild-type Jurkat cells. Moreover, a dominant-negative form of JNK enhanced NF-κB activation, suppressed caspase-8 recruitment in DISCs. However, how DR5 stimulation by AD5-10 induced ROS accumulation and how JNK activation impairs the function of mitochondria remain to be investigated.

Caspase-Independent Autophagy Signaling

Autophagic cell death has been involved in physiological cell death during development and reported in cancer cells treated with chemicals or irradiation. TRAIL also can induce caspase-independent autophagic cell death in normal epithelial cells and the breast cancer cell line MCF-10A (Mills et al. 2004), implicating that DR4 and/or DR5 are involved in the autophagic cell death as well as apoptosis. Park et al. (2007) recently reported that an agonistic antibody, single chain variable fragment (scFv) HW1, which specifically binds to DR5, triggered autophagic cell death of cancer cells dominantly through JNK pathway in a caspase-independent manner (Fig. 4). Analysis of the signaling complex induced by HW1 binding to DR5 exhibits the recruitment of TNF receptor (TNFR)-associated death domain (TRADD) and TRAF2 to the receptor, but not FADD, caspase-8, or RIP, which is distinct from the canonical DISC induced by TRAIL. Analyses of upstream kinase(s) for JNK activation upon HW1 binding to DR5 revealed that JNK activation was most likely mediated by TRAF2-MKK4/MKK7-dependent signaling cascade (Park et al. 2009). DR5-stimulated JNK activation by HW1 resulted in upregulation of Beclin-1 expression, Bcl-2 phosphorylation, and p53 phosphorylation, suggesting that these pro-autophagic signaling pathways are involved in the autophagic cell death (Park et al. 2009). The DR5-mediated autophagy signaling sensitized both TRAIL-sensitive and TRAIL-resistant tumor cells with much less cytotoxicity on normal cells (Park et al. 2007, 2009), providing a new strategy for the elimination of cancer cells through the nonapoptotic cell death.

Resistance to DR4- and DR5-Mediated Apoptotic Cell Death Signaling

Many highly malignant tumor cells (>50%) even expressing DR4 and/or DR5 remain resistant to TRAIL-induced and/or anti-DR4/DR5 agonistic mAb-mediated apoptosis, the underlying mechanism of which has been poorly understood and varies with the cellular context (Ashkenazi 2008; Fox et al. 2010; Johnstone et al. 2008). Potential resistance mechanisms are numerous and include loss/mutation of death receptors, overexpression of decoy receptors, overexpression of cellular FLICE inhibitory protein (c-FLIP), absence of proper *O*-glycosylation in the receptors, and/or complex downstream regulation of the extrinsic and intrinsic apoptotic pathways (Gonzalvez and Ashkenazi 2010).

Summary

The agonists against DR4 and/or DR5, including recombinant TRAIL and mAbs, have demonstrated anti-cancer activities both as monotherapy and in combination with anti-cancer agents in preclinical and clinical studies with no apparent systemic toxicity (Ashkenazi 2008; Fox et al. 2010; Johnstone et al. 2008). All of the receptor agonists in clinic have been reported to induce tumor cell death through the caspase-dependent apoptosis (Ashkenazi 2008; Johnstone et al. 2008). Depending on the external stimuli and specific cell types, however, DR4 and/or DR5 can also transduce multiple cellular signaling pathways in a caspase-dependent or caspase-independent manner, including JNK, p38, and NF-κB signaling. These distinct signaling can exert ROS-mediated apoptosis or autophagic cell death, although the components of which remain largely undefined. Recent clinical data of TRAIL and agonistic mAbs have shown much less tumor killing activities in patients than those observed in preclinical studies. Accordingly, deep understanding of the diverse molecular signaling mechanisms mediated by DR4 and/or DR5 and their cross-talks leading to a final outcome of the stimulation will be essential to design next-generation agonists targeting DR4 and/or DR5.

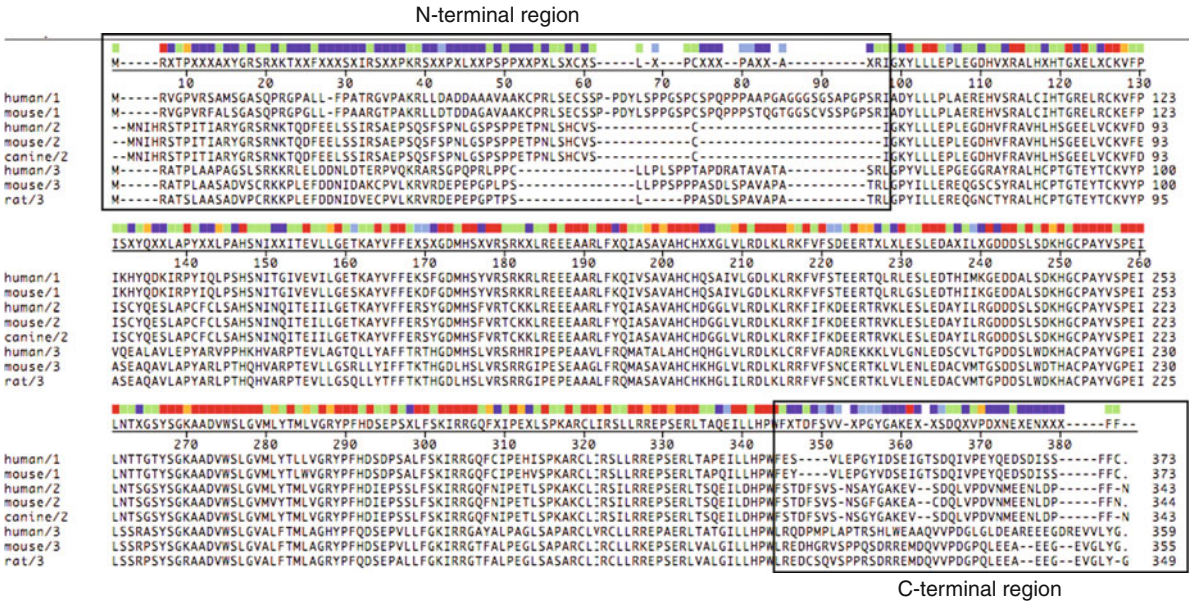
Historical Background

Discovery of Tribbles Genes

Advances in large scale sequencing projects (both cDNA and genome sequencing) combined with the advent of high throughput analytical approaches to detect the targets of certain genes and the molecular consequences of cellular stimulation led to the identification of a number of genes previously unknown to science. A good example of such genes is the tribbles family, where a number of independent strands of research recognized these genes as important regulators and/or targets of cellular function in a range of biological systems.

The name tribbles (TRIB) dates back to a string of papers that published the identification of a novel gene, controlling cell division in early *Drosophila* development. These reports defined an important regulatory role for tribbles in cell cycle progression during the closure of the ventral furrow (Grosshans and Wieschaus 2000), gastrulation (Seher and Leptin 2000), and oogenesis (Rorth et al. 2000). In these studies, absence of trb allowed the premature mitosis of mesodermal cells thus disrupting gastrulation. Tribbles was also identified as a gene that when overexpressed yielded abnormal numbers of germ cells. These experiments defined a molecular role for trb in cell cycle progression by promoting proteolysis of the *Drosophila* cdc25 homologues, *string* and *twine* which dephosphorylate tyrosine 15 of the mitotic cyclin-dependent kinase cdc2 to promote its activation. Thus, trb coordinates mitosis with cell fate determination, and in the absence of this protein mitosis occurs prematurely. Overexpression of trb in *Drosophila* caused oocytes to divide more slowly than normal and become abnormally large. Many subsequent research published in mammalian systems is compatible with these early findings and suggests that tribbles proteins represent an important control point of fundamental cellular processes, such as apoptosis, cell division, and cellular activation.

In parallel to the above studies, mammalian tribbles orthologues have been reported, under a variety of names. Tribbles-2 (C5FW) was described as one of the up-regulated genes in dog thyroid in response to mitogens (Wilkin et al. 1996, 1997). Tribbles-1 (C8FW) was then subsequently reported by this group as a close homologue of tribbles-2 (Wilkin et al. 1997). The first study reporting tribbles-3



Tribbles, Fig. 1 Alignment of vertebrae tribbles-1/2/3 proteins by using Clustal W method. *Red* indicates the strongest and *black* the weakest conservation across the sequences. The N- and C-terminal regions are highlighted in boxes

(Neuronal cell death Inducible Putative Kinase, NIPK) was published by Mayumi-Matsuda et al., demonstrating an increased expression for this gene during neuronal cell death induced by NGF-depletion (Mayumi-Matsuda et al. 1999). These reports were shortly followed by a rapidly increasing body of studies reporting on the functional importance of tribbles, identifying tribbles interacting proteins, and proposing models for their molecular mode of action. This literature has been reviewed systematically in (Docherty and Kiss-Toth 2010; Hegedus et al. 2006, 2007; Kiss-Toth 2005, 2007, 2011).

Below, our current understanding of key aspects of tribbles function will be summarized, as well as some of the key outstanding questions.

Evolution of Tribbles

A comprehensive bioinformatics analysis was performed to identify tribbles orthologues in a range of species and track the origins of this gene family (Hegedus et al. 2006). Systematic analysis of the available EST information in the NCBI database revealed that tribbles-like proteins can already be identified in protozoan species, suggesting that this is an evolutionally ancient, conserved gene. These findings are compatible with the notion that tribbles control fundamental aspects of cellular function. Results of this analysis have also shown that (almost invariably) there is a single tribbles gene per organism in invertebrates. However, all vertebrate species genomes seem to encode for a number of tribbles paralogues. Whilst fish and mammalian species contain three tribbles-like genes, amphibians and birds are missing tribbles-3. Analysis of syntenic regions across vertebrate species suggests that this is due to the loss of a chromosomal segment encoding trb-3 and several other neighboring genes between fish and "modern" amphibians.

Putative Structure of Tribbles Proteins

Tribbles proteins are comprised of three distinct domains (Fig. 1). The N-terminal region of the protein is particularly rich in serine and proline residues, suggesting that this region might be important in protein–protein interactions. It has been shown that this domain is necessary for the nuclear localization of tribbles-1 and -3. The central region of the protein contains an amino acid sequence, which is highly similar to the catalytic domain of serine/threonine kinases. However, some motifs, believed to be crucial to the kinase activity, are missing from tribbles. In particular, kinase sub-domains I, VIB, and VII are absent in tribbles, which suggests that this domain is catalytically inactive and implies evolutionary conservation for structural reasons, necessary for the biological activity of these proteins.

Tribbles, Table 1 Summary of tribbles-1/2/3 interacting molecules

Tribbles	Interacting partner	Tissue/cell type	Reference
1	12-lipoxygenase (12-LOX)	Yeast two-hybrid	Tang et al. (2000)

A single study, using cells under non-stimulated conditions, has addressed the issue of catalytic activity of tribbles, with negative results. However, it remains plausible that tribbles only have kinase activity when activated, as is the case for many serine-threonine kinases.

Intracellular Expression

Most published data on intracellular distribution of tribbles to-date is based on experiments using overexpression systems. Based on these data, tribbles-1 and -3 appear to be localized in the nucleus, whilst tribbles-2 being expressed mostly in the cytoplasm. However, immunostaining of tissues for endogenous tribbles suggests that all three human tribbles orthologues can localize in cytoplasm as well as in the nucleus.

Of note, tribbles expression has been reported to be highly regulated. On one hand, this takes place in a tissue specific manner; thus, expression levels of tribbles family members are tightly controlled during differentiation. Further, cellular stimulation also leads to rapid and often transient changes in tribbles levels. In addition to the control of transcription, tribbles proteins are also thought to be highly unstable, as putative motifs responsible for protein degradation have been predicted in many tribbles orthologues (Hegedus et al. 2007). However, experimental evidence for the stability of tribbles is still somewhat scarce.

Molecular Mechanisms of Tribbles Action

Tribbles Interacting Proteins

A large number of proteins have been reported as tribbles binding partners. These interactions are summarized on Table 1. The relevance of most of these findings is discussed in the appropriate sections below.

Tribbles Mediated Control of Signal Transduction

Control of signal transduction networks has been suggested as the main mode of action for tribbles. So far, three main concepts have been established.

A number of studies reported that specific pathways of the mitogen activated protein kinase (MAPK) signaling system are controlled by tribbles, much of this specificity is thought to be due to the tissue specific differences in tribbles expression and/or the altered

expression of tribbles binding partners. In general, tribbles proteins are thought to bind to the middle layer of the three MAPK cascades and thus control the activity of MAPKK proteins (Eder et al. 2008; Gilby et al. 2010; Sung et al. 2007). These interactions and their biological consequences have mainly been investigated in the context of regulating inflammatory responses of vascular and immune cells.

The second major concept by which tribbles are proposed to regulate cell function is via their interaction with Akt/PKB serine-threonine kinases. It has been suggested that the insulin activated PI3K/PKD/Akt signaling pathway is controlled by this interaction, namely, by a polymorphic variant (Q84R) of tribbles-3 that can affect Akt binding. However, the molecular data on the functional importance of this interaction are somewhat conflicting, some studies demonstrating that trb-3 inhibits Akt activity, whilst others found no modulation of Akt-dependent pathways. It is likely that these discrepancies have arisen due to differences in the cell types and/or stimuli used in the various studies, which would also reinforce the notion that intracellular signals are transmitted via large multi-protein complexes and the exact composition of these may be cell type specific. Thus, trb-3/Akt interaction may have different functional consequences, depending on the microenvironment.

Finally, tribbles are thought to control the turnover of other proteins via their interaction with specific ubiquitin ligases. The first line of evidence for such a regulatory mechanism came from *Drosophila* studies, published by Roth et al., demonstrating that the turnover of fly C/EBP (*slbo*) protein is controlled by the Ubp64 ubiquitin ligase, via a tribbles-dependent mechanism (Rorth et al. 2000). Recently, a similar model was put forward in a mammalian setting, reporting that tribbles-1 and -2 but not tribbles-3 are able to promote degradation of C/EBP (Dedhia et al. 2010).

Tribbles Mediated Control of Gene Expression

In addition to interacting with signaling proteins, tribbles have also been reported to bind to several transcription factors and control their transcriptional activity. The first and so far best characterized example of such studies was published by Ord, where they showed that tribbles-3 binds to ATF4 and inhibits the transcriptional activity of this protein (Ord and Ord 2003). Interestingly, whilst tribbles -1 and -2 appear to promote degradation of C/EBP proteins, and tribbles-3 controls ATF4, these two transcription factors seem to cooperate and control the expression of tribbles-3 itself (Ohoka et al. 2005). Putting these findings together, it is likely that complex regulatory feedback loops exist whereby members of the tribbles protein family regulate each other's expression.

Tribbles and Disease

Since their discovery, tribbles have been associated with a number of human diseases, ranging from diabetes, lipid disorders, cardiovascular disease, cancer as well as neurological disorders, such as narcolepsy. Many of these observations were initially correlative and have later been backed-up by functional studies, as summarized below.

Type 2 diabetes: Shortly after the initial characterization of *Drosophila* tribbles, a paper published by Marc Montminy's group have shown that tribbles-3 interacts with unphosphorylated Akt and reduces its activity (Du et al. 2003). Thereby, tribbles-3 was suggested as a novel, stress induced negative regulator of insulin signaling. A follow-on work from this group reported that trb-3 levels were reduced in liver via PPARα and that this is a mechanism to improve glucose tolerance, thus maintain glucose homeostasis. In line with these studies, a polymorphic variant (Q84R) of human tribbles-3 was subsequently identified as a risk factor for the development of type 2 diabetes (Prudente et al. 2009). However, there are also published reports, which suggest that the physiological action of tribbles-3 might be more complex than suggested by these models. A study using primary rat hepatocytes found no role for tribbles-3 in insulin-mediated control of glucose homeostasis (Iynedjian 2005). Further, tribbles-3 deficient mice appear to have a normal glucose tolerance and insulin signaling (Okamoto et al. 2007). Therefore, whist there is strong evidence that tribbles-3 might play a role in the control of insulin signaling and thus contribute to the development of type 2 diabetes, its action is likely to be influenced by other, yet undefined factors.

Lipid metabolism, hyperlipidemia: A molecular study of spontaneous mutations in mice revealed a disorder called fatty liver dystrophy, which is characterized by transient hypertriglyceridemia and fatty liver during the neonatal period, followed by development of a peripheral neuropathy. Dysregulation of tribbles-3 (*fld2*) has been identified in this mouse strain (Klingenspor et al. 1999), which raised the possibility

that elevated trb-3 levels may contribute to the development of this syndrome. However, there is a clear need for further studies to explore the validity of this hypothesis.

Recent genome-wide association studies (GWAS) have identified a number of genes, not previously associated with dysregulated lipid levels in humans. One of these novel candidates is tribbles-1, which was first associated with serum triglyceride levels (Kathiresan et al. 2008) and subsequently with elevated total- and LDL-cholesterol, as well as with an increased risk of coronary heart disease (Tai et al. 2009).

Cancer: An increasing body of evidence has accumulated in recent years to suggest an important role for tribbles in the development of cancer. This is not entirely surprising, given the original observations in *Drosophila*, where tribbles was shown to inhibit cell cycle progression. However, the role tribbles play in the mammalian setting is still somewhat controversial, as discussed below.

A number of cancer types (including colon cancer, acute myeloid leukemia (AML), gliomas, mammary tumors, etc.) have been reported, in which the expression of tribbles proteins appears to be dysregulated. However, the best-studied example is one of AML. Nakamura and his team have suggested that tribbles-1 cooperates with *Hoxa* and *Meis1* in promoting AML. This group as well as work published by Warren Pear and his colleagues suggested a similar model for tribbles-2 and proposed the tribbles-dependent degradation of C/EBP as the molecular mechanism for this. However, a recent analysis of a large microarray dataset over 300 of human AML samples revealed that tribbles-1 and -2 are expressed at particularly low levels in groups where C/EBP levels were reduced. Thus, further work is clearly needed to address the molecular contribution of tribbles in the development of AML.

Narcolepsy: The latest in the list of diseases associated with tribbles is a chronic sleep disorder, called narcolepsy. It has been long suggested that autoimmunity may contribute to the onset of this disease but thus far no autoantigens were identified. However, recent reports from three independent groups have identified that the presence of anti-tribbles-2 antibodies is associated with this disease. However, the mechanism by which this contributes to disease development is currently unclear.

Summary

Tribbles proteins have become of substantial interest for biomedical research over the last decade, as they appear to control the action of key signal transduction pathways, regulate the turnover as well as the action of transcription factors. As they are believed to be pseudokinases, tribbles are most probably exerting their function via interacting with other proteins and modulating their activity. Whist there is a rapidly increasing body of literature to underline their importance in the development of human disease, many basic aspects of their action and the mechanism by which they contribute to the normal physiology and pathology of these diseases is currently unclear and will require further research.

Historical Background

Calcium is integrated in many physiological processes like muscle contraction, hormone secretion, and intracellular signaling processes (calcium signaling). Prerequisite for this role is the 10,000-fold gradient across the plasma membrane with 2.5 mM extracellular and resting intracellular calcium ion concentration of approximately 100 nM. Calcium ATPases (▶ Plasma membrane calcium-transporting ATPase) and transporters manage the extrusion of calcium whereas calcium-permeable ion channels enable rapid increases in intracellular calcium up to micromolar concentrations. The biological functions of calcium are mediated by direct calcium binding of the modulated proteins or by protein–protein interaction with calcium sensor proteins (calmodulin, CaBP, calcineurin, S100, NCS, etc.). In excitable cells like neurons, heart or skeletal, or smooth muscle cells, the calcium current is mediated by voltage–gated calcium channels. The molecular identity of the ion channels mediating hormone-induced calcium entry in non-excitable cells like endothelial, epithelial, immune cells remained mysterious for a long time. While it was clear that in mammals, receptor-stimulated calcium entry depends on the phospholipase C activity, parallelly in *Drosophila melanogaster*, a protein named Transient Receptor Potential (TRP) was identified and described as a phospholipase C–modulated, calcium-permeable ion channel involved in phototransduction (Montell and Rubin 1989). Upcoming genome and expression profiling projects with expressed sequence tags allowed the cloning of the first mammalian TRP-homologous proteins, the ion channels of the classic TRP family (TRPC). Other approaches identified additional TRP-homologous proteins establishing the melastatin-like and vanilloid-like TRP subfamilies, TRPM and TRPV, respectively (Harteneck et al. 2000; Montell et al. 2002; Wu et al. 2010). With the identification of TRPV1 (vanilloid receptor 1, VR1) as molecular target of capsaicin, another fascinating feature of TRP channels being target of many secondary plant compounds became obvious as well as the involvement of TRP channels in sensory functions (Caterina et al. 1997). Nowadays, the TRP superfamily comprises also the mucolipins (TRPML) and the polycystines (TRPP), calcium-permeable channel proteins with similar transmembrane topology and other

similarities (Montell et al. 2002; Venkatachalam and Montell 2007; Wu et al. 2010). Despite their common structure and sequence identities, the members of the TRP superfamily are involved in many different cellular functions and are integrated in a variety of physiological processes. The basis for the versatility being integrated in so many signaling cascades is founded in the fact that TRP channels as nonselective ion channels are permeable for sodium, calcium, and other divalent cations. The ratio for the main charge carriers, sodium and calcium, varies within the superfamily from highly calcium-selective ion channels (TRPV5 and TRPV6) to calcium-activated, calcium-impermeable, sodium channels (TRPM4 and TRPM5) and represents an important biophysical feature for the characterization of TRP channels in a physiological context.

For the identification, cloning, and biochemical and physiological characterization, common experimental approaches are used, whereas patch clamp as well as calcium imaging techniques provide direct evidence of the channel activity. The patch clamp techniques use small pipettes and directly measure currents carried by the channels studied, whereas calcium imaging approaches depend on intracellular calcium-binding indicator dyes showing differences in fluorescence in the presence and absence of calcium, thereby allowing the measuring of intracellular calcium concentration as a readout of channel activity. The following entry will give an introduction in the broad field of TRP channel research orientated on the TRP channel classification.

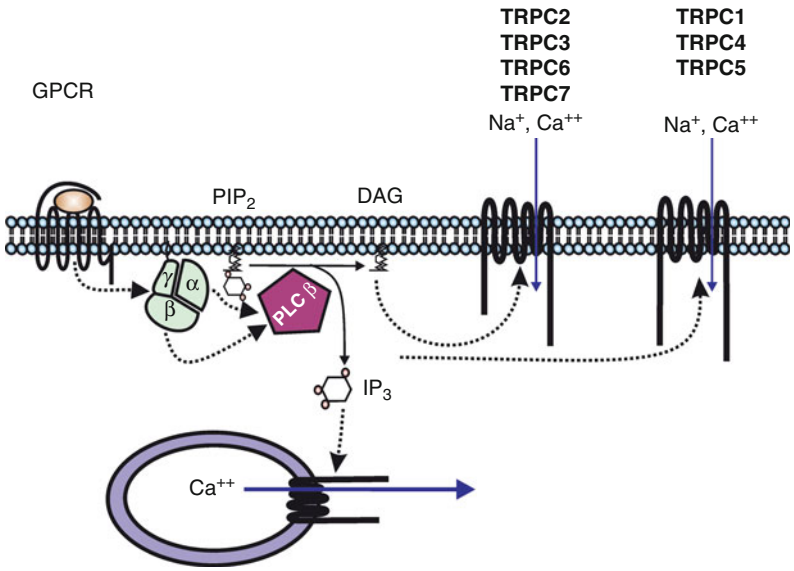
TRPA1 Channel as Signaling Molecule

TRPA1 was initially cloned starting from an up-regulated EST in many tumor cells and described as ANKTM1 based on the most significant structural property of the protein sequence, the abundance of many N-terminal ankyrine-like repeats (Basbaum et al. 2009; Patapoutian et al. 2009). This feature, ANKTM shares with the fly and worm TRP channels of the NOMPC family. The NOMPC channels of *Drosophila melanogaster* and *Caenorhabditis elegans* are involved in mechanotransduction. Based on the similarity, mammalian ANKTM1 was temporarily discussed as putative mechanosensitive ion channels probably involved in hearing (Christensen and Corey 2007). The absence of deafness in ANKTM knockout animals however showed that ANKTM1 is not involved in hearing. TRPA1 plays an important role as cold and chemo sensor in mammalian nociceptive neurons. As protein sensing cold temperatures, TRPA1 is also activated by several cooling compounds like menthol or icilin and on the other hand by many pungent structures like allylisothiocyanate (mustard oil) or allicin or methyl paraben or cinnamaldehyde. The great variety of chemical structures activating TRPA1 and thereby mediating pain and triggering inflammatory processes makes TRPA1 an important target in the pain field.

TRPC Channels as Signaling Molecules

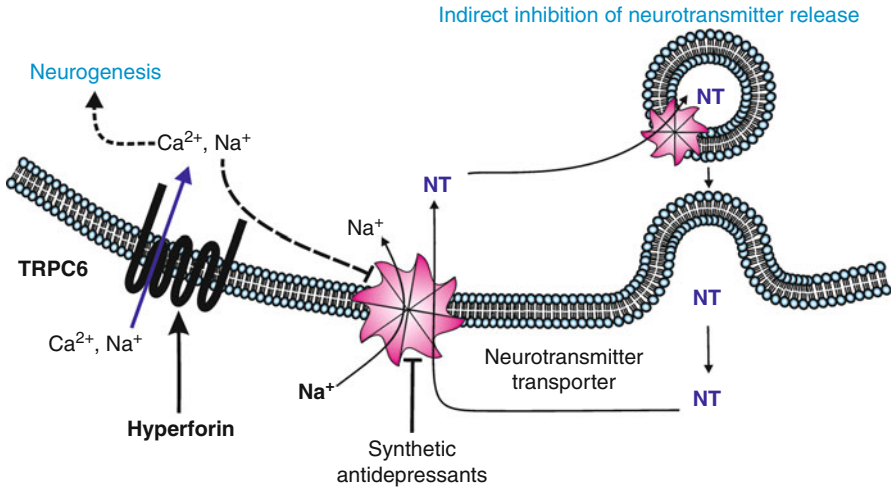
The classic TRP channel family comprises seven different genes with proteins showing the highest sequence similarity to the prototypic *Drosophila* TRP (Harteneck et al. 2000; Montell and Rubin 1989; Venkatachalam and Montell 2007; Wu et al. 2010). Like the prototypic fly channel, the mammalian channel proteins are involved in receptor-regulated calcium entry (Birnbaumer 2009). Stimulation of receptors by hormones, neurotransmitter (GPCR, photoreceptor), and light in *Drosophila* results in the phospholipase C–mediated breakdown of phosphatidylinositides, leading to the formation of inositol 1,4,5-triphosphate and diacylglycerol (Fig. 1). Inositol 1,4,5-triphosphate induces calcium release from intracellular stores via the activation of inositol 1,4,5-triphosphate receptors (▶ IP3 receptor), whereas diacylglycerol directly activates mammalian classic transient receptor potential (TRPC) channels (TRPC2, TRPC3, TRPC6, and TRPC7) in a protein kinase C–independent manner. The prerequisite of phospholipase C stimulation has been shown for TRPC1, TRPC4, and TRPC5 currents; however, the molecular mechanism is still unclear.

TRPC1 is transcribed in nearly all cells, whereas the other TRPC channels show a distinct and characteristic expression profile being adapted to cellular requirements; nevertheless, in many cell types, two and more TRPC channels can be found. On the other hand, the broad expression profile of TRPC channels makes it difficult to assign distinct physiological function to one gene. TRPC2 being expressed in the rodent vomeronasal organ is clearly an exception. In man, TRPC2 is a pseudogene; the transcribed mRNA is functionless due to various stop codons. However, in rodents, the transcription of the TRPC2 gene results in



TRP (Transient Receptor Potential Cation Channel), Fig. 1 Activation pathway of mammalian receptor-activated TRPC channels. G-protein-coupled receptor (GPCR)–mediated activation of phospholipase C isoforms (PLC βγ) result in the breakdown of phosphatidylinositides (PIP_2), leading to the formation of inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 is the ligand of IP_3 receptors, which are located in the endoplasmic reticulum. Upon activation, IP_3 receptors mediate Ca^{2+} release from intracellular stores, whereas DAG directly activates mammalian TRPC2, TRPC3, TRPC6, and TRPC7 channels. In contrast to the current molecular understanding of the signaling cascade resulting in the stimulation of TRPC2, TRPC3, TRPC6, and TRPC7, the molecular mechanism for the stimulation of TRPC1, TRPC4, and TRPC5 is unclear. The prerequisite of phospholipase C activation in the activation of TRPC1, TRPC4, and TRPC5 is accepted

a functionally active protein involved in sensory response to pheromones. Genetic inactivation of TRPC2 in mice leads to loss of sex discrimination of male mice. Data from TRPC4 knockout mice approaches show that TRPC4 is involved in microvascular permeability. TRPC3 and TRPC5 are discussed to be involved in neuronal differentiation and growth cone guidance. TRPC6 expressed in vascular smooth muscle cells was discussed to be involved in blood pressure regulation. However, the characterization of TRPC6 knockout mice surprisingly showed a slightly increased blood pressure resulting from increased basal activity of TRPC3, up-regulated in TRPC6 knockout mice. The diversity of cellular function of the genes of the TRPC family became visible by reports showing that gain-of-function mutations of TRPC6 resulted in progressive kidney failure and focal segmental glomerulosclerosis (FSGS). The physiological role of TRPC6 in the kidney proposed from the analysis of the genetic disease is that TRPC6 expressed in podocytes is involved in hormone-dependent size regulation of the glomerular slit-diaphragm. Gain-of-function mutation of TRPC6 results in increased calcium load of the podocytes, induction of calcium-dependent apoptosis, progressive loss of podocytes, and glomerulosclerosis responsible for proteinuria found in these patients. The complexity of the different physiological function mediated by TRPC6 became obvious, when TRPC6 was identified as the molecular target of hyperforin, the active principle of St. John Wort extracts, a remedy for the treatment of moderate to mild depression (Fig. 2). The antidepressive action of hyperforin results from the direct activation of TRPC6, leading to enhanced intracellular calcium as well as sodium concentrations. By increasing intracellular sodium, the neurotransmitter uptake is indirectly inhibited by the impairment of the electrochemical gradient of sodium as basis for the reuptake of serotonin, dopamine, and noradrenaline. Like synthetic antidepressive drugs directly blocking the neurotransmitter transporter, hyperforin mediates neurotrophic effects in a TRPC6-dependent manner probably by calcium-induced differentiation processes. Calcium-dependent differentiation processes are regulated in a dual manner. Hyperforin or diacylglycerol concentration regulates TRPC6 activity



TRP (Transient Receptor Potential Cation Channel), Fig. 2 Proposed model of hyperforin-induced, TRPC6-mediated effects in neurons. Synthetic antidepressants block plasma membrane neurotransmitter transporter proteins, thereby increasing concentration and exposure time of neurotransmitters. In contrast to this mode of action, the antidepressive effects of hyperforin are mediated using another pathway. By activation of TRPC6 channels permeating sodium and calcium, the electrochemical gradient of sodium across the plasma membrane prerequisite for the function of the plasma membrane neurotransmitter transporter is reduced, resulting in an indirect inhibition of neurotransmitter uptake. On the other hand, TRPC6-mediated calcium entry may trigger calcium-dependent differentiation processes responsible for changes in neuronal plasticity by still unclear intracellular pathways

and thereby the intracellular calcium concentrations. On the other hand, puromycin treatment of rats leads to increased TRPC6 expression in podocytes and proteinuria, whereas treatment of keratinocytes with betulin or other triterpens also increases TRPC6 expression and enhances keratinocytes differentiation. The duality of wanted as well as unwanted effects induced by the modulation of TRPC6 expression and activity demonstrates that the intracellular calcium concentrations are regulated within a tight interval with serious effects in case of imbalances. These observations transmitted to drug research and therapy show that both blocking as well as stimulating strategies will make sense in particular pathophysiological situations.

TRPM Channels as Signaling Molecules

Melastatin, the founding member of the melastatin-like TRP family, was identified within a screen for proteins differentially regulated in melanocytes and melanoma cells (Harteneck 2005; Venkatachalam and Montell 2007; Wu et al. 2010). Analysis of clinical data showed that the presence of melastatin expression in melanoma patients inversely correlates with the severity and survival. Although melastatin is the first member of the TRPM family, its activation mechanism and physiological role is still unclear. In line with the first description as protein involved in melanocyte physiology, several reports confirmed this view. A completely unexpected function, the integration in retinal signal processing, has recently been discovered by the identification of TRPM1 expression in retinal ON bipolar cells. The critical role of TRPM1 in mammalian phototransduction is also highlighted by several reports describing TRPM1 mutations in patients suffering from congenital stationary night blindness.

From sequence similarity, TRPM3 is phylogenetically the closest neighbor to melastatin. Several stimuli for the activation of TRPM3 have been reported. TRPM3 is activated by hypotonic extracellular solution and represents together with TRPV4, the volume-regulated TRP channels in the kidney. With the help of pharmacological tools, calcium entry induced by the application of hypotonic extracellular solutions can be assigned to TRPV4 and TRPM3 (Harteneck and Reiter 2007; Liedtke 2007; Vriens et al. 2009; Woudenberg-Vrenken et al. 2009). While TRPV4 is activated by 4α-Isomers of phorbolesters and is blocked by ruthenium red, TRPM3 is activated by sphingosine and by pregnenolone-sulfate and blocked by gadolinium ions. TRPM3 is expressed in oligodendrocytes in the brain,

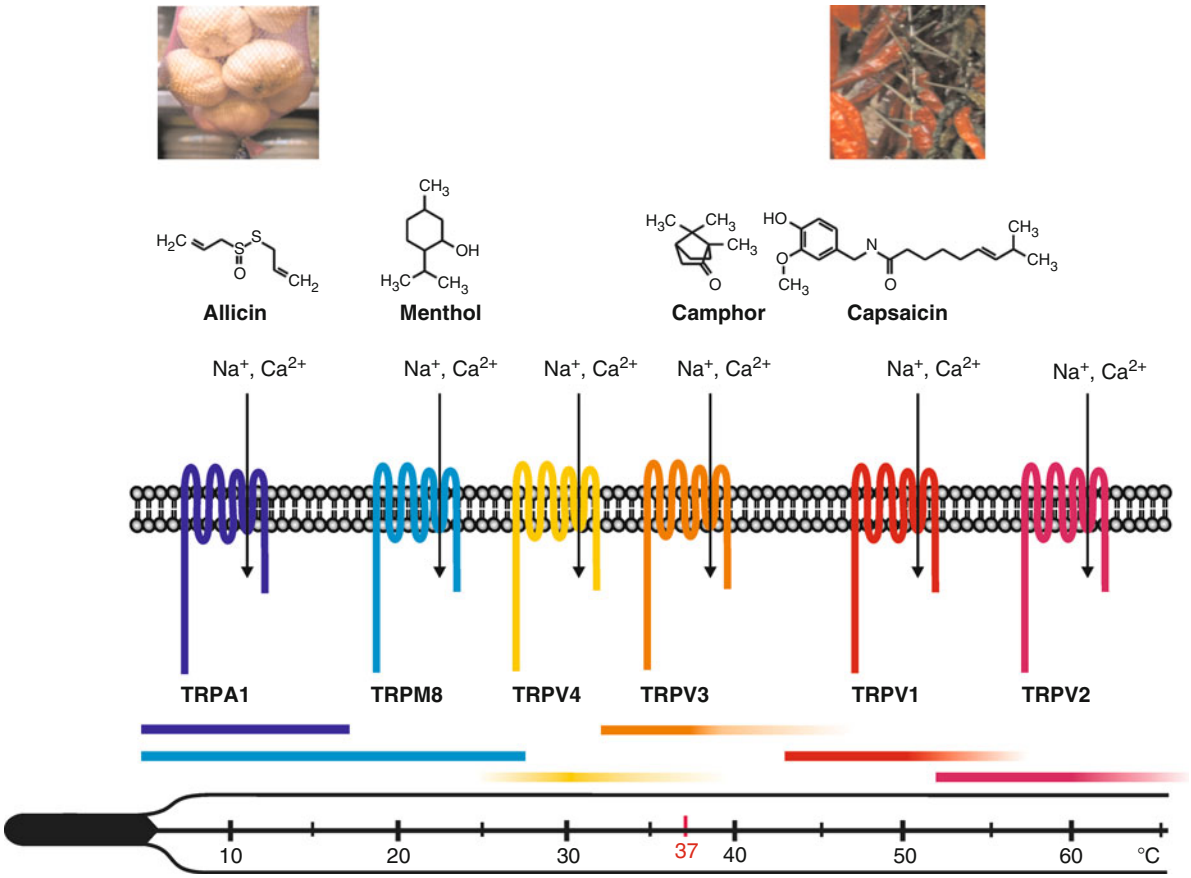
in renal epithelial and pancreatic beta cells. The phylogenetically next neighbors to TRPM1 and TRPM3 are TRPM6 and TRPM7. Latter are involved in the body magnesium homeostasis. While TRPM7 is ubiquitously expressed, TRPM6 is expressed in epithelial cells of the gut and the kidney and responsible for magnesium absorption and reabsorption. Loss-of-function mutations in TRPM6 are linked to autosomal-recessive hypomagnesemia with secondary hypocalcemia. TRPM6 and TRPM7 as well as TRPM2 (see below) share a common structural feature. All three genes code for chimeric proteins combining a hexahelical transmembrane channel forming domain with a C-terminal enzymatic active domain. In the case of TRPM6 and TRPM7, the pore-forming domains are fused to atypical alpha kinase-like structures. The functional role for the enzymatic domain is still under dispute. TRPM6 and TRPM7 are permeable for magnesium and for other essential divalent cations like Ca^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+} as well as toxic cations like Ba^{2+}, Sr^{2+}, Ni^{2+}, Cd^{2+} (Hoenderop and Bindels 2008; Woudenberg-Vrenken et al. 2009). While divalent ions are the preferentially carried ion of TRPM6- and TRPM7-mediated currents, TRPM4 and TRPM5 form ion pores impermeable for divalent ions and allow selectively sodium to pass. As sodium channels, TRPM4 and TRPM5 are paradoxically activated by increased intracellular calcium concentrations and represent calcium-activated calcium channels. TRPM4 being ubiquitously expressed is involved in the mast cell activation and the release of inflammatory mediators. Furthermore, TRPM4 contributes to the neurogenic regulation of blood pressure by modulating central catecholamine release. In contrast to TRPM4, the expression of TRPM5 is restricted to a few cell types. TRPM5 is expressed in taste buds of the tongue and involved in the sensation of bitter and sweet taste. The remaining two TRPM channels proteins, TRPM2 and TRPM8, can also be discussed in the light of sensory functions. As already mentioned, TRPM2 represents a chimeric protein having an ADP-ribose hydrolase domain C-terminal to the pore-forming transmembrane domains. Simultaneously to the ADP-ribose hydrolysing activity of the C-terminal enzymatic domain, TRPM2 is activated by ADP-ribose and it has been shown that the C-terminal part is essential for the function as pore-forming channel protein. Increased intracellular ADP-ribose concentrations are linked to genotoxic and/or oxidative stress of cells, leading to the activation of the poly (ADP-ribose) polymerase (PARP) modulating protein stability by the mono- and poly-ADP-ribosylation of proteins. This process of protein stability regulation is additionally controlled by an enzyme called poly (ADP-ribose) glucohydrolase (PARG). PARG reduces the posttranslational poly-ADP-ribose modifications to mono-ADP-ribosylation, thereby increasing the intracellular ADP-ribose concentration leading to the activation of TRPM2. In whole cell calcium imaging experiments, the extracellular application of hydrogen peroxide results in the activation of TRPM2 validating its function as redox sensor. While TRPM2 is highly expressed in immune cells and at low levels in some neurons making the discussion of TRPM2 as redox sensor difficult, TRPM8, the cold sensor, is mainly expressed in sensory neurons. TRPM8 is activated at temperatures between 8°C and 28°C as well as secondary plant compound menthol and synthetic cooling compounds. Together with TRPA1, TRPM8 represents the cold sensors in human. Noxious cold is mediated by TRPA1 (Fig. 3).

TRPML Channels as Signaling Molecules

Mucolipidosis Type IV is an autosomal-recessive neurodegenerative lysosomal storage disorder caused by mutations in TRPML 1 (Montell et al. 2002; Puertollano and Kiselyov 2009). TRPML1 like the other members of the mucolipin family (TRPML1-3) is described to be located as integral membrane proteins of intracellular vesicles especially the lysosomes and probably activated by protons. The lysosomes in mucolipidosis IV patients are enlarged arguing for defects of the intracellular turnover and storage of lipids such as phospholipids, sphingolipids, gangliosides, and mucopolysaccharides. Based on this observation, a contribution of mucolipin channels in the intracellular trafficking and handling of lysosomes is discussed and provides hypotheses for further research.

TRPP Channels as Signaling Molecules

The autosomal-dominant polycystic kidney disease (ADPKD) is characterized by cysts formation in the kidney, a malformation of the renal tubular structure



TRP (Transient Receptor Potential Cation Channel), Fig. 3 TRP channels as thermo sensors. The diagram summarizes the secondary plant compounds and temperature ranges activating temperature-sensitive TRP channels. TRPA1 is activated by pungent and cooling compounds and is activated by temperatures below 17 °C, whereas TRPM8 is activated at temperatures below 27 °C and cooling compounds like menthol. TRPV4 is activated at intermediate temperatures and extracellular hypotonic solutions (see volume-regulated TRP channels TRPV4 and TRPM3). TRPV3 mainly expressed in keratinocytes is activated by temperature from 31 °C to 39 °C and camphor. TRPV1, also named vanilloid receptor 1 or capsaicin receptor 1, is activated by capsaicin and temperature above 42 °C, whereas TRPV2 is activated by heat above 51 °C

(Montell et al. 2002; Zhou 2009). The cyst formation is linked to the disruption of the functional TRPP1/TRPP2 complex. TRPP1, a huge protein consisting of a complex N-terminal extracellular ligand binding and 11 transmembrane domains, and TRPP2, a calcium-permeable ion channel, form a receptor–effector complex implicated in various biological functions, such as cell proliferation, sperm fertilization, and mechanosensation.

TRPV Channels as Signaling Molecules

Vanilloid structures, derivates of vanillin comprising eugenol, zingerone, and capsaicin, are found in many splice plants and known for their individual characteristic flavor. Beside the use as spice, vanilloid-containing plant extracts are used as remedy in the various traditions of folk medicine. The therapeutic and experimental uses of capsaicin in pain treatment inspired research resulting in the unraveling of the molecular target of capsaicin. The molecular target, an ion channel related to *Drosophila* TRP, was named capsaicin or vanilloid receptor and became eponym of the subgroup or structurally related ion channels of the TRP channel superfamily (Caterina et al. 1997). The vanilloid-like TRP channels comprise six members, four proteins (TRPV1 to TRPV4) like TRPV1 are nonselective ion channels involved in thermosensation (Basbaum et al. 2009; Liedtke 2007;

Talavera et al. 2008; Vriens et al. 2009; Wu et al. 2010), while two ion channels (TRPV5 and TRPV6) represent highly calcium-selective ion channels (Hoenderop and Bindels 2008; Woudenberg-Vrenken et al. 2009). Initially described as calcium transporter, TRPV5 and TRPV6 are responsible for the uptake and reuptake of calcium in the gut and kidney, respectively. Expressed in the epithelial cell layers of the gut and kidney, the activity is transcriptionally controlled in a vitamine-D3-dependent manner.

Capsaicin, the ingredient in chili pepper, causing burning and pain activates TRPV1, the heat sensor, activated by increased temperatures under physiological conditions. The capsaicin receptor being expressed in dorsal root ganglia senses increasing temperatures with a threshold of around 42°C. The activation of TRPV1 is realized as heat and burning, the same sensation caused by capsaicin. Illustrative for the modulation of the 42°C threshold of TRPV1 is the burning pain after the application of ethanol or acids in wounds as TRPV1 activity is dramatically enhanced at normal body temperature in the presence of increased proton concentration or in the presence of around 3% ethanol. Since the first description of TRPV1 as the molecular target of capsaicins, many pain-inducing chemicals and toxins have been described as TRPV1 ligands. The warm and heat sensors (TRPV1 to TRPV4) and the cold sensors (TRPM8 and TRPA1) represent the thermosensors of the human body and cover the complete temperature range necessary for human life (Fig. 3). As warning sensors expressed in dorsal root ganglia, the thermo-TRPs are also involved in sensation and modulation of pain and therefore interesting as molecular targets for new pain-treating drugs.

Summary

Transient receptor potential (TRP) channels are a large family of nonselective, calcium-permeable channel proteins activated and regulated by a diversity of mechanisms. TRP channels respond to intracellular stimuli such as calcium, metabolites of the arachidonic acid, or phosphatidylinositol signal transduction pathways. TRP channels sense environmental stimuli such as changes in temperature, osmolarity, and pH and represent the molecular target of pheromones, taste, and secondary plant compounds. The broad function in physiology proposed by the expression profiles of TRP channels becomes visible by the association of TRP channel mutations with hereditary diseases or the analysis of TRP channel knockout mice. The diversity of the chemical structures and the selectivity of the natural occurring compounds modulating TRP channels show the possibility for the pharmacological modulation of TRP channels and inspire to develop new synthetic structures for TRP channel interference at bench and bedside.

Historical Background

Since 1934, it has been understood that urea plays a key role in the generation of concentrated urine (Gamble et al. 1934). Functional measurements of urea transport in the kidney inner medullary collecting duct (IMCD), performed in the 1980s, provided evidence for the existence of urea transporter proteins (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Currently, two families of urea transporters have been cloned: *SLC14A1*, the UT-B urea transporter originally isolated from erythrocytes; and *SLC14A2*, the UT-A group with six distinct isoforms described to date (reviewed in [Sands and Layton 2009; Sands and Layton 2008]) (Table 1). In the

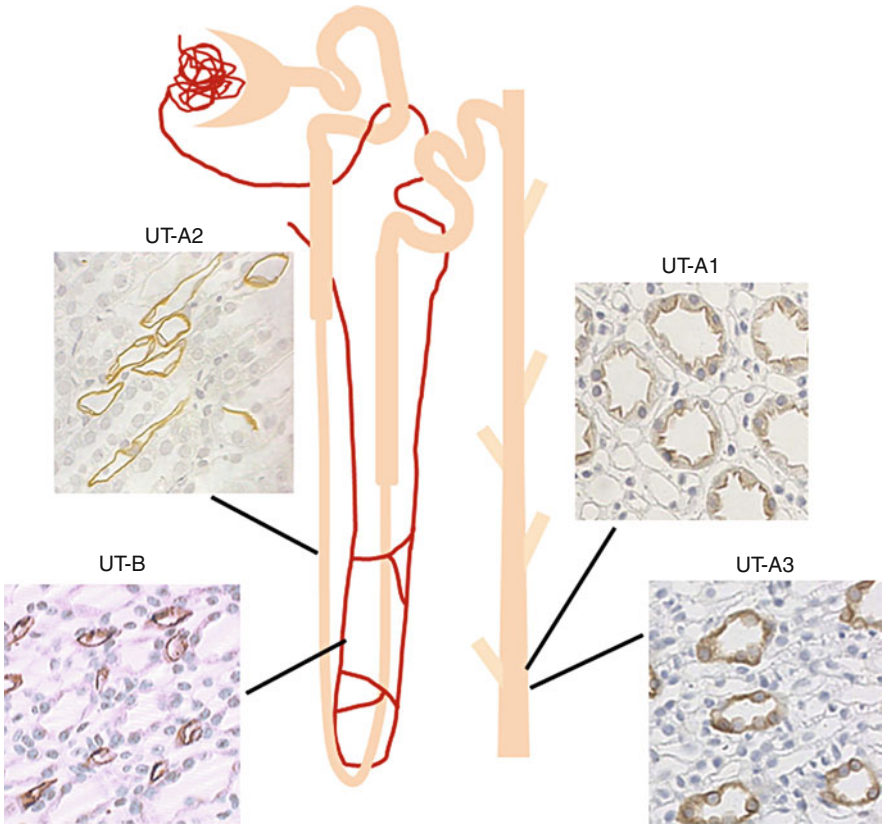
kidney, UT-A1 and UT-A3 are expressed in the IMCD; UT-A2 is expressed in the thin descending limb (tDL); and UT-B is located primarily in the descending vasa recta and red blood cells (Fig. 1). Although the exact location has yet to be determined, UT-A4 is expressed in rat kidney medulla but not in the mouse medulla (reviewed in [Sands and Layton 2009; Sands and Layton 2008]).

The UT-A family of urea transporters currently consists of six protein isoforms. The four renal isoforms are shown in Fig. 2. UT-A1 is the largest protein containing 11 transmembrane helices. Helices 6 and 7 are connected by a large intracellular loop that recent studies show is crucial to the functional properties of UT-A1 (Blount et al. 2008; Mistry et al. 2010; Klein et al. 2010). UT-A3 is the N-terminal half of UT-A1 while UT-A2 is the C-terminal half of UT-A1. UT-A4 is the N-terminal quarter of UT-A1 spliced to the C-terminal quarter. Although the need for the multiple isoforms of UT-A is not completely understood, a recent crystal structure of a bacterial urea-conducting channel, dvUT, suggests that these transporters require some sort of oligomeric organization to function (Levin et al. 2009).

The UT-B gene can produce two isoforms, UT-B1 and UT-B2, each of which are tissue specific. Despite the expression of two distinct transcripts (4.4 and 2 kb) cloned for the human UT-B1 transporter, both appear to encode for a single 43 kDa protein. Sequence alignment with other urea transporters shows that UT-B1 shares more than 60% identity with UT-A2. Additionally, hydrophilicity profiles indicate that UT-B1 and UT-A2 proteins show similar topology (reviewed in [Bagnasco 2006]). Another isoform of UT-B, UT-B2 is expressed in the bovine rumen but has not yet been detected in humans. Interestingly, UT-B2 is not regulated by vasopressin, cAMP, calcium, or protein kinases.

Acute Regulation of Urea Transport by Vasopressin

When the body is dehydrated, vasopressin (also known as antidiuretic hormone) is released (Fig. 3). When vasopressin is increased, the hormone binds to the V_2 vasopressin receptor, located on the basolateral membrane of the IMCD, and activates the heterotrimeric G protein, Gs_{α}. Activation of the G protein stimulates ▶ adenylyl cyclase to synthesize cAMP. The increase of intracellular cAMP stimulates several downstream proteins including protein kinase A (PKA) and Epac (exchange protein directly activated by cAMP). Both are involved in the vasopressin-mediated increase in urea permeability (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Vasopressin also increases urea flux in freshly isolated IMCD cell suspensions (Zhang et al. 2002), UT-A1-MDCK cells (Fröhlich et al. 2006), UT-A1-mIMCD3 cells (Klein et al. 2010), and mUT-A3-MDCK cells



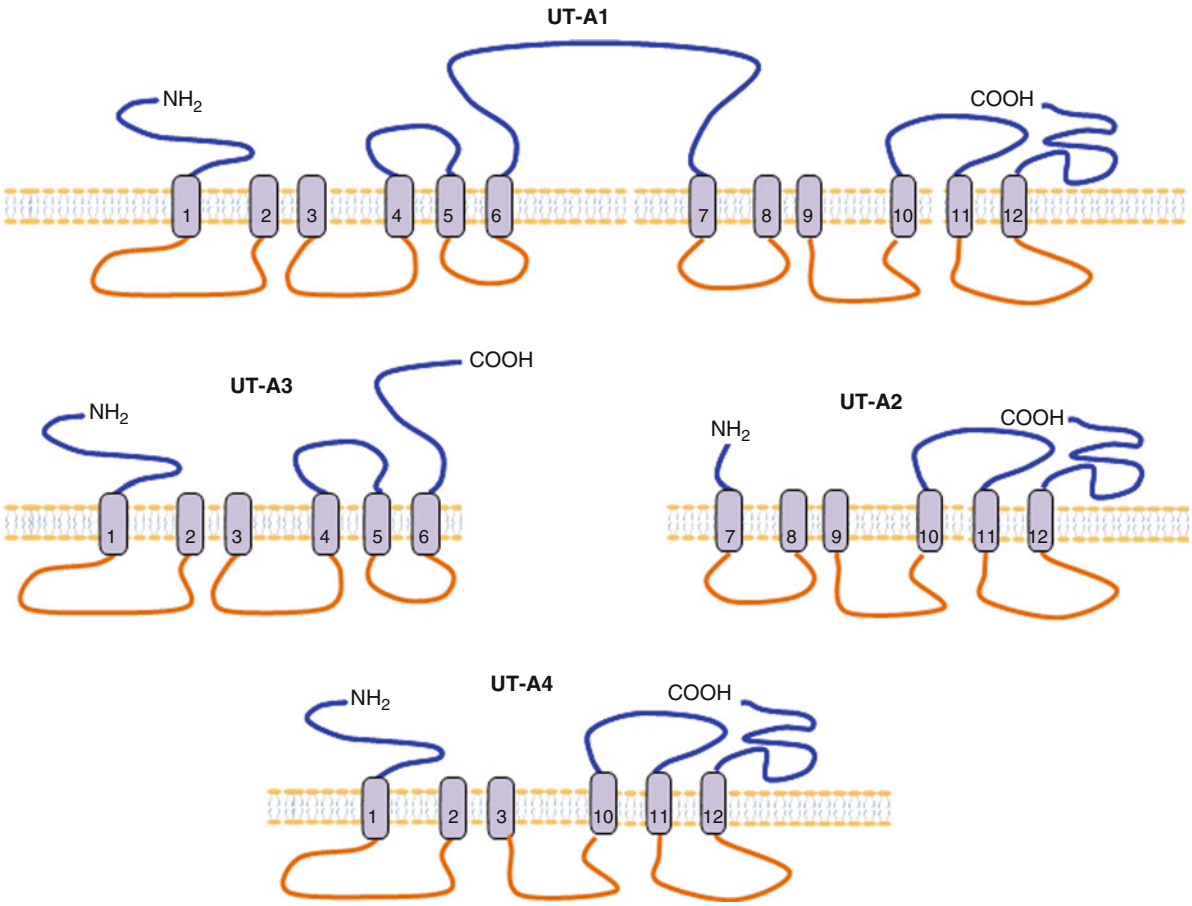
UT (Urea Transporter), Fig. 1 Location of the Renal Urea Transporters. UT-A2 is found in the thin descending limbs of Henle's loop in the inner stripe of the outer medulla. UT-A1 and UT-A3 are expressed in the IMCD. UT-A1 is primarily found in the cytosol and the apical membrane of the cell whereas UT-A3 is located in the cytosol and the basolateral membrane of the IMCD. UT-B is located primarily in the descending vasa recta and red blood cells

(Stewart et al. 2009). The acute effect of vasopressin on UT-A2 is still not understood. One group of studies showed that vasopressin and cAMP increased urea flux in mUT-A2-MDCK cells (Potter et al. 2006); however, other work found that treatment with cAMP or forskolin did not increase urea transport via UT-A2 (Fenton et al. 2002). It was recently demonstrated that cAMP-treated oocytes that have been injected with UT-A2 fail to display increased urea flux (Mistry et al. 2010). Further work will be needed to address the acute regulation of UT-A2 by vasopressin. The acute regulation of UT-A1 and UT-A3 has been studied in great detail, which is further discussed below.

Phosphorylation

An in silico analysis of the amino acid sequence of the urea transporter reveals a large number of consensus phosphorylation sites for variety of kinases including several PKA consensus phosphorylation sites for both UT-A1 and UT-A3 (Fig. 4). In rat terminal IMCDs, vasopressin increases the phosphorylation of both UT-A1 and UT-A3, with a similar time-course and dose-response for that observed in the vasopressin-stimulated increase in urea permeability in perfused rat terminal IMCDs (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Vasopressin, acting through cAMP, stimulates Epac, which also increases urea permeability and UT-A1 phosphorylation in rat IMCDs (Wang et al. 2009).

Vasopressin stimulation results in the direct phosphorylation of UT-A1 at S486 and S499 in rat kidney (corresponding to S477 and S490 in the human UT-A1 sequence) (Blount et al. 2008). Both of these residues are located in the large intracellular loop that is unique to UT-A1. Studies show that attaching the loop region of UT-A1 (aa 460–532) that contains S486 and S499 to UT-A2 confers vasopressin sensitivity to UT-A2 (Mistry et al. 2010) confirming the importance of these phosphorylation sites. Site directed mutagenesis revealed that neither of the two PKA consensus sites



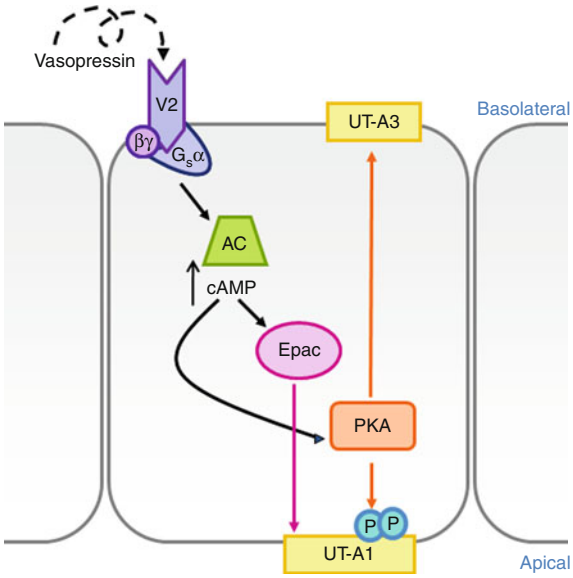
UT (Urea Transporter), Fig. 2 Four Renal Isoforms of UT-A. This schematic demonstrates that UT-A1 is the largest protein transcribed from the UT-A gene containing 11 transmembrane helices. UT-A3 is the N-terminal half of UT-A1 and UT-A2 is the C-terminal half of UT-A1. UT-A4 is the N-terminal quarter of UT-A1 spliced to the C-terminal quarter. Loop regions shown in blue are intracellular whereas those highlighted in orange are extracellular. Transmembrane structure prediction was based on the GES-scale (Goldman Engelman Steitz) analysis of the primary structure which employees hydropathy calculations in combinations with helical probabilities

(S85 or S92) in mouse is involved in vasopressin-induced phosphorylation (reviewed in [Sands and Layton 2009; Sands and Layton 2008]); however, vasopressin does increase phosphorylation at S84 in rat UT-A1 and UT-A3 (Hwang et al. 2010). The vasopressin-stimulated phosphorylation site in human UT-A3 has not been determined as S84 is not conserved in the human sequence.

Plasma Membrane Accumulation

Vasopressin increases the plasma membrane accumulation of UT-A1 and UT-A3 in IMCDs from normal rats but not from either vasopressin-deficit Brattleboro rats or water diuretic rats (Blount et al. 2007; Klein et al. 2006). When forskolin is used to stimulate cAMP instead of vasopressin, the plasma membrane accumulation of UT-A1 is increased in IMCDs from normal and diuretic rats (Klein et al. 2006). Activating Epac also increases UT-A1 plasma membrane accumulation in rat IMCDs (Wang et al. 2009).

UT-A1 apical plasma membrane accumulation is increased by vasopressin or forskolin in UT-A1-MDCK cells (Chen et al. 2006; Klein et al. 2006) and UT-A1-mIMCD3 cells (Klein et al. 2010). Mutation of both of the PKA sites in UT-A1, S486 or S499, eliminates vasopressin stimulation of UT-A1 apical plasma membrane accumulation and urea transport. Interestingly, increased membrane insertion of UT-A1 requires that both PKA sites are functional as mutation of either S486 or S499 individually has



UT (Urea Transporter), Fig. 3 Vasopressin Signaling in the IMCD. When increased, vasopressin binds to the vasopressin receptor, V_2 located on the basolateral cell membrane and activates the heterotrimeric G protein, Gs_α. Activation of the G protein stimulates adenylyl cyclase (AC) to synthesize cAMP. Increased cAMP can activate two downstream targets, Epac and PKA; both have shown to affect urea transporter function. Increased levels of cAMP lead to direct phosphorylation of UT-A1 and UT-A3. Direct phosphorylation of UT-A1 is required for apical membrane insertion. UT-A3 membrane accumulation is also increased in the presence of high cAMP levels

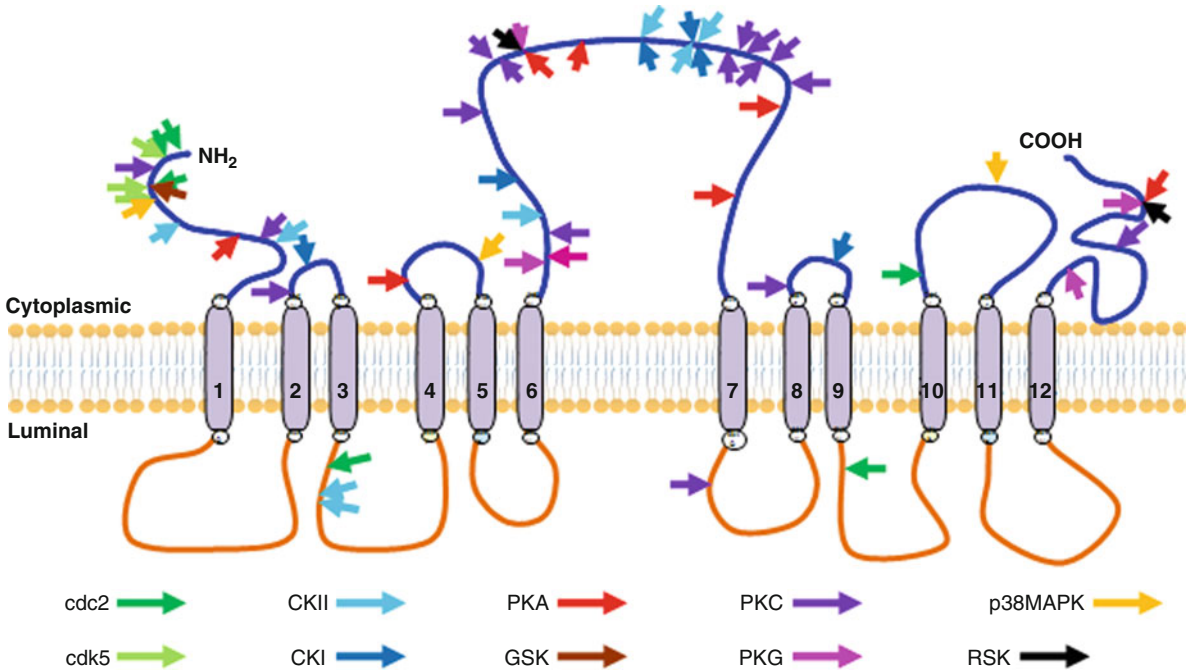
no effect on cAMP-mediated UT-A1 trafficking (Blount et al. 2008). An antibody that specifically detects UT-A1 phosphorylated at the S486 site was used to confirm that vasopressin increases UT-A1 accumulation in the apical plasma membrane and that the S486-phospho-UT-A1 form is primarily detected in the apical plasma membrane (Klein et al. 2010).

Acute Regulation of Urea Transport by Hyperosmolality

Depending upon the hydration status of an animal, the osmolality of the renal medulla varies over a wide range. Increasing osmolality rapidly increases urea permeability in rat terminal IMCDs, even in the absence of vasopressin, suggesting that hyperosmolality is an independent regulator of urea transport. Increasing osmolality has an additive stimulatory effect on urea permeability when vasopressin is present. Both phloretin and thiourea inhibit hyperosmolality-stimulated urea permeability. Hyperosmolality, like vasopressin, increases urea permeability by increasing the V_{max} rather than the K_m. However, these two agonists stimulated urea permeability through different signaling pathways: hyperosmolality via increases in intracellular calcium and PKC; vasopressin via increases in cAMP and PKA activity. These various aspects of hyperosmolar influences on urea permeability are reviewed in (Sands and Layton 2009; Sands and Layton 2008). Hypersomolality, like vasopressin, increases the phosphorylation and the plasma membrane accumulation of both UT-A1 and UT-A3 (Blessing et al. 2008; Blount et al. 2007; Klein et al. 2006). Thus, both hyperosmolality and vasopressin rapidly increase urea permeability but they do so via different signaling pathways. The effects of vasopressin and tonicity are compared in Table 2.

Acute Regulation of Urea Transport by Other Factors

In addition to vasopressin regulation of urea permeability, several other hormones have been shown to affect urea transporter function. Angiotensin II increases both vasopressin-stimulated urea permeability and UT-A1 phosphorylation in rat terminal IMCDs via a PKC-mediated effect. Angiotensin II does not affect urea permeability in the absence of vasopressin (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Increased levels of glucagon, another hormone that activates the production of cAMP, was shown to have varied effects on urea transport between studies. In one study, glucagon decreased urea permeability in perfused rat terminal IMCDs and UT-A1 protein abundance by stimulating a PKC signaling pathway (Yano et al. 2008). However, in other studies, glucagon did not alter basal or vasopressin-stimulated urea permeability, nor cAMP production, in either the initial or terminal IMCD (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Oxytocin stimulates urea permeability by binding to V_2-receptors and increasing cAMP production. Alpha-2 adrenergic agonists, such as clonidine and epinephrine, inhibit vasopressin-stimulated urea permeability in the rat terminal IMCD. Likewise, furosemide and amphotericin B also inhibit vasopressin-stimulated urea permeability; however, neither atrial natriuretic peptide nor insulin alters urea permeability in perfused rat terminal IMCDs (reviewed in [Sands



UT (Urea Transporter), Fig. 4 Consensus Phosphorylation Sites in Human UT-A1. The human UT-A1 sequence was analyzed using the NetPhosK 1.0 Server. Arrows indicate predicted sites with a greater than 50% of phosphorylation by the indicated kinase

UT (Urea Transporter), Table 2 Comparison of vasopressin and hyperosmolality in the IMCD. Original citations are reviewed in Sands and Layton 2008, 2009

Property	Vasopressin	Hyperosmolality
Signaling pathway	cAMP and adenylyl cyclase	Intracellular calcium and PKC
Inhibitors	Phloretin, thiourea	Phloretin, thiourea
V_{max}	Increases	Increases
K_m	Unchanged	Unchanged
Phosphorylation	Increases UT-A1 and UT-A3	Increases UT-A1 and UT-A3
Plasma membrane accumulation	Increases UT-A1 and UT-A3	Increases UT-A1 and UT-A3
UT-A Promoter I activity	No effect of cAMP (and no consensus CRE)	Increases via TonE and TonEBP

and Layton 2009; Sands and Layton 2008]). These collective findings suggest that there are many other complex signaling cascades involved in urea transporter function that remain to be elucidated.

Long-Term Regulation of Urea Transport by Vasopressin

Vasopressin may also exert long-term regulation of UT-A1 and UT-A3 through changes in protein abundance. Two approaches that have been used to vary vasopressin levels in animals are: alter endogenous vasopressin levels by altering hydration status; and administering exogenous vasopressin, or dDAVP, a V_2-selective vasopressin receptor agonist, to induce a constant high level of vasopressin.

UT-A1

Treating Brattleboro rats (which lack endogenous vasopressin) with vasopressin for 5 days decreases UT-A1 protein abundance in the inner medulla.

Similarly, terminal IMCDs from water-loaded (3 days) rats have higher basal and higher vasopressin-stimulated urea permeabilities and increased UT-A1 expression by immunohistochemistry than from rats given water ad libitum. The changes in UT-A1 protein abundance in response to changes in vasopressin levels or hydration state do not appear to be regulated by transcription (reviewed in [Sands and Layton 2009; Sands and Layton 2008]).

When vasopressin is administered to Brattleboro rats for a longer period of time (12 days), UT-A1 protein abundance is significantly increased. Similarly, water-loaded (2 weeks) rats have significant decreases in UT-A1 protein abundance. The delayed increase in UT-A1 protein abundance following vasopressin administration to Brattleboro rats is consistent with the time course for the increase in inner medullary urea concentration (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). Analysis of the UT-A promoter I may explain this time-course since it does not contain a cAMP response element (CRE) in the 1.3 kb that has been cloned and thus cAMP does not increase promoter I activity. However, a tonicity enhancer element (TonE) is present in UT-A promoter I and hyperosmolality increases promoter activity. Thus, increasing vasopressin may initially increase the transcription of the Na-K-2Cl co-transporter, NKCC2/BSC1, in the thick ascending limb; the increase in NaCl reabsorption will in turn increase inner medullary osmolality, which will in turn increase UT-A1 transcription through TonE (reviewed in [Sands and Layton 2009; Sands and Layton 2008]).

UT-A2 and UT-A3

The mRNA abundances of UT-A2, UT-A2b, UT-A3, and UT-A3b are decreased in the inner medulla of 3 day water-loaded rats and increased in: (1) 3 day water restricted rats and mice, (2) rats receiving dDAVP for 3 weeks, and (3) Brattleboro rats treated with vasopressin for 1 week (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). UT-A2 and UT-A3 protein expression are decreased in 3 day water-loaded rats without a change in the subcellular distribution of either urea transporter. UT-A2 protein abundance is increased by 7 days of dDAVP administration to Brattleboro rats. UT-A2 regulation could involve transcriptional mechanisms stimulated by vasopressin since UT-A2 is under the control of UT-A promoter II, which contains a CRE element and its promoter activity is increased by cAMP (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). UT-A3, like UT-A1, is under the control of UT-A promoter I, which contains TonE. Tonicity-responsive transcription of UT-A3 would explain the increased UT-A3 protein abundance observed in water deprived rats (reviewed in [Sands and Layton 2009; Sands and Layton 2008]).

Urea Transporter Knockout Mice

Within the last decade, several animal models have been developed to examine the role or the urea transporters in vivo. Each was shown to have urine concentrating defects supporting the hypothesis that urea transporters must be present for proper urine concentration (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). The significant findings are discussed in detail below.

UT-A1/UT-A3 Knockout Mice

Mice lacking both UT-A1 and UT-A3 have reduced urine concentrating ability, reduced inner medullary interstitial urea content, and lack vasopressin-stimulated urea transport in their IMCD (reviewed in [Fenton and Knepper 2007]). These mice are able to concentrate their urine almost as well as wild-type mice when both are fed a low-protein diet, supporting the hypothesis that IMCD urea transport contributes to urine concentrating ability by preventing urea-induced osmotic diuresis (reviewed in [Fenton and Knepper 2007]). Inner medullary tissue urea content was markedly reduced following water restriction, but there was no measurable difference in NaCl content between UT-A1/UT-A3 knockout mice and wild-type mice (reviewed in [Fenton and Knepper 2007]). This finding has been interpreted both as being inconsistent with the predictions of the passive mechanism (Fenton and Knepper 2007) as well as supporting it (Pannabecker et al. 2008).

UT-A2 Knockout Mice

Mice lacking UT-A2 mice have a reduced urine concentrating ability (Uchida et al. 2005). The reduction in urine concentrating ability is less severe than in the UT-A1/UT-A3 knockout mice and likely results from impairment of urea recycling (Uchida et al. 2005).

UT-B1 Knockout Mice

Mice lacking UT-B1 mice have impaired urine concentrating ability, achieving a maximal urine osmolality of 2,400 mOsm/kg H_2O as compared to 3,400 in a wild-type mouse (Yang et al. 2002). This phenotype is similar to humans lacking UT-B1, the Kidd antigen, who are unable to concentrate their urine above 800 mOsm/kg H_2O, even following overnight water deprivation and exogenous vasopressin administration (reviewed in [Sands and Layton 2009; Sands and Layton 2008]). These findings support the hypothesis that urea transport in red blood cells is necessary to preserve the efficiency of countercurrent exchange (reviewed in [Fenton and Knepper 2007; Sands and Layton 2009; Sands and Layton 2008]).

Summary

Urea plays a critical role in the urinary concentrating mechanism, and therefore, in the regulation of the body's water balance. The kidney needs to be able to regulate urea excretion in order to vary urine osmolality and maintain (or restore) plasma osmolality within (to) the normal range. Functional data suggested that urea transport in the IMCD was mediated by specific urea transporter proteins. Subsequent molecular approaches resulted in the cloning of two gene families for facilitated urea transporters, UT-A and UT-B. Since the identification of the four UT-A renal isoforms and UT-B in the vasa recta, great strides have been made toward the understanding of the regulatory signaling mechanisms that control urea permeability. Vasopressin and hypertonicity regulate UT-A1 and UT-A3 by changes in phosphorylation as well as by changes in plasma membrane accumulation. In addition to acute regulation by vasopressin, urea transporter protein abundance is also regulated by chronic vasopressin exposure. Genetically engineered mice that lack one of the urea transporter proteins show that urea transporters play a critical role in the urine concentrating mechanism. Further use of advancing technology including the generation of transgenic animals and proteomic data will continue to elucidate the complex signaling cascades that regulate the urine concentration mechanism.

Historical Background

VRK3 is a member of the vaccinia-related kinase family (Manning et al. 2002), which comprises a group of three proteins, of which two, VRK1 and VRK2, are catalytically active. VRK3 has substitutions in key residues within its catalytic domain and is therefore a pseudokinase without kinase activity (Nichols and Traktman 2004). The biological effects of VRK3 are mediated by protein–protein interactions. VRK3 can de-activate mitogen-activated protein (MAP) kinase signaling in the nucleus by activating phosphatases such as VHR, which dephosphorylates extracellular signal-regulated protein kinase (ERK), and reducing its ability to activate transcription.

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

VRK3 Gene Expression

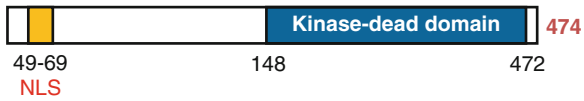
The human *VRK3* gene is located in chromosome 19q13.33, has 15 exons, and its mRNA is 1.9 kb in length (Nichols and Traktman 2004); and although there are several alternative messages, only one protein has been identified.

Murine *VRK3* gene is expressed throughout mouse embryonic hematopoietic development. Peak expression occurs in liver at days E11.5 to E12.5, followed by an order of magnitude drop at day E13.5 to E15.5. Expression levels recover again by day E17.5 in embryogenesis. In fetal peripheral blood lymphocytes expression is high at days E10.5 to E11.5, which is followed by a two- to threefold reduction. Expression levels then remain constant until the end of fetal development (Vega et al. 2003). In the adult mouse, VRK3 mRNA is expressed at similar levels in the liver, kidney, muscle, thymus, and bone marrow. Expression in the adult spleen is one order of magnitude lower (Vega et al. 2003). In an independent study, mouse VRK3 mRNA expression was detected at very high levels in kidney, testis, and small intestine. VRK3 protein was also detectable at significant levels in heart, kidney, and testis, and at lower levels in lung, stomach, liver, spleen, and skeletal muscle. However, the variations in protein expression were much less significant and do not correspond with the large variations in mRNA expression (Kang and Kim 2008).

In rat embryos, the highest VRK3 expression was detected between E15 to E17. However, this study examined whole-embryo expression only during days E13 through E17 (Kang and Kim 2008). VRK3 is highly upregulated in some rat tissues including kidney and testis, which correlates with reduced levels of phospho-ERK (Kang and Kim 2008). Intriguingly, it has been reported that ERK activity promotes transcription of VRK3, suggesting the existence of a feedback inhibition mechanism (Kang and Kim 2006, 2008).

VRK3 Protein Structure

The VRK3 protein has 474 aminoacids and 52.8 kDa (Fig. 1). The crystal structure of VRK3 reveals that despite conservation of the kinase domain fold (PDB: 2JII), mainly in its surface, it presents several changes that render it catalytically inactive, but may function as a scaffold protein and it maintains the overall structure of the kinase domain (Scheeff et al. 2009). The inactivating substitutions occurred early in evolution, and they hinder binding to ATP. VRK3 also has differences in the activation loop, in which a helix is replaced by a kink (Scheeff et al. 2009). Human VRK3 is a pseudokinase and plays a scaffolding role in the nucleus where it recruits the VHR phosphatase (Kang and Kim 2006, 2008). However, the mechanism through which its interaction with VHR is regulated has not been identified. VRK3 is a nuclear protein and has a nuclear localization signal in its N-terminal region (Nichols and Traktman 2004).



Vaccinia-Related Kinase-3 (VRK3), Fig. 1 Structure of human VRK3. NLS: nuclear localization signal

Studies with GFP-hVRK3 fusion proteins revealed that the protein is located in the nucleus. A bipartite nuclear localization signal is found within the first 149 amino acids of VRK3 (Nichols and Traktman 2004). No variant proteins have been identified in vivo (Nichols and Traktman 2004).

VRK3 Signaling

Unlike other vaccinia-related kinases, VRK3 does not have kinase activity. Although it contains a weakly conserved catalytic domain that is related to casein kinases, this domain has several substitutions in residues that are crucial for catalytic activity (Nichols and Traktman 2004). Indeed, its structure reveals that it has a poorly conserved catalytic site, but a highly conserved kinase fold (Scheeff et al. 2009). The human (h)VRK3 and mouse (m)VRK3 proteins are catalytically inactive (Nichols and Traktman 2004) and VRK3 does not bind ATP (Scheeff et al. 2009).

However, VRK3 plays a scaffolding role in the nucleus (Kang and Kim 2006). Human VRK3 is able to directly interact with, and enhance, the activity of the tyrosine phosphatase VHR. This interaction results in dephosphorylation of phospho-ERK1/2 and subsequent downregulation of ERK signaling in the nucleus (Kang and Kim 2006, 2008). Furthermore, in rat neurons treated with cisplatin, the expression levels of

VRK3 and the DUSP6 phosphatase are selectively reduced, resulting in an increased and sustained accumulation of phospho-ERK in these cells (Gozdz et al. 2008). Activation of ERK by phorbol ester (PMA: phorbol-12-mirystate 13-acetate), an analog of diacylglycerol, induces an increase in VRK3 levels, thus establishing a negative feedback in MAPK signaling mediated by VRK3 (Kang and Kim 2006, 2008).

In an analysis of the kinome in response to EGFR signaling, VRK3 and ▶ VRK2 correlated with low levels of p-ERK (Komurov et al. 2010), which is consistent with its role in recruiting phosphatases and dephosphorylating associated proteins.

Human VRK3 also preferentially interacts with the GDP-bound form of the ▶ Ran small GTPase, but the functional significance of this interaction is not known (Sanz-Garcia et al. 2008).

Summary

VRK3 is the most divergent member of the VRK family. It has no kinase activity due to several substitutions in key residues within its catalytic domain. VRK3 is mostly located within the nucleus and appears to play a scaffold role, where it downregulates MAPK signaling and reduces the level of p-ERK by recruiting the VHR phosphatase.

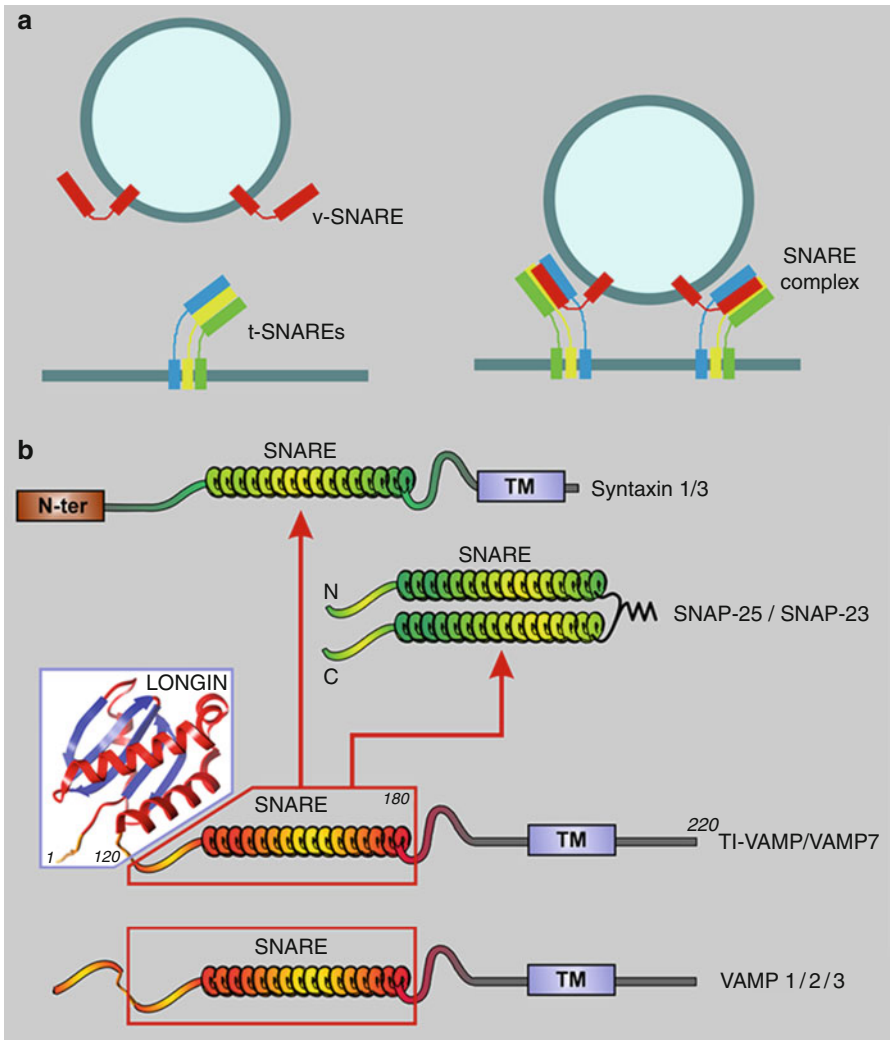
Overview

Intracellular membrane trafficking in eukaryotes is a multiple-step process that can be artificially divided in the budding of vesicles from a donor compartment, their translocation into the cytoplasm along cytoskeletal elements, their tethering and subsequent fusion with the membrane of the target compartment. Membrane fusion involves SNARE proteins, classified into two categories, vesicular (v)-SNAREs and target (t)-SNAREs present on the acceptor membrane. It is the specific pairing of v-SNAREs with their cognate t-SNAREs *in trans* that is responsible for bringing the lipid bilayers together for membrane fusion and the zippering of SNAREs provides the required energy (Fig. 1). This review focus on the discovery of SNAREs and then on four of the nine v-SNAREs: the clostridial neurotoxin sensitive VAMPs 1, 2, and 3 and on Tetanus neurotoxin-Insensitive Vesicle-Associated Membrane Protein, TI-VAMP/VAMP7.



VAMP1/2/3/7,
Fig. 1 Functions and structures of SNARE proteins. (**a**) Membrane fusion involves two types of SNARE proteins, vesicular (v)-SNAREs (in *red*) and target (t)-SNAREs (in *yellow*, *green* and *blue*) present on the acceptor membrane. It is the specific pairing of v-SNAREs with their cognate t-SNAREs *in trans* that form the *SNARE complex* (*right panel*) responsible for bringing the lipid bilayers together for membrane fusion. (**b**) The different structures of SNAREs are represented. t-SNAREs (*top* in *yellow* and *green*) and v-SNAREs (*bottom* in *red*). All SNAREs (v-and t-) share a segment in their cytosolic domain called the *SNARE motif* (boxed in *red* for the v-SNAREs). These domains are responsible for SNAREs interactions by their capacity to assembly into four-helix bundles when forming *SNARE complexes* represented in A. In comparison to VAMP 1/2/3 (100–116aa in human), TI-VAMP (220aa) possesses a long amino-terminal domain (Longin domain) which adopts a "profilin-like" structure, represented in the *blue* box

VAMP7, unlike the first ones, possess a long amino-terminal domain called the Longin domain and thus defining the Longin subfamily of v-SNAREs. Here are reviewed the current knowledge on the functions of four Vesicle Associated Membrane Proteins (VAMPs), VAMPs 1, 2, 3, and 7. VAMPs 1–3 play major role in endosomal vesicular fusion including the recycling of synaptic vesicles and receptors whereas VAMP7 plays multiple functions in post-Golgi trafficking pathways regulating epithelial and neuronal morphogenesis. The role of SNAREs in membrane fusion is now well established, nevertheless, the high homology of v-SNAREs and their apparent redundancy now raise the question of their specificities that still have to be investigated. Also little is known on SNARE mediated fusion regulation. This will certainly be addressed in the next few years.

VAMP Family Members

VAMP1: Vesicle-Associated Membrane Protein 1, Synaptobrevin 1, Syb1, Syb-1, VAMP-1, DKFZp686H12131
VAMP2: Vesicle-Associated Membrane Protein 2, Synaptobrevin 2, Syb2, Syb-2, VAMP-2, FLJ11460
VAMP3: Vesicle-Associated Membrane Protein 3, Cellubrevin, Cb, Ceb, VAMP-3, Synaptobrevin 3, Syb3

VAMP7: Vesicle-Associated Membrane Protein 7, Tetanus neurotoxin Insensitive Vesicle-Associated Membrane Protein (TI-VAMP, TIVAMP, Ti-VAMP), Synaptobrevin-like protein1, Synaptobrevin like 1, Sybl1, VAMP-7, FLJ53045, FLJ53762, FLJ54296

Historical Background: The SNAREs Discovery

VAMP stands for Vesicle-Associated Membrane Protein (For reviews see, Jahn and Scheller 2006). Seven VAMPs have been described: 1, 2, 3, 4, 5, 7, and 8. The first discovered were VAMPs 1 and 2 initially identified as synaptic vesicle proteins thus also called Synaptobrevins 1 and 2. They were then found to be the target of clostridial neurotoxins: botulinum neurotoxins B, D, F, and G and tetanus neurotoxin. Major breakthrough to define VAMPs function originated down the line of in vitro experiments aimed at characterizing transport between Golgi membranes (Balch et al. 1984). Indeed, fusion of Golgi vesicles with acceptor membranes is inhibited by pretreatment of cytosol with the cysteine alkylating agent NEM (N-ethylmaleimide) (Orci et al. 1989). The NEM-sensitive cytosolic component, essential for intra Golgi transport after coat recruitment and vesicle formation, is NSF protein (for *N*EM *S*ensitive *F*actor), the mammalian homologue of Sec18p identified by Novick and Schekman (Block and Rothman 1992). Whereas NSF could be found associated with membrane, purified NSF would not bind to Golgi membranes unless cytosol was added. This triggered the search and purification of the *S*oluble *N*SF *A*ttachment *P*roteins or SNAPs. The homologous proteins α-, β-, and γ-SNAP were purified from bovine brain based on their ability to attach NSF to Golgi membranes and thus restore transport in the in vitro assay. As with NSF, a yeast mutant (Sec17) also identified in the screen of Novick and Schekman failed to restore SNAP activity, but could be rescued by addition of purified mammalian SNAP further strengthening the view that membrane fusion depended on a conserved fusion machinery. Consequently, three proteins were isolated from bovine brain as SNAP receptors which had been previously cloned and found to be associated with the presynaptic terminal: VAMP/Synaptobrevin, Syntaxin 1, and SNAP25. Further characterization of the complex formed by VAMP/Synaptobrevin, Syntaxin 1, and SNAP25 revealed that all three SNAP receptors or "SNARE" proteins are present in a single 20S particle together with NSF and SNAP, and that the ATPase activity of NSF dissociates the complex. An essential role of Synaptobrevin in neurotransmitter release was proposed simultaneously by demonstrating that Synaptobrevin is the target of several neurotoxins. Indeed, clostridial neurotoxins, the most potent blockers of neurotransmitter release, are proteases which cleave the synaptic SNARE proteins Synaptobrevin, SNAP25 or Syntaxin 1. Taking all these observations into consideration, Rothman and colleagues suggested a molecular mechanism, which would explain vesicle docking and fusion in molecular terms, the so-called *SNARE hypothesis* (Fig. 1a) (Söllner et al. 1993a, b; Rothman and Warren 1994): It is now well known that each transport step within the eukaryotic cell is mediated by an original SNARE complex composed of one protein in the vesicle (the v-SNARE also called VAMP) and several in the target membrane (the t-SNAREs). These now historical findings suggested an important role for SNARE proteins at a late step in membrane fusion, a conclusion which has now been largely validated by a large series of experiments in vitro and in vivo. Indeed, SNARE-mediated lipid mixing can be efficiently recapitulated in vitro assays reconstituting fusion with v-SNARE and t-SNARE proteins into separate liposome populations. These assays allowed for identification of lipidic and proteic regulations such as Sec1/Munc18 family of proteins (for a summary of some important results obtained with these in vitro experiments see Ji et al. 2010).

Structure and Function

All SNAREs (v-and t-) share a segment in their cytosolic domain called the *SNARE motif* which can be considered the signature of these proteins (For reviews see, Proux-Gillardeaux et al. 2005a; Jahn and Scheller 2006). It consists of a domain of 60–70 amino acids (Fig. 1b) that is unstructured in solution but yet capable to adopt an α-helicoidal structure upon assembly into four-helix bundles when forming *SNARE complexes* with t-SNAREs.

Membrane fusion requires the assembly of few SNARE complexes (Mohrmann et al. 2010; van den Bogaart et al. 2010), which are composed of one SNARE motif provided by the donor membrane v-SNARE and three SNARE motifs provided by two or three acceptor membrane t-SNAREs. In the best so far characterized SNARE complex, one α-helix is contributed by the v-SNARE VAMP2, one by Syntaxin 1 and two are contributed by SNAP25. Hence, the SNARE core complex consists of four entwisted alpha-helices in which the 'a' and 'd' positions of the SNARE heptad repeats form a 16-layered hydrophobic core with a conserved ionic layer present at the center. This layer, also called the 'zero' layer, is composed of one arginine residue(R), contributed by the v-SNARE, forming hydrogen bonds with three glutamines (Q), each provided from the t-SNAREs. This results in another classification of the v- and t-SNAREs as R-and Q-SNAREs, respectively.

The assembly of v- and t-SNAREs into "trans" complexes likely bridges the opposing lipid bilayers of membranes belonging to donor and acceptor compartments, bringing them in proximity by "zippering" of the coiled–coil domains and inducing their fusion (Li et al. 2007).

Nine v-SNAREs/R-SNAREs have been identified in the human genome, VAMP1, 2, 3, 4, 5, 7, 8, Sec22 and Ykt6. v-SNAREs are small abundant C-terminally anchored type II membrane proteins (Fig. 1b). They vary in their structure and size extension in their amino-terminus part as detailed afterward in the VAMP7 paragraph. The membrane anchor of VAMPs is a transmembrane domain. Although a high level of homology between these proteins and the fact that common properties have been pointed out from structural and functional studies of SNAREs, the different v-SNAREs also have specific characteristics. Notably, the different VAMPs show different membrane fusion efficiency in cell fusion assay. VAMPs 1 and 3 being the most efficient, whereas VAMPs 4, 7, and 8 exhibit 30–50% lower fusion activities (Hasan et al. 2010).

VAMP1-3

VAMPs 1 and 2, also known as Synaptobrevins 1 and 2, are preferentially expressed in the brain where they are associated with synaptic vesicles and are implicated in neurotransmitter release (For reviews see, (Proux-Gillardeaux et al. 2005a; Montecucco et al. 2005). Despite very high homology, they show a differential distribution in the rat brain, with partial overlap. VAMP2 is the most abundant isoform and is widely distributed whereas VAMP1 is less abundant and the main isoform in certain areas (e.g., zona incerta of the subthalamus or nerve terminals surrounding thalamic neurons) (Raptis et al. 2005). VAMP1 plays also an important role implicated in neurotransmitter release at the neuromuscular junction, the synaptic connection between nerve and muscle (Liu et al. 2011).

VAMP3 is the non-neuronal isoform of VAMP2, with a widespread tissue distribution, and participates to regulated and constitutive exocytosis. It has been localized to early endosomes. VAMP3 is also detected in the nervous system, but it is expressed at significant levels only by glia and vascular cells. It has been implicated for instance in the CNS myelination by oligodendrocytes (Feldmann et al. 2011). VAMPs1/2, albeit primarily neuronal, are also expressed by certain non-neuronal cells in which they are involved in various regulated secretory processes. For example, VAMP2 is associated with insulin secretory granules in pancreatic beta cells in the Islets of Langerhans and mediates insulin release (Hou et al. 2009). Interestingly, as for neurotransmitter release, insulin secretion is directly triggered by Ca2+ dependent Insulin granule fusion with the plasma membrane, a process which is lost in Type 1 diabetes with the destruction of beta cells.

Like VAMPs 1 and 2 in neurons, VAMP3 is sensitive to clostridial neurotoxins. Two approaches were undertaken to unravel the function of VAMP2/3: first, a pharmacological approach with clostridial neurotoxins that cleave VAMPs1, 2 and 3, antibodies directed against VAMP 2 or 3, or recombinant VAMPs deleted of their C-terminal transmembrane domains, and second, a genetic approach by mutating the gene in fly and mouse or RNA-mediated interference (RNAi) in cultured cells.

1. *Clostridial neurotoxins* (tetanus neurotoxin (TeNT) and botulinum neurotoxins B, D, F, and G) cleave VAMPs 1, 2 and 3. Clostridial neurotoxins block neurotransmitter release in vivo and in cultured neurons. TeNT-expressing bipolar cell axons

further show synapse formation defects in the retina (Kerschensteiner et al. 2009). In non-neuronal cells, TeNT inhibits the recycling of plasma-membrane receptors including: transferrin receptor, T-cell receptors to the immune synapse, and integrin β_1 in epithelial cells (Proux-Gillardeaux et al. 2005b; Skalski and Coppolino 2005; Tayeb et al. 2005; Hager et al. 2010; Skalski et al. 2010); it inhibits retrograde transport from early endosomes to the Golgi apparatus, apical transport of H^+-ATPase in kidney epithelial cells, and cytokine secretion (Murray et al. 2005); and it decreases the efficiency of phagocytosis by inhibiting focal exocytosis at sites of phagocytosis in macrophages, as does botulinum neurotoxin B. TeNT also impairs cell adhesion and cell migration (Proux-Gillardeaux et al. 2005b; Tayeb et al. 2005; Luftman et al. 2009; Skalski et al. 2010; Veale et al. 2010) and the release of retroviruses. In polarized MDCK cells, TeNT inhibits basolateral sorting of AP-1B dependant cargos (Fields et al. 2007). VAMP3 also plays a role in autophagocytosis in the fusion between MVBs with autophagosomes to generate the amphisome, allowing the maturation of the autophagosome (Fader et al. 2009). Antibodies directed against VAMP3 inhibit α-granule secretion in permeabilized platelets (Flaumenhaft 2003). The cytoplasmic domain of VAMP3 is also a potent inhibitor of both α-granule and dense granule secretion in permeabilized platelets (Polgar et al. 2002).

2. *VAMP2-null mice* show an almost complete block of neurotransmitter release leading to death at birth and a strong inhibition of synaptic vesicle endocytosis. It is unclear if neuronal synapses are fully normal in this mutant in vivo. *VAMP3-null mice* do not show a strong phenotypic defect except for a decrease in phagocytosis of zymosan in macrophages. The *VAMP2–VAMP3 double-knockout mice* show that VAMP3 contributes to secretion in chromaffin cells (Borisovska et al. 2005) but the lethality at birth of these mice prevents further analysis in vivo. Nevertheless, in neurons, the phenotype of VAMP2–VAMP3 double-knockout mice is identical with the single VAMP2 knockout (Deak et al. 2006), thus confirming that VAMP3 is not expressed in neurons as suggested previously. Silencing of VAMP3 by RNAi inhibits the delivery of tumor necrosis factor-α to the plasma membrane in macrophages (Murray et al. 2005; Kay et al. 2006). Functional at least partial redundancy with VAMP4, VAMP7, or VAMP8 may explain the fact that impairment of phagocytosis of zymosan in macrophages was the only clear defect observed in *VAMP3*-null mice. The ortholog of VAMP3 in *Drosophila melanogaster* is the ubiquitously expressed Syb, N-Syb being restricted to neuronal cells. Syb and N-Syb are functionally interchangeable. The loss of Syb in a somatic clone of cells is lethal (Bhattacharya et al. 2002).

VAMP7

In contrast to VAMPs 1, 2, and 3, VAMP7 is resistant to clostridial neurotoxins (tetanus and botulinum neurotoxins B, D, F, and G) (For reviews see, Proux-Gillardeaux et al. 2005a; Chaineau et al. 2009; Pryor and Luzio 2009). For that reason, VAMP7 was also called Tetanus neurotoxin-Insensitive Vesicle-Associated Membrane Protein (TI-VAMP). VAMP7 is also called Synaptobrevin-like 1 (Sybl1), it is encoded by the first pseudoautosomal gene found to be X and Y inactivated *Sybl1* gene is ubiquitously expressed and is extremely conserved. In adult rat brain, VAMP7 is localized in the somatodendritic compartment of neurons and also in subsets of axon terminals including, the hippocampal mossy fibers of the dentate gyrus and of CA3, the striatal peridendritic terminal plexuses in the globus pallidus, substantia nigra pars reticulata, peridendritic plexuses in the central nucleus of the amygdala, and the primary sensory afferents in the dorsal horn of the spinal cord. Unlike the brevins (VAMPs 1, 2, 3 and 8), but like Syntaxins, VAMP7 possess a long amino-terminal extension of about 100 amino acids, also called the "Longin" domain (Fig. 1). Thus VAMP7 is seen as the prototype of the family of 'Longin' v-SNAREs also containing Sec22 and Ykt6. Their Longin domains adopt a conserved globular "profilin-like" structure, similar to the profilin domain of the human SEDL protein and of domain present in the sigma and mu subunits of the AP-2 clathrin adaptor complex. This domain adopts a closed conformation onto their SNARE domain to prevent the formation of SNARE complexes (Vivona et al. 2010). In VAMP7, the Longin domain has two functions: it inhibits the formation of SNARE

complexes and it binds to the δ subunit of the molecular coat AP-3 protein to target VAMP7 to late endosomes or synaptic vesicles. Interestingly, the homologous of VAMP7 in Dictostelium discoideum has been shown to interact with all four Adaptor Protein complexes (AP-1, 2, 3, and 4) and at least AP-2 and AP-3 participate in the sorting of VAMP7 to the endocytic pathways. The endocytosis of VAMP7 depends on interaction with Hrb, a sorting mechanism which depends on the Longin domain. VAMP7 interacts with plasma membrane and endosomal target SNAREs. VAMP7 localizes to the trans-Golgi network (TGN) (Burgo et al. 2009; Danglot et al. 2010) and to late endosomes and lysosomes and synaptic vesicles in certain neurons. VAMP7 allows for heterotypic fusion between endosomes and lysosomes. VAMP7 is also involved in fusion of secretory vesicles with the plasma membrane, which is necessary for phagocytosis, neurite growth, axonogenesis, lysosomal and granule secretion in polarized, migrating, and invading cells. VAMP7 mediates the transport of rafts to the cell surface and rafts are involved in immune and neuronal synapse formation (Bunnell et al. 2002; Francesconi et al. 2009). A function of VAMP7 has been linked to immune responses through focal secretion in plants (Kwon et al. 2008).

Acknowledgments We apologize to all the authors that are not cited in the text due to strict reference limitation, we have cited very few reviews on the topic and only the most recent papers that were not cited in these. Historical Background

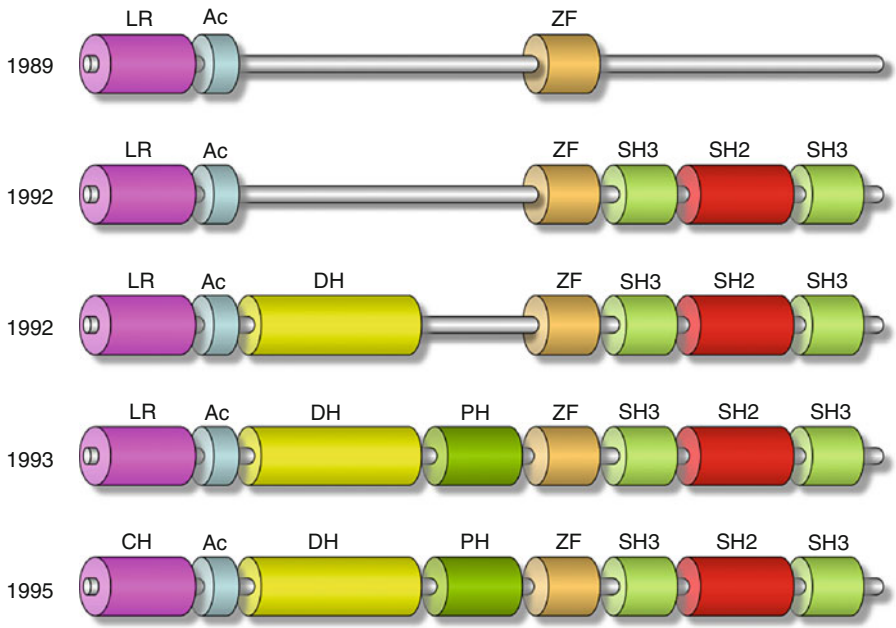
The Vav family is a group of signal transduction molecules that work primarily as phosphorylation-dependent GDP/GTP exchange factors (GEFs) for GTPases of the Rho/Rac subfamily. This family is composed of three members in vertebrates (Vav1, Vav2, and Vav3) and single representatives in invertebrate species (known generically as Vav). Instead, Vav proteins are not present in unicellular organisms or plants. The first member of this family was discovered in 1989 due to the spurious stimulation of its transforming activity during transfections of a human tumor–derived genomic DNA in rodent fibroblasts (Katzav et al. 1989). Since that oncogene was the sixth one isolated in Mariano Barbacid's lab, it received the name of the sixth letter of the Hebrew alphabet (*Vav*). The product encoded by the proto-oncogene was designated as Vav or, taking into consideration its molecular weight and the notation for oncogenes at that time, as $p95^{vav}$. The Vav2 and Vav3 proteins were subsequently identified in human



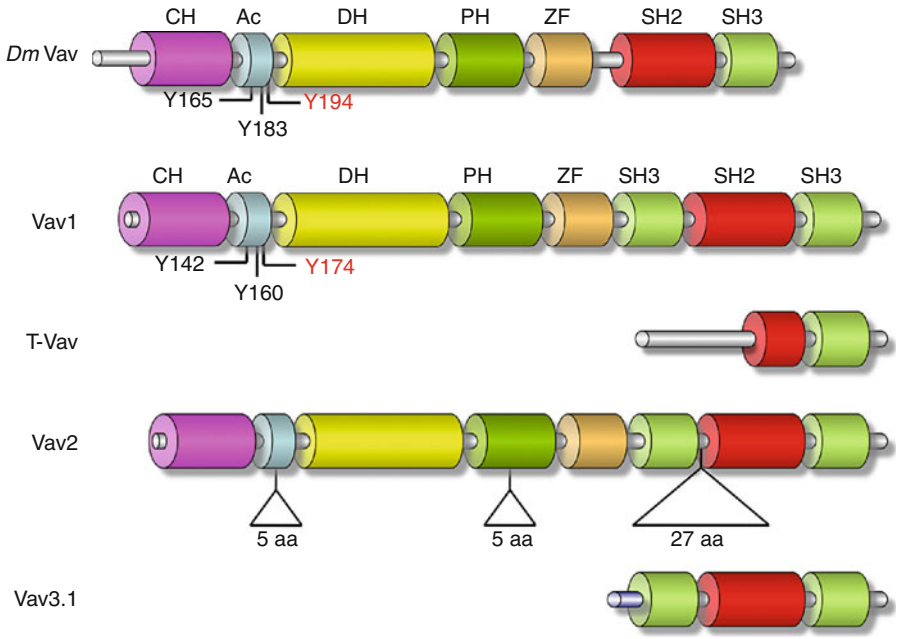
Vav Family,
Fig. 1 Evolution of the structural composition of Vav family proteins. The years in which the domains were discovered are indicated on the left. LR, leucine-rich/helix-loop-helix domain. The rest of abbreviations are described in the main text

and rodent species between 1995 and 2000. Since then, $p95^{vav}$ was re-baptized as Vav1 to maintain a consistent nomenclature within the family. The explosion of gene data derived from current genome sequencing efforts has led to the discovery of the rest of the Vav family members present in vertebrate and invertebrate species in the last decade.

The function of Vav1 could not be easily inferred upon its isolation, since many of the currently known structural domains had not been characterized at that time (Fig. 1). Due to this, the initial structure described for Vav1 only included the Ac, the ZF, and a putative N-terminal leucine-rich region/helix-loop-helix domain (Fig. 1) (Katzav et al. 1989). The presence of the latter domain, which is commonly found in transcriptional factors, led to the idea that Vav1 was perhaps a transcriptional factor. The concept that Vav1 was a signal transduction molecule implicated in protein tyrosine kinase–dependent routes crystallized in 1992 upon the discovery that this protein contained ▶ Src-homology (SH) regions and that it could become tyrosine phosphorylated upon stimulation of both mitogenic and antigenic receptors (Bustelo and Barbacid 1992; Bustelo et al. 1992). The discovery that Vav1 was a phosphorylation-dependent Rho/Rac GEF was reported 5 years later (Crespo et al. 1997). This final step allowed to obtain an integrated view of the mechanisms mediating the activation of Vav proteins during physiological and oncogenic conditions. However, a complete view of the mechanism by which the catalytic activity of these proteins was regulated by tyrosine phosphorylation could not be achieved until 2010 (Yu et al. 2010). Since 1994, extensive work using model organisms demonstrated that these proteins, either alone or acting together in a concerted manner, modulate important biological processes in vivo in species ranging from *C. elegans* to mice. This chapter will provide an overall view of the current knowledge about the structure, biological function, and regulatory mechanisms of these proteins. Readers can find further information in published reviews (Bustelo 2000, 2001; Turner and Billadeau 2002; Tybulewicz et al. 2003) and in the UCSD-Nature Molecular Pages initiative available online (Bustelo 2008; Bustelo and Couceiro 2008).

Structure

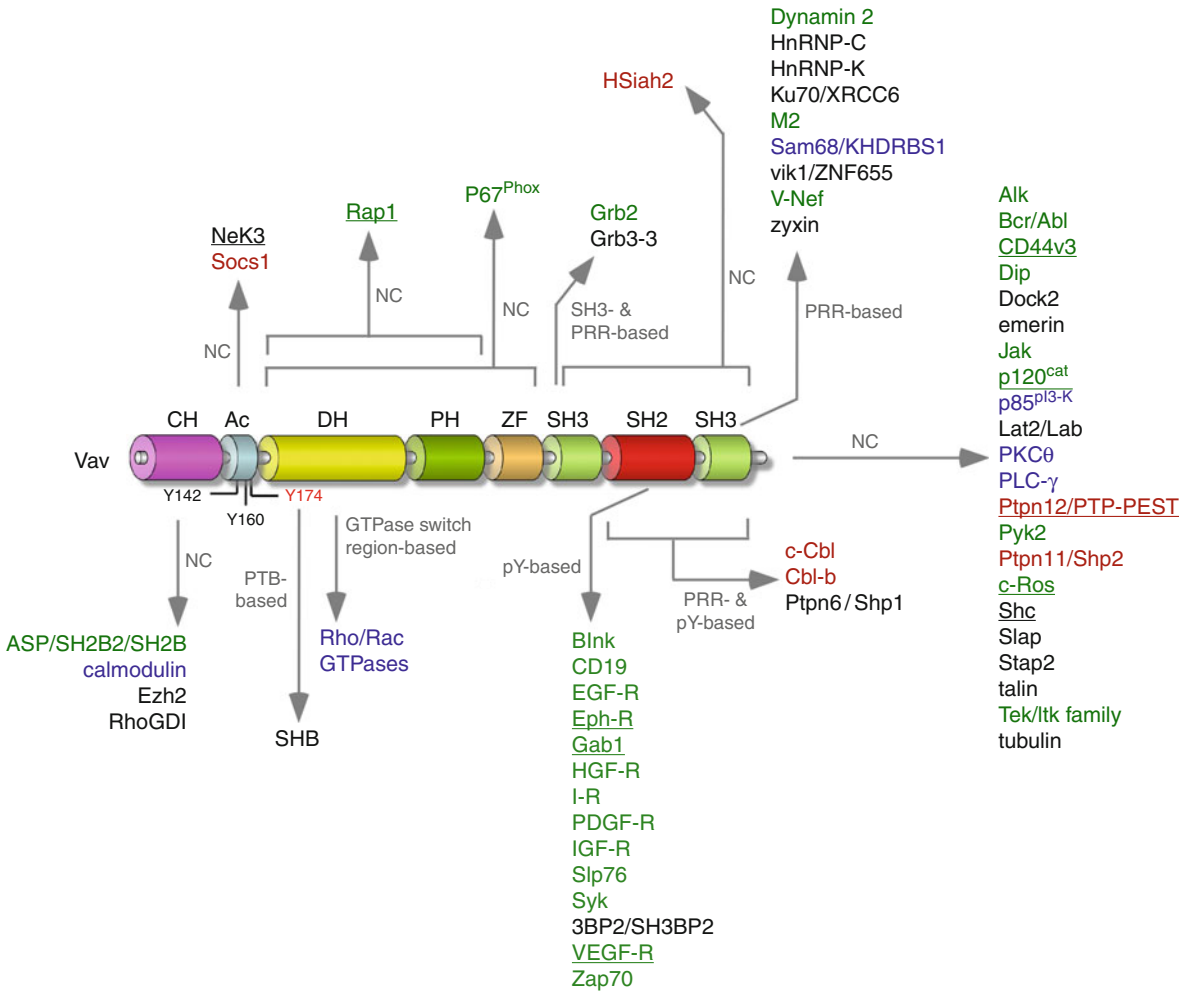
All vertebrate and prochordate Vav family members contain eight different structural domains: a calponin-homology (CH) region, an acidic (Ac) domain, a Dbl-homology region (DH), a pleckstrin-homology (PH) domain, a zinc finger (ZF) region, two SH3 domains, and a SH2 region (Figs. 1 and 2). Vav family proteins from invertebrate species lack the most N-terminal SH3 region (Fig. 2). *Vav* family genes can generate a number of Vav isoforms by differential splicing



Vav Family, Fig. 2 Structure of Vav family members and main isoforms. The structure of *D. melanogaster* (*Dm*) and mammalian Vav family members and isoforms are depicted. In addition to the structural domains present in those proteins, the three regulatory phosphorylation sites present in the Ac domains of Vav family proteins are shown. The main phosphosite is indicated in red. The lengths of the insertions that can be found in Vav2 isoforms are also indicated. aa, amino acid

(Fig. 2). The functional significance of these alternative isoforms is currently unknown. Although all the domains present in Vav proteins are commonly found in many signaling molecules, Vav proteins are the only ones combining on the same molecule a DH-PH-ZF cassette and a SH2 region (Bustelo 2000). This is due to their quite specific requirements for catalysis (see section Biological Activity) and activation (see section Regulation of Biological Activity), respectively.

Current evidence suggests that each structural domain has multifunctional roles, participating in intramolecular regulatory actions, protein–protein interactions, and/or effector roles (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The N-terminal CH and Ac regions participate in phosphorylation-dependent intramolecular interactions that regulate the catalytic activity of Vav proteins (see below, section Regulation of Biological Activity) and, at the same time, establish physical interactions with other proteins (Fig. 3). Although the functional significance of most of those interactions is still unclear, some of them appear to be important for either the activation of specific Vav family members (i.e., APS contributes to Vav3 activation; Fig. 3) or the assembly of downstream, T-cell-specific functions (i.e., calmodulin, Fig. 3) (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The Vav family DH regions are the catalytic domains that stimulate GDP/GTP exchange on Rho/Rac proteins and, at the same time, participate in the formation of heteromolecular interactions that contribute to either the activation ($p67^{Phox}$, Fig. 3) or subcellular localization (Rap1, Fig. 3) of specific Vav family members (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The Vav family PH and ZF domains form a structural unit with the DH domain that favors the formation of a catalytic competent conformation of the DH region (Chrencik et al. 2008; Rapley et al. 2008). The most N-terminal SH3 domain and an adjacent upstream proline-rich region (PRR) participate in the formation of protein–protein interactions with Grb2 family members (Grb2, Grb3-3; Fig. 3). The interaction with Grb2 is important to allow the association of Vav proteins with specific transmembrane proteins (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The Vav family SH2 domains are crucial for the activation of Vav family proteins during signal transduction, because they allow the interaction of the inactive Vav proteins with a wide spectrum of activated, tyrosine-phosphorylated transmembrane and cytoplasmic tyrosine kinases (Fig. 3). In addition, it favors the interaction of active Vav proteins with cytoplasmic proteins (Slp76, Blnk) that participate in their signal transduction pathways (Fig. 3) (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The most C-terminal SH3 domain participates in the formation of extensive heteromolecular interactions with PRR-containing



Vav Family, Fig. 3 Vav-binding partners. Proteins playing positive, negative, and effector roles are depicted in green, red, and blue, respectively. Note however that some regulatory proteins play also downstream roles (i.e., Blnk, Slp76). Proteins with unclear function in the Vav route are shown in black. Molecules identified only in either Vav2 or Vav3 are underlined. Proteins that bind to Vav proteins in co-immunoprecipitation experiments through uncharacterized mechanisms are indicated on the right. The structural domains and type of interactions are also indicated. PTB, phosphotyrosine-binding domain; pY, tyrosine phosphorylation. NC, not characterized

proteins (Fig. 3). Some of those SH3 partners facilitate the translocation of Vav proteins (dynamin 2, Fig. 3) or participate in the catalytic-independent effector functions of these proteins (Sam68; Fig. 3). However, the functional significance of many of the Vav family C-terminal SH3–binding partners remains to be determined (Bustelo 2000, 2008; Bustelo and Couceiro 2008). Interestingly, the Vav C-terminal SH3 region is also the docking site for proteins encoded by viral pathogens such as the human immunodeficiency virus (HIV, v-Nef protein) and γ-herpesvirus (M2 protein). The interaction of those two proteins allows the spurious, stimulus-independent activation of some Vav family proteins during viral infections. Some of the C-terminal Vav domains act coordinately in the formation of intermolecular associations with proteins that negatively modulate Vav-dependent pathways such as Cbl family members, hSiah2, and the protein tyrosine phosphatase ▶ Ptpn6/Shp1 (Fig. 3) (Bustelo 2000, 2008; Bustelo and Couceiro 2008). It is likely that the Vav structural domains will participate in additional heteromolecular interactions, because Vav proteins can co-immunoprecipitate with a large collection of signaling proteins (Fig. 3) (Bustelo 2000, 2008;

Bustelo and Couceiro 2008). Although the function of most of those interacting molecules in the context of Vav-dependent routes is still unknown, some of them have been shown to act as upstream kinases (Alk, Bcr/Abl, Jak), facilitators of the translocation of Vav proteins to the plasma membrane (CD44v3, Dip, $p120^{Cat}$, Pyk2, Itk), effector molecules ($p85^{PI3\text{-}K}$, PKCθ, phospholipase-γ (PLC-γ) family members), and as Vav family inhibitors (Ptpn11 and Ptpn12 protein tyrosine phosphatases) (Fig. 3).

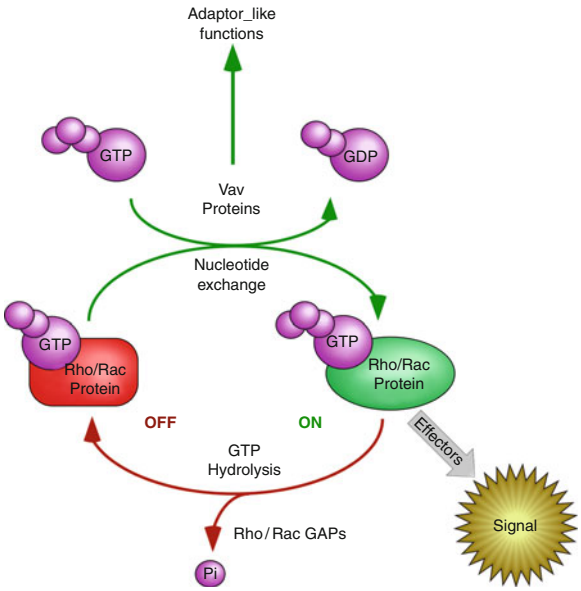
It is conceivable that all Vav family members will share most of those interactions, although current evidence indicates that some selectivity must exist. For example, M2 and v-Nef interact with Vav1 and Vav2 but not with Vav3. Likewise, dynamin 2 binds to Vav1 but not to the other two mammalian Vav family members. A detailed, side-by-side comparison of the signaling properties of all Vav family members is still needed in order to fully understand the level of overlap and phylogenetic conservation of the Vav family interactomes.

Expression

Vav1 is primarily expressed in hematopoietic cells both in the embryonic and adult periods. Vav2 and Vav3 are also expressed in hematopoietic cells but, unlike the case of Vav1, also show high levels of expression in non-hematopoietic tissues (Bustelo 2000). *C. elegans* Vav is detected in contractile organs such as the pharynx, proximal gonad, intestine, body wall muscle, and vulval epithelia (Norman et al. 2005). *D. melanogaster* Vav is ubiquitously expressed during early embryos and accumulates in both the central nervous system and invaginating midgut at later embryonic stages (Malartre et al. 2010). These data indicate that Vav1 is, so far, the Vav family member with a more restricted pattern of expression.

Biological Activity

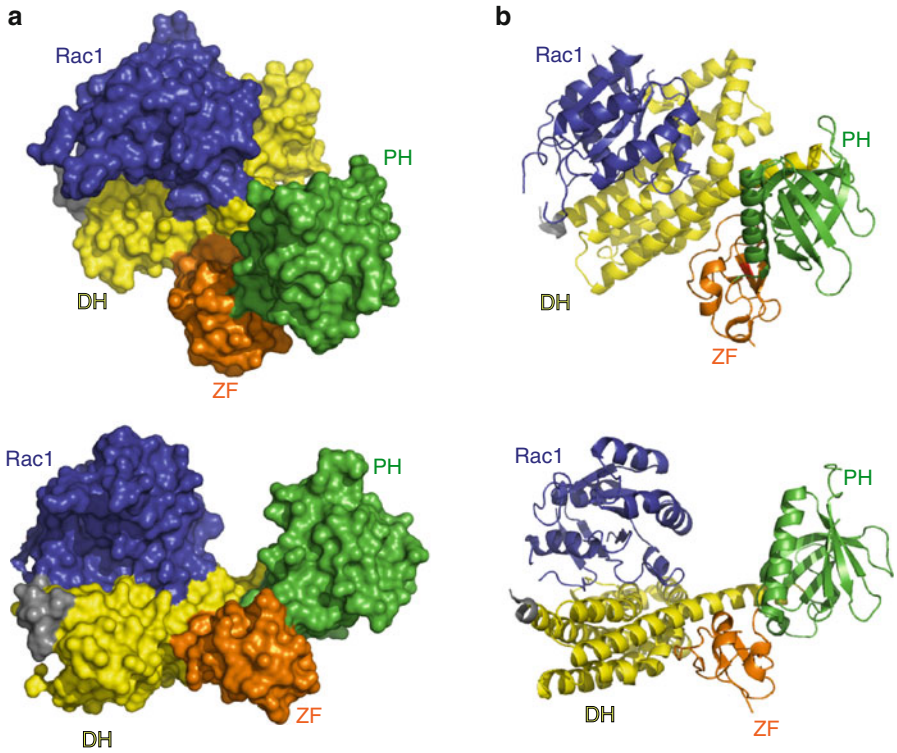
The main known function of Vav family proteins is to act as GEFs for Rho/Rac subfamily GTPases (Crespo et al. 1997; Movilla and Bustelo 1999; Schuebel et al. 1998). This activity favors the rapid shift of those GTP-binding proteins from the inactive (GDP-bound) to the active (GTP-bound) state during signal transduction (Fig. 4). Vav proteins promote the activation of Rac subfamily GTPases (e.g., Rac1, RhoG) and, to a lower extent, of Rho (e.g., RhoA) subfamily proteins in vitro. There is discrepancy about the possible



Vav Family, Fig. 4 Vav family proteins work as Rho/Rac GEFs and adaptor proteins. Inactive and active conformations of the GTPase substrates are indicated in red and green, respectively. GAPs, GTPase-activating proteins that favor the transition of Rho/Rac proteins from the active state to the inactive state; Pi, inorganic phosphate released upon GTP hydrolysis

activation of Cdc42 among different reports (Bustelo 2000, 2008; Bustelo and Couceiro 2008). Unlike other activators of Rho/Rac proteins whose enzyme activity relies exclusively within the catalytic DH region, the catalysis of nucleotide exchange on GTPase substrates requires the entire DH-PH-ZF cassette. The structural details of the catytically competent Vav1 DH-PH-ZF structure and the Vav1/Rac1 complex have been recently described using crystallographic methods (Fig. 5) (Chrencik et al. 2008; Rapley et al. 2008). Vav proteins require prior phosphorylation on three tyrosine residues present in the Ac domain (Y174 and, to a lesser extent, of Y142 and Y160; Figs. 2 and 3) by upstream protein tyrosine kinases to become catalytically active (see below, section Regulation of Biological Activity). Due to this, Vav proteins always work downstream of transmembrane receptors that contain either intrinsic (i.e., transmembrane protein tyrosine kinase receptors such as those for epidermal growth and platelet-derived growth factors) or associated (i.e., antigen receptors) tyrosine kinase activity (Bustelo 2000, 2008; Bustelo and Couceiro 2008).

Consistent with their role as Rho/Rac GEFs, Vav proteins induce Rho-/Rac-dependent biological



Vav Family, Fig. 5 3D structure of the Vav1 DH-PH-ZF cassette bound to Rac1 in surface (**a**) and ribbon (**b**) views. The N-terminal region of the Vav1 DH domain is shown in gray. The structures shown at the bottom have been rotated ≈ 90º in their horizontal axis relative to those shown in the top

responses in tissue culture such as F-actin polymerization, invasiveness, motility, integrin-mediated adhesion, cell cycle transitions, or metastasis. They also stimulate canonical signaling pathways located downstream of Rho/Rac GTPases such as p21-activated kinases (Pak), c-Jun N-terminal kinase (JNK), the nuclear factor kappa-light-chain-enhancer of activated B cells (► NF-κB), activator protein-1 (AP-1) family proteins, and serum responsive factor (SRF) (Bustelo 2000, 2008; Bustelo and Couceiro 2008; Turner and Billadeau 2002). The crucial importance of Vav family–dependent pathways in vivo has been demonstrated by analyzing the phenotypes of single or compound null mutations in model organisms. In agreement with its hematopoietic-specific pattern of expression, it has been shown that mouse Vav1, either alone or in combination with the rest of Vav family members, plays crucial roles in the development, selection, and effector functions of lymphocytes (Table 1) (Bustelo 2008; Bustelo and Couceiro 2008; Turner and Billadeau 2002; Tybulewicz et al. 2003). Signaling defects have been also found in a large variety of hematopoietic cells including platelets, neutrophils, macrophages, mast cells, natural killer cells, and dendritic cells (Table 1) (Bustelo 2008; Bustelo and Couceiro 2008; Turner and Billadeau 2002). In the case of Vav2- and Vav3-deficient mice, defects have been also observed outside the hematopoietic system. Those include dysfunctions in axon guidance, angiogenesis, bone remodeling, cerebellar development, and cardiovascular system homeostasis (Table 1) (Bustelo 2008; Bustelo and Couceiro 2008). The signaling dissection of those defects indicates that Vav proteins are essential for a large number of signaling responses induced by antigen receptors in hematopoietic cells. Those include: (1) T-cell and B-cell receptor responses that contribute to cytoskeletal rearrangement, formation of lymphocyte/antigen-presenting cell contacts, and lymphocyte responsiveness. (2) Signaling diversification events such as the stimulation of phoshatidylinositol-3 kinase (PI3-K)/Akt-, PLC-γ-, Ras/Erk-, PKC-, ► PKD-, and PLD-dependent routes. (3) Activation of downstream transcriptional factors such as the nuclear factor of activated T cells (► NFAT), ► NF-κB, SRF, and AP-1 family proteins. (4) Expression of lymphocyte surface markers and cytokines. (5) Modulation of cell cycle regulators and survival pathways (Bustelo 2008; Bustelo and Couceiro 2008; Turner and Billadeau 2002; Tybulewicz et al. 2003). In non-hematopoietic cells, Vav proteins have been

Vav Family, Table. 2 Phenotypes derived from the alteration of the function of invertebrate species Vav family members

Organism	Phenotype
C. elegans	
Gain-of-function[a]	• Hypercontracted muscles
Loss-of-function[b]	• Feeding problems during early development • Larval lethality • Defective pharyngeal contractility • Defective and arrhythmic ovulation and defecation cycles • Increased activity of Lin-12/Notch, leading to the generation of hermaphrodites with multiple pseudovulvae
D. melanogaster	
Gain-of-function	• Defective dorsal closure • Problems in myoblast fusion • Defective migration of caudal visceral mesodermal cells • Dysfunctional tracheal development
Loss-of-function	• Semilethal embryonic lethality, some of which can be due to improper eclosion of flies from eggs due to locomotor deficits • Flies that escape embryonic lethality display severe locomotor defects and a "shaky" phenotype • Axon guidance defects • In combination with loss of Trio (another Rac1 GEF), embryonic patterning defects and aggravation of the axon guidance defects found in embryos lacking either Vav or Trio. • In combination with loss of Sos1 (a Rac1/Ras GEF), aggravation of the axonal problems found in the absence of Vav

[a]Gain-of-function refers to phenotypes obtained upon the ectopic expression of oncogenic versions of these proteins in the respective species

[b]Loss-of-function refers to phenotype derived from animals in which the *Vav* family genes have been inactivated by genetic techniques

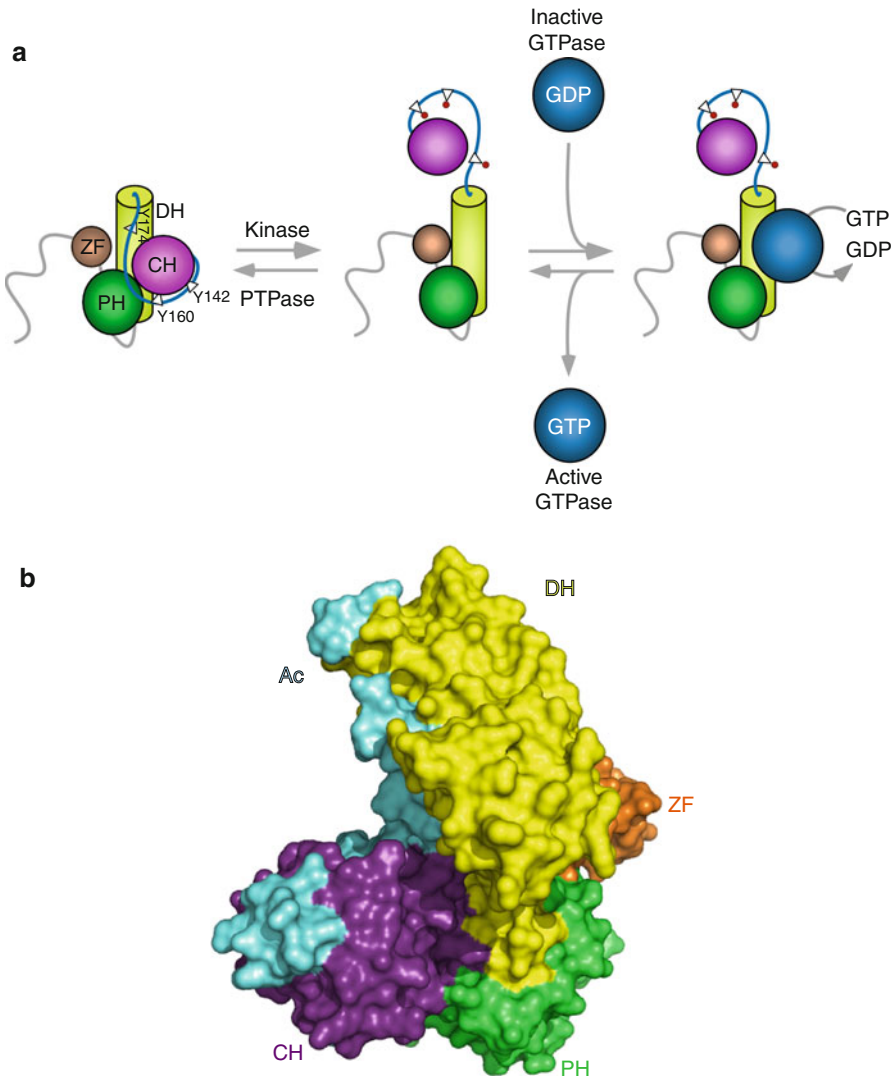
shown to be important for ▶ Eph receptor signaling during angiogenesis and axon guidance as well as for the proper assembly of nitric oxide–dependent signals in vascular smooth muscle cells (Bustelo 2008; Bustelo and Couceiro 2008).

In invertebrates, *C. elegans* Vav is important for the rhythmic behavior of a number of tissues, leading to improper pharyngeal contractility as well as defective ovulation and defecation activities. This leads to larval lethality when its locus is disrupted genetically in this nematode (Table 2) (Norman et al. 2005). *D. melanogaster* Vav is important for neuronal axon guidance and proper locomotor coordination (Table 2) (Malartre et al. 2010). These phenotypes are in agreement with the expression patterns of these two Vav family members in those two species and consistent with their role as Rac-specific GEFs.

Vav proteins can also work as adaptor molecules due to the extensive formation of heteromolecular complexes that they can assemble in vivo (Figs. 3 and 4). Recently, this adaptor role has been formally demonstrated using a knock-in mouse expressing a catalytically inactive Vav1 mutant. In these mice, it has been shown that the activation of PLC-γ-dependent routes in T cells can be fully achieved in a GTPase-independent manner (Saveliev et al. 2009).

Regulation of Biological Activity

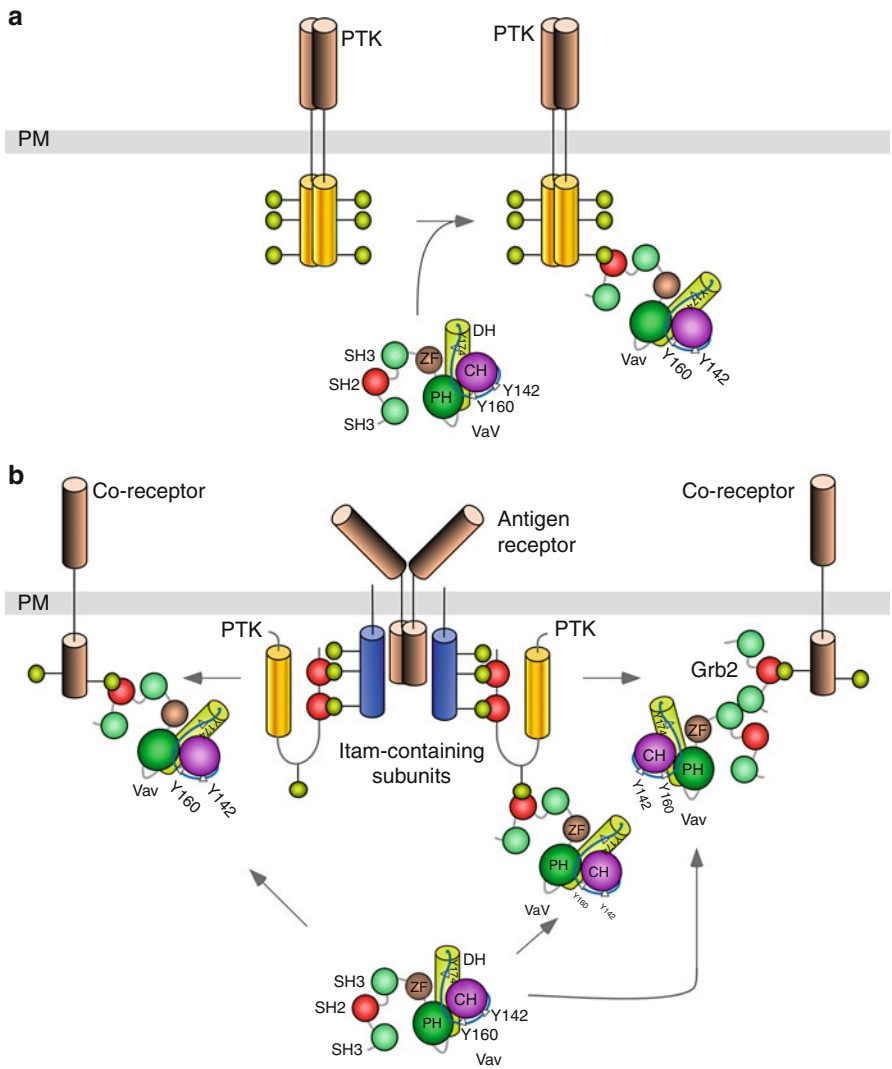
The main regulatory control of Vav family proteins is the modulation of their catalytic activity by direct tyrosine phosphorylation (Crespo et al. 1997; Movilla and Bustelo 1999; Schuebel et al. 1998). Recent crystallographic studies using a Vav1 CH-Ac-DH-PH-ZF fragment have helped in understanding the intramolecular mechanism that regulates this regulatory step (Fig. 6) (Yu et al. 2010). These analyses indicate that the inactive, non-phosphorylated state of Vav1 is maintained through extensive interactions among: (1) The CH domain and the PH, DH, and two tyrosine residues (Y142 and Y160) present in the Ac region. (2) The Ac region with the PH domain. (3) A tyrosine residue of the Vav1 Ac region (Y174) with the GTPase-binding domain of the Vav1 DH region. All these interactions induce cooperatively a "closed" conformation of Vav1 that is totally incompatible with the binding of GTPase substrates to the catalytic region (Fig. 6). The phosphorylation of the three Ac phosphosites leads to the release of those intramolecular inhibitory interactions, the exposure of the GTPase-binding site, and effective catalytic reactions (Fig. 6). Biochemical and signaling evidence indicates that this mechanism is conserved in all Vav family members studies so far, including *C. elegans* and *D. melanogaster* Vav proteins.



Vav Family, Fig. 6 Intramolecular mechanism controlling the enzyme activity of Vav proteins. (**a**) Schematic representation of the phosphorylation-dependent activation of Vav proteins during physiological conditions. In the inactive state (*left*), Vav proteins are in a closed conformation incompatible with GTPase binding. Upon association with protein tyrosine kinases, Vav proteins become phosphorylated (*red balls*) on three phosphosites (*open triangles*) present in the Ac region, leading to the opening of the molecule and optimal catalytic activity toward Rho/Rac proteins. Active forms of Vav proteins return to the inactive conformation by dephosphorylation by protein tyrosine phosphatases (PTPase). (**b**) 3D structure showing the inhibited state of non-phosphorylated Vav1 based on a recent word done with the Vav1 CH-Ac-DH-PH-ZF fragment (Yu et al. 2010). The continuity of the Ac region is broken since it could not be crystallized in some specific areas

Vav proteins are also controlled by other regulatory steps in vivo. The most important is the translocation of the proteins from the cytosol to the plasma membrane, a step required for the interaction with both upstream tyrosine kinases and membrane-localized downstream effectors. In non-hematopoietic cells, the membrane translocation of Vav family proteins usually involves a single event mediated by the direct interaction of the Vav SH2 region with the autophosphorylated tyrosine kinase receptors (Bustelo 2000, 2008; Bustelo and Couceiro 2008). Once bound to them, Vav proteins become transphosphorylated by the associated kinase (Fig. 7a). In the case of lymphocytes, the translocation of Vav proteins usually entails their interaction with membrane-localized proteins. These can be either transmembrane co-receptors (CD28, CD19) or plasma membrane inner leaflet–associated adaptor molecules (linker for activation of T cells or ▶ Lat) (Fig. 7b). The association with co-receptors is either by direct physical contact (i.e., the association of the Vav SH2 domain with a phosphorylated residue located on the cytoplasmic tail of CD19) or carried out indirectly using bridge molecules (i.e., the binding of Gbr2 to the CD28 co-receptor) (Fig. 7b). The association with membrane-anchored adaptors entails the use of signaling adaptors such as the Vav-binding proteins Grb2, Slp76, Blnk, Pyk2, and Itk (Bustelo 2000, 2008; Bustelo and Couceiro 2008).

Current evidence suggest that the biological activity of Vav proteins can be regulated by additional

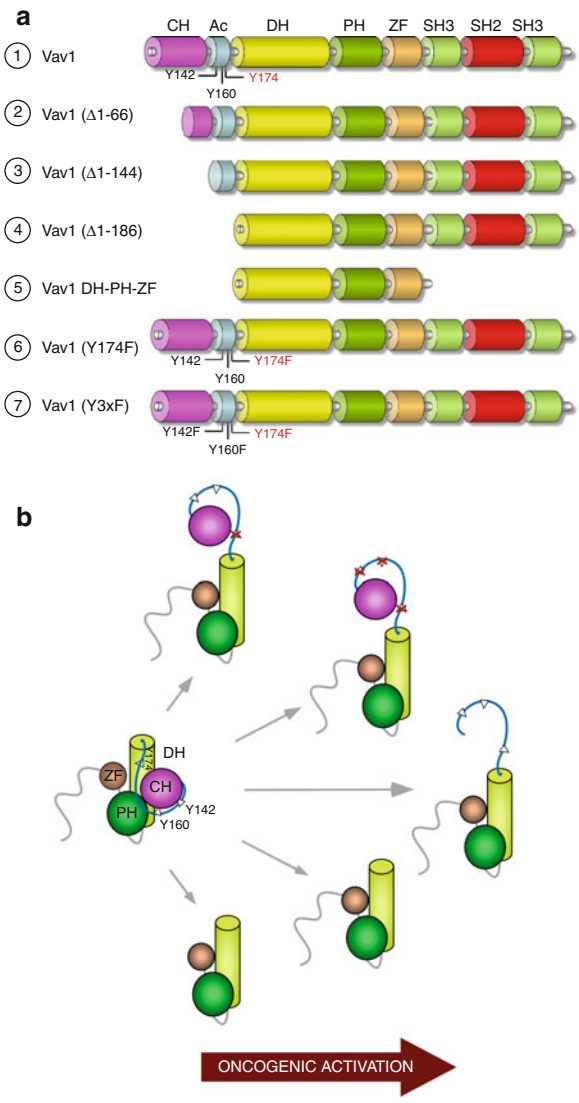


Vav Family, Fig. 7 Examples of the interaction of Vav proteins with transmembrane receptors. (**a**) Direct interaction of Vav proteins with autophosphorylated receptors with intrinsic tyrosine kinase activity. (**b**) Vav proteins can establish direct physical interactions with intracellular tyrosine kinases of Syk/Zap70 family (*center*) and with lymphoid co-receptors (i.e., CD19, *left*). Vav proteins can also interact with other co-receptors (i.e., CD28) via Vav-binding proteins such as Grb2 (*right*). In A and B, kinase domains are shown in dark yellow. Phosphorylation sites are indicated as yellow spheres. Vav and Grb2 SH3 are shown in light green. SH2 domains of Vav, Grb2, and the cytoplasmic tyrosine kinase are shown in red. The rest of Vav domains and residues depicted in this figure have been described in the legend to Fig. 6. Note that for the sake of simplicity, two types of co-receptors have been included together in this figure despite the fact that they are not co-expressed in the same lymphoid cell types. Likewise, the translocation of Vav proteins can be mediated by other molecules as indicated in the main text. ITAM, immunoreceptor tyrosine-based activation motif; PM, plasma membrane; PTK, protein tyrosine kinase

posttranslational mechanisms including caspase-dependent cleavage during anergic T-cell conditions, Cbl family–dependent ubiquitinylation, arginine methylation and, possibly, lysine acetylation (Bustelo 2000, 2008; Bustelo and Couceiro 2008). The physiological significance of all those posttranslational modifications remains to be fully determined. Recent observations indicate that the levels of some *Vav* family mRNAs (human *Vav3*, *C. elegans Vav*) can be regulated by microRNAs.

Implication of Vav Family Proteins in Pathological States

Mutations that eliminate the intramolecular contacts that inhibit the catalytic activity of mammalian Vav proteins lead to the generation of oncogenic proteins (Fig. 8) (Bustelo 2000, 2008; Bustelo and Couceiro 2008). Similar mutations have been also described in *C. elegans* and *D. melanogaster Vav* family genes (Couceiro et al. 2005; Norman et al. 2005), leading to tumorigenesis and developmental problems in the respective species (Table 2). These alterations have only academic interest, because no mutations have been found so far for any *Vav* family gene in either tumors or other pathologies. In vivo, the deregulation of Vav family proteins appears to occur through changes in either the expression or phosphorylation levels of the wild type proteins. For example, Vav1 is detected overexpressed in subsets of pancreatic, lung, and hematopoietic tumors. Higher levels of Vav1 expression, linked to the presence of an intronic single nucleotide polymorphism on its gene, seem to be associated with human cohorts with a higher tendency to develop multiple sclerosis. Hyperphosphorylation of Vav family proteins has been observed in cancer cells expressing oncogenic versions of protein tyrosine kinases (i.e., Alk, Bcr/Abl) or, alternatively, displaying active, mitogen-dependent autocrine loops. Finally, it has been observed that Vav1 and Vav3 can become upregulated in lymphocytes upon infection of viral pathogens encoding Vav family–interacting molecules such as v-Nef and M2. This viral-dependent activation is important for the infectivity cycle and the establishment of the latency stage of HIV and γ-herpesvirus, respectively. On the other side of the coin, a blockage in activation of Vav1 has been detected in anergic T cells via a caspase-dependent proteolysis. The actual significance of those inhibitory events has not been fully studied so far. Taken together, these results suggest that Vav proteins may play important roles in a number of high-incidence illnesses such as cancer, autoimmune disease, and viral pathogenesis.



Vav Family, Fig. 8 Oncogenic activation of Vav proteins. (**a**) Scheme of wild type and oncogenic versions of Vav1. The first oncogenic version described was a truncated Vav1 protein lacking the first 66 N-terminal amino acids (protein 2). Similar mutations have been described in other Vav family members. (**b**) Depiction of the intramolecular changes taking place in Vav family proteins upon oncogenic activation. When present, the C-terminal SH3-SH2-SH3 region is presented as a wavy gray lane for the sake of simplicity

Summary

Despite the progress during made these last 30 years in this field, many challenges lie still ahead in this field. Hence, the role of other posttranslational modifications on Vav activity is not known yet. There is also a lack of information regarding the functional significance of many of the Vav-interacting proteins identified to date or, in a related topic, the relative contribution of both GTPase-dependent and independent routes to the biological responses regulated by those proteins. Another issue of interest is the level of functional

redundancy/signaling specificity existing among the three mammalian Vav family members. In this regard, current data indicate that Vav proteins have both unique and overlapping functions depending on the cell type and/or biological response analyzed. However, these analyses have been done in a limited number of cell types, so a comprehensive view of the level of functional redundancy among Vav family members is still missing. Finally, there is still very scant information about the actual implication of Vav proteins in pathological states and, as consequence, no solid information is available about the possible interest of these proteins as drug targets to treat human disease. The available collection of animal models for this protein family will be an important tool in the near future to address that question. Collectively, this future work will give a holistic and, hopefully a final, picture of the implication of this important protein family in physiological and pathological responses.

VDR, The Vitamin D Receptor

Marina Rode von Essen and Carsten Geisler
Department of International Health, Immunology and Microbiology, University of Copenhagen, Copenhagen, DK, Denmark

Synonyms

Calcitriol receptor; Nuclear receptor subfamily 1, group I, member 1 (NR1I1); Vitamin D receptor (VDR)

Historical Background

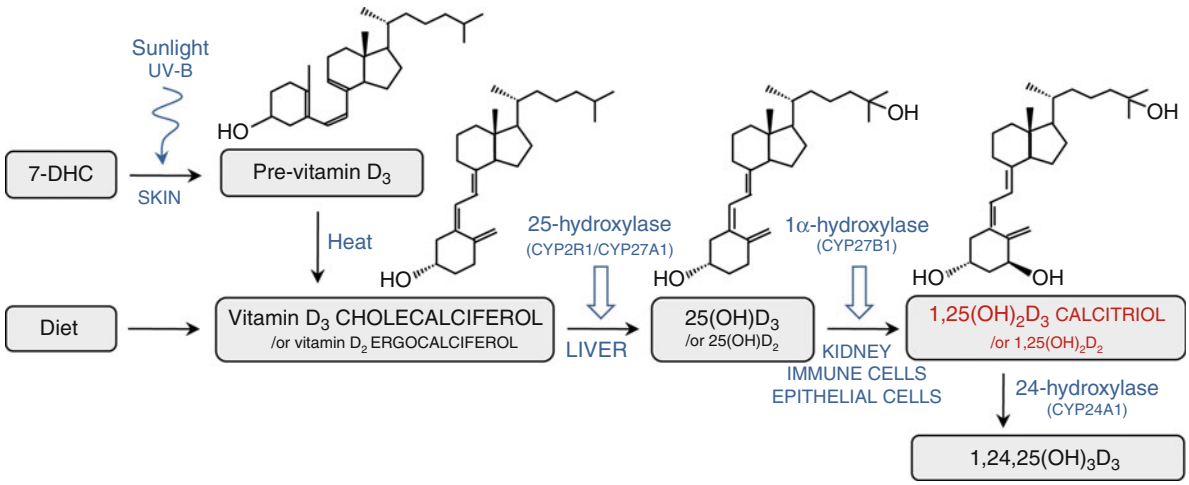
Almost from the time life began, vitamin D has been produced by plants and animals. As the structures of plants and animals became more complex, the sites of vitamin D production, its subsequent metabolism, as well as its sites of action separated. The ability to transport and metabolize vitamin D into more active forms therefore evolved. The metabolic active form $1,25(OH)_2D_3$ of vitamin D exerts its actions through interaction with the vitamin D receptor, VDR (Bikle 2011). Although not as ancient, VDR has been highly conserved between species through evolution (Hochberg and Templeton 2010).VDR is found in almost all cells and tissues of higher-order animals, further emphasizing the importance of the receptor. Evidence for the existence of VDR was first provided in 1969 by Haussler and Norman (Feldman et al. 2005), and since then a substantial amount of data on the structure and function of VDR has been accomplished.

The Source and Metabolism of the Vitamin D Receptor Ligand

Vitamin D is known as "the sunshine vitamin" as humans acquire more than 90% of the vitamin D needed from the sun. During exposure to sunlight, ultraviolet B (UVB) radiation is absorbed by 7-dehydrocholesterol (7-DHC) present in the skin generating previtamin D_3, which quickly is transformed into the stable vitamin D_3 (Fig. 1).Very few foods naturally contain vitamin D, however, egg yolks, cod liver oil, beef liver, some fungi, and in particular oily fish such as salmon, mackerel, and sardines make up a minor source of vitamin D (Holick 2004; Feldman et al. 2005). Two forms of vitamin D can be obtained by nutritional intake: vitamin D2 (ergocalciferol) and vitamin D3 (cholecalciferol), the latter from foods of animal origin. Regardless of the source of vitamin D, it needs to be hydroxylated twice in order to become biologically active (Jones et al. 1998). The first hydroxylation step is catabolized in the liver by the enzyme 25-hydroxylase (CYP2R1/CYP27A1) generating $25(OH)D_3$ (or D_2), and the second by the related 1α-hydroxylase (CYP27B1) mainly in the kidney resulting in the metabolic active calcitriol $1,25(OH)_2D_3$ (or D_2). There is little evidence that the two active forms D_3 and D_2 differ in their mode of action (Feldman et al. 2005). $1,25(OH)_2D_3$ limits its own activity in the target organs by inducing 24-hydroxylase (CYP24A1), transforming $1,25(OH)_2D_3$ to ten times less biologically active $1,24,25(OH)_2D_3$, and thus preventing excessive vitamin D signaling (Fig. 1) (Jones et al. 1998).

Mechanism of Action, the Vitamin D Receptor

$1,25(OH)_2D_3$ exerts its actions by binding to the vitamin D receptor, VDR. VDR is a ligand-dependent transcription regulator molecule belonging to the superfamily of nuclear receptors. In the absence of $1,25(OH)_2D_3$ VDR is distributed largely to the cytoplasm. Upon ligand interaction VDR dimerizes with the retinoid x receptor (RXR) and translocates to the nucleus. Here the VDR-RXR heterodimer binds to vitamin D response elements (VDREs) present in the promoter region of responsive genes (Fig. 2)



VDR, The Vitamin D Receptor, Fig. 1 Production and metabolism of vitamin D. Vitamin D_3 is produced either from conversion of 7-DHC in the skin through sunlight exposure or from precursors in food. In the liver vitamin D_3 is hydroxylated in position 25, generating $25(OH)D_3$. A second hydroxylation in position 1 produces the active metabolite $1,25(OH)_2D_3$. This step mainly takes place in the kidneys, but also in other tissues expressing the enzyme 1α-hydroxylase

(Nagpal et al. 2005; Feldman et al. 2005). Almost 3% of the human genes include a VDRE and hence their expression can be modulated accordingly. Although various noncanonical VDREs have been described, canonical VDREs are defined as a direct repeat of 5′-AGG/TTCA-3′ or a minor variation of this motif separated by three nucleotides (Dusso et al. 2005; Nagpal et al. 2005; Feldman et al. 2005). Depending on the target gene, either co-activators or corepressors are attracted to the complex to induce or repress gene transcription (Jones et al. 1998; Nagpal et al. 2005).

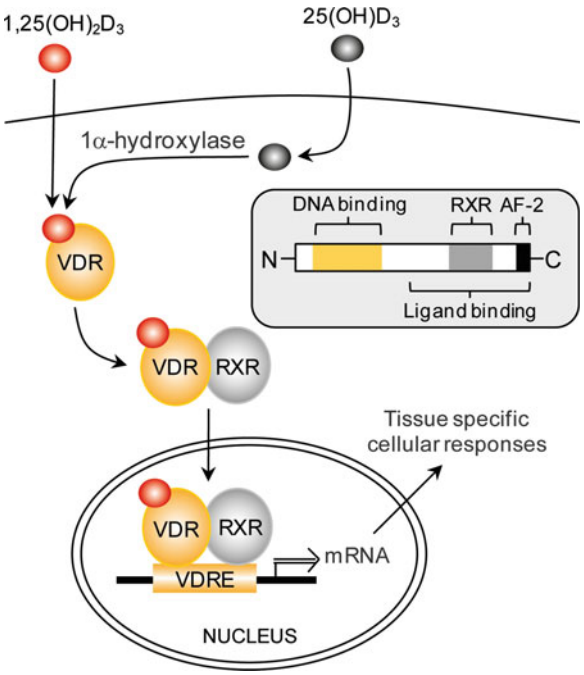
Besides regulation through VDREs of target genes, VDR can inhibit the expression of some genes by antagonizing the action of certain transcription factors, such as ▶ NFAT and NF-κB (Nagpal et al. 2005). An example is the VDR-dependent inhibition of the cytokines IL-2 and GM-CSF which appears more complex than the involvement of positive and negative VDREs. Here, VDR first competes with NFAT1 for binding to the enhancer motif of the NFAT1-activator protein 1 (AP1) and subsequently VDR binds to c-Jun. This co-occupancy of VDR-c-Jun to AP1 leads to inhibition of activated IL-2 and GM-CSF expression (Nagpal et al. 2005).

To fully accomplish its functions, the VDR protein is divided into an N-terminal domain including the DNA-binding region and a multifunctional C-terminal domain harboring the ligand-binding region, the RXR heterodimerization motif, and a ligand-dependent transactivation function (AF-2). The C-terminal domain consequently exerts absolute regulatory control over the DNA-binding properties of the VDR (Fig. 2) (Jones et al. 1998; Feldman et al. 2005).

Regulation of Vitamin D Receptor Activity

Due to the influence of VDR on such a broad array of genes, its activity is ascribed strict control. Besides the obvious limitations of VDR activity due to availability of the VDR ligand, $1,25(OH)_2D_3$ also directly influences the expression of VDR. Cells treated with $1,25(OH)_2D_3$ induce VDR-mRNA and furthermore stabilize the mRNA, increasing the total amount of cellular VDR. VDR expression can also be modulated by numerous other physical stimuli such as dietary composition (calcium and phosphorus), steroid hormones and retinoids, growth factors, and peptide hormones (Feldman et al. 2005).

The various physiological inputs that affect VDR levels involve complex interactions among the intracellular signaling transduction pathways. As an example, cellular response to the parathyroid hormone (PTH) activates protein kinase A (PKA) causing an increase in VDR level, whereas stimuli that induce protein kinase C (PKC) activity lead to a decrease in VDR expression. Given the central role of PKA and PKC in the integration of cellular responses to



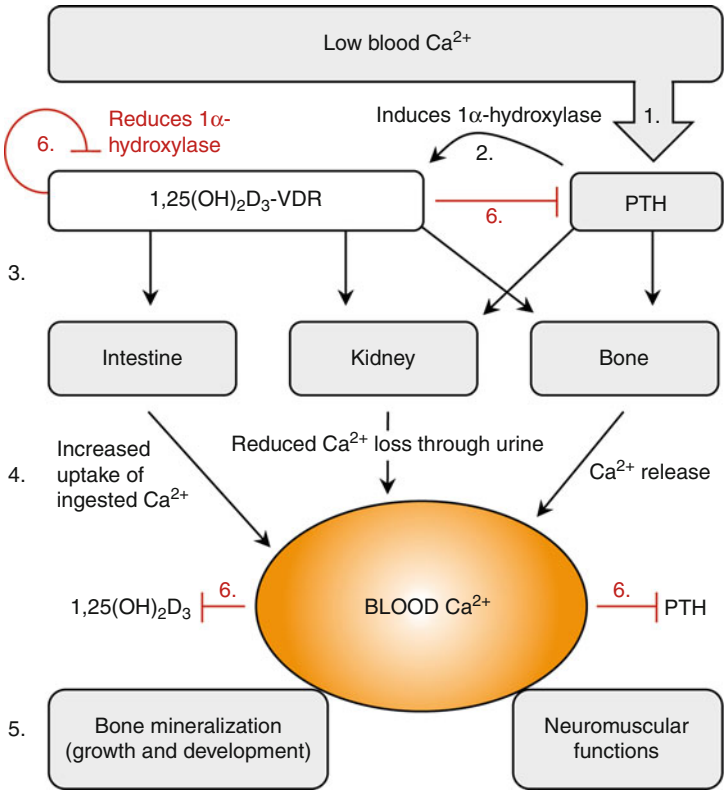
VDR, The Vitamin D Receptor, Fig. 2 The mechanism of VDR action. Binding of VDR to its ligand, $1,25(OH)_2D_3$, enables dimerization of VDR and RXR, allowing nuclear translocation and binding of the VDR-RXR complex to VDREs in the promoter region of responsive genes. Binding to the VDREs is accompanied by formation of a large complex including either co-activators or corepressors leading to induction or inhibition of target genes, respectively. A schematic illustration of the VDR gene is depicted in the *box*

extracellular stimuli, these pathways are central in the mechanisms that regulate VDR levels in target cells (Feldman et al. 2005). A signaling pathway to induce VDR expression not including PKA and PKC has recently been described in human naïve T cells of the immune system. Here, the cellular response to a foreign pathogen induces the expression of VDR through activation of the kinase p38, a process mandatory for the activation of the naive T cells (von Essen et al. 2010). In addition, cellular signaling motivating physical interaction of VDR-$1,25(OH)_2D_3$ with SUG1 of the proteasome complex targets VDR for ubiquitination and subsequent proteolysis (Dusso et al. 2005). Regulation of VDR expression and abundance is therefore an important mechanism for the modulation of cellular responsiveness to $1,25(OH)_2D_3$ and hence for controlling a variety of cellular functions. It is also possible that phosphorylation of VDR, which induces a conformational change that releases corepressors as well as posttranslational VDR modifications, plays a role in regulating the activity of VDRs (Dusso et al. 2005).

Biological Functions of the Vitamin D Receptor

$1,25(OH)_2D_3$ is traditionally viewed as an endocrine hormone whose function is to regulate calcium and phosphorus homeostasis. Without proper maintenance of blood calcium levels, bone is under-mineralized, and if the calcium levels drop further, neuromuscular functions fail and death can occur as a result of tetany (spasms) (Plum and DeLuca 2010). Low blood levels of calcium induce the parathyroid gland to release PTH which results in a rapid mobilization of calcium from bone, an increase in calcium reabsorption from kidneys, and stimulates the transcription of 1α-hydroxylase (in the kidneys) resulting in the production of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ in conjunction with VDR then stimulates intestinal absorption of calcium and phosphorus, and like PTH, mobilizes calcium (and phosphorous) from the bones and reduces the loss of calcium through the urine. To ensure that no excess calcium is released to the blood, $1,25(OH)_2D_3$-VDR together with the elevated serum levels of calcium suppress 1α-hydroxylase transcription and stimulate 24-hydroxylase in the kidneys along with repression of PTH production and release from the parathyroid gland (Fig. 3) (Plum and DeLuca 2010; Feldman et al. 2005). In this way, the vitamin D endocrine system manages to maintain extracellular calcium levels within narrow limits, a process vital for normal cellular function and bone integrity.

Within the last two decades it has been clear that VDRs are not only present in tissues associated with calcium and phosphorus metabolism, but also in "nonclassical" organs like immune cells, brain, eyes, heart, pancreatic islets (β cells), muscle, adipose tissue, thyroid, parathyroid, and adrenal glands, suggesting a broader role for VDR (Baeke et al. 2010; Feldman et al. 2005). In particular, its role in the immune cells has received much attention due to a great potential as a preventive or therapeutic target in a variety of inflammatory and autoimmune diseases as well as in cancer. The immune system is divided into an innate immune system that makes up the critical first line of defense against invading pathogens and an adaptive immune system containing pathogen-specific cells to

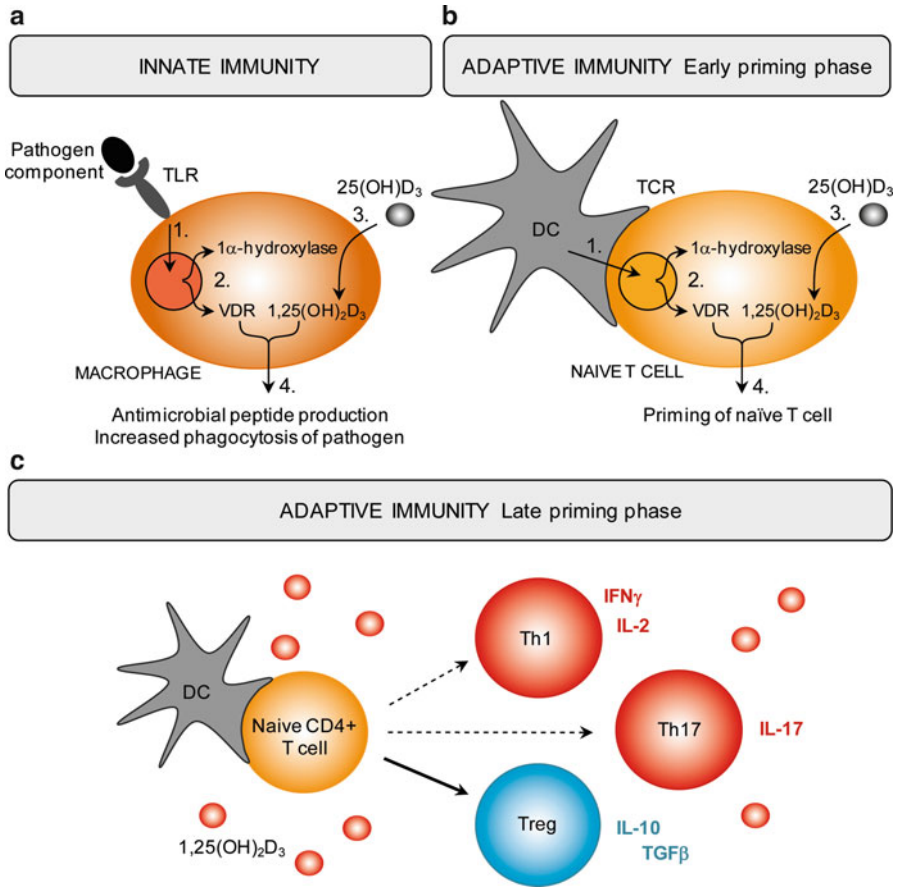


VDR, The Vitamin D Receptor, Fig. 3 The role of $1,25(OH)_2D_3$-VDR in maintaining calcium homeostasis. (1) Low blood calcium levels induce PTH release from the parathyroid gland. (2) PTH induces 1α-hydroxylase transcription generating $1,25(OH)_2D_3$. (3–4) PTH and $1,25(OH)_2D_3$ increases the blood calcium level through different mechanisms, (5) Necessary for maintaining neuromuscular functions and bone strength. (6) The elevated blood calcium levels and $1,25(OH)_2D_3$ suppress the production of PTH, and limit the production of $1,25(OH)_2D_3$, thereby completing the endocrine loop

combat the foreign intruder (Abbas et al. 2007). VDR is widely expressed in most immune cell types and consequently $1,25(OH)_2D_3$ has proven to have potent immunomodulatory effects on cells of both the innate and adaptive immune systems. Notably, several of these cells also express vitamin D activating enzymes such as 1α-hydroxylase, allowing local activation of vitamin D (Bikle 2009; Baeke et al. 2010).

An important mechanism used by macrophages of the innate immune system to clear an infection is the production of antimicrobial peptides that kill the pathogen. When macrophages sense the presence of a foreign pathogen through surface toll-like-receptors(TLRs), VDR and 1α-hydroxylase are upregulated and $1,25(OH)_2D_3$ produced from circulating $25(OH)D_3$. Activation of the VDR subsequently induces the production of antimicrobial peptides, followed by killing of, for example, mycobacterium tuberculosis. In addition, $1,25(OH)_2D_3$ has been shown to enhance the phagocytic capacity of macrophages, which further promotes adaptive immunity (Fig. 4) (Bikle 2009; Baeke et al. 2010).

For adaptive immunity to be encouraged, naïve T lymphocytes (T cells) must receive an activation signal from antigen-presenting cells like macrophages and in particular dendritic cells (DCs). Depending on the nature of the signal provided and the local environment, the lymphocytes can pursue different developmental programs (Abbas et al. 2007). Both DCs and T cells express the VDR and 1α-hydroxylase and have been identified as direct targets of $1,25(OH)_2D_3$ (Baeke et al. 2010). As for innate immunity, $1,25(OH)_2D_3$ has been shown to promote adaptive responses; $1,25(OH)_2D_3$-VDR is required for the early phase of T-cell priming as VDR-signaling induces expression of PLC-γ1, which is mandatory for differentiation of the naïve T cells (von Essen et al. 2010). Still, the most well-known described effect of $1,25(OH)_2D_3$ on adaptive immunity is that of inhibition (Bikle 2009; Baeke et al. 2010; van Etten and Mathieu 2005). DCs under the influence of $1,25(OH)_2D_3$ alter their phenotype to favor differentiation of a regulatory subset of T cells (Treg) with immune suppressive functions, instead of priming the T-cell subset with inflammatory effects (Th1 and Th17). Both Th1 and Th17 cells are commonly accepted to be main players in the development and progression of various inflammatory and autoimmune



VDR, The Vitamin D Receptor, Fig. 4 Proposed model for the immunomodulatory effects of $1,25(OH)_2D_3$-VDR. *Innate immunity*. (**a**) (1) In response to TLR stimulation, (2) macrophages induce expression of 1α-hydroxylase and VDR, (3) leading to production of $1,25(OH)_2D_3$ and activation of VDR, (4) promoting the production of antimicrobial peptides and increased phagocytosis of the pathogen. *Adaptive immunity*. (**b**) (1) In response to DC-induced TCR stimulation, (2) naive T cells induce expression of 1α-hydroxylase and VDR, (3) leading to production of $1,25(OH)_2D_3$ and activation of VDR, (4) encouraging priming of the naïve T cells. (**c**) In the secondary lymphoid organs, where T-cell priming takes place, an increase in $1,25(OH)_2D_3$ is expected. $1,25(OH)_2D_3$ influences the DCs to favor differentiation of Treg cells as opposed to Th1 and Th17 effector T cells. $1,25(OH)_2D_3$ also enhances the function of the Treg cells and inhibits the function of Th1 and Th17 cells. Dotted lines and text rendered in red indicate inhibitory actions of $1,25(OH)_2D_3$ and black lines and text rendered in blue increased actions

diseases. Furthermore, $1,25(OH)_2D_3$ also directly modulates the function of the different T-cell subsets. Treg cells increase their ability to suppress immunity and the effector T cells decreases their ability to proliferate and exert their effector functions, for example, through secretion of cytokines. The net result is downregulation of the effector T-cell response (Fig. 4) (van Etten and Mathieu 2005). The apparent discrepancies of the influence of $1,25(OH)_2D_3$ on adaptive immunity might be explained by the availability of $1,25(OH)_2D_3$ at the different stages of an immune response. Early studies have shown a pro-proliferative effect of low concentrations of $1,25(OH)_2D_3$ on T cells (Lacey et al. 1987), whereas more recent studies using higher concentrations have shown the exact opposite. Although it has to be investigated, one can speculate that the modest quantity of $1,25(OH)_2D_3$ present at the beginning of an immune response is sufficient to induce T-cell priming, whereas the increasing amount supposedly generated during the response exerts a negative feedback to ensure that the immune system does not overreact.

VDR-Mediated Signaling in Health and Disease

Allelic variants (polymorphisms) of the VDR gene which occurs naturally in the human population are associated with various medical conditions such as decreased bone density, tendency to hyperparathyroidism (excess PTH production), and susceptibility to infections, autoimmune diseases, and cancer. This may in part be due to the effect of VDR polymorphism on VDR-mRNA stability and reduced expression of VDR (Feldman et al. 2005). The importance of such changes in VDR expression for disease development is strengthened by the observation that low VDR expression is associated with more invasive and lethal tumors (Hendrickson et al. 2011; Lopez et al. 2010) perhaps due to less proliferative control and apoptosis induction, which are two major processes modulated by VDR-signaling.

In addition to allelic variations of the VDR gene, two rare genetic disorders have been described in which either the CYP27B1 gene or the VDR gene itself contain mutations that render the gene products nonfunctional. In patients with a nonfunctional 1α-hydroxylase (due to a mutation in CYP27B1) $1,25(OH)_2D_3$ is no longer synthesized. Individuals with a nonfunctional VDR suffer from absence of VDR-signaling giving rise to the disease hereditary vitamin D resistant rickets (HVDRR). Both diseases are characterized by hypocalcemia (low blood calcium), hyperparathyroidism, and early onset of rickets (bone deformities in children). Even though the two diseases appear alike, a crucial difference is the blood level of $1,25(OH)_2D_3$: It is almost absent in patients with 1α-hydroxylase deficiency, whereas it is exceedingly high in HVDRR. The apparent consequence is that patients with a defect CYP27B1 gene respond to treatment with $1,25(OH)_2D_3$ and can expect complete remission of the disease, whereas most HVDRR-affected individuals are resistant to vitamin D therapy. In this case, intensive calcium therapy is used, surprisingly reversing all aspects of the disease. As there are only very few cases of HVDRR and as the abnormalities are corrected relatively early in life, long-term effects of defective VDR-signaling such as development of autoimmune diseases and cancer have not been observed (Malloy and Feldman 2010). A promising model system regarding these issues is a mouse model in which the VDR gene has been deleted, or in which severe vitamin D deficiency has been introduced through a vitamin D depleted diet. These mice do show increased sensitivity to certain autoimmune diseases, and are also more prone to oncogene- and chemocarcinogen-induced tumors (Bouillon et al. 2008). Furthermore, it has been demonstrated in a variety of animal disease models that pretreatment with $1,25(OH)_2D_3$ is effective in preventing the onset of both multiple sclerosis, type I diabetes, rheumatoid arthritis, and inflammatory bowel disease (Nagpal et al. 2005; Guillot et al. 2010).

Consistent with the observations from mice models, an inverse association between the vitamin D status (blood level of $25(OH)D_3$) and development of a variety of autoimmune and inflammatory diseases as well as an increased risk for development of certain types of cancers has been described in epidemiological studies in humans (Nagpal et al. 2005; van Etten and Mathieu 2005; Guillot et al. 2010; Luong and Nguyen 2010). Even so, many of the epidemiological studies performed measured the vitamin D status at the time of disease diagnosis. It therefore has to be considered that the low vitamin D status could be a consequence of disease development rather than a direct cause, as daily routines and habits are often changed upon development of these diseases (e.g., more indoor activities). Thus, the usage of the vitamin D status as a "probability marker" for disease development awaits clarification through future studies.

Summary; Future Directions

VDR is a nuclear, ligand-induced transcription factor that in complex with hormonally active vitamin D, $1,25(OH)_2D_3$, regulates the expression of more than 900 genes involved in a wide array of physiological functions, for example, calcium homeostasis, growth control, differentiation, and immune responses.

The ligand for VDR, $1,25(OH)_2D_3$ is attained mainly from 7-DHC in the skin. 7-DHC is transformed to a vitamin D precursor through UVβ irradiation from the sun. This vitamin D precursor can also be obtained in minor amounts through diet. Either way, two hydroxylation steps involving 25-hydrolylase and 1α-hydroxylase transform the precursor into its active metabolite. Once formed $1,25(OH)_2D_3$ binds to VDR in the target cell and enables the receptor to bind to RXR and translocate into the nucleus where it

participates in the regulation of the expression of a great variety of genes. In the target cell, $1,25(OH)_2D_3$ limits its own activity by inducing the enzyme 24-hydroxylase that transforms $1,25(OH)_2D_3$ to a less active metabolite. Other mechanisms important for the regulation of VDR activity include control of VDR expression and possibly phosphorylation and posttranslational VDR modifications. The biological functions of VDR are numerous, with its role as a regulator of blood calcium and phosphorus level as the most commonly known. However, lately the role of VDR in modulating immune responses has been the focus of many studies.

It is generally accepted that vitamin D deficiency is highly prevalent in many populations around the world (Baeke et al. 2010). Therefore, vitamin D supplementation represents an attractive strategy to ensure sufficient $25(OH)D_3$ levels for adequate bone metabolism and immune functions thereby eliminating one of the proposed risk factors that may underlie inflammatory or autoimmune diseases as well as certain types of cancer. In addition to a potential disease-preventive role of $1,25(OH)_2D_3$, the immunomodulating effects of vitamin D suggest that vitamin D holds therapeutic promises in inflammatory and autoimmune diseases. In a variety of animal studies, $1,25(OH)_2D_3$ has been shown either to halt progression or reduce disease severity, counting a mouse model for multiple sclerosis, type I diabetes, rheumatoid arthritis, and inflammatory bowel disease (Nagpal et al. 2005; Plum et al. 2010; Guillot et al. 2010). Unfortunately, the therapeutic application of $1,25(OH)_2D_3$ is obstructed by toxicity issues as the supraphysiological doses needed to exert an immune inhibitory effect elicit unfortunate calcemic side effects. To overcome this limitation, structural analogues of $1,25(OH)_2D_3$ are being designed that have reduced calcemic effects with similar immunoregulatory activity (Yee et al. 2005). Today, such analogues have become first-line therapy for treatment of psoriasis. The vitamin D analogue is applied topically onto the psoriasis plaques where it inhibits the massive keratinocyte proliferation and the underlying inflammation. Due to its short half-life after it enters circulation, it is destroyed before it has an opportunity to affect calcium homeostasis (Yee et al. 2005). A similar "soft-drug-approach" cannot be employed for other inflammatory, autoimmune, and cancer diseases as a systemic effect (not including calcemic effects) would be the goal of therapy. However, the development of orally available noncalcemic and even tissue-specific vitamin D analogues is a working field in progress, and the prospect of vitamin D therapeutics for treating diseases beyond metabolic bone disorders seems promising.

Historical Background

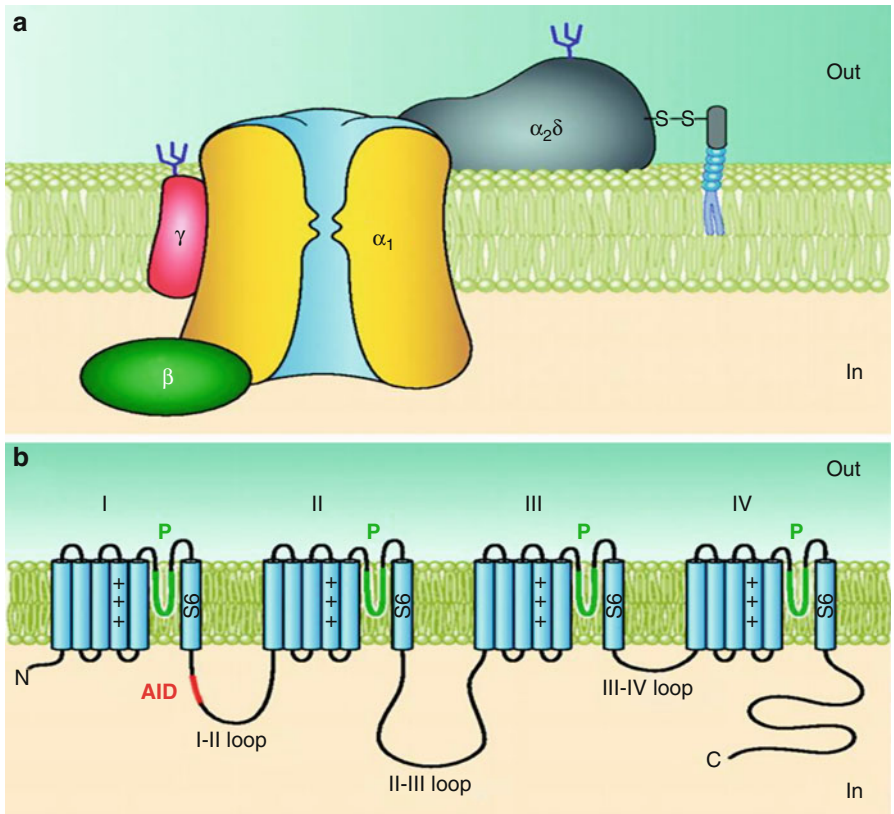
Voltage-gated calcium channels (CaV) are a family of complex proteins that conduct Ca^{2+} into the cell cytoplasm through a large pore-forming α_1 subunit of 190–250 kDa. They are divided into three major families CaV1.x, CaV2.x, and CaV3.x based on sequence homology of the α_1 subunit. In turn, each subfamily is comprised of four (CaV1.1–CaV1.4) or three (CaV2.1–2.3; CaV3.1–3.3) members derived from separate genes (Catterall et al. 2005). The α_1 subunits are variably associated with β, $\alpha_2\delta$, and γ accessory proteins that modulate expression, targeting, voltage dependence, and kinetic characteristics (Fig. 1a) (Catterall et al. 2005; Buraei and Yang 2010). Moreover, splice variants of the α_1 subunit can account for tissue-specific behavior. Alternate classification schemes exist. Table 1 shows the early nomenclature; L-, P/Q-, N-, R-, and T-type, and its relationship to more modern schemes based on sequence identification. The order of molecular identification of the α_1 subunit defines the skeletal muscle α_1 subunit as α_{1S}, and subsequent genes as α_{1A}–α_{1I} (i.e., a total of ten genes: α_{1S}, α_{1A}–α_{1I}). Amino acid homology can exceed ~80% within families but may be less than 30% between families (Fig. 2). In all cases, α_1 subunit structure includes four homologous domains (I–IV) each of which is comprised of six (S1–S6) membrane-spanning regions (Fig. 1b). Voltage sensing resides in the S4 regions of the domains, and the reentrant "P-loop" between S5 and S6 provides the selectivity filter. Other important regions include the inactivation gate and, in some channels, a site for calmodulin binding. The site of CaM binding to the IQ domain of the C-terminus has been proposed to confer local (near the channel pore) versus global (cytoplasmic) sensing of calcium (Liang et al. 2003). Both N-terminal and C-termini are intracellular. CaV bear structural resemblance to voltage-gated potassium and sodium channels, implying a common ancestry. Indeed, minor modifications within the pore-forming sequences of CaV can yield Na^+ selectivity and CaV commonly conduct Na^+ ions in Ca^{2+}-free extracellular solutions. These channels are of ancient origin; examples of each subfamily are found in *Caenorhabditis elegans*.

Voltage-Dependent Gating: Activation, Inactivation, Deactivation

As implied by the name, the open probability of CaV channels is regulated or "gated" by membrane potential. The electrical field within the plasma membrane is "sensed" by displacement of positively charged residues of the S4 transmembrane segment. The macroscopic behavior of CaV currents in whole cell voltage clamp experiments is complex. The CaV channels in a cell can be coordinately induced to conduct divalent ions by sequentially clamping the transmembrane potential to a low value (typically −90 to −110 mV) where "*inactivation*" is removed, making the channels available to open. From that available state, a rapid membrane depolarization to voltage that exceeds threshold level "*activates*" channel opening. Some CaV are "high voltage activated" (HVA) meaning that activation requires a large depolarization. In contrast, others are "low voltage activated" (LVA) such that only a small depolarization to more negative membrane potentials is sufficient. Invariably, whether HVA or LVA characterizes the subgroup, channel opening is followed by spontaneous closure to reenter the "*inactivated*" state. The rate at which channels inactivate is often characteristic of CaV families and subfamilies. Finally, activated channels can be "deactivated" (distinct from inactivation). Deactivation occurs when open channels are induced to close by repolarizing the membrane before the channels have entered the inactivated state. Following deactivation, in contrast to channels in the inactivated state, rapid sequential repolarization-depolarization can activate channel opening. In addition to voltage-dependent gating, CaV can be inhibited or activated by phosphorylation events involving protein kinase C (PKC), cyclic nucleotide–dependent protein kinases (e.g., cGMP-PKG, cAMP-PKA), ▶ MAP kinases, and calmodulin-dependent kinases Camk (Buraei and Yang 2010; Huc et al. 2009).

Channel Pharmacology

Prior to the elucidation of sequence information that led to CaVX.x and α_{1X} designations in Table 1, CaV classification was partially based on electrophysiological study of voltage dependence and kinetics. For example, the L-type channel is high voltage activated



Voltage-Gated Calcium Channels: Structure and Function (CACNA), Fig. 1 Voltage-gated calcium channel (CaV) structure. (**a**) CaV are comprised of the α_1 pore-forming subunit and accessory $\alpha_2\delta$, β, and γ accessory proteins. (**b**) Topology of CaV α_1 subunit. The α_1 subunit is comprised of four domains (I–IV) each of which contains six membrane-spanning regions (S1–S6) and an intramembranous "P" loop that forms the selectivity filter. Voltage sensing is attributed to membrane-potential-dependent displacement of positively charged residues in the S4 region. The α interaction domain (AID, *red*) on intracellular loop I-II binds the β subunit (Adapted with permission from Zafir, B. and Yang, J., Phys Rev 90:1461, 2010)

(i.e., requires a **L**arge depolarization) and has a slowly inactivating current, thus L- or "*L*ong-lasting" behavior. In contrast, low voltage activated T-type channels (i.e., LVA requiring a small depolarization) rapidly inactivate, thus T- or "*T*ransient" behavior. The "T" of T-type CaV can also be thought of as representing the *T*iny conductance of individual channels. Early separation of CaV classes depended on such kinetic information and the efficacy with which pharmaceuticals induce blockade. Probably the

best-known and therapeutically exploited agents are the dihydropyridine, phenylalkylamine, and benzothiazepine compounds that provide relatively specific CaV1.x, L-type channel inhibition. Moreover, agonists such as BAYK8644 and FPL64176 serve as L-type channel openers. T-type, CaV3.x channels are relatively insensitive to those agents. Modifications of structure to generate compounds such as mibefradil, pimozide, and efonidipine have yielded alternate organic compounds that can block T-type channels although none of them are fully specific at high concentrations (Catterall et al. 2005; Kochegarov 2003; Striessnig and Koschak 2008). In many cases, where organic compound specificity is absent or lacking, peptide inhibitors isolated from venoms have filled roles in the study and identification of CaV subfamilies. A non-exhaustive summary of organic agents and venomous peptides that block CaV subclasses is in provided in Table 2.

Human Disease Associations and Effects of Gene Deletion

CaV subtypes are widely expressed in neural- and extraneural-excitable cells, including myocardium, skeletal muscle, and smooth muscle. In addition, they are variably expressed in a wide variety of other tissues where their functions are often poorly understood. Table 3 provides a summary of known human disease associations and phenotypic effects of gene deletion. These are summarized in following paragraphs.

CaV1.x, L-Type Channels: Expression and Disease Association

The CaV1.1 (α_{1S}) L-type voltage-gated calcium channel carries a slowly activating inward current and acts as the voltage sensor for calcium signaling via the type 1 ►ryanodine receptor (RyR1, ►RyR) in skeletal muscle. Association of CaV1.1 with RyR1 in the plasmalemmal junction facilitates rapid Ca^{2+} release from sarcoplasmic reticulum (SR) stores (Striessnig et al. 2010; Cannon 2010). Hypokalemic period paralysis type 1 (HPP1) is characterized by attacks of weakness or paralysis, often precipitated by stress, temperature change, exercise, or carbohydrate meals. HPP1 has been most frequently traced to neutralizing point mutations of arginine residues within the S4 voltage-sensing region of CaV1.1. It has been proposed that this modification gives rise to an abnormal "gating pore" current when the S4 region is realigned during depolarization. The role of hypokalemia may be related to its ability to reduce conductance of inward rectifier K^+ channels Kir (potassium inwardly rectifying channel) favoring a depolarizing shift in membrane. Malignant hyperthermia (MH) is a potentially lethal disorder in which affected individuals develop skeletal muscle contractures, ATP depletion, lactic acidosis, and fever upon exposure to anesthetics or muscle relaxants. The majority of mutations that induce MH are found in the RYR1 SR Ca^{2+} release channel, but others have been traced to CaV1.1. In the latter case, point mutations within the cytoplasmic region that links repeats III and IV or modifies the inner arginine of I-S4 are at fault. The III-IV linker region couples CaV1.1 to RYR1 and confers voltage sensing. Depolarization-induced conformational changes lead to rapid RYR1-mediated Ca^{2+} release. In mice, CaV1.1 deficiency is manifest as muscular dysgenesis, an autosomal recessive phenotype that leads to early death of pups by asphyxiation (Striessnig and Koschak 2008).

CaV1.2 (α_{1C}) is a widely expressed channel subject to extensive alternate splicing. It is present in brain, where it is the dominant L-type isoform; in heart,

where it conducts Ca^{2+} during the plateau phase of the action potential; in smooth muscle, where it mediates the Ca^{2+} entry required for contraction; in neuroendocrine cells, where it is involved in insulin secretion; and in T-lymphocytes, where it affects immunity (Striessnig et al. 2010; Liao and Soong 2010). The relative predominance of separate exons in heart and smooth muscle accounts for variable ability of organic L-type channel blockers to modify contraction and affect heart rate. Gain-of-function and loss-of-function mutations in CaV1.2 underlie human Timothy and Brugada syndromes, respectively (Liao and Soong 2010).

Timothy syndrome, previously known as the long QT syndrome, is associated with syndactyly, neurological manifestations such as autism and depression, facial malformations, structural cardiac defects, early death, and predisposition to infection. The gain of function results in prolonged inward current due to slowing of inactivation and thus, enhanced Ca^{2+} entry through affected channels. It is inherited in an autosomal dominant pattern, as new mutations, or from an affected parent who is mosaic for the channel. Mutation in the mutually exclusive cardiac CaV1.2 exon yields the type 2 variant of Timothy syndrome (TS type 2, TS2) characterized by cardiac arrhythmias and absence of syndactyly. Brugada syndrome arises most often from mutations in the α_1 subunit of the NaV1.5 voltage-gated sodium channel NaV (sodium channel, voltage-gated, type V) but can also result from mutations in CaV1.2 α_1 or β_{2b} accessory subunits. Brugada patients are prone to sudden death from cardiac arrhythmias and exhibit short QT intervals and elevated ST segments on electrocardiogram. Extracardiac manifestations are generally mild or absent. Complete deletion of CaV1.2 yields embryonic lethality at day 12.5 when it is required to sustain myocardial contraction. As expected, conditional knockout of CaV1.2 from smooth muscle yields hypotension. Conditional knockout of the channel from cerebral cortex and hippocampus leads to loss of spatial memory (Striessnig and Koschak 2008).

Both voltage-dependent inhibition (VDI) and calcium-dependent inhibition (CDI) are characteristics of CaV1.2 behavior. The former is best studied as the spontaneous inactivation that occurs when Ba^{2+} (rather than Ca^{2+}, which affects CDI) is the current-carrying ion. VDI may depend upon interactions of the pore with the I-II intracellular loop. In calcium signaling, CDI depends upon interactions of Ca^{2+} ion with the calcium-sensing accessory subunit calmodulin (CaM) that binds to the IQ motif on the C-terminus of the channel (Minor and Findeisen 2010). Thus, CaM acts as an inhibitory sensor of Ca^{2+} that limits Ca^{2+} entry. Ba^{2+} cannot substitute for Ca^{2+} in CaM binding so that inactivation is prolonged when Ba^{2+} is charge carrier. Stated another way, with Ba^{2+}, CDI is lost and VDI can be studied in isolation.

CaV1.3 (α_{1D}) is expressed in brain, heart, and retina. The behavior of CaV1.3 is distinct from CaV1.2 in that the former activates more rapidly and at more negative potentials. Moreover, CaV1.3 lacks the calcium-dependent inactivation (CDI) exhibited by CaV1.2 and some other CaV channels. Only recently has a human channelopathy been traced to CaV1.3 manifest as deafness and bradycardia. That phenotype parallels deafness and sinoatrial node dysfunction of CaV1.3 knockout mice (Baig et al. 2011). Deletion of CaV1.3 in the heterozygous state may be without consequence. The homozygous knockout mouse, however, is deaf and bradycardic but viable and fertile (Striessnig and Koschak 2008). Deafness occurs because CaV1.3 is vital to proper function of inner ear hair cells of the cochlea. The associated bradycardia is benign and overcome during exercise (Striessnig and Koschak 2008; Striessnig et al. 2010).

CaV1.4 (α_{1F}) is found in retina and human deficiency leads to X-linked congenital stationary night blindness, type 2 (CSNB2) and its variants, X-linked cone-rod dystrophy-3 (CORDX3), and Aland Island eye disease or Forsius-Eriksson syndrome (Striessnig et al. 2010). The channel is characterized by rapid activation, occurring at relatively low membrane potentials below −40 mV, and slow inactivation which, like CaV1.3, is related to absence of CDI. CSNB2 patients exhibit variable manifestations of decreased visual acuity, particularly in dim light, myopia, and nystagmus. Associated mutations may yield loss of function, gain of function, or abnormalities in gating. Mutations in other proteins such as calcium-binding protein-4 can yield the CSNB2 phenotype. CaV1.4 is involved in control of neurotransmission in retinal photoreceptors (like CaV1.3 in cochlear hair cells). The relatively low voltage-dependent activation threshold of CaV1.3 and CaV1.4 may be vital to enhance their window current (Ca^{2+} influx related to the membrane potential range over which channels can activate and escape durable inactivation). The window current of CaV1.3 and CaV1.4 probably facilitates tonic neurotransmitter release in cochlear hair cells and retina, respectively. Structurally, absence of CDI results from the presence of an inhibitory domain near the calmodulin-binding site (IQ domain) on the channel C-terminus. Mutation or elimination of that motif can restore CaM-dependent CDI. Moreover, deletion of the inhibitory domain may occur as a normal splice variant in CaV1.3. An autoinhibitory domain of CaV1.2, generated by proteolytic cleavage of the C-terminus, may serve an analogous inhibitory function in cardiac myocytes (Hulme et al. 2006).

CaV2.x, P/Q-, N-, and R-Type Channels: Expression and Disease Association

CaV2.1 (α_{1A}) P/Q-type channels are predominantly expressed in the central nervous system where they are coupled to exocytosis at synapses. Human loss of function is associated with three autosomal dominant disorders: familial hemiplegic migrane type 1 (FHM1), episodic ataxia type 2 (EA2), and spinocerebellar ataxia type 6 (SA6) (Pietrobon 2010). FHM1 patients suffer from migraine headache with aura along with motor weakness or frank hemiplegia. Severely affected individuals may exhibit seizures, depression of consciousness, confusion, and prolonged weakness. Some FHM1 families exhibit cerebellar atrophy, progressive ataxia, cognitive impairment, and nystagmus. EA2 manifests in early life with symptoms such as episodic ataxia, loss of coordination, dysarthria, vertigo, and nausea. SA6 manifests later in life as progressive ataxia and cerebellar atrophy that associates with expansion of C-terminal polyglutamine repeats of splice variants. P/Q variants have been proposed to confer susceptibility to generalized seizures (Khosravani and Zamponi 2006) Homozygous CaV2.1 deficiency in mice leads to severe forms of neurological dysfunction involving dystonia, weakness, and ataxia (e.g., Tottering mice). The majority of pups do not survive to weaning and progressive decrease in cerebellar volume is associated with loss of Purkinje and granular cells. Heterozygous mice do not suffer similar neurodegeneration (Striessnig and Koschak 2008).

CaV2.2 (α_{1B}), N-type channels are predominantly expressed in the central nervous system and syndromes traced to their deficiency in humans have not been reported. Mice deficient in the α_{1B} subunit are viable and fertile. Reduced responses to some pain stimuli (Kim et al. 2001), enhanced aggression, and enhanced locomotor activity have been documented (Striessnig and Koschak 2008; Nakagawasai et al. 2010).

CaV2.3 (α_{1E}), R-type channels are widely expressed in neuronal tissue, and have also been found in retina, kidney, pancreatic islets, neuroendocrine cells of the GI tract, and spleen. CaV2.3 has several splice variants and is involved in diverse physiological functions, neurotransmitter release, neuronal plasticity, responses to fear and pain, insulin release, and reproduction. Human disorders traceable to α_{1B} mutations have not been reported; however, the channel is believed to be involved in predisposition to seizure and seizure propagation (Weiergraber et al. 2006). These and other CaV isoforms are targeted by many antiepileptic pharmaceuticals. Mice deficient in α_{1B} have been generated and studied extensively. They show altered responses to some forms of noxious stimuli, impaired spatial memory in maze testing, and disturbances in glucose tolerance and insulin release (Striessnig and Koschak 2008).

CaV3.x, T-Type Channels: Expression and Disease Association

CaV3.x, T-type channels are widely expressed in neural and extraneural tissues. Their behavior is generally distinguished from CaV1.x, L-type channels by their low activation thresholds and tendency toward rapid activation and inactivation (CaV3.3 is an arguable exception). They are also distinguished by their lower Ba^{2+} to Ca^{2+} conductance ratio, small single channel currents, and insensitivity to dihydropyridines (Huc et al. 2009; Perez-Reyes 2006; Zamponi et al. 2010). Their best-known roles involve pacemaker functions in heart and brain. They are known to be modulated by cyclic nucleotide–dependent protein kinases (PKA, PKC) (Huc et al. 2009).

CaV3.1 (α_{1G}), T-type channels are expressed predominantly in brain, and notably in thalamocortical relay neurons (TRN) where they participate in spike and wave discharges. CaV3.1 has also been reported in diverse tissues such as sinoatrial node, vascular smooth muscle, endothelia, myometrium, preadipocytes, outer hair cells, and testis. Human diseases associated with CaV3.1 have not been reported and murine deficiency yields a viable phenotype without gross abnormalities. CaV3.1 deficiency leads to inability to induce spike and wave discharges in TRN and, when superimposed by cross breeding, renders mouse models of absence seizures resistant to seizure events (Striessnig and Koschak 2008). Loss of CaV3.1 also leads to enhanced visceral pain, loss of T-type currents in sinoatrial node, and bradycardia in freely moving mice.

CaV3.2 (α_{1H}), T-type channels are expressed predominantly in brain, kidney, liver, and heart. In humans, CaV3.2 variants have been associated with susceptibility to absence epilepsy in Chinese Han children. Other human variants have been proposed to increase susceptibility to generalized seizures.

Murine homozygous deletion of CaV3.2 yields a viable and fertile phenotype that experiences delayed growth. Interestingly, CaV3.2 deficient mice exhibit constitutively contracted coronary arteries and myocardial fibrosis (Chen et al. 2003). A physical association between CaV3.2 and large conductance calcium-dependent potassium (BKCa) channels in coronary artery was found in wildtype mice but absent in CaV3.2 knockouts. Thus, it is possible that elimination of stimulation of BKCa might underlie enhanced coronary vasomotor tone in CaV3.2$^{-/-}$. In a manner analogous to increase in visceral pain induced by CaV3.1 deficiency, knockout of CaV3.2 leads to increase in peripheral pain from thermal or mechanical stimuli (Striessnig and Koschak 2008).

CaV3.3 (α_{1I}), T-type channels are expressed in brain and spinal cord with limited expression in adrenal and thyroid. When compared to either CaV3.1 or CaV3.2, CaV3.3 exhibits slower activation and inactivation rates (Huc et al. 2009; Perez-Reyes 2006). Information on its tissue-specific functions is sparse. Neither human disease association nor effects of murine gene deletion have been reported.

Summary

Voltage-gated calcium channels are large complex proteins evolved from ancient origins. Over the last 30 years, enormous progress has been made in their molecular identification (Table 1). Their predominant expression in excitable tissues such as the nervous system, skeletal muscle, and smooth muscle is consistent with regulation of those tissues through modulation of membrane potential and the important role of Ca^{2+} ions in intracellular calcium signaling. Much information has also been derived from associations between naturally occurring mutations and human disease. The associated gain-of-function and loss-of-function phenotypes that lead to alteration of neuromuscular functions are consistent with their expected roles. In many cases, the diseases are mimicked by effects of targeted murine gene deletions (Table 3). Pharmacological study remains challenging due to lack of selective organic compounds that are capable of blocking conduction of ions through the various subclasses (Table 2). Efforts to identify such compounds through high-throughput screening methods may bridge the gap and lead to new probes of physiological function as well as pharmaceutical antiarrhythmic, antiepileptic, and antihypertensive agents.

Synonyms

Vaccinia-related kinase 1; Vaccinia virus B1R-related kinase 1; VRK-1

Historical Background

VRK proteins were identified as two human EST sequences whose translation products have homology with the kinase domain in vaccinia virus B1R kinase, from where its name is derived. During its evolution and adaptation to its host, the virus incorporated this cellular sequence required for viral DNA replication.

VRK1 Gene Structure and Expression

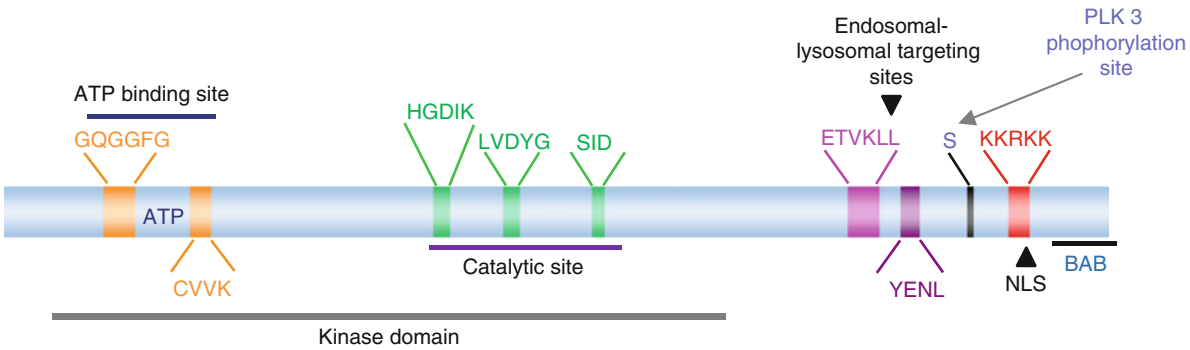
The human *VRK1* gene is located on the chromosomal region 14q32.2, containing 14 exons and coding for a protein with 396 amino acids. This gene has a polymorphism, marker rs722869, which is useful in the identification of population structure and genetic ancestry (Lao et al. 2006). Chromosomal translocations in the region do not affect VRK1. No mutation in this gene has been reported in human cancer.

VRK1 is expressed in all types of human and murine cells tested (Nichols and Traktman 2004), particularly at very high levels if they are proliferating (Nezu et al. 1997; Santos et al. 2006). In murine embryonic hematopoietic development, the highest level of expression is achieved between days E11.5 and E13.5, a time of massive hematopoietic-liver expansion (Vega et al. 2003).

Loss of VRK1 by siRNA results in a block in cell cycle progression, since VRK1 is an early response gen following stimulation by growth factors and is necessary for G0 exit (Valbuena et al. 2008b). VRK1 knockdown mice, which have a 15% residual level, are infertile because of loss of spermatogonia and have chromosomal meiotic aberrations (Wiebe et al. 2010).

VRK1 Protein Structure and Subcellular Localization

VRK (vaccinia-related kinases) are a new group of Ser-Thr kinases in the human kinome (Manning et al. 2002) and have homology to the catalytic domain of the B1R kinase of vaccinia virus that is required for viral DNA replication (Nichols and Traktman 2004). In yeast, there is no orthologous gene, and in invertebrates *Drosophila melanogaster* and *Caenorhabditis elegans*, there is only one VRK protein (Klerkx et al. 2009). In mammals, there are three members, two of which



VRK1, Fig. 1 Human VRK1 protein structure. *BAB* basic-acid-basic motif, *NLS* Nuclear localization signal, *PLK3* polo-like kinase 3

(VRK1 and VRK2) are catalytically active (Lopez-Borges and Lazo 2000; Nichols and Traktman 2004), and a third one, VRK3, which is not active and might function as a scaffold protein (Kang and Kim 2006). The VRK catalytic domain has substitutions in several key residues making it an atypical kinase (Nichols and Traktman 2004). The relative conservation of the catalytic domain of VRK proteins indicates they can have an overlap of potential substrates in vitro, and the in vivo substrates are likely to be determined by subcellular localization.

Structurally, the three VRK proteins differ in their regulatory region located C-terminal on VRK1(3OP5) (Fig. 1) and VRK2, and N-terminal on VRK3. These regulatory regions are unrelated among them and have no homology to any known feature identified in other proteins. The length of the regulatory region is variable. It is approximately 100 amino acids in VRK1 and 200 amino acids in VRK2; thus, their subcellular localization and regulation is likely to be different among mammalian VRK proteins and those of lower eukaryotes.

VRK1 interacts by its C-terminal region with nuclear RAN, a small GTPase, which can regulate the kinase activity; RAN bound to GDP, but not to GTP, inhibits its kinase activity (Sanz-Garcia et al. 2008). This region also contains nuclear import and export localization signals, an endosomal-lysosomal targeting sequence, as well as a BAB (basic-acid-basic) motif of unknown function.

VRK1 is a protein mostly located within the nucleus, and it is outside the nucleolus (Lopez-Borges and Lazo 2000; Vega et al. 2004), a major fraction of which is interacting with chromatin (Kang et al. 2007). However, there is a minor cytoplasmic subpopulation located in the Golgi apparatus (Lopez-Sanchez et al. 2009). In some cell types, particularly in secretory epithelial cells, VRK1 is also present in the cytosol (Valbuena et al. 2007a), but the regulation of VRK1 subcellular localization is not known.

VRK1 Phosphorylation Targets and Role in Nuclear Dynamics

VRK1 regulates several transcription factors associated with cellular responses to stress and cell cycle progression. VRK1 phosphorylates the JUN oncogene in residues Ser63 and Ser73; these residues are the same targeted by JNK (Jun N-terminal kinase). This permits an additive activation of JUN-dependent transcription in situations of suboptimal activation of the JNK and VRK1 signaling pathways (Sevilla et al. 2004a).

The transcription factor ATF2 is phosphorylated in residues Ser62 and Thr73 by VRK1 (Sevilla et al. 2004b). These residues are in the same region, but are different from the Thr69 and Thr71 targeted by JNK. Thus they can have an additive effect even at maximum stimulation of VRK1 and JNK signaling pathways (Sevilla et al. 2004a). Furthermore, residues Ser62 and Thr72 are activated in response to cAMP signals mediated by PKA, which can cooperate with VRK1 in case of suboptimal stimulation. VRK1 phosphorylates CREB1 in Ser133 and is integrated in the transcriptional protein complex required for cyclin D1 (CCND1) gene expression (Kang et al. 2008), consistent with a VRK1 role in cell cycle entry and progression (Valbuena et al. 2008b).

VRK1 has been shown in several processes required for cell division. VRK1 phosphorylates histone H3 in Thr3 and Ser10 inducing chromatin condensation in mitosis (Kang et al. 2007; Sanz-Garcia et al. 2008). VRK1 protein level is higher in mitosis and is detected in chromatin, where it regulates the interaction of H3 with gamma heterochromatin protein 1 (HP1γ) (Kang et al. 2007).

VRK1 phosphorylates BAF, a protein regulating assembly and disassembly of the nuclear envelope (Nichols et al. 2006). BAF phosphorylation by VRK1 can inhibit the preintegration complex of retroviruses (Suzuki et al. 2010).

VRK1 interacts with RAN, the only nuclear small GTPase (Sanz-Garcia et al. 2008). RAN is implicated in nuclear transport and has an asymmetric distribution in the nucleus determined by its binding to either GDP or GTP. In mitosis, RAN-GTP is proximal to the spindle. RAN is an allosteric regulator of VRK1 activity. RAN-GDP inhibits VRK1 kinase activity on substrates such as p53 and histone H3, and VRK1 is active when it is bound to RAN-GTP (Sanz-Garcia et al. 2008). This effect indicates that VRK1 activity in the nucleus is likely to be asymmetric and dependent on its localization, despite an apparent homogeneous distribution of this protein. In some cells, VRK1 is detected in the nucleolus, but its significance is not known.

VRK1 Regulating p53 and Cell Cycle Processes

VRK1 phosphorylates p53 uniquely in Thr18 (Lopez-Borges and Lazo 2000). This phosphorylation prevents p53 interaction with HDM2 and favors its interaction with transcriptional cofactors. Thus VRK1 induces a stabilization and accumulation of p53 that exerts its known biological effects (Vega et al. 2004). A persistent accumulation of p53 is deleterious for the cell. Thus it is necessary to downregulate p53, but this requires also removing its VRK1 stabilizer. p53, with P300 as coactivator, activates transcription of DRAM (Valbuena et al. 2008a), a new gene that targets VRK1 for proteolytic degradation in the lysosome (Valbuena et al. 2006). Its mechanism involves part of the autophagic pathway implicated in removal of stable proteins, such as VRK1. In tumors with p53 mutations, this autoregulatory loop is not induced and there is an accumulation of VRK1 (Valbuena et al. 2007b). VRK1 appears to play a fundamental role allowing cells to respond to DNA damage and initiate protective responses (Vega et al. 2004).

VRK1 gene expression is regulated by entry in cell cycle after stimulation with serum and is expressed at the same time as MYC and FOS, two early genes and positively correlated with phospho-RB. Serum withdrawal results in loss of VRK1 gene expression (Valbuena et al. 2008b). VRK1 knockdown prevents cell division (Vega et al. 2004), causes loss of RB phosphorylation, and there is an accumulation of p27, suggesting a cell cycle blockade (Valbuena et al. 2008b). VRK1 gene expression precedes that of Cyclin D1 (CCND1gene) before the (restriction point in) G1 (Valbuena et al. 2008b), and VRK1 protein forms part of the transcriptional complex on the CCND1 gene promoter (Kang et al. 2008). In mitosis, there is a fragmentation of the Golgi apparatus required for its distribution into daughter cells; this process is induced by MEK1 and PLK3, and in which VRK1 is a downstream step. The VRK1 subpopulation located in Golgi apparatus is an essential component of the MEK1-Plk3 signaling pathway required for Golgi fragmentation in mitosis, in which Plk3 directly phosphorylates VRK1 in Ser342 (Lopez-Sanchez et al. 2009). Consistent with cell cycle defects is the phenotype of hypomorphic VRK1 knockdown mice (15% residual normal protein) of murine VRK1 that have a loss of spermatogonia and sterility (Wiebe et al. 2010).

VRK1 in Human Diseases

VRK1 is expressed at high level in most tumors, probably reflecting its association with proliferation, since it positively correlates with cell cycle markers cdk2, p63, and survivin, as shown in head and neck squamous cell carcinomas (Santos et al. 2006). In lung cancer with p53 mutations, there are also very high levels of VRK1, reflecting the disruption of its autoregulatory loop (Valbuena et al. 2007b). In breast cancer, VRK1 overexpression identifies a subgroup with poorer prognosis (Finetti et al. 2008).

The homozygous mutation R358Stop causes a syndrome characterized by pontocerebellar hypoplasia, spinal-muscular atrophy, mild mental retardation, and death in childhood (Renbaum et al. 2009). Heterozygous carriers have no pathology.

Summary

VRK1 is a Ser-Thr kinase functionally associated with entry in cell cycle, and is required for nuclear envelope dynamics, chromatin condensation, and Golgi fragmentation.

VRK1 is mostly located in the nucleus and in the Golgi apparatus. Among its substrates are several transcription factors: p53, c-Jun, ATF2, and CREB1. VRK1 probably acts cooperating with other signaling pathways that also phosphorylate these transcription factors. VRK1 stabilizes p53 by a specific phosphorylation in Thr18 and after induction of p53 responses, there is a VRK1 downregulation in the lysosome and in which the autophagic pathway participates in a p53-dependent manner. VRK1 contributes to chromatin condensation and nuclear envelop kinetics by phosphorylation of histone H3 and BAF. VRK1 is downstream of MEK1 and Plk3 in the pathway inducing Golgi fragmentation during mitosis. VRK1 is expressed in most tissues, is necessary in the early G1 phase for entry in cell cycle, and is associated with proliferation markers (Klerkx et al. 2009).

Historical Background

Mammalian VRK (vaccinia-related kinases) were originally identified as two human EST, ▶ VRK1 and VRK2, expressed in proliferating cell lines and regenerating liver. These EST have homology to the catalytic region of the B1R kinase of vaccinia virus (Nezu et al. 1997) that is expressed early in viral infection, and is required for viral DNA replication. These VRK proteins were classified as a new group of Ser-Thr kinases in the human kinome diverging very early from the same branch that led to casein kinase I (CK1) (Manning et al. 2002). This family has only one ortholog gene in invertebrates, such as *Caenorhabditis elegans* or *Drosophila melanogaster*, and is not present in yeast (Klerkx et al. 2009).

VRK2 Gene and Expression

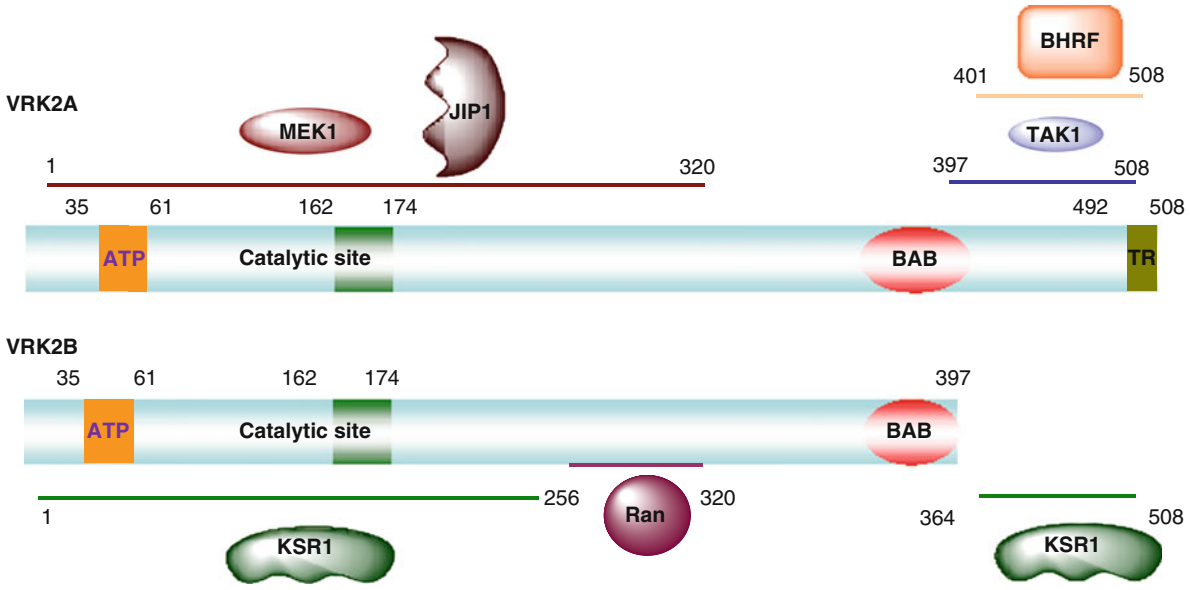
The human *VRK2* gene is located in chromosome 2p16.1 and generates two messages by alternative splicing. Their translation generates two protein isoforms, VRK2A (also known as VRK2) and VRK2B. The VRK2A corresponds to the full-length protein and is expressed from a message of 1,833 nucleotides coding for a protein of 508 amino acids. The alternatively spliced variant includes a novel exon and generates a message of 1,877 nucleotides. The additional exon has 44 nucleotides, and is the new exon 13. The message for isoform B has an inframe termination codon, generating a shorter protein of 397 amino acids that is truncated and lacks the C-terminal region that is present in isoform A (Blanco et al. 2006; Nichols and Traktman 2004).

Human VRK2 RNA is detected in many tissues, particularly those with high proliferation activity such as tumor cell lines. Fetal tissues express higher levels than adult organs (Nezu et al. 1997; Nichols and Traktman 2004).VRK2A has been detected in all cell types examined, whereas VRK2B has only been detected in cells in which VRK1 is cytoplasmic. Therefore, VRK2B might be functionally redundant with VRK1 in some roles not yet identified (Blanco et al. 2006).

During hematopoietic development in murine embryos, the highest level of VRK2 expression is achieved at days E11.5 to E13.5, in thymus, spleen, and liver, at a time of massive hematopoietic-liver expansion (Vega et al. 2003). Expression increases again at day 17.5, just before delivery. In adult mice high RNA levels are present in liver, kidney, and muscle (Vega et al. 2003).

VRK2 Protein Structure and Subcellular Localization

The amino acid sequence of human VRK2 is slightly different from other VRK kinases and contains amino acid substitutions in several key residues, but it is still



VRK2, Fig. 1 Structure of human VRK2A and VRK2B isoforms and their protein interactions. ATP (position of ATP binding site). Catalytic site is indicated. *BAB* basic-acid-basic region, *TM* transmembrane region, *VEA* three terminal amino acids in VRK2B isoform, which are different, from VRK2A. The interacting proteins and the location of the regions of interaction with other proteins are also indicated. Some of the interactions are common to both isoforms

catalytically active (Nichols and Traktman 2004; Blanco et al. 2006). The crystal structure of the catalytic domain of human VRK2 (PDB: 2V62) has been determined and it differs in the activation segment from the catalytically inactive VRK3 (Scheeff et al. 2009). VRK2A and VRK2B proteins have a strong autophosphorylation activity in multiple residues (Blanco et al. 2006; Nichols and Traktman 2004). However, both VRK2 proteins are also likely to be regulated and be the target of other kinases not yet identified. The C-terminal region is very different between VRK2A and VRK2B. VRK2A is the normal full-length protein and has 508 amino acids. VRK2A has a conserved BAB (basic-acid-basic motif) of unknown function in its C-terminal region, and the last amino acids are hydrophobic and form a typical transmembrane anchoring region. VRK2B is the result of alternative splicing in some cells and has 397 residues, of which the first 394 are identical to the corresponding region in VRK2A (Fig.1), and its last three residues are different (VEA), thus it lacks most of the C-terminal region present in VRK2A. Neither isoform has a nuclear localization signal. Several proteins have been identified interacting with different regions of VRK2A or VRK2B (Fig. 1).

The human VRK2A protein is located in the endoplasmic reticulum (ER), partly in the perinuclear area (Nichols and Traktman 2004). The VRK2A isoform has a hydrophobic membrane-anchoring domain that is not present in isoform VRK2B. VRK2A localizes to endoplasmic reticulum (ER) membranes and colocalizes with the ER markers calnexin and calreticulin, and is the isoform present in all cell types (Blanco et al. 2006; Nichols and Traktman 2004). VRK2A also colocalizes with mitochondria, as detected by its colocalization with the Mitotracker reagent (Blanco et al. 2006). VRK2B lacks the C-terminal region and its transmembrane hydrophobic tail, thus it is not bound to membranes. Thus, VRK2B isoform is detected as granular deposits in both cytoplasm and nucleus, and its expression is restricted to some cells by unknown reasons, but it is a regulated expression (Blanco et al. 2006).

VRK2 Phosphorylation Substrates and Protein Interactions

The two VRK2 isoforms, which differ in their subcellular location, seem to have similar substrate

specificity in vitro. Both VRK2A and VRK2B phosphorylate human ▶ TP53 at Thr 18 (equivalent to mouse Thr 21) (Blanco et al. 2006). It is not known if the mitochondrial VRK2A phosphorylates mitochondrial p53.

VRK2A, both murine and human, as well as VRK1 are able to phosphorylate the N-terminal region of ▶ BAF, a small protein that interacts with DNA, and is required for nuclear envelope assembly. Phosphorylation of BAF by VRK1 results in loss of binding to DNA and inhibits nuclear envelope assembly (Nichols et al. 2006). VRK2, like VRK1, is also able to phosphorylate the amino terminus of BAF (barrier to autointegration factor) protein, which is required for assembly of the nuclear envelope, and also causes loss of BAF binding to DNA (Nichols et al. 2006). The unique *C. elegans* orthologue for the VRK family, Vrk1-1, also phosphorylates BAF (Gorjanacz et al. 2008). This BAF phosphorylation impairs the formation of retroviral MoMLV (Moloney-murine leukemia virus) integration complexes (Suzuki et al. 2010).

VRK2A phosphorylates the JIP1 scaffold protein, but its significance is unknown since its effects on MAPK signaling are independent of phosphorylation and only require the protein interaction (Blanco et al. 2007, 2008).

The autophosphorylation activity of both VRK2 proteins can be inhibited in vitro by a stable interaction between the small nuclear GTPase ▶ Ran in a nucleotide-free or GDP-bound conformation. The GTP-bound form of Ran has no apparent effect on VRK2 kinase activity (Sanz-Garcia et al. 2008). VRK2A has a membrane-targeting domain that allows VRK2A to localize to intracellular membranes in the endoplasmic reticulum and mitochondria. VRK2B lacks this domain.

The large carboxy-terminal region of VRK2A can interact with other proteins, such as the JIP1 (Jun amino-terminal kinase (JNK)-interacting protein 1) (Blanco et al. 2007, 2008) and KSR1 scaffold proteins (Fernandez et al. 2010), and thus inhibits signal transduction, but they interact in a different manner. In these complexes, VRK2A also directly interacts with different mitogen-associated protein kinases, such as MEK1 (Fernandez et al. 2010) and TAK1 (Blanco et al. 2007, 2008).

VRK2A also directly interacts with the scaffold KSR1, implicated in signal transmission from EGF, ERBB2, KRAS, and BRAF signals that activate AP1-dependent transcription (Fernandez et al. 2010). In this complex, VRK2 also directly interacts with MEK1 (Fernandez et al. 2010).

The C-terminal region of VRK2A interacts with an Epstein-Barr Virus (EBV) protein, BHRR1, which is a homologue of BCL2 and enhances cell survival, but no interaction with human BCL2 has been detected (Li et al. 2006).

VRK2 Modulates MAPK Signaling

VRK2A isoform modulates signaling mediated by MAPK pathways. This action is mediated by a direct interaction between a scaffold protein and VRK2A, and does not depend on its kinase activity. Stress responses, such as hypoxia (Blanco et al. 2007), and response to inflammatory cytokines, such as interleukin-1β (IL-1β) (Blanco et al. 2008), mediate signals by activation of Jun-dependent transcription. These responses are inhibited by VRK2A which forms a macromolecular complex, signalosome, which is anchored to endoplasmic reticulum membranes. In this complex, VRK2A interacts with TAK1, the first MAP kinase (MAPKKK) and the JIP1 scaffold protein (Blanco et al. 2007, 2008). This complex prevents the incorporation of JNK (c-Jun N-terminal kinase), which cannot be activated by phosphorylation, inhibiting c-Jun dependent transcription. The amount of VRK2A in the cells seems to control the fraction of JIP1 free and bound, thus creating a compartmentalization with two complexes, one active without VRK2A, and another inactive with VRK2A.

Many proliferative responses mediated by oncogenes are transmitted by MAPK complexes resulting in the activation of RAF-MEK-ERK pathway, which is assembled on the KSR1 scaffold protein. Among the activated oncogenes that can be modulated by VRK2A are ERBB2, RAS, and RAF. VRK2A directly interacts with MEK1 and KSR1 preventing the activation of ERK1 and ▶ p90RSK (Fernandez et al. 2010). VRK2A does not affect signals that partly use this pathway, such as AKT. In this way, VRK2A inhibits at a downstream level the signal initiated in ERBB2,

which is amplified in many tumor types. Also reduced level of P-ERK was observed in the presence of VRK2, and VRK3, in the analysis of the EGFR response pathway (Komurov et al. 2010).

VRK2 in Human Pathology: Breast Cancer and Viral Infections

VRK2 levels in human breast cancer correlated positively with estrogen and progesterone receptors. VRK2 was inversely correlated with ErbB2, thus Erb2+ breast cancer have low levels of VRK2. VRK2 can block the signal mediated by MAPK in response to EGF or its receptors (ERBB family), as well as signals from mutated RAS or BRAF. By reducing VRK2 levels, inhibition of MAPK pathway transcriptional signaling is partly removed in these tumors (Fernandez et al. 2010). This downstream inhibitory effect of VRK2A on MAPK can also be occurring in other tumors with mutations along this signaling pathway, but it needs to be demonstrated.

VRK2 received its name from the homology of its catalytic domain and that of the unique vaccinia virus kinase B1, which is required for Vaccinia virus DNA replication early in infection. Despite their divergence, VRK2 and ▶ VRK1 are able to partially rescue replication of vaccinia virus strains with defective B1 kinase (Boyle and Traktman 2004),

Epstein-Barr Virus (EBV) expresses the BHRF1 protein that is a homologue of mammalian Bcl2, which has a protective role and favors cell survival. BHRF1 interacts with the C-terminal region of VRK2A, and if VRK2A levels are high cells are protected against apoptosis, and this protection depends on the interaction and not on the kinase activity of VRK2 (Li et al. 2006).

Summary

VRK2 is a Ser-Thr kinase and has two isoforms, cytosolic and nuclear. The full-length VRK2 cytosolic isoform (A) inhibits MAPK signaling by a direct interaction with the corresponding JIP1 or KSR1 scaffold proteins. As a consequence, high levels of VRK2A inhibit in a dose-dependent manner signals mediated by the TAK1-MKK7-JNK in response to hypoxia or interleukin, and the signal of the ERBB2-RAS-RAF-MEK-ERK pathway. Downregulation of VRK2A relieves this inhibition and allows signal transmission in response to stimuli initiated in receptor-tyrosine kinases (RTK), such as ERBB2. Thus, in breast cancer VRK2A and ERBB2 present an inverse correlation.

Wiskott-Aldrich Syndrome Protein and SCAR Homolog; WASP and SCAR Homolog

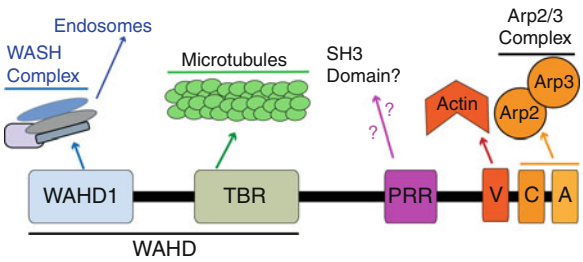
Historical Background

WASH (Wiskott-Aldrich Syndrome Protein and SCAR Homolog) was initially identified in 2007 as a novel member of the WASP (Wiskott-Aldrich Syndrome Protein) superfamily of nucleation-promoting factors (NPFs) (Linardopoulou et al. 2007). In addition to WASH, this family includes the founding member WASP as well as N-WASP (Neuronal Wiskott–Aldrich Syndrome Protein), three WAVE/SCAR (WASP family Verprolin-homologous protein/Suppressor of cAR) isoforms, WHAMM (WASP Homolog associated with Actin, Membranes, and Microtubules), and JMY (Junction Mediating and Regulatory Protein) (Campellone and Welch 2010). WASH orthologs are evolutionarily conserved from humans through *Entameba* and WASH mRNA (Messenger RNA) is ubiquitously expressed in human tissues (Linardopoulou et al. 2007). Further work comparing known genome sequences revealed that WASH is conserved down to the green algae *Ostreocuccus* and that divergent WASH homologs can even be found in members of the plant kingdom (Veltman and Insall 2010). The *wash* gene was found to be essential for *Drosophila melanogaster* viability and reduction of WASH levels in female *Drosophila melanogaster* rendered them sterile (Linardopoulou et al. 2007; Liu et al. 2009). While most species contain a single WASH ortholog, higher order primates and humans were found to posses multiple *wash* gene copies located in subtelomeric chromosomal regions (Linardopoulou et al. 2007). Significantly, WASH contains an evolutionarily conserved C-terminal VCA (verprolin homology, central hydrophobic, acidic region) domain, which is required for both profilin G-actin sequestration and Arp2/3 binding and activation leading to subsequent actin polymerization (Fig. 1) (Linardopoulou et al. 2007). A C-terminal VCA domain is a hallmark of the WASP family of NPFs (Campellone and Welch 2010). Similar to other NPFs of the WASP superfamily, WASH was found to induce Arp2/3-mediated actin polymerization and branched actin network formation in vitro (Linardopoulou et al. 2007; Liu et al. 2009).

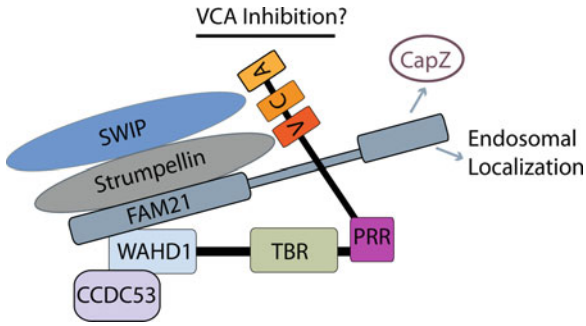
WASH Protein Structure

In addition to the conserved C-terminal VCA domain found in all WASP superfamily members, WASH also contains a proline-rich domain (PRD) located adjacent to the VCA, as well as a distinct N-terminal regulatory region (Linardopoulou et al. 2007; Rottner et al. 2010). As depicted in Fig. 1, this unique N-terminus of

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,



WASH, Fig. 1 *Functional Domains of WASH*. The N-terminal domain of WASH has been termed the WAHD (WASH Homology Domain) and is composed of the WAHD1 (WASH Homology Domain 1) and the TBR (Tubulin-Binding Region). The WAHD1 has been shown to be responsible for binding to the SHRC member FAM21 which is responsible for localizing WASH to endosomes. The TBR has been shown to bind to tubulin. The centrally located PRR (proline-Rich Region) currently has no identified binding partners. The V (verprolin homology) C (central hydrophobic) A (acidic region) at the C-terminus of WASH binds actin monomers and the Arp2/3 complex and induces branched actin network formation



WASH, Fig. 2 *Members and Function of the WASH Regulatory Complex (SHRC)*: The SHRC is composed of five members. WASH, FAM21, CCDC53, Strumpellin, and SWIP (Strumpellin- and WASH-Interacting Protein). It appears that the N-terminus of FAM21 is responsible for integration of WASH into the SHRC while a capping protein interaction motif in the C-terminus is responsible for binding to CapZ outside of the SHRC. It also currently appears that the C-terminal region of FAM21 is responsible for the endosomal localization of the SHRC. It is currently thought that the actin polymerization activity of the VCA domain of WASH is auto-inhibited by incorporation into the SHRC

WASH is comprised of the WASH homology domain 1 (WAHD1) followed by the tubulin-binding region (TBR), and these two domains are collectively referred to as the WASH homology domain (WAHD) due to conservation among WASH orthologs (Gomez and Billadeau 2009). The WAHD1 is critical for assembly into the WA*SH R*egulatory *C*omplex (SHRC) and will be discussed in detail below. WASH was found to co-immunoprecipitate with tubulin following T cell receptor ligation and the TBR was identified to directly interact with microtubule dimers in vitro (Gomez and Billadeau 2009). Significantly, *Drosophila* WASH has been shown to bundle microtubules and mammalian WASH has been reported to interact with g-tubulin (Liu et al. 2009; Monfregola et al. 2010). Unlike other NPF family members, WASH demonstrates endosomal localization in a variety of cell lines (Derivery et al. 2009; Duleh and Welch 2010; Gomez and Billadeau 2009). The N-terminal WAHD1 of WASH mediates its targeting to endosomes via interaction with the the SHRC member, FAM21 (Family number 21 (WASH Complex Subunit FAM21C)) (Fig. 1) (Gomez and Billadeau 2009). Currently, the PRD of WASH has not been linked to any specific functions, but the PRDs of other WASP superfamily members have been reported to be responsible for binding to a number of SH3 (SRC Homology 3 Domain)-containing proteins (Stradal et al. 2004). However, the proline-rich region of WASH does not harbor any canonical type I or type II SH3-binding motifs. Importantly, these domains appear to be conserved throughout most of the currently identified WASH homologs suggesting that all of these domains may play an evolutionarily important role in WASH function (Veltman and Insall 2010).

WASH Regulatory Complex

Two members of the WASP family, WASP and WAVE (WASP family Verprolin-homologous protein), exist in unique macromolecular complexes that are responsible for the stabilization and regulation of these NPFs as well as their subcellular localization (Campellone and Welch 2010). Similar to these WASP NPFs, WASH also exists in a large pentameric macromolecular complex (Fig. 2) (Derivery et al. 2009; Gomez and Billadeau 2009; Jia et al. 2010). Using bovine, murine, *Drosophila*, and human models, the components of the SHRC have been identified as: FAM21, Strumpellin, coil-coil-domain-containing protein 53 (CCDC53), and the previously undefined KIAA1033, now designated SWIP (*S*trumpellin- and *W*ASH-*I*nteracting *P*rotein) (Derivery et al. 2009; Jia et al. 2010). Detailed genetic analysis has found a significant degree of evolutionary co-conservation between WASH and members of the SHRC.

Specifically, of the 33 organisms genomes found to contain a WASH homolog, 90% or more also contained the other four SHRC components (Veltman and Insall 2010). Significantly, this suggests that the function of WASH is dependent upon the presence and proper assembly of the SHRC.

While the WASH complex also interacts with the actin capping protein CapZ, it currently appears that CapZ is a peripheral component of the complex, as the stability of CapZ is not subject to the expression of the core SHRC members. However, the core complex members do exhibit structural interdependency for their stability (Derivery et al. 2009; Gomez and Billadeau 2009; Jia et al. 2010). The C-terminus of the SHRC member FAM21 has been shown to bind to CapZ via a capping protein interaction motif, while FAM21 itself assembles directly into the SHRC via its N-terminus (Fig. 2) (Gomez and Billadeau 2009; Jia et al. 2010). Importantly, expression of a FAM21 mutant that could not interact with CapZ was still able to organize the SHRC and localize to endosomes (Gomez and Billadeau 2009; Jia et al. 2010). This suggests that CapZ is a peripherally associated member of the SHRC that might be critical for the activities of the SHRC at endosomal structures. While the function of each individual member of the SHRC is yet to be elucidated, it is important to note that suppression of individual complex members by RNA (Ribonucleic Acid) interference in HeLa cells results in downregulation of other complex components, with suppression of FAM21, Strumpellin, and SWIP affecting all complex components, while suppression of WASH or CCDC53 results in the downregulation of each other with only limited effect on the stability of the other members of the complex (Jia et al. 2010). However, it should be noted that mouse embryonic fibroblasts and T cells deficient in WASH show marked depletion of all complex members (J.T. Piotrowski, T.S. Gomez and D.D. Billadeau, unpublished observation).

Activation of Arp2/3 by WASP and WAVE is constitutively inhibited by either auto-inhibition (WASP) or by assembly of WAVE into the pentameric WRC (WAVE Regulatory Complex) (Ramesh and Geha 2009; Stradal and Scita 2006). As would be expected, recombinant full length WASH, which is highly unstable and aggregates in solution, or the C-terminal VCA domain was found to strongly induce Arp2/3-mediated actin polymerization (Derivery et al. 2009; Duleh and Welch 2010; Linardopoulou et al. 2007; Liu et al. 2009). However, it has been subsequently shown that assembly of WASH into the recombinant SHRC abrogates WASH-mediated Arp2/3 actin polymerization suggesting that like other WASP superfamily members, WASH is constitutively inhibited (Fig. 2) (Jia et al. 2010). While it is currently unclear how the actin polymerization activity of WASH is activated in vivo, it appears that the complex may exist in both active and inactive conformations as the denatured SHRC allowed WASH-mediated Arp2/3 actin polymerization to proceed in vitro (Jia et al. 2010).

Significantly, the SHRC is composed of proteins that have been subject to limited investigation. However, it has been recently demonstrated that the SHRC components contain significant structural homology to members of the WRC with similarity found between SHRC/WRC members: SWIP/SRA1 (Specifically Rac-associated protein 1), Strumpellin/NAP1, and helical regions within the N-termini of WASH and WAVE, as well as CCDC53 and HSPC300 (Heat-Shock Protein C300) (Jia et al. 2010). No significant structural conservation was found between the remaining SHRC member FAM21 and the WRC member Abi1/2 (Jia et al. 2010). However, it should be noted that both members contain highly helical N-terminal regions, which are necessary for complex assembly (Jia et al. 2010). Importantly, it was found that the conserved region in WASH was required for SHRC assembly and the structurally conserved region in CCDC53 was both necessary and sufficient for complex stability. In the same report, it was also found via electron microscopy that the WASH complex and the WAVE complex take on similar structures suggesting the possibility that they assemble in a similar fashion (Jia et al. 2010). Furthermore, the previous structural predictions of WRC assembly were recently confirmed by analysis of the actual crystal structure of the WRC, which demonstrated that the two large highly helical proteins, Sra1 and Nap1, interact and form an elongated pseudo-symmetric dimer forming a platform upon which a trimer containing WAVE1, Abi2, and HSPC300 assembles (Chen et al. 2010). Importantly, the two structurally conserved helical regions of WAVE1 and HSPC300, found in WASH and CCDC53 respectively, interact with two helices of Abi2, as well as making extensive interactions with Sra1. Mutation of key residues aimed at disrupting this four helical bundle

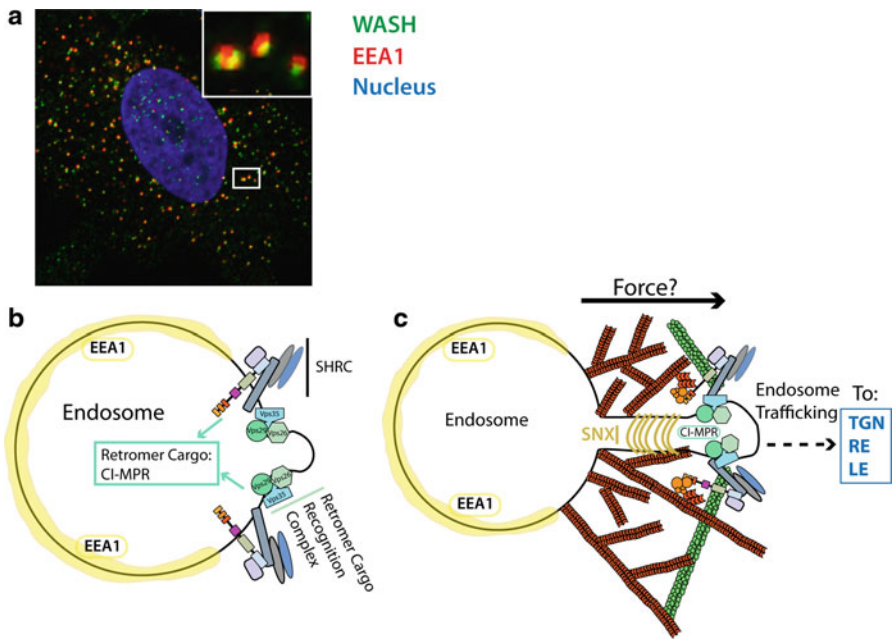
destabilizes the entire WRC (Chen et al. 2010). Lastly, the structure of the WRC indicates that the VCA of WAVE1 makes significant contacts with Sra1 as well as intramolecular associations resulting in inhibited activity toward Arp2/3 (Chen et al. 2010). Although a high-resolution structure of the SHRC remains to be made, these many structural similarities, coupled with the overall similar shape and size of the SHRC and the WRC, suggest that the SHRC is analogously organized as a large SWIP:Strumpellin platform upon which a helical bundle consisting of the N-termini of WASH:CCDC53:FAM21 assemble, with the WASH VCA sequestered by a similar mechanism (Fig. 2).

WASH Localization and Function

It was initially demonstrated that *Drosophila wash* was required for viability and that flies lacking *wash* were unable to reach the prepupal stage (Linardopoulou et al. 2007). *Drosophila* WASH has been further shown to bundle and crosslink both actin filaments and microtubules (MT) at the fly oocyte cortex as well as playing a critical role in maintaining the actin cytoskeleton in the nurse cells surrounding the oocyte (Liu et al. 2009). Work in this same model has reported that WASH, via the N-terminal WAHD1 domain, associates directly with the GTPase Rho1 and actin nucleation factor Spire while associating indirectly with the protein Cappuccino (Liu et al. 2009). While *Drosophila* WASH was reported to function as a Rho effector, mammalian WASH does not appear to function as a Rho effector (Jia et al. 2010; Liu et al. 2009). However, the GTPase Rac1 has been shown to have a weak interaction with the mammalian SHRC, yet it appears that Rac1 is unable to activate the SHRC (Jia et al. 2010). Thus it is currently unclear how the SHRC or WASH itself is activated in vivo. Future studies aimed at identifying the signaling pathways regulating WASH activity will greatly enhance our understanding of the function of WASH in cellular processes.

Three independent studies have confirmed that mammalian WASH possesses a punctate localization pattern in numerous mammalian cell lines and that WASH specifically colocalizes to early and recycling endosomes, which is consistent with the finding that both F-actin and Arp2/3 localize with early endosomes (Fig. 3a) (Derivery et al. 2009; Duleh and Welch 2010; Gomez and Billadeau 2009). It is possible that WASH regulates this specific localization of Arp2/3 as suppression of WASH results in reduced Arp2/3 levels at the early endosome (Derivery et al. 2009). Consistent with the role of WASH in recruiting Arp2/3 and accumulating F-actin at endosomal subdomains, MEFS (Mouse Embryonic Fibroblasts) genetically depleted of WASH lacks Arp2/3 and F-actin at endosomes (T.S. Gomez and D.D. Billadeau, unpublished observation). It currently appears that the C-terminal region of SHRC member, FAM21, is responsible for the localization of WASH to endosomes as expression of the N-terminus of FAM21 is capable of assembling the SHRC, but it no longer localizes to endosomal subdomains. Conversely, expression of the C-terminal region of FAM21 lacking the WASH-interacting region (amino acids 1–220) efficiently localizes to endosomes (Gomez and Billadeau 2009). Interestingly, it has been reported that FAM21 interacts with phospholipids via its C-terminus suggesting that WASH localization may be in part mediated by FAM21 binding to endosomal membranes or via other protein–protein interactions (Jia et al. 2010).

WASH may function in a variety of endosomal sorting and maturation pathways but there is much to clarify in the field. WASH has been reported to colocalize with epidermal growth factor (EGF) following internalization, and suppression of WASH may result in defective EGF transport to late endosomes, but there have been conflicting reports over whether WASH actually plays a role in the degradation of EGFR (Epidermal Growth Factor Receptor) (Duleh and Welch 2010; Gomez and Billadeau 2009). WASH has also been implicated in the regulation of transferrin recycling in mouse fibroblasts suppressed for WASH, but no such role was found using transformed human cells (Derivery et al. 2009; Duleh and Welch 2010). Additionally, WASH has been reported to regulate the trafficking of the cation-independent mannose-6-phosphate receptor (CI-MPR) (Gomez and Billadeau 2009). Under steady-state conditions, the CI-MPR is primarily localized to the trans-Golgi network (TGN) due to the action of the mammalian retromer complex, consisting of Vps35 (Vacuolar protein sorting-associated protein 35), Vps26 (Vacuolar protein sorting-associated protein 26), Vps29 (Vacuolar protein sorting-associated protein 29), and various sorting nexin (SNX) proteins, which is responsible for "retrograde"



WASH, Fig. 3 *Localization and Function of WASH*. (**a**) *WASH Localizes with Early Endosomes*. HeLa cells with the nucleus stained in blue are stained for the early endosome marker EEA1 (Early Endosome Antigen 1) in red and WASH in green. WASH localizes in a punctate pattern demonstrating endosomal localization. The white box in the upper right shows an enhanced view of WASH and EEA1 staining. (**b**) *Model of WASH Recruitment to Early Endosomes*. In a proposed model, WASH and the SHRC are localized to EEA1-coated endosomes by an interaction with the Retromer Cargo Recognition Complex of Vps26, 29, and 35. This Vps trimer is responsible for recruiting retromer cargo such as CI-MPR. It is proposed that this localization of the SHRC takes place at the site of endosomal membrane "budding." (**c**) *Model of WASH-Facilitated Endosomal Trafficking*. In this proposed model WASH is required to initiate Arp2/3-mediated actin polymerization at the site of endosomal sorting. The WASH-induced actin polymerization provides the physical force required to drive the scission of endosomal membranes that is required for trafficking of endosomal cargo. It is proposed that sorting nexins (SXN) may also play an important role by driving endosomal tubulation

endosome to Golgi transport (Anitei et al. 2010; Bonifacino and Hurley 2008). Importantly, the SHRC localizes with VPS35, SNX1, and SNX2 (Gomez and Billadeau 2009), and depletion of Vps35, which effectively removes Vps26 and Vps29 from endosomes, and results in SHRC dispersal (Harbour et al. 2010) (T.S. Gomez and D.D. Billadeau, unpublished observation). This suggests that retromer accumulation on endosomal subdomains leads to SHRC recruitment and function at these specific endosomal structures. Importantly, suppression of WASH results in CI-MPR dispersal from its normal localization near the TGN to endosomes (Gomez and Billadeau 2009). Consistent with missorting of CI-MPR by the retromer in WASH-depleted cells, the total levels of CI-MPR were also reduced indicating that CI-MPR was likely being shunted into the lysosomal pathway, a feature consistent with retromer deregulation (Gomez and Billadeau 2009). Thus it appears that WASH participates in retromer-mediated endosomal transport of cargo to the Golgi (Fig. 3b, c). It is important to note that so far WASH does not appear to regulate endocytosis, as it has been shown that WASH fails to localize with clathrin at the site of the plasma membrane or affect TCR (T cell Receptor) internalization rate (Gomez and Billadeau 2009). While there is no clear consensus on the exact function of WASH in each of these cellular trafficking pathways, the current reports are suggestive of WASH plays a key role in the regulation of actin assembly on early endosomes and the subsequent membrane remodeling that occurs during endosomal sorting and trafficking (Fig. 3b, c).

Interestingly, all three current reports on the function of mammalian WASH noted that upon suppression of WASH, the normally spherical early endosomes became enlarged and elongated resulting

in the endosomal network taking on a tubulation phenotype (Derivery et al. 2009; Duleh and Welch 2010; Gomez and Billadeau 2009). It was reported that depolymerization of microtubules in WASH-depleted cells prevented this endosomal tubulation from occurring (Derivery et al. 2009). Additionally, blocking the VCA domain of WASH in vivo induced endosome tubulation (Derivery et al. 2009). Coupled with the fact that WASH is known to interact with microtubules via its TBR and the C-terminal VCA domain has been shown to induce Arp2/3-mediated actin nucleation, it seems likely that the ability of WASH to interact with these two key cytoskeleton components is a critical part of its ability to influence endosomal membrane shape and dynamics (Derivery et al. 2009; Gomez and Billadeau 2009). Finally, it has been reported that the GTPase dynamin, which possesses a well-characterized role in membrane fission, immunoprecipitates with endogenous WASH, which suggests the possibility that dynamin may also play a role in WASH-mediated endosomal fission (Derivery et al. 2009). It has been widely proposed that WASH is required to mediate actin polymerization at the site of endosomal sorting and that this polymerization provides the physical force required to drive the constriction and eventual scission of endosomal membranes allowing for the proper cellular sorting and trafficking of endosomal cargo (Fig. 3b, c) (Derivery et al. 2009; Duleh and Welch 2010; Gomez and Billadeau 2009). This model, which requires further elucidation, if proved correct, could closely mimic the role of N-WASP-mediated Arp2/3 activity in driving membrane scission during endocytosis at the plasma membrane (Takenawa and Suetsugu 2007).

It should be briefly noted that WASH has been found to localize to the site of *Salmonella* cellular entry and that depletion of WASH in fibroblasts reduced the level of *Salmonella* invasion (Hänisch et al. 2010). Furthermore, the SHRC member, FAM21, has been reported to facilitate vaccina virus entry into HeLa cells via dynamin-mediated endocytosis and that knockdown of FAM21 resulted in reduced cellular entry of vaccina virus (Huang et al. 2008). Consistent with other reports of WASH localization, it appears that FAM21-mediated vaccina virus penetration occurs through clathrin-independent endocytosis (Gomez and Billadeau 2009; Huang et al. 2008). It is possible that actin polymerization mediated by the WASH complex may play an important role in pathogen-directed membrane remolding and subsequent intracellular invasion. It is unclear if this function of WASH is related to its regulation of endosomal sorting.

Summary

WASH is a recently identified member of the WASP superfamily of Arp2/3 NPFs. A highly evolutionarily conserved protein, the gene for WASH in humans and higher order primates has variable copy numbers with gene copies located within subtelomeric regions. The protein itself has been shown to posses several conversed domains: an N-terminal WAHD1, a C-terminal VCA, and a central PRD preceded by a TBR (Fig. 1). Like other WASP superfamily members, WASH is integrated into a multiprotein complex and the activity and stabilization of WASH is regulated and dependent upon the pentameric SHRC (Fig. 2). The SHRC has been found to contain a high degree of homology to the pentameric WRC, which regulates its subcellular localization and activity toward Arp2/3. Unlike the WRC however, it does not appear that the SHRC functions downstream of Rac1. While no activator of WASH has been established, the intrinsic activity of WASH toward Arp2/3 is inhibited upon assembly into the SHRC, suggesting that WASH activation is likely to be regulated in vivo by currently undefined molecular mechanisms. Unique among the WASP superfamily, WASH localizes to early endosomal subdomains enriched in retromer subunits and is responsible for endosomal localization and activity of Arp2/3 (Fig. 3a). The N-terminal region of the SHRC member FAM21 mediates this endosomal localization. Depletion of WASH has been shown to result in a tubulation phenotype in which endosomes lose their spherical shape and become enlarged and elongated. It appears that WASH plays a key role in the sorting and trafficking of early endosomes, and that as a result WASH may specifically help regulate EGFR and transferrin trafficking and degradation pathways. It is also clear that WASH is involved in the proper function of retromer-mediated transport from endosomes to the Golgi. As a recently discovered NPF, there is much to be learned in the future about the role of WASH in cellular signaling and function. As the

extent of endosomal-based signaling becomes better understood, the mechanisms by which WASH regulates cytoskeleton dynamics and endosomal trafficking will be even more important to understand.

Historical Background

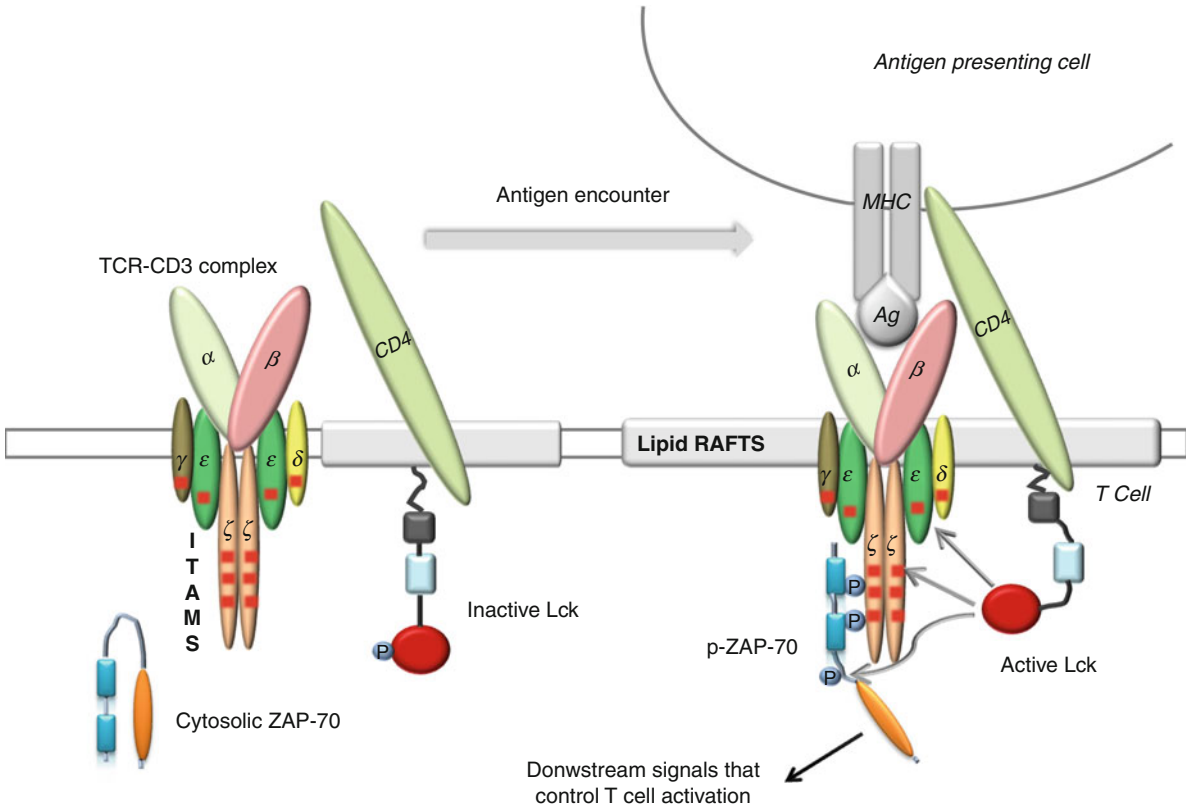
Since its initial discovery in 1992 by the Weiss group, ZAP-70 (ζ-associated protein of 70 kDa) has attracted significant attention as a central player in the early steps of T-cell antigen receptor (TCR) signaling during T-cell development and activation.

TCR engagement results in a dynamic phosphorylation cascade primarily regulated by two different families of *P*rotein *T*yrosine *K*inases (PTKs), the Src-(*SaRC*oma) and the Syk/ZAP-70 PTKs. When the TCR αβ heterodimer binds *p*eptide-MHC (pMHC), the non-covalently associated ▶ CD3ζζ homodimer is phosphorylated by the Src kinase Lck on two specific tyrosine residues located in the consensus sequence known as *I*mmunoreceptor *T*yrosine-based *A*ctivation *M*otif (ITAM). These motifs, present in the cytosolic tail of all invariant signaling subunits of the TCR complex (CD3γ, δ, ε and η/ζ chains), consist of the consensus amino acid sequence [(D/E)xxYxxI/Lx(6–8)YxxI/L]. ZAP-70 binds the doubly phosphorylated ITAMs through its tandem *S*rc *H*omology *2* (SH2) domains and is thereby recruited to the activated TCR complex near the plasma membrane. This allows its activation by relieving the autoinhibited conformation of the tyrosine kinase, which is further stabilized by Lck-mediated phosphorylation. Thus, the catalytic function of ZAP-70 is activated both through interaction with and phosphorylation by Lck and by autophosphorylation. Active ZAP-70 can then phosphorylate the downstream molecules in the TCR signaling pathway (Fig. 1).

Among the most important substrates of ZAP-70 are two adapter proteins, *S*H2-domain-containing *L*eukocyte *P*hosphoprotein of 76 kDa (▶ SLP-76) and *L*inker of *A*ctivated *T* cells (▶ LAT). When phosphorylated, these adapters mediate the recruitment of several signaling molecules that can lead to T-cell activation, proliferation, cytokine production, and differentiation.

The key role of ZAP-70 in T-cell development and activation, dramatically documented by a *S*evere *C*ombined *I*mmuno*D*eficiency Syndrome (SCID) in humans, has resulted in quantum advances in our understanding of its structure and regulation. This interest has been further kindled by the discovery of its implication in human diseases as diverse as a primary severe combined immunodeficiency disorder and B-cell *C*hronic *L*ymphocytic *L*eukemia (B-CLL) (Pezzicoli and Baldari 2005) (Au-Yeung et al. 2009) (Bene 2006) (Wang et al. 2010).

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

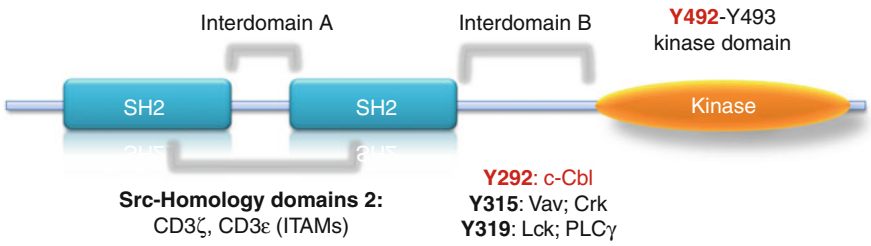


ZAP-70, Fig. 1 *ZAP-70-dependent TCR proximal signaling*. In quiescent conditions ZAP-70 is a cytosolic protein in an autoinhibited conformation. After TCR engagement by p-MHC ZAP-70 is recruited to phophorylated CD3ζ and is activated by the Src kinase Lck and autophosphorylation. This event is crucial for the downstream signaling events that lead to gene transcription and cellular responses

Structure and Regulation

ZAP-70 is closely related to *s*pleen t*y*rosine *k*inase (Syk) and together they constitute the Syk/ZAP-70 family of PTKs, sharing approximately 70% of amino acid sequence similarity. These proteins are characterized by the presence of two tandemly arranged SH2 domains at the N-terminus, spaced by an interdomain A and followed by an interdomain B and a C-terminal catalytic domain (Fig. 2).

ZAP-70 coordinates, together with the Src kinase Lck, the onset the TCR signaling cascade. At variance with Lck, which is provided of a lipid moiety constitutively targeting it to the plasma membrane, in quiescent T lymphocytes ZAP-70 is predominantly cytosolic. ZAP-70 activation and its juxtaposition to its protein substrates occur however in a membrane-proximal localization. This change in subcellular localization is mediated by its interaction with the doubly phosphorylated ITAMs on the ζ chains of the CD3 complex. The phosphorylation event within the cytosolic tails of the multiple ITAMs of the ζ chains is critical for ZAP-70 recruitment and activation and requires the binding of both SH2 domains. Binding studies have shown that the tandem SH2 domains of ZAP-70 have a high affinity for the doubly tyrosine-phosphorylated CD3ζ ITAMs, although other SH2-domain-containing molecules are able to transiently bind monophophorylated ITAMs at early steps (e.g., Grb2, ▶ phosphoinositide 3-kinase, p52Shc). The importance of the SH2 domains in the stable recruitment of ZAP-70 to the activated TCR and ZAP-70 activation is underlined by the decrease in total numbers of peripheral T lymphocytes and impaired in vivo peripheral T-cell responses in a transgenic mouse expressing a truncated dominant



ZAP-70, Fig. 2 *ZAP-70 structure*. Schematic representation of the domain organization of ZAP-70 and its tyrosine phosphorylation sites

negative form of ZAP-70 (ZAP-NC) consisting of only the tandem SH2 domains (Au-Yeung et al. 2009) (Humphrey et al. 2005).

Once recruited, ZAP-70 is activated by phosphorylation on a number of tyrosine residues. These events are important not only for its activation but also for recruitment of the other components of the proximal TCR signaling machinery. In this respect, interdomain B plays a critical role as it contains three tyrosine residues, Y292, Y315, and Y319, that have been identified as phosphorylation sites interacting with important downstream signaling molecules such as ▶ Vav, PLCγ, and CrkII.

Y292 is the best characterized negative regulatory site, initially identified as a site of interaction with the ubiquitin-ligase Cbl (*C*asitas *B*-lineage *l*ymphoma) in a screen of a degenerate phosphopeptide library using Cbl-PTB. Consistent with this finding, ZAP-70 failed to bind Cbl in a *knockin* mouse expressing a ZAP-70 mutant lacking Y292. T cells expressing the ZAP-70Y292F mutant display enhanced TCR signaling, resulting in increased interleukin-2 (IL-2) and interferon-γ (▶ IFN-γ) production. Moreover, ZAP-70Y292F expressing T cells have a slower rate of ligand-induced TCR downmodulation. This may be accounted for by the fact that, by interacting with ZAP-70, Cbl may promote degradation of the CD3ζ chains. The low molecular weight phosphotyrosine phosphatase (LMPTP) specifically dephosphorylates Y292 of ZAP-70, thereby preventing its inactivation.

Both Y315 and Y319 have a positive regulatory function in ZAP-70 activity and have been discovered as autophosphorylation sites. Y315 is a site of interaction for the proto-oncogene product, Vav. The point mutation Y315F not only abrogates Vav/ZAP-70 interaction but also prevents Vav phosphorylation and activation of the Ras-▶ MAP kinase pathway. More recently, ZAP-70 has been implicated in cell adhesion, as shown by the fact that ZAP-70, upon Vav phosphorylation, promotes the dissociation of Vav1 from the actin adapter, talin, which activates α4β1 integrin for T-cell adhesion. Furthermore, it has been shown that Y315 interacts with *C*T10 *r*egulator of *k*inase *II* (CrkII) and that this interaction is regulated by Lck, suggesting that this tyrosine residue may be phosphorylated by Lck as well as autophosphorylated. The CrkL-ZAP-70 complex is implicated in WASP recruitment to immunological synapse to initiate actin polymerization. A mutation in the CrkL SH3.1 domain results in the disruption of the complex and impairment of F-actin reorganization and IL-2 production.

On another hand, Y319 has been linked to *p*hospho-*l*ipase Cγ (PLCγ) and calcium signaling. Expression of a ZAP-70 mutant carrying a Y319F substitution results in a decrease in PLCγ phosphorylation that determines an alteration in TCR-induced Ca^{2+} mobilization. This mutant is also characterized by an impairment in the interaction with Lck due to the fact that Y319 mediates an SH2-dependent interaction between Lck and ZAP-70. Moreover, recent mutational and crystallographic studies have highlighted the possibility that both Y315 and Y319 may control the autoinhibited conformation of ZAP-70 that regulates its catalytic activity. In fact, mutation of these two tyrosine residues to phenylalanine stabilizes the autoinhibited structure of ZAP-70 and alanine substitution partially restores the phenotype. Interestingly, the crystal structure of recombinant autoinhibited ZAP-70 (YY315/319FF), solved at 2.6 Ångström, showed that the catalytic domain has a conformation similar to inactive Src kinases.

The kinase domain contains two important tyrosine residues, Y492 and Y493, that are *trans*-phosphorylated by Lck or autophosphoryled. Y493 was initially identified as a site of phosphorylation by Src PTKs. Mutational analysis has provided evidence for a crucial role for this residue in ZAP-70 activation and TCR-mediated induction of IL-2 expression in T lymphocytes. Conversely, the ZAP-70Y492F mutant displays an increased kinase activity which suggests

the possibility that Y492 may be a negative regulatory site. However, the fact that Y492 is phosphorylated under conditions in which ZAP-70 is fully activated may be compatible with the loss of the ability to bind another residue in the kinase domain, thereby preventing the formation of a structure less accessible to the substrate. Finally, a more recent crystallographic study showed that a truncated form of ZAP-70 (rhZAP-$70_{327–606}$) in complex with staurosporine can acquire an open active conformation even in the absence of phosphorylation of Y492 and Y493. Two other residues in the catalytic domain, Y593 or Y598, are important for the acquisition of the open conformation, as shown by the impairment in kinase activity in ZAP-70 mutants lacking either of these residues.

After receptor engagement, ZAP-70 also associates to the Shc adapter which couples the activated TCR to Ras. This association, which is mediated by the Shc PTB domain, contributes to TCR signaling. The putative Shc binding site on ZAP-70 is Y474 and a point mutation in this residue prevents ZAP-70 interaction with Shc and the subsequent binding of Shc to phospho-ζ, resulting in impaired TCR-dependent gene activation.

Phosphorylated ZAP-70 kinase can therefore interact with downstream molecules, participating in the assembly of a multimolecular cluster of proteins provided by phosphotyrosine binding domains that activates the downstream cascade of TCR signaling. In this cascade, two well-characterized substrates of ZAP-70 are LAT and SLP-76. These proteins are the two major adapters in TCR signaling which mediate the recruitment of crucial components such as *g*rowth factor *r*eceptor *b*ound protein *2* (Grb2), PLCγ, and Vav, which in turn mediate the activation of the Ras-MAPK pathway, the calcium signaling pathway, and the actin-remodeling network, respectively. These signaling modules are integrated to promote to T-cell activation.

Summarizing, following TCR stimulation activated Lck phosphorylates the ITAMs in the CD3 complex. Phosphorylation of the CD3ζ chains is the critical event for ZAP-70 recruitment and auto/*trans*phosphorylation. Activated ZAP-70 phosphorylates LAT and SLP-76 which recruit numerous other molecules involved in the regulation of downstream TCR signaling events that allow the T-cell response (Fischer et al. 2010) (Smith-Garvin et al. 2009).

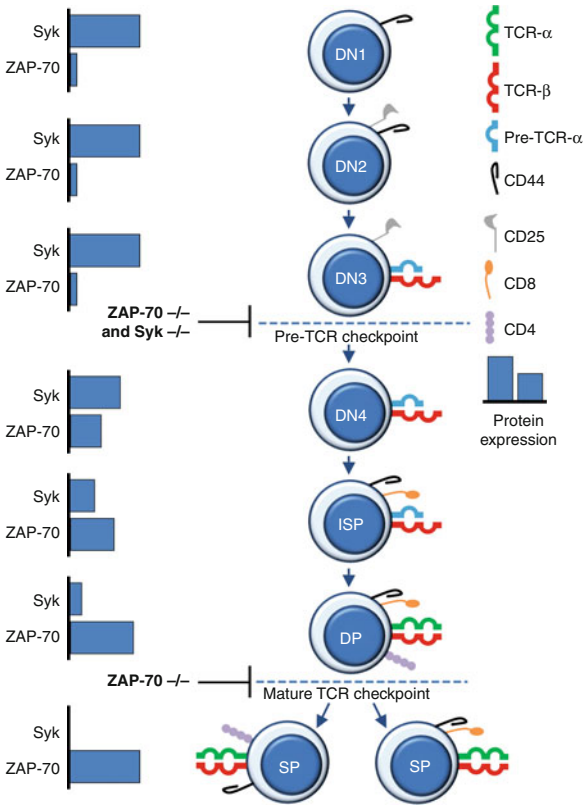
ZAP-70 in T-Cell Development

In the thymus, the developing thymocytes pass through a series of distinct phases characterized by changes in the status of protein expression, both in the cytoplasm and at the cell surface. These changes reflect the state of functional maturation of the cell, so that a particular combination of cell surface proteins distinguishes thymocytes at different stages of differentiation. In this developmental process two critical checkpoints, regulated by TCR signaling, allow the correct selection of thymocytes.

Syk and ZAP-70 have different expression patterns and roles in this process. ZAP-70 expression increases during thymocyte development, in particular after the DN4 ($CD4^-CD8^-$ Double Negative 4) stage, defined by the $CD25^-CD44^-$ phenotype. Conversely, Syk expression is very high during the early steps of thymocyte development (from DN1 to DN4), followed by a decrease in the protein levels beginning from pre-TCR selection until it becomes undetectable in mature T cell.

The first checkpoint is the pre-TCR β-chain selection at the DN3 ($CD4^-CD8^-$ Double Negative 3) stage, defined by the $CD25^+CD44^-$ phenotype. At this stage, ZAP-70 and Syk appear to have a redundant function, as neither ZAP-70 nor Syk knockout thymocytes have any evident defect. Nevertheless, mice knockout for both ZAP-70 and Syk display a total block of thymocyte maturation at the DN3 stage, indicating a fundamental function of these kinases in this process.

The second checkpoint is the positive/negative selection at the DP ($CD4^+CD8^+$ Double Positive) stage. To successfully pass through this checkpoint, the mature αβ-TCR needs to recognize with intermediate affinity a self-peptide presented by the MHC complex. The signal triggered by the engaged TCR must be indeed strong enough to induce positive selection of the thymocyte, but not so strong to induce thymocyte deletion by apoptosis (negative selection), which occurs when the TCR encounters a high-affinity (autoreactive) self-peptide. At this stage of thymocyte development, Syk expression is not required, as documented by the fact that Syk deficient mice show a normal progression in thymocyte maturation. In contrast, ZAP-70 deficient mice harbor a complete block of both positive and negative selection, and hence fail to progress beyond the DP stage, which results in the



ZAP-70, Fig. 3 *ZAP-70/Syk in T-cell development*. The expression profile of ZAP-70 and Syk throughout thymocyte development in schematized. Double knockout of ZAP-70 and Syk causes thymocyte arrest at the pre-TCR checkpoint (DN3), while ZAP-70 knockout causes their arrest at the mature TCR checkpoint (DP)

lack of both in mature single positive (SP) $CD4^+$ and $CD8^+$ thymocytes and peripheral T cells (Fig. 3) (Au-Yeung et al. 2009) (Wang et al. 2010).

Expression and Immunopathological Phenotype

ZAP-70 is mainly a T cell restricted gene and it is essentially expressed in thymocytes and peripheral T cells. The crucial importance of this gene is confirmed by the discovery, in 1994, of a form of severe combined immunodeficiency (SCID), which is due to the lack of functional ZAP-70, as well as by the study of *zap-70*-null allele mouse model.

In humans, this primary immunodeficiency is characterized by the selective absence of peripheral $CD8^+$ T cells and by a normal number of circulating $CD4^+$ T cells that are however non-functional, as they fail to respond to TCR-mediated stimuli in vitro. Conversely ZAP-70-deficient mice have neither $CD4^+$ nor $CD8^+$ single positive T cells in the periphery, because thymocyte development is blocked at the double positive (DP) stage. However, in humans the mechanism for a selective $CD8^+$ selection remains unclear and could depend on a stronger interaction between Lck and the coreceptor CD4 determining a sort of signaling compensation.

In Inbred Strange (ST) mice, a spontaneously arising point mutation has been identified within the highly conserved consensus DLAARN of the kinase domain of ZAP-70. Mice homozygous for this mutation are devoid of mature T cells because T-cell development is arrested at the DP stage, similar to the *ZAP-70* gene targeted mouse model. A human patient with SCID caused by a similar mutation has been subsequently reported. Similar to the ZAP-70 deficient SCID patients, this patient was characterized by a normal number of circulating $CD4^+$ T cells. The mechanism that causes the selective defect in $CD8^+$ cells in human SCID patients remains so far unclear (Fischer et al. 2010) (Au-Yeung et al. 2009).

A point mutation in the *ZAP-70* gene has been also associated to autoimmunity. In 2003, Sakaguchi and colleagues characterized a new mouse strain, named SKG, derived from BALB/c mice and naturally predisposed to develop chronic arthritis. These mice showed the typical features of rheumatoid arthritis (RA) with severe synovitis and hypergammaglobulinemia, the former due to a massive infiltration of leukocytes into the synovia. They also developed high titers of rheumatoid factor (RF), resembling RA in human patients. Moreover, adoptive transfer of spleen and lymph node $CD4^+$ T cells from arthritic SKG mice produced a similar arthritis in BALB/c nude mice, indicating that T cells are responsible for the priming of the disease. It must be highlighted that SKG mice develop spontaneous inflammatory arthritis when kept in a conventional animal facility where there is a certain level of pathogen exposure contrarily to what happens in SPF conditions, where the onset of arthritis in SKG mice requires fungal challenge. These SKG mice carry a missense mutation (W163C) within the C-terminal SH2 domain of ZAP-70 which causes an attenuation of TCR signaling. In particular, phosphorylation of ZAP-70, LAT, and PLCγ is reduced in SKG thymocytes and T cells following TCR

engagement, leading to an attenuation in downstream events, such as intracellular calcium influx and MAPK activation. The attenuation of TCR signaling compromises both positive and negative selection of SKG thymocytes, leading to a dangerous positive selection of autoreactive T cells.

Recently a hypomorphic ZAP-70 mutant has been reported. This mouse has a knockin alanine substitution of YY315/319 in interdomain B. YYAA mice have autoantibodies against rheumatoid factor however, at variance with SGK mice, they do not develop arthritis. The milder phenotype may be accounted for by differences in the T-cell repertoire, due to a less severe impairment in negative selection compared to SKG mice.

Last year, ZAP-70 has been proposed as a biomarker of B-cell activation in a scenario of autoimmunity. Ectopic expression of ZAP-70 is indeed increased in synovial fluid B cells from RA patients, and this correlates with improved B-cell survival in vitro, further strengthening the link between ZAP-70 and autoimmunity, and specifically RA (Thomas et al. 2008).

In addition to T-cell lineage, ZAP-70 has been identified in the sibling cell type Natural Killer (NK) cells. This cell type plays a crucial role in the antivirus and antitumor immune response and contributes to regulate helper T-cell differentiation through the production of IFNγ. NK cells express a multitude of germline-encoded receptors and ZAP-70/Syk are involved in positive signaling downstream of the activating receptors Fcγ receptor IIIA (CD16) and Fcγ receptor IIC (CD32). Following stimulation with specific antibodies, FcγIIIA or IIC become phosphorylated within their ITAMs, causing the recruitment and phosphorylation of ZAP-70/Syk. Interestingly, this also applies to the c3 isoform of FcγII, which lacks a canonical ITAM within its cytosolic tail. CD16 mediates another important aspect for NK-cell activation because it induces the ubiquitination of ZAP-70 and Syk, leading to their degradation via the proteasome, a mechanism probably involved in the fine-tuning of positive signals and in the eventual biological output.

NK cells also express another class of receptor, the KIRs (Killer cell Inhibitory Receptors), among which Ly49D and H have a non-inhibitory activity. In fact, they do not contain an immunoreceptor tyrosine-based inhibitory motif (ITIM) but are able to associate with the coreceptor DAP12, involved in the positive regulation of NK cells. DAP12 recruits ZAP-70 and Syk via their SH2 domains, although the stimulation of Ly49D only induces the activation of Syk.

In the last few years, the interest of ZAP-70 has been predominantly focused on its involvement in B-cell chronic lymphocytic leukemia (B-CLL) as a prognostic marker. B-CLL is a B-cell malignancy characterized by the accumulation of monoclonal B cells with a morphology characteristic of small mature lymphocytes. These cells are $CD19^+$, $CD5^+$, and $CD23^+$ and they accumulate in blood, bone marrow, lymph nodes, and spleen, leading, in some cases, to a progressive enlargement of these lymphoid organs, anemia, and trombocytopenia. This type of leukemia occurs with a heterogeneous clinical course which is strictly related to some molecular and cellular markers. Among these, one of the most important prognostic markers is the mutational status of the immunoglobulin heavy chains (IgVH). A significant proportion of B-CLL patients have somatic hypermutations in the rearranged variable regions of the IgH genes, while the others have unmutated IgVH genes. The latter are characterized by a more rapid disease progression and shorter survival. A poorer prognosis is also frequently associated with surface expression of CD38. The discovery that ZAP-70 is ectopically expressed in the leukemic cells from CLL patients with poor prognosis, in frequent association with unmutated IgVH genes, has provided an important new prognostic marker for this disease. Very recently it has been reported that p66Shc, a pro-apoptotic adapter which interacts with ZAP-70 in TCR signaling, is downregulated in B-CLL patients, with the lowest expression levels associated to an unfavorable prognosis.

The finding that ZAP-70 is expressed in CLL B-cells has suggested the possibility that it might play a role in BCR signaling. ZAP-70 is in fact able to associate with the BCR complex and leads to a more sustained BCR signaling in CLL B-cells compared to normal B cells. However, this feature of CLL $ZAP\text{-}70^+$ B-cells is independent of ZAP-70 kinase activity and is related instead to its adapter function. ZAP-70 expression is however not limited to leukemic B cells. It has in fact been recently reported that ZAP-70 is also expressed in normal B cells and is implicated in B-cell development. This process occurs predominantly in the bone marrow where immature B cells cross different checkpoints which control the

rearrangement of immunoglobulin gene segments (VDJ). The transition from pro-B cells to pre-B cells requires positive signals that are critically dependent on the receptor-associated transmembrane molecule Igα and Igβ, which contain an ITAM. Similar to T cells, BCR stimulation induces ITAM phosphorylation and recruitment of Syk, leading to cell activation. Nevertheless, B-cell development is only partially blocked in the absence of Syk, which was taken as a proof that another kinase is able to propagate the signals independently of Syk. This has been identified as ZAP-70, and in fact the absence of both ZAP-70 and Syk results in a complete block in B-cell development at the pro-B cell stage. Consistent with this finding, ZAP-70 is expressed in all immature B cells. ZAP-70 expression has also been found in tonsillar and splenic B lymphocytes which show an activated phenotype. In this study, the authors demonstrate that ZAP-70 becomes phosphorylated in response to BCR engagement, further supporting a role for ZAP-70 in normal B cells.

The implication of ZAP-70 in the pathogenesis of diseases of abnormal T-cell activation, as well as its restricted tissue specificity, underscores it as an attractive drug target. Although at present there is no drug which can selectively inhibit ZAP-70, an inhibitor modeled to specifically target an analogue-sensitive ZAP-70AS was recently found to potently inhibit TCR signaling and T-cell activation, thereby providing the proof-of-concept that ZAP-70 manipulation may provide the basis for the treatment of autoimmune diseases and hematological malignancies characterized by alterations in ZAP-70 expression or activity (Montserrat 2006; Wiestner 2005; Wang et al. 2010).

Summary

The protein tyrosine kinase ZAP-70 is a crucial molecule for T-cell activation, where it orchestrates the early steps in antigen receptor signaling. This entry provides a brief overview of the structure and regulation of ZAP-70, as well as of its role in T-cell development and activation. The alterations in ZAP-70 expression and/or activity in a number of pathological settings, together with its restricted tissue specificity, identify this molecule as a potential valuable drug target.

Zinc Transport in the Pancreatic β-Cell: Roles of ZnT (*SLC30A*) and ZiP (*SLC39A*) Family Members

Elisa A. Bellomo and Guy A. Rutter
Section of Cell Biology, Division of Diabetes, Endocrinology and Metabolism, Faculty of Medicine, Imperial College London, South Kensington, London, UK

Synonyms

SLC30A; SLC39A; ZiP; ZnT

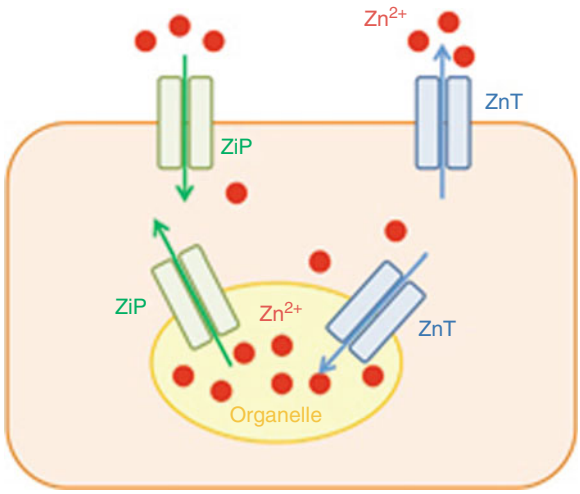
Historical Background

Zinc is an essential component of many proteins and is crucial for several cellular functions such as cell mitosis, gene expression, and modulation of cellular receptors (Lichten and Cousins 2009). Failure to regulate zinc homeostasis thus leads to the development of a variety of pathologies, and mutations in several zinc transporter genes are linked to diseases in man. Hypozincemia is a condition where insufficient zinc is available for metabolic needs. It is usually the result of inadequate dietary intake of zinc but can also be associated with malabsorption. Diarrhea, *acrodermatitis enteropathica*, chronic liver and renal disease, diabetes and other chronic illnesses are all associated with zinc deficiency.

Increasing evidence suggests that changes in the expression or activity of specific zinc transporters might play a role in regulating the general zinc homeostasis. In this entry, the function of zinc transporters and zinc-binding proteins will be reviewed, with particular attention to the role that these molecules may play in the endocrine pancreas and in the development of diabetes mellitus.

Zinc Transporters

Under normal physiological conditions, the intracellular free Zn^{2+} concentration ($[Zn^{2+}]_{cyt}$) is thought to be in the picomolar range (Vinkenborg et al. 2009), while the level in the plasma can reach micromolar level



Zinc Transport in the Pancreatic β-Cell: Roles of ZnT (*SLC30A*) and ZiP (*SLC39A*) Family Members, Fig. 1 Mechanisms involved in controlling Zn^{2+} homeostasis. Zn^{2+} homeostasis is tightly controlled in all cell types. The main proteins involved in maintaining low cytosolic Zn^{2+} levels include the Zn^{2+} transporters ZnT (which transport Zn^{2+} from the cytosol inside intracellular organelles on in the extracellular space) and ZiP (which concentrate Zn^{2+} in the cytosol moving the ion from intracellular compartments or from the extracellular space)

(Simons 1991) (though free plasma concentrations of Zn^{2+} are thought to be much lower, possibly in the nanomolar range). Therefore, the cellular Zn^{2+} content needs to be tightly regulated by both zinc transporters and zinc-binding proteins (Fig. 1).

There are two main classes of zinc transporters in mammalian cells: the ZnT family (coded by the *Slc30a* genes) is thought to move Zn^{2+} from the cytosol in the extracellular space or inside storage organelles, therefore decreasing the intracellular $[Zn^{2+}]$; the ZiP (Zrt-, Irt-like proteins) family (coded by the *Slc39a* genes), on the other hand, is believed to transport Zn^{2+} into the cytosoplasm, hence increasing the $[Zn^{2+}]_{cyt}$ (Lichten and Cousins 2009). Fifteen members of the ZiP family and ten members of the ZnT family have so far been identified. While ZiP importers possess eight transmembrane (TM) domains and extracytosolic N- and C- termini, ZnT transporters possess six TM domains with both the N- and C-termini situated in the cytosol (Lichten and Cousins 2009). For both families, the TM domains form the pore of the transporter and Zn^{2+} binds to the histidine situated between the domains (Lichten and Cousins 2009). Several ZnTs and ZiPs are ubiquitously

expressed while others display tissue specificity and are localized on specific intracellular membranes or on the plasma membrane. The physiological importance of these transporters is highlighted by the fact that some physiopathological conditions are the result of mutation in genes coding for Zn^{2+} transporters. For instance, mutations in the ZiP4 coding gene are linked to the autosomal recessive disorder *acrodermatitis enteropathica*, while alteration in ZnT2 gene expression have also been linked to Alzheimer's disease (Lichten and Cousins 2009). Finally, voltage-dependent Ca^{2+} channels (VDCCs), expressed in human tissues and involved in regulating insulin secretion, are also able to transport Zn^{2+} (Huang et al. 2000).

Zinc and Diabetes

The original observation that the total pancreatic Zn^{2+} concentration was reduced to about 50% in diabetic compared to nondiabetic cadavers (Scott and Fisher 1938) focused attention on the relationship between Zn^{2+}, the pancreas and diabetes and subsequent observations confirmed the link between Zn^{2+} and this disease (Williams et al. 1995). Several reports have shown that type 2 diabetic (T2D) patients display a marked decrease in total plasma Zn^{2+} compared to control patients (Williams et al. 1995), indicating that hyperglycemia may interfere with Zn^{2+} absorption in the kidney causing hyperzincuria. However, an important question is whether the hyperzincuria is a cause or an effect of T2D. There is evidence from clinical studies indicating that Zn^{2+} deficiency (due to dietary insufficiency) might predispose to diabetes mellitus and some of its complications (Kanoni et al. 2011). However, interpretation of these results is challenging, given technical difficulties in defining the onset of the disease, measurements of free versus bound Zn^{2+}, as well as factoring in variations resulting from different long-term dietary status and different treatment regimes.

Zinc Transporters in Pancreatic Islets

The pancreas contains one of the highest total Zn^{2+} concentrations of the body (0.14 mg of Zn^{2+} per g of pancreas) (Scott and Fisher 1938), consistent with the fact that these ions play an important role in insulin storage and secretion in pancreatic β-cells. In these cells, Zn^{2+} is complexed with the insulin hexamer in the dense core granules, where the concentration of the ion reaches very high levels (Hutton et al. 1990).

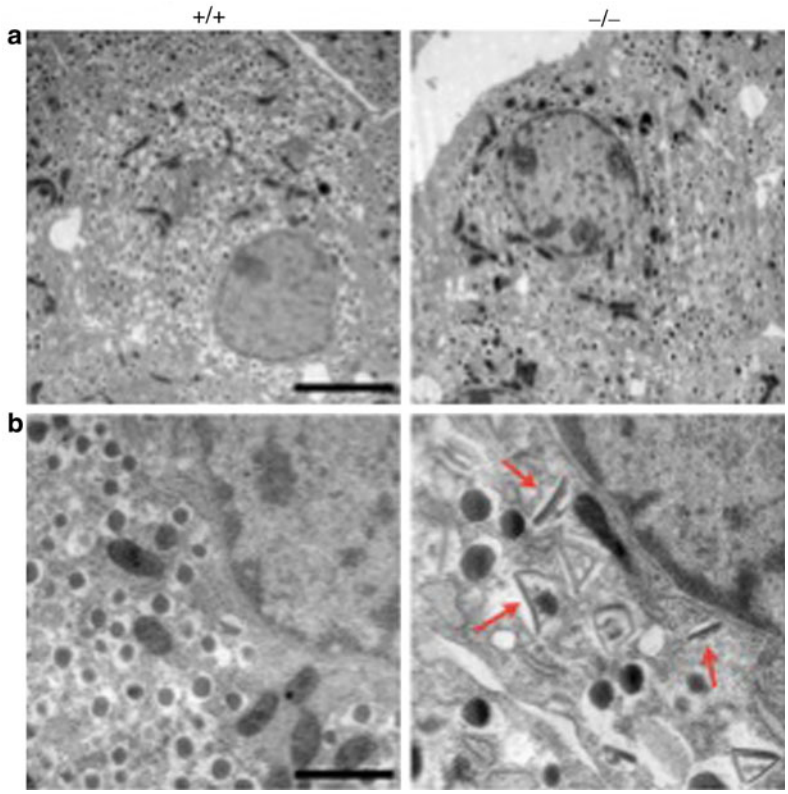
Evidence for ZiP and ZnT transporters' expression in the pancreas is quite limited and very controversial, although most studies agree on the fact that ZiP6 and ZiP7 coding genes are the most abundantly expressed in mouse and human islets as well as in the MIN6 mouse insulinoma β-cell line (Wijesekara et al. 2009). Similarly, ZnT1 and ZnT4-9 genes are also expressed in human and mouse islets and in MIN6 β-cells (Wijesekara et al. 2009); however, ZnT5 and ZnT8 appear to be the most abundant (Wijesekara et al. 2009).

ZnT3

Recently, ZnT3 has been shown to be expressed in the INS-1 β-cell line, but the cellular localization of this particular protein has not yet been established. In the hippocampus, however, ZnT3 has been found to localize to synaptic vesicles (Palmiter et al. 1996). *Smidt* and colleagues (2009) have demonstrated that ZnT3 may play an important role in the regulation of Zn^{2+} homeostasis with effect on insulin production and glucose metabolism. Indeed, silencing of this protein lowered insulin secretion in vitro and affected in vivo glucose metabolism after mice were rendered diabetic with streptozotocin treatment (Smidt et al. 2009). When ZnT3 was silenced in a rat β-cell line, an increased apoptosis was observed, while insulin secretion was reduced (Smidt et al. 2009). Despite these findings, others including ourselves (Nicolson et al. 2009) have found that ZnT3 expression in the endocrine pancreas is almost undetectable (Wijesekara et al. 2009). The reasons for these discrepancies are unclear.

ZnT5

Despite being expressed in many tissues, ZnT5 levels are more abundant in the endocrine pancreas, being, together with ZnT8, the most abundant zinc transporter within islets. In pancreatic β-cells, ZnT5 immunoreactivity is localized to both the Golgi apparatus and to insulin-containing vesicles (Kambe et al. 2002) where the transporter may serve to transport the ion inside the granule. ZnT5 expression is also present in pancreatic α-cells (Gyulkhandanyan et al. 2008), although its intracellular localization and role in the latter cell type, still remains to be elucidated.



Zinc Transport in the Pancreatic β-Cell: Roles of ZnT (*SLC30A*) and ZiP (*SLC39A*) Family Members, Fig. 2 Electron micrographs of $ZnT8^{+/+}$ and $ZnT8^{-/-}$β-cells. Transmission electron microscopy images of isolated islets from $ZnT8^{+/+}$ and $ZnT8^{-/-}$12-week-old male mice at different magnifications. Three islets each from three pairs of littermate mice were serially sectioned to a depth of 20 ± 1 μm. (**a**) Overview (scale bar 10 μm) of a β-cell from $ZnT8^{-/-}$ and control animals. (**b**) Higher magnification (scale bar 1 μm) reveals the appearance of rod-shaped core granules in $ZnT8^{-/-}$ cells, indicated by *red arrows* (see also (Nicolson et al. 2009))

ZnT8

ZnT8, which shares many structural properties with the other ZnTs, was recently cloned by *Chimienti* and colleagues (2006). *SLC30A8* expression is highly restricted to the pancreas, specifically to the islets, as demonstrated by oligonucleotide microarray analysis of mouse tissues which demonstrated that ZnT8 is essentially an endocrine pancreas-specific Zn^{2+} transporter (Seve et al. 2004). Expression of a ZnT8-EGFP chimera revealed close colocalization with insulin-containing granules in the rat insulinoma cell line INS-1 (832/13) (Chimienti et al. 2006), and argued that Zn^{2+} uptake by these organelles may be essential for insulin storage and processing. Correspondingly, overexpression of this transporter also led to increase in both total cellular Zn^{2+} concentration and glucose-stimulated insulin secretion (Chimienti et al. 2006).

Supporting a role for ZnT8 in the storage and/or secretion of insulin in man, a single nucleotide polymorphism (SNP) in the *SLC30A8* gene (rs13266634 C/T), coding for ZnT8, is associated with an elevated risk of T2D (Sladek et al. 2007). The risk variant incorporates an arginine residue at position 325 in the C-terminus of ZnT8 as opposed to a tryptophan, a change which lowers the activity of the transporter (Nicolson et al. 2009).

The above polymorphism is associated with metabolic phenotypes that differ depending on the population studied. In a German cohort of diabetic patients, the SNP has been associated with reduced insulin secretion stimulated intravenously and impaired proinsulin conversion, while insulin resistant appeared normal. Studies on French subjects showed that patients carrying the "at-risk" form of ZnT8 have increased fasting glycemia and decreased insulin secretion. Interestingly, no relationship between *SLC30A8* polymorphism and β-cell function was found in other studies (Rutter 2010).

ZnT8 is thus important as it provides Zn^{2+} for insulin maturation and storage in pancreatic β-cells (Hutton et al. 1990). Indeed, through the generation of mice bearing null alleles it has also been demonstrated that the absence of ZnT8 leads to the formation of amorphous β-cell granules (frequently lacking a dense core of crystalline insulin, Fig. 2) and mild glucose intolerance (Nicolson et al. 2009), data that are consistent with a role for abnormal β-cell Zn^{2+}

homeostasis in the pathogenesis of diabetes mellitus (Scott and Fisher 1938). Although there are apparent differences in the phenotype of the systemically null mice (see review by Rutter (2010)), it is noteworthy that β-cell-specific deletion leads to a striking metabolic phenotype and changes in the expression of β-cell restricted genes (Wijesekara et al. 2010).

The expression of the above zinc transporters varies considerably among species (mouse, rat, and human) and also between different strains of mice. It is therefore important to consider these differences while discussing and investigating human diseases such as diabetes. CD1 mouse islets, for instance, appear to contain higher level of ZnT4 and ZnT5 than human, while the relative abundance of ZnT8 is higher in human compared to mouse pancreas. This would in part explain why a single nucleotide polymorphism in the gene coding for ZnT8 in human increase the risk of developing type 2 diabetes, while the complete ablation in mouse only give such a mild phenotype.

ZiP Importers

The ZiP family of transporters can be subdivided into four subfamilies named subfamilies I and II, LIV-1 and gufA. The LIV-1 family, whose founding member is ZiP6 (coded by the *Slc39a6* gene), contains nine members in mice, of which only some have been characterized in details. There are not many information about ZiP proteins in pancreatic β-cells. This field is still in its primordial stage and almost certainly new and interesting result will appear soon. However, some preliminary evidence exists for the role of ZiP4 in pancreatic cancer and of ZiP6, 7, and 8 in the regulation of β-cell zinc homeostasis (Bellomo et al. 2011).

ZiP4

ZiP4 plays a role in Zn^{2+} homeostasis by sensing the dietary zinc levels. However, recent studies indicate that ZiP4 is overexpressed in human pancreatic cancer, and aberrant expression of ZiP4 contributes to pancreatic cancer growth (Li et al. 2007). Zinc availability is also important for tumor growth and progression as Zn^{2+} is a cofactor for many enzymes involved in processes such as hypoxia, angiogenesis, cell proliferation, and metastasis (Li et al. 2007). ZiP4, by regulating interleukin-6 (IL-6) and subsequently STAT3 and Cyclin D1, might regulate these events (Zhang et al. 2010). Indeed, several studies indicate that the silencing of ZiP4 decrease the metastatic ability of pancreatic cells, suggesting that this could be a new drug target for pancreatic cancer treatment (Zhang et al. 2010).

ZiP6

Functional analysis of cells overexpressing ZiP6 indicate that this protein localizes to the plasma membrane where it acts as a zinc importer (Lichten and Cousins 2009). Elevated expression of ZiP6 is observed in tissues sensitive to steroid hormones and the abundant expression of ZiP6 in HeLa cells and lung carcinoma cell lines, as well as in breast cancer with metastatic ability, indicate a role for this protein in breast cancer progression (Taylor and Nicholson 2003).

ZiP7

ZiP7 appears to be ubiquitously expressed (Lichten and Cousins 2009). Overexpression of ZiP7 in a breast cancer cell line causes an increase in intracellular Zn^{2+}, as expected for a Zn^{2+} importer. However, ZiP7, in contrast to ZiP6 and the majority of other ZiP proteins, localizes to the Golgi apparatus/endoplasmic reticulum, suggesting that a zinc-release mechanism can indeed take place in cells (Taylor et al. 2007).

ZiP8

First identified as a cadmium transporter, ZiP8 expression is found in lung, kidney, testis, liver, brain, and the small intestine. When overexpressed in cells, ZiP8 localization was found primarily on the plasma membrane. However, the localization of the protein appeared to change depending on the zinc concentration in the medium, consistent with an effect of Zn^{2+} to cause the transporter to internalize (Wang et al. 2007).

ZiP6, 7, and 8 have recently been suggested to play an important role in the regulation of Zn^{2+} metabolism in pancreatic β-cells (Bellomo et al. 2011). Indeed, when mouse islets were incubated with high (16.7 *vs* 3 mM) concentrations of glucose, the mRNA level of these three transporters increased. These changes were accompanied by an increased concentration of cytosolic Zn^{2+}, as measured using a highly selective recombinant probe for the cytosolic compartment ("eCALWY-4") (Vinkenborg et al. 2009). Further experiments demonstrated that the observed increase in cytosolic [Zn^{2+}] was likely to be a consequence of the increased expression of these transporters, notably

ZiP6, as an increased expression was observed not only at the mRNA but also at the protein level. Despite ZiP8 expression, in pancreatic islets, is low, it is important to note that under high stress, achieved by treatment with high glucose and the potassium channel opener diazoxide, its expression increased hugely. This was correlated with a much higher increase in cytosolic zinc than that observed after incubation in high glucose alone.

These data suggest an interesting hypothesis. First of all, upon stimulation with glucose, pancreatic β-cells not only promote insulin secretion but also insulin granule biogenesis. A newly formed granule not only needs a complete complement of intragranular proteins, but also requires high concentration of Zn^{2+} in order to properly store newly synthesized insulin. In this context, the fact that an increase in ZiPs together with cytosolic Zn^{2+} occurs after glucose stimulation can be considered a physiological adaptation. However, if the concentration of glucose remains elevated for longer period of time or if the stress level of pancreatic islets increase (events observed in the pathogenesis of type 2 diabetes), then the Zn^{2+} level could increase over a "safe" threshold leading, perhaps, to events such apoptosis to occur and therefore increasing the risk for diabetes.

Future Perspectives

While the role of ZnT8 in the mammalian β-cell is now difficult to refute, those of ZiP family members will require future work involving gene silencing ex vivo or knockout strategies in mice. An intriguing unanswered question is the extent to which these proteins influence not only insulin secretion, but also the storage and release of other islets hormones, including glucagon, given the reasonably abundant expression of ZnT8 in the α-cells (Nicolson et al. 2009). The extent to which the activity of these proteins is modified posttranslationally (by phosphorylation or other means) in either cell type is also completely unknown at present, and represents an exciting area for potential future exploration. The development of pharmacological agents able to modify the expression or activity of these proteins (and notably that of ZnT8, given its remarkably restricted expression to islet cells (Chimienti et al. 2006)) may also offer important new approaches toward controlling the release of endocrine pancreatic hormones and thus offer novel treatment for certain forms of diabetes.

Summary

Zinc plays a fundamental role in the biology of insulin secretion, acting in particular to stabilize the insulin crystal, but also potentially to regulate a variety of cellular processes ranging from transcription to ion channel activity. Here, we review the biology of the two key families of zinc transporters (ZnTs) and importers (ZiPs) with a particular focus on their role in the pancreatic β-cell. Recent genetic data in man, and the results of mouse knockout studies, have highlighted the importance of the secretory-granule-localized zinc transporter, ZnT8, encoded by *SLC30A8* in the pathology of both type 1 and type 2 diabetes. Likewise, cellular studies have revealed that the expression of several key ZiP family members and the free cytosolic concentration of zinc are dynamically regulated in response to the chief physiological stimulus for insulin secretion, glucose. Zinc transporters may thus represent potential interesting targets for pharmacological intervention in certain forms of diabetes mellitus, by controlling insulin and/or glucagon release.

Zfp202; Zinc finger protein 202

Historical Background

In 1998, ZNF202 was initially cloned and described as testis-specific zinc finger transcription factor (Monaco et al. 1998). Two years later, in 2000, a linkage analysis in Utah pedigrees suffering from hypoalphalipoproteinemia could identify a new low HDL locus on chromosome 11q23 distinct from the apolipoprotein AI/CIII/AIV/AV gene cluster (Kort et al. 2000). In addition to low HDL cholesterol, family members very frequently exhibited early onset of coronary heart disease (Kort et al. 2000). The newly identified locus contains the gene of the zinc finger transcription factor ZNF202 (Monaco et al. 1998; Wagner et al. 2000). A bioinformatics approach screening for ZNF202 transcription factor binding sites revealed that the ZNF202 gene product is a transcriptional repressor that binds to elements found predominantly in genes that either participate in lipid metabolism or being involved in processes related to energy metabolism and vascular disease (Wagner et al. 2000). Based on published linkage analysis and apparent transcriptional function of ZNF202, ZNF202 was proposed as a candidate susceptibility gene for human dyslipidemia and atherosclerosis for the first time.

Genomic Structure and Functional Domains

The ZNF202 gene consists of ten exons with a 4 kb mRNA. Two different ZNF202 isoforms m1 and m3

can arise by alternative splicing between exons 5 and 6 (Monaco et al. 1998;Wagner et al. 2000). The ZNF202 m1 form encodes a full-length 648 amino acid protein containing an N-terminal SCAN domain, a Krüppel-associated box (KRAB), and eight C_2–H_2-C-terminal zinc fingers. In contrast, the ZNF202m3 isoform encodes a 142 amino acid protein solely consisting of an isolated SCAN domain (Wagner et al. 2000). SCAN domains have been identified in various C_2–H_2-zinc finger transcription factors including ZNF191, ZNF202m1, SCAN domain protein 1 (SDP1), and NIRF where they are usually located in the N-terminal domain (Honer et al. 2001). Yeast-two hybrid studies revealed that SCAN motifs associate selectively with each other and that SCAN-mediated oligomerization may play a regulatory role in DNA binding activity as well as in transcriptional modulation (Schumacher et al. 2000).

The transcriptional repression capacity is mainly mediated by the KRAB domain which is present in one third of all zinc finger transcription factors. This domain consists of approximately 75 amino acid residues including two predicted amphiphatic α-helices (Margolin et al. 1994), which are highly conserved from yeast to man. For sufficient repression a 45 aa segment containing one of the two α-helices is necessary and sufficient. KRAB-mediated gene silencing requires the universal corepressor KRAB-associated protein-1 (KAP-1) which is able to bind the KRAB domain via its RING-B box-coiled coil (RBCC) domain. KAP-1 in turn recruits nonhistone chromosomal proteins of the heterochromatin protein-1 (HP-1) family (Lechner et al. 2000) and thereby prevents promoter activation.

The binding of ZNF202 binding to specific promoter sequences is mediated by its eight consecutive C_2-H_2 zinc finger motifs located in the C-terminal region. The consensus binding sequence for ZNF202 is a GnT (5′-GGGGT-3′) motif, which is found in a variety of promoters of genes associated with lipid metabolism (Wagner et al. 2000).

Regulation of ZNF202 Expression and Modulation of ZNF202 Function

Although initially identified as a testis-specific transcription factor (Monaco et al. 1998), ZNF202 mRNA is also expressed in numerous other tissues including heart, intestine, liver, kidney, and leukocytes (Porsch-Ozcurumez et al. 2001). In THP-1 cells as well as in native human macrophages, ZNF202 mRNA is inversely regulated with its target genes ABCA1 and ApoE during macrophage differentiation and foam cell formation. Upregulation of both genes was accompanied by a simultaneous downregulation of both ZNF202 mRNA isoforms (Langmann et al. 2003). Conversely, deloading of macrophage foam cells with HDL_3 caused upregulation of ZNF202 mRNA. Consistent with those mRNA expression data, reporter gene assays revealed a highly active ZNF202 core promoter region (247 bp upstream of the transcription initiation site) in THP-1 monocytes, which loses its activity upon macrophage differentiation. A GC-box and an Ets motif binding PU.1 has been identified (Langmann et al. 2003) as crucial elements for ZNF202 promoter activity.

Besides the control of ZNF202 gene expression, ZNF202 function may also be regulated via interactions with other SCAN domain proteins. In yeast two-hybrid studies, the zinc finger protein ZNF191 and SCAN domain protein 1 (SDP1) as well as the ZNF202 m3 isoform encoding an isolated SCAN domain were identified as ZNF202 interacting proteins (Schumacher et al. 2000). Data from other transcription factors like GAGA which self-oligomerizes via its BTB/POZ domain provide evidence that the oligomerization status of transcription factors modulates their DNA binding affinities (Espinas et al. 1999).

In addition to ZNF202 SCAN domain interactions, SDP-1 has been shown to prevent binding of the universal corepressor KAP-1 to ZNF202 thereby abolishing its repressional capacity (Porsch-Ozcurumez et al. 2001). Binding of SDP1 to ZNF202 was confirmed in another study demonstrating high amino acid identity of human SDP1 protein with the murine PPARγ2 coactivator PGC-2 (Babb and Bowen 2003). PGC-2 contains a partial SCAN domain and increases transcriptional activity of PPARγ and the estrogen receptor. Similar to PGC-2, SDP-1 was able to bind PPARγ2 through its SCAN domain and to enhance PPARγ2-induced gene transcription without altering the affinity of PPARγ2 for its ligands (Babb and Bowen 2003). The capability of SDP1 to interact with ZNF202 and PPARγ2 as two crucial transcription factors involved in lipid metabolism suggests that SCAN domain proteins such as SDP1 could function as important coregulators in lipid metabolism. Moreover, this interaction may define new regulatory

loops for target genes of both ZNF202 and PPARγ2 like ABCA1 playing a key role in reverse cholesterol transport. One the one hand ZNF202/SDP1 interactions prevent binding of KAP-1 resulting in a derepression of ABCA1. Otherwise, SDP1 coactivation of PPARγ2 may further induce ABCA1 gene transcription via activation of the liver X receptor α (LXR) promoter (Chinetti et al. 2001). These regulatory pathways may also involve other LXR target genes like SREBP1c, a master regulator of fatty acid and triglyceride biosynthesis.

The role of the SCAN encoding ZNF202 isoform m3 and ZNF191 remains still unclear. ZNF202m3 may impair repressional activity of the ZNF202 full-length form by modulating the formation of functional SCAN domain zinc finger transcription factors that is able to bind KAP-1. However, in contrast to the m1 form ZNF202m3 does not coactivate PPARγ (Babb and Bowen 2003).

The related factor ZNF191 contains a SCAN domain and a zinc functional zinc finger region (Honer et al. 2001). The physiological role of a potential interaction of ZNF202 with ZNF191 has not been elucidated so far.

ZNF202 Target Genes

The majority of ZNF202 target genes was identified by a whole genome bioinformatic survey of ZNF202 binding sites. Up to now, several of these targets have been confirmed by EMSA and functional promoter assays. The constantly growing list of ZNF202 regulated genes includes receptors, signaling molecules, transcription factors and enzymes and apolipoproteins involved in glucose and lipid metabolism. The ZNF202 target genes and related disease are listed in Table 1 and have been reviewed in Schmitz et al. (2004). The central ZNF202 target genes in lipid and glucose metabolism and in vascular growth are briefly emphasized below.

Apo AI/CIII/AIV Gene Cluster

ApoAIV together with apoAI and apoE represent the major apolipoprotein components of mature HDL-particles. The *apoAIV* gene is localized in a gene cluster with apoAI and apoCIII on chromosome 11q23-q24. ApoAIV is preferentially expressed in intestinal mucosa and brain and is suggested to play a role in intestinal lipid absorption. Additional functions of apoAIV include LCAT activation and promotion of cellular cholesterol efflux as well as modulation of LPL activation by apoCII. ApoCIII which is expressed in liver and to a minor amount in the intestine participates in the regulation of triglyceride-rich lipoproteins and is a major component of chylomicrons and VLDL. Similar to apoAIV, apoCIII is able to modulate LPL activity by a noncompetitive inhibition. GnT motifs acting as ZNF202 binding sites were identified within the apoAIV promoter region as well as within the apoCIII enhancer (Wagner et al. 2000), and in vitro binding to both promoter sites as well as transcriptional repression has been verified (Porsch-Ozcurumez et al. 2001; Wagner et al. 2000). Both, the apoAIV promoter and the apoCIII enhancer are induced by the ZNF202 target gene HNF4.

Apolipoprotein E

Together with PLTP, CETP, and apoCI, apoE facilitates cellular cholesterol efflux. In addition, it forms a major constituent of chylomicrons, VLDL, and their remnants, as well as certain subclasses of HDL and serve as ligands for receptor-mediated uptake by the liver and adipocytes. ApoE is expressed in liver and in a variety of peripheral tissues including monocytes/macrophages, astrocytes, microglia, and keratinocytes. ApoE is inversely regulated with its repressor ZNF202 during monocyte differentiation and foam cell formation (Langmann et al. 2003).

Phospholipid Transfer Protein

Two main functions contribute to the regulatory role of PLTP in HDL metabolism. First, PLTP is able to transfer phospholipids and triglycerides mainly from triglyceride-rich lipoproteins to nascent HDL particles upon lipoprotein lipase-mediated lipolysis. Second, PLTP activity results in the release of small lipid-poor pre-β-HDL particles, which are efficient acceptors of cholesterol from peripheral cells. Concomitantly, large α-HDL particles are produced. An increase in ApoE HDL and PLTP activity and a decrease in ApoAI/CETP containing HDL was found in patients with severe sepsis. These findings suggest that PLTP contributes to the delivery of phospholipids and energy substrates to tissues during inflammation.

The PLTP promoter contains a confirmed binding site for ZNF202 (Wagner et al. 2000) and members of the nuclear receptor family.

ZNF202, Table 1 ZNF202 target genes and related diseases

Gene		Chromosomal locus	OMIM	Human disease association
Lipid metabolism				
Apolipoprotein AI/CIII/AIV/AV gene cluster		11q23	*107680 *107720 *107690 *606368	ApoAI/CIII deficiency
Apolipoprotein E/CI/CIV/CII gene cluster		19q13.2	*107741 *107710 #207750	ApoE polymorphisms, atherosclerosis, Alzheimer's disease; Hyperlipoproteinemia type IB
Phospholipid transfer protein	PLTP	20q12-q13.1	*172425

GOS24		19q13.1	*190700	

ATP Binding Cassette Transporters A1 and G1

ABCA1 functions as a key regulator of cellular lipid efflux and of plasma HDL pool size, and mutations of ABCA1 have been causatively linked to familial HDL deficiency syndromes. Macrophage cholesterol and phospholipid efflux also involves the half-size transporter ABCG1. For both ABCA1 and ABCG1 promoters, specific binding of ZNF202 and a dose-dependent inhibition of promoter activity by ZNF202 was shown. Moreover, HDL and apoAI-mediated cholesterol and phospholipid efflux was significantly reduced in ZNF202 transfected RAW264.7 cells. This strong inhibition of cellular lipid efflux was not only observed at the basal level, but is also almost completely abolished by oxysterol dependent induction of ABCA1-mediated lipid efflux (Porsch-Ozcurumez et al. 2001). These data nicely demonstrate that the repressor capacity of ZNF202 is even able to abolish the LXR/RXR sensitivity of both promoters.

Hepatic Triglyceride Lipase

Similar to lipoprotein lipase (LPL), hepatic triglyceride lipase (HTGL) reveals not only enzymatic activity with both triglyceride lipase and phospholipase A1 activity but also is able to enhance LDL receptor-mediated uptake of remnant lipoproteins as an enzymatically inactive protein. HTGL binding is able to bind the LDL receptor and thereby enhances VLDL catabolism. Distinct HTGL promoter polymorphisms are associated with dyslipidemia and insulin resistance as well as response to lipid-lowering treatment.

Lipoprotein Lipase

Triglyceride-rich lipoproteins are major targets of LPL-mediated generation of fatty acids. In addition to the hydrolytic activity, LPL may promote particle binding to the GPI-anchored HDL-binding protein, the LDL-receptor, VLDL-receptor, and members of the LDL-related receptor family resulting in uptake of lipoprotein particles. Enzymatically inactive LPL is also able to mediate selective uptake of lipoprotein-associated cholesteryl esters.

Lecithin Cholesterol Acyltransferase

Lecithin cholesterol acyltransferase (LCAT) is a key enzyme in HDL metabolism converting ApoAI containing pre-β-HDL precursors to mature cholesteryl ester-rich αHDL catalyzing the transfer of linoleic acid from the sn-2 position of lecithin to free cholesterol, generating cholesteryl ester and lysolecithin. Mutations of LCAT in humans with either partial or complete absence of plasma LCAT activity lead to fish eye disease and familial LCAT deficiency, which are characterized by markedly reduced plasma HDL levels and corneal clouding. Thus, downregulation of LCAT gene expression by ZNF202 via the identified GnT motif (-1101/-1087) (Wagner et al. 2000) in the LCAT promoter may be of clinical importance.

Phosphatidyl Ethanolamine *N*-Methyltransferase

The phosphatidylethanolamine *N*-methyltransferase (PEMT) catalyzes the conversion of phosphatidylethanolamine (PE) to phosphatidylcholine (PC) in three consecutive methylation reactions using *S*-adenosylmethionin as a substrate. PC is the primary phospholipid of all classes of lipoproteins in mammals and is required for secretion of lipoproteins and bile salt micelles, and is additionally involved in cellular signaling.

Proteolipid Protein

Myelin proteolipid protein (PLP) is an integral membrane protein and the most abundant protein of the central nerve system. The main source of PLP are oligodendrocytes, but small amounts are also synthesized by Schwann cells in the peripheral nervous system. PLP functions involve membrane adhesion and compaction of myelin, maturation of oligodendrocytes, and maintenance and survival of axons. Diseases resulting from PLP gene abnormalities include Pelizaeus-Merzbacher disease and spastic paraplegia type 2. Pelizaeus-Merzbacher disease is characterized by dysmyelination of the CNS and reduced number of mature oligodendrocytes leading to symptoms like nystagmus, psychomotor retardation, spasticity, and ataxia which develop shortly after birth. Spastic paraplegia type 2 shares the same clinical features, but has a later onset and milder phenotype. As ZNF202 is significantly expressed in the central nerve system, repression of ZNF202 might be of clinical relevance for these disorders. This is supported by recent GWA-studies where a ZNF202 SNP was associated with movement-related adverse antipsychotic effects {Aberg et al. 2010 241/id}.

Hepatic Nuclear Factor 4

In addition to genes involved in the metabolism of triglyceride-rich lipoproteins and HDL, ZNF202 target genes include several genes suggested to contribute broadly to glucose metabolism and diabetes. One of these genes is hepatic nuclear factor 4 (HNF4), a member of the family of nuclear hormone receptors binding fatty acids as endogenous ligands. HNF4 is involved in the regulation of a number of other identified ZNF202 targets. These include ZNF202-dependent suppression of the ApoAI/CIII/AIV/AV and the ApoE/CIV/CII gene cluster, and in addition, the downregulation of HNF4 as a well-known activator of these genes. Besides these ZNF202 targets HNF4 also activates sterol 27-hydroxylase which generates the endogenous LXR-ligand in cholesterol-loaded cells, amino acid and glucose metabolism, and other transcription factors like PPARα and HNF1α. Mutations in the human *HNF4α* gene cause maturity onset diabetes of the young (MODY) 1, a rare form of non-insulin-dependent diabetes mellitus and, in addition to HNF1α, HNF4α is able to directly activate the insulin promoter. In addition, HNF4α is one of the transcription factors required for full transcriptional

activation of the hepatic PEPCK gene, a rate-controlling enzyme of hepatic gluconeogenesis. Induction of PEPCK gene expression by HNF4 and GR is strongly coactivated by PGC-1, another key modulator of hepatic gluconeogenesis and central target of the insulin-cAMP axis in hepatocytes. In brown fat and skeletal muscle PGC-1 is dramatically elevated upon cold exposure and increases UCP-1 transcription via PPARγ and thyroid hormone receptor activation. Moreover, PGC-1α was shown to drive the formation of slow twitch muscle fibers.

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF) is well-known to play a central role in angiogenesis during embryogenesis, wound healing, tumor growth, and chronic inflammatory diseases, e.g., rheumatoid arthritis. The biological activities of VEGF are mediated through two receptor protein tyrosine kinases, Flt-1 (VEGF-R1) and KDR/Flk-1 (VEGF-R2). mRNA levels of both receptors are reduced upon treatment with PPARγ ligands accompanied by an inhibition of VEGF-induced angiogenesis. *VEGF* gene expression is repressed by the oncogenes *p53* and *p73* in different tumors and together with repression by ZNF202 may influence tumor angiogenesis.

ZNF202 in Disease

First evidence for a role of ZNF202 in vivo was given by data from the Copenhagen City Heart Study demonstrating an association between a common variant in ZNF202, A154V, and increased risk for ischemic heart disease and myocardial infarction in women. However, the A154 genotype did not predict risk in men and findings for ZNF202 A154V were independent of further adjustment for lipid profile (Stene et al. 2006a), In addition, a homozygosity for a common promoter variant in the *ZNF202* (g.-660A>G) gene was demonstrated to be associated with decreased transcriptional activity in vitro predicting severe atherosclerosis and increased risk of ischemic heart disease (Stene et al. 2008). Comparable to the A154V genotype, ZNF202 g.-660A>G genotype was not associated with variation in plasma levels of total cholesterol, apoB and LDL-cholesterol, HDL-cholesterol, apoAI and triglycerides (Stene et al. 2008). Similarly, no major contribution of single nucleotide polymorphisms in the protein-coding region to serum HDL cholesterol levels in Danish adults could be detected (Stene et al. 2006b) suggesting that the observed effect on vascular disease may be due to other than lipid-related ZNF202 targets.

More recent studies identified ZNF202 as a candidate gene in other diseases independent of atherosclerosis. In a genome-wide association study searching for genetic susceptibility to extrapyramidal side effects as response to antipsychotic drugs, a SNP located in ZNF202 (rs2126709) reached genome-wide significance (Aberg et al. 2010). Since the major myelin protein, proteolipid protein (PLP), which is mutated in Pelizaeus-Merzbacher disease is a target of ZNF202 this could be a first feasible link between ZNF202 and disorders of the central nervous system.

Another work identified the alpha-methylacyl-coenzyme A racemase (AMACR) as a novel ZNF202 target gene. AMACR regulates peroxisomal β-oxidation of phytol-derived branched-chain fatty acids that may serve as energy source for malignancies and is established as a diagnostic marker in prostate cancer and also suspected to be involved in colon cancer. In colon adenocarcinoma an in vivo deletion hotspot of the ZNF202 binding site has been identified that is supposed to influence the grade of differentiation of tumor cells (Zhang et al. 2009).

By high-throughput SNP and expression analysis, ZNF202 was also identified as candidate gene for non-syndromic oral clefts (Park et al. 2006) suggesting a role in embryonic development.

Summary

In terms of the physiological importance of the in vitro identified ZNF202 target genes in the cellular transport of lipids and lipid metabolism in general ZNF202 was mainly investigated as master regulator of lipid metabolisms. The effects of ZNF202 as transcriptional repressor of lipid efflux by affecting ABCA1 and ABCG1 expression and the functional impact on apolipoprotein E, AIV and AV expression clearly substantiated these findings.

However, in vivo ZNF202 may have a much broader role that differs from the in vitro data, e.g., human angiogenesis or energy metabolism by controlling key genes of glucose and fatty acid metabolism. This is clearly supported by the so far published studies that could demonstrate a relationship between ZNF202 and vascular or neurodegenerative disease but not with lipid metabolism.

Studies working out the in vivo effect in particular in animal models of ZNF202 deletion/overexpression will be needed to provide further insight into the functions of this transcriptional repressor. If it is possible to identify a phenotype in such animals, we may get a better picture of the role of ZNF202. This could also be the basis for pharmacological studies for successful ZNF202 modulation.
